*For adults age 18 and older, based on the average of two or more readings taken at each of two or more visits after an initial screening.

change in either stroke volume or heart rate alters cardiac output.

Stroke Volume Conditions that *increase cardiac output* by increasing stroke volume include:

- Increased blood volume (as occurs during pregnancy, for example).
- More forceful contraction of the ventricles (as occurs during exercise, for example).

Conditions that *decrease cardiac output* by decreasing stroke volume include:

- Dehydration
- Active bleeding
- Damage to the heart (as seen after myocardial infarction, or heart attack)

Heart Rate Up to a point, an increase in heart rate increases cardiac output. However, a very rapid heart rate limits the time allotted for the ventricles to fill, resulting in decreased stroke volume and, ultimately, decreased cardiac output.

Peripheral Resistance

Peripheral resistance refers to arterial and capillary resistance to blood flow as a result of friction between blood and the vessel walls. Increased peripheral resistance creates a temporary increase in BP. The amount of friction or resistance depends on blood **viscosity** (thickness), arterial size, and arterial **compliance** (elasticity). The walls of the veins are thin and very distensible, so they have little influence on peripheral resistance and BP.

Blood Viscosity Blood viscosity influences the ease with which blood flows through the vessels. Viscosity is determined by the **hematocrit** (the percentage of red blood cells in plasma). Any disorder that increases hematocrit (e.g., dehydration) increases blood viscosity and, therefore, BP. Conversely, a low hematocrit, as seen in anemia, lowers viscosity and may reduce BP.

Arterial Size The smaller the radius of a blood vessel, the more resistance it offers to blood flow. Constricted arteries prevent the free flow of blood and, subsequently, increase BP. Dilated arteries allow unrestricted flow of blood, thereby reducing blood pressure. The sympathetic nervous system controls vasoconstriction and vasodilation.

Arterial Compliance Arteries with good elasticity can distend and recoil easily and adequately. When age- or disease-related changes in arterial structure cause a loss of elasticity, peripheral resistance, and possibly BP, increase. **Arteriosclerosis** (hardening of the arteries) is a common contributor to increased BP in middle-aged and older adults.

Blood Volume

The normal volume of blood in the body is about 5 liters (5,000 mL). A significant volume decrease, as occurs with hemorrhage or other fluid losses, reduces vascular volume, and BP falls. When vascular volume is increased above the norm, as occurs with renal (kidney) failure and fluid retention, BP increases.

What Factors Influence Blood Pressure?

Blood pressure normally changes from minute to minute with changes in activity or in body position. Therefore, you must establish *BP patterns* rather than relying on individual BP readings when determining whether a client's BP is normal or abnormal. This is even more important for older adults because their BP tends to fluctuate even more. The following are some factors that affect the BP:

Developmental Stage An average newborn has a systolic BP of about 60 to 80 mm Hg and a diastolic BP of 40 to 50 mm Hg (Lowdermilk, Perry, Cashion, et al., 2012). It increases gradually throughout childhood. A child or adolescent's BP depends on body size; therefore, a smaller child or adolescent has a lower blood pressure than does a larger child.

Both systolic and diastolic BP continue to increase with age as a result of decreased arterial compliance and changes in the left ventricular wall. These normal aging process changes can lead to cardiovascular instability (Lange, 2012).

For BP normal ranges for various age groups,

Go to Chapter 20, **Tables, Boxes, Figures: ESG Table 20-1,** on Davis*Plus*.

Gender The average BP for men is slightly higher than that for women of comparable age, although the difference is not considered significant. After menopause, a woman's BP tends to increase, possibly due to a decrease in estrogen.

Family History A family history of hypertension markedly increases the likelihood of an individual's developing hypertension.

Lifestyle Increased sodium consumption, smoking, and consumption of three or more alcoholic drinks per day have been shown to elevate BP. Caffeine may raise BP for a short while after ingestion, but it has no long-term effect on the BP.

Exercise Physical fitness has been shown to reduce BP in many individuals. However, muscular exertion temporarily increases BP as a result of increased heart rate and cardiac output. You should, therefore, wait about 30 minutes before you assess the BP of someone who has been physically active.

Body Position BP is higher when a person is standing than when sitting or lying down. Readings are higher if taken with the client's arm above heart level or if the arm is unsupported at the client's side. Seated readings are higher if the client's feet are dangling rather than resting on the floor or if the legs are crossed at the knees.

Stress Fear, worry, excitement, and other stressors cause BP to rise sharply because of sympathetic nervous system stimulation (fight-or-flight response). One example of this is "white-coat hypertension." This occurs when a patient's BP is elevated in the physician's office or clinic—a situation in which he is likely to experience stress—but not at other times. However white-coat hypertension may indicate what happens during other times of stress, so if it is consistently displayed, treatment may be indicated.

Pain Pain often causes the BP to increase. However, severe or prolonged pain can significantly decrease BP.

Race African Americans have a higher rate of hypertension than do European Americans, and they have a higher incidence of complications and hypertension-related deaths (McCance & Heuther, 2010).

Obesity As a rule, obesity increases BP. This increase is related to the additional vascular supply required to perfuse the large body mass and the resultant increase in peripheral resistance.

Diurnal Variations Generally, BP varies according to the person's daily schedules and routines. BP is lower while the person is sleeping and when he first gets up, rising during the day and dropping again toward bedtime.

Medications Many medications alter BP. This effect may be intended, as with antihypertensive medications, or unintended, such as the drop in BP that often results when a client receives pain medication. Many over-the-counter preparations, herbal products, and illicit drugs can affect BP.

Diseases Diseases that affect the circulatory system or any of the major organs of the body (e.g., the kidneys) may affect BP.

Genetic Variations/Genes Researchers used the recognized 29 genetic variants known to influence systolic and diastolic blood pressure to develop a genetic risk score. Twenty-nine percent of people with the top 10% of genetic risks had hypertension compared with 16% in the lowest risk groups (National Institute of Health, 2011).

Think**Like a Nurse** 20-9

- Evaluate the following adult blood pressures. Are they high, low, or normal?
  116/90 mm Hg
  80/50 mm Hg
  184/102 mm Hg
  140/90 mm Hg
  40/0 mm Hg
- What theoretical knowledge did you use in evaluating the blood pressures?

PracticalKnowledge knowing **how**

Now that you understand the concept of perfusion and how blood pressure is maintained and regulated, you are ready to gain the practical knowledge of how to assess and support this aspect of physical functioning.

ASSESSMENT

Blood pressure may be assessed directly or indirectly.

Direct Measurement In the *direct method*, a catheter is threaded into an artery under sterile conditions and attached to tubing that is connected to an electronic monitoring system. The pressure is constantly displayed as a waveform on the monitor screen. Although the direct method of measuring BP is very accurate, its use is confined to critical care areas and surgery because of the risk of sudden arterial blood loss.

Indirect Measurement Usually you will measure BP via the *indirect*, or *noninvasive*, *method*. This is an accurate estimate of arterial BP that can be performed in any clinical or community setting. For a summary of a procedure for noninvasive blood pressure monitoring, see the Highlights of Procedures box. For the complete procedure,

Go to **Procedure 20-6: Measuring Blood Pressure,** in Volume 2.

For an animated visual explanation of blood pressure readings,

Go to Student Resources **Animations: Reading Blood Pressure,** on Davis*Plus*.

What Equipment Do I Need?

You will need a stethoscope, a blood pressure cuff and sphygmomanometer, or an electronic blood pressure monitor to assess blood pressure. Electronic monitoring is gradually replacing the stethoscope and sphygmomanometer in inpatient settings. However, a common stethoscope and sphygmomanometer are generally sufficient to hear most clients' blood pressures. When blood pressure is weak, ultrasonic stethoscopes are useful for magnifying sound waves occurring during systole.

Evidence-based guidelines suggest that using the bell of the stethoscope enables you to hear blood pressure sounds more accurately, especially at diastolic pressures (Perloff, Grim, Flack, et al., 1993; Shindler, 2007; Vital Signs, 1999). However, most people use the diaphragm because it is easily placed and because some stethoscopes do not have a bell (see Fig. 20-4). The key to clarity of sound is to use a high-quality stethoscope with short tubing.

A **sphygmomanometer** consists of a vinyl or cloth cuff, a pressure bulb with a regulating valve, and a manometer (Fig. 20-8). Blood pressure cuffs contain an inflatable rubber bladder.

The cuff is attached to a gauge or manometer and a valved pressure bulb that inflates the bladder (Fig. 20-9). Cuffs can be placed on either the upper arm or midthigh and are supplied in various sizes.

FIGURE 20-8 Types of manometers: *top left*, aneroid; *top right*, mercury; *bottom*, electronic.

Sphygmomanometers are either aneroid or mercury. **Aneroid** manometers have dials that register BP by pointers attached to a spring. **Mercury** manometers measure BP using a calibrated upright tube containing mercury (see Fig. 20-8, top). As the bladder of the cuff is inflated, the pressure pushes the column of mercury up the tube. The column of mercury falls as the cuff is deflated. Mercury manometers are not as popular as aneroid manometers because they pose a health hazard if the mercury tube is broken. They are however, easier to maintain and more accurate than aneroid manometers, which

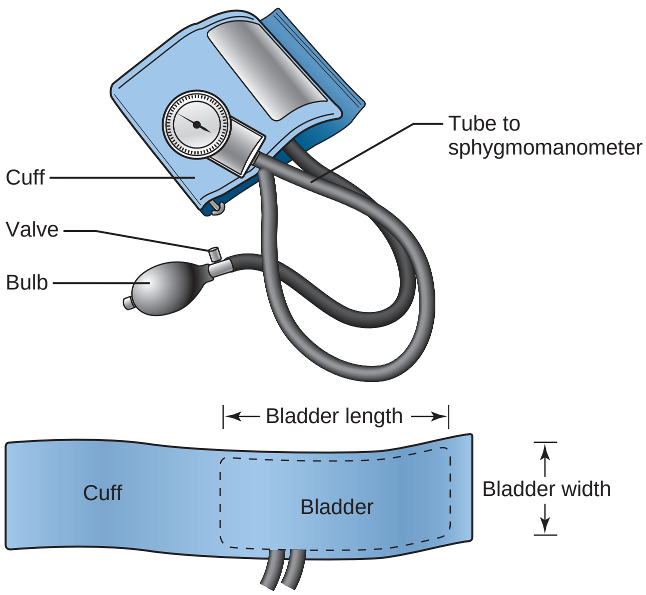

FIGURE 20-9 A blood pressure cuff showing placement of bladder within the cuff.

require frequent calibration. In 1998, the American Hospital Association and the EPA recommended that the healthcare industry eliminate mercury-containing waste by the year 2005 (EPA, 2001, 2012). Most healthcare agencies have committed to or phased out the use of mercury-containing products (Mercury-Free Health Care, n.d.).

Electronic blood pressure monitors use either microphones to sense sounds or sensors that detect pressure waves as blood flows through arteries (Fig. 20-8, bottom). They can be set to monitor and record BP at timed intervals and do not require the use of a stethoscope. They measure systolic, diastolic, and mean arterial pressures. Electronic monitors are useful when you must monitor BP frequently (e.g., during surgery or when a client is critically ill). However, some evidence suggests that they may be less accurate than auscultated blood pressures (Bern, Brandt, & Mbelu, 2007; Nelson, Kennedy, & Regnerus, 2008), so you should auscultate a baseline BP before initiating automatic monitoring (Pickering, Hall, Appel, et al., 2005).

Many clients use a version of the electronic BP monitor in their homes. These devices can be purchased in grocery stores and pharmacies. They are useful for screening, but clients should seek follow-up care when readings are not within their normal range. The accompanying Home Care box identifies teaching topics for clients using electronic BP monitors.

What Cuff Size Should I Use?

The *width* of the bladder of a properly fitting cuff will cover approximately two-thirds of the *length* of the upper arm (or other extremity) for an adult, and the entire upper arm for a child (Fig. 20-10) (National Heart, Lung, and Blood Institute, 1996, revised 2005, 2007). Alternatively, you can check that (1) the *cuff width* is 40% of the arm circumference and (2) the *length* of the bladder encircles 80% of the arm in adults (Tomlinson, 2010).

Using a cuff or bladder of the incorrect size can result in a measurement error of as much as 30 mm Hg. If the cuff is too narrow, your reading will be too high; if it is too wide, the reading will be too low. Although cuffs are manufactured in various sizes, in practice, you will

Home Care

Teaching Your Client Self-Monitoring of Blood Pressure

Various models of common, acceptable BP devices are available for self-monitoring using the upper arm (finger monitors are inaccurate) (American Heart Association, 2012).

A wrist monitor for blood pressure.

- With a portable home device, the client simply pushes a button, and the cuff inflates and deflates automatically. The device provides an electronic digital readout of the BP. Because these devices are sensitive, arm movement or improper cuff placement can cause inaccurate readings. Also, these devices must be recalibrated at least every 6 to 12 months.
- Some grocery stores, fitness clubs, and other public places have stationary automatic BP devices for public use. The person places his arm in the cuff, which fits over his clothing. The machine gives a visual display of the BP reading. The accuracy of these machines varies.

Benefits of Self-Monitoring

- May detect high BP in those who have not previously had a problem (screening).
- Allows for observation of the BP *pattern* over time, rather than a one-time office reading. The results can be analyzed to distinguish "white-coat hypertension" from actual hypertension.
- For clients with hypertension, self-monitoring increases participation in treatment and may improve compliance with treatment.

Home Care

Teaching Your Client Self-Monitoring of Blood Pressure—cont'd

Disadvantages of Self-Monitoring

- Possible incorrect use of the BP device
- Needless anxiety over a single elevated reading
- Clients with hypertension may make adjustments to their medications based on the BP readings without consulting their care provider.

Nursing Implications

- Teach proper use of the self-measurement devices.
- Periodically evaluate the client's technique.
- Teach the meaning of BP readings and the need to look for patterns from multiple readings, not just a single reading.
- Explain the need for calibration of the home-monitoring device at least once a year or according to the manufacturer's instructions.
- Have the client bring the home-monitoring device to clinical visits so that readings can be compared with simultaneously recorded auscultatory readings.
- Teach the client to have abnormally high or low readings (occurring on more than one occasion) rechecked by a healthcare provider. Home readings of 135/85 or higher should be considered elevated.
- Advise the client to keep a written record of BP readings, including the date and time for each, and bring it to each clinic or office visit.

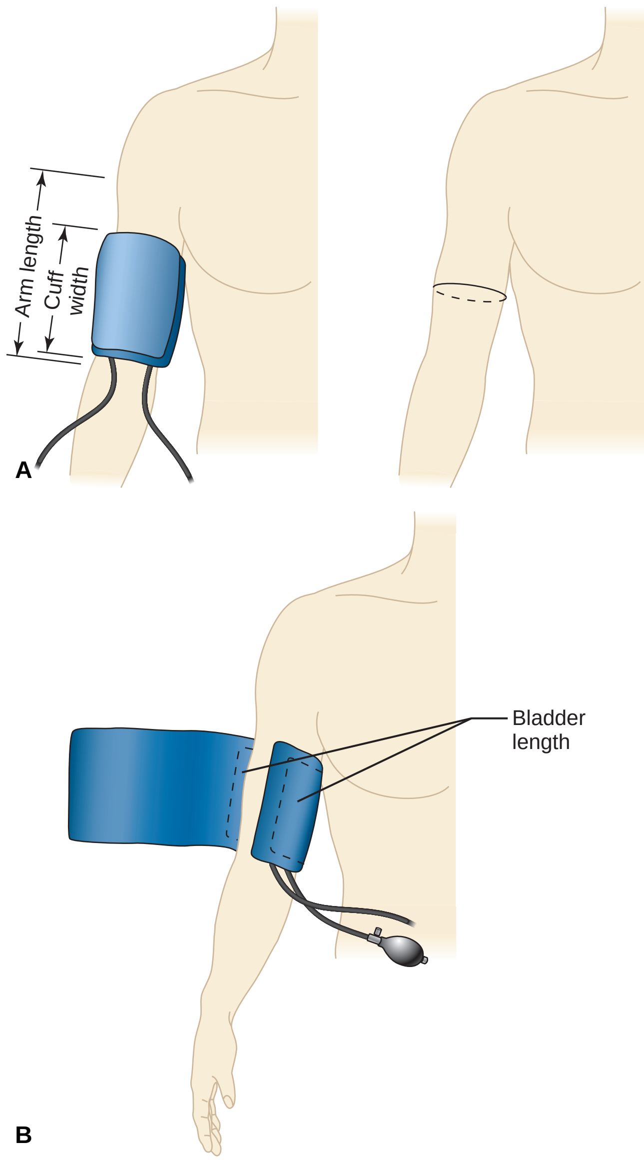

FIGURE 20-10 Determining correct BP cuff size. *A*, The cuff width should be two-thirds of the length of the upper arm, or should encircle 40% of the arm. *B*, The length of the bladder should encircle 80% of the upper arm.

probably have access to only two or three different adult sizes. If you must use a cuff of the improper size, (1) it is better to use one that is too large than one that is too small, and (2) be sure to document the cuff size along with the BP reading. Even if you do have a cuff of the proper size, it is helpful to document the size anyway: (1) for consistency, and (2) because it provides evidence of accuracy in making treatment decisions.

Refer to Table 20-6 for information about cuff sizes in centimeters; also,

Go to **Clinical Insight 20-1, Choosing a Blood Pressure Cuff Size,** in Volume 2.

Which Site Should I Use?

You usually use the *brachial artery* for assessing BP. However, the condition of the client's arm as well as other factors can interfere with accurate BP measurement. Avoid assessing blood pressure in an arm that has an intravenous access device, renal dialysis fistula, or skin graft; that is paralyzed, diseased, or has extensive trauma; that has a cast or dressings; or that is on the same side of breast or shoulder surgery. In these and similar instances, you can use the forearm, thigh, or calf. Systolic pressure may be 20 to 30 mm Hg higher in the lower extremities than in the arms, but diastolic pressures are similar. Also, forearm and upper arm readings may not be interchangeable. Document the site used. For a summary of the procedure for measuring blood pressure, see the Highlights of Procedures box. For the entire procedure,

Go to **Procedure 20-6: Measuring Blood Pressure,** in Volume 2.

Also refer to the QSEN Box, Using Evidence to Support Clinical Practice.

Auscultating Blood Pressure

Blood pressure can be measured indirectly by auscultation or palpation. The preferred, and most commonly used, method is auscultation; however, palpation is

Quality and Safety Education for Nurses

Using Evidence to Support Clinical Practice

Chapter Key Concept: *Perfusion (blood pressure)*

Competency: *Evidence-Based Practice (Knowledge, skills, attitudes)**

Background: It is essential to measure blood pressure accurately for appropriate treatment and management (Turner, Burns, Chaney, et al., 2008; Elliott & Coventry, 2012). Accuracy and reliability of blood pressure measurement are improved by proper patient position, arm position, and timing. Research shows a correlation between increased readings and timing of the measurement, positioning of the patient (standing, versus sitting in a chair, versus sitting on examining table) and positioning of the arm at the level of the heart (Pickering, Hall, Appel, et al., 2005; Tomlinson, 2010; Turner, Burns, Chaney, et al., 2008).

Scenario: A 70-year-old obese patient is seen at the ambulatory care setting with a history of hypertension and peripheral vascular disease. You are assessing the vital signs to provide data for medication management. Prior to taking the patient's blood pressure you obtain an aneroid sphygmomanometer and then request she sit in a chair and extend one arm while supporting the arm at level of the heart. Another nurse states, "You don't need to do all that."

Think about it:

- What factors could influence the accuracy of the blood pressure assessment in this patient?
- What evidence will you give the other nurse for your actions and how will you locate best evidence to support your response?
- What other actions should you institute to maintain accuracy in blood pressure measurement?

*For specific Knowledge, Skills, and Attitudes,

Table 20-6 ➤ Blood Pressure Cuffs: Acceptable Bladder Sizes*

CUFF TYPE——>	NEWBORN	INFANT	CHILD	SMALL ADULT	ADULT	LARGE ADULT	ADULT THIGH
Arm circumference at midpoint (cm)**	< 6	6–15	16–21	22–26	27–34	35–44	45–52
Bladder width (cm)	3	5	8	12	16	16	16
Bladder length (cm)	6	15	21	22	30	36	42

Sources: Perloff, Grim, Flack, et al. (1993); Pickering, Hall, Appel, et al. (2005).
*The National Heart, Lung, and Blood Institute states that practically speaking, "correct cuff size equals the largest cuff that will fit on the upper arm with room below for the stethoscope head" (2007).
**Arm circumference is half the distance from the acromion to the olecranon process. If correct size not available, use next larger (rather than smaller) size.

useful in certain situations. When auscultating BP, place your stethoscope over an artery, inflate the cuff, and listen for sounds as you deflate the cuff.

As you *inflate* the cuff, the artery is occluded as the pressure of the cuff exceeds the pressure in the artery. At that point, blood flow through the artery is halted, and no sound can be heard. As you *deflate* the cuff, blood begins to flow rapidly through the partially open artery, producing turbulence that you will hear through the stethoscope as a tapping sound.

- *The first sound* you hear when the cuff is slowly deflated is the systolic pressure.
- *The disappearance of sound* identifies the diastolic BP. When the artery is no longer compressed, blood flows freely, and no sound is heard.

The sounds you listen for when you assess BP are called **Korotkoff sounds.** These sounds, described by Russian neurologist Nicolai Korotkoff in 1906, are used to describe the sounds of blood pulsating through arteries (Fig. 20-11).

1st sound—As you deflate the BP cuff, you will initially hear a sound that occurs during systole. It is a tapping sound that corresponds to the pulse (systolic BP).
2nd sound—Occurs as you further deflate the cuff. It is a soft, swishing sound caused by blood turbulence.
3rd sound—Begins midway through the BP and is a sharp, rhythmic tapping sound.
4th sound—Like the third sound, but softer and fading.
5th sound—Silence; it corresponds with diastole (diastolic BP).

You will not always be able to identify each of the five sounds. In some clients the sounds are distinct, but in others you will note little difference between beginning and ending sounds. To hear these sounds,

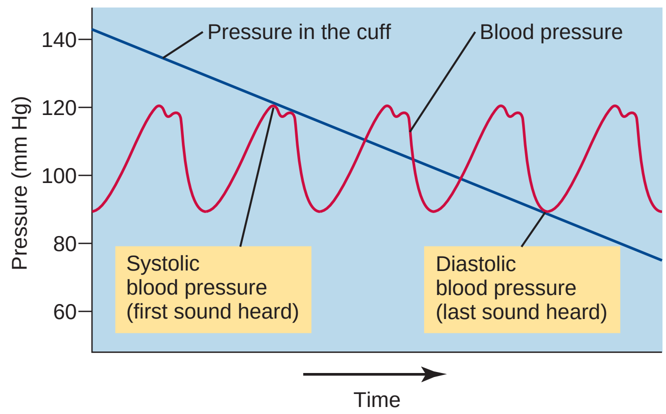

FIGURE 20-11 Relationship of blood pressure to changes in cuff pressure and the first and fifth Korotkoff sounds (BP 120/80).

Go to **Sounds, Blood Pressure Sounds,** on Davis*Plus*.

Also go to Chapter Resources, **Chapter 20, Resources for Caregivers and Health Professionals: Sounds,** on Davis*Plus*.

Palpating Blood Pressure

When the BP is difficult to hear (e.g., in shock, or other conditions that compromise circulation) you can use palpation alone. You can usually palpate only the systolic BP, because diastolic pressure is difficult to feel. To learn this technique,

Go to **Procedure 20-6, Variation D, Palpating the Blood Pressure,** in Volume 2.

Using Palpation With Auscultation

You should use palpation with auscultation for calculating the proper cuff inflation pressure before auscultating the BP and for detecting an auscultatory gap, to be discussed shortly.

Calculating Proper Inflation Pressure

The first time you measure a client's BP, you do not know what the systolic BP will be. Should you pump the cuff to 200 mm Hg, just to be sure you don't miss the first sound? The answer is NO. If you overinflate the cuff, the patient will feel discomfort. However, if you underinflate it (e.g., stop inflating at 110 mm Hg), you may miss the first sound and obtain an incorrect reading.

You can use palpation with auscultation to estimate the systolic BP. This helps ensure that you inflate the cuff to the proper level to obtain an accurate reading. To learn how to perform this method,

Go to **Procedure 20-6, Measuring Blood Pressure,** in Volume 2

Recognizing an Auscultatory Gap

If the client has hypertension, as you auscultate the BP during deflation of the cuff you may note the loss of sounds for as much as 30 mm Hg, followed by the return of sound. This loss and later return of sound is referred to as an **auscultatory gap**. Palpating first and then auscultating (as described in the preceding paragraphs) ensures that you will not miss the isolated first sound. You should record the range of pressures in which the gap occurs (e.g., BP left arm, sitting, 170/90 with an auscultatory gap from 170 to 140). Failure to recognize an auscultatory gap can result in a serious misreading of the systolic BP. For tips that will help ensure the validity of your BP measurements,

Go to Chapter 20, **Clinical Insight 20-2: Taking an Accurate Blood Pressure,** in Volume 2.

KnowledgeCheck 20-6

- Which of the Korotkoff sounds would you record as the systolic pressure?
- Which of the Korotkoff sounds would you record as the diastolic pressure?
- A nurse is auscultating a BP. He hears the first sound at 170 mm Hg. The sound disappears immediately. At 150 mm Hg, the sound appears again and continues until there is silence at 80 mm Hg. The pressures were taken in the client's right arm while the client was lying down.
  How should the nurse record these pressures?
  How do you explain what happened?

ANALYSIS/NURSING DIAGNOSIS

Hypotension and hypertension are medical diagnoses or, more commonly, symptoms rather than nursing diagnoses. However, they may be the etiology of nursing diagnoses—for example, Risk for Falls related to orthostatic hypotension.

Example Problem: Hypotension

Hypotension is diagnosed when systolic blood pressure is less than 100 mm Hg. A low blood pressure is usually not considered a problem. However, further evaluation is always called for if:

- The client is also experiencing dizziness, fatigue, concentration problems, activity intolerance, or shortness of breath, or
- The low blood pressure is of sudden onset.

Hemorrhage and heart failure are two causes of hypotension. Very low BP (hypovolemic shock) is a medical emergency. If you need more information on hypovolemic shock, consult a medical-surgical nursing text.

Orthostatic, or postural, hypotension occurs when a person's BP drops suddenly on moving from a lying position to a sitting or standing position. Orthostatic hypotension is defined as a decrease of 10 mm Hg in standing blood pressure when associated with dizziness and/or fainting (Joint National Committee, 2004). Postural hypotension results from peripheral vasodilation without a compensatory increase in cardiac output. It is most likely to occur in older adults, pregnant women, clients on prolonged bed rest, and clients with decreased blood volume (e.g., from dehydration or recent blood loss).

The following are examples of nursing diagnoses with hypotension as the etiology.

- Risk for Falls related to dizziness secondary to postural hypotension
- Fear of falling related to fainting secondary to postural hypotension

Example Problem: Hypertension

A transient elevation in BP is a normal response to physiological or psychological stress (e.g., after eating, after exercise). **Prehypertension** is a BP reading of 120 to 139 mm Hg systolic or 80 to 89 mm Hg diastolic, obtained with two readings taken 6 minutes apart, with the patient sitting. **Hypertension** is a persistently higher than normal BP. It is diagnosed when BP is above 140 mm Hg systolic or above 90 mm Hg diastolic on two or more separate occasions. Physiologically, hypertension is related to thickening of the arterial walls and decreased elasticity of the arteries.

Hypertension is a major cause of illness and death in the United States. Hypertension increases the stress on the heart and blood vessels, and if untreated, it may lead to heart attack, heart failure, peripheral vascular disease, kidney damage, or stroke (American Heart Association, n.d.a). The severity of the disorder is directly related to the degree of elevation; however, the latest guidelines (Joint National Committee, 2004) recommend that even prehypertension be treated by lifestyle modifications to prevent coronary artery disease. The diagnosis of hypertension is often delayed because symptoms are mild or absent. Those who experience symptoms may complain of early morning suboccipital headaches, fatigue, and visual changes.

Primary, or **essential**, **hypertension** is diagnosed when there is no known cause for the BP elevation. Essential hypertension accounts for at least 90% of all cases of hypertension. Although no single cause is identified, family history, age, race, obesity, diet, heavy alcohol consumption, smoking history, high cholesterol levels, and stress all contribute to the development of essential hypertension.

Secondary hypertension occurs when there is a clearly identified cause for the persistent rise in BP. A variety of renal and endocrine disorders may lead to secondary hypertension. Several prescription and nonprescription drugs can also cause BP elevation (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], oral contraceptives, some decongestants, and adrenal steroid hormones). Nicotine and caffeine cause transient (temporary) BP increases. Other causes of hypertension include use of cocaine, amphetamines, and other illicit drugs, as well as chronic overuse of alcohol. Treatment is directed at eliminating the underlying cause.

Hypertension is not a nursing diagnosis; it is a medical diagnosis. However, there are nursing diagnoses associated with it, as in the following examples:

- Risk for Decreased Cardiac Output occurs as a response to hypertension (i.e., hypertension is the etiology of this nursing diagnosis). As blood pressure rises, peripheral resistance increases. Over time the heart is unable to compensate, and cardiac output declines.
- Some nursing diagnoses may be the contributing factors for hypertension, for example:
  Imbalanced Nutrition: More than Body Requirements may be used if obesity (more than 20% above ideal body weight) is a factor in a patient's hypertension.
  Imbalanced Nutrition: More than Body Requirements (for salt) could be used for a client whose high dietary sodium intake is contributing to hypertension.
- Hypertension may be a defining characteristic (symptom) of some nursing diagnoses, for example: Anxiety and Pain may cause an increase in BP.
- Hypertension may create a diagnosis of Deficient Knowledge related to the need to make lifestyle changes.

PLANNING OUTCOMES/EVALUATION

You may need goals for overall blood pressure monitoring, but more likely you will use them for problems related to hypotension and hypertension.

Outcomes for Example Problem: Hypotension

The *NOC outcomes and goals* you use depend on the nursing diagnosis (the problem caused by the hypotension). For Risk for Falls, you might use NOC's Falls Occurrence. You might write *an individualized goal* such as, "Patient will have no falls while walking."

Outcomes for Example Problem: Hypertension

The NOC standardized outcome for assessing the blood pressure is Vital Signs Status. If it becomes necessary to monitor cardiac output, you could use the labels of Cardiac Pump Effectiveness and Circulation Status.

Individualized goals/outcome statements are developed from the nursing diagnosis. For example, for Decreased Cardiac Output, goals might be, "BP will be at least 110/80," and "Extremities will be warm to the touch with quick capillary refill." If the nursing diagnosis were Imbalanced Nutrition: More Than Body Requirements, the desired outcomes would address the target weight for the client and the ideal number of calories to be consumed.

Also go to Chapter Resources for Chapter 20, **Standardized Language, NOC Outcomes and NIC Interventions Associated With Abnormal Vital Signs,** on Davis*Plus*.

PLANNING INTERVENTIONS/IMPLEMENTATION

NIC standardized interventions for monitoring VS include the following:

Vital Signs Monitoring applies to monitoring an abnormal blood pressure.

Hemodynamic Regulation would be used to evaluate Decreased Cardiac Output.

Go to Chapter Resources for Chapter 20, **Standardized Language,** on Davis*Plus*.

Interventions for Example Problem: Hypotension

NIC standardized interventions will be determined by the nursing diagnosis you use. For example, for Risk for Falls related to orthostatic hypotension, you might use the following: Fall Prevention; Self-Care Assistance: Transfer; and Surveillance: Safety.

Specific nursing activities, regardless of the nursing diagnosis, must address the etiology. For example, when you detect orthostatic hypotension:

1. Help the client lie down.
2. Next, obtain *orthostatic vital signs*—that is, take the pulse and BP with the client supine, sitting, and standing. Take each reading 1 to 3 minutes after the client changes position. Notify the provider or nurse in charge of the measurements.
3. When documenting orthostatic vital signs, record the client's position in addition to the pulse and BP measurements (e.g., supine P = 80, BP = 150/90; sitting P = 84, BP = 140/84; standing P = 90, BP = 104/60).

Interventions for Example Problem: Hypertension

Specific nursing activities for the patient with hypertension depend on whether hypertension is primary or secondary and on specific orders from the physician. Nursing activities and focused assessments that address hypertension, regardless of its cause, include the following:

Focused Assessments

- *Monitor all VS.* An elevated BP may affect the client's other VS. Watch for increases in pulse and respiratory rate.
- *Monitor the patient's activity tolerance.* The patient's degree of involvement in care, orientation, and level of fatigue while experiencing hypertension are all important indicators of decreased cardiac output.
- *Accurately measure intake and output.* If intake is appreciably greater than output, the increased blood volume will cause the BP to rise further. Pay attention to free fluids as well as fluid in food sources. Also monitor for edema, which is an indicator of fluid retention.
- *Weigh the client regularly.* Weight loss of as little as 10 lb (4.5 kg) lowers BP in many overweight persons with hypertension. Weight gain may signal poor compliance with the treatment plan and/or indicate fluid retention.
- *Collect and assess laboratory data as ordered.* Blood urea nitrogen (BUN), creatinine, electrolytes, hemoglobin, hematocrit, and lipid levels must all be assessed regularly.

Administering Medications

Administer antihypertensive medications as prescribed to control blood pressure. Unless the healthcare provider instructs otherwise, antihypertensives may best be taken at bedtime. Research has found that taking at least one antihypertensive medication at night decreases the risk of cardiovascular disease (Keller, 2011).

Assess the client's attitude and beliefs about taking antihypertensive medications. Research shows that older adults with negative beliefs about their medication are more likely to be noncompliant in maintaining the medication regime (Ruppar, Dobbels, & Geest, 2012). You should help the client understand and gain realistic expectations regarding the medication therapy.

Teaching for Self-Care

- *For self-monitoring of BP,* see the box Home Care: Teaching Your Client Self-Monitoring of Blood Pressure. One study has found that self-monitoring better predicted clinical outcomes than single office measurements (Ransome, 2005).
- *For client teaching regarding hypertension*, see the box Self-Care: Teaching Your Client About Hypertension.
- *Teach stress management and relaxation techniques.*

Such training has been effective in helping older adults with systolic hypertension to eliminate at least one antihypertensive drug and reduce their BP to target levels (Dusek, Hibberd, Buczynski, et al., 2008).

- *Teach and encourage self-management of behaviors;* provide positive feedback when the patient makes lifestyle changes.
- *Certain alternative therapies may help lower blood pressure* (see the box Complementary & Alternative Modalities).

Complementary & Alternative Modalities (CAM)

Alternative Therapies for Lowering Blood Pressure

According to a recent American Heart Association Scientific statement, some alternative methods reduce blood pressure—particularly aerobic exercise and resistance training—can be considered adjunctive to the medical therapies of diet and medication. Biofeedback techniques (isometric handgrip exercise and device-guided slow breathing) are likely to reduce blood pressure by a small amount, but the evidence is not as strong. Evidence is insufficient to support use of the following as adjunctive treatments for hypertension: meditation, yoga, relaxation therapy, stress-reduction techniques, and acupuncture.

KnowledgeCheck 20-7

- Which of the following patients has hypertension? One with a BP of:
  150/80 on two separate occasions
  180/100 on one occasion
  138/88 on two occasions
- Which of the following client(s) has/have *primary* hypertension?
  Client A, who is obese and has a high sodium intake
  Client B, who is in renal failure
  Client C, who has hypertension induced by pregnancy
  Client D, who has a family history of hypertension

Self-Care

Teaching Your Client About Hypertension

Teach the client and family about lifestyle changes for preventing and managing hypertension.

- Limit salt intake to 1 teaspoon per day (2,400 mg of sodium).
- Consume a diet high in potassium (e.g., fresh fruits and vegetables, such as bananas, potatoes, yogurt, and acorn squash).
- Consume a diet high in calcium (e.g., milk and milk products, sardines, molasses, tofu).
- Limit alcohol intake to 1 or 2 drinks per day for men; 1 for women. (One drink is a can of beer, one jigger of liquor, or a glass of wine. Wine is preferred.)
- Maintain ideal body weight; lose weight if overweight.
- For overall cardiovascular health, reduce saturated fat and cholesterol intake.
- Eliminate smoking.
- Engage in aerobic exercise (30 to 45 minutes, several days a week, or a total of 150 minutes per week).
- Try to reduce stress and stressful situations.
- Teach the client that even one lifestyle change has effects similar to treatment with a single antihypertensive drug. More than one change has an even more positive effect on the BP.

Teach the client about monitoring his blood pressure at home.

- Monitor blood pressure at home to determine whether lifestyle modifications and/or medications are effective.
- Keep a record of your BP readings that contain the date, time, systolic and diastolic numbers, and any information that you want your provider to know.
- Take your BP whenever you experience symptoms such as headaches, dizziness, etc.
- Use an upper arm or wrist BP monitor that has been validated.
- Take your BP equipment when you visit your healthcare provider to check your monitor for accuracy.
- Follow the researchers' and manufacturer's guidelines for arm position and recalibration. This is especially true for wrist monitors (Dourmap, Girerd, Marquand, et al., 2010; Zeng, Huang, Sheng, et al., 2012).

Teach the need for follow-up assessments.

For BP of:			Teaching Points
Systolic		**Diastolic**	**Analysis and Client Action**
<120 mm Hg	and	<80 mm Hg	Normal Blood Pressure Recheck at each healthcare encounter or at least every 2 years.
120–139 mm Hg	Or	80–89 mm Hg	Prehypertension Review lifestyle modifications and make follow-up visits as your primary healthcare provider advises. If you have not seen a provider, consult one within 1 to 2 months.
140–159 mm Hg	Or	90–99 mm Hg	High Blood Pressure—Stage 1 (Note: This may differ slightly for older adults.) Review lifestyle modifications and schedule follow-up with a healthcare provider within 1 to 2 months.
160 or higher mm Hg	Or	100 or higher mm Hg	High Blood Pressure—Stage 2 Consult the primary care provider within 1 week, or immediately if the clinical situation warrants.

ThinkLike a Nurse 20-10

Recall the clients in the Meet Your Patients scenario. Lucas is 35 years old. He has been under a lot of stress. His blood pressure is 150/98.

- To evaluate his BP, what else do you need to know about Lucas's situation (the context)?
- What possible actions should you consider while meeting with Lucas?
- What is the theoretical knowledge (rationale) to support your decisions?

PUTTING IT ALL TOGETHER

In the hospital setting, you will usually take a complete set of VS on patients at regular intervals. In ambulatory care settings, the VS you measure may vary according to the client's chief complaint. Regardless of setting, you will need to use clinical judgment about which VS to measure and how often to measure them.

Evaluating Vital Signs

You should evaluate the client's VS on the basis of known norms as well as the particular client's trends. Suppose your client's BP has consistently been 150 to 160/90 over the past 3 days. This afternoon his BP is 108/60. Although this BP is theoretically normal, it is significantly different from his norm. Therefore, you must evaluate the cause of the change. Has there been a change in the other VS? Has there been a change in the client's medications or condition? How does the client feel? Has his activity level been altered by the change in BP? This change may be positive or negative. You must put all the VS and other clinical signs together to determine your course of action.

A high fever can cause BP to drop precipitously. Suppose this client's temperature is 103.5°F (39.7°C). In that case, in addition to his drop in BP, you should also anticipate a rise in pulse and respiratory rate. What should you do? Your action depends on the client's condition and the context. What else is going on in the situation? If medication for the fever has been prescribed for the client, you would administer the medication and evaluate the VS again at frequent intervals. If the VS do not improve, you would then notify the primary care provider.

Now change the context slightly. Add to your preceding data that the client has undergone a surgical procedure and is not taking any antibiotics. Now what should you do? If your answer is to notify the primary care provider, you are correct. Always evaluate all the VS as a unit. A sudden change in the client's condition requires you to thoroughly assess the client and report your findings to the primary care provider.

A change in a client's VS may also be a positive sign. For instance, if the client has been in severe pain for 3 days and has finally obtained pain relief, a decrease in BP probably indicates that the current medication regimen has provided better control of the pain. You would still need to monitor the VS at more frequent intervals, however, to ensure that the BP does not continue to fall.

Delegating Vital Signs

In many healthcare settings, several providers interact with the clients. VS may be obtained by nursing assistants or other unlicensed personnel.

When working with complex or critical patients, you should carefully consider whether to delegate VS to a NAP. The significance of the VS results must be analyzed in relation to other assessment data.

If you are working in a team nursing model as the registered nurse (RN), you are responsible for reviewing and interpreting the findings of all NAPs. This includes evaluating the technique of NAPs and the accuracy of their measurements. The professional nurse *never* relinquishes the responsibility for interpretation of VS trends and decisions based on abnormal VS findings. As a student nurse, you are responsible for functioning within your scope of knowledge. If you are unsure how to interpret the meaning of a patient's VS, you must discuss the findings with your instructor and/or the nurse assigned to care for your client. Even though you are participating in the client's care, the assigned nurse maintains responsibility for client oversight.

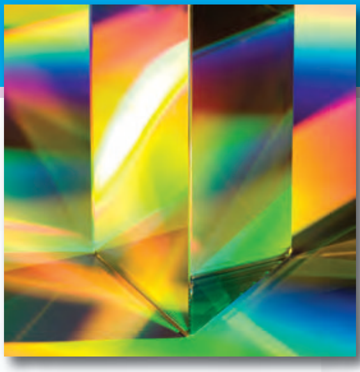
CHAPTER 21



Communication & Therapeutic Relationships

Learning Outcomes

After completing this chapter, you should be able to:

- Define communication.
- Identify the three basic levels of communication.
- Discuss the elements of the communication process.
- List the characteristics of verbal and nonverbal communication.
- Analyze factors that influence the communication process.
- Describe the elements of collaborative professional communication.
- Explain how relationships and roles influence communication.
- Describe the role of communication in each of the four phases of the therapeutic relationship.
- Compare and contrast techniques that enhance communication to techniques that hinder communication.
- Communicate with clients with impaired hearing, speech, or cognition.
- Communicate with clients whose culture or language is different from yours.
- Write a nursing care plan for a client experiencing impaired communication.

Key Concepts

Communication

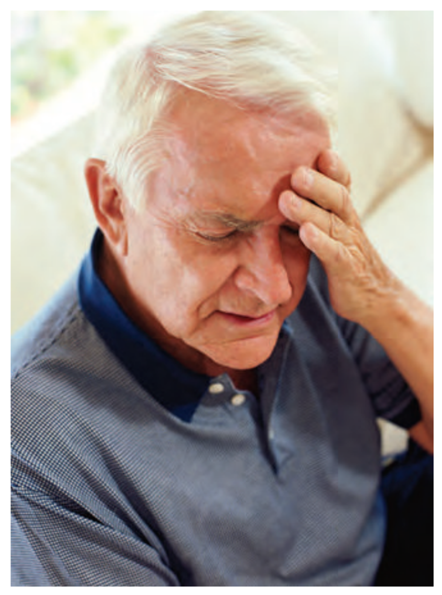
Meet Your Patient



You have been assigned to care for John Barker, a 56-year-old man admitted to the hospital with bleeding in the lower gastrointestinal tract. When you approach Mr. Barker to introduce yourself, you find him in his room with his wife at the bedside. They are holding hands, and clearly both have been crying. You begin by saying, "Good afternoon, Mr. Barker, I am a nursing student from the nearby university. I've been assigned to care for you tomorrow." Mr. Barker swallows hard and says, "I don't think you'll be able to do anything for me!" His wife says, "Don't take it personally. It's not a good time right now. Please just leave us alone."

You leave the room unsure how to respond. When you go to the unit station to review the chart, the charge nurse says, "Oh my! You've been assigned to him? I hope you've got a lot of experience." As you review the chart, you realize that Mr. Barker was just informed that he has metastatic colon cancer and probably has only a few months to live.

Theoretical Knowledge knowing why

As a resource to you while you are learning what it means to care for patients in difficult situations such as Mr. Barker's, you might look to the following professional and regulatory agencies that stress the importance of good communication:

- **Quality and Safety Education for Nurses (QSEN).** To provide for patient safety, nurses need to effectively communicate their concerns about hazards and errors to patients, families, and the healthcare team (Cronenwett, Sherwood, Barnsteiner, et al., 2007).
- **The Joint Commission (2013).** The Joint Commission National Patient Safety Goal 2, aims to improve patient safety by improving communication among caregivers.
- **The Joint Commission (2010b).** Performance standards state that patients have the right to receive effective, understandable information.

As you read this chapter, you will gain theoretical and practical knowledge to help you to communicate effectively with patients, families, and other members of the healthcare team.

ABOUT THE KEY CONCEPTS

In this chapter you will learn how **communication techniques** link to the concept of **communication**, and how they both help you to form **therapeutic relationships**. With an understanding of these and the related concepts, you will be able to communicate more effectively with patients, families, and members of the healthcare team.

WHAT IS COMMUNICATION?

Communication is a dynamic, two-way process of sending and receiving messages. The messages may be verbal, nonverbal, or both, and they may involve two or more people. As such, communication forms the basis for sharing meaning and building effective working relationships among individuals, families, and the healthcare team. Successful communication occurs when providers understand and use information shared by their patients when devising a plan for care. Likewise, patients must also be able to accurately comprehend information in a way that enables them to participate responsibly in their own care (The Joint Commission, 2010a, 2010b).

Communication is more than the act of talking and listening (Box 21-1). It is a basic function of human life. From the first cry of a newborn to the whisper of a patient who is dying, the primary purpose of communication is to share information and obtain a response. People use communication to meet their physical, psychosocial, emotional, and spiritual needs.

BOX 21-1 ■ What Is Communication?

Communication is . . .

- Sharing or transmitting thoughts or feelings
- A way to meet physical, psychosocial, emotional, and spiritual needs
- A process—the act of sending, receiving, interpreting, and responding to a message
- Content—the actual subject matter, words, gestures, and substance of the message

Communication Occurs on Many Levels

When we think about communication, we usually imagine a dialogue between two individuals. But communication actually occurs on any of many levels.

Intrapersonal Communication is conscious internal dialogue, sometimes known as self-talk. Constructive affirmations, or positive self-talk (e.g., "This will work! I can do it"), promote success in a task. In contrast, negative self-talk (e.g., "I can't do this, it is too difficult") may adversely affect a person's ability to complete a task. Nurses often engage in intrapersonal communication. For example, if you enter a room and notice that your patient is pale, diaphoretic, and moaning, you may ask yourself, "What's happened? This client appears to be in a lot of pain."

Interpersonal Communication occurs between two or more people. Face-to-face conversation between two people is the most frequent form of interpersonal communication. Nurses use interpersonal communication to gather information during assessment, to teach about health issues, to explain care, and to provide comfort and support. In addition to communicating directly with clients, professional nurses communicate with other nurses and healthcare team members to provide comprehensive care for clients. Because professional nurses are accountable for appropriate delegation of activities, they must also communicate effectively with nursing assistive personnel (NAP).

Group Communication is interaction that occurs among several people. *Small-group communication* occurs when you engage in an exchange of ideas with two or more individuals at the same time. Examples of small-group communication include staff meetings, committee meetings, educational groups, self-help groups, and family teaching sessions. Working with groups requires effective communication skills and a basic understanding of group processes—discussed later in the chapter.

Public Speaking is a unique form of group communication. Generally, the speaker addresses a dozen to hundreds of people, with varying degrees of interaction. Speakers may deliver a speech, talk directly with a small group of audience members, or have open discussion with the group. Nurses engage in public speaking to educate groups of people about health issues, to lobby for health legislation, and to address colleagues at professional conferences.

KnowledgeCheck 21-1

- What is the purpose of communication?
- Describe the three levels of communication.
- What level of communication was used in the Meet Your Patient scenario?

ThinkLike a Nurse 21-1

Evaluate your own skills with the three levels of communication.

Communication Involves Content

Communication has two major components: content and process. Both are important for effective communication. The **content** of communication describes the actual subject matter, words, gestures, and substance of the message. It is the message that everyone may hear or see. For example, suppose your client said, "I slept through lunch." This statement is open to interpretation. We cannot tell—without also observing him, knowing his history, and so on—whether he thinks this is a good thing because he wanted or needed rest, or a bad thing because he is so exhausted, or a complaint about the staff because they did not wake him for lunch, or an apology and request for a late lunch. As you can see, the words are just a part of communication. You must also consider the process.

Communication Is a Process

Process refers to the act of sending, receiving, interpreting, and reacting to a message. The communication process has five elements: sender, message, receiver, feedback, and channel. Figure 21-1 illustrates the relationship among these elements.

- The **sender** begins the conversation to deliver a message (content) to another person. The sender, also called the *source* or the *encoder,* uses verbal and nonverbal methods to transmit the message.
- **Encoding** refers to the process of selecting the words, gestures, tone of voice, signs, and symbols used to transmit the message. For example, as a beginning nursing student, you might feel anxious about caring for Mr. Barker (Meet Your Patient). How could you communicate your concerns to your instructor? You might directly state, "It makes me nervous to be assigned to him"; or you might avoid eye contact with your instructor and tell her, "I'm going to need some help today." Both styles communicate your anxiety, but they are encoded differently. Encoding is affected by the situation, the nature of the message, the mood of the sender, and the relationship between sender and receiver.
- The **message** is the verbal and/or nonverbal information the sender communicates. It might be content of a conversation, a speech, a gesture, a letter, and so forth. Effective messages are complete, clear, concise, organized, timely, and expressed in a manner that the receiver can understand. The message must be appropriate for the situation and for the developmental level of the person receiving the message.
- The **channel** is the medium used to send the message. Face-to-face communication is a commonly used channel. Nurses frequently use touch as a nonverbal way to communicate caring and concern. Other channels include written pamphlets, audiovisual aids, recordings, telephone and text messages, and the Internet. When choosing the best channel for communicating, consider the type of message, its purpose,

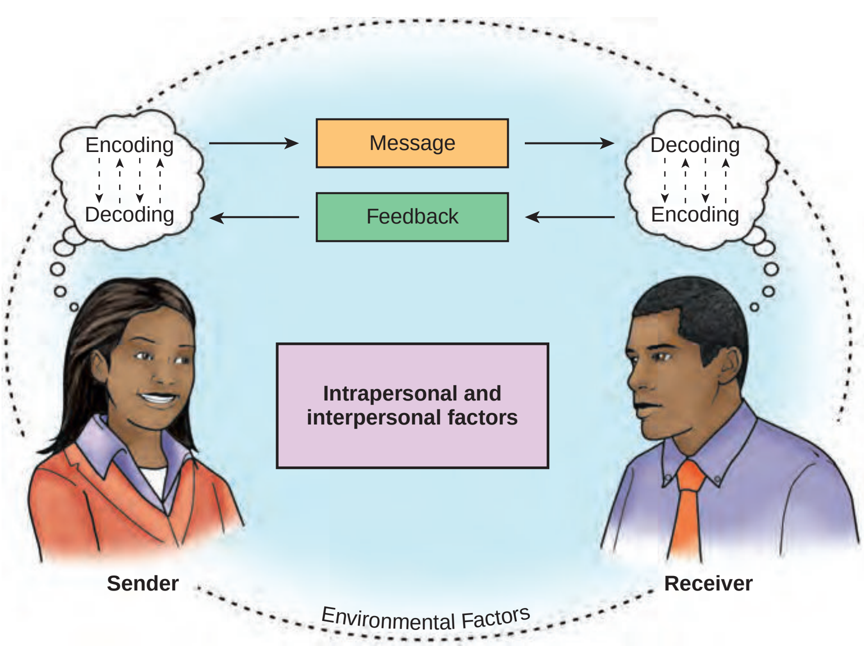


FIGURE 21-1 Communication: A sender encodes and transmits a message to a receiver, who decodes it and transmits feedback.

and the size of the audience. In Mr. Barker's case (Meet Your Patient), for example, touching his hand while remaining silent might send a clearer message of caring than any words you could say.

- The **receiver** is the observer, listener, and interpreter of the message. **Interpretation**, also called **decoding**, refers to relating the message to your past experiences to determine the sender's meaning. The receiver uses visual, auditory, and tactile senses to decode the message. If the decoded meaning matches the intended meaning, then the message was effective. However, messages are sometimes misinterpreted, especially when the receiver is not physically or emotionally ready to receive the message. For example, if you approached your instructor to discuss your concerns about Mr. Barker when she was assisting with an emergency, she might be unable to receive your message.
- **Feedback** may be verbal, nonverbal, or both. Once the receiver has received and interpreted the message, he may be stimulated to respond by providing feedback to the sender. Feedback validates that the receiver received the message and understood it as the sender intended. Verifying the message avoids confusion.

KnowledgeCheck 21-2

Using the Meet Your Patient scenario, identify at least one sender, one message, one receiver, one channel, and one example of feedback.

Verbal Communication

People send and receive messages both verbally and nonverbally. The two forms of communication occur spontaneously and simultaneously. **Verbal communication** is the use of spoken and written words to send a message. It is influenced by such factors as educational background, culture, language, age, and past experiences. Verbal communication is generally a conscious act in which the sender is able to select the most effective words to communicate a message. When delivering a verbal message, the goal is that the receiver will understand both your words and your meaning. Many factors, including the following, affect how a message is received.

Vocabulary

Healthcare workers have a large vocabulary of technical terms and jargon. However, laypersons are often unfamiliar with healthcare language and find its use intimidating, or at best puzzling. Consider the following example, in which a nurse says:

> *"You are scheduled for surgery tomorrow. You need to be NPO after 2400. I'll be in to prep the op site at about 8. You'll need to void before your pre-med. After that we'll move you to a gurney and transfer you to the holding area."*

Do you think most clients would understand this message? Do *you* understand all the words? For various reasons (e.g., being embarrassed at not knowing), many clients hesitate to ask questions to clarify what said the healthcare provider says. How much better it would be if the nurse had said:

> *"Your surgery will be tomorrow morning. You will not be able to eat or drink anything after midnight. I'll come in about 8 in the morning to clean your hip and get it ready for the operation. Then you'll need to urinate before I give you some medicine to relax you. After that, we'll put you on a cart and roll you up to the operating area."*

Key Point: ***It is your responsibility to deliver messages that the client can understand; therefore, use medical terms only when you are certain the listener understands them.***

When encoding a message, consider the receiver's age, knowledge, education, and any cultural differences, including primary language spoken. (These factors are discussed shortly.) Encourage feedback to be sure that the receiver understood the message as you intended.

Denotative and Connotative Meaning

Denotation is the literal (dictionary) meaning of a word. In contrast, **connotation** is the implied or emotional meaning of the word. Consider the following examples:

A mother says to her infant, "Don't cry, baby."
A 40-year-old man says to his nurse, "Would you rub my back, baby?"
A 10-year-old boy says to another boy, "You're a baby!"

The denotative meaning of *baby* is a very young child who is not yet able to walk. However, the connotative meaning is different in each example. In the first example, the connotative meaning is the same as the denotative meaning. In the second example, the nurse might interpret it as a sexist remark; and in the last example, the 10-year-old boy undoubtedly meant *baby* as an insult. As you can see, words are often value-laden or biased. The situation, qualities of the participants, and the words they choose all affect interpretation. Use terms that provide clear, objective data and are not open for misinterpretation.

ThinkLike a Nurse 21-2

Think of two other examples in which the connotative meaning may be different from the denotative meaning.

Pacing

What happens when a professor talks very slowly during a lecture? Do you find your mind wandering: "I need to take the dog to the vet. . . . What shall we have for dinner? . . ." The pace and rhythm of the delivery can alter the receiver's interpretation of the message. A rapid pace does not allow the receiver to track what the speaker is saying, so the receiver may become frustrated and lose interest. The pace must be slow enough for the receiver to interpret one thought before the sender moves on to the next thought, but must also be fast enough to maintain the listener's interest. Pausing at intervals gives the listener time to respond.

Intonation

Tone of voice, or **intonation**, reflects the feeling behind the words. We get a sense of a person's intonation by listening to the *pitch* (high or low), *cadence* (rising and falling of the pitch), and *volume* (soft or loud). For example, experiment with the variety of ways you might say, "Your test results are in."

Pitch, cadence, and volume can either reinforce or contradict the message. When spoken at a moderate pitch and volume, with a falling cadence, the words, "I understand that I am to report at noon," can be a simple confirmation that the person has received the message while conveying emotions. People tend to lose interest when someone speaks in a monotone (does not vary the pitch, cadence, and volume). Before presenting lengthy information, whether to an individual or to a group, experiment with these variables to ensure that the listener remains engaged with your topic.

When electronic messaging is used, the receiver does not have the advantage of intonation or body language. This may lead to miscommunication. People sometimes insert *emoticons* (symbols such as "smiley faces"), uppercasing, and punctuation, such as exclamation marks, to provide cues to the emotional tone of a message.

Clarity and Brevity

Clarity in communication requires that you select words that convey the intended meaning and that you make sure your spoken words and the nonverbal language send the same message. You can achieve brevity by using the fewest words possible. A conversation that is clear and brief holds the interest of all parties and effectively conveys the intended messages.

Timing and Relevance

Timing is crucial. Before starting a conversation, assess your client. A person who is distracted by pain, hunger, or other physiological needs will not receive the message as you intended it. Similarly, a client attempting to cope with stressors, such as limited finances, an upcoming surgery, or a terminal diagnosis, may be unable to listen effectively.

- **Consider the presence of others.** Asking a client about a personal issue in a public corridor may inhibit his response. You will receive a different response if you ask the same question in a more private setting. In contrast, if you are instructing a client about a recommended diet, be sure that the person who is responsible for shopping and cooking is also present. If your client does neither in his household, he may pay little attention to your instruction—it will not be relevant to him.
- **Communication is effective when both parties value the interaction and find the discussion relevant.** To teach your client about his medicines, choose a time when he is alert, pain-free (or with a manageable pain level), and not distracted. Begin by reminding him of the purpose of the discussion: "I'm going to teach you how to take this medication so that it effectively controls your pain."
- **The interaction must allow time for response.** A rapid flow of questions or one-sided conversation inhibits interaction.

Credibility

Clients judge the **credibility** (or believability) of the message by the trustworthiness of the sender. Your credibility depends on a pattern of honest and timely response to patient concerns, as well as congruence between your verbal and nonverbal communication.

- **Give information only if you are certain of the facts.** As a nurse, you will be called on to provide information on a wide range of topics. Give information only if you are certain of the facts. A response such as, "I don't know, but I'll find out and let you know" is far more credible than an incorrect answer or a guess.
- **If a situation makes you uncomfortable, it is better to acknowledge your discomfort than to risk loss of credibility.** For example, you may feel uncomfortable talking to Mr. Barker (Meet Your Patient) about his recent diagnosis. You may be tempted to say, "Maybe the test results are wrong," or "The timeline is just a guess. I think you can beat this." This approach avoids uncomfortable discussion and may make the patient feel better temporarily. However, a more honest approach would be to tell Mr. Barker that you would like him to talk with a counselor or hospital chaplain.
- **Always be open and honest with patients.** Deceiving patients can take many forms, but it always destroys trust. Trust in their care providers helps patients feel less vulnerable. If you tell the patient you will be right back with pain medication but forget to return until she reminds you an hour later, she may doubt your credibility. False reassurance (e.g., telling him that the procedure won't hurt or everything will be okay) also reduces your credibility and conveys to the patient that he can't trust you to tell him the truth.
- **To be credible, your nonverbal communication must match your spoken words.** For example, if your client asks you whether his wound is "ugly," he will pay attention to your facial expressions as well as your spoken response. If you respond that "the wound looks good," but frown or fail to make eye contact, the client will most likely believe that you are not being completely honest. This may jeopardize future interactions.

Humor

Laughter can create physiological changes that contribute to well-being and provide an emotional release in a tense situation, thus positively influencing the patient's attitude and healing. Humor is highly subjective and personal; and it also depends on cultural norms. Use humor cautiously, and never direct humor at the client, disease process, or treatment team. Misused humor can have a negative effect on self-esteem, self-confidence, or the client's confidence in the treatment team. Consider the different effects the following uses of humor might have. Imagine that your patient has had vomiting and diarrhea for the past 8 hours. When you enter the room you jokingly say, "Oh my! You look like you had too much to drink last night." Although the intent was to lighten the mood, this statement may offend your patient. In contrast, imagine that you notice that an older patient thoroughly enjoys visits from his young grandchildren. You might consider sharing with him an amusing story about your own children.

Nonverbal Communication

Nonverbal communication (or body language) is the exchange of messages without the use of words. Verbal communication is a highly conscious activity in which we choose words to communicate. Nonverbal communication occurs on a more unconscious level. Because nonverbal language emerges from how the sender is feeling, it more accurately conveys the true meaning of a message. It may thereby reinforce or contradict the spoken message. For example, Mr. Barker (Meet Your Patient) uses few words. However, he is tearful and distressed. That body language gives you valuable insight into how he is adjusting to the news of his cancer. Let's look at some nonverbal messages.

Facial Expression

Expressions of the face and especially the eyes are some of the most obvious forms of nonverbal communication. Facial expressions communicate joy, anger, sadness, concern, or fear. Raised eyebrows, staring, squinting, or darting eyes all convey meaning.

Smiling is one expression that everyone understands. In contrast, the interpretation of many other facial expressions is culturally dependent. For example, downcast eyes may indicate sadness, poor self-esteem, a desire to avoid the conversation, respect, powerlessness, or submissive behavior. In Western cultures, eye contact usually indicates an interest in the conversation and a willingness to communicate; however, in Eastern cultures, the amount of eye contact considered acceptable varies. Chapter 15 discusses cultural variations.

A mismatch between your verbal message and facial expression may cause the client to doubt your credibility (Fig. 21-2). For example, suppose that a patient states, "I just had my pain pill. Why is my pain still so bad?" You answer, "The medication should take effect within a few more minutes. If it doesn't, call me." Imagine the different effect this reply would have if you were smiling, frowning, raising one eyebrow, or avoiding eye contact.

FIGURE 21-2 The nurse's facial expression is not appropriate because the patient appears to be in distress.

Posture and Gait

Body position, gait, and posture offer clues to a person's attitudes, emotions, physical well-being, and self-concept. When you see someone with an erect posture, head held high, and a quick gait, what do you think? In Western culture, these are nonverbal indicators of health and a sense of self-assuredness. In contrast, a slow, shuffling gait may signify someone who is ill, has pain, is depressed, or has poor self-esteem.

Personal Appearance

Clothing and personal appearance provide clues to a person's feelings, socioeconomic status, culture, and religion. A person who is ill, tired, or depressed may lack energy for hygiene and grooming. Lack of attention to personal appearance is especially significant in a person who typically engages in meticulous grooming. As with all nonverbal data, you need to investigate the meaning of personal appearance to avoid drawing erroneous conclusions.

Dress and accessories are powerful cultural clues. Does the patient dress in a style that differs from local custom? Are pieces of jewelry or religious medallions visible? These are clues to the patient's values, as well as the patient's socioeconomic status. Pay attention to these clues, but do not make assumptions from them. A person who wears an elaborate religious medal may like the ornamentation but not espouse the beliefs that are attached to the symbol.

Key Point: ***Have you thought about what your own personal appearance conveys to your patients and colleagues?***

Most people express their individuality through their clothing, hairstyle, and so on. Nurses, however, must also consider how patients perceive them and whether their appearance helps or hinders their patient relationships. Issues of safety and cleanliness are also essential for nurses, when choosing clothing, hairstyles, and body adornment (e.g., jewelry, nail polish, tattoos, body piercings). The traditional white nursing uniform has been almost completely replaced by scrubs of various colors, which makes it difficult for patients to differentiate nurses from the rest of the healthcare team. To counteract this, some agencies are assigning colors for various personnel (e.g., blue for physicians, purple for nurses).

Gestures

Hand and body gestures emphasize and clarify the spoken word. They are good indicators of the feeling tone behind the conversation. Imagine that your client says, "I'm okay." What might it mean if he accompanies his statement with a broad grin and raised arms? What might it mean if, instead, he lowers his head to his hands?

Gestures vary widely among individuals and cultures, so use them with caution. For example, consider the gesture of a "V" made with the second and third fingers of the hand. To some people, this is a peace sign; to others, it also represents the number two; and still others may attach no meaning to it at all. Gestures can help you communicate with individuals with impaired verbal communication, but only if you and the patient agree on the meaning of the gestures.

Touch

Touch can convey affection, caring, concern, and encouragement (Fig. 21-3). Avoid using touch when dealing with someone who is angry or mentally disturbed because the touch may be misinterpreted (e.g., as a sign of aggression or sexual attraction). Although touch can be highly effective, use it with sensitivity to the situation, environment, culture, and receptivity of the patient.

FIGURE 21-3 The nurse conveys genuine caring using touch.

For examples of therapeutic nonverbal behaviors and how patients may interpret them,

Go to **Clinical Insight 21-1: Enhancing Communication Through Nonverbal Behaviors,** in Volume 2.

KnowledgeCheck 21-3

- Identify the components of verbal and nonverbal communication.
- What action should you take when there is a discrepancy between the client's spoken word and nonverbal body language?

Toward Evidence-Based Practice

Cousin, G., Mast, M. S., Roter, D., et al. (2012). Concordance between physician communication style and patient attitudes predicts patient satisfaction. *Patient Education and Counseling, 87*(2), 193–197.

This study investigated the impact of physicians' communication style on patient satisfaction. In a study of patients with recurrent headaches, researchers found that a high caring physician communication style led to higher satisfaction than a low caring one.

Griffiths, J., Speed, S., & Keeley, P. (2012). A caring professional attitude: What service users and carers seek in graduate nurses and the challenge for educators. *Nurse Education Today, 32*(2), 121–127.

Researchers compared the qualities emphasized in a nursing curriculum and those valued by patients. A diverse sample of patients expressed value in technical competence, knowledge, and willingness to seek information. Additionally, they overwhelmingly prioritized caring professional attitude, which included empathy, communication skills, and nonjudgmental, patient-centered care.

1. Suppose you are a graduate nurse working in an intensive care unit of a large teaching hospital. You are providing care to the following three patients. What are some ways you would communicate caring to these patients and their families? List at least three strategies for each patient.
   a. 65-year-old man 3 hours post-op after repair of an abdominal aortic aneurysm. Your patient is intubated and breathing with the assistance of a mechanical ventilator. He is fully alert and responsive after surgery.
   b. 88-year-old frail woman with delirium receiving a blood transfusion for a lower GI bleed.
   c. 3-year-old child with an acute epiglottitis whose parents are not in the unit.

2. What pitfalls in communicating would you avoid in caring for your patients?

ThinkLike a Nurse 21-3

- Observe an interaction between family members or your fellow students. Look for congruence between verbal and nonverbal communication. Strategize what you would say to validate the intended meaning when the two modes of communication are not in agreement.
- Recall the brief interaction with the charge nurse in the Meet Your Patient scenario. What might you say or do in response?

WHAT FACTORS AFFECT COMMUNICATION?

The following is a discussion of the major factors, in addition to verbal and nonverbal language, that affect communication.

Environment

Communication is most successful in an environment that is quiet, private, free of unpleasant smells, and at a comfortable temperature. As a beginning student, you are aware of the noises and distractions in the clinical setting. However, experienced nurses become accustomed to such distractions. Be sensitive to how the environment is affecting your client. Background noise is distracting, interferes with hearing, and can create confusion. Being around others in pain or distress creates anxiety and fear; lack of privacy may cause embarrassment. All of those feelings may prevent your patient from sharing personal information.

Think creatively to secure the most comfortable environment possible for communicating with patients and families. Hospital chapels, foyers, and activity rooms may be ideal locations for conversation. To discuss private matters, consider talking with the patient in a conference room rather than a shared room. If none of these is possible, at least close privacy curtains and turn off the radio or television.

Developmental Variations

Physical and cognitive development, language skills, level of education, and maturity influence the communication process. Thus, you will need to modify your communication strategies to fit your client's developmental level. By the time you enter nursing practice, your goal should be to communicate effectively, respectfully, and compassionately with patients at all developmental stages.

- *Infants and young toddlers* with limited language skills communicate nonverbally. Your response may combine verbal and nonverbal communication. For example, if a hospitalized 1-year-old cries out for his mother, you might cuddle the child with his favorite toy and reassure him saying "Mama will be back very soon."
- *Older toddlers and preschoolers* have more verbal ability. Although they may prefer to have a parent present, they are likely to talk with you and answer questions.
- *School-age children* are usually quite comfortable interacting verbally. Pay attention to their vocabulary as they speak, and be sure to match it to the extent possible, using words and phrasing the child will understand.
- By the time children reach *adolescence*, most can process abstract concepts. As a result, they are usually able to understand disease processes, treatments, and other health issues. Bear in mind that children with chronic health problems that have required frequent interventions are often more knowledgeable than would be expected for their age.

Older adults may be affected by **sensory alterations**, such as hearing loss or vision changes, or any of a variety of healthcare problems that affect cognition, such as dementia. Communication strategies for these situations are discussed in the Planning Interventions/Implementation section of this chapter.

Gender

Males and females communicate differently and may interpret the same communication differently. Women tend to communicate to form connections and establish relationships (Tannen, 2001). In contrast, male communication styles typically focus on goals, tasks, and maintaining independence and favorable positions in a hierarchy.

These communication patterns have their roots in early socialization differences. Traditionally, boys are socialized to participate in competitive team sports. Through this play, they learn how to compete, strategize, and win or lose. In contrast, young girls are more likely to engage in one-on-one or fantasy play that requires cooperation and focuses on fairness and negotiation. This early socialization is carried over into communication patterns. Men are more likely to be comfortable in situations that result in a win or loss, whereas women are more likely to attempt to reach consensus. Male communication tends to be purpose driven: more about conveying information and accomplishing a goal, whereas female communication is more relationally driven.

Gender differences in communication are important to nurses because male and female patients may communicate their needs very differently. Similarly, the gender of the nurse may affect the response to the patient's requests. For example, a female patient might state, "I feel so lousy today." A female nurse may interpret this as a desire to talk. In contrast, a male nurse may discuss pain control.

Personal Space

People vary in the amount of physical space they are comfortable with when communicating. The distance they maintain between one another is influenced by the relationship of the individuals, the nature of the conversation, the setting, and cultural influences (Fig. 21-4). Also see Chapter 15 for cultural preferences for personal space. Hall (1992) describes four distinct distances influencing communication: intimate distance, personal distance, social distance, and public distance.

Intimate Distance is the area immediately surrounding people that they define as their "private space." People prefer to maintain intimate distance between themselves and others during interactions. In Western cultures, intimate distance is within 18 inches of the other person. Within this distance, people can sense each other's smell and body heat and usually can hear each other speaking at a low volume. It is also at this distance that body contact occurs. As a nurse, you invade a client's intimate distance to perform assessments and procedures. You even breach a client's intimate distance when touching a hand or shoulder to offer support. This may make some clients uncomfortable.

Key Point: ***Before providing nursing interventions in the client's intimate distance, discuss what you are about to do. It is best to ask the client's permission, even for gentle touch, if you are in the slightest doubt about his receptivity.***

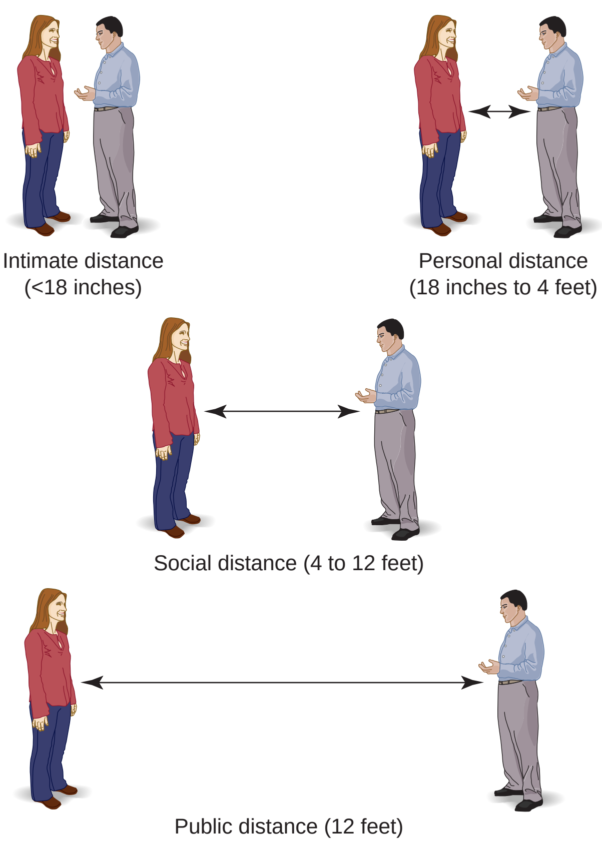

FIGURE 21-4 The distance that individuals who are engaged in communication maintain between one another is influenced by their relationship, the nature of the conversation, the setting, and cultural influences.

Personal Distance is a distance of 18 inches to 4 feet. Your interactions with clients and healthcare team members will commonly occur in this range. This distance facilitates sharing of feelings or personal thoughts and is appropriate to maintain when communicating caring or concern.

Social Distance is a distance of 4 to 12 feet. It is used in more formal interaction or when communicating with a group of individuals at the same time. At this distance, individuals are not within range to be physically touched. The volume of the spoken words may be loud enough for others to overhear, so people share personal feelings and thoughts less often at this distance. For example, if you stand by a client's door and ask how she is feeling, you will likely receive a more impersonal response than if you were to ask the same question at her bedside.

Public Distance is considered to be beyond 12 feet. This distance requires loud and clear enunciation for communication. This distance is characterized by a lack of individuality and a greater focus on the group or community.

Territoriality

Territoriality refers to the space and things that an individual identifies as belonging to him. Territories may be bounded and visible to others or may be defined by the individual in a way not noticeable to others. In a hospital setting, many clients consider everything within the curtain boundary to be their territory. Clients may be offended if you change, rearrange, or interfere with this territory by moving furniture, discarding objects, or borrowing items from the room, even if they are institutional property. To establish trust, you must request permission to rearrange the client's territory. Also recognize that hospitalized clients are not in their "home" territory and are therefore, likely to be less at ease during interactions.

Sociocultural Factors

Culture and socioeconomic status strongly influence communication. Facial expressions, nonverbal communication, and even the selection of whom to interact with are affected. For example, in some cultures it would be unacceptable for a male nurse to address and provide care to a female patient.

Social status also plays a role in communication. Have you ever been present while a physician explained a treatment plan to a patient? Often the patient asks no questions or nods approval, yet barrages you with questions when the physician leaves. This may be because many clients perceive less social distance between themselves and the nurse. Social distance can also play a role in how health professionals view patients. For example, you may see impoverished patients being treated with less respect than wealthy members of the community, although this is obviously unethical.

Roles and Relationships

Think of the way you interact with your instructor. Compare this with the way you interact with your classmates. What are the differences? The roles and relationships of the sender and receiver affect the choice of vocabulary, tone of voice, use of gestures, and distance associated with the communication.

Many patients have stereotyped notions about nurses. Some may view you as an authority figure. Others may perceive nursing as a lowly occupation limited to matters of comfort and hygiene, and may not choose to have conversation with you. Still others become confused by the fact that many healthcare workers, such as medical assistants and nursing assistive personnel (NAPs), call themselves nurses in spite of the fact that they cannot legally use the title. If you are working with NAPs or other team members, be sure to clarify their roles with the patient so he can communicate his questions and concerns to the appropriate healthcare provider.

KnowledgeCheck 21-4

- What are the major factors that affect communication?
- In what distance(s) do most nurse–client interactions occur?

WHAT IS COLLABORATIVE PROFESSIONAL COMMUNICATION?

Communication is essential to collaborative practice among nurses, physicians, and health professionals from other disciplines. Each of you shares the common goal of providing optimal patient care. This goal guides the manner in which you communicate—at the bedside, at the nurse's station, in care conferences, or via the patient record. Nurses also communicate with peers and colleagues in order to contribute to their professional development. See Box 21-2 for statements from professional organizations about collaborative communication.

Think of communication styles as a continuum from passive, through assertive, to aggressive. A **passive**

BOX 21-2 ■ Collaborative Professional Communication

American Nurses Association (ANA) (2010)

Standards of professional performance stress the importance of communication to collegiality, leadership, and collaboration. The following are some of the competencies for these standards. The registered nurse:

Standard 11. Communication

- Assesses communication format preferences of healthcare consumers, families, and colleagues.
- Assesses his or her own communication skills in encounters with healthcare consumers, families, and colleagues.
- Seeks continuous improvement of communication and conflict resolution skills.
- Conveys information to healthcare consumers, families, the interprofessional team, and others in communication formats that promote accuracy.
- Questions the rationale supporting care processes and decisions when they do not appear to be in the best interest of the patient.
- Discloses observations or concerns related to hazards and errors in care or the practice environment to the appropriate level.
- Maintains communication with other providers to minimize risks associated with transfers and transition in care delivery.
- Contributes her or his own professional perspective in discussion with the interprofessional team.

Standard 12. Leadership

- Develops communication and conflict resolution skills.
- Communicates effectively with the healthcare consumer and colleagues.

Standard 13. Collaboration

- Communicates effectively with the healthcare consumer, the family, and healthcare providers regarding healthcare consumer care and the nurse's role in the provision of care.
- Applies group process and negotiation techniques with healthcare consumers and colleagues.

Standard 14. Professional Practice Evaluation

- Provides peers with formal or informal constructive feedback regarding their practice or role performance.

American Association of Critical-Care Nurses (AACN)

Skilled communication is necessary to a healthy work environment. Nurses must be proficient in communication skills. Critical elements of communication include the following:

- Focusing on finding solutions and achieving desirable outcomes
- Seeking to protect and advance collaborative relationships among colleagues
- Inviting and hearing all relevant perspectives
- Striving for goodwill and mutual respect
- Building consensus and arriving at common understanding
- Achieving congruence between words and actions, and holding others accountable for doing so
- Developing proficiency with communication technologies (AACN, 2005)

Quality and Safety Education for Nurses (QSEN)

Communication is essential for teamwork and collaboration. On graduation from nursing school, you should be able to analyze differences in others' communication style preferences and describe the impact of your own communication style on others (Cronenwett, Sherwood, Barnsteiner, et al., 2007).

The Joint Commission (2013)

The 2013 National Patient Safety Goals added Goal 2.03.01, which calls for getting important test results to the right staff person on time. The broad Goal 2 calls for improving the effectiveness of communication among caregivers.

approach avoids conflict and allows others to take the lead. It tends to be submissive, helpless, indecisive, apologetic, or whining. "Whatever you want. I don't want you to change anything for me," is an example of a passive approach. In contrast, an **aggressive approach** forces others to lose. The goal is to win and be in control. "My way is the correct way. You don't know what you're talking about" typifies an aggressive approach. Other aggressive characteristics include being bossy, arrogant, opinionated, sarcastic, manipulative, intolerant, or overbearing.

Why might you adopt a **nonassertive style**? As you have learned, men and women tend to communicate differently. The same is true when communicating with persons of higher or lower status. When speaking to physicians, some nurses still communicate their needs in a style that assures physicians that they are not telling them what to do (e.g., "Do you think Mrs. King's heart rate is a little fast today?" instead of "Mrs. King's heart rate was 120 beats per minute at 0800." This has been referred to as the "doctor–nurse game" (Stein, Watts, & Howell, 1990). Such unclear, indirect communication contributes to errors and poor patient outcomes.

Communicating Assertively

Assertive communication is the expression of a wide range of positive and negative thoughts and feelings in a style that is direct, open, honest, spontaneous, responsible, and nonjudgmental. Assertiveness recognizes your rights while still respecting the rights of others. It allows you to take responsibility for your own thoughts and actions without blaming others, encourages feedback, and enables you to find mutually satisfying solutions to conflict by confronting people constructively.

Effective communication and teamwork are essential for the delivery of high-quality, safe patient care. To avoid communication failures that can lead to unanticipated adverse events in patients, nurses must speak up when they have concerns and take the necessary steps to communicate assertively and collaboratively with the healthcare team.

A study exploring nurses' perception of their ability to speak up and be heard in the workplace environment found open communication leads to better patient care, improved safety, and better staff satisfaction (Garon, 2012). To advocate for clients, you must question care decisions that don't seem right to you, and assertively discuss errors or poor clinical judgment with coworkers.

So how do you communicate assertively?

- *Question care decisions openly and honestly*. Refuse to play the doctor–nurse game. Avoid beginning your statements with self-effacing statements that fail to take credit for your contributions (e.g., "You may disagree with this, but . . ."). Be frank, but be flexible and open-minded.
- *Use "I" statements*. An "I" statement should include the elements of behavior (or facts), feeling, and effect (on you). For example, instead of saying, "Why haven't you ordered Mrs. Johnson's pain medications yet?" you might say, "I telephoned you this morning about Mrs. Johnson's lack of pain relief, but I don't see a change in her analgesic order. I am concerned about her discomfort and the effect it may have on her willingness to ambulate."
- *Focus on the issue, not the participants.* For example, "I think this approach might be the best, but I'd like to hear your thoughts."
- *Use effective nonverbal language.* Your body and verbal language should be congruent. Eye contact demonstrates interest and shows sincerity. Use a calm, well-modulated voice tone, and add appropriate gestures for emphasis.
- *Don't invite negative responses*. For example, say, "I would really appreciate it if you could help me weigh Mr. Max on the bed scale," rather than, "Can you help me weigh him?"
- *Use "fogging" to help you accept criticism without becoming anxious or defensive*. Acknowledge that there may be some truth to it, but remain the judge of your own action Suppose Mrs. Johnson's physician says, "Are you playing pharmacist today?" You might respond, "I agree that I may not be a pharmacist and that I do not know everything there is to know about analgesics. However, Mrs. Johnson needs pain relief and I need your assistance with pain medication."
- *Use negative inquiry.* You might choose, in the preceding situation, to use negative inquiry. You would reply, "So you believe that I do not have adequate knowledge to discuss Mrs. Johnson's pain control?"
- *Strive for a workable compromise*, but not if it affects patient well-being or your feelings of self-respect. Suppose an administrator comes to a patient's room while you are inserting a nasogastric tube and says, "I need to see you right now. Come to the desk immediately." An example of a workable compromise would be to say, "I understand that you need to talk to me right away, and I need to finish what I am doing. So what about meeting you at the desk as soon as I finish, in about 10 minutes?"
- **Key Point: Use "critical (CUS) language."** ***Remember the words Concerned, Uncomfortable, and Safety—as in, "I'm concerned, I'm uncomfortable, this is unsafe, or I'm scared" (Leonard, Graham, & Bonacum, 2004). Some organizations identify a code phrase for themselves, for example, "I need clarity." When anyone there says, "I need clarity," the receiver of the request must stop and listen attentively while the sender asserts the issues that need to be clarified (Amer, 2013).***

It may help to practice ahead of time how you want to look and sound before attempting assertive communication. Assertiveness is a learned skill. Role-playing with a colleague can build your confidence.

For a summary of assertive communication techniques, see Box 21-3. Also,

Go to Chapter 21, **Clinical Insight 21-2, Techniques for Assertive Communication,** in Volume 2.

Using Standardized Communication Tools

Doctors and nurses often have different communication styles. Nurses are taught to be more descriptive of clinical situations, whereas physicians learn to be very concise. Standardized communication tools are quite effective in overcoming differences in nurse–physician communication styles, and conveying key information clearly and concisely. Structured communication tools not only ensure accuracy but also create an environment for individuals to speak up and express concerns, thus improving interdisciplinary communication and patient outcomes.

A well-known and highly effective method for team communication and collaboration is the **SBAR** model. The acronym represents **S**ituation, **B**ackground, **A**ssessment, **R**ecommendation. For a summary of this model,

Go to Chapter 21, **Clinical Insight 21-3, Communicating With SBAR,** in Volume 2.

If you need other information about giving a verbal report, also see Chapter 18.

Using the Patient Rounds Approach

Patient rounding is a collaborative approach in which physicians and nurses gather at the patient's bedside to discuss goals for care and/or changes in the plan of care and to answer the questions of the patient, family, and healthcare staff. Meeting for rounds allows the nurse to provide input, which results in improved nurse and physician working relationships and professional satisfaction (Chapman, 2009).

BOX 21-3 ■ Five Steps for Assertive Communication

1. Get the person's attention.
2. Express your concern.
3. State the problem.
4. Propose an action.
5. Reach a decision.

Source: Leonard, M., Graham, S., & Bonacum, D. (2004). The human factor: The critical importance of effective teamwork and communication in providing safe care. *Quality and Safety in Health Care*, *13*(Suppl.), 85–90.

WHAT IS THE ROLE OF COMMUNICATION IN THERAPEUTIC RELATIONSHIPS?

Caring is integral to a therapeutic nurse–patient relationship, which according to Benner (1984) is the hallmark of nursing practice. She uses the terms of connectedness and involvement to describe nursing. These terms are also the foundation of meaningful communication (Alpers, Jarrell, & Roxena, 2013). In today's demanding environment, nurses multitask and function with many competing priorities. Because of this, they run the risk of conveying a rushed, noncaring attitude to patients. This can be frustrating to patients and exhausting for nurses.

A **therapeutic relationship** focuses on improving the health of the client, whether an individual or community. The client gains information and knowledge and works through issues, concerns, and problems related to health status, treatments, and nursing care. **Therapeutic communication** is client-centered communication directed at achieving client goals. It is used to establish the therapeutic relationship, provide and obtain healthcare information, and express interest, concern, and caring for the client and family.

Communication Is Essential to All Phases of the Therapeutic Relationship

The therapeutic relationship consists of four phases. As you read about each phase, notice the fundamental role of client-focused communication.

Pre-interaction Phase Even before you meet the client, the pre-interaction phase is established. You begin establishing communication by gathering information about the client, but the nurse and client do not have direct communication. As a student, you initiate this phase as you prepare for clinical days. The client also experiences a pre-interaction phase when she identifies the need for healthcare.

Orientation Phase The phase begins when you meet the client and introduce yourself and your role in the relationship. You then address him by his preferred name and/or title. In the orientation phase before collecting personal or health information, inform the client that pertinent information will be shared with the healthcare team (Nurses Association of New Brunswick, 2011).

The goal of this phase is to establish rapport and trust through the use of verbal and nonverbal communication. When rapport is established, patients are more likely to express their concerns openly and seek emotional support (Joanna Briggs Institute, 2011). As patients may not be immediately ready to communicate, it is important to be sensitive to the patient's mood, past experience, and overall physical and psychological state. Try to understand the cause of the client's behavior, comments, and attitudes, and respond with patience and wisdom. Orientation ends when the relationship has been defined.

Working Phase The bulk of therapeutic communication occurs in the **working phase**, the active part of the relationship. During this phase, the nurse communicates caring, the patient expresses thoughts and feelings, mutual respect is maintained, and honest verbal and nonverbal expression occurs. Key communication goals are to assist the client to clarify feelings and concerns. A professional relationship is courteous, competent, trustworthy, and confidential, and accomplished by active listening and other techniques of therapeutic communication presented later in this chapter.

Termination Phase The conclusion of the relationship marks the **termination phase**, whether at the end of the nurse's shift or on the client's discharge from the unit, facility, or service. Reviewing and summarizing help to bring the relationship to a comfortable conclusion. If communication has been effective, the termination phase prepares the nurse and client for future interactions. Unsuccessful communication may affect the client's health outcomes or understanding of his disease process, as well as affect the nurse's job satisfaction.

ThinkLike a Nurse 21-4

Recall the scenario of Mr. Barker (Meet Your Patient).

- What phase of the therapeutic relationship is illustrated in the scenario?
- How might the interaction between you and Mr. Barker change if it occurred in a different phase of the therapeutic relationship?
- What could you have done differently?

Therapeutic Communication Has Five Key Characteristics

The therapeutic relationship requires conscious use of your knowledge and skills to effect change in the patient. This is often called the *therapeutic use of self*. Therapeutic use of self requires some practice for you to recognize the boundaries of a therapeutic relationship and to keep the focus on the patient rather than on your own feelings and experiences. Five qualities characterize communication in the therapeutic relationship: empathy, respect, genuineness, concreteness, and confrontation. Box 21-4 identifies skills associated with these qualities. Later, the chapter presents specific strategies for enhancing communication, as well as barriers to therapeutic communication. Look for these techniques and barriers in any conversation you analyze.

Empathy The desire to understand and be sensitive to the feelings, beliefs, and situation of another person is called **empathy**. Empathy is more than sharing of information. Empathy requires you to be willing to adapt your style, tone, vocabulary, and behavior to create the

Quality and Safety Education for Nurses

Limits and Boundaries of Therapeutic Relationships

Chapter Key Concept: *Therapeutic Relationships*

Competency: *Patient-Centered Care (Knowledge, Skill)**

What are boundaries? Boundaries define personal space and allow people to communicate comfortably. This box illustrates the effects of boundaries on the competency, Patient-Centered Care, and the key concept, therapeutic relationships. Therapeutic (professional) relationships have stricter boundaries than personal relationships: Questions and comments made to friends may be inappropriate between colleagues or with clients. Moreover, boundaries between patients and care providers are not equal and are not always clear. Patients are asked intimate details of their lives, are physically exposed, and are often dependent on the care provider. Behaviors that suggest you might have boundary issues include:

- Thinking about or socializing with the patient while away from work.
- Disclosing personal information.
- Engaging in physical contact, flirting, or discussing sexual attraction, including by texting or online messaging.

Think about it: How do those factors make patients vulnerable? What Knowledge and Skills do you need to develop trust-based therapeutic relationships with patients and families? What can you do to help them maintain their dignity?

Actions: In developing professional and therapeutic boundaries, try to achieve the "zone of helpfulness." That is, find a balance between under-involvement on one end and over-involvement on the other (National Council of State Boards of Nursing [NCSBN], 2009). The NCSBN calls for nurses to:

- Show respect for human dignity.
- Avoid personal gratification at the patient's expense.
- Never interfere in the patient's personal relationships.
- Promote patient autonomy and self-determination.
- Understand that the nurse–patient relationship is based on trust.

Nurses have a moral duty to protect patients from inappropriate relationships. Patient-centered care is only possible when boundaries are respected and patients and their families feel safe.

BOX 21-4 ■ Skills Needed in a Therapeutic Relationship

The ability to:

- Appreciate experiences and beliefs that differ from your own.
- Recognize and interpret verbal and nonverbal messages.
- Guide the interaction to accomplish goals.
- Determine *whether* communication is taking place.
- Speak when appropriate and remain silent when appropriate.
- Adapt to the pace, tone, and vocabulary of the client.
- Evaluate your own participation in an interaction.

best approach for each client situation. It is relatively easy to have empathy for people who are like you and who are likeable. It is more difficult to connect with people you see as "difficult" or "different." To empathize with a client, you must look beyond outward appearance or behavior and put yourself, mentally and emotionally, in the client's place. This will help you appreciate the uniqueness of the client and better understand his needs.

Respect In the therapeutic relationship, you communicate **respect** by valuing the client and being flexible to meet the client's needs. As a nurse, you must be willing to adjust to your client rather than expecting the client to adjust to you, the healthcare environment, or hospital routines. Most healthcare experiences strip the client of power—clothes are removed, roles are discontinued or altered, people are separated from loved ones and familiar surroundings, and schedules are changed. When a relationship is grounded in respect, both parties maintain power and self-esteem. You show your respect for clients in the way you address them, the words and intonation you choose, and in your acknowledgment of their strengths and needs. Making even minor adjustments, such as delaying breakfast for an hour to allow the client to sleep, communicates that you respect the client's wishes.

Genuineness When interviewing clients, we expect them to respond truthfully. After all, many healthcare decisions are based on the client's responses. Similarly, clients have a right to expect truthful responses from healthcare providers as well. **Genuineness** is the ability to respond honestly. If you are unable to answer a client's question, do not offer guesses. Be honest. Tell the client you need assistance before you can answer the question. Genuineness also involves willingness to self-evaluate. How well did I communicate? Did I handle that situation appropriately? How could I improve my communication?

Concreteness and Confrontation In a therapeutic relationship, you must offer understandable responses to a client's questions and concerns. To do so requires you to express in concrete, specific terms what you mean. The message must be constructed and delivered in a manner that is suitable for the client. Communication is a reciprocal process. If your client is unable to express his thoughts clearly, you must be willing to confront her to request clarification. Similarly, you must be willing to be confronted if you are unclear.

Communication Is Important in Group Helping Relationships

Most of our previous discussion focused on one-on-one communication. However, nurses frequently communicate with groups. Group communication occurs when you interact with a family, a community, or a committee. Groups can enhance problem-solving and creativity, generate understanding and support, enhance morale, and provide affiliation.

Task Groups are formed to address a task or fulfill a need. Members are chosen based on ability to complete the task or defined project. Short-term groups dissolve once the task is completed. *Short-term groups* might include a task force to address holiday scheduling or a panel to critique response to a disaster drill. Because the time together is limited, the focus of communication is on the task at hand. Often, time to develop rapport or relationships is limited. Direct verbal communication with congruent nonverbal communication allows the group to function most effectively.

Ongoing Groups address issues that are recurrent. Committees are a form of task group. Common ongoing committees in healthcare organizations include quality assurance, infection control, and discharge planning. A committee has a chairperson who may be elected from within or appointed. Members have designated roles within the groups (e.g., recorder, time keeper). In small groups, all members have an opportunity to communicate their opinions. In larger groups, patterns of communication form; some members voice their opinion regularly, whereas others are often silent. When not all members speak, it is essential to examine nonverbal behavior to determine whether the nonspeaking members are in agreement.

Self-Help Groups are voluntary organizations composed of individuals with a common need. Alcoholics Anonymous may be the most widely recognized self-help group. Other well-known self-help groups include Weight Watchers, Narcotics Anonymous, and Reach for Recovery (for women with breast cancer).

Nurses may be members, facilitators, or consultants for self-help groups. Members are encouraged to share experiences and seek support from other members of the group. Members who have met the goals of the group often serve as the group facilitator by leading the interactions, or simply arranging meeting logistics. Healthcare professionals or experts in the field may be consulted to offer guidance or education to the group. Self-help groups most often have face-to-face meetings; but may also participate through social networking or blog groups, or receive information via newsletters. Communication of shared interests or needs is the link that holds these groups together.

Therapy Groups are organized to help individual members cope with challenging personal issues or stressful life events, such as divorce, death of a spouse, or new motherhood. Therapy groups may also address ways improve relationships and improve communication between or among people. These groups are also called self-awareness or growth groups. They may be ongoing or have a designated length of operation.

Community, public health, and psychiatric nurses sometimes facilitate therapy groups. Group facilitators arrange the time and place of the group and often introduce topics for discussion.

Work-Related Social Support Groups help members of a profession cope with the stress associated with their work. Social support groups provide an opportunity to share concerns and offer mutual support through formal meetings with a facilitator or informal drop-in events.

Formation of a group does not guarantee its success. To be successful, a group must have characteristics that allow the group to function and achieve its goals (Box 21-5).

KnowledgeCheck 21-5

- Identify and describe the phases of the therapeutic relationship.
- What are the five characteristics of therapeutic communication?
- Describe the difference between a task group and a self-help group.
- Compare and contrast the role of a therapy group with a work-related support group.

BOX 21-5 ■ Characteristics of a Successful Group

A successful group has:

- Clearly defined purpose
- Shared set of guidelines under which the group functions
- Sense of shared responsibility
- Shared leadership
- Mutual trust
- Comfort among members
- Climate that is cohesive but does not stifle individuality
- Members who are willing to share feelings, concerns, or beliefs
- Flexibility to change what is not working

ThinkLike a Nurse 21-5

Review the local newspaper, hospital bulletin board, Internet search engines, and the school intranet. Identify at least three group helping experiences available. How might you learn more about these organizations? How would you determine whether they are resources that you might make available to your patients?

PracticalKnowledge knowing how

Therapeutic communication is used throughout the nursing process. In the next few sections we will explore communication problems as well as therapeutic interventions.

ASSESSMENT

Assessment is essential to effective communication. You should assess for factors that alter a client's ability to receive, process, or transmit information, such as the following:

- *Language barrier.* Imagine how difficult it would be if you became ill while traveling in a country where you were unable to speak or read the language. How would you communicate that you were nauseated or in pain; how would you tell a care provider the point at which the symptom started or what makes it worse? Also consider your client's education and literacy. You cannot assume that everyone has an extensive vocabulary, nor that they can read and write.
- *Cognitive skills.* Difficulty understanding or engaging in communication may signal cognitive impairment. Developmental delays and pathology or injury of the central nervous system affect language and cognitive skills.
- *Sensory perceptual alterations.* Assess hearing and vision. Assess for **aphasia** (a difficulty expressing or interpreting messages that may develop after cerebrovascular accident [stroke] or neurological disease). Drug or alcohol intoxication can also interfere with perception and the ability to perceive or receive accurate information.
- *Physiological barriers.* These may include respiratory problems, loose-fitting dentures, or cleft palate, which may interfere with speaking.

For guidelines for a focused communication assessment,

Go to Chapter 21, **Assessment Guidelines and Tools,** in Volume 2.

ANALYSIS/NURSING DIAGNOSIS

Communication can be the problem or the etiology of a nursing diagnosis. The following NANDA-I diagnosis labels describe communication problems. Note that communication problems may involve the inability to receive, interpret, or express spoken, written, and nonverbal messages.

- *Readiness for Enhanced Communication* is appropriate when the client expresses willingness to enhance communication that is already effective.
- *Impaired Verbal Communication* is an appropriate diagnosis if the client has (1) expressive aphasia or a physiological problem such as dyspnea, stuttering, or laryngeal cancer that impairs the ability to speak; or (2) receptive aphasia or sensory deficits that impair the ability to receive messages.
- *Impaired Communication* is the preferred diagnosis if the client is unfamiliar with the dominant language or has some other difficulty receiving and sending messages. Note that this is not a NANDA-I label.

Etiologies of Communication Diagnoses

Your assessment data will help you determine whether communication impairment is the primary problem or whether it is a result of other health problems. Some nursing diagnoses may cause or contribute to communication problems. For example:

- Clients with Acute or Chronic Confusion often have difficulty expressing or receiving verbal and nonverbal messages. Confusion may be related to physical or mental health problems, or may be a side effect of medications or sleep deprivation.
- Mental health problems can also lead to communication problems. For example, Anxiety impairs the ability to deliver and receive messages, and Chronic or Situational Low Self-Esteem often results in limited interaction with others.

Communication as Etiology of Other Nursing Diagnoses

Impaired Verbal Communication may be the etiology of other nursing diagnoses, for example:

- Anxiety r/t inability to communicate needs
- Social Isolation r/t difficulty maintaining relationships secondary to Impaired Verbal Communication
- Impaired Social Interaction r/t inability to carry on conversation
- Chronic Low Self-Esteem r/t fear of conversing with others secondary to stuttering

PLANNING OUTCOMES/EVALUATION

NOC standardized outcomes associated with Impaired Verbal Communication include Communication, Communication: Expressive, and Communication: Receptive. To see selected indicators for those outcomes,

Go to Chapter 21, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Impaired Verbal Communication,** on Davis*Plus*.

Using NOC indicators with the outcomes, you can develop goals for clients' communication problems.

Individualized client outcomes and goals depend on the nursing diagnosis you identify. For example, for Impaired Verbal Communication, you might write the following desired outcomes. The client:

- Uses alternative methods of communication (e.g., writing, picture board, gestures) effectively (specify time frame).
- Demonstrates minimal frustration with communication difficulties (specify time frame).
- Communicates effectively using a translator or interpreter.
- Interprets messages accurately, as evidenced by appropriate verbal or nonverbal feedback.

PLANNING INTERVENTIONS/IMPLEMENTATION

Examples of *NIC standardized interventions* for Impaired Verbal Communication are Active Listening; Communication Enhancement: Hearing Deficit, Speech Deficit; Dementia Management; and Environmental Management. For other NIC interventions and selected nursing activities,

Go to Chapter 21, **Standardized Language,** on Davis*Plus*.

Specific nursing activities for communication problems depend on the etiology of the problem and on the goals selected. The focus of nursing interventions is to facilitate communication and to resolve or reduce the factors interfering with it.

Enhancing Therapeutic Communication

The following are techniques and activities you can implement immediately to improve your communication with patients and others.

Active Listening

People often think of listening as a passive activity. If you have ever been in a one-sided conversation, you are certainly aware that listening can be passive. In contrast, an active listener uses all senses to focus on the sender's message. An active listener gives full attention and allows the sender the opportunity to complete comments without interruption. To listen actively, pay attention to verbal and nonverbal communication and look for congruence. If a message is unclear, seek clarification through use of probing questions or reflective comments, such as "Tell me more," or "When you say . . . what do you mean?"

You can demonstrate active listening by facing your client, making eye contact, and focusing the conversation on issues of importance to the client (Fig. 21-5). If you must take notes during the conversation, record only key words to stimulate your memory at another time. Taking extensive notes distracts you from active

FIGURE 21-5 Active listening using full attention, direct eye contact, and caring touch.

BOX 21-6 ■ Communicating With Care

- Keep your attention in the moment and on the patient.
- While the patient is sharing personal information, tune in and do not multitask.
- Face the person. Lean in. Pay attention.
- Maintain eye contact while listening.
- Do not interrupt the patient.
- Avoid glancing at your cell phone or watch. And never text while the patient is talking.
- Do not casually talk with coworkers while the patient is waiting.

Source: Adapted from Leebov, W. (2011, July 11). Nursing communication: How to make sure patients feel our caring. Retrieved May 5, 2013, from http://allnurses.com/showthread.php?t=378288

listening. Active listening behaviors convey caring; signal a willingness to listen; and provide a comfortable environment for the client to share his concerns (Box 21-6).

Failure to listen to your client will result in missed messages or misinterpretation. Consider this example:

Patient: I guess I'm going to surgery tomorrow.
Nurse: [*Checking the IV fluids and hanging a medication*] Uh-huh.
Patient: The surgeon says I'll be in intensive care for a few days.
Nurse: [*Looking at the drainage in the urine collection bag*] Okay. Your urine looks good.
Patient: I guess this is pretty risky surgery.
Nurse: [*Recording on the flowsheet*] Yep.

How do you think the patient must feel in this situation? The patient is clearly expressing concern about his upcoming surgery and seems to want to talk about it with the nurse. However, the nurse is busy with a variety of tasks and is not paying attention to the conversation. Undoubtedly, the patient will continue to feel anxious. In fact, his unsuccessful attempts to communicate may even increase his anxiety. If the nurse were listening, this would be an excellent opportunity to discuss the patient's concerns, provide preoperative teaching, and help the patient ease his anxiety.

Establishing Trust

Mutual trust is an essential component not just of professional communication, but also of therapeutic communication because it facilitates disclosure and honesty. As you and the client establish trust, the client can more easily relay information and share feelings. To establish trust, always greet the client by name, listen actively, respond honestly to the client's concerns, and provide care competently and consistently.

Being Assertive

An assertive person is one who is able to express himself effectively and directly communicate his point of view while still respecting the viewpoint and beliefs of others. Because assertive communication is based on mutual respect, the therapeutic relationship is a safe place for clients to convey their needs and concerns without feeling judged. As needed, review assertiveness and collaborative professional communication, earlier in this chapter (e.g., Box 21-3).

Restating, Clarifying, and Validating Messages

Restating means using your own words to summarize the message you received from the client. This demonstrates concern, active listening, and understanding of what the patient has said. Below is an example:

Client: I'm so worried about this diabetes. I have young kids. I want to see them grow up. Every diabetic I've known has died young.
Nurse: Diabetes is a serious disease. I under stand your worry about its effects on you. However, we want to focus on becoming well controlled so that you can avoid complications.

Clarifying messages helps ensure that you have accurately interpreted the information. For instance, you might state, "I'm not sure what you mean when you say you're so worried about your diabetes." Or, "When you say you're worried, what do you mean?"

To **validate** the message, ask the client whether you are making a correct interpretation: "When you say you're worried about your diabetes, do you mean you are afraid you will die soon?" These techniques help to identify client concerns and focus communication. They are especially helpful if the client is unclear or vague with a message.

Interpreting Body Language and Sharing Observations

Be attentive to what the patient says and how she says it. Note the tone of voice, rate of speech, distance, eye movement, facial expressions, and gestures. Look for congruence between the spoken message and the nonverbal message. If there is inconsistency, share your observations with the patient. You can share your observations by describing the patient's body language or tone of voice. For example, you might state, "I know you said you feel well, but your voice and hands are trembling. How can I help you?" Or more simply, "You're frowning. Has something upset you?"

Exploring Issues

Ask open-ended questions to obtain a clear understanding of an issue and follow your client's thoughts (see Chapter 3). Probing comments, such as "Tell me more," or "What does that mean to you?" encourage your client to share information.

Using Silence

Learn to be comfortable with silence. When you remain attentive, silence demonstrates acceptance and allows clients to organize their thoughts and so provide further information. It is especially effective if your client is emotionally upset.

Summarizing the Conversation

At the end of the conversation, summarize what you have heard. For example, you might say, "Today we talked about diet, exercise, and medications for high blood pressure. Your job now is to review the handouts and start taking your medication every morning. I'll see you in 2 weeks when you return for your follow-up visit." Summarizing demonstrates active listening and allows the client to clarify any misunderstandings.

Process Recordings

Therapeutic communication requires practice. A strategy commonly used to improve communication skills is called *process recording*. In **process recording**, two people converse while a third records the conversation. Afterward, the participants analyze the interaction. Audio recording can facilitate process recording. It effectively captures the words and intonation of the conversation, but must be supplemented by notes describing the nonverbal communication. Videotaping allows participants to examine both verbal and nonverbal communication. As you examine an interaction, look for communication skills discussed in Box 21-4.

Barriers to Therapeutic Communication

As you learn to communicate therapeutically, you may find yourself thinking, doing, or saying things that seem to close down your conversation. If so, acknowledge your error and return to therapeutic patterns. The following sections describe the most common barriers to therapeutic communication.

Asking Too Many Questions

Asking questions at the appropriate time is important. However, asking too many questions, especially closed questions (requiring only a yes or no answer), can make clients feel they are being interrogated. Excessive questioning may suggest insensitivity or lack of respect for the client's issues, as in the following dialogue:

Patient: I feel lousy today.
Nurse: Didn't you sleep well?
Patient: No, hardly at all.
Nurse: Did you take anything to help you sleep?
Patient: No.
Nurse: Do you think you should have taken something?
Patient: I guess.
Nurse: Why didn't you tell the night nurse you needed something?
Patient: I don't know.

As you can see, this approach controls the range and nature of responses that the client provides. In contrast, open-ended questions stimulate conversation and exploration. Contrast the preceding conversation with the conversation below.

Patient: I feel lousy today.
Nurse: Lousy? Tell me more.
Patient: Well, my back and neck hurt, and I hardly slept at all. I thought it would go away, but I just lay in bed last night worrying.
Nurse: What kind of things are you worrying about?
Patient: I'm worried about . . .

In the second conversation, the nurse asked open-ended questions. These prompts encouraged the patient to discuss his concerns.

Asking Why

In many health situations, we want to learn why a patient acted or responded as he did. However, directly asking for reasons suggests criticism to some people. If you ask, "Why did you stop taking your medication?" the patient may become defensive and stop talking. A more subtle approach is usually more comfortable for the patient. You might ask, "What concerns do you have about your medicines?" or "Tell me more about your experience with the medication." Both of these approaches will help you gather more information about the client's concerns, without suggesting criticism. Review the first dialogue in the previous section, Asking Too Many Questions, for another example of the effect of "why" questions. How do you think this patient felt?

Fire-Hosing Information

Sometimes a healthcare provider might meet with a patient or family and deliver an overwhelming amount of information. The patient or family members might understand what the provider said, but afterward remember only a fraction of it. Or they might feel stunned, confused, intimidated, and helpless. Instead, engage your patient in a *dialogue* in which you give important information while your patient shares his own concerns and questions. You can then ask him how he understands what has been shared and clarify when needed.

Changing the Subject Inappropriately

Abruptly changing the topic of discussion makes you seem uninterested. This often occurs when the nurse is intent on one issue and the patient is focused on another. For example, imagine that you want to tell the patient about a change in the scheduling for a diagnostic test before you forget. As you enter the room, your patient says, "I am having a lot of pain in my knee today." This situation requires you to address the patient's concern first and postpone discussing the schedule change until the patient can be receptive to the information. In an ongoing dialogue, changing the subject can stop the flow of conversation cold. Both patients and nurses sometime use this tactic to avoid discussing sensitive topics. The following is an example:

Nurse: This must be a tough time for you. Your wife is very sick. How are you handling this?
Patient's husband: Yes, it's tough, but I went out to a movie last night. Have you seen that new movie with the avatars? The special effects . . .

Your relationship with the patient's husband and the facts of the patient situation would determine whether you would redirect this conversation back to the original subject or allow him to wander. You may choose to give the husband more time to be comfortable with you before approaching this topic again.

Failing to Probe

Failing to probe can result in incomplete assessment and affect the quality of your care. A thorough assessment requires you to explore issues in detail. Review the following conversations.

Patient: I'm having a lot of discomfort in my back.
Nurse: How much does it hurt?
Patient: Quite a bit. I had trouble sleeping last night.
Nurse: I'll get you something for pain.

Compare that conversation with the next example, in which the nurse gathers additional data.

Patient: I'm having a lot of discomfort in my back.
Nurse: Tell me about the discomfort.
Patient: It hurts a lot. I had trouble sleeping last night.
Nurse: When did you first notice this pain?
Patient: It started in the middle of the night.
Nurse: What does it feel like?
Patient: I feel sore. I'd like to turn over to my side, but I can't because of this heavy cast.
Nurse: Let me help you turn. (*Assists patient to turn and uses pillows to hold the patient on her side*)
Patient: Oh, that feels better!
Nurse: How is the discomfort now?
Patient: It's pretty much gone.
Nurse: I'm glad you're feeling better. Would you like something for pain as well?
Patient: I think I'm okay now.

In the second example, the nurse followed her original question with additional probing questions. A few additional questions helped clarify what the patient needed and led to immediate comfort.

Expressing Approval or Disapproval

Although it may be appropriate with friends and family, you should be cautious about offering approval or disapproval within the nurse–patient relationship. Although it may seem supportive, expressing approval can inhibit further sharing—it puts you in the position of being the judge of what is "right." This often prompts the patient to continue to seek approval. He thinks, "I'd better be careful; she may not approve of the next thing I was going to tell her. She expects me to be *this* way." Consider instead offering recommendations and allowing the patient to choose. Read the following exchange.

Patient: I've decided I'm going to have the surgery.
Nurse: That's great. I think you made the right choice.

Compare that conversation with the following example.

Patient: I've decided I'm going to have the surgery.
Nurse: Tell me about your decision.
Patient: Well, my shoulder has been bothering me for several months now. I know I said I wanted to put off surgery, but I think I'll have a faster recovery if I just get the surgery done now.
Nurse: So your choices are to do a trial of physical therapy and anti-inflammatory medicines, to try a steroid injection, or to have surgery.

Patient: Right. But there's a good chance I'll still need surgery even if I try the therapy or medicines. The only thing that will actually fix the problem is surgery. The others don't guarantee improvement.

Can you see how different the conversation becomes if the nurse does not express approval? By allowing the patient to discuss the choices, the nurse has empowered the patient to make his own healthcare decisions.

Offering Advice

Offering an opinion is rarely helpful. Avoid statements such as, "If I were you . . ." or, "You should . . ." These statements impose your opinion on your clients. In effect, your statements function as approval if they agree with the client's thoughts or disapproval if they do not. As with other forms of approval or disapproval, conversation halts. If the client asks, "What should I do?" help clarify the options, and provide her with information about the choices. Giving the client your solution negates the client's opportunity to participate as a mutual partner in the decision-making process.

Providing False Reassurance

Providing reassurance helps to ease concern, offers comfort, and communicates empathy. So it is an appropriate and therapeutic action—if the reassurance is warranted. For example, consider the client who comes to the emergency department (ED) for treatment of an acute episode of asthma. Because anxiety exacerbates asthma, it is certainly therapeutic to reassure the client that he will be cared for promptly and effectively. In contrast, false reassurance is a barrier to therapeutic communication. When clients or family members ask for information or tell you that they are worried, it is easy to reassure them that everything will be okay. However, such responses are uninformed, inaccurate, and may feel dismissive—even condescending—to the receiver. Examine the following scenario:

You are a nurse working at the triage station in the local ED. Your role is to evaluate the condition and prioritize the care of all clients on their arrival. An ambulance arrives with a man complaining of severe chest pain. He is ashen and short of breath. He tells you his pain is "crushing." Suspecting a heart attack, you immediately move him to the critical care bay of the ED and request urgent evaluation. Several minutes later his wife arrives by private car and approaches the triage station. She anxiously asks, "How is my husband?" How would you respond?

It may feel natural to offer a response such as, "Don't worry, everything will be all right." But do you really know that will be the case? A better approach is to provide accurate information: "I had him immediately taken in for treatment. I'll get you in to see him as soon as I can. Please have a seat, and I'll check on him." This comment is accurate, calming, and avoids misleading the person.

Stereotyping

As discussed in Chapter 15, racial, cultural, religious, age-related, or gender stereotypes distort assessment and prevent you from recognizing the patient's uniqueness. Examples of statements reflecting a stereotype include "He's old, he won't remember anything you tell him," and "Men are always the biggest crybabies about pain." Such comments may shut down communication and escalate tension. Avoid their use with patients and colleagues.

Stereotypes may be blatant or subtle. Blatant examples, such as those above, are easily recognized and may create an intense reaction. Subtle stereotypes, however, may be equally disruptive to care. Subtle stereotypes common in healthcare include the following:

- Believing a patient will be calm and know what to expect because he has had previous hospitalizations for the same diagnosis, has had previous surgeries or other procedures, or was given information about his condition
- Assuming that patients will understand their healthcare because of their educational level or work experience, for example, expecting that a physician who has suffered a heart attack needs no explanation of her care
- Expecting all patients with the same surgery or diagnosis to experience similar responses

Using Patronizing Language

Patronizing language communicates superiority or disapproval. Statements such as, "You know better than that," are patronizing and offensive to the client. Condescending approaches, such as, "You should have used the call button before you got up. You're lucky you didn't hurt yourself," do not communicate respect for the client.

Have you heard staff call clients "Sweetie," "Dearie," or "Mama"? The term *elderspeak* describes ways that healthcare workers may unintentionally show disrespect to elderly patients by using such phrases and speaking to them in a high-pitched, slow, repetitive, childlike voice. Staff may also alter pronouns, saying, for example, "Are we ready for our bath?" Although the intent is to communicate caring, many patients are offended because it sounds as though you are speaking to a child. Research indicates mentally competent nursing home residents are irritated by elderspeak, and that people with moderate Alzheimer's disease become more agitated and resistant to care if they are addressed in this manner (Williams, Herman, Gajewski, et al., 2008).

Key Point: ***When you first meet your client, use a formal title—Mr., Ms., Dr. and so on. In the orientation phase of the relationship, ask your patient how he would prefer to be addressed.***

If the patient is unable to respond, ask family members how to address the patient. This conveys respect, which is essential to a therapeutic relationship.

KnowledgeCheck 21-6

Identify at least five barriers to communication.

Enhancing Communication With Clients From Another Culture

Healthcare facilities should provide interpretation (including translation) services as necessary (The Joint Commission, 2010b). Many health facilities have inhouse translation services available for communication with non-English-speaking patients. Translators may also be available through telephone contact; a few are linked via computer to a healthcare interpreter network to enable video teleconferencing.

Use relatives as translators only if there are no other options. It is often culturally unacceptable to have family members ask personal questions. As a result, translations may be altered or questions remain unasked. See Chapter 15 for additional information on the use of translators.

Non-English-speaking patients are increasingly more common in the healthcare setting. If you do not speak the primary language of the patient, many hospitals employ translators: however, it is good to learn a few key words to help you communicate until a translator arrives. Additionally, Internet and mobile technologies offer applications for translating English into various other languages. For a list of a few useful Spanish terms, for examples, and for guidelines for communicating with clients from other cultures,

Go to Chapter 21, **Clinical Insight 21-4: Communicating With Clients From Another Culture,** in Volume 2.

Enhancing Communication With Clients Who Have Impaired Hearing or Speech

For guidelines to help you communicate with clients who have speech, visual, or hearing deficits, respectively,

Go to Chapter 21, **Clinical Insight 21-5: Communicating With Clients Who Have Impaired Speech,** in Volume 2.

Go to Chapter 30, **Clinical Insight 30-2: Communicating With Visually Impaired Clients,** in Volume 2.

Go to Chapter 30, **Clinical Insight 30-3: Communicating With Hearing-Impaired Clients,** in Volume 2.

Enhancing Communication With Clients With Impaired Cognition or Decreased Level of Consciousness

Communicating with cognitively impaired clients can be difficult, time consuming, and frustrating for even the most experienced healthcare provider. This might be a patient with acute illness or neurological injury, a patient with congenital abnormality, a person with sensory or language deficits, or an older adult with dementia. In the hospital setting, impairments are heightened as a result of the effect of illness, changed routines and environment, and medication. As a result, the patient may be unable to understand explanations, follow directions, ask for help, or report symptoms (Zembrzuski, 2013, revised).

Key Point: ***It is critical that you make every effort to communicate whether or not the client can understand you.***

For guidelines to help you communicate with clients with impaired cognition or consciousness,

Go to Chapter 21, **Clinical Insight 21-6: Communicating With Clients Who Have Impaired Cognition or Consciousness,** in Volume 2.

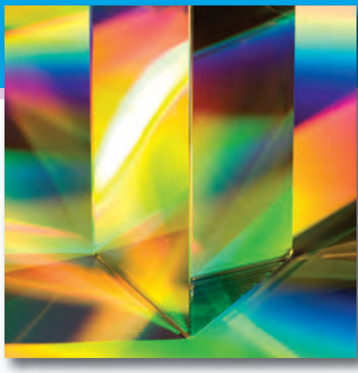
CHAPTER 22



Health Assessment

Learning Outcomes

After completing this chapter, you should be able to:

- Identify the purposes and components of a physical examination.
- Discuss the differences among a comprehensive, focused, and ongoing physical examination.
- Describe how to prepare for a physical examination.
- Demonstrate the skills used in physical examination.
- Explain adaptations that may be required when you examine clients of various ages.
- Identify the components of the general survey.
- Conduct a full physical examination of a client.
- Discuss the expected findings of a physical examination.
- Document the findings of a physical examination.
- Perform a brief bedside physical examination.

Key Concepts

Health assessment
Nursing assessment
Physical assessment

Related Concepts

See the Concept Map on Davis*Plus*.

Meet Your Patient

Nam Nguyen is scheduled for a comprehensive physical exam at the family health center at 1400 today. As you recall, he has previously been seen and evaluated by Zach Jackson, RN, FNP. Mr. Nguyen has medical diagnoses of hypertension, degenerative joint disease, obesity, and heavy tobacco use. During his earlier visit, Zach instructed Mr. Nguyen on a low-salt, low-fat diet and advised him to lose weight and quit smoking. Zach also ordered lab work to establish a baseline for wellness and detect abnormalities that might indicate illness. Review the results of Mr. Nguyen's lab work that follow.

At today's visit, Zach will perform a comprehensive physical examination of Mr. Nguyen and review his lab results. After Nam's appointment, Yen Nguyen will also have a comprehensive exam.

Laboratory Data for Nam Nguyen

Name: Nam Nguyen **DOB:** 7/12/50
Acct#: K00205412 Family Medicine Center, J. Miller

Test	Result	Reference Range*
CBC/Differential		
WBC	5.6 x 10^3/mm^3	5–10 x 10^3/mm^3
Hemoglobin	14.8 g/dL	M: 14–18 g/dL F: 12–16 g/dL
Hematocrit	45.1%	M: 42–52% F: 37–47%
RBC count	5.1 million/mm^3	M: 4.7–5.14 million/mm^3 F: 4.2–4.87 million/mm^3
MCV	84 mm^3	85–95 mm^3
MCH	29 pg	28–32 pg
MCHC	34%	33–35%
Neutrophils	57%	59%
Lymphocytes	30%	34%
Monocytes	5%	4%
Eosinophils	2.5%	2.7%
Basophils	0.7%	0.5%
Platelet count	197,000/mm^3	150,000–400,000/mm^3

Test	Result	Reference Range*
Comprehensive Metabolic Panel		
Sodium	138 mEq/L	135–145 mEq/L
Potassium	4.3 mEq/L	3.5–5.0 mEq/L
Chloride	101 mEq/L	97–107 mEq/L
Carbon dioxide	27 mEq/L	23–29 mEq/L
BUN	16 mg/dL	10–31 mg/dL
Creatinine	0.8 mg/dL	M: 0.6–1.2 mg/dL F: 0.5–1.1 mg/dL
Glucose	156 mg/dL	75–110 mg/dL
Albumin	4.0 g/dL	19–60 years: 3.2–4.8 g/dL
Total protein	7.2 g/dL	6.8–8.0 g/dL
ALT (alanine aminotransferase, also called SGPT)	18 units/L	M: 10–40 units/L F: 7–35 units/L
ALP (alkaline phosphatase)	43 units/L	M: 35–142 units/L F: 25–125 units/L
AST (aspartate aminotranspeptidase, also called SGOT)	26 units/L	M: 19–48 units/L F: 9–36 units/L
Bilirubin, total	0.7 mg/dL	0.3–1.2 mg/dL
Calcium	8.5 mg/dL	8.2–10.2 mg/dL

Test	Result	Reference Range*	
Lipid Panel**			
Total cholesterol	201 mg/dL	<200 200–239 >240	-Desirable -Borderline high -High
LDL cholesterol (Primary target of therapy)	140 mg/dL	<100 mg/dL 100–129 mg/dL 130–159 160–189 >190	-Optimal -Near optimal/ above optimal -Borderline high -High -Very high
HDL cholesterol	34 mg/dL	<40	-Low
Triglycerides	196 mg/dL		

**To interpret lipid panel results, follow the most recent guidelines of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Blood Cholesterol in Adults available at www.nhlbi.nih.gov/guidelines/cholesterol/atglance.pdf. The reference range figures in this table will undoubtedly be revised (and lowered) by NCEP in the near future.

Also, the norms for an individual patient's lipid panel depend on the calculation of risk factors. Nam is hypertensive, is obese, and has an elevated blood sugar. His norms reflect high risk for coronary heart disease; they would be about <160 for total cholesterol, <100 for triglycerides, <100 for LDL, and >45 for HDL.

Test	Result	Reference Range*
Urinalysis		
Appearance	Clear	Clear
Color	Amber	Light yellow to amber
Odor	Aromatic	None–aromatic
pH	6.0	5.0–9.0
Specific gravity	1.012	1.001–1.035
Leukocyte esterase	Negative	Negative
Nitrites	Negative	Negative
Ketones	Negative	Negative
Protein	5 mg/dL	<20 mg/dL
Crystals	None	In acid urine: uric acid, calcium oxalate, amorphous urates In alkaline urine: triple phosphate, calcium phosphate, ammonium biurate, calcium carbonate, amorphous phosphates
Casts	None	None, except rare hyaline
Glucose	Negative	Negative
WBC	1/hpf	<5/hpf
RBC	1/hpf	<5/hpf
PSA (prostate-specific antigen)	2.8 ng/mL	<4 ng/mL
Fecal occult blood screen		
Sample #1 — negative		
Sample #2 — negative		
Sample #3 — negative		

*For most studies, each laboratory establishes its own reference range.

Theoretical Knowledge knowing why

In this chapter, theoretical knowledge consists mostly of information about the key concepts. You will see how an understanding of the key concepts will prepare you and the client for the examination, and help you to modify your assessments for different age groups.

ABOUT THE KEY CONCEPTS

Health assessment is a comprehensive assessment of the physical, mental, spiritual, socioeconomic, and cultural status of an individual, group, or community. **Nursing assessments** focus on the client's functional abilities and physical responses to illness and other stressors. In contrast, medical assessments focus on disease and pathology. As a nurse practitioner, Zach Jackson combines the nursing and medical approaches. **Physical assessment**, or physical examination, consists of the techniques used to gather objective data about the body.

PHYSICAL EXAMINATION

A complete health assessment includes both a nursing history and a physical examination. In addition to physical examination, you will also ask questions to obtain subjective data about each body system or area. This may be done in a separate nursing interview or as you perform the physical examination. Both the interview and the exam require tact and sensitivity.

What Are the Purposes of a Physical Examination?

A physical examination is performed for any of several reasons:

- *To obtain baseline data.* Data about the patient's physical status and functional abilities serve as a baseline for comparison as the patient's health status changes.
- *To identify nursing diagnoses, collaborative problems, and wellness diagnoses.* Problem statements form the basis for the plan of care and help you to address the patient's nursing care needs.
- *To monitor the status of a previously identified problem.* For example, Mr. Nguyen has already begun treatment for hypertension. Today's examination will be linked to the lab results to further explore the status of his hypertension.
- *To screen for health problems.* Regular checkups can help to identify health problems at early stages. Because Mr. Nguyen has an enlarged prostate, a prostate-specific antigen (PSA) test was done to screen for prostate cancer.

The type of physical examination you perform will depend on the client's health status, the nature of the client encounter, and the setting. For example, at an outpatient appointment for an annual physical, on a client's admission to an inpatient setting, or at the initial home health visit, you would perform a **comprehensive physical assessment**, which includes a health history interview and a complete head-to-toe examination of every body system. In an emergency situation, your assessment will be rapid and focused on the presenting problem. A **focused physical assessment** pertains to a particular topic, problem, body part, or functional ability rather than overall health status, and it adds to the database created by the comprehensive assessment. A **system-specific assessment** is a focused assessment limited to one body system (e.g., the lungs, the peripheral circulation). The following are examples of focused and system-specific physical assessments, respectively:

- Assessing bowel sounds when a client has abdominal pain
- Listening to breath sounds, counting respirations, and obtaining pulse oximetry readings to assess a patient's respiratory status

Ongoing assessment is performed as needed, after the initial database is completed, and, ideally, at every interaction with the patient. For example, on a medical–surgical unit, each nurse who provides care to a client conducts a brief ongoing assessment to determine changes in the client's status and evaluate client outcomes. For more details on the types of assessment, see Chapter 3. For a form to use in making a brief bedside assessment,

Go to Chapter 22, **Procedure 22-20, Brief Bedside Assessment,** in Volume 2.

How Do I Prepare to Perform a Physical Examination?

You should develop a systematic approach and follow the same order each time you perform a physical exam. This will help you recall the steps and include all important data. A **head-to-toe approach** starts at the head and neck and progresses down the body, examining the feet last. A **body systems approach** examines each system in a predetermined order (e.g., musculoskeletal, cardiovascular, neurological). Whatever the approach, prepare yourself, the environment, and the client before you begin.

Prepare Yourself

Preparing for a physical examination requires theoretical knowledge of anatomy and physiology, examination equipment and techniques, therapeutic communication, and documentation. Self-knowledge is also important. How comfortable are you when performing an examination? What skills do you need to review or practice? Will you need assistance to perform some aspects of the exam? Will you need help documenting your findings?

Honestly evaluate your strengths as well as areas that need improvement. Be sure to seek help from your instructor, an experienced nurse, fellow students, or other healthcare providers as needed.

Before approaching the patient, familiarize yourself with his situation. What are the patient's main health concerns? What is the purpose of your exam? For instance, if you are doing a focused assessment of a client's wound, you will need to learn about the wound being examined. Is there a dressing over the wound? What supplies will you need to remove and replace the dressing? Has the patient required pain medication before exams in the past? Reviewing previous findings helps you work efficiently and to formulate any questions you might want to ask the patient.

Finally, unless this is an initial assessment, review the nursing plan of care and keep it in mind as you examine the patient. Your assessment data may lead to modification or updating of the care plan.

Prepare the Environment

Key Point: ***Physical examination requires you to observe and touch the client's body, so privacy is essential.***

You will need a room with curtains or a door to shield the client from view. For additional privacy, drape your client and uncover only the area you are examining. For convenience you may use bed linens and/or a gown to drape. Disposable paper drapes are also available.

Because you will need to hear the patient and listen to a variety of sounds during the exam, turn off the television, radio, or other media. You will need good lighting to observe subtle changes in skin and body contours. Adjust the temperature of the room according to patient comfort.

Determine the instruments and equipment you will need. Take everything you need so that you will not have to leave the client to obtain supplies. To see commonly used equipment,

Go to the box, **Equipment Needed for Physical Examination,** in Procedure 22-1, of Volume 2.

Prepare the Client

In most clinical settings, you must examine a client often to evaluate a changing status, and timing will be decided by the client's condition rather than by convenience. However, when possible, select a time when the client is comfortable and receptive to the exam. Avoid conducting the exam when the client is in pain or is hungry, tired, anxious, or unwilling to cooperate in the assessment.

Take the time to establish rapport with the client, to help him relax and cooperate fully in the assessment. Introduce yourself, ask the client how he wishes to be addressed, and explain what you will be doing. Ask the client to void before the examination; this promotes relaxation and also makes it easier to palpate the abdomen. Always alert the client before touching him. For example, before you start to palpate the neck for lymph nodes, say, "I'm going to feel your neck now." Proper positioning during the exam also promotes comfort (see the following section). Pay attention to the pace of your exam, being careful not to prolong it and tire the client.

Key Point: ***Consider developmental and cultural differences. For example, some clients may wish to have a family member present during an exam; some may require a same-sex clinician. If you and the client do not speak the same language, arrange to have an interpreter present.***

Quality and Safety Education for Nurses

Health Assessment and Cultural Adaptation

Chapter Key Concept: *Health Assessment (related concept: Developmental Stages)*

Competency: *Patient-Centered Care (Knowledge, skills, attitudes)**

Background: When performing a health assessment, adaptation for the developmental age of the client is a widely accepted nursing practice. It is also important to adapt for the client's culture. In order to engage diverse clients and respond to their preferences and values, culturally competent communication must be an integral component when initiating the health assessment according to Chircop, Edgecombe, Hayward, et al. (2013). The QSEN competency of patient-centered care promotes the same principle. Four areas that demonstrate cultural adaptation in the health assessment are eliciting client preferences regarding: (1) comfort with touch, (2) comfort with exposure (modesty), (3) need for personal space, (4) and need for the presence of a support person (Chircop, Edgecombe, Hayward, et al., 2013).

Scenario: A client who speaks Portuguese requires an interpreter while hospitalized. You are assigned to complete the initial health assessment.

Think about it: (1) To whom does the nurse direct the questions and make eye contact with when obtaining the history, the interpreter or the client? Discuss how your response supports cultural adaptation. (2) Formulate questions for the nursing history to elicit client preferences regarding comfort with touch, comfort with exposure, personal space, and the presence of a support person.

Sources: Chircop, A., Edgecombe, N., Hayward, K., et al. (2013).

As reference for your QSEN log box, the KSA that is most pertinent is: *Elicit patient values, preferences and expressed needs as part of clinical interview, implementation of care plan and evaluation of care.*

For specific Knowledge, Skills, and Attitudes,

Go to the QSEN Web site at **http://qsen.org/competencies/pre-licensure-ksas/**

KnowledgeCheck 22-1

- What are the purposes of a physical examination?
- Describe how you would prepare for a physical exam.

ThinkLike a Nurse 22-1

- The nurse conducts a physical assessment for Nam and Yen Nguyen (see Meet Your Patient) at an outpatient clinic. Discuss the differences between their planned experience and a focused physical exam of a hospital inpatient.
- Identify a plan to practice and improve your assessment skills.

How Do I Position the Client for a Physical Examination?

The client will need to assume a variety of positions during a comprehensive physical examination. To begin the examination, seat the client on the side of the bed or examination table. Face the client, and establish eye contact. This helps to build rapport and put the client at ease. If your client is unable to sit, assist him to a position on his back with the head of the bed elevated. An upright position allows the client to expand his lungs fully and is useful for assessing vital signs, the head and neck, the heart and lungs, the back, and the upper extremities.

As you place your client in positions that allow you to best observe the body system you are examining, be alert to special needs that call for you to modify the position. For example, a patient with a cervical spine problem would need a neck roll when lying supine. Table 22-1 illustrates and describes the major positions you will need to use.

KnowledgeCheck 22-2

Identify the best position for examining the lungs, heart, pulses, and abdomen.

Table 22-1 ➤ Positioning the Client

POSITION AND DESCRIPTION	COMMENTS
Standing	
Upright posture with both feet flat on the floor **posture with both feet flat on the floor**	Use to examine the musculoskeletal and neurological systems and to assess gait and cerebellar function. Clients who are weak or who have poor balance may not be able to assume this position.
Sitting	
Sitting upright at side of bed or exam table 	Use to assess vital signs, head and neck, chest, cardiovascular system, and breasts. If your client is weak, he may need assistance to maintain this position.
Supine	
(Including Fowler's and semi-Fowler's positions) Lying flat on the back with arms and legs fully extended 	Use to assess the abdomen, breasts, extremities, and pulses. If your client becomes short of breath, raise the head of the bed (HOB). In Fowler's position, the head is elevated 60°. In semi-Fowler's position, the head is elevated only 30°–45°.

Continued

Table 22-1 ➤ Positioning the Client—cont'd

POSITION AND DESCRIPTION	COMMENTS
Dorsal Recumbent	
Supine with knees flexed 	Use for abdominal assessment if your client has abdominal or pelvic pain. Flexing the knees promotes relaxation of the abdominal muscles.
Lithotomy	
Dorsal recumbent position at end of table with feet in stirrups, legs flexed, and widely open 	Use for a female pelvic exam; provides maximum exposure of genitals. Older patients may need support to assume and maintain this position. The patient's legs are exposed here to illustrate position. To see a privacy drape refer to Procedure 25-4, Providing Perineal Care.
Sims'	
Flexion of the hip and knees in a side-lying position 	Use to examine the rectal area. Use for a female pelvic exam if the patient is unable to assume the lithotomy position. Do *not* use if the client has had total hip replacement.
Prone	
Lying on stomach (A small pillow under the abdomen makes this position more comfortable.) 	Use to examine the musculoskeletal system, especially hip extension; may also be used to examine the back and buttocks. May be difficult to assume by clients with respiratory problems.

Table 22-1 ➤ Positioning the Client—cont'd

POSITION AND DESCRIPTION	COMMENTS
Lateral Recumbent	
Lying on the side in a straight line 	Left lateral recumbent is used to evaluate heart murmur or during a thorough cardiovascular assessment. This position brings the heart closer to the chest wall. If the client cannot assume this position, listen to the heart with the client seated and bending forward.
Knee–Chest	
On hands and knees with head down and buttocks elevated 	Provides good visualization for examining the rectal area. However, it is not used often because it is embarrassing and uncomfortable for the client.

What Techniques Do I Need to Perform a Physical Examination?

The skills used in physical examination include inspection, palpation, percussion, auscultation, and sometimes olfaction. You will use these skills in that order, with one exception: When performing an abdominal assessment, perform auscultation before percussion and palpation to avoid disturbing the abdominal sounds.

Inspection is the use of sight to gather data. You begin to use **inspection** the moment you meet the client and continue as you observe the person's gait, personal hygiene, affect, and behavior during the general survey. You will also use inspectiand such abnormalities as edema, masses, or areas of tenderness. As you begin and move through the assessment of each body system, always inform the client that you are about to touch him, and use a gentle approach. Be certain your hands are warm. Begin with light pressure to detect surface characteristics. Then move to deep palpation to assess the underlying structures. Examine last any areas of discomfort or sensitivity. Following is a list of the most common palpation techniques, using different parts of the hand.

- *Fingertips:* Use for fine tactile discrimination, including assessment of skin texture, swelling, and specific locations of pulsations and masses.
- *Dorsum of hand:* Use for temperature determination.
- *Palmar surface of hand:* Use for locating general area of pulsations.
- *Grasping with fingers and thumb:* Use to detect the position, shape, and consistency of a mass.

Percussion is tapping your fingers on the skin using short strokes. Tapping (**percussing)** produces vibrations, and the resulting sound allows you to determine location, size, and density of underlying structures. Percussion is especially useful when assessing the abdomen and lungs. Percussion takes practice. To learn more about percussion, including direct and indirect percussion and terminology for the notes you may hear,

Go to Chapter 22, **Clinical Insight 22-1: Performing Percussion,** in Volume 2.

A quiet environment allows you to perceive the subtle differences in percussion notes. To listen to some percussion sounds,

Go to Student Resources, **Sound Files: Percussion Sounds,** on Davis*Plus*.

Auscultation is the use of hearing to gather data. **Direct auscultation** is listening without using an instrument. If you have heard wheezing or chest congestion without the use of a stethoscope, you have already performed direct auscultation. **Indirect auscultation** is listening with the help of a stethoscope. The stethoscope has two end pieces, the diaphragm and the bell.

- Use the diaphragm to listen to high-pitched sounds that normally occur in the heart, lungs, and abdomen. Press the diaphragm hard enough to produce an obvious ring on the patient's skin.
- Use the bell to hear low-pitched sounds, such as extra heart sounds (murmurs) or turbulent blood flow, known as bruits. Apply the bell lightly with just enough pressure to produce an air seal with its entire rim.

To improve your skill in indirect auscultation,

Go to Chapter 22, **Clinical Insight 22-2: Performing Auscultation,** in Volume 2.

Olfaction is the use of the sense of smell to gather data. Some clinicians may not consider **olfaction** a formal assessment skill; however, you will certainly use this skill in the clinical setting. Olfaction adds information to the data you collect through the other techniques. Consider these examples:

- If a client is slurring his words, you will want to look for data that reveal the cause of the problem. Slurred speech might be caused by a stroke or by sedative medications. However, if the client smells of alcohol you would first investigate recent alcohol use as a probable cause for the slurred words.
- If an older client smells of urine, you would want to assess for problems with leakage of urine or inability to perform self-care.
- If the client's breath has a "fruity" or "acetone" odor, you would suspect ketoacidosis (which may accompany diabetes). You would know to assess the urine for ketones and contact the primary care provider if necessary. You would also ask the client about dietary patterns, because a high-protein, high-fat, low-carbohydrate diet can cause a buildup of ketones in the blood.

KnowledgeCheck 22-3

- Identify five physical assessment skills.
- In what order are these skills performed?

ThinkLike a Nurse 22-2

Think about olfaction as an assessment technique. Give two or three additional examples of data you might collect through the use of smell.

How Do I Modify Assessment for Different Age Groups?

The basic techniques of physical assessment remain the same for all age groups. However, your approach will vary according to the developmental stage of your patient.

Infants

Use the assessment as an opportunity to teach the parent about normal growth and development. Infants usually feel most secure if a parent holds them during the examination, either against the chest or, for older infants who can sit without support, on the parent's lap. Otherwise, position an infant on a padded examination table.

If there are siderails, raise them to prevent falling. Do not leave the infant's side or turn your back on the infant.

Toddlers

Toddlers can be challenging to examine. They are interested in exploring the environment, but they also like to stay close by a parent, often in the parent's lap. Because they may be fearful of invasive procedures such as examination of the oral cavity or inner ear, perform these procedures last. Most toddlers enjoy making choices, so use this characteristic to promote the toddler's cooperation. For example, you might provide a choice by saying, "Should I listen to your chest first, or should we see how much you weigh?" Allow the child to show you his developmental skills. If he needs assistance to remove clothing, have the parent help, and observe how the parent and child interact. Always praise the toddler for his abilities and cooperation. This sets the stage for positive feelings about healthcare.

Preschoolers

Preschool children are developing initiative and, as a result, usually cooperate with an examination. However, children of this age have fantasies and fears that may arise during the examination. For example, they may object to a noninvasive procedure because they believe it will cause pain or injury, or they may refuse to step on the scale because to them it resembles a monster. In such cases, it may be helpful to demonstrate the procedure on a doll or have the parent step on the scale before you approach the child.

As appropriate, allow the preschool child to sit in a parent's lap if she wishes. By age 5, most children will be comfortable enough to lie on the examination table if a parent is present. Let the child help with the exam. For example, have her hold equipment or remember her height and weight. Give reassurance as you go through the examination: for example, "Your lungs sound very healthy." Always compliment the child on her cooperation.

School-Age Children

The school-age child has a rapidly expanding vocabulary and usually seeks approval of parents, teachers, and healthcare providers. Develop rapport by asking the child about his favorite school or play activities. Allow the child to undress himself and get up and down from the exam table. Demonstrate your equipment before you use it. The school-age child will be interested in how his body works, so use this opportunity for teaching.

Adolescents

The adolescent is self-conscious and introspective and may wish to be examined without parents or siblings present, at least during the more personal aspects of the exam. Offer this choice. Adolescents often worry about the "normalcy" of their changing bodies and appreciate respect for their privacy. Be certain to discuss the normal physiological changes that accompany puberty. If you need to review those changes, see the section on adolescence in Chapter 9.

Adolescent behavior may be strongly influenced by peer values, so emphasize lifestyle habits that promote wellness, including a healthful diet; adequate rest and exercise; and avoidance of tobacco, alcohol, and other drugs. Also discuss sexually transmitted infections and cancer, particularly testicular cancer and human papillomavirus. The first pelvic examination and breast examination usually take place in the teen years. Because suicide is the third leading cause of death among adolescents, you should also use this opportunity to screen for depression and suicide risk (see Chapter 13 for a review of depression and suicide).

Young and Middle Adults

Most young and middle adults are able to cooperate during a physical examination and do not require a modified approach. Modifications may be required if the client has acute or chronic illness or cannot understand or follow instructions.

Older Adults

Older adults are adjusting to changes in physical abilities and health. As part of a comprehensive exam, assess the client's support system and ability to perform activities of daily living. Observe your client's energy level during the physical examination and provide rest periods if needed. If the client tires easily, arrange the exam sequence to limit position changes. Also be aware that stiff muscles and arthritic joints may make it impossible for the client to assume certain positions. Older adults may have impaired vision or hearing, so you may need to adapt your techniques to compensate for this. Obtain feedback to be sure the patient is seeing and hearing you adequately.

The acronym SPICES will help you to remember common problems of the elderly that require nursing intervention (Fulmer, 1991, 2007) and to focus your assessment as you perform a comprehensive physical examination:

S—Sleep disorders
P—Problems with eating or feeding
I—Incontinence
C—Confusion
E—Evidence of falls
S—Skin breakdown

KnowledgeCheck 22-4

What exam modifications, based on developmental stage, should you consider for the following clients (Meet Your Patient)?

- Nam Nguyen
- Nam's 3-year-old grandson, Kim Phan
- Nam's elderly mother, Mai Nguyen

PracticalKnowledge knowing how

The remainder of the chapter discusses each of the components of a comprehensive physical examination. The Highlights of Procedures box near the end of this chapter summarizes the entire comprehensive physical assessment, including a summary of the general survey. For a step-by-step approach to perform each assessment,

Go to Chapter 22, **Procedures,** in Volume 2.

As you perform your physical assessments, you may wish to refer to laboratory tests associated with each of the systems you are assessing. You can find some normal lab values in the Laboratory Data for Nam Nguyen (Reference Ranges) at the beginning of this chapter. For a list of laboratory tests,

Go to Chapter 22, **Supplemental Materials: Laboratory and Diagnostic Tests by System,** on Davis*Plus*.

THE GENERAL SURVEY

The general survey is your overall impression of the client. It begins at first contact and continues throughout the exam. When you discover a deviation from normal in the general survey, you will explore it further during focused assessment of that body system. For example, if on meeting the patient you notice a drooping eyelid (**ptosis**) on one side of her face, you will keep that in mind as you perform the neurological assessment. Ptosis may be caused by a stroke or neurological injury. For a step-by-step approach,

Go to Chapter 22, **Procedure 22-1: Performing the General Survey,** in Volume 2.

The following are aspects of the general survey.

Appearance and Behavior

Observe the client's general characteristics. Are his speech and behavior appropriate for his developmental stage? Look for indications of his mood and mental status—for instance, does he make eye contact with you? Notice any signs of distress, either physical or emotional. Observe the condition of your client's face, and note the quality of the visible skin. For example, excessive wrinkling of the skin from sun exposure, tobacco use, or illness may make the client appear older than his stated age. Be sure to consider cultural background, because this may influence your findings and interpretation.

Body Type and Posture

Next, observe your client's body size, build, and gait. As you introduce yourself and greet him, assess his muscle strength, mobility, and skin temperature and texture. Posture is also a clue about overall health status. A slumped position may indicate fatigue, depression, osteoporosis, or pain. If your client is immobile, observe his ability to move from side to side and change positions in the bed. Are the client's body movements smooth and coordinated? Does he use a cane or other assistive device? An unsteady gait may be associated with joint, muscle, or neurological disorders. Focused assessments in the remainder of the exam will help to reveal the exact meaning of such cues.

Speech

As you speak with the client and ask health-related questions, look for clues offered by his speech.

- Inappropriate or illogical responses may be associated with psychiatric disorders.
- Difficulty speaking or changes in voice quality may indicate a neurological problem.
- Rapid speech may be a sign of anxiety, hyperactivity, or use of stimulants.
- Hoarseness could indicate inflammation in the throat from infection, overuse, a foreign body, or perhaps a tumor or other obstructive material.
- Slow speech may be due to depression, sedation from medications, or neurological disorders.
- Vocabulary and sentence structure provide information about the client's educational level and comfort with the language.
- A foreign accent with hesitancy and/or sparse verbalization may signal a language barrier and a need for an interpreter.

Dress, Grooming, and Hygiene

A client's ability to dress and perform personal hygiene is affected by physical and emotional well-being. An unkempt appearance may reflect chronic pain, fatigue, depression, or low self-esteem. Poor hygiene may indicate a self-care deficit of physical or mental origin, or lack of easily accessible bathroom facilities.

Mental State

Mental state includes level of consciousness and capacity to interact. If the client has an altered mental status, ask a family member about the onset of the change.

Keep in mind that many medications, especially in older adults, may contribute to confusion or other changes in mental status.

- Bizarre responses may signal a psychiatric problem.
- Lethargy may be due to medications; depression; or a neurological, thyroid, liver, kidney, or cardiovascular disorder.
- Confusion and irritability may indicate hypoxia or medication side effects.
- Inability to provide a health history or to recall information may indicate a neurological disorder.

Vital Signs

You should assess vital signs as a part of the general survey and with subsequent assessments. Analyze for trends. See Chapter 20 for a complete discussion of vital signs, if needed.

Height and Weight

Height and weight provide valuable information about your client's growth and development, nutritional status, overall general health, and risk for various diseases such as diabetes and heart disease. These data are important for proper dosing of medication. For adults who can stand, measure height and weight using a platform scale with a sliding ruler (Fig. 22-1). When possible, the client should wear minimal clothing (gown) and no shoes. If the client cannot stand safely, use a bed scale. To measure an infant's length, use a stationary measure. Because children have frequent changes in growth, their measurements are documented on growth charts for easy monitoring and comparison to age- and gender-related standards. For growth charts for males and females from birth to 20 years of age,

Go to Chapter 22, **Supplemental Materials: Growth Charts,** on Davis*Plus*.

Body mass index (BMI) evaluates the relationship between height and weight. You can calculate the BMI for adults using a BMI calculator or table. For a BMI table,

Go to Chapter 22, **Procedure 22-1: Performing the General Survey,** in Volume 2.

Because the proportion of fat to muscle affects BMI calculation, the BMI is not useful for athletes (who have a larger proportion of muscle), for pregnant and

FIGURE 22-1 For adults, measure height with the client's back to the platform scale.

lactating women (who have a larger blood and tissue volume), for growing children, or for frail and sedentary older adults.

Once you have completed your general survey of the client, you can begin to focus on each body system. Whether you are doing a complete or focused physical assessment, remember that all body systems are interrelated. A problem in one system may affect or be affected by other systems.

THE INTEGUMENTARY SYSTEM

The integumentary system consists of the skin, hair, and nails. In a comprehensive exam, you assess this system briefly in the general survey, and then in greater detail as you move to examine other areas of the body. This allows the client to remain draped as long as possible.

The Skin

To perform a skin assessment, observe skin color, lesions, and other characteristics. Also notice unusual odors. An unpleasant body odor may be a sign of poor hygiene, the presence of a wound, or underlying disease. Excessive sweating may be related to activity (e.g., if the client has just finished exercising), thyroid problems, or overactive sweat glands. An odor of urine or stool may indicate a nursing diagnosis of Self-Care Deficit or Bowel or Urinary Incontinence.

For a summary of skin assessment, refer to the Highlights of Procedures box near the end of this chapter. For step-by-step instructions,

Go to Chapter 22, **Procedure 22-2: Assessing the Skin,** in Volume 2.

Skin Color

Skin color varies according to age and race, although each person's skin color is fairly uniform. Exposed areas, such as the hands, face, and neck, are often darker than unexposed areas, whereas the palms, soles, and nailbeds are lighter than the rest of the skin. In people with dark skin, the lips are also usually lighter than surrounding skin. Variations in skin color commonly seen in neonates and infants include the following:

- **Mongolian spots** are benign, blue-black birthmarks that occur on the lower back and buttocks of black, Hispanic, Native American, and Asian babies. They are the result of pigmented cells in the deeper areas of skin. Most fade by age 2 but can persist until early adolescence.
- **Capillary hemangiomas**, sometimes known as "stork bites," are small, irregular pink-red areas that are often seen around the face and nape of the neck in newborns. They typically disappear in infancy although they can persist until age 5.
- **Café-au-lait spots** are light brown birthmarks that can occur anywhere on the body. The name of these birthmarks is French for "coffee with milk" because of their light-brown color. Most often café-au-lait spots are not associated with medical problems, although they can sometimes signal a genetic disorder.

Table 22-2 discusses the significance of other skin color variations that may be seen in clients of any age.

Skin Characteristics

As does color, the temperature, texture, and turgor of the skin offer clues to the client's health status. Although it is not technically a skin characteristic, you should also check for edema while you are assessing the skin.

Skin Temperature Use the dorsum of the hand or fingers to assess skin temperature. Compare the temperature of the hands with that of the feet, and compare the right side of the body with the left. The skin should feel warm, but keep in mind that the temperature should be consistent with the room temperature and the patient's activity level. Be sure to check the temperature of the skin over any area of erythema. When accompanied by warmth, erythema may indicate infection or inflammatory changes.

If the patient's skin feels excessively warm, validate your data: Check her temperature to determine whether she has a fever. Hyperthyroidism stimulates the metabolism and may also elevate skin temperature. Excessive coolness may be due to poor peripheral circulation, shock, exposure to cold, or hypothyroidism.

Table 22-2 ➤ Common Skin Color Variations

COLOR VARIATION AND DESCRIPTION	SIGNIFICANCE
Pallor	
In light-skinned clients: extreme paleness; skin appears white; loss of pink or yellow tones. In dark-skinned clients: a loss of red tones	May be related to poor circulation or a low hemoglobin level (anemia). Best sites to assess for pallor include the oral mucous membranes, conjunctiva, nailbeds, palms, and soles of feet.
Cyanosis	
A blue-gray coloration of the skin, often described as ashen	If seen in the lips, tongue, mucous membranes, and facial features, it is known as *central cyanosis* and is associated with hypoxia. **Acrocyanosis**, which is bluish discoloration of palms and soles in the first few hours to days of life, is normal in newborns. Cold causes the lips to turn blue but the tongue is not affected. Cyanosis may also be seen in the extremities, especially hands and feet, after exposure to extreme cold.
Jaundice	
A yellow-orange cast to the skin	Often associated with liver disorders. Best sites to assess for jaundice include the sclera, mucous membranes, hard palate of the mouth, palms, and soles. Jaundice in the newborn is a normal finding in the first few weeks of life unless there is blood incompatibility or a congenital disorder.
Flushing	
A widespread, diffuse area of redness	Generalized redness of the face and body may occur as a result of fever, excessive room temperature, sunburn, polycythemia (an abnormal increase in red blood cells), vigorous exercise, or certain skin conditions, such as rosacea.
Erythema	
A reddened area	Associated with rashes, skin infections, prolonged pressure on the skin, or application of heat or cold.
Ecchymosis	
Bruised (blue-green-yellow) area	May be seen anywhere on the body. The color will vary based on the age of the injury. May indicate physical abuse, internal bleeding, side effect to medication, or bleeding disorder. To review assessing for abuse, refer to Procedure 9-1, Assessing for Abuse, in Volume 2. Also, Go to Chapter 9, **Example Problem: Abuse, Neglect, and Violence**, in Volume 1.
Petechiae	
Tiny, pinpoint red or reddish-purple spots	Visible in the skin due to extravasation (leakage from vessels) of blood into the skin. May be associated with a variety of disorders and medications.
Mottling	
Bluish marbling	Occurs in light-skinned clients, especially when cold. In newborns mottling indicates overstimulation of the autonomic nervous system.

Skin Moisture Normally the skin is warm and dry. Excessive moisture may result from hyperthermia, thyroid hyperactivity, anxiety, or **hyperhidrosis** (excessive sweating). Oily skin is often seen with acne. Dry skin may result from dehydration, chronic renal failure, hypothyroidism, excessive exposure, or overzealous hygiene.

Skin Texture Normal skin is smooth and soft. The following factors affect skin texture:

- *Exposure.* Exposed areas tend to be drier and coarser in texture, as do the elbows and knees.
- *Age.* The skin of infants and young children is very smooth because of lack of exposure to the environment.

- *Hyperthyroidism and other endocrine disorders.* These may cause the skin to become coarse, thick, and dry.
- *Impaired circulation.* Peripheral arterial insufficiency is associated with smooth, thin, shiny skin with little to no hair. In contrast, venous insufficiency leads to thick, rough skin that is often hyperpigmented.

Skin Turgor refers to the elasticity of the skin, which provides data about hydration status. Poor turgor, or **tenting** (skin that tends to stay pinched for a few seconds), may be a sigh of dehydration. Elasticity decreases with age, so tenting may also be seen with normal aging. Edema or scleroderma creates tension in the tissues preventing the skin from being pinched up.

Edema, an excessive amount of fluid in the tissues, is an abnormal finding. It is common in clients with congestive heart failure, kidney disease, peripheral vascular disease, or low albumin levels. A client with edema may tell you his skin feels "tight" or say, "My shoes don't fit any more." Swollen tissue may feel tender to the touch. Edema is not actually a condition of the skin, but it is convenient to assess for it while assessing the skin. Table 22-3 provides a grading system for edema.

Skin Lesions

Any **lesion**, variation in pigment, or break in continuous tissue requires assessment. Lesions considered to be normal variations and not harmful include:

- **Milia.** White raised areas on the nose, chin, and forehead of newborns. These lesions, which resemble "whiteheads," are due to retention of sebum in the maturing sebaceous glands. They disappear during infancy.
- **Nevi (moles), freckles, birthmarks.**
- **Skin tags.** Tiny tags or buds of skin usually around skin creases, in middle and older adults
- **Striae.** Silver-to-pink "stretch marks" in pregnant women, women who have had children, and anyone who has experienced significant weight fluctuations.

Table 22-3 ➤ Assessing Edema

SCALE	DESCRIPTION
Trace	Minimal depression with pressure.
+1	2 mm depression; rapid return of skin to position.
+2	4 mm depression that disappears in 10–15 seconds.
+3	6 mm depression that lasts 1–2 minutes. Area appears swollen.
+4	8 mm depression that persists for 2–3 minutes. Area is grossly edematous.

Abnormal lesions are classified as primary or secondary.

- **Primary skin lesions.** Develop as a result of disease or irritation. The pustules of acne are an example.
- **Secondary skin lesions.** Develop from primary lesions as a result of continued illness, exposure, injury, or infection, such as the crusts that form from ruptured pustules.

When you observe a lesion, evaluate it for size, shape, pattern, color, distribution, texture, surface relationship, exudate, tenderness, pain, or itching. The table, Describing Skin Lesions, at the end of Procedure 22-2 should help you to categorize lesions. Also see the Abnormal Atlas at the end of Chapter 22 in Volume 2 to view abnormal lesions associated with particular conditions such as cellulitis and scabies.

Go to Chapter 22, **Procedure 22-2: Assessing the Skin, and Abnormal Atlas, Skin Lesions,** in Volume 2.

Evaluate all skin lesions for the possibility of malignancy, especially those located in a site exposed to chronic rubbing or other trauma. Ask the client whether he has any newly developed moles or skin lesions or whether there has been any change in the appearance of existing lesions. You can remember the warning signs of malignant lesions by thinking of the letters ABCDE:

Asymmetry
Border irregularity,
Color variation,
Diameter greater than 0.5 cm
Elevation above the skin surface.

KnowledgeCheck 22-5

- What aspects of the skin should you assess?
- What assessments should you perform if you find a lesion?
- What warning signs lead you to suspect a malignant lesion?

The Hair

When assessing the hair, inspect and palpate for color, texture, and distribution, as well as the condition of the scalp. The hair should be clean and free of debris. A client who does not properly groom her hair may need help with other self-care tasks.

Color There is a wide range of naturally occurring hair color. Age-related graying of the hair varies among individuals according to their genetic background. White hair accompanied by very pale skin is seen in a condition known as **albinism**, or lack of pigment.

Texture Normal hair texture varies from fine to coarse. However, hair that is exceptionally dry and coarse hair may be a sign of hypothyroidism; very fine, silky hair may indicate hyperthyroidism.

Distribution Generally the hair is evenly distributed on the scalp, and fine body hair is present over the body. Men often have more hair on the face, chest, and back. Alterations in hair distribution may be signs of disease.

- **Alopecia** (hair loss) along the temples and in the center of the scalp is considered a normal balding pattern in men and is largely genetically based. Diffuse alopecia can be caused by chemotherapy for the treatment of cancer, by nutritional deficiencies, or by endocrine disorders. Thinning hair can also occur in the perimenopausal period when hormone levels are fluctuating. Patchy hair loss may be caused by fungal infections of the scalp, hair pulling, constant wearing of caps, or **alopecia areata**, a benign autoimmune disorder.
- **Hirsutism** (excess facial or trunk hair) may be due to endocrine disorders or steroid use.

Scalp Normally the scalp is smooth, firm, symmetrical, nontender, and without lesions. Common deviations include an asymmetrical or bumpy scalp due to trauma or lesions, and scaly flakes or patches due to fungal infection (e.g., dandruff), dermatitis, or psoriasis. Tenderness may indicate a localized infection or trauma. In newborns, **cradle cap**—scaly white patches over the scalp due to secretion of sebum—is common. It can be removed with washing and gentle scrubbing.

Pediculosis In addition, the hair should be free of debris and **pediculosis** (head lice infestation). Head lice are tiny, very mobile, and difficult to see. You may find it easier to see the eggs, or **nits**, that are deposited on the hair shaft close to the scalp. For a step-by-step description of assessing the hair, see the Highlights of Procedures box near the end of this chapter, and

Go to Chapter 22, **Procedure 22-3: Assessing the Hair,** in Volume 2.

The Nails

Healthy nailbeds are level, firm, and similar to the color of the skin. The nail is smooth and uniform in texture. Examine nails on both hands and feet. However, you may defer examination of the toenails until you are assessing the peripheral circulation. Variations in color, shape, or texture may indicate health problems. For illustrations of nail variations and for a step-by-step description of nail assessment, see the Highlights of Procedures box near the end of this chapter, and

Go to Chapter 22, **Abnormal Atlas,** and **Procedure 22-4: Assessing the Nails and Abnormal Atlas,** respectively, in Volume 2.

Nail Color

Pink nails with rapid capillary refill indicate circulation to the extremities. Pale or cyanotic nailbeds are seen in clients with circulatory or respiratory disorders that result in anemia or hypoxia. Other color abnormalities that you may encounter include the following:

- *Half-and-half nails,* in which a distal band of reddish-pink covers 20% to 60% of the nail. These occur in clients with low albumin levels or renal disease.
- *Mees' lines,* which are transverse white lines in the nailbed. They are seen in clients who have experienced severe illnesses or nutritional deficiencies.
- *Splinter hemorrhages,* which are small hemorrhages under the nailbed. They are associated with bacterial endocarditis or trauma.
- *Black nails,* resulting from blood under the nail, are seen after local trauma. Nails can also drop after blunt trauma.
- *White spots* may indicate zinc deficiency.

Nail Shape

A change in nail shape may indicate underlying disease. Figure 22-2 illustrates the typical nail plate angle of 160°. Clubbing, in which the nail plate angle is 180° or more, is associated with long-term hypoxic states, such as occur with chronic lung disease (see Procedure 22-4, in Volume 2). Spoon-shaped nails may result from iron deficiency.

Nail Texture

Nails are normally smooth in texture. You may see the following indications of problems:

- Thickened nails may result from poor circulation.
- A thick nail with yellowing is an indication of fungal infection known as *onychomycosis.*
- Brittle nails are seen with hyperthyroidism, malnutrition, calcium and iron deficiency, and repeated use of harsh nail products.
- Soft, boggy nails are seen with poor oxygenation.

The tissue surrounding the nail should be smooth epidermis. Chronic nail-picking results in callus formation

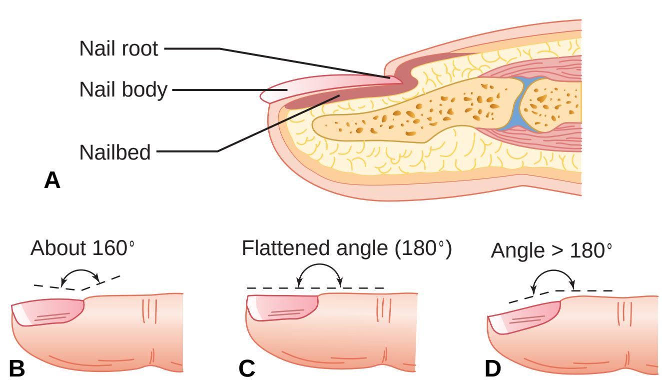


FIGURE 22-2 Nails. *A,* Parts of the nail. *B,* The normal nail plate angle is 160°. *C,* A nail plate angle of 180° or more is known as clubbing. *D,* Late clubbing from long-term hypoxia.

around the nail. Occasionally the surrounding skin becomes inflamed. This condition, known as *paronychia*, is painful and may require drainage if infection is present.

ThinkLike a Nurse 22-3

You are caring for a woman who has no hair on her head. How might you determine the cause of her hair loss? What other assessments should you perform?

THE HEAD

Assessment of the head is often referred to by the acronym HEENT: head, eyes, ears, nose, and throat. You will use all the assessment techniques—inspection, palpation, percussion, and auscultation—in the HEENT exam.

The Skull and Face

Taking individual variation into account, on inspection the skull should be rounded and the face symmetrical in appearance and movement. Inspect head size; if it seems unusual, measure it.

- A large head in an adolescent or adult may be associated with **acromegaly**, a disorder associated with excess growth hormone. Head size is familial, as well.
- **Microcephaly,** an abnormally small head size, is seen in clients with certain types of mental retardation.

Also inspect for shape and symmetry of the head:

- Asymmetry may be the result of trauma, surgery, neuromuscular disorder, paralysis, or congenital deformity.
- In infants, abnormal shape or flattening of the skull may result from trauma during a vaginal birth or placing the baby in the same position for several hours every day.
- In infants and children, a head that is growing disproportionally faster than the body may be a sign of **hydrocephalus** (an accumulation of excessive cerebrospinal fluid).
- Facial appearance that is inconsistent with gender, age, or racial/ethnic group may indicate an inherited or chronic disorder, such as Graves' disease, hypothyroidism with myxedema, or Cushing's syndrome.

Palpate the skull. It should be smooth to palpation, with no unusual contours or bulges. Contour abnormalities, bulging, or tenderness may be a result of trauma, congenital anomalies, or surgery. Irregular jaw movement or cracking of the jaw may indicate **TMJ (temporomandibular joint) syndrome.**

The Highlights of Procedures box near the end of this chapter summarizes the assessment of the face. For the entire procedure, and an Abnormal Atlas of facial abnormalities,

Go to Chapter 22, **Procedure 22-5: Assessing the Head and Face,** in Volume 2.

The Eyes

In examining the eyes, you will inspect and palpate the external eye structures, assess vision, and examine the internal eye structures. The Highlights of Procedures box near the end of this chapter summarizes the eye exam. For step-by-step instructions,

Go to Chapter 22, **Procedure 22-6: Assessing the Eyes,** in Volume 2.

For convenience, you may wish to perform some cranial nerve testing along with the eye exam (e.g., corneal reflex, pupillary reaction, accommodation, and extraocular movements). For instructions on performing a cranial nerve examination,

Go to Chapter 22, **Procedure 22-16: Assessing the Sensory-Neurological System,** in Volume 2.

External Structures

To review the structure of the external eye, see Figure 22-3. Normal eyelid margins are moist and pink with short lashes that are evenly spaced and curl outward. The lower eyelid margin appears at the bottom edge of the iris, and the upper eyelid covers half the upper iris. The conjunctiva is smooth, glistening, and peach in color, with minimal blood vessels present. There should be no pallor, dryness, or edema.

Eyelids The following are common abnormal findings on the eyelids:

- Crusting, scales, or swelling of the lid is associated with infection of the eyelids or eyelashes.
- A **pterygium** is a growth or thickening of conjunctiva from the inner canthus toward the iris.
- **Ectropion**, an everted eyelid, is commonly seen in older adults secondary to loss of skin tone. It can lead to excessive dryness of the eyes.
- **Entropion**, an inverted eyelid, can lead to corneal damage.
- **Ptosis**, or drooping of the lid, may be seen in clients who have experienced a stroke (cerebrovascular accident [CVA]) or Bell's palsy (paralysis of the facial nerve). To see ptosis and other abnormalities,

Go to Chapter 22, **Procedure 22-5: Assessing the Head and Face,** and **Abnormal Atlas,** in Volume 2.

Sclera and Conjunctiva Associated disorders may include infection, allergies, injuries, and liver disorders. For example, yellow (**icteric**) sclera may be seen with an elevated bilirubin. Blood visible in the sclera is known as a **subconjunctival hemorrhage** and may be related to trauma or hypertension.

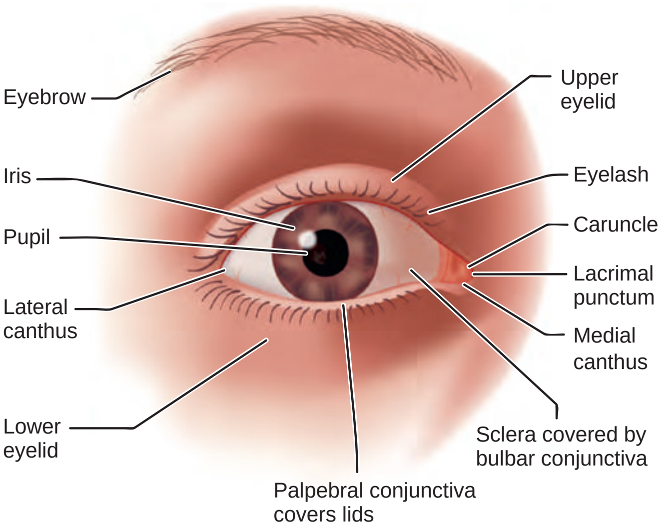

FIGURE 22-3 The external eye and eyelid.

Lens and Cornea The lens and the **cornea**, or outermost layer of the eyeball, are transparent, smooth, and moist. Roughness or irregularity of the cornea is seen with trauma or a corneal abrasion.

Lens opacities, known as **cataracts**, are frequently seen in older adults and may impair vision.

Pupils The **pupils** should be uniform in color, equal in size, and round. They should **accommodate** equally; that is, the pupils constrict and the eyes converge (cross) as a person attempts to focus on an object moving toward him. This is typically charted as PERRLA: pupils equal, round, reactive to light and accommodation. The following are common pupillary abnormalities:

- Sluggish accommodation may be caused by anticholinergic drugs or advanced age.
- Failure of one or both pupils to accommodate may reflect a cranial nerve III problem or **exophthalmos** (associated with hyperthyroidism).
- Congenital cataracts, although rare, may be seen in infants and are checked during an eye exam using the "red reflex." Congenital cataracts cause "lazy eye" or amblyopi and can lead to other eye problems such as nystagmus, strabismus and inability to fix a gaze upon objects.
- Cloudy pupils, a finding related to cataracts, are commonly seen in older adults.
- **Mydriasis** (enlarged pupils) may be seen with glaucoma, an increase in intraocular pressure.
- Many medications affect pupil size (e.g., *mydriatics* are used to dilate the pupil to allow better visualization of the internal eye during examination.
- **Miosis** (constricted pupils) often results from medications to treat glaucoma.
- **Anisocoria** (unequal pupils) may be seen with central nervous system disorders such as stroke, head trauma, or cranial nerve injuries. In some individuals, anisocoria may be normal.

Visual Acuity

Visual acuity is a measure of the eye's ability to detect the details of an image. When testing visual acuity, you will assess distant, near, peripheral, and color vision. Nurses usually perform screening tests of visual acuity. Other testing is performed by nurses in advanced or specialty practice or by an optometrist or ophthalmologist as needed.

Distance Vision

Use the Snellen chart from a distance of 20 feet to assess distance vision. Assess each eye separately, and then assess both eyes together. Normal vision is a measure of clear vision at 20 feet (20/20) in the right eye, left eye, and both eyes. If a patient hesitates when reporting the letters or symbols he sees on the Snellen chart, document "with hesitation." If the person misses one or two items in a line, record the number of items missed.

Myopia, or diminished distant vision, is associated with a smaller fraction. For example, 20/100 vision means that to see text a person with normal vision can read at 100 feet, the client has to stand just 20 feet from the Snellen chart. A child's distance vision does not reach 20/20 until around 6 or 7 years of age.

Near Vision

Test near vision by having the client read newsprint from a distance of 35.5 cm (14 in.). A client with normal near vision will be able to read the newsprint without hesitation with either eye and both eyes. With **hyperopia**, or diminished near vision, the client must hold the paper more than 35.5 cm (14 in.) away. As we age, the lens of the eye naturally loses some ability to accommodate to near objects. In clients older than 45 years of age, diminished near vision is known as **presbyopia**.

Color Vision

Color vision is the ability to detect color. **Color blindness** may be genetically inherited (usually seen in males), or it may result from macular degeneration or other diseases that affect the cones of the eye. Use the color bars at the base of the Snellen chart to test color vision. *Ishihara cards* are specialized cards that enable thorough testing for color blindness. They contain embedded figures within a field of color. A person with normal color vision will be able to successfully identify the figures in the cards or the bars on the base of the Snellen chart; one who is color blind will not. To see Snellen chart and Ishihara cards,

Go to Chapter 22, **Procedure 22-6: Assess the Eyes,** in Volume 2.

Visual Field

Visual field is the area the eye is able to observe. It is related to peripheral vision and extraocular muscle (EOM) function. Visual field abnormalities may be caused by problems with cranial nerves III, IV, and VI or with the retina. Poorly controlled diabetes, cataracts, macular degeneration, and advanced glaucoma are other disorders that limit the visual field. **Peripheral vision** describes the boundaries of the visual field while the eye is in a fixed position. The common phrase, "I see you out of the corner of my eye," refers to peripheral vision.

The EOMs control the movement of the eye and eyelids and allow you to track movement. Three cranial nerves (CN) innervate the EOM. They are CN III (oculomotor), CN IV (trochlear), and CN VI (abducens). CN III also works together with CN II (optic) to control the pupillary reaction to light. Figure 22-4 illustrates the eye positions affected by the EOM and the corresponding cranial nerves.

Strabismus (crossed eye) is a condition in which one or both eyes deviate from the object they are looking at. It is normal during the first 1 or 2 months of life. After that, it may be caused by weak intraocular muscles or a lesion on the oculomotor nerve. Constant strabismus of one eye may result in **amblyopia** ("lazy eye"), in which the brain does not fully acknowledge the images seen by the amblyopic eye. This creates reduced vision in that eye, not correctable by glasses or contact lenses.

Internal Structures of the Eye

Use an ophthalmoscope to visualize the internal structures of the eye (the optic disc, physiological cup, retinal vessels, retinal background, and macula). This is an advanced assessment technique; however, advanced practice nurses and registered nurses on specialty units do perform it with training. Advanced practice nurses use this technique to gain information about certain diseases that affect the eye, such as hypertension and diabetes.

KnowledgeCheck 22-6

- What are the major components of an eye assessment?
- Identify the cranial nerves involved with eye movement and function.

The Ears and Hearing

The ears are involved in both hearing and equilibrium. The **external ear** collects and conveys sound waves to the middle ear. It protects the middle ear from environmental factors such as humidity and temperature and prevents entry of foreign matter. The **middle ear** contains the tympanic membrane and cavity, the eustachian tube, and the **ossicles** (the small bones of the middle ear: the malleus, incus, and stapes). The middle ear conducts sound waves to the inner ear. The **inner ear** is responsible for hearing and equilibrium. Figure 22-5 illustrates the structures of the ear.

Nurses are usually responsible only for screening the ears and making referrals. However, in some settings nurses perform advanced assessments. For procedure steps and guidelines for using the otoscope and tuning fork, as well as for other aspects of ear examination, see the Highlights of Procedures box near the end of this chapter and

Go to Chapter 22, **Procedure 22-7: Assessing the Ears and Hearing,** in Volume 2.

Examining the External and Middle Ear

On inspection, the ears should be of equal size and similar appearance. Normally the pinna is level with the corner of the eye and within a 10° angle of vertical position (shown in Procedure 22-7 in Volume 2). Altered placement of the ear may be a sign of hearing deficit or genetic disorders, including Down syndrome. There should be no lesions or drainage. Bloody drainage may result from trauma. Purulent drainage may be seen with infection.

On palpation, the external structures of the ear are smooth, nontender, pliable, and without nodules. A painful auricle or tragus may be associated with **otitis externa** (an outer ear infection), whereas tenderness behind the ear is seen with **otitis media** (a middle ear infection).

Otoscopic Examination As you begin the otoscopic examination, you may notice that the external auditory canal contains **cerumen** (wax), which protects the middle ear from excessive drying. However, it should not completely obstruct the ear canal. Cerumen may be

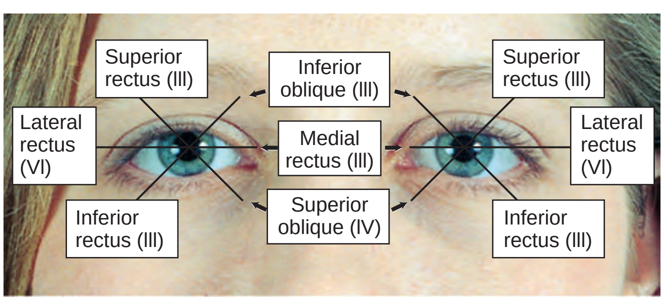

FIGURE 22-4 Cranial nerves and the extraocular muscles.

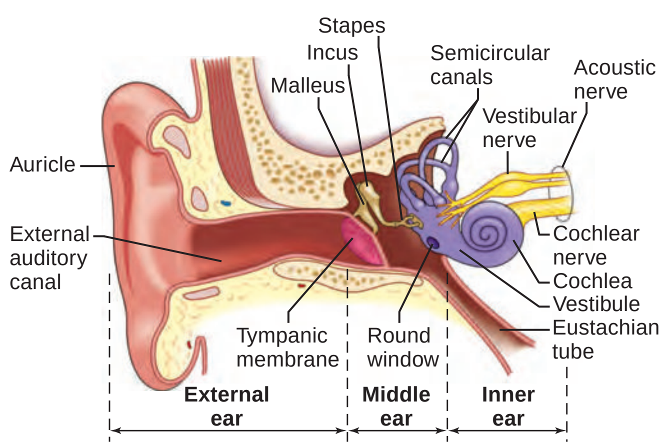

FIGURE 22-5 Cross section of the ear.

black, dark red, yellowish, or brown in color and waxy, flaky, soft, or hard, with no odor; all are normal variations. Be careful as you manipulate the otoscope, because the inner two-thirds of the canal can be tender with the pressure and manipulation of the otoscope head.

Normally the **tympanic membrane (TM)** is pearly gray, shiny, and translucent. The structures of the middle ear should be visible through the membrane. Changes in its appearance arise from abnormalities such as otitis media (which causes a red, bulging TM) and the presence of pressure equalization tubes in young clients with chronic ear infections.

Assessing Hearing

To assess hearing, you will need a quiet room and a tuning fork. Gross hearing ability includes the ability to hear both high- and low-pitched tones. A client who hears low tones will be able to hear and repeat words whispered from 1 to 2 feet behind him. The client can hear high tones if he is able to hear a watch ticking at 5 inches (12 to 13 cm) from each ear.

The Weber and Rinne Tests

Hearing involves transmission of sound vibrations and generation of nerve impulses along CN VIII. The **Weber test** assesses both aspects. When you place a vibrating tuning fork on the center of the client's head, he should be able to sense the vibration equally in both ears. Record a positive Weber test if the vibration is louder in one ear.

If the Weber test is positive, you will need to perform the Rinne test to assess the type of hearing problem. The **Rinne test** also uses a tuning fork to compare air conduction (AC) and bone conduction (BC). Normally AC is twice as long as BC. For step-by-step instructions for performing the Weber and the Rinne tests,

Go to Chapter 22, **Procedure 22-7: Assessing the Ears and Hearing,** in Volume 2.

The Romberg Test

Along with the cerebellum and midbrain, *vestibular cells* in the ear are responsible for maintaining equilibrium. To assess equilibrium, perform the Romberg test. The client should be able to stand with feet together and eyes closed, and maintain balance with minimal swaying. Swaying and moving (positive Romberg) may indicate a vestibular or cerebellar disorder. You may prefer to perform the Romberg test with examination of the neurological system instead of with the ears.

KnowledgeCheck 22-7

Your client has a negative Weber test. What further testing is required?

ThinkLike a Nurse 22-4

What type of symptoms would you expect a client to be experiencing if he had a positive Romberg test?

The Nose

The nose and sinuses (Fig. 22-6) are part of the respiratory system and are the organs of smell. Vaporized molecules sniffed into the upper nasal cavities trigger receptors that generate impulses along the olfactory nerve (CN I) that travel to olfactory centers in the temporal lobes.

The sense of smell diminishes in older adults because of a gradual decrease in and atrophy of the olfactory nerve fibers.

See the Highlights of Procedures box near the end of this chapter for a summary of the examination steps. For the complete procedure, along with expected findings,

Go to Chapter 22, **Procedure 22-8: Assessing the Nose and Sinuses,** in Volume 2.

The Mouth and Oropharynx

The structures of the mouth include the lips, tongue, teeth, **gingiva** (gums), uvula, hard and soft palate, and salivary glands and ducts (Fig. 22-7). On external

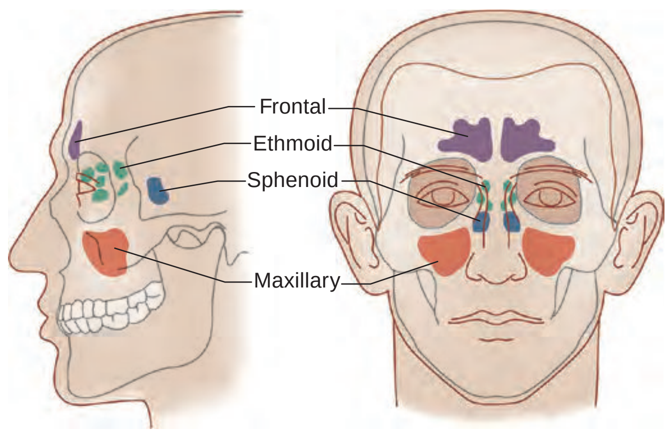

FIGURE 22-6 Paranasal sinuses: frontal, ethmoid, sphenoid, and maxillary.

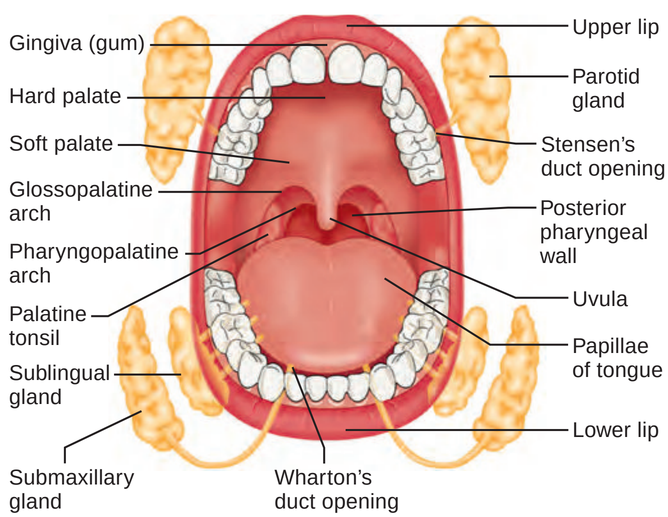

FIGURE 22-7 Structures of the mouth.

inspection, the mouth and lips should be symmetrical and without lesions, swelling, or drooping. For an illustration of structures of the mouth, illustrations of abnormal conditions, and instructions for examining the mouth and oropharynx,

Go to Chapter 22, **Procedure 22-9: Assessing the Mouth and Oropharynx,** in Volume 2.

Also see the Highlights of Procedures box near the end of this chapter.

The Lips, Buccal Mucosa, and Gingiva

The lips, **buccal mucosa** (mucous membrane of the cheeks), and gums should be smooth, moist, and pink in color. Increased pigmentation (e.g., bluish or dark patches) occurs in dark-skinned clients. No lesions should be present. The following are abnormal findings:

- Pallor may indicate anemia or inadequate oxygenation.
- **Gingivitis** is a sign of periodontal disease. You will see red, swollen, or spongy, bleeding gingiva and receding gum lines. The gums may be tender.
- **Parotitis** is an inflammation of the parotid salivary gland.
- **Stomatitis** is inflammation of the oral mucosa.
- **Leukoplakia** (thick, elevated white patches) that do not scrape off may be precancerous lesions; white, curdy patches that scrape off and bleed indicate **thrush** (a fungal infection).
- Redness or abrasions of the gingiva may be caused by poorly fitted dentures.
- **Aphthous ulcers** are small, painful vesicles with a reddened periphery and a white or pale yellow base. **Canker sores** are a benign type of aphthous ulcer believed to be caused by viral infection, allergies, stress, or trauma. So-called "major" aphthous ulcers may be caused by herpes simplex virus, human immunodeficiency virus, and bacterial infections.

When inspecting the mouth, be sure to ask your client about use of tobacco, either smoked or chewed. Both forms are associated with increased risk for oral cancer.

The Teeth

Healthy adults typically have 28 teeth, or 32 if the wisdom teeth are present. The teeth should be fixed to the gum and without obvious debris or darkening that may indicate caries. Tooth decay and periodontal (gum) disease are common. Poor oral hygiene is a major contributing factor for both. As you examine the mouth and teeth, talk to the patient about his oral care. Recommend tooth brushing after each meal, daily flossing, and dental checkups every 6 months. See Chapter 25 for a more complete discussion of oral hygiene and prevention of periodontal disease.

The Tongue

When inspecting the mouth, carefully examine all aspects of the tongue: dorsal, ventral, and lateral. The **tongue** should be moist, symmetrical, slightly rough, smooth, pink, and freely movable. The following are abnormal findings:

- Limited mobility of the tongue
- Deviation from the midline, which may be caused by damage to the hypoglossal nerve (CN XII)
- **Glossitis** (inflammation of the tongue)
- A dry, furry tongue, which is associated with dehydration
- A black, "hairy" tongue, which is associated with fungal infections
- Reddened mucosa, ulcerations, and absence of papillae which may indicate allergy, inflammation, or infection
- Swelling, nodules, or ulcers
- A smooth, red tongue, which may occur in clients who have a deficiency of iron, vitamin B^{12}, or vitamin B^{3}

The Hard and Soft Palates and Oropharynx

The hard palate, soft palate, and oropharynx should be pink, moist, and intact. No lesions, swelling, erythema, or discharge should be present. If the tonsils are present, they should be symmetrical, small in size, and free of exudate in a healthy person. The uvula is midline and should rise on **phonation** (vocalization).

THE NECK

The neck has components of the musculoskeletal, neurological, vascular, respiratory, endocrine, and lymphatic systems. The sternocleidomastoid and trapezius muscles form the landmarks of the neck, known as the **anterior and posterior triangles**. The symmetrical neck muscles center and coordinate movement of the head. Asymmetrical head position may result from damage to the muscles, swelling, or masses. Painful or erratic movement may be due to a benign condition, such as muscle spasm, or to significant problems, including meningitis, neurological injuries, or chronic arthritis.

The trachea, thyroid gland, anterior cervical nodes, and carotid arteries are positioned in the anterior triangle; the posterior cervical nodes are in the posterior triangle. You will palpate the tracheal rings and the cricoid and thyroid cartilage in the midline of the anterior neck. For a summary of assessment step, see the Highlights of Procedures box near the end of this chapter. For the complete procedure and for illustrations of structures of the neck,

Go to Chapter 22, **Procedure 22-10: Assessing the Neck,** in Volume 2.

The Thyroid Gland

Normally the thyroid is smooth, firm, and nontender. It is often nonpalpable. Thyroid abnormalities are common. An enlarged thyroid may be associated with either hypothyroidism or hyperthyroidism. Thyroid tenderness usually results from inflammation. Thyroid masses may be malignant but are usually benign.

The Cervical Lymph Nodes

The cervical lymph nodes occur in three chains. The anterior chain is in the anterior triangle, the posterior chain in the posterior triangle. There is a deep cervical chain under the sternocleidomastoid muscle. The lymph nodes are generally not palpable, although occasionally nodes can be felt, especially in young children. Normal nodes are small in size (less than 1 cm), mobile, soft, and nontender. You should describe enlarged nodes (greater than 1 cm in diameter) according to their location, size, shape, consistency, mobility, and tenderness. Enlarged or tender nodes may be caused by infection, malignancy, and other diseases. For illustrations and step-by-step instructions, see Procedure 22-10.

ThinkLike a Nurse 22-5

A client complains of sore throat, fever, chills, and runny nose. What assessments should you perform?

THE BREASTS AND AXILLAE

The breasts consist of glandular, adipose, and connective tissue; smooth muscle; and nerves (Fig. 22-8). The functions of the female breast are sexual stimulation and milk production for nourishing offspring. Breast size and shape vary among women, and commonly one breast is slightly larger than the other. At puberty, the ovaries produce estrogen and progesterone, which stimulate the breasts to develop. The menstrual cycle, pregnancy, and breastfeeding also enlarge breast tissue. Although breasts are thought of as female organs, men also have breasts. However, because of limited estrogen and progesterone levels, male breasts develop only minimally.

Breast tissue and lymph drainage for the breast extend up into the axilla. The majority of breast tumors are found in the tail of Spence, in the axilla. A breast exam therefore always includes an exam of the axillae. Many women have breast reconstruction, either after breast removal as a result of cancer or breast augmentation for cosmetic reasons. These women should not omit breast examination, and it is performed in exactly the same way as for natural breasts.

Clinical Breast Examination You should perform a breast exam for the woman if she cannot do it herself, and demonstrate the procedure as part of client teaching for self-care. Clinical breast exams should be done annually for women aged 40 and older, and every 1 to 3 years for women aged 20 to 39 (American Congress of Obstetricians and Gynecologists [ACOG], 2011). Guidelines vary as to the age at which women should start having clinical breast exams (CBE) and mammograms to screen for breast cancer.

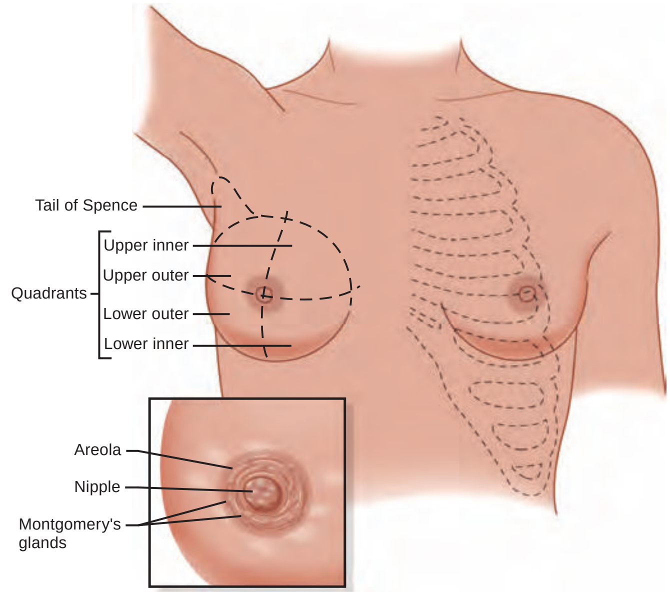

FIGURE 22-8 Breast tissue extends up into the axilla.

Key Point: ***Researchers agree that patients who perform a breast self-exam (BSE) should be trained in proper technique in order to avoid falsely negative findings (ACOG, 2009; Smith, Cokkinides, Brooks, et al., 2011; Smith, Duffy, & Tabár, 2012).***

Chapter 42 includes a thorough discussion of teaching your client how to perform a breast self-exam.

Mammography and Thermography Annual or biennial mammograms or breast thermography most commonly begin after age 40, or at a younger age and more often for those at high risk. ACOG recommends annual mammograms (ACOG, 2011; American Cancer Society, n.d., last revised 2013a, n.d., last revised 2013b).

Controversy exists about whether women should continue to have mammograms after age 74 (refer to Chapters 10 and 42).

For a summary of breast examination, see the Procedure Highlights box at the end of this chapter. For a step-by-step guide to examining the breasts and axillae,

Go to Chapter 22, **Procedure 22-11: Assessing the Breasts and Axillae,** in Volume 2.

ThinkLike a Nurse 22-6

What strategies might encourage more women to regularly perform breast self-examination, if your agency has decided to promote that measure?

THE CHEST AND LUNGS

The chest, or thorax, is the bony cage that protects the heart, lungs, and great vessels. The ribs, sternum, and vertebrae form the chest. Be systematic in your assessment: Always assess the areas of the chest and lungs in the same order. To learn how to assess the chest and lungs,

Go to Chapter 22, **Procedure 22-12, Assessing the Chest and Lungs**, in Volume 2.

For a summary, see the Highlights of Procedures box near the end of this chapter.

Chest Landmarks

Before beginning the thoracic exam, review the following important landmarks that will help you visualize the underlying structures and perform an accurate assessment.

- *Anterior chest*—Identify positions vertically on the anterior chest in relation to the ribs. For example, the space between the 5th and 6th ribs is known as the 5th intercostal space (5th ICS). You can easily palpate the ribs and count the spaces if you remember that the 1st rib is tucked up next to the clavicle (Fig. 22-9A).
- *Anterior chest*—Use a series of imaginary vertical lines (Fig. 22-9B) with the rib spaces to further aid in identifying locations on the anterior chest. For instance, the apex of the heart is usually located in the 5th intercostal space at left midclavicular line (5th ICS MCL).
- *Posterior chest*—Identify positions vertically in relation to the vertebra (Fig. 22-10B). The prominent vertebra at the base of the neck is the 7th cervical vertebra (C7). The next one down is T1 (1st thoracic). Counting down to about T9 should be adequate.
- *Lateral and posterior chest*—Use imaginary lines on the lateral and posterior chest as well. Figure 22-10, parts A and C, illustrates the location of these lines. Notice that the anterior axillary line can be used to locate sounds on both the anterior and lateral chest.

Chest Shape and Size

The normal adult chest is symmetrical and rises and falls with respirations. The chest diameter expands up to 3 inches (7.6 cm) with deep inspiration. The anteroposterior diameter of the chest (side view) is about half the size of the lateral diameter (front or back view). This is written as AP: Lateral = 1:2). In young children, the chest is apple-shaped. This change is also seen, regardless of age, in clients who have chronic obstructive pulmonary disease (COPD), a disorder associated with long-term smoking. Figure 22-11 illustrates the normal chest ratio and the barrel chest appearance that develops with COPD, in which the anteroposterior and lateral diameters may be equal.

Spinal alterations, such as **kyphosis** (excessive curvature of the thoracic spine) and **scoliosis** (lateral curvature of the spine) alter the shape of the thoracic cage.

Osteoporosis, a common disorder associated with aging, is associated with increased porosity of the vertebrae. As a result, vertebrae may compress or collapse, shortening the length of the spine and pushing the ribs forward and downward.

Breath Sounds

Listen to breath sounds in a quiet room by auscultating one full respiratory cycle at each site. Directly apply the stethoscope to the client's skin. Compare breath sounds bilaterally. Three types of breath sounds are heard (Fig. 22-12).

- **Bronchial breath sounds** are loud, high-pitched, tubular sounds; expiration is of longer duration than inspiration. Air moving through the trachea produces these sounds, which you will hear best over the

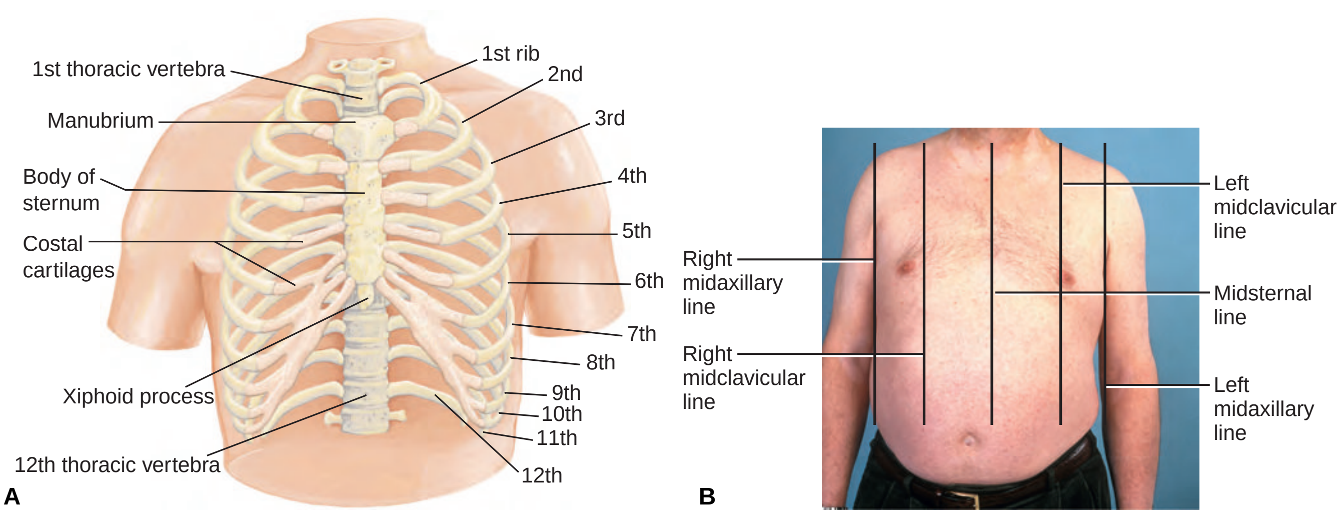

FIGURE 22-9 *A*, The anterior thoracic cage and the bony landmarks. *B*, A series of imaginary vertical lines is used to describe locations on the chest.

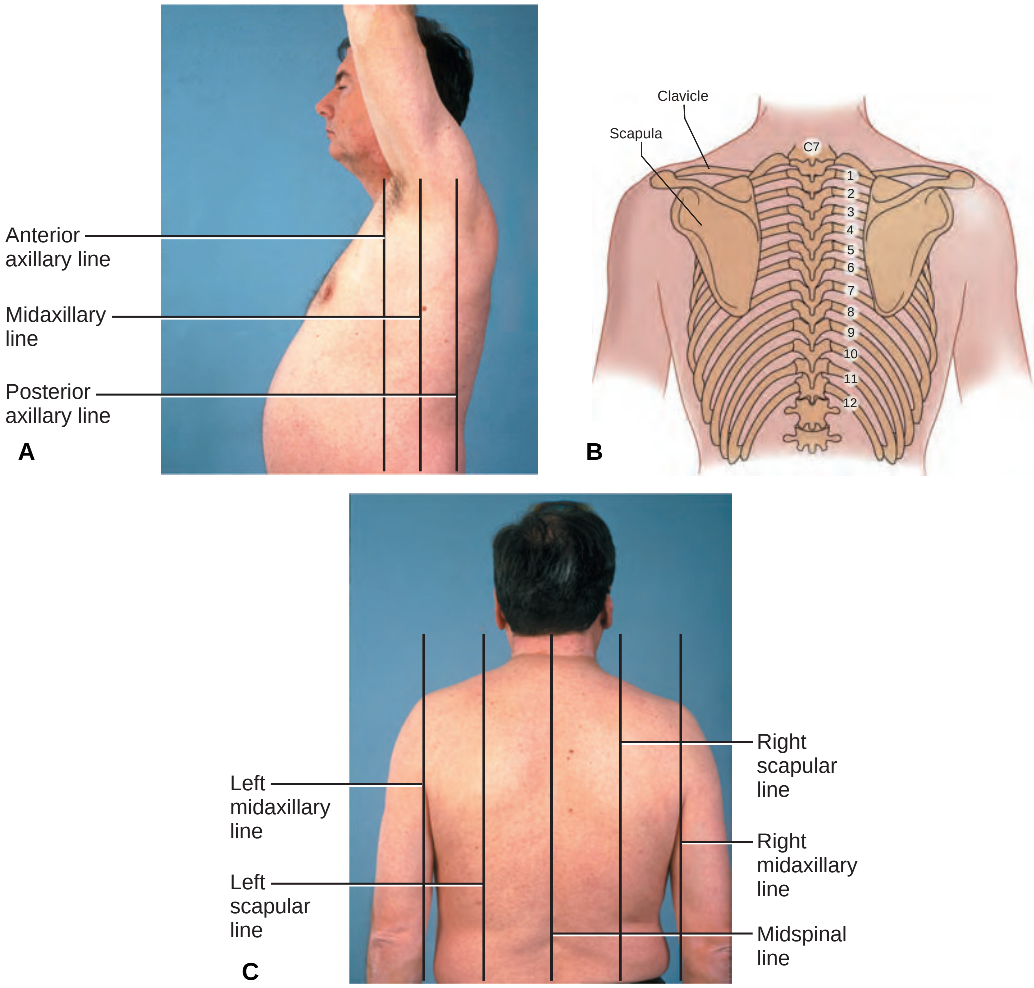

FIGURE 22-10 *A*, Lateral chest landmarks. *B*, The vertebrae are the landmarks on the posterior chest. *C*, Landmark lines on the posterior chest.

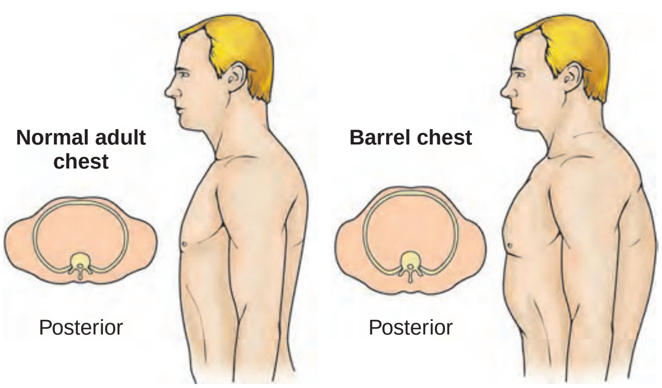

FIGURE 22-11 The normal anteroposterior to lateral ratio is 1:2. The lateral aspect of the chest increases dramatically with COPD, leading to a barrel chest appearance.

trachea on the anterior chest and below the nape of the neck on the posterior chest.

- **Bronchovesicular breath sounds** are medium-pitched with an equal inspiratory and expiratory phase. Air moving through the large airways of the bronchi produces these sounds, which you will hear best over the 1st and 2nd ICS adjacent to the sternum on the anterior chest and between the scapula on the posterior chest.
- **Vesicular breath sounds** are soft, low-pitched, breezy sounds with a lengthy inspiratory phase and a short expiratory phase. Air moving through the smaller airways produces these sounds, which you will hear best over the lung fields.

Breath sounds that differ from those above are abnormal. **Diminished breath sounds** are heard with poor inspiratory effort, in the very muscular or obese, or with restricted airflow. **Misplaced breath sounds** (e.g., bronchial breath sounds heard over the lung fields) indicate constriction of flow. **Adventitious breath sounds**, such as wheezes, rhonchi, and rales, are sounds heard over normal breath sounds. If an abnormal sound is heard, have the client cough and listen again. Other abnormal findings include **bronchophony**, **whispered pectoriloquy**, and **egophony**. These are abnormal voice sounds that result from consolidation of lung tissue. To find a discussion of these and to listen to normal and adventitious breath sounds,

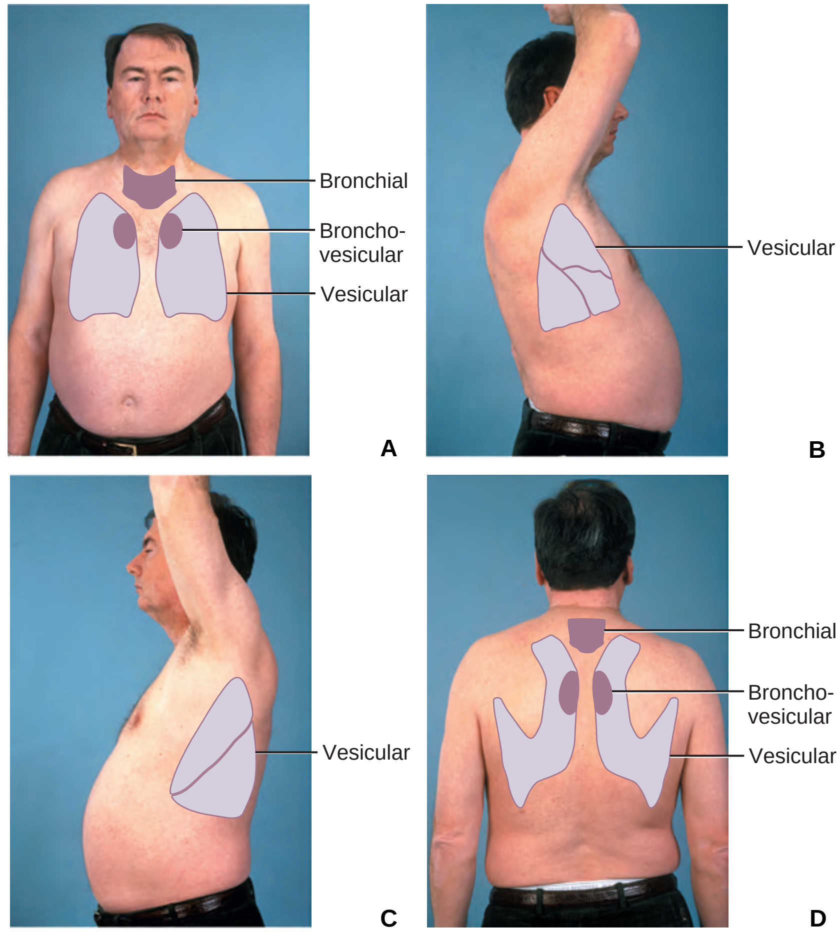

FIGURE 22-12 Normal breath sounds. *A*, Anterior. *B*, Right lateral. *C*, Left lateral. *D*, Posterior.

Go to Chapter 22, **Supplemental Materials: Abnormal Voice Sounds,** and the various **sound files** for normal and abnormal breath sounds in the Student Resources, on Davis*Plus*.

For more information about the respiratory system, see Chapter 36. The Highlights of Procedures box at the end of this chapter summarizes respiratory assessment. For a table describing abnormal breath sounds and the procedure for performing a respiratory assessment,

Go to Chapter 22, **Procedure 22-12, Assessing the Chest and Lungs,** in Volume 2.

KnowledgeCheck 22-8

- List and describe the location of the horizontal and vertical landmarks of the anterior chest.
- List and describe the location of the horizontal and vertical landmarks of the posterior chest.
- List and describe the location of the vertical landmarks of the lateral chest.

THE CARDIOVASCULAR SYSTEM

The cardiovascular system consists of the heart and the blood vessels. The heart is a muscle that pumps blood throughout the body. In a healthy adult, it is about the size of a clenched fist. The blood vessels, which make up the vascular system, have two main networks: the pulmonary circulation and the systemic circulation. See Chapter 37 if you need to review the anatomy of the cardiovascular system.

Oxygen-depleted blood circulates from the heart into the lungs, where it is oxygenated, then back to the heart. This system is known as the **pulmonary circulation**. From the heart, the blood enters the **systemic circulation**. The left ventricle is the largest chamber of the heart. It pumps blood into the systemic circulation via the arterial system. The arteries subdivide many times, becoming smaller and smaller until they separate, in the tissues and organs, into capillaries. It is at the capillary level that oxygen is delivered to the tissues. The venous system collects the oxygen-depleted blood and returns it to the right atrium of the heart to begin the circuit again. **Coronary circulation**, which circulates blood through the heart itself, is a part of the systemic circulation. For further discussion on pulmonary circulation and oxygenation, see Chapter 37. For animated presentations of the circulatory system and oxygen transport,

Go to Student Resources, **Animations: Blood Flow and Carbon Dioxide/Oxygen Transport,** on Davis*Plus*.

The Highlights of Procedures box at the end of this chapter summarizes assessment of the heart and vascular system. For a complete step-by-step procedure,

Go to Chapter 22, **Procedure 22-13: Assessing the Heart and Vascular System,** in Volume 2.

The Heart

The heart is positioned at an angle on the left side of the chest in the 3rd, 4th, and 5th intercostal spaces (ICS). To facilitate auscultation of specific heart sounds, perform the cardiac assessment with the client in three positions: sitting, supine, and left lateral recumbent.

Clients with chronic heart or lung problems may have little cardiac reserve, so minimize position changes to conserve your client's energy.

Be systematic. To keep from missing important parts of the exam, always listen in the same order to all the areas. To help minimize your client's anxiety, explain that it always takes time to examine the heart and circulatory system.

The Cardiac Cycle

During a cardiac cycle, the atria and ventricles alternately contract and relax to fill and empty; while the atria are contracting (emptying), the ventricles are relaxing (filling), and vice versa. **Systole** refers to the contraction, or emptying, of the ventricles. **Diastole** refers to the relaxation, or filling, phase of the ventricles.

Inspecting and Palpating the Heart

Begin with the client sitting (Fig. 22-13). Observe the **precordium**, the area of the chest over the heart, for visible pulsations. A small pulsation at the 5th ICS midclavicular line, also known as the **point of maximal impulse (PMI)**, is normal. Other visible pulsations on the precordium, known as **heaves** or **lifts**, are associated with an enlarged ventricle.

Palpate for vibrations. A **thrill** is a vibration or pulsation palpated in any area except the PMI. A thrill is associated with abnormal blood flow and usually has an accompanying **murmur** (additional heart sound).

Auscultating the Heart

Auscultate to establish cardiac rate and rhythm and to identify normal and abnormal heart sounds. A quiet room is essential. You can hear heart sounds from any location on the anterior chest wall. However, the four sites located over the heart valves are the preferred listening areas. Table 22-4 and Figure 22-13 describe these locations. To learn more about auscultating the precordium,

Go to Chapter 22, **Procedure 22-13, Assessing the Heart and Vascular System,** in Volume 2.

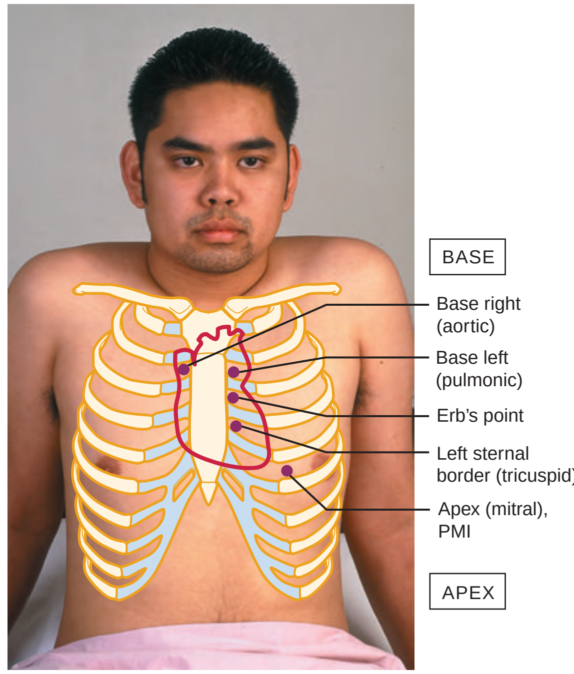

FIGURE 22-13 Cardiac auscultation sites.

Table 22-4 ➤ Locations for Assessing the Heart

TITLE	STRUCTURE ASSESSED	LOCATION
Base Right	Aortic valve	2nd ICS right sternal border
Base Left	Pulmonic valve	2nd ICS left sternal border
Left Lateral	Tricuspid valve	4th ICS left sternal border
Apex	Mitral valve	5th ICS MCL

Auscultate in an orderly fashion. Start at the aortic area, and move gradually through each landmark. The following is a mnemonic you may use to recall the order of the heart sound landmarks:

***A**unt* Aortic
***P**olly* Pulmonic
***T**akes* Tricuspid
***M**eds* Mitral

Listen carefully at each site to each component of the heart sounds.

First Heart Sound The first heart sound (S_1, or "lub") results from the closure of the valves between the atria and ventricles. S_1 ("lub") is a dull, low-pitched sound, loudest over the mitral and tricuspid areas. S_1 marks the beginning of systole.

Second Heart Sound The second heart sound (S_2, or "dub") corresponds to closure of the semilunar valves (between the ventricles and the great arteries exiting the heart). "Dub" is higher in pitch and shorter than the S_1 "lub." The S_2 is loudest at the aortic and pulmonic areas. S_2 marks the beginning of diastole. Normally, the mitral and tricuspid valves and the aortic and pulmonic valves close within a fraction of a second from each other. This near simultaneous closure results in a singular S_1 and S_2 sound. However, a split sound may occur, at either S_1 or S_2, if there is a delay in closure of one of the valves.

Third Heart Sounds A third heart sound (S_3), heard immediately after S_2, has a gallop cadence that follows the rhythm of the word "KenTUCKy." It is best heard at the apical site with the client lying on his left side. An S_3 is normal in young children and adolescents when they are sitting or lying, but it disappears when they stand or sit up. It is also a normal variant in the third trimester of pregnancy. In adults, an S_3 that does not disappear with position change is abnormal and represents heart failure or volume overload.

Fourth Heart Sounds A fourth heart sound (S_4), heard immediately before S_1, has a rhythm that follows the word "FLOrida." S_4 is best heard at the apical site, using the bell of the stethoscope, with the client lying on his left side. An S_4 is normal in athletes and some older clients. It may also be heard in adults with coronary artery disease, hypertension, and pulmonic stenosis. To listen to heart sounds,

Go to Student Resources, **Sound Files, Heart Sounds,** on Davis*Plus*.

Murmurs **Murmurs** are additional sounds produced by turbulent flow through the heart. Some murmurs are "innocent," but others represent pathology such as alteration in valve structure. Identifying and classifying a murmur are advanced skills that require practice. To learn more about assessing murmurs, see the Highlights of Procedures box, and

Go to Chapter 22, **Procedure 22-13: Assessing the Heart and Vascular System,** in Volume 2. Also go to Chapter 22, **Supplemental Materials: Heart Murmurs,** and **Tables, Boxes, Figures: ESG Table 22-1,** on Davis*Plus*.

Think**Like a Nurse** 22-7

What findings would you anticipate when assessing Mr. Nguyen's (Meet Your Patient) thorax?

The Vascular System

The vascular system is a network of arteries and veins that transport oxygen, carbon dioxide, and nutrients to the cells of the body. Arteries carry blood away from the heart: The pulmonary arteries carry oxygen-depleted blood from the right ventricle to the lungs, whereas the systemic arteries carry oxygenated blood from the left ventricle to the body periphery. Veins carry blood toward the heart: The pulmonary veins transport oxygenated blood from the lungs to the left atrium, whereas the systemic veins return oxygen-depleted blood from the periphery to the right atrium of the heart.

The Central Vessels

The carotid arteries and internal jugular veins run alongside the sternocleidomastoid muscle on both sides of the neck (Fig. 22-14). These central vessels provide circulation to the brain.

The Carotid Arteries

Because the carotid arteries are large and close to the heart, you can easily feel a pulse over the carotid artery even when it is difficult to palpate a peripheral pulse.

Never palpate both carotid arteries at the same time because bilateral pressure may impair cerebral blood flow. Palpate very lightly and avoid massaging the carotid artery, because pressure on the carotids will cause the pulse rate to drop, and can even lead to cardiac arrest. As a general rule, avoid palpating the carotids except during cardiopulmonary resuscitation or when it is necessary to assess them for a specific reason (such as in a comprehensive physical exam, or when an underlying pathology makes it necessary to establish that circulation to the head is adequate).

Turbulent blood flow through the carotid artery produces a whooshing sound known as a **bruit**, which you can auscultate using a stethoscope. The following conditions cause turbulence: **carotid stenosis** (narrowing from plaque), increased cardiac output secondary to fluid overload, use of stimulants, and hyperthyroidism. If you hear a bruit, lightly palpate the neck for thrills (pulsations or vibrations), which further confirm turbulent flow.

Bruits are common among older adults.

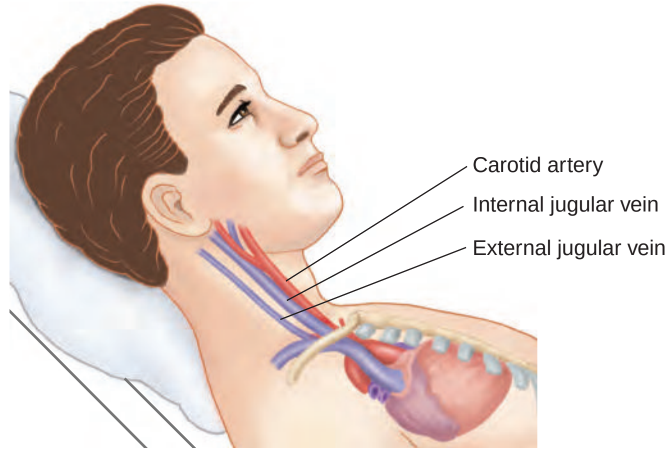

FIGURE 22-14 The central vessels.

The Jugular Veins

The jugular veins return blood from the brain to the superior vena cava. The external jugular veins are superficial; the internal jugular veins are deep. Normally the jugular veins are flat when the client is in an upright position and distend when the client lies flat. Jugular venous distention (JVD) is seen when the right side of the heart is congested because of inadequate pump function. The best position for assessment of JVD is semi-Fowler's (30° to 45° angle)

The Peripheral Vessels

The peripheral vessels supply blood to all the body cells. The **arteries** are a high-pressure system with several palpable pulse sites. The **veins** are a low-pressure system with valves to prevent backflow caused by gravity. The veins return blood to the heart via the continuing pressure from the arterial system and pumping action of the adjacent skeletal muscles. If you were to lay out all the blood vessels in the peripheral system of an average sized person, you would find more than 60,000 miles of arteries, arterioles, capillaries, and venules.

You will assess the peripheral vascular system by:

- *Measuring the blood pressure* (see Chapter 20), usually at the start of the exam as part of the general survey.
- *Palpating the peripheral pulses* (see Chapter 20). In a healthy individual, pulses will be regular, strong, and equal bilaterally. Weak, absent, or asymmetrical pulses may indicate partial or complete occlusion of the artery. Other signs of arterial occlusion include pain, pallor, cool temperature, paresthesia, or paralysis.
- *Inspecting and performing tests for adequate perfusion*.

The data you obtain when inspecting and palpating the integumentary system provide some information about peripheral tissue perfusion. Recall that when an area is not adequately oxygenated, the skin may be pale, cyanotic, cool, and shiny; hair growth may be sparse; and there may be clubbing of the nails. Inadequate tissue oxygenation may be a result of chronic pulmonary problems; however, it can also result from impaired central or peripheral circulation.

Also assess the veins for signs of distention. Superficial spiderlike veins, especially on the lower extremities, may occur with normal aging. Ropelike distended veins, or **varicosities**, may be painful. If a client has varicosities, assess for valve competence using the **manual compression test**. To see that,

Go to Chapter 22, **Procedure 22-13, Assessing the Heart and Vascular System,** in Volume 2.

KnowledgeCheck 22-9

Identify the precautions to take when evaluating the carotid arteries.

THE ABDOMEN

The method most commonly used to identify the location of assessment findings is the four-quadrant method, which divides the abdomen into four sections by "drawing" a line vertically from the xiphoid process to the symphysis pubis and a horizontal line at the level of the umbilicus (Fig. 22-15).

For the rarely used nine-region method,

Go to Chapter 22, **Tables, Boxes, Figures: ESG Table 22-2, The Nine Regions of the Abdomen**; and **ESG Figure 22-1, The Nine Regions of the Abdomen,** on Davis*Plus*.

Examination of the abdomen differs in sequence from all other body systems. Percussion and palpation stimulate the bowel and may alter bowel sounds. Therefore, you should inspect and auscultate before performing percussion and palpation. To promote comfort, ask the client to empty his bladder before the examination. Have the client assume a supine position with flexed knees. This relaxes the abdominal muscles and is usually the most comfortable position. If the client has a painful area, examine that area last to minimize discomfort during the rest of the exam.

Inspecting the Abdomen

The skin over the abdomen is usually paler than that over other parts of the body. The abdomen should be symmetrical with a rounded contour and sunken umbilicus. You may be able to see peristalsis and aortic pulsations on a very thin client, but in most clients usually you will see no movement. In clients with abdominal distention, the skin appears taut. Distention may be

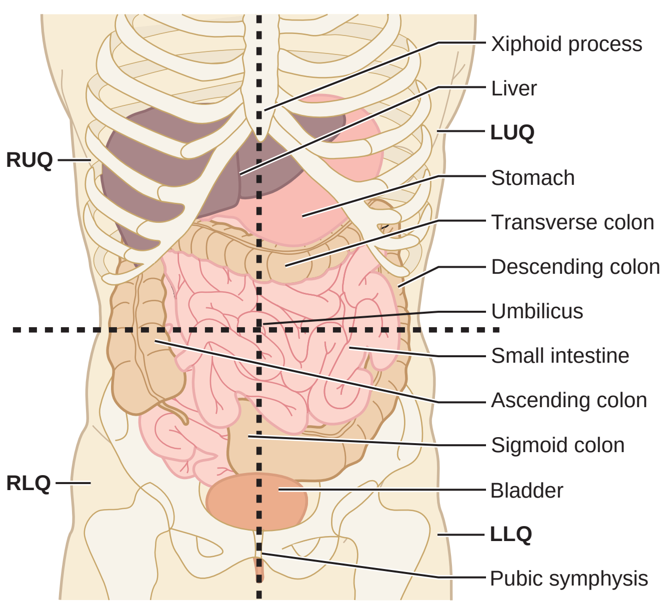

FIGURE 22-15 The four abdominal quadrants.

normal, as with pregnancy, or it may be due to gas or fluid retention or to bowel obstruction. See Figure 22-16 for normal variations in abdominal shape.

Auscultating the Abdomen

Proceed in an organized manner, listening in several areas in all four quadrants. Use the same pattern for every examination so that it becomes a habit.

First Auscultate Bowel Sounds Bowel sounds are high-pitched, irregular gurgles or clicks lasting one to several seconds and occurring every 5 to 15 seconds (or 5 to 30 times per minute) in the average adult. If the client has a nasogastric (NG) tube that is attached to suction, discontinue the suction or clamp off the tube while listening for bowel sounds. Otherwise, you may mistake the sound of suction in the stomach for bowel sounds. Bowel sounds may be:

- **Normal.** Audible, occurring every 5 to 15 sec (or 5–30 times per min) in a healthy adult.
- **Hyperactive (hyperperistalsis).** Loud, rushing sounds occurring every 2 or 3 sec (or more than 30 per min); may indicate diarrhea, early bowel obstruction, or gastroenteritis (infection of the GI tract).
- **Hypoactive (hypoperistalsis).** Very faint and infrequent (fewer than 5 sounds per min); may occur after abdominal surgery or with bowel obstruction, infection, or problems of innervation.
- **Absent.** None after listening for 5 min.

To hear some bowel sounds,

Go to **Sound Files: Bowel Sounds,** on Davis*Plus*.

Next Auscultate the Major Arteries Major arterial vessels lie in the abdomen below the intestines. Listen over the aorta and the renal, iliac, and femoral arteries for the presence of bruits.

Percussing the Abdomen

Use indirect percussion to assess for fluid, air, organs, or masses. Normally there is generalized tympany over the bowels (due to the presence of gas) and the abdomen is nontender, soft, and without masses. You will hear dullness when percussing organs, masses, or fluids. Some practitioners include percussion of the kidney with the abdominal examination.

Palpating the Abdomen

Begin with light palpation to put the patient at ease. Palpate for tenderness and guarding in all four quadrants. Palpation of the liver and spleen is an advanced technique not usually performed by staff nurses, except perhaps in some specialty areas. The Highlights of Procedures box at the end of this chapter summarizes abdominal assessment. For the complete procedure,

Go to Chapter 22, **Procedure 22-14: Assessing the Abdomen,** in Volume 2.

KnowledgeCheck 22-10

- What strategies can you use to make the client more comfortable during an abdominal assessment?
- Identify the sequence of assessment for the abdominal exam.

THE MUSCULOSKELETAL SYSTEM

The musculoskeletal system consists of bones, muscles, and joints. Bone is complex living tissue that responds to nutrition, stress, and illness. The bones include *long bones*, such as the humerus and tibia; *flat bones*, such as the sternum and ribs; and *irregular bones*, such as the vertebrae and pelvis. Tendons, ligaments, and cartilage serve as connecting structures. **Bursae**, small disc-shaped, fluid-filled sacs, act as cushions to reduce friction between the joint and the tendons that cross over the joint (Fig. 22-17). The musculoskeletal system provides shape and support to the body, allows movement, protects internal organs, produces red blood cells in the bone marrow, and stores calcium and phosphorus.

Assessment of the musculoskeletal system includes evaluation of the client's posture, gait, bone structure, muscle function, and joint mobility. The procedure is summarized in the Highlights of Procedures box at the end of this chapter. For step-by-step instructions,

Go to Chapter 22, **Procedure 22-15: Assessing the Musculoskeletal System,** in Volume 2.

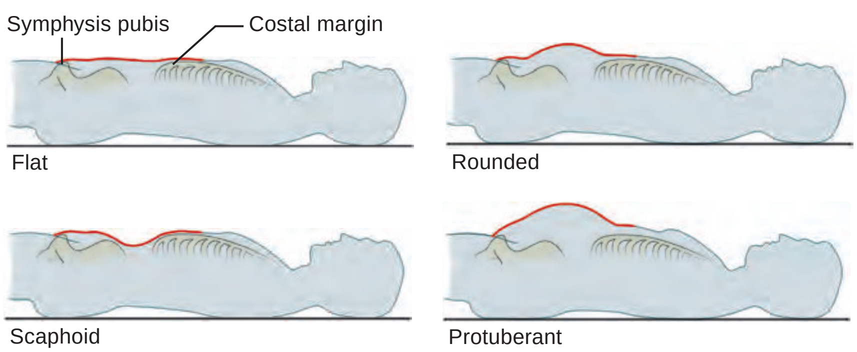

FIGURE 22-16 Normal variations in abdominal contour.

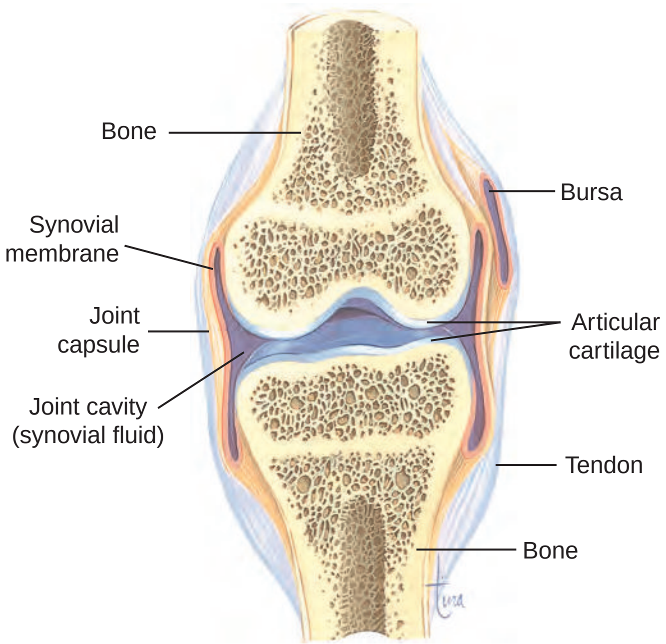

FIGURE 22-17 Many synovial joints have bursae that act as cushions against friction.

Body Shape and Symmetry

To assess bone structure, examine body shape and symmetry. Major deformities in bone structure affect posture and gait. The client should be able to stand upright with the neck and head midline. There are four normal curvatures of the spine (see Procedure 22-15). The cervical and lumbar are concave, and the thoracic and sacral are convex. Commonly seen abnormalities include **kyphosis** (accentuated thoracic curve), **scoliosis** (lateral "S" deviation of the spine), and **lordosis** (accentuated lumbar curve).

Balance, Coordination, and Movement

Walking is a complex task involving balance, coordination, and movement. Pay attention to the *base of support* and *stride* as the client walks. A wide base of support or shortened stride may indicate a balance problem. If the client has an altered gait, try to identify the specific portion of the gait that is abnormal. Abnormal gait may be caused by muscle hypertonicity (e.g., from stroke or brain tumor), lumbar disc problems, muscle atrophy, nerve damage, Parkinson's disease, cerebral palsy, multiple sclerosis, or spinal tumors. If you need additional information on gait, see Chapter 32.

As you perform each assessment, pay attention to the client's stability and level of comfort. Do not attempt movements that may produce pain or cause the client to fall. For example, recall that Mr. Nguyen (Meet Your Patient) has bilateral knee pain. Before asking him to perform deep knee bends or hop in place, you would want to assess his pain and its triggers.

Joint Mobility and Muscle Function

Any joint deformity requires investigation. Color changes in a joint indicate inflammation or infection. If you see erythema or swelling, investigate further by feeling for warmth. Determine any effect the deformity has on function.

Joints should move freely and without pain or **crepitus** (clicking or grating at a joint). To assess function, test range of motion (ROM) and muscle strength. **Active ROM** requires the client to move the joint through its full ROM. **Passive ROM** is used when the client is unable to exercise each joint independently. Instead, you support the body and move each joint through its ROM. Assess **muscle strength** along with movement by asking the patient to perform ROM while you apply resistance to the part being moved. For more information about the musculoskeletal system, see Chapter 32.

ThinkLike a Nurse 22-8

As you recall, Mr. Nguyen (Meet Your Patient) is obese and has been having pain in both of his knees.

- What history questions would you ask him to assess his knee pain?
- What would you do to examine his knees?

THE NEUROLOGICAL SYSTEM

The neurological system controls or affects the function of all body systems and allows interaction with the external world. Its work is carried out through the transmission of chemical and electrical signals between the brain and the rest of the body. The basic functions of the nervous system are cognition, emotion, memory, sensation and perception, and regulation of homeostasis.

A comprehensive neurological assessment takes hours to complete and is usually reserved for clients with symptoms of neurological problems. As a staff nurse in general practice, you usually perform only portions of a neurological exam. In the next few sections, we look at the components of a focused neurological exam. For a summary, see the Highlights of Procedures box at the end of this chapter. For the complete procedure,

Go to Chapter 22, **Procedure 22-16: Assessing the Sensory-Neurological System,** in Volume 2.

Developmental Considerations

When interpreting a neurological exam, consider the following developmental changes and modifications:

Infants Reflexes present at birth include rooting, sucking, palmar grasp, tonic neck reflex (fencing), and Moro. These reflexes disappear during infancy. With neurological injury, as may occur with stroke or trauma, these reflexes may return, indicating severe neurological problems. To review these reflexes, refer to Chapter 9.

Young Children Because language skills and motor development are age-dependent, the Denver Developmental Screening Test (Denver II, 1990) is used as a neurological screen for young children. The Denver II examines motor, language, and coordination skills. It requires specialized training to administer and evaluate.

For toddlers and older children, you can usually perform a comprehensive neurological exam with age-appropriate modifications. For example, when testing for smell, use materials that a young child knows, such as bananas or apples.

Older Adults With advanced age, changes commonly observed are slower reaction time, a decreased ability for rapid problem-solving, and slower voluntary movement. The number of functioning neurons decreases. However, intelligence, memory, and discrimination do not change with normal aging. Neurological deficits in older adults are usually the result of adverse effects of medications or medication interactions, nutritional deficits, dehydration, cardiovascular changes that alter cerebral blood flow, diabetes, degenerative neurological conditions (e.g., Parkinson's disease or Alzheimer's disease), alcohol or drug use, depression, or abuse.

Cerebral Function

Cerebral function refers to the client's intellectual and behavioral functioning. It includes level of consciousness, orientation, mental status and cognitive function, and communication.

Level of Consciousness

Decreased level of consciousness is often the first sign of neurological deterioration. **Level of consciousness (LOC)** includes arousal and orientation. Arousal may range from alert to deeply comatose. Arousal is classified based on the type of stimuli (auditory, tactile, or painful) required to produce a response from the client. An alert client responds to *auditory stimuli* (e.g., verbal communication or noise).

Key Point: ***Remember, if your client does not speak your language he may not respond to questions or commands.***

If the client does not respond to auditory stimuli, try *tactile stimuli.* Begin with gentle touch to awaken the client and capture attention. Be aware that many clients who have hearing deficits lip-read to compensate. If you catch the client's attention by touching her hand, she may be able to respond to the combined auditory and visual stimuli. If still no response is obtained, use *painful stimuli* (e.g., squeezing the trapezius muscle). Clients who respond to painful stimuli withdraw when pressure is applied.

Document LOC by describing the client's response or by using the Glasgow Coma Scale (GCS) to grade eye, motor, and verbal responses. The GCS evaluates eye opening, motor responses, and verbal responses. Its limitations are that it relies heavily on vision and verbal interaction, and does not evaluate brainstem reflexes. A systematic review of evidence suggests that best practice should include use of the GCS plus other evaluation of brainstem reflexes, eye examination, vital signs, and respiratory assessment. A newer tool, the Full Outline of UnResponsiveness (FOUR), provides additional information beyond that of the GCS. Both scales are included in Volume 2 for you to use in clinical settings.

Go to Chapter 22, **Procedure 22-16: Assessing the Sensory–Neurological System, Glasgow Coma Scale, and Full Outline of UnResponsiveness Scale,** in Volume 2.

If you are not using the GCS, use the following terms to describe LOC.

- **Alert.** Follows commands in a timely fashion.
- **Lethargic.** Appears drowsy, easily drifts off to sleep.
- **Stuporous.** Requires vigorous stimulation before responding.
- **Comatose.** Does not respond to verbal or painful stimuli.

Although those terms are widely used, a thorough description is preferable. Look at the following two chart entries:

Example 1. Pt lethargic.
Example 2. Pt responds to repeated tactile and verbal stimulation. Quickly drifts off to sleep if stimulation is discontinued.

As you can see, the second charting entry provides significantly more information than the first.

Orientation

Orientation refers to the client's awareness of time, place, and person.

- **Time orientation** includes awareness of the year, date, and time of day. Older adults who become disoriented to time usually think it is an earlier date. If a client offers a bizarre time or futuristic date, consider psychiatric concerns as the cause of disorientation. Hospitalized patients are subjected to lights and noise around the clock; are roused in the middle of the night for medications or time-sensitive treatments; and are given anesthesia and pain medications that alter their sense of awareness, so they easily become disoriented to time.
- **Orientation to place** involves awareness of surroundings. The patient should know that he is, for example, in the hospital and not in church. Patients who have been moved (e.g., from the emergency department to a ward bed) may not recall their room number but are easily reoriented.
- **Orientation to person** involves recognition of familiar persons and self-identity. The client should be able to

state her name or identify people in photographs at the bedside. Because a client may meet many health professionals during a hospitalization, she may not be able to recall your name unless you have had repeated encounters with her.

Mental Status and Cognitive Function

Mental status and cognitive function include behavior, appearance, response to stimuli, speech, memory, communication, and judgment. By this point in the exam, you would have already interviewed the client and talked with him while performing the exam, so you would have a good deal of information about his mental status and cognitive function. You would have already assessed posture, gait, motor movements, dress, and hygiene through the general survey and the musculoskeletal exam; and you would be aware of the client's mood based on his tone of voice, actions, and statements.

Many clinicians choose to screen for mental status and cognitive function by asking questions of the client as they assess other body systems. This type of informal assessment helps relax the client. If you choose this method, observe for clarity of thought, appropriate content, concentration, memory, and ability to perform abstract reasoning. Normal findings include the ability to express and explain realistic thoughts with clear speech; speak with a smooth, natural pattern; follow multistep directions; listen; answer questions; and recall significant past events.

Cranial Nerve Function

Cranial nerve assessment is a key component of the neurological exam. The cranial nerves control a variety of sensory and motor functions (Table 22-5 and Fig. 22-18).

Reflex Function

Deep tendon reflexes (DTRs) are automatic responses that do not require conscious thought from the brain. A reflex produces a rapid, involuntary response that occurs at the level of the spinal cord (Fig. 22-19). Because the brain is not involved, muscle response is instantaneous. Intact sensory and motor systems are required for a normal reflex response. Each DTR corresponds to a certain level of the cord and is graded on a 0 to 4+ scale. To see the scale,

Procedure 22-16, Assessing the Sensory-Neurological System, in Volume 2.

You can elicit **superficial reflexes** by swiftly and lightly stroking a body part (e.g., with the reflex hammer). Superficial reflexes are graded as positive or negative.

Table 22-5 ➤ Cranial Nerves

CRANIAL NERVE NUMBER & NAME	TYPE OF NERVE	FUNCTION OF NERVE
I. Olfactory	Sensory	Smell
II. Optic	Sensory	Visual acuity, visual fields, and ocular fundi
III. Oculomotor	Motor	EOM, pupil constriction
IV. Trochlear	Motor	EOM
V. Trigeminal: 3 branches	Sensory and motor	Corneal reflex; scalp, teeth, and facial sensation; and jaw movement
VI. Abducens	Motor	EOM
VII. Facial	Motor and sensory	Facial movement, sense of taste
VIII. Auditory	Sensory	Hearing and equilibrium
IX. Glossopharyngeal	Motor and sensory	Swallowing, gag response, tongue movement, taste, secretion of saliva
X. Vagus	Motor and sensory	Sensation of pharynx and larynx; motor activity of swallowing and vocal cords; sensory in cardiac, respiratory, and blood pressure reflexes; peristalsis; digestive secretions
XI. Spinal accessory	Motor	Head movement and shoulder elevation; motor to larynx (speaking)
XII. Hypoglossal	Motor	Tongue movement

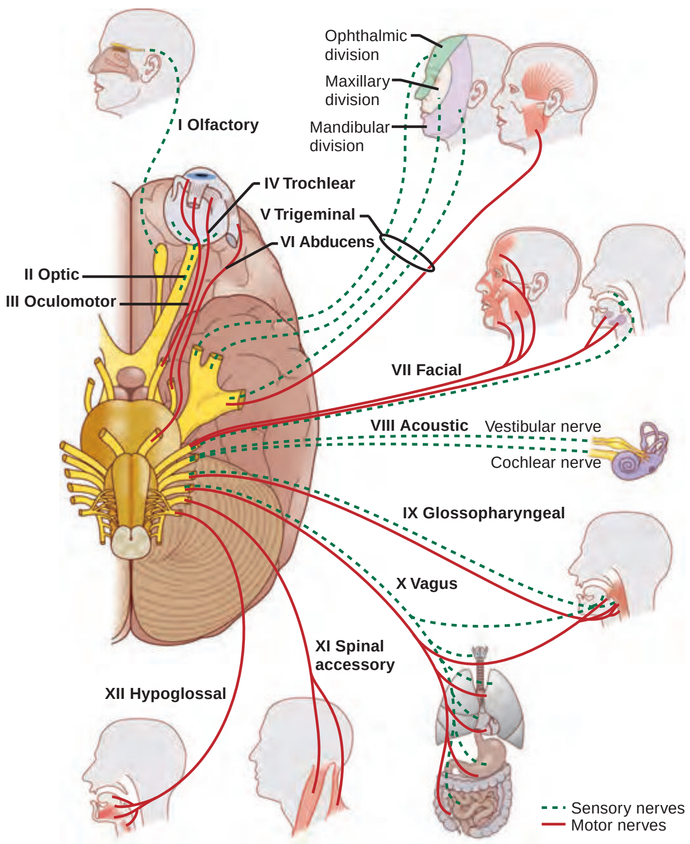

FIGURE 22-18 Origin of cranial nerves.

Sensory Function

To assess sensory function, ask the client to keep his eyes closed as you apply various stimuli. Ask him to indicate when he feels a sensation. Vary your location and approach so that you test sensation, not pattern recognition. If you notice an area of altered sensation, systematically assess the area to define the border of the change. Usually you will limit your testing to the upper and lower extremities and the trunk. If the client has known or suspected deficits, you should test at numerous other sites. For techniques for assessing reflexes and sensory function,

Go to Chapter 22, **Procedure 22-16: Assessing the Sensory-Neurological System,** in Volume 2.

Motor and Cerebellar Function

The neurological system coordinates the function of the skeleton and muscles. Motor pathways transmit information between the brain and muscles and the muscles control movement of the skeleton. The cerebellum helps coordinate muscle movement, regulate muscle tone, and maintain posture and equilibrium. The cerebellum is also largely responsible for **proprioception**, or body positioning. Disorders of motor and cerebellar function result in pain or problems with movement, gait, or posture. Thus, when you assess the musculoskeletal system, you also assess the motor functions of the neurological system.

KnowledgeCheck 22-11

- Identify and describe the components assessed in the neurological exam.
- What approach to assessment should you take if:
  Your client has no neurological problems but you are performing a comprehensive exam?
  Your client is hospitalized for a documented cerebrovascular accident?
  Your client has been admitted with an acute head injury and the extent of neurological injury is unknown?

THE GENITOURINARY SYSTEM

In most practice settings, nurses assess only the patient's external genitalia and inguinal lymph nodes. Nurse practitioners and physicians perform comprehensive examinations of the female and male reproductive and urinary systems, as do nurses working in specialty areas. However, even as a novice nurse you may assist with exams or just be present as a witness or to provide emotional support to the client.

The genitourinary system includes both the reproductive system and the urinary system (Figs. 22-20 and 22-21). Because assessment focuses on elimination and sexual and reproductive function, it might be embarrassing or uncomfortable for many people. A competent, professional approach is needed. Your confidence and ease with these topics will help the client to feel more relaxed.

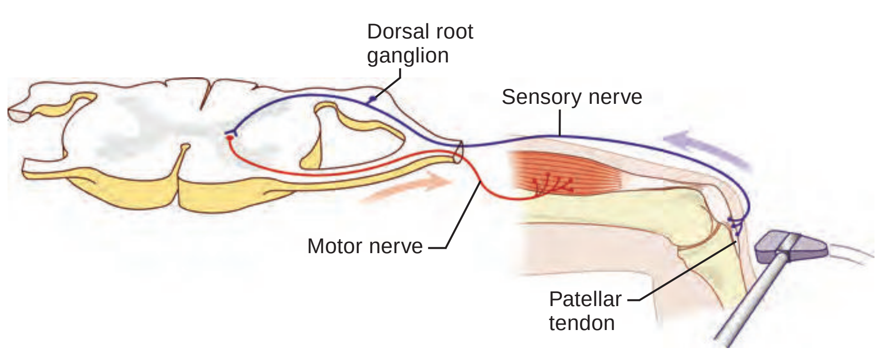

FIGURE 22-19 Reflex arc.

The Male Genitourinary System

A complete examination includes assessment of the external genitalia, evaluation for hernias, and a rectal exam for prostate screening. The penis and scrotum are examined by inspection and palpation. You will assess some of the urinary system organs when examining the back (kidneys, ureters) and the abdomen (bladder); the prostate gland is palpated during the exam of the rectum and anus (discussed later in this chapter). For steps to follow in examining the male genitourinary system, see the summary in the Highlights of Procedures box at the end of this chapter and

Go to Chapter 22, **Procedure 22-17: Assessing the Male Genitourinary System,** in Volume 2.

As a result of the scarcity of clear, scientific evidence, the American Academy of Pediatrics no longer recommends newborn male **circumcision** (excision of the foreskin of the penis) as a routine practice. However, circumcision is tied to some religious and cultural beliefs (e.g., among Jews and Muslims), so it is still common.

A **hernia** is a protrusion of the intestine (or other organ) through the wall that contains it. In men, this is most likely to be a protrusion of the intestine either through the abdominal wall (**direct hernia**) or into the inguinal canal and possibly into the scrotum (**indirect hernia**). A hernia may be a small protrusion or it may cause pain and distention as a loop of bowel extends into the scrotum. An **umbilical hernia** (fairly common in infants) is an outward bulging due to delayed closure around a small muscle around the umbilicus (belly button). For an illustration of an umbilical hernia,

Go to **Procedure 22-14: Assessing the Abdomen,** in Volume 2.

KnowledgeCheck 22-12

- What assessment techniques are used when examining the male genitourinary system?
- What is the most common hernia occurring in men?

The Female Genitourinary System

You may be called upon to assist with a comprehensive examination. For a procedure for inspecting external female genitalia and palpating inguinal lymph nodes, see the Highlights of Procedures box at the end of this chapter and,

Go to Chapter 22, **Procedure 22-18: Assessing the Female Genitourinary System,** in Volume 2.

External Examination

For adolescents and young women who are not sexually active, an external GU examination includes the inspection of the amount and distribution of pubic hair, the skin of the pubic area, and the external genitalia; and palpation of the inguinal lymph nodes.

Internal Examination

Women who are sexually active; who have abnormal findings on external examination; who have abdominal, pelvic, or genitourinary complaints; or who are on hormone therapy require an internal genital examination. The exam includes the following:

- Palpation of Bartholin's glands and Skene's ducts (Fig. 22-21).
- Assessment of vaginal muscle tone and pelvic musculature
- Speculum examination
- Bimanual examination, wherein the examiner palpates the cervix, uterus, and adnexal tissues using one or two fingers within the vagina and the other hand

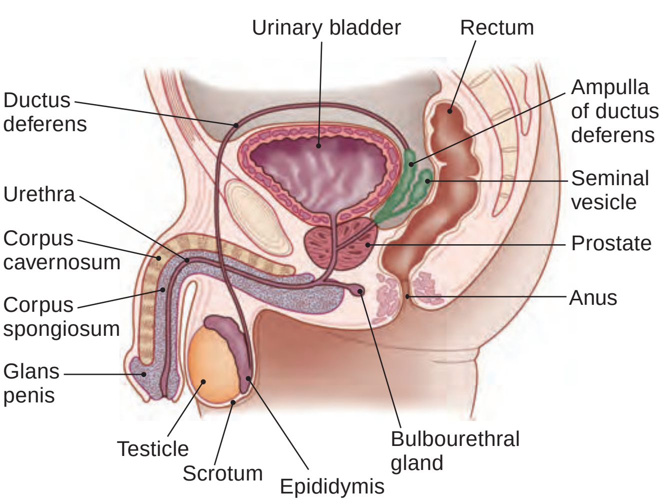

FIGURE 22-20 The male genitourinary system.

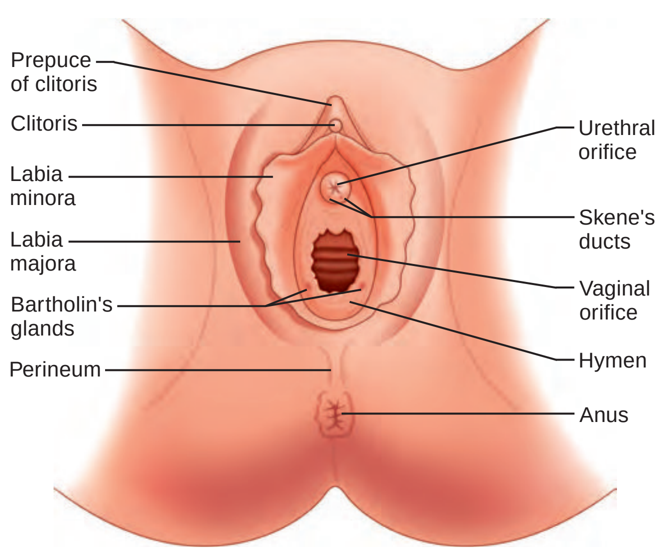

FIGURE 22-21 External female genitalia.

on the outside to help bring the inner structures toward the two hands.

Pap Smear Recent changes to major guidelines recommend, in general, less frequent routine Papanicolaou tests (Pap smears) to screen for cervical and uterine cancer. They recommend the following for women:

- Younger than age 21: Do not be screen, regardless of whether they are sexually active or have other risk-taking behaviors.
- Ages 21 through 29: Screen every 3 years.
- Ages 30 to 65: Screen every 3 to 5 years (and follow the advice of their provider).
- Older than age 65: Do not routinely screen unless they are at high risk. However, a recent study states that the cancer incidence rates used for guidelines do not account for high prevalence of hysterectomy in the United States. This has the largest impact on older, black women. Authors recommend that the risk and screening guidelines be reconsidered (Rositch, Nowak, and Gravitt, 2014)
- Those with certain vulnerabilities (e.g., weakened immune system, HIV-positive) should have a Pap test every year (Agency for Healthcare Research and Quality [AHRQ], 2005, last revised 2013; American Cancer Society, n.d.b, revised 2013)

Key Point: ***National screening guidelines vary, and they change frequently.***

Additional cultures or screens may be done if there is unusual discharge or risk of sexually transmitted infection. A **speculum examination** is performed to collect specimens and assess the cervix. To learn about assisting with a speculum exam, see Clinical Insight 22-3,

Clinical Insight 22-3, Assisting with a Speculum Exam, in Volume 2.

KnowledgeCheck 22-13

What are the responsibilities of the nurse during an internal exam of the female genitourinary system?

The Anus, Rectum, and Prostate

Examining the rectum and anus is the last aspect of a comprehensive examination. For the female client, this exam is usually performed at the end of a bimanual pelvic examination while the client is still in the lithotomy position. Usually a male client assumes the Sims' position, and you perform the exam after completing your examination of the genitals. For a summary of this procedure, see the Highlights of Procedures box at the end of this chapter. For a step-by-step procedure,

Go to **Procedure 22-19: Assessing the Anus and Rectum,** in Volume 2.

Inspect the anus and rectum for skin condition and hemorrhoids and palpate for muscle tone, masses, and tenderness. Skin irritation and erythema are common in clients who have diarrhea and infants and toddlers who wear diapers. **Hemorrhoids** (dilated, usually painful, anal vessels) may be seen in clients with a history of constipation. Many women develop hemorrhoids with pregnancy and childbirth.

A comprehensive examination for a man should include a digital rectal examination to assess for prostate enlargement. An enlarged prostate may indicate benign enlargement of the prostate, which is common in men older than age 50; or it may indicate prostatitis. A hard nodule or multiple nodules may indicate prostate cancer.

ThinkLike a Nurse 22-9

How will examination of the rectum and anus differ for Nam and Yen Nguyen (Meet Your Patient)?

DOCUMENTING PHYSICAL ASSESSMENT FINDINGS

Zach Jackson has completed his physical assessment of Nam Nguyen (Meet Your Patient). Below is his charting entry. Recall that Zach is an advanced practice nurse and has performed a comprehensive physical assessment. Therefore, this examination and charting entry are more extensive than what would be expected of a staff nurse. Keep in mind that you should use only abbreviations on your clinical agency's approved list.

General Survey 56-year-old obese man presents to the clinic for a physical exam in no apparent distress. Pt appears stated age; is well dressed and groomed; and alert and oriented to time, place, and person. Speech is clear, response and affect appropriate. Moves all extremities well, gait steady and balanced. Smells of cigarettes.

Height	5 ft 4 in.
Weight	185 lb (84 kg)
BP	166/100
Pulse	88 beats/min
RR	22 breaths/min
Temp	98.5°F (36.9°C), oral
BMI	33

Integumentary Skin even in color, warm & dry, good turgor, no suspicious lesions. Well healed scar in right inguinal area. Hair clean, coarse, evenly distributed. Some graying. Nails pink, brisk capillary refill, no clubbing.

Head & Neck Normocephalic, erect, midline. Scalp mobile, no lesions, tenderness, or masses. Facial features symmetrical. Thyroid gland symmetrical and not enlarged; cervical lymph nodes not palpable or tender.

Eyes Snellen = right eye 20/100, left eye 20/100, both eyes 20/100. Color vision intact. Difficulty noted with near vision. Visual fields normal by confrontation. Extraocular movements intact. PERRLA at 3 mm by direct and consensual. Eyes clear and bright, + blink, no lid lag or abnormalities. Anterior chamber clear. Cornea & iris intact. Sclera white, conjunctiva clear. Lacrimal glands and ducts nontender. + red reflex bilateral, discs flat with sharp margins, vessels intact, retina & macula even in color.

Ears, Nose, & Throat Skin intact, no masses, lesions, or discharge. Position WNL. External ears nontender to palpation. + whisper test. Weber—no lateralization. External canals clear without redness, swelling, lesions, or discharge. Tympanic membranes intact, light reflex and bony landmarks visible; frontal and maxillary sinuses nontender. Nares patent, able to distinguish familiar odors, mucosa pink, no discharge, septum intact with no deviation.

Mouth Lips, oral mucosa, gingivae pink with no lesions. All teeth present and in good repair. Pharynx pink, tonsils absent, palate intact. Symmetrical rise of the uvula, + gag and swallow reflex. Tongue smooth, pink, symmetrical, mobile, without lesions, taste intact (correctly identified sweet, salty, and sour).

Respiratory Respirations 22 breaths/min and unlabored. Trachea midline, AP < transverse chest diameter. Chest expansion symmetrical. No tenderness, scars, masses, or lesions. Diaphragmatic excursion 5 cm. Lungs clear to auscultation.

Cardiovascular PMI @ MCL at 5th ICS, P 85, regular, no murmurs, gallops, or thrills present; pulses +2, no bruits or thrills, no varicosities; jugular venous pulsation 2 cm at 45°. Carotids without bruits.

Breasts Symmetrical. No masses, lymphadenopathy, or discharge.

Abdomen Abdomen soft, rounded, no masses or pulsations. Surgical scar R inguinal area. + bowel sounds, + tympany throughout.

Musculoskeletal Normal spinal curvature. Joints and muscles symmetrical, no deformity. + Bilateral knee pain (right more than left). Full ROM in upper and lower extremities, + 5 muscle strength, moderate crepitus right knee.

Neurological Awake, alert, and oriented to time, place, and person. CN I–XII intact. Gait steady and coordinated; negative Romberg; unable to do deep knee bends due to pain. Point-point localization, superficial and deep sensation intact, + 2 deep tendon reflexes.

Genitourinary Circumcised male; penis nontender, no masses, urethral meatus midline, no discharge; testicles descended bilaterally, nontender, inguinal and femoral canals free of masses, prostate small, smooth, mobile, nontender. Rectal wall smooth, no masses, stool hemoccult negative.

Highlights of Procedures 22-1 through 22-20

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the skill. Use these procedure highlights later to help you review key steps.

Note: Throughout the assessment, compare findings on both sides of the body.

Procedure 22-1: Performing the General Survey

- Observe the patient's apparent age, sex, race, facial expression, body size and type, posture, movements, speech, grooming, dress, hygiene, mental state, and affect.
- Identify any signs of distress.
- Measure vital signs.
- Measure height and weight, and calculate body mass index (BMI).
- Consider the client's cultural/ethnic background, gender, and developmental stage.
- Review history data that may influence general survey findings, including usual state of health, current health problem, allergies, and unexplained changes in weight.
- Perform functional and SPICES assessments for older adults.
- Note verbal and nonverbal responses throughout exam.

Procedure 22-2: Assessing the Skin

- Techniques: Inspection, palpation, and olfaction
- Assess both exposed and unexposed areas.
- Inspect skin color; note any unusual odors.
- Inspect and palpate any lesions. Describe their size, shape, color, distribution, texture, surface relationship, and exudate.
- Evaluate the lesions for possible malignancy, remembering the mnemonic ABCDE.
- Use dorsal aspect of your hand to palpate skin temperature.
- Check skin turgor.
- Palpate skin for texture, moisture, and hydration.
- Review history that may influence skin findings.

Procedure 22-3: Assessing the Hair

- Techniques: Inspection and palpation
- Assess scalp hair and body hair.
- Inspect hair for color, quantity, distribution, condition of scalp, and presence of lesions or pediculosis.
- Palpate the texture of the hair.
- Palpate the scalp for mobility and tenderness.

Procedure 22-4: Assessing the Nails

- Techniques: Inspection and palpation

- Inspect the nails for color, condition, and shape.
- Palpate the texture of the nails.
- Assess capillary refill.
- Assess factors that may alter nail assessment findings (e.g., a cold environment may slow capillary refill).
- Examine nails on both hands and feet.
- You may defer examination of the toenails until you assess peripheral circulation.

Procedure 22-5: Assessing the Head and Face

- Techniques: Inspection, palpation
- Inspect the head for size, shape, symmetry, and position.
- Compare side to side throughout the exam.
- Inspect the face for expression and symmetry.
- Palpate the head for masses, tenderness, and scalp mobility.
- Palpate the face for symmetry, tenderness, muscle tone, and TMJ function.

Procedure 22-6: Assessing the Eyes

- Techniques: Inspection and palpation
- Assess distance vision using a Snellen chart.
- Test near vision by measuring the client's ability to read newsprint at a distance of 14 inches (35.5 cm).
- Test color vision by using color plates or the color bars on the Snellen chart.
- Assess peripheral vision by determining when an object comes into sight.
- Assess EOMs by examining the corneal light reflex, observing the six cardinal gaze positions, and performing the cover/uncover test.
- Inspect the external eye structures.
- Test the corneal reflex with a cotton wisp, if appropriate.
- Check pupil reaction for direct and consensual response.
- Assess accommodation by having the patient focus on an approaching object.
- Palpate the external eye structures.

Procedure 22-7: Assessing the Ears and Hearing

- Techniques: Inspection and palpation
- Inspect the external ear for placement, size, shape, symmetry, and the condition of the skin.
- Palpate the external structures of the ear for skin condition and tenderness.
- Inspect the tympanic membrane and bony landmarks.
- Assess gross hearing with the whisper and watch-tick tests.
- Perform the Weber test to assess hearing loss.
- Perform the Rinne test to identify whether hearing loss is conductive or sensorineural.

Procedure 22-8: Assessing the Nose and the Sinuses

- Techniques: Inspection and palpation
- Insert the speculum about 1 cm, and then open it as much as possible.
- Inspect the external and internal structures of the nose.
- Transilluminate and palpate the sinuses.
- Palpate the external structures of the nose.

Procedure 22-9: Assessing the Mouth and Oropharynx

- Techniques: Inspection and palpation
- Inspect the lips, oral mucosa, gums, teeth, and bite.
- Inspect the hard/soft palate, tonsils, and uvula.
- Inspect the tongue and frenulum; inspect under the tongue.
- Palpate the lips and tongue for tenderness and muscle tone.
- Test the gag reflex by touching the back of the soft palate with a tongue blade.

Procedure 22-10: Assessing the Neck

- Techniques: Inspection and palpation (auscultation as needed)
- Inspect the neck. Note symmetry, ROM, and the skin condition.
- Palpate the cervical lymph nodes. Note the size, shape, symmetry, consistency, mobility, tenderness, and temperature of any palpable nodes.
- Palpate the thyroid. If it is enlarged or if there is a mass, auscultate.

Procedure 22-11: Assessing the Breasts and Axillae

- Techniques: Inspection and palpation
- Inspect the breasts and axillae for skin condition, size, shape, symmetry, and color.
- Inspect the nipples for discharge. Culture any discharge, if present.

If you notice an open lesion or nipple discharge, wear procedure gloves to palpate the breasts.

- Palpate the breasts using the vertical strip method, pie wedge method, or concentric circles method.
- Palpate the nipples, areolae, and lymph nodes.

Procedure 22-12: Assessing the Chest and Lungs

- Techniques: Inspection, palpation, percussion, auscultation
- Assess respirations by counting the rate and observing the rhythm, depth, and symmetry of chest movement.
- Inspect the chest for anteroposterior to lateral ratio, costal angle, spinal deformity, respiratory effort, and skin condition.
- Palpate the trachea.
- Palpate the chest for tenderness, masses, or crepitus; chest excursion, and tactile fremitus.
- Percuss the chest; percuss diaphragmatic excursion.
- Auscultate breath sounds.

(Continued)

Procedure 22-13: Assessing the Heart and Vascular System

- Techniques: Inspection, palpation, auscultation
- If possible, work from your patient's right side.
- Inspect the neck for pulsations.
- Measure jugular venous pressure (JVP).
- Inspect the precordium for pulsations.
- Palpate the carotid arteries.
- Palpate the precordium for pulsations, lifts, heaves, or thrills.
- Auscultate the carotid arteries with the bell of the stethoscope.
- Auscultate the jugular veins with the bell of the stethoscope.
- Auscultate the precordium at the apex, left lower sternal border, base left, and base right. Use the bell and then the diaphragm of the stethoscope.
- Palpate the peripheral pulses. Any abnormalities require further evaluation.

Procedure 22-14: Assessing the Abdomen

- Techniques: Inspection, auscultation, percussion, palpation (in that order)
- Have the client void before the exam.
- Position the client supine with the knees slightly flexed.
- Inspect the abdomen.
- Auscultate the abdomen for bowel sounds and bruits.
- Use indirect percussion to assess at multiple sites in all four quadrants.
- Using your fist or blunt percussion, percuss the costovertebral angle bilaterally to assess for kidney tenderness.
- Lightly palpate throughout the abdomen by pressing down 1 to 2 cm in a rotating motion. Identify surface characteristics, tenderness, muscle resistance, and turgor.
- Use deep palpation to palpate organs and masses.

Procedure 22-15: Assessing the Musculoskeletal System

- Techniques: Inspection and palpation
- Compare bilaterally during the assessment.
- Assess posture, body alignment, and symmetry.
- Assess the spinal curvature.
- Examine the gait by assessing the base of support, stride, and phases of the gait.
- Assess balance through tandem walking, heel-and-toe walking, deep knee bends, hopping, and the Romberg test.
- Assess coordination by testing finger–thumb opposition, rhythmic movements of lower and upper extremities, and rapid alternating movements.
- Test the accuracy of movements by having the client touch his finger to his nose with his eyes closed.
- Measure limb length and circumference.
- nspect muscle symmetry.
- Perform range of motion of all joints.
- Assess muscle strength by having the client perform ROM against resistance.

Procedure 22-16: Assessing the Sensory-Neurological System

- Assess behavior.
- Determine level of arousal.
- Determine level of orientation.
- Assess memory.
- Assess mathematical and calculation skills.
- Assess general knowledge.
- Evaluate thought processes.
- Assess abstract thinking.
- Assess judgment.
- Assess communication ability.
- Test cranial nerves.
- Test superficial sensations; begin with most peripheral part of the limb.
- Test deep sensations: vibratory and kinesthetic.
- Test discriminatory sensations: stereognosis, graphesthesia, two-point discrimination, point localization, and sensory extinction.
- Test deep tendon reflexes: biceps, triceps, brachioradialis, patellar, and Achilles.
- Test superficial reflexes.
- Assess for dementia in institutionalized older adults.

Procedure 22-17: Assessing the Male Genitourinary System

- Techniques: Inspection and palpation
- Inspect the external genitalia, including color, discharge, and the pattern of hair distribution.
- Palpate for lumps, masses, hernias, or enlarged lymph nodes.

Procedure 22-18: Assessing the Female Genitourinary System

- Techniques: Inspection and palpation
- Inspect the external genitalia, including hair distribution; skin, mucosa; urethral meatus; and vaginal introitus, color, discharge, and lesions.
- Palpate Bartholin's and Skene's glands.
- Assess vaginal and pelvic muscle tone.
- Palpate lymph nodes and possible hernia sites.

Procedure 22-19: Assessing the Anus and Rectum

- Inspect the external anal area, sphincter tone, and stool for occult blood.

Highlights of Procedures 22-1 through 22-20

- Palpate the anus and rectum for muscle tone and masses.
- For women, assessment of the anus and rectum is usually performed at the end of the internal pelvic exam; for men, it is done after the genitourinary exam.

Proedure 22-20: Brief Bedside Assessment

- Modify the procedure to fit the patient's health status.
- Observe the environment and the patient's general appearance.
- Measure vital signs, pain status, and pulse oximetry.
- Use a systematic (e.g., head-to-toe) approach.
- Assess the integument (hair, nails, and skin).
- Assess the head and neck (ears, eyes, lips, tongue and oropharynx, carotids)
- Assess the back with patient sitting (including breath sounds).
- Assess the anterior chest (heart and lungs).
- Assess the abdomen with patient supine.
- Assess urinary status.
- Assess upper extremities, including edema and capillary refill.
- Assess lower extremities, including edema and capillary refill.
- Assess for spinal deformities with patient standing.
- Assess balance, coordination, ROM, and gait.
- Check Babinski and Homan's reflexes.

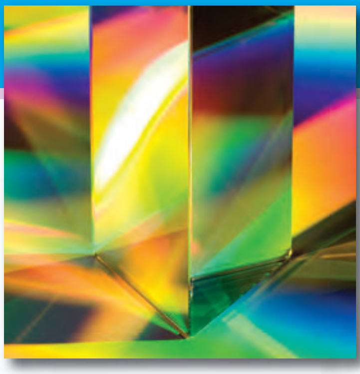
CHAPTER 23



Promoting Asepsis & Preventing Infection

Learning Outcomes

After completing this chapter, you should be able to:

- Discuss the six links in the chain of infection.
- Describe the stages of a typical infectious process.
- Describe four processes involved in primary, secondary, and tertiary defenses.
- Identify activities that promote immune function.
- Discuss the factors that place an individual at increased risk for infection.
- Explain why it is important to be aware of emerging infectious diseases.
- Explain why multidrug-resistant pathogens are of special concern in healthcare.
- Use standard precautions to prevent transmission of infection through blood and body fluids.
- Describe additional precautions that must be taken when there is concern about contact, droplet, or airborne disease transmission.
- Compare and contrast methods of preventing infection by breaking the chain of infection.
- Implement measures to prevent healthcare-related infections.
- Use medical asepsis when providing care to clients.
- Discuss infection prevention and control measures in the home and community.
- Implement sterile technique in selected patient care activities.
- Discuss the nurse's role in recognizing, preventing, and helping to contain the spread of a biological epidemic.

Key Concepts

Infection
Medical asepsis
Surgical asepsis
Body defenses
Infection prevention and control

Drug-Resistant Pathogens

Meet Your Nursing Role Model

Stephanie Sergi is the 7-year-old daughter of Jason Sergi. Jason works as a nurse on a busy labor and delivery unit in a major medical center. One night at the dinner table, Stephanie asks, "Daddy, what was the most important thing you did at work today?" Jason takes a few minutes to consider his reply. Finally Jason answers, "I washed my hands—a lot."

Jason tells his daughter that he also assisted in the births of five infants, resuscitated one of the infants who was initially struggling for breath, and identified several problems that prevented complications or even death of mothers in labor. "Daddy, I don't understand why you think washing your hands was so important," Stephanie protested. "Look at all the *really* important things you did today!"

As you read this chapter, think back to Jason's discussion with his daughter. Perhaps you will someday say the same thing to your child or anyone who asks about your day.

ABOUT THE KEY CONCEPTS

A grasp of the broad concept of **infection** will enable you to promote biological safety for your clients, using **infection prevention and control** activities. Those activities include **medical and surgical asepsis** and interventions to support patients' body defenses.

Theoretical Knowledge knowing **why**

Research continues to lead to the discovery of new infectious microorganisms. Researchers are currently investigating the role of viruses in the development of cancer and other diseases. For example, virally induced cancers include Hodgkin's disease, Kaposi's sarcoma, and cervical cancer. Other research is investigating the role that certain species of bacteria play in burn treatment and healing (Peral, Huaman Martinez, & Valdez, 2009).

WHY MUST NURSES KNOW ABOUT INFECTION PROCESSES?

The goals of infection prevention and control discussed in this section are to:

- Protect patients from healthcare-related infections. Healthcare-associated infections will affect 1 out of every 20 hospitalized patients (Centers for Disease Control and Prevention [CDC], n.d.a).
- Meet professional standards and guidelines.
- Protect yourself from diseases. You must know how to avoid contact with infectious material and exposure to diseases such as AIDS, hepatitis B and C, and drug-resistant tuberculosis, as well as the many common illness-producing microorganisms you will encounter.
- Help lower the cost of healthcare. Healthcare-associated infections are responsible for between $28 and $33 billion dollars annually (Agency for Healthcare Research and Quality [AHRQ], 2012a).

In this chapter, you will learn how infections occur and about measures to prevent them. We will discuss healthcare-associated infections and related professional standards and guidelines.

Healthcare-Associated Infections

The term **healthcare-associated infections (HAIs)** refers to infections associated with healthcare given in any setting (e.g., hospitals, home care, long-term care, and ambulatory settings). The term **nosocomial infections** refers more specifically to hospital-acquired infections. Healthcare-associated infections aggravate existing illness and lengthen hospital stay and recovery time. HAIs are the leading complication of hospital care and one of the 10 leading causes of death in the United States (AHRQ, 2011; Klevens, Morrison, & Nadle, 2007; Siegel, Rhinehart, Jackson, et al., 2007) and are preventable (Cardo, Dennehy, Halverson, et al., 2010). Approximately 1 out of every 20 hospitalized patients will contract an HAI (CDC, n.d.a). You may be surprised at these facts. After all, healthcare workers are supposed to cure, not harm, people. But when people come to hospitals (and other facilities) for care, they come into contact with many personnel and patients. Ill patients are vulnerable to infection, and they are a source of infection for others. In addition, they undergo invasive procedures (e.g., injections), which can introduce infectious organisms into their body.

Professional Standards and Guidelines

Because HAIs lead to patient suffering and increased healthcare costs, many states have enacted laws requiring healthcare organizations to make information about HAIs available to the public. Various government, professional, and accrediting organizations have created quality-control guidelines for healthcare agencies and professionals. The following are important examples:

The Centers for Disease Control and Prevention (CDC), a federal agency, has an extensive Web site devoted to infection control and prevention in healthcare settings. To access this site and retrieve Infection Control Guidelines,

Go to http://www.cdc.gov/hai/

Among the U. S. Department of Health and Human Services (2011) goals for the healthcare setting are to:

- Reduce catheter-associated adverse infections by 50%.
- Reduce targeted antimicrobial-resistant bacterial infections by 50%.
- Reduce surgical site infections by 25% over the course of five years.
- Reduce catheter-associated urinary tract infections by 25%.

The Agency for Healthcare Research and Quality (AHRQ) has a Web site featuring links to information, tools, and resources on HAIs. The site contains resources for healthcare providers and consumers, and highlights AHRQ-funded research and initiatives to reduce HAIs. To access this site,

Go to http://www.ahrq.gov/qual/hais.htm

The Joint Commission is a quality oversight agency. Their standards of performance include extensive criteria describing what healthcare organizations must do to minimize the risks of infection. In addition, Goal 7 of their National Patient Safety Goals for 2012 is to "reduce the risk of health care associated infections" (The Joint Commission, 2012). The Infection Control Initiatives present strategies for healthcare providers to prevent infection in inpatient and community-based settings. To read these initiatives,

Go to http://www.jointcommission.org/assets/1/6/2011_NPSGs_HAP.pdf

Quality and Safety Education for Nurses (QSEN) is a group of educators that was formed to address the challenge of preparing nurses with the competencies necessary to improve the quality and safety of their places of work—competencies that you should have on completing your nursing education. Safety is one of the six competencies you should have on completing your nursing education. Although QSEN does not specifically say that safety includes being safe from infection, they make several broad statements regarding knowledge, skills, and attitudes about safety that do apply to infection. For example, you should be able to:

- Demonstrate knowledge of basic scientific methods and processes (e.g., infectious process, inflammatory process).
- Minimize risk of harm to patients and providers (e.g., infectious diseases) through both system effectiveness and individual performance.
- Demonstrate effective use of technology and standardized practice (e.g., CDC guidelines for infection control) that support safety and quality (Cronenwett, Sherwood, Barnsteiner, J., et al., 2007).

To access the QSEN Web site,

Go to http://www.qsen.org

American Nurses Association (ANA) Using the same broad understanding as for the QSEN competencies, you should assume that the following criteria from Standard 5 of *Nursing: Scope & Standards of Practice* (2010) apply to infection prevention and control:

- Partners with the person/family/significant others/caregiver to implement the plan in a safe and timely manner.
- Implements the plan in a timely manner in accordance with the patient safety goals.

HOW DOES INFECTION OCCUR?

Imagine that your clinical instructor alerts you to an outbreak of infectious disease in the hospital where you have your assignment. The hospital census is currently more than 200 patients. So far, 14 have become infected, and one has died. Have you ever wondered how infections are spread and why they seem to affect some people more than others?

Infections Develop in Response to a Chain of Factors

The process by which infections spread is commonly referred to as the **chain of infection**. It is made up of six links, all of which must be present for the infection to be transmitted from one individual to another (Fig. 23-1). Here we describe each of the six links. Later in the chapter we discuss how to interrupt the chain to limit the spread of infection. For information about common disease-producing microorganisms and their transmission,

Go to Chapter Resources, **ESG Table 23-1, Common Pathogens,** on Davis*Plus*.

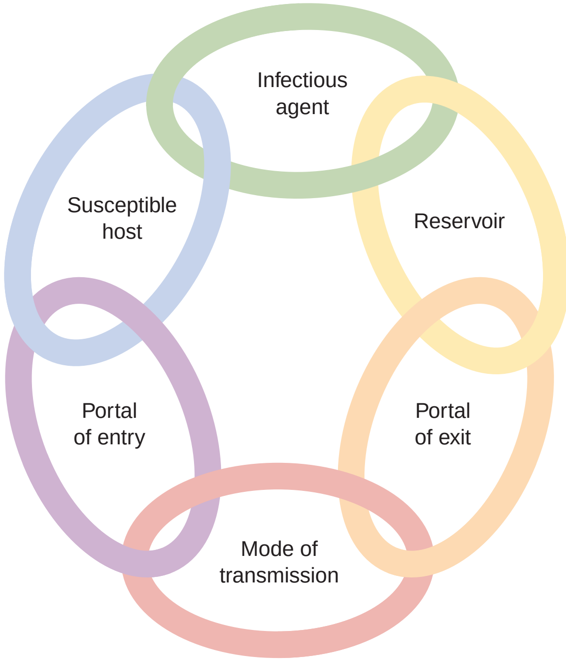

FIGURE 23-1 All of the six links in the chain of infection must be present for infection to be transmitted from one person to another.

Infectious Agent

Some microorganisms live on or in the human body without causing harm. For instance, the *Staphylococcus* bacteria growing on human skin are usually harmless. Other microorganisms are beneficial or even essential for human health and well-being. They are referred to as **normal flora.** Normal flora in the intestine aid in digestion and synthesize vitamin K, and release vitamin B_{12}, thiamine, and riboflavin when they die. In addition, they limit the growth of harmful bacteria by competing with them for available nutrients.

Flora There are two types of normal flora: transient and resident. **Transient flora** are normal microbes that a person picks up by coming in contact with objects or another person (e.g., when you touch a soiled dressing). You can remove these with handwashing. **Resident flora** live deep in skin layers, where they live and multiply harmlessly. They are permanent inhabitants of the skin, and cannot usually be removed with routine handwashing. They are not usually harmful unless they enter the deep tissues (e.g., as through an open wound) or unless the patient is especially vulnerable to disease.

Pathogens These microorganisms are capable of causing disease. The largest groups of pathogenic microorganisms are bacteria, viruses, and fungi (which include yeasts and molds). Less common pathogens are protozoa, helminths (commonly called worms), and *prions*, which are infectious protein particles that cause certain neurological diseases. In addition, normal flora may become pathogenic if disease or injury permits them to enter body regions they do not normally inhabit. For instance, rupture of the bowel through trauma or disease allows intestinal microbes to enter the abdominal cavity or bloodstream, where they cause infection.

Once a pathogen gains entry into a host, four factors determine whether the person develops infection:

- **Virulence** of the organism (its power to cause disease)
- Ability of the organism to survive in the host environment
- Number of organisms (the greater the number, the more likely they are to cause disease)
- Ability of the host's defenses to prevent infection

Reservoir

A **reservoir** is a source of infection: a place where pathogens survive and multiply. The human body is the most common reservoir for pathogens. Animals, insects, and humans are other living reservoirs. Nonliving reservoirs include soil, water, food, and environmental surfaces. Examples include contaminated water, stagnant ponds, garbage, soiled diapers, wound dressings, and raw sewage. In healthcare facilities, many surfaces act as reservoirs. Microorganisms have mass, and they eventually fall to the floor or onto bedside tables, chairs, or equipment. Other surfaces, such as sinks, toilets, bed rails, and bed linens, may also become reservoirs because of their proximity to patients, family members, and healthcare providers harboring pathogens, such as *Legionella* spp. In this manner, some hands-free faucets are reported to have higher levels of disease-carrying bacteria (e.g., *Legionella* spp.) than conventional, manually operated faucets (American Society for Healthcare Engineering [ASHE] and the Association for Professionals in Infection Control & Epidemiology [APIC], 2011), although there are controversial reports of design flaws with some hands-free faucets in the flow of water, resulting in contamination with hazardous bacteria (Johns Hopkins Medicine, 2011).

Some people are capable of defending themselves from active disease but harbor the pathogenic organisms within their bodies. These individuals, called **carriers**, have no symptoms of disease, yet they serve as reservoirs and can pass the disease to others.

Most pathogens prefer a warm, moist, dark environment. To live and thrive in humans, microbes must be able to use the body's precise balance of food, moisture, nutrients, electrolytes, pH, temperature, and light. Food, water, and soil that provide these conditions may serve as nonliving reservoirs, as well.

Nutrients Bacteria can rapidly multiply in food left at room temperature. For example, the species *Salmonella enteritidis*, which causes salmonellosis ("food poisoning"), can multiply in raw and undercooked meat and eggs. To prevent the growth of pathogens, many foods are cooked at high temperatures and stored in a cool environment. Alternatively, many foods are prepared with a concentration of solutes that inhibits the growth of pathogenic microbes. This concept underlies the salting of meats and the production of fruit jellies, jams, and preserves.

Moisture Pathogens require moisture for survival, for example, the moist environment of wounds, the genitourinary tract, the throat, and airways. However, the spores formed by some bacteria allow them to live without water (e.g., the *Bacillus* and *Clostridium* species, both of which cause foodborne disease).

Temperature For most pathogens, the ideal temperature for existence is 95°F (35°C). Environments that are either too hot or too cold for a particular species will slow its growth or even kill the entire population. In part, the microbes that are pathogenic to humans are so because they thrive at about the same temperature as the human body. Thus, a fever in response to infection can inhibit and even kill invading pathogens.

Oxygen Many bacteria and most protozoa and fungi are **aerobic**. That is, they must have oxygen to live and grow. For example, the yeast *Candida albicans* causes infections in the oral mucosa ("thrush") and the vaginal mucosa. **Anaerobic organisms** do not require oxygen for growth and may even be killed in its presence. One example is *Clostridium tetani*, a spore-forming bacterium, which causes tetanus when a spore enters the body through an open wound.

pH and Electrolytes To live in humans, pathogens need the body's precise balance of moisture, sugars, pH (acidity), and electrolytes. Most prefer a pH range of 5 to 8. Therefore, they cannot survive in the highly acidic environment of the stomach. When patients take antacids, stomach pH increases and removes this defense. The organisms multiply and can then cause infection in other systems, such as the lungs. Microbes that have a higher or lower pH and electrolyte concentration than the human body are not pathogenic to human beings. That's why, for example, the bacteria that thrive in the Great Salt Lake would not cause infection on your skin.

Light Microbes grow best in dark environments (e.g., inside the body, deep in wounds, and under dressings). Ultraviolet light is sometimes used to remove pathogens such as *Staphylococcus*, *Salmonella*, and viruses from surgical instruments and other objects. It is also used to disinfect drinking water in developing countries to prevent diseases such as cholera and typhoid fever.

KnowledgeCheck 23-1

- What is a pathogen?
- What is the role of normal flora?
- Identify at least five reservoirs of infection.

Portal of Exit

A contained reservoir is only a potential source of infection. For infection to spread, a pathogen must exit the reservoir. In the case of human or animal reservoirs, the most frequent **portal of exit** is through body fluids, including blood, mucus, saliva, breast milk, urine, feces, vomitus, semen, or other secretions. The body's natural response to foreign materials, including pathogens, is to

PICOT

Situation: The handoff report has been concluded in an ICU. The Unit Manager alerted the staff that there has been an increase in enterococci-related urinary tract infections (UTIs) on the unit, and the infection control team will be following several of the unit's clients. The primary nurse is preparing to bathe a client in the intensive care unit (ICU), and notices that the basin is wet from the previous bath. Knowing that bacteria need a damp environment to grow, she wonders whether the bath basin might be a reservoir for enterococci. What question might the nurse ask to guide her in a search for evidence?

PICOT Components

P	Population/client	=	Intensive care unit patients
I	Intervention/indicator	=	Basin bath
C	Comparator/control	=	Absence of hospital associated urinary tract infection
O	Outcome	=	Enterococci urinary tract infection
T	Time	=	During ICU stay

Searchable Question: How do __________(P) who receive/are exposed to __________(I) develop __________ (O) as compared to __________(C) during __________(T)?

Example of Evidence: Hospital-associated infections (HAIs) are linked to a high number of client deaths every year. It is important to identify possible reservoirs for pathogen colonization, and minimize the client risk of infection. Johnson, Lineweaver, and Maze (2009) cultured 92 bath basins at three acute care hospitals, including three ICUs. Of the samples cultured, 98% grew some form of bacteria. The most common organisms identified were enterococci, *Staphylococcus aureus*, vancomycin-resistant enterococci, methicillin-resistant *S. aureus*, *Pseudomonas aeruginosa*, *Candida albicans*, and *Escherichia coli*. Although this sample is small, it clearly indicates that bath basins are a reservoir for bacteria, and nurses need to be aware that the basin is a potential source of HAI, especially in the at-risk client.

Practice Change: As a result of her findings in the literature, the nurse resolved to dry bath basins well after using them and to talk to colleagues about doing the same. She also suggested to the Unit Manager that the unit should look into the feasibility of using disposable bath basins.

Source: Johnson, D., Lineweaver, L., Maze, L. M., (2009). Patients' bath basins as potential sources of infection: A multicenter sampling study. *American Journal of Critical Care, 18*(1), 31–38, 41. doi:10.4037/ajcc2009968

try to expel them. If you have a pathogen in the respiratory system, you cough and sneeze. If it is in the gastrointestinal system, you vomit or experience intestinal cramping and diarrhea. Microbes responsible for sexually transmitted infections can exit via semen, vaginal secretions, or blood that is present during sex.

Cuts, bites, and abrasions also provide an exit for body fluid. Blood and pus seeping from a wound help transport pathogens away from the broken skin but become a portal by which infection may be transmitted to others. In healthcare-related infections, puncture sites, drainage tubes, feeding tubes, and intravenous lines commonly serve as routes for pathogens to exit the body.

Mode of Transmission

Contact, either direct or indirect, is the most frequent **mode of transmission** of infection. **Direct contact** between two people usually involves touching, kissing, or sexual intercourse. Animals commonly transmit infection via scratching and biting as well. **Indirect contact** involves contact with a **fomite**, a contaminated object that transfers a pathogen. For example, suppose that while you are charting you begin to sneeze or cough. If you cover your nose and mouth with your hand and then resume charting, you may transmit pathogens to the pen, paper, and chart (or keyboard). Shoes, eyeglasses, stethoscopes, and other items we wear also commonly serve as fomites, as do contaminated needles. Some microbes can live only a few seconds on fomites; others can live for years. It depends on the type of microorganism and the environment.

Droplet Transmission Infection is passed when the pathogen travels in water droplets expelled as an infected person exhales, coughs, sneezes, or talks. It may also occur during suctioning and oral care. The usual method of transmission is for the droplet to be inhaled or enter the eye of a susceptible person. Although droplets can travel only a few feet from the infectious person, within that distance they may readily contaminate fomites that then transmit the organism by contact.

Airborne Transmission Microorganisms that float considerable distances on air currents can pass infection to vulnerable hosts. Airborne pathogens can travel through heating and air-conditioning systems to infect large numbers of people. Sweeping a floor or shaking out contaminated bed linens can stir up airborne microorganisms and launch them on air currents—imagine a flying magic carpet (of pathogens). The agents of measles and tuberculosis, as well as many fungal infections, are commonly transmitted in this manner.

Vector This is an organism that carries a pathogen to a susceptible host, typically by biting or stinging, creating another portal of entry into the body. The mosquito is a common vector for diseases, including malaria, yellow fever, and the West Nile virus. Ticks, fleas, mites, and other insects also carry various diseases.

Portal of Entry

Pathogens can enter the body through various **portals of entry**. Normal body openings, such as the conjunctiva of the eye, the nares (nostrils), mouth, urethra, vagina, and anus are potential portals of entry, as are abnormal openings, such as cuts, scrapes, and surgical incisions. Vectors, such as mosquitoes, create portals of entry when they bite through the skin. In healthcare settings, common portals of entry include wounds, surgical sites, and insertion sites for tubes or needles.

Susceptible Host

A **susceptible** (or *compromised*) **host** is a person who is at risk for infection because of inadequate defenses against the invading pathogen. Various factors can increase susceptibility to infection, among them: age (the very young or very old), compromised immune system (as in those receiving immune suppression for organ transplantation or treatment of cancer or chronic illness), and immune deficiency conditions (e.g., HIV, leukemia).

ThinkLike a Nurse 23-1

You are working as a nurse on a medical-surgical unit. What roles might you play in the chain of infection?

Infections Can Be Classified in Various Ways

Infections are classified according to their location in the body, whether it is the patient's first infection, where it was acquired, and how long it lasts.

Local or Systemic Some infections cause harm in a limited region of the body, such as the upper respiratory tract, the urethra, or a single bone or joint. Such infections are said to be **local**. In contrast, **systemic** infections occur when pathogens invade the blood or lymph and spread throughout the body. **Bacteremia** is the clinical presence of bacteria in the blood, whereas **septicemia** is symptomatic systemic infection spread via the blood.

Primary or Secondary A **primary infection** is the first infection that occurs in a patient. Especially in immunocompromised patients, one or more **secondary infections** may follow a primary infection. For example, a frail client infected with pneumonia may develop herpes zoster (shingles, a viral infection related to past infection with varicella) related to the stress of illness.

Exogenous or Endogenous Healthcare providers need to determine the source of pathogens in a patient infected while he is in the facility. In **exogenous healthcare-related infections**, the pathogen is acquired from the healthcare environment. In **endogenous healthcare-related infections**, the pathogen arises from the patient's normal flora, when some form of treatment (e.g., chemotherapy or antibiotics) causes the normally harmless microbe to multiply and cause infection. For example, a yeast infection may develop in a client receiving antibiotics after surgery.

Acute or Chronic Infections that have a rapid onset but last only a short time, such as the common cold, are said to be **acute**. In contrast, **chronic infections** (e.g., an abscess) develop slowly and last for weeks, months, or even years. Some chronic infections, such as relapsing fever, recur after periods of remission. **Latent infections** cause no symptoms for long periods of time, even decades. Tuberculosis and human immunodeficiency virus (HIV) are examples. HIV typically causes an initial, brief illness that is then followed by about 10 years of latency before the patient begins to experience symptoms of AIDS.

Infections Follow Predictable Stages

Many infections follow a fairly predictable course of events, although the precise duration and intensity of symptoms in each stage vary from one individual to another:

- **Incubation** is the stage between successful invasion of the pathogen into the body and the first appearance of symptoms. In this stage, the person does not suspect that he has been infected but may be capable of infecting others. This stage may last only a day, as with the influenza virus, or as long as several months or even years, as with tuberculosis.
- The **prodromal stage** is characterized by the first appearance of vague symptoms. For example, a person infected with a cold virus may experience a mild throat irritation. Not all infections have a prodromal stage.
- **Illness** is the stage marked by the appearance of the signs and symptoms characteristic of the disease. If the patient's immune defenses and medical treatments (if any) are ineffective, this stage can end in the death of the patient.
- **Decline** is the stage during which the patient's immune defenses, along with any medical therapies, successfully reduce the number of pathogenic microbes. As a result, the signs and symptoms of the infection begin to fade.
- **Convalescence** is characterized by tissue repair and a return to health as the remaining number of microorganisms approaches zero. Convalescence may require only a day or two or, for severe infections, as long as a year or more.

Why Should Nurses Be Aware of Emerging Pathogens and Diseases?

An **epidemic** is an outbreak of a disease that suddenly affects a large group of people in a geographic region (e.g., a city or state) or in a defined population group (e.g., children, healthcare workers). A **pandemic** is an exceptionally widespread epidemic—that is, one that affects a large number of people in an entire country or worldwide. Examples of pandemics are H1N1 influenza ("swine flu") and malaria.

You should also know the term *emerging infectious disease*. Although there are various definitions, you can think of **emerging infectious diseases** as:

- Newly identified diseases caused by an unrecognized microorganism (e.g., the virus causing AIDS was unknown before 1980) or a known organism (e.g., enterovirus D68, *Streptococcus* infection causing toxic shock syndrome)
- Diseases occurring in new geographic areas (e.g., 2014 ebola pandemic originating from western Africa, West Nile virus in the Western hemisphere) or settings, such as *Clostridium difficile*, which was primarily a hospital-acquired infection and now occurs in the community
- Microorganisms in animals that extend their host range to begin infecting humans (e.g., avian influenza, or "bird flu"; and the H1N1 virus).
- Microbes that evolve to become more virulent (e.g., a strain of *Escherichia coli*, which now causes severe illness)
- Known diseases that dramatically increase in incidence (e.g., mumps and pertussis, also known as whooping cough)
- Organisms that are deliberately altered for bioterrorism (e.g., the contamination of some mail in the United States with *Bacillus anthracis* [anthrax] in 2001).
- Most emerging pathogens are viruses. For a brief discussion of some important emerging infections,

Go to **Supplemental Materials: Emerging Infectious Diseases,** and **Reading More About Promoting Asepsis & Preventing Infection,** on Davis*Plus*.

Continental and intercontinental travel contributes to the spread of emerging pathogens throughout the world. Air travel enables a person to infect people headed for widespread locations, often before the reservoir person shows symptoms of the disease. Cooperative efforts among many disciplines and organizations worldwide are required to limit the spread of infectious diseases. To this end, the World Health Organization (WHO) has chosen as the first "global patient safety challenge" the reduction of HAIs. More than 15,000 healthcare facilities in 169 countries have registered for the WHO's "Save Lives: Clean Your Hands" program (World Health Organization, 2011, 2012). Also, The Joint Commission (2012b) requires hospitals to have an emergency management plan for responding to large numbers of infectious patients who might need to be treated as a result of an epidemic.

Example Problem: Drug-Resistant Pathogens

Some microorganisms, mostly bacteria, have mutated to develop resistance to one or more classes of antimicrobial drugs. These organisms are said to be **drug-resistant or multidrug-resistant**. Today antibiotic resistance is one of the most significant challenges in treating patients with severe infectious diseases. During the last several decades, the prevalence of multidrug-resistant organisms (MDROs) in U.S. hospitals and medical centers has increased steadily. MDROs are a serious problem because options for treating MDRO infections are limited. Furthermore, they are associated with serious illness, increased mortality, and increased hospital lengths of stay and costs.

A variety of risk factors are associated with MDRO infections (CDC, n.d.b, n.d.f; Siegel, Rhinehart, Jackson, et al., 2006). Among them are the following:

- Severe illness
- Previous exposure to antimicrobial agents (e.g., antibiotics)
- Underlying diseases or conditions that make it difficult for the person to fight infection (in particular, chronic renal disease, insulin-dependent diabetes mellitus, peripheral vascular disease, dermatitis, skin lesions)
- Invasive procedures and devices, such as dialysis, urinary catheterization, and intravenous lines
- Repeated contact with the healthcare system, especially acute care facilities, and especially intensive care units (where infection rates tend to be highest)
- Advanced age

MDROs are transmitted by the same routes as other microorganisms. A major factor, though, is transmission in healthcare settings via the hands of healthcare workers, especially for methicillin-resistant *Staphylococcus aureus* (MRSA), *C. difficile*, and vancomycin-resistant enterococci (VRE), discussed following. Other significant MDROs include multidrug-resistant tuberculosis (MDR-TB), penicillin-resistant *Streptococcus pneumoniae*, multidrug-resistant *E. coli*, and *Klebsiella pneumoniae.* If you need more information about diseases caused by those organisms, consult a medical-surgical textbook or,

Go to **Supplemental Materials: What Are Drug-Resistant Pathogens?,** on Davis*Plus*.

Methicillin-Resistant Staphylococcus aureus (MRSA)

Staphylococcus aureus lives on the skin and in the nose, usually without causing problems. If a person does have a "staph" infection it is normally treated with methicillin, but methicillin-resistant *S. aureus* (MRSA) can't be killed by this drug. More than a million hospitalized patients acquire MRSA infection each year in the United States (APIC, 2010); it can be fatal. The organism is spread by skin-to-skin contact, and by living in crowded conditions. Control of MRSA has become a national priority.

Because MRSA can survive on hands, clothing, environmental surfaces, and equipment, it is easily spread to vulnerable patients in healthcare settings. Healthcare institutions are targeting MRSA with staff education, aggressive handwashing and use of alcohol-based handrubs for 20 to 30 seconds for hand hygiene before touching a patient, increased use of protective gloves and gowns, and targeted screening (Klevens, Morrison, Nadle, et al., 2007; Upshaw-Owens & Bailey, 2012).

Vancomycin-Resistant Enterococci

Enterococci, normal residents in the intestines and the female genital tract, also occur in the environment. Most VRE infections occur in hospitals. Their spread is attributed to failure to follow infection control measures (Rice, 2001). VRE are a leading cause of healthcare-acquired bacteremia (bacteria in the blood), surgical wound infection, and urinary tract infection. Risk factors include previous long-term antibiotic treatment, weakened immune system, surgical procedures, long-term devices (e.g., urinary catheters), or colonization by VRE (CDC, 2011).

Clostridium difficile

About 3% of healthy adults carry a harmless version of *C. diff*. However, it can become harmful when antibiotics destroy healthy bacteria that normally protect against the disease. The newer *C. diff.* strain is resistant to nearly all antibiotics and virulent enough to cause sepsis, lasting intestinal damage, the need for colon removal, and even death. It thrives in hospital environments, so the federal government is pressuring physicians and hospitals to better enforce sanitation standards and to prevent the overprescription of antibiotics. However, because spores survive for days on surfaces such as doorknobs and toilet seats, at least 10% of *C. diff.* infections are acquired outside the hospital (CDC, 2012). Prevention of transmission in a healthcare facility focuses on the following:

Application of contact precautions for patients with diarrhea
Accurate identification of patients
Rigorous cleaning of patient rooms and equipment
Consistent hand hygiene, using soap and water rather than alcohol-based handrubs for mechanical removal of spores

A bleach-containing disinfectant for environmental disinfection

Handwashing with soap and water. Alcohol-based handrubs are not effective because they do not destroy *C. diff.* spores.

ThinkLike a Nurse 23-2

Why are emerging infections of special concern in healthcare?
Why are MDROs of special concern in healthcare?

WHAT ARE THE BODY'S DEFENSES AGAINST INFECTION?

The human body has three "lines of defense" against infectious disease:

- Primary defenses—Certain anatomical features limit the entry of pathogens.
- Secondary defenses—Protective biochemical processes fight pathogens that do enter.
- Tertiary defenses—The presence of pathogens activates immune responses against specific, recognized invaders.

The primary and secondary lines of defense are nonspecific; that is, they have no means of adapting their response to each specific invader. Instead, they act in precisely the same way against any and all intruders, from a simple cold virus to deadly fungal spores.

Primary Defenses

The "soldiers" in the first line of defense are the structural barriers of the human body. These **primary defenses** prevent organisms from entering the body. The normal flora of the body provide one such defense. Any treatment that disturbs the balance between the normal flora and other microorganisms can increase the client's risk of developing disease. For example, when broad-spectrum antibiotics are used to treat infection, they may eliminate normal flora in addition to those causing the infection. This allows other kinds of pathogens to multiply, producing a **superinfection**. Other primary defenses are as follows:

- *Skin.* The surface of intact, healthy skin is tough and resilient and prevents entry of many pathogens. The normal flora of the skin inhibit multiplication of other organisms, including pathogens, that land on the skin.
- *The respiratory tree.* The nares, trachea, and bronchi are covered with mucous membranes that trap pathogens, which are then expelled. The nose contains hairs that filter the upper airway; and the nasal passages, sinuses, trachea, and larger bronchi are lined with cilia, tiny hairlike cells that sweep microorganisms upward from the lower airways. Coughing and sneezing forcefully expel organisms from the respiratory tract.
- *Eyes*. The lacrimal glands produce tears that contain lysozyme, an antimicrobial enzyme. This means that tears help the body to wash infective organisms from the eyes.
- *The mouth*. The mouth normally has a large number of pathogenic microorganisms, but saliva, like tears, contains lysozyme and helps continually wash microbes from the teeth and gums. The rich blood supply of the mouth swiftly transports defensive blood cells (discussed later in this section) that keep the microorganisms in check. In addition, normal flora of the mouth compete for nutrition with invading organisms, thereby limiting the number of pathogens.
- *The gastrointestinal tract*. Many pathogens that reach the stomach are destroyed in its acidic environment. Those that successfully enter the small intestine face the antimicrobial action of bile. Simple peristalsis as well as diarrhea and vomiting are other first-line defense mechanisms for pathogens that invade the gastrointestinal tract. In addition, normal flora in the intestine secrete antibacterial substances.
- *The genitourinary tract*. Like the respiratory tree, the genitourinary tract is protected with mucous membranes. The epithelial cells lining the urethra and anus secrete mucus, which adheres to pathogens to promote their excretion through urine and stool. Urine itself is highly acidic and contains lysozyme. Mucous membranes lining the vagina also help keep pathogens from establishing colonies there. In addition, the high acidity and normal flora of the vagina keep pathogens in check.

Secondary Defenses

Pathogens that dodge the primary defenses and gain entry into the body begin to release wastes and secretions and to cause the breakdown of cells and tissues. The presence of such chemicals activates a set of **secondary defenses**.

- **Phagocytosis**—the process by which phagocytes (specialized white blood cells [WBCs]) engulf and destroy pathogens directly is called phagocytosis. Phagocytic WBCs include neutrophils, monocytes, and eosinophils. Table 23-1 summarizes the types of white blood cells and their roles in defending against infection.
- **The complement cascade**—a process by which a set of blood proteins, called complement, triggers the release of chemicals that attack the cell membranes of pathogens, causing them to rupture. Complement also signals basophils (WBCs) to release histamine, which prompts inflammation.
- **Inflammation**—a process that begins when histamine and other chemicals are released either from damaged cells, or from basophils being activated by complement. With inflammation blood vessels dilate and become more permeable, which increases the flow of phagocytes, antimicrobial chemicals, oxygen, and nutrients to the affected area. The classic signs and symptoms of inflammation are localized warmth and erythema (redness), which develop as blood flow is increased. In addition, fluid leaking from the more permeable blood vessels accumulates in the surrounding tissue, causing edema, which in turn prompts pain as pressure is exerted on nerve endings (Bauman, Machunis-Masuoka, & Tizard, 2006).
- **Fever**—a rise in core body temperature that increases metabolism, inhibits multiplication of pathogens, and triggers specific immune responses (discussed

Table 23-1 ➤ Types and Functions of White Blood Cells

TYPE	FUNCTION
Granular	
Basophils: 0.5%–1% of total WBCs	Release histamine and heparin granules as part of the inflammatory response. Percentage normal during infections.
Eosinophils: 1%–3% of total WBCs	Destroy helminths; mediate allergic reactions; have limited role in phagocytosis. Percentage increases in parasitic infections.
Neutrophils: 55%–70% of total WBCs	Phagocytize pathogens
Agranular	
Lymphocytes: 20%–35% of total WBCs	T cells—responsible for cell-mediated immunity; recognize, attack, and destroy antigens. B cells—responsible for humoral immunity; produce immunoglobulins to attack and destroy antigens. Percentage of total lymphocytes increases in viral infection and chronic bacterial infection; decreases in sepsis.
Monocytes: 3%–8% of total WBCs	Able to phagocytize directly as well as to differentiate into macrophages, which help clean up damaged or injured tissue. Percentage increases in tuberculosis, protozoal, and rickettsial infections.

Note: Laboratory values alone are not adequate for diagnosing infection. Presence of clinical signs (e.g., fever, pain, swelling) must be assessed.

shortly). Believing that low-grade fevers are a necessary natural defense mechanism, many clinicians do not treat a fever unless it's greater than 102°F (38.9°C).

Tertiary Defenses

Immunity against an infection is achieved through the presence of antibodies that neutralize or destroy toxins or disease-producing organisms. **Active immunity** occurs when the body makes its own antibodies or T cells to protect the body against a pathogen. Immunity can also be achieved when a person is given antibodies to a pathogen rather than producing them through her own immune system, called **passive immunity** (Box 23-1).

Why is it that people who recover from an infectious disease like measles or chickenpox never get the disease again, even if they are repeatedly exposed to the virus? The reason is **specific immunity**: the process by which the body's immune cells "learn" to recognize and destroy pathogens they have encountered before.

The cells involved in specific immunity are white blood cells called **lymphocytes**, which are produced from stem cells in the red bone marrow. Lymphocytes that grow to maturity in the bone marrow are designated *B lymphocytes*, or *B cells*, whereas those that mature in the thymus are designated *T lymphocytes*, or *T cells.*

Key Point: ***Remember that* T *cells mature in the Thymus; and* B *cells mature in Bone marrow.***

After they have matured, most B cells and T cells travel to the lymph nodes, spleen, and other sites of lymphatic tissue. From all of these locations, lymphocytes seek out foreign cells and other matter to target for destruction. Lymphocytes recognize foreign substances by the molecules present on their surfaces. These molecules that trigger a specific immune response are called **antigens**. The two types of specific immunity involving B cells and T cells are discussed next.

Humoral Immunity

The humoral immune response (or antibody-mediated response) protects the body by circulating antibodies to fight against pathogens. The body's defense system acts by producing specialized white blood cells (leukocytes) to seek out and destroy invaders by any of the following methods (Fig. 23-2; Box 23-2):

- *Phagocytosis.* Antibodies do not phagocytize directly, but instead signal leukocytes (macrophages and neutrophils) to attack the pathogens to which the antibodies are bound.
- *Neutralization*. By binding to a pathogen's attachment sites, antibodies disable the pathogens by adhering to the invading body cells. Thus, although they are not destroyed, the pathogens become ineffective.
- *Agglutination*. Antibodies have two attachment sites; therefore, each antibody can attach to two pathogenic cells in a population. This quality causes the cells to clump together (agglutinate), reducing the cells' activity and increasing the likelihood that the group will be detected by leukocytes and phagocytized.

BOX 23-1 ■ Four Types of Immunity

Natural active immunity—After a person becomes ill with an infection, the body produces its own antibodies to fight the disease-causing organism and protect from infection in the future (e.g., influenza).

Natural passive immunity—Immunity results when natural antibodies are passed from one body to another, such as from mother to baby through the placenta, or through breast-feeding.

Artificial active immunity—An immune response occurs when the body is exposed to weakened or dead pathogens in a vaccine. The body then makes T cells or antibodies to keep from actually developing the illness (e.g., tetanus, measles). This type of immunity offers long-lasting or even lifetime protection.

Artificial passive immunity—Protection from infection is achieved when a person receives serum from another person or animal that has already produced antibodies against the pathogen (e.g., serum for treatment of rabies or botulism).

- *Activation of complement and inflammation*. Antibodies trigger the complement cascade and stimulate the release of inflammatory chemicals to destroy the antigen.

Cellular Immunity

Cellular (cell-mediated) immune response acts directly to destroy pathogens (i.e., viruses, fungi, protozoans, cancers) without using antibodies but rather activating **phagocytes** and T and B cells. Four types of T cells play a role in fighting infection (Fig. 23-3):

- *Cytotoxic (killer) T cells* directly attack and kill body cells infected with pathogens.
- *Helper T cells* play a supportive role in cell-mediated responses by secreting **interleukin**, which attracts infection-fighting white blood cells.

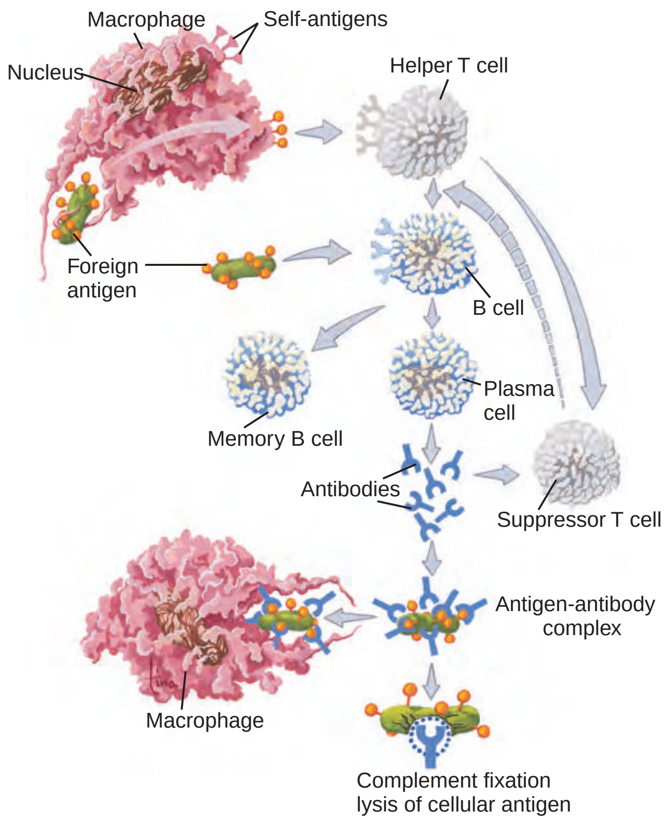

FIGURE 23-2 The humoral immune response produces antibodies to destroy antigens.

BOX 23-2 ■ Immunoglobulin (Ig) Classes

- **IgM** is the first antibody to appear when an antigen (e.g., pathogen) is encountered. It is also involved in agglutination with incompatible blood types.
- **IgG** is the most common immunoglobin in the body. It takes at least 10 days for IgG to be produced in response to an initial infection. IgG is the only immunoglobulin that can cross the placenta to provide temporary immunity to the fetus/infant.
- **IgE** is the immunoglobulin primarily responsible for the allergic response.
- **IgA** is found in mucous membranes in the intestines, respiratory and urinary tracts, saliva, tears, and breast milk. IgA provides additional immune protection by secreting around the body openings.
- **IgD** forms on the surface of B cells and traps the potential pathogen to prevent it from replicating and causing disease.

For a more extended explanation of immunoglobulins,

Go to Chapter 22, **Supplemental Materials, Humoral Immunity,** on Davis*Plus*.

- *Memory T cells*. The first time an antigen invades the body, T cells form that respond to that specific antigen. With subsequent infections, the memory T cells are able to increase the speed and amount of the T-cell response.

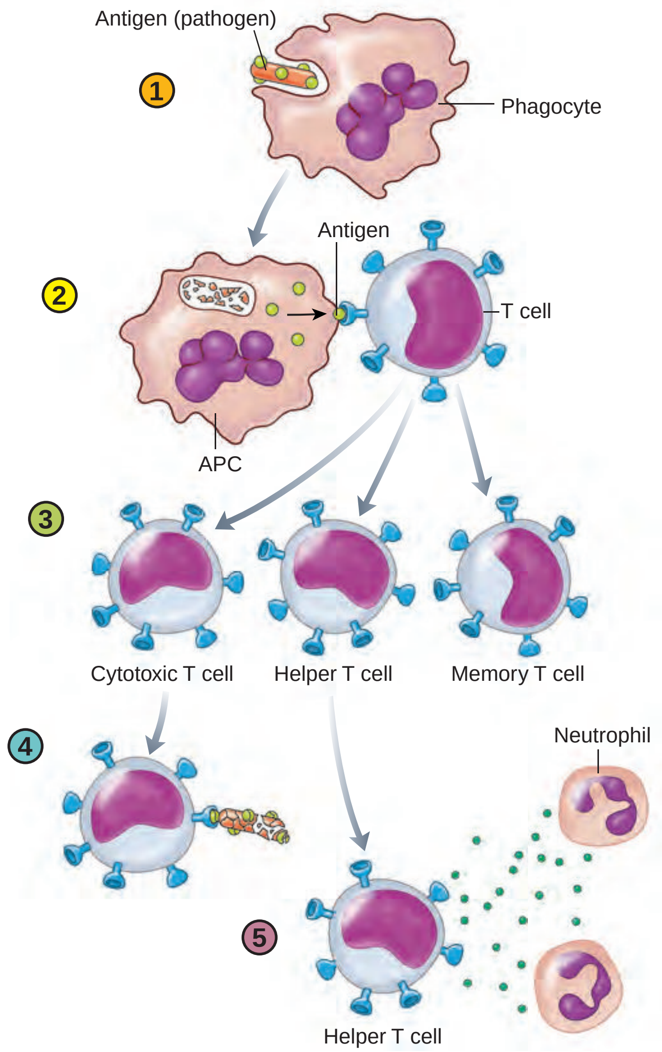

FIGURE 23-3 The cell-mediated immune response causes white blood cells to attack antigens.

- *Suppressor T cells* are thought to stop the immune response when the infection has been contained (also see Fig. 23-2).

KnowledgeCheck 23-3

- Identify and describe the purpose of the body's three major lines of defense against infection.
- If a patient's lab work reveals that IgM, but not IgG, is present in the blood, what could you conclude about this infection?

WHAT FACTORS INCREASE HOST SUSCEPTIBILITY?

Anything that weakens the defenses makes a person more susceptible to infection. In addition, any factors that increase the person's exposure to pathogens, such as working at a day-care center or being a nurse, increase the risk for infection. Some of the most common factors are discussed below.

Developmental Stage Young children are vulnerable because their immune systems are immature and have had limited exposure to pathogens. Children frequently begin to have more infections when they start interacting with people outside their family (e.g., when they begin day care or start school). With exposure, the body's natural defense systems turn on to protect from infection. This is a natural process known as acquiring **active immunity**.

Older adults are also susceptible hosts because the immune response declines with aging. Skin, a primary defense, becomes less elastic and more prone to breakdown with aging. Elders also tend to be less active, and their nutrition may be inadequate.

Breaks in the First Line of Defense A break in the skin, whether caused by a surgical procedure, skin breakdown, an insect bite, or insertion of an intravenous device, creates a portal of entry for infectious microorganisms.

Illness or Injury Recuperation from infection or injury limits the physical resources available to combat a new pathogen.

Tobacco Use Smoking is a major risk factor for pulmonary infections. Smoking interferes with normal respiratory functioning, including the ability to move the chest, cough, sneeze, or have full air exchange. Chemicals in tobacco paralyze cilia; thus, secretions pool in the lower airways, creating a favorable environment for bacterial growth. Although tobacco users are most profoundly affected by these changes, people exposed chronically to secondhand smoke (e.g., bartenders, children of smokers) are also affected by these changes and are at increased risk for infection.

Substance Abuse Alcohol curbs hunger because it contains many calories. As a result, many chronic alcohol users do not consume an adequate diet. Alcohol is also toxic to the liver and to the cells lining the intestinal mucosa. Inhaled substances, such as marijuana and cocaine, affect respiratory cilia in a manner similar to tobacco. Any substances that affect orientation and energy level will diminish food intake, activity, rest, and hygiene—factors that support host defenses. Injecting substances leads to breaks in skin integrity, further increasing the risk of infection.

Multiple Sexual Partners The number of sexual partners is directly related to the risk of sexually transmitted infections and cervical cancer.

Environmental Factors Increased exposure to pathogens in one's work situation (e.g., kindergarten teacher, healthcare worker), living situation (e.g., nursing home, parents with young children who are in preschool), and other environmental factors increase one's risk for infection.

Chronic Disease Many chronic diseases diminish the body's ability to fight infection. Diseases that impair peripheral circulation, such as uncontrolled hypertension (high blood pressure) and diabetes mellitus, make the patient prone to infection in the extremities. Poor circulation prevents antibodies and T cells from reaching the pathogens and damages tissue, making it easier for pathogens to enter. Leukemia, a form of cancer of the blood, increases the production of abnormal white blood cells, but these cells are ineffective in combating infection. Because HIV infects T cells, a patient with AIDS has a reduced ability to fight off secondary infections.

Medications Some medications are given for the purpose of reducing the immune response, for example, to patients receiving organ or tissue transplants. For most patients, however, decreased immunity is an unwanted side effect of treatment. Even common medications, such as nonsteroidal anti-inflammatory agents (NSAIDs) (e.g., ibuprofen), decrease the immune response. As a side effect, some medications, such as chemotherapeutic agents, decrease the production of white blood cells or cause the cells produced to be abnormal. Even antibiotics can increase the risk for infection. For example, an antibiotic given for a respiratory infection may cause a vaginal yeast infection because it destroys colonies of normal vaginal flora, allowing the harmful microbes to thrive. Such **superinfections** (opportunistic growth of harmful transient pathogens that are normally kept in check) can be extremely challenging to treat.

Invasive Nursing and Medical Procedures Several procedures are associated with an increased risk of infection. For example, urinary catheterization may injure the fragile urethral mucosa, provide a direct pathway for pathogens into the bladder, and prevent the normal flushing of the urethra. Also, an IV line inserted to infuse an antibiotic may serve as a portal of entry for pathogens to enter a patient's body.

KnowledgeCheck 23-4

What factors increase a client's risk for infection?

ThinkLike a Nurse 23-3

Consider your current lifestyle. How would you evaluate your ability to support your body's defenses?

ThinkLike a Nurse 23-4

Recall the scenario of Jason Sergi, the labor and delivery nurse, and his daughter (Meet Your Nursing Role Model). Why did Jason say that handwashing was the most important thing he did at work that day? Explain your answer by referring to all of the links in the chain of infection.

Practical Knowledge knowing how

As a nurse you will have direct contact with patients who are infected with a variety of pathogens or who are at increased risk for infection. The remainder of this chapter provides practical information for preventing infection in your clients and for caring for clients with infection.

ASSESSMENT

Some elements of the nursing history and physical assessment focus specifically on the risk factors and symptoms of infection.

Nursing History

To elicit information related to infection, ask the client about the following:

- Any exposure to pathogens in the environment, including at work, recent or international travel, contact with people who are ill, and unprotected sexual behavior
- If the patient is febrile ask, "Have you recently traveled outside the country?"
- Any unusual foods or products ingested
- Past and present disease or injury history
- Medications, over-the-counter preparations, herbal products, alcohol intake, and any substances currently in use
- Current level of stress
- Immunization history
- Symptoms of illness

Physical Assessment

Observe the patient's general appearance: Does he seem fatigued? Is he diaphoretic? Is he wrapped in blankets or complaining of feeling chilled? Does the patient appear well nourished? Are the mucous membranes dry? Does the skin have normal elasticity (turgor)? Physical assessment includes a thorough examination of the skin. Look for signs of local infection evidenced by pain, redness, swelling, and warmth. Note the presence or absence of any rashes, along with any breaks or reddened areas of the skin. Patients with poor peripheral circulation often have various skin discolorations, rather than signs of inflammation, when experiencing an infection. Swollen lymph nodes indicate the possible presence of an infection in the area that drains into the nodes. Elevated temperature and pulse rate are classic signs of an infection.

It is important to remember that the presence of one infection does not eliminate the risk for an additional infection. For example, a patient being treated with IV medications for a wound infection is at risk for infection at the IV site, as well as for a superinfection or an infection related to insufficient immunizations. For a list of tests commonly used to evaluate evidence of or risk for infection,

Go to Chapter 23, **Diagnostic Testing, Common Tests for Evaluating the Presence of or Risk for Infection,** in Volume 2.

Each specific test should be evaluated based on the patient's condition, age, and coexisting conditions.

ANALYSIS/NURSING DIAGNOSIS

The following two NANDA-I diagnoses directly pertain to infection:

Readiness for Enhanced Immunization Status This is a wellness diagnosis, used to describe a person who is already following the local, national, and/or international standards of immunization, but who wants to enhance behavior to prevent infectious disease, and learn more about providers of immunizations, possible problems associated with immunizations, knowledge of standards, and record keeping.

Risk for Infection Virtually any patient in a healthcare setting is at Risk for Infection due to exposure to pathogens in the environment. Use this diagnosis only for patients who are at higher than usual risk (e.g., those with poor nutritional status) and who need nursing interventions to help prevent infection. Do not use it for the generic assessments you do routinely for all patients (e.g., assessing temperature, routine examination of surgical incision). Patients with actual infection are managed collaboratively with the healthcare team. Examples of appropriate use of this diagnosis include the following:

- Risk for Infection r/t altered immune response secondary to corticosteroid therapy
- Risk for Infection r/t impaired skin integrity and poor nutritional status

Infection may be a medical diagnosis or the etiology of other nursing diagnoses, such as Fatigue, Risk for Imbalanced Body Temperature, or Pain. Patients with infection may experience other health problems due to their infected status. For example:

- Social Isolation r/t communicable disease (e.g., tuberculosis [TB])
- Deficient Diversional Activity r/t inability to leave room secondary to protective isolation

Other diagnostic statements may apply, depending upon the patient's condition, treatment ordered, and the patient's response to illness. For a care plan and care map for Risk for Infection,

Go to Chapter 23, **Care Plan** and **Care Map,** on Davis*Plus*.

PLANNING OUTCOMES/EVALUATION

For NOC standardized outcomes for Risk for Infection,

Go to Chapter 23, **Standardized Language,** on Davis*Plus*.

Individualized goals/outcomes statements depend on the specific nursing diagnosis and etiology. For example, for an undernourished woman, if the nursing diagnosis is Risk for Infection r/t intravenous puncture site and probable invasive procedures secondary to active labor, an appropriate goal would be:

> *Patient will show no signs of localized infection at the infusion site, as evidenced by the absence of swelling, redness, excessive warmth, pain, or drainage.*

You will evaluate the nursing care plan by examining the extent to which such goals have been met.

PLANNING INTERVENTIONS/IMPLEMENTATION

When caring for a patient at risk for infection, nursing activities are aimed at breaking the chain of infection at every possible link. Some of the most common reasons patients are diagnosed with Risk for Infection are exposure to pathogens, compromise to their normal defense mechanisms, increased physiological stress, or inadequate immune response. Direct nursing care toward these concerns, and provide the following broad interventions:

- Reduce exposure to pathogens through the use of aseptic technique (discussed shortly).
- Maintain skin integrity and support natural defenses against infection.
- Reduce stress.
- Promote immune function through collaborative care.
- Provide supportive measures to decrease the length of time that invasive devices, such as intravenous lines and urinary catheters, are needed by a patient.

For NIC standardized interventions for Risk for Infection:

Go to Chapter 23, **Standardized Language,** on Davis*Plus*.

Specific nursing activities will be based on the unique situation of the client, as described in the etiology of the diagnostic statement. For example:

- For clients who have had surgery and general anesthesia or who are at risk for pneumonia, promote coughing and deep breathing on a regular basis.
- For clients being mechanically ventilated, provide special oral care designed to prevent ventilator-associated pneumonia. (See the accompanying QSEN box for an example.)
- For older adults, especially those who or frail or in a debilitated state and those living in a group residence, encourage immunizations that can help them to acquire immunity from some communicable diseases, such as influenza.
- Healthcare workers can also benefit from immunizations to protect them from HAIs.
- Community health nurses can limit disease transmission through surveillance of the community, tracking of disease patterns, and initiation of prompt treatment.
- For clients who have breaks in the skin or incision sites, provide regular assessment for infection status and follow appropriate medical or surgical asepsis guidelines.
- For all clients at risk for infection, provide care that is based on principles of medical asepsis.

Other preventive nursing activities are discussed in the following sections. They include providing client teaching, supporting host defenses, and practicing medical and surgical asepsis.

Providing Client Teaching

Clients and caregivers in their own homes are usually at less risk for infection than they are in the hospital. The client and caregiver share the same potential pathogens and antibodies, and there is limited exposure to others with illness. Nevertheless, to protect their own health and the health of others, clients need to understand basic principles of medical asepsis, personal hygiene, and infection control. You should also teach them to recognize signs and symptoms of infection; and for those who have an infection, help them to understand that particular organism and disease process. For information about teaching infection control in the home and community, see Home Care: Preventing Infection in the Home and Community. To help clients avoid acquiring or spreading community-acquired MRSA (CA-MRSA), see Self-Care: Teaching Your Patient About Preventing the Spread of CA-MRSA.

Promoting Wellness to Support Host Defenses

Efforts to promote wellness help break the chain of infection by strengthening a person's defenses against invading pathogens. Lifestyle factors essential for promoting host defenses are healthful nutrition, adequate hygiene, rest and exercise, stress reduction, and immunizations.

Nutrition An acute infection depletes the body's nutritional stores. Therefore, it is important to monitor and support client nutrition, including protein, vitamins, minerals, and water. Nutrients are required to replace lost stores, to maintain production of white blood cells, and to repair damaged tissues. Fever and increased secretions of mucus, which are common defenses against infection, increase water loss. Additional water is needed to supplement the lost fluid and to support the increased metabolic rate that occurs with a fever. Chapter 27 further discusses the importance of adequate nutrition.

Hygiene is crucial for maintaining intact skin, a primary host defense. Encourage frequent handwashing, as well as regular showering or bathing, to decrease the bacterial count on the skin. However, be aware that overzealous cleanliness diminishes the skin's natural oils and may lead to cracking of the skin. Chapter 25

Quality and Safety Education for Nurses

Successful QI Project: Improving the Rate of Ventilator-Associated Pneumonia (VAP)

Key Concept: *Infection prevention and control*

Competency: *Quality Improvement (Knowledge, Skills, Attitudes)**

You and your colleagues have the privilege and opportunity to become partners in improving the quality of patient care. Think about the following project and consider what Knowledge, Skills, and Attitudes were required for its success and how they relate to the key concept.

Situation: Nurses and physicians at the Mercy Medical Center Critical Care Unit in Springfield, Maine, wanted to decrease their rate of ventilator-associated pneumonia (VAP). They collected data to establish the existing rate of 12.6 cases per 1,000 ventilator days.

Intervention developed: Nurses provided oral care with cetylpyridinium chloride (Oral-B) using a suction toothbrush every 4 hours. After that, they cleaned each patient's mouth with a hydrogen peroxide–treated suction swab, performed deep oropharyngeal suctioning, and applied mouth moisturizer.

Result: Incidence of VAP declined 72%, and after changing the tooth cleanser to chlorhexidine gluconate, by an impressive 90%!

Time Frame	Intervention	Cases/1,000 Vent Days	% of Decline
2004	Usual care	12.6	
5/2005–12/2005	Oral care protocol introduced	4.12	67%
2006	Oral care protocol maintained	3.57	72%
2007	Oral care protocol maintained; tooth cleanser changed to chlorhexidine gluconate (Peridex)	1.3	90%

Think about it:

- What QSEN Knowledge and Attitudes did the nurses and team members need before changing the care of patients on ventilators?
- How is a meaningful and measurable outcome an essential Skill for effective quality improvement interventions? Is the outcome a direct result of the care?
- What is your attitude about the significance of the team's work? How will the team's efforts affect patients?

Source: Hutchins K., Karras, G., Erwin, J., et al. (2009).

Go to the QSEN Web site at **http:www.qsen.org.ksas_prelicensure.php**

Self-Care

Teaching Your Patient About Preventing the Spread of CA-MRSA

As measures to prevent community-acquired MRSA, everyone should:

- Take antibiotics as prescribed. Complete the course of medication as recommended until it is finished.
- Contact your healthcare provider if the infection doesn't improve after a few days of taking an antibiotic.
- Never use antibiotics prescribed for someone else; and do not give your medication to others.
- Follow your healthcare provider's recommendations for influenza and pneumonia vaccinations. Preventing respiratory infections decreases antibiotic use.
- Make sure your healthcare providers clean their hands before they touch you. This is one of the most important infection prevention and control measures.
- Wash your hands often with soap and water. Wash for 15 to 30 seconds, or as long as it takes to sing the "Happy Birthday" song.
- Use alcohol-based hand sanitizer if soap and water are not available or hands are not visibly soiled. Sanitizer should have at least 60% alcohol.
- Avoid sharing personal items (e.g., towels, makeup, combs, clothing).
- Pay attention to symptoms that may indicate an infection (e.g., drainage from or inflammation of a wound), and contact your healthcare provider immediately.
- Cough and sneeze into your elbow and wash your hands after using a tissue.

Clients who have MRSA on their skin or who are infected with MRSA should be taught to:

- Keep all sores and cuts clean and covered with bandages.
- When changing a bandage:

  Don't touch the sore with your bare hands. Wear gloves.

(*Continued*)

Self-Care

Teaching Your Patient About Preventing the Spread of CA-MRSA—cont'd

Immediately discard the soiled bandage and gloves in a trashbag where no one else can touch them.

Wash your hands after removing the gloves.

- Avoid touching other people's cuts or bandages.
- Avoid close-contact activities until your skin infection is healed, unless you can ensure that your sore will not come in contact with another person (e.g., if your sore can be well covered by a bandage and clothing).
- Shower daily, using antibacterial soap if your healthcare provider advises it.
- Wash your clothing, towels, and bedding separately from other family members' items. Use warm or hot water and bleach, if possible. Use warm or hot setting on the dryer.
- Wash exercise clothes after each use.

Sources: Adapted from CDC (n.d.e), *Antibiotic/antimicrobial resistance.* Retrieved November 2012, from http://www.cdc.gov/drugresistance/about.html; Holcomb, S. S. (2008). MRSA infections. *Nursing2008, 38*(6), 33; Leung-Chen, P. (2008). Emerging infections. Everybody's crying MRSA. *American Journal of Nursing, 108*(8), 29–31.

Home Care

Preventing Infection in the Home and Community

- To disinfect the home environment, use and teach caregivers to create a dilute bleach solution. Mix 1 part regular-strength bleach to 50 parts water. The mixture may be stored for a month in an opaque container.

NEVER mix the solution with other household cleaners.

- Procedures performed using sterile technique in the hospital (e.g., urinary catheterization) are often performed by clean procedure in the home because of the decreased risk of infection.
- Washing dishware and eating utensils in a dishwasher with hot water and detergents is sufficient decontamination.
- Healthcare workers in the home are a potential source of pathogens and should use caution to avoid infecting the client.
- If the client or family member is capable and willing to perform the required treatment, provide the necessary teaching; the client will have less exposure to pathogens than he would should a healthcare provider came to the home to provide care.
- Assess for subtle signs of infection: temperature increase, fatigue, lymph gland enlargement, delayed healing of wounds, fever, chills, or drainage.
- Instruct clients and family members in the signs and symptoms of infection and how and when to contact their primary care provider to report these findings.
- Advise those planning international travel to get their vaccinations before departing, especially for travel to Africa, South-Central Asia, or Central America, where they may contract malaria, dengue, rickettsiosis, and influenza.
- Teach clients and family members basic hygiene and infection prevention measures in the home, including:

The importance of handwashing before preparing food, before eating, after going to the bathroom, blowing the nose, and before putting the hands near the face.

Keeping the home environment clean to create an optimal environment for care

Safe food preparation and storage (see Chapter 27)

Not sharing personal care items (e.g., towels, washcloths, toothbrushes, combs)

- Teach clients and family members actions they can take to help prevent infection when they are outside the home, including:

Washing hands and not touching surfaces in a public bathroom

Carrying and using antibacterial hand gel, as needed while in public places

Using a wet-wipe on the receiver and mouthpiece of public phones before making a call

Washing hands upon returning home (e.g., from shopping)

Asking healthcare providers to wash their hands before physical contact, if they have not done so

Using tongs, not fingers, to get food from serving trays in grocery stores and restaurants

- For additional information on home care practices, see Chapter 43.

focuses on the importance of hygiene for health. Also see the Home Care box.

For the immunocompromised or bed-bound hospitalized patient, the American Association of Critical-Care Nurses (AACN) (2013) advocates daily bedside baths using filtered tap water and disposable basins, including prepackaged bathing products. Nurses should use disposable cloths with 2% chlorhexidine gluconate (CHG) to reduce colonization of specific bacteria and infections with MDROs.

Rest and Sleep Rest and sleep renew the body and mind and conserve strength. Sleep needs vary, and there is really no "correct" amount or pattern of sleep. However, sleep of 6 to 9 hours per night is considered fully restorative for most people.

Exercise and Activity Research demonstrates that exercise is just as important as rest and sleep. Too little activity causes circulation to slow and the lungs to supply less oxygen. Excessive exercise leads to fatigue and joint injury. Chapters 32 and 34 provide in-depth discussion on rest, sleep, activity, and exercise.

Stress Reduction Whether physical or mental, stress decreases the body's immune defenses. Numerous studies demonstrate a correlation between increased stress and increased disease (Cousins, 1979; Franco, de Barros, Nogueira-Martins, et al., 2003; Schneider, Alexander, Staggers, et al., 2005; Tegethoff, Greene, Olsen, et al., 2011). Laughing, in contrast, increases oxygenation, promotes body movement, and increases immune responses. See Chapter 12 for further details on the effects of stress, if you wish.

Immunizations Immunization via vaccination can protect against several infectious diseases (e.g., measles, mumps, and other childhood diseases; pneumonia; influenza; smallpox; shingles). Unfortunately, some pathogens, such as the virus that causes the common cold, mutate too rapidly for an immunization to be developed. Encourage clients to follow recommendations for immunizations. For most diseases, at least 85% of the population must be immunized in order to protect the entire population from the disease. If you need specific recommended immunizations throughout the life span and their role in health promotion, see Chapters 9 and 10 for various age groups, and

Go to Chapter 9, **ESG Figures 9-1, 9-2,** and **9-3** on Davis*Plus*.

Also

KnowledgeCheck 23-5

What actions improve host ability to prevent infection?

PRACTICING MEDICAL ASEPSIS

Asepsis is a term that means absence of contamination by disease-causing microorganisms. **Medical asepsis** ("clean technique") refers to procedures that decrease the potential for the spread of infections. You probably already practice medical asepsis in other settings without realizing it. For example, at home you wash your hands before and after handling foods. Before chopping food, you make sure the cutting board and utensils you use are clean. After using it, you wash the board with hot, soapy water. In the healthcare setting, medical asepsis includes hand hygiene, environmental cleanliness, standard precautions, and protective isolation.

The effectiveness of these measures, and the patient's safety, depend on nurses' rigorously and consistently following the principles of asepsis. When you are hurrying, you may be tempted to take shortcuts or forget to follow a guideline. Remember: You are putting your patient, and possibly yourself, at risk for an infection that could cause serious illness. Assume every patient is potentially infected or colonized with an organism that could be transmitted to others.

Maintaining Clean Hands

Key Point: ***Hand hygiene is the single most important activity for preventing and controlling infection.***

The WHO has chosen as the first "global patient safety challenge" the reduction of HAIs, with the theme, "clean care is safer care." They have made hand hygiene the cornerstone strategy because it is simple, standardized, low cost, and based on solid scientific evidence.

Although you may think you already know how to wash your hands, remember that in healthcare settings you are coming in contact with pathogens that are potentially dangerous to you and your patients. Decisions about the type of hand hygiene to use, how long to wash, when to wash, and so on are based on the amount of contact you have with patients or contaminated objects, as well as the patient's infection status and susceptibility to infection. Handwashing involves five key factors: time, water, soap, friction, and drying (Fig. 23-4). The following briefly summarizes the CDC recommendations for these factors (Boyce & Pittet, 2002). For more specific details and guidelines to use when making handwashing decisions,

Go to **Clinical Insight 23-1: Guidelines for Hand Hygiene,** in Volume 2.

- *Time*. In a nonsurgical setting, wash the hands vigorously for at least 15 seconds, longer if hands are visibly soiled. In a surgical setting wash for 2 to 6 minutes, depending on the soap or other product used.
- *Water*. Use warm water and rinse off soap completely. Hot water and soap increase the potential for skin breakdown.

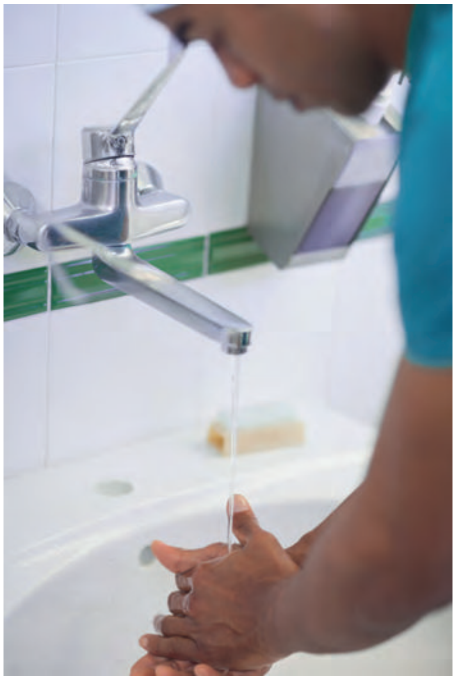

FIGURE 23-4 Clean hands reduce the risk of transmitting infection.

- *Soap*. Use agency-approved soap. The CDC (2002) recommends using a 60% alcohol-based solution (rubs, sprays, gels) for routine hand cleansing, and plain or antimicrobial soap and water when hands are visibly dirty. Iodine compounds are also effective, but usually too irritating for regular hand hygiene.

If there is a potential for contact with bacterial spores (e.g., when caring for a client with a *C. diff.* infection), you must wash your hands with soap and water; alcohol-based solutions are not effective against spores.

If you are interested in a comparison of the effectiveness of various hand-hygiene antiseptic agents,

Go to Chapter 23, **DP Table 23-2,** on Davis*Plus*.

- *Friction*. Rub all surfaces of the hands and wrists vigorously, including the backs of the hands and between the fingers. Remove jewelry and clean areas underneath. Clean underneath the fingernails using an orangewood stick.
- *Drying*. Use single-use towels or hand dryers to remove all moisture after washing the hands. If using antimicrobial hand gels, apply and rub hands until dry.

For a step-by-step procedure on hand hygiene,

Go to Chapter 23, **Procedure 23-1: Hand Hygiene,** in Volume 2.

In addition to handwashing, you should keep your fingernails short. According to the CDC (2002), long nails, artificial nails, nail extenders, fingernail polish, watches, and rings with stones can harbor microorganisms. Even shorter nail length of 2 mm or less is preferred (Association of periOperative Registered Nurses [AORN], 2004; Boyce & Pittet, 2002; Pratt, Pellowe, Wilson, et al., 2007; Rupp, Fitzgerald, Puumala, et al., 2008). Drying, chaffing, and chapping commonly occur with frequent handwashing and application of petroleum-based skin products. These skin irritations and interruptions can harbor microbes that can be passed from one person to another.

The most important aspect of medical asepsis is hand cleanliness. Clean hands markedly decrease the transmission of infection.

Despite the importance of clean hands, research demonstrates that clinical staff do not consistently observe hand hygiene guidelines (Pratt, Pellowe, Wilson, et al., 2007).

It is the responsibility of healthcare workers to perform standard of care. Failure to do so is medical negligence and can result in harm to the patient. Breaks in sterility or even witnesses to errors in sterility may lead to patient neglect. In 2008, Medicare stopped paying for patient complications arising from certain hospital-acquired infections, which in many cases result from poor handwashing. You can help improve clinical practice by serving as a role model for good hand hygiene.

Maintaining a Clean Environment

A clean environment includes the surfaces in a patient's room, as well as supplies, equipment, and other objects brought into the room. An object is contaminated if it becomes unclean—that is, if you suspect it may contain pathogens. The floor, soiled dressings, used tissues, sinks, commodes, and bedpans are other examples of contaminated items. Agency policies determine whether a reusable item is cleaned, disinfected, or sterilized, based on how the item is used.

Cleaning

Cleaning is the removal of visible soil (organic and inorganic) from objects and surfaces. It normally is accomplished manually or mechanically using water with detergents or enzymatic products. A goal of medical asepsis is to keep all public and patient care areas within the facility clean and free from dust, debris, and contamination. Any spilled liquids, dirty surfaces, or potentially contaminated areas should be cleaned immediately. In your home, you use hot water and general cleaning supplies. However, healthcare facilities use special techniques and cleaning solutions formulated to inhibit microbial growth. Items must be cleaned thoroughly before they can be disinfected or sterilized.

Disinfecting

Disinfection removes virtually all pathogens on inanimate objects by physical or chemical means, including steam, gas, chemicals, and ultraviolet light. Disinfection reduces microbial populations, but it does not guarantee that all pathogens are eliminated, because certain viruses, other pathogenic microbes, and spores can remain (Bauman, Machunis-Masuoka, & Tizard, 2006). Chemical germicides can achieve three levels of disinfection. *High-level disinfection* kills all organisms except high levels of bacterial spores. *Intermediate-level disinfection* kills mycobacteria, most viruses, and bacteria. *Low-level disinfection* kills some viruses and bacteria. Disinfection is used for semicritical and noncritical items:

- **Semicritical items** are those that contact mucous membranes or nonintact skin. This category includes reusable devices, such as flexible endoscopes and respiratory therapy and anesthesia equipment. They must be free of all microorganisms except bacterial spores, so they must at least be disinfected, and sometimes sterilized.
- **Noncritical items** are supplies and equipment that come in contact with intact skin but not mucous membranes. They do not carry a high risk of infection transmission, and they can be decontaminated where they are used. Examples of noncritical patient care items are bedpans, stethoscopes, and blood pressure cuffs. Examples of noncritical environmental surfaces include floors, food utensils, bed linens, and bed rails (CDC, 2008). Disinfection is adequate for noncritical items.

Sterilizing

Sterilization is the elimination of all microorganisms (except prions) in or on an object. The most common sterilizing methods used in hospitals are (1) autoclaving with moist heat, (2) ethylene oxide gas at low heat, (3) dry heat, and (4) low temperature hydrogen peroxide gas (AORN, 2012). Sterilization is used when absolute purity of an object or surface is critical.

- **Critical items** are ones that pose a high risk for infection if they are contaminated with any microorganism. Critical items include those that enter the vascular system or sterile tissue, or through which blood flows. Examples are intravenous catheters, needles for injections, urinary catheters, surgical instruments, some wound dressings, and chest tubes.

If you need more specific information on methods for disinfection and sterilization of patient-care items and environmental surfaces,

Go to Chapter 23, **ESG Table 23-3, Methods for Disinfection and Sterilization of Patient-Care Items and Surfaces,** on Davis*Plus*.

Specially trained personnel carry out disinfection and sterilization in most agencies. As a nurse, you must be familiar with the agency's policies and procedures for cleaning, handling, and transporting items to be disinfected and sterilized, and for working collaboratively with other departments (e.g., the housekeeping department) to keep the patient care area as clean and free of clutter as possible. Clients and caregivers are usually at less risk for infection in their own homes than they are in the hospital. They share the same potential pathogens and antibodies, and there is limited exposure to others with illness and to care providers carrying unusual pathogens, so levels of disinfection and sterilization may differ.

For more specific information about maintaining a clean environment in institutional and home care,

Go to Chapter 23, **Clinical Insight 23-2, Providing a Clean Patient Environment,** in Volume 2.

CDC Guidelines for Preventing Transmission of Pathogens

In addition to handwashing and maintaining a clean environment, you should follow other precautions to protect yourself and your patients. CDC guidelines provide for two tiers of protection.

- **Standard precautions**, the first tier of protection, apply to care of all patients.
- **Transmission-based precautions**, the second tier of protection, outline precautions to be taken based on the mode of transmission of the infection (Siegel, Rhinehart, Jackson, et al., 2007). Recall from the discussion on the chain of infection that pathogens may be transmitted by contact, droplet, or air. Each mode of transmission requires a different approach to prevent infection.

FIGURE 23-5 Several types of face masks and eye shields are available.

Table 23-2 provides a summary comparison of standard and transmission-based precautions. For detailed guidelines to aid you in following both types of precautions,

Go to Chapter 23, **Clinical Insight 23-3, Following CDC Standard Precautions,** and **Clinical Insight 23-4, Following Transmission-Based Precautions,** in Volume 2.

Personal Protective Equipment The CDC recommends and the U.S. Occupational Safety and Health Administration requires employers to provide personal protective equipment (PPE) for healthcare workers (e.g., gloves, gowns, face masks, and eye protection) (U.S. Department of Labor, n.d.). This equipment is to be used in standard precautions as well as transmission-based precautions. Figure 23-5 provides examples of face masks and eye protection equipment. Procedure Highlights 23-2 through 23-8 summarize the steps for donning and removing PPE. For complete instructions,

Go to **Procedure 23-2: Donning Personal Protective Equipment (PPE),** and **Procedure 23-3: Removing Personal Protective Equipment (PPE),** in Volume 2.

KnowledgeCheck 23-6

Under what circumstances are standard precautions used?

Intervention for Example Problem: Preventing MDROs

Evidence suggests that MDROs are carried from one person to another via the hands of healthcare personnel.

To prevent MDROs, you must adhere strictly to published recommendations for hand hygiene, glove use, and isolation precautions; and for performing invasive procedures such as intravenous and urinary catheterization and care of central venous ports.

Table 23-2 ➤ Comparison of CDC Standard and Transmission-Based Precautions

STANDARD PRECAUTIONS	TRANSMISSION-BASED PRECAUTIONS
Tier I Precautions	**Tier 2 Precautions**
Use with all clients, in all settings, regardless of suspected or confirmed presence of infection.	Use for patients known or suspected to be infected or colonized with infectious agents.
Principle: All blood, body fluids, secretions, excretions except sweat, nonintact skin, and mucous membranes may contain pathogens.	*Principle:* Routes of transmission for some microorganisms are not completely interrupted using standard precautions alone. Used *in addition to* standard precautions.
Include: Hand hygiene; use of gloves, gown, mask, eye protection, or face shield (depending on expected exposure); and safe injection practices. Does not completely protect against microorganisms spread by contact, droplets, or through the air. **New Elements of Standard Precautions** Added for protection of patients more than of healthcare personnel. They include: Respiratory hygiene and cough etiquette Safe injection practices Wearing a mask when performing special lumbar puncture procedures	Three categories of precautions: *Contact Precautions*—For organisms spread by direct contact with the patient or his environment. This is the most common form of transmission. *Droplet Precautions*—For pathogens spread through close respiratory or mucous membrane contact with respiratory secretions (e.g., sneezing, coughing, talking); pathogens that do not remain infectious over long distances. *Airborne Precautions*—For pathogens that are very small and remain infectious over long distances when suspended in the air; and easily transmitted through air currents (e.g., fanning linens, ventilating systems).

Source: Siegel, J. D., Rhinehart, E., Jackson, M., et al. (2007). *2007 guideline for isolation precautions: Preventing transmission of infectious agents in the healthcare setting.* Retrieved November 12, 2012, from http://www.cdc.gov/hicpac/2007IP/2007isolationPrecautions.html

For a list of actions you can take to help prevent MDROs,

Go to **Clinical Insight 23-5, Preventing Multidrug-Resistant Organism Infections,** in Volume 2.

Protective Environment in Special Situations

Patients who are immunosuppressed (e.g., receiving chemotherapy) may be placed in a special form of isolation, called protective isolation or reverse isolation. However, the CDC states that standard and transmission-based precautions are adequate protection for most of those patients. They recommend a "protective environment" only for a special class of stem cell transplant patients who are neutropenic (have a low white blood cell count secondary to chemotherapy). Most of the recommendations are engineering and environmental services rather than nursing measures. If you are interested in learning the details of maintaining a protective environment,

Go to **Clinical Insight 23-6, Maintaining a Protective Environment in Special Situations,** in Volume 2.

Patients with compromised immunity are more likely to become infected by pathogens harbored in their own bodies than from pathogens transmitted by other people (Siegel, Rhinehart, Jackson, et al., 2007). Therefore, except for the special situation described, standard and transmission-based precautions should protect even unusually vulnerable patients from organisms brought in by healthcare workers and visitors.

Nevertheless, you may see what has been called **protective isolation** being used for clients with low WBC counts, clients undergoing chemotherapy, or clients with large open wounds or weak immune systems. Protective isolation usually includes following standard precautions, placing the patient in a private room; restricting visitors; wearing a mask, gown, and gloves for patient care; and special cleaning or disposal of the patient's equipment and supplies. Some units, such as neonatal intensive care units, burn units, and labor and delivery suites, may follow some aspects of protective isolation all the time. Most of these precautions are described by standard and transmission-based precautions.

Control of Potentially Contaminated Equipment and Supplies

Whenever possible, use disposable equipment in an isolation room. Nondisposable equipment and supplies require special handling.

- **Protective Isolation** If a client is in protective isolation, be sure that equipment has been disinfected *before*

Toward Evidence-Based Practice

Labeau, S. O., Witdouck, S. S., Vandijck, D. M., et al. (2010). Nurses' knowledge of evidence-based guidelines for the prevention of surgical site infection. *Worldviews on Evidence-Based Nursing,* 7(1), 16–24.

The purpose of this study was to evaluate intensive care unit (ICU) nurses' specific knowledge of surgical site infection prevention guidelines preparatory to developing an online infection prevention education module. Survey data were collected from 650 intensive care nurses who attended the Flemish Society for Critical Care Nurses Congress regarding their knowledge of the current evidence-based CDC recommendations for prevention of surgical site infection. The study results concluded that ICU nurses' knowledge of surgical site infection prevention can be substantially improved through ongoing education and training.

Broex, E. C. J., van Asselet, A. D. I., & Bruggeman, C. A. (2009). Surgical site infections: How high are the costs? *Journal of Hospital Infection, 72,* 193–201.

The authors reviewed 16 studies from hospitals throughout the world published between 2004 and 2008. They examined the effects of facility-acquired infections on patients' length of stay, hospital costs, and societal costs, including effects on patients and their families. The study authors concluded that surgical site infection (SSI) is responsible for a significant increase in healthcare-related costs: up to two times the cost of a patient without an SSI.

Bailey, R. R., Stuckey, D. R., Norman, B. A., et al. (2011). Economic value of dispensing home-based preoperative chlorhexidine bathing cloths to prevent surgical site infection. *Infection Control and Hospital Epidemiology, 32*(5), 465–471.

The objective of this research was to examine the economic value of providing preoperative chlorhexidine bathing cloth kits for home use by orthopedic patients, with the goal of preventing surgical site infection (SSI). The study results indicated that even with low (50%) patient compliance, routine distribution of preoperative chlorhexidine bathing cloth kits is a cost-effective strategy to prevent SSI.

Kamel, C., McGahan, L., Polisena, J., et al. (2012). Preoperative skin antiseptic preparations surgical site infections: A systematic review. *Infection Control and Hospital Epidemiology, 33*(6), 608–617.

A systematic review of literature published between January 2011 and June 2011 was conducted examining data from 20 randomized and nonrandomized controlled trials of preoperative skin antisepsis. Results indicated that preoperative surgical showers using an antiseptic preparation effectively reduces skin flora and bacterial colonization and may reduce surgical site infection (SSI) rates.

Jakobsson, J., Perlkvist, A., & Wann-Hansson, C. (2011). Searching for evidence regarding using preoperative disinfection showers to prevent surgical site infections: A systematic review. *Worldviews on Evidence-Based Nursing, 8*(3), 143–152.

The purpose of this study was to determine how many preoperative showers using a disinfecting agent are needed to effectively reduce bacteria on the skin and decrease the risk of surgical site infection (SSI). Data from 10 studies on preoperative disinfection showers published in the United States and Europe between 1987 and 2008 were analyzed. The analysis did not reveal consistent data on the optimal number of preoperative showers with a disinfecting agent.

1. From these abstracts, what do you know about the purpose of these studies?

2. What do the Jakobsson and Kamel studies conclude about preoperative disinfective showers to surgical sites?

3. In what way do the data in the study conducted by Labeau support the other studies? What were the limitations of this study?

Go to Chapter 23, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

it is taken into the room. Take linens and dishes directly to the protective isolation room, and hand them to someone wearing the required protective garb.

- **Transmission-based Isolation** If the client is in transmission-based isolation, disinfect the equipment *on removal* from the room. When removing linens or nondisposable items from a room with contact, droplet, or airborne isolation, place them in special isolation bags.

Disposing of Used Isolation Supplies Place contaminated disposable equipment and materials containing body fluids in special isolation bags. This process requires two healthcare workers. The worker inside the room wears protective clothing and handles only contaminated items. The second worker stands at the door and holds the isolation bag open. The first worker places items inside the bag without touching the outside of the bag. If the bag contains linens, the isolation bag is closed and placed in a laundry hamper. Securely close an isolation trash bag, and place it in a special isolation trash container. Special disposal methods are used to prevent these objects from going into a landfill, where they could become a reservoir of infection. Because this trash is much more expensive to process, take care to put *only* contaminated materials in the contaminated trash.

Sharps Disposal Always place disposable needles, syringes, and other sharp items, such as broken glass, in special disposable sharps containers immediately after their use. Never recap a contaminated needle. Refer to Chapters 24 and 26 for further information on preventing needlestick injuries.

Laboratory Specimens Laboratory specimens contain blood and body fluids and are always considered contaminated. Label the specimen container in a clean area before taking it to the patient. Have the specimen collected by a healthcare worker wearing appropriate protective clothing. Once the specimen is collected, place it in a special transport bag. Do not allow the outside of the bag to touch any contaminated item, including your gloves.

For specific guidelines on care of contaminated equipment and supplies,

Go to Chapter 23, **Clinical Insight 23-2, Providing a Clean Patient Environment; Clinical Insight 23-3, Following CDC Standard Precautions;** and **Clinical Insight 23-4, Following Transmission-Based Precautions,** in Volume 2.

Supporting the Psychological Needs of Patients in Isolation

Remember, isolation precautions are designed to prevent the spread of disease. It is the disease that is being isolated, *not* the person who has the disease. Patients who are in isolation continue to have a need for human contact. In fact, isolation may produce anxiety and increase the desire for human contact. When caring for a client in isolation, search for ways to reassure and maintain contact with the patient. Possible solutions include the following:

- When wearing the required protective equipment, touch the patient.
- Organize the time you spend in the patient's room to include time for discussion about how the client is coping with isolation.
- If the patient is in droplet isolation, remember that the danger area is 3 feet from the patient. You can go to the door of the room and speak to the patient without a mask.
- Reassure the patient that precautions are temporary.
- Explain that the precautions and the PPE protect you and the patient, as well as family members and other patients.

KnowledgeCheck 23-7

- If you needed to disinfect a sink in a client's home, what would you use?
- List at least three actions clients can take to help avoid infection when they are out in the community.

PRACTICING SURGICAL ASEPSIS

Sterile means "without life." If an object is sterile, it contains no life and therefore no infectious organisms. The exception is *prions,* the protein particles that cause severe neurological degeneration in animals and humans, such as in bovine spongiform encephalopathy (BSE, also known as "mad cow disease") in cattle and Creutzfeldt-Jakob disease (CJD) in humans. Researchers

Highlights of Procedures 23-1 through 23-8

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 23-1: Hand Hygiene

If using alcohol-based handrubs:

1. Use alcohol-based handrubs when hands are not soiled.
2. Cover all surfaces of fingers and hands.
3. Rub together until dry.

Procedure 23-2: Donning Personal Protective Equipment (PPE)

- Before exposure, don appropriate PPE according to standard precautions or transmission guidelines.
- Wear an N-95 respirator mask for airborne isolation.
- Wear a surgical mask for droplet isolation.

Procedure 23-3: Removing Personal Protective Equipment (PPE)

- Remove PPE at doorway before leaving patient room, or in an anteroom.
- Avoid contaminating self, others, or environment when removing equipment.
- Considered contaminated: front areas, sleeves, head cover, mask, and gloves of the PPE.
- Considered clean: the inside of the gown, gloves, and head cover; the ties on the mask; and ties in the back of the gown.
- Always remove gloves first when removing PPE, unless gown ties in front.

Highlights of Procedures 23-1 through 23-8

Procedure 23-4: Surgical Handwashing: Traditional Method

- Don surgical shoe covers, cap, and face mask before the scrub.
- Use warm water.
- Perform a prewash, using soap and water.
- Clean under your fingernails under running water.
- Wet the scrub sponge, and apply a generous amount of antimicrobial soap.
- Using a circular motion, scrub all surfaces of nails, hands, and forearms at least 10 times, or the length of time specified by agency policy.
- Rinse hands and arms by keeping your fingertips higher than your elbow.
- Grasp a sterile towel, and back away from the sterile field.
- Thoroughly dry your hands before donning sterile gloves.

Procedure 23-5: Surgical Handwashing: Brushless System

- Don surgical shoe covers, cap, and face mask before the scrub.
- Use warm water.
- Perform a prewash, using soap and water.
- Clean under your nails under running water.
- Apply a generous amount of antimicrobial soap.
- Using a circular motion, scrub all surfaces of nails, hands, and forearms at least 10 times, or the length of time specified by agency policy.
- Rinse hands and arms by keeping your fingertips higher than your elbow.
- Grasp a sterile towel, and back away from the sterile field.
- Thoroughly dry your hands before donning sterile gloves.

Procedure 23-6: Sterile Gown and Gloves (Closed Method)

- Put on shoe covers, hair covers, and mask before scrub
- Perform surgical scrub.
- Grasp the gown at the neckline, and slide your arms into the sleeves without extending your hands through the cuffs.
- Have a coworker pull the shoulders of the gown up and tie the neck tie.
- Don gloves using the closed method by keeping your hands covered at all times, first with the gown cuffs, and then with the sterile gloves.
- Secure the waist tie on your gown by handing it to a coworker and turning to receive it.
- Keep your hands within your field of vision at all times.
- Do not turn your back to a sterile field.

Procedure 23-7: Sterile Gloves (Open Method)

- Remove all jewelry, including rings and watches.
- Place the glove package on a clean, dry surface.
- Open the inner package so that the cuffs are closest to you.
- Apply the glove of your dominant hand first by touching only the inside of the glove (the folded-over cuff) with your nondominant hand.
- Apply the second glove by touching only the outer part of the glove with your already-gloved hand; keep your sterile thumb well away from your bare skin.
- Do not touch the gloves to any unsterile items.

Procedure 23-8: Sterile Fields

- Prepare the sterile field as close as possible to the time of use.
- Do not cover the sterile field once established.
- Do not turn away from the sterile field.
- Inspect for package integrity, inclusion of sterile indicator, and/or expiration date. Do not use outdated items.
- Clear a space and prepare the patient before setting up the sterile field.
- Establish the sterile field with a sterile drape or sterile package wrapper.
- Add items to the sterile field by gently dropping them onto the sterile field.
- Pour sterile solutions into a sterile bowl or receptacle without touching the bowl or splashing onto the sterile field.
- Don sterile gloves and perform the procedure.

have not yet determined what types of antimicrobial techniques are successful in destroying prions. Inanimate objects, such as surgical equipment, gauze dressings, or wound irrigation fluid, may be sterile. However, humans will always have microorganisms in and on their bodies; and researchers have not yet determined what types of techniques, if any, can destroy prions.

Surgical asepsis, or **sterile technique**, requires creation of a sterile environment and use of sterile equipment. It differs from medical asepsis in that it is more complex and it is not required for use with all patients. Sterilization can be accomplished through the use of special gases or high heat. Surgical equipment and implanted devices are examples of materials that must be sterilized. If you need more information about sterilization processes,

Go to Chapter 23, **ESG Table 23-3, Methods for Disinfection and Sterilization of Patient-Care Items and Surfaces,** on Davis*Plus*.

To create a sterile area, housekeeping personnel perform extensive cleaning using special solutions and procedures. All health personnel working in the area must wear appropriate surgical attire and perform a surgical hand scrub.

Levels of Asepsis Recent guidelines suggest using modified sterile technique for many bedside procedures that have traditionally used sterile technique (e.g., tracheostomy care and wound care).

- **Sterile technique** is the use of sterile gloves and sterile supplies (e.g., drapes, wound dressings, instruments, water).
- **Modified sterile technique** is the use of nonsterile procedure gloves with sterile supplies.
- **Clean technique** is the use of clean hands or nonsterile gloves and clean, rather than sterile, supplies (e.g., tap water).

Performing a Surgical Scrub

A surgical scrub is a modification of the handwashing procedure described earlier (see Table 23-3 for a comparison). It traditionally involves an extended scrub of the hands using a sponge, nail cleaner, and a bactericidal scrubbing agent. A newer method uses a brushless scrub, using a bactericidal scrubbing agent. All methods require a prewash before the surgical scrub. For a summary of the steps involved, see the Highlights of Procedures box for Procedures 23-4 and 23-5. For the full procedures,

Go to **Surgical Handwashing: Traditional Method** and **Surgical Handwashing: Brushless System** procedures, in Volume 2.

Donning Surgical Attire

Burn units; labor and birth units; and some surgical wards, intensive care units, nurseries, and oncology wards require surgical attire for patient caregiving. In each of these units, nurses care for clients who are at increased risk for infection or are undergoing an invasive procedure that places them at increased risk. The goal on all of these units is to protect the patient from infection transmitted by healthcare workers.

All personnel on these units don *clean* surgical attire, or scrub suits, when they arrive on the unit. These scrub suits should not be worn outside the unit. If you must transport a patient to another area or leave the unit to gather supplies, wear a covering over the scrub suit. Remove the covering on your return to the unit. Additional precautions include a disposable hat to cover the hair, shoe coverings, and face masks.

Personnel engaged in surgery or certain invasive procedures must dress in *sterile* surgical attire. As a beginning student, you will soon find yourself in such a situation. Initially your role will be limited to observation, but you will need to be prepared for these experiences.

First you will change into a scrub suit, apply shoe coverings, and put on a disposable hat. Wash your hands, and apply a face mask. If there is potential for spray of fluids, wear a face mask with eye shield. Be sure to adjust the mask so that it is comfortable to breathe through. Once you have adjusted the mask, perform the surgical scrub. If a surgical gown is required, don it after the hand scrub.

If you are applying full surgical attire, you will need to apply gloves using a closed method, after you have put on your gown. Once you don sterile gloves, you may touch only sterile items. The Highlights of Procedures box pertains to donning sterile attire. For complete instructions,

Go to **Procedure 23-6: Donning Sterile Gloves and Gown (Closed Method)** and **Procedure 23-7, Sterile Gloves (Open Method);** in Volume 2.

You will often wear sterile gloves for procedures that do not require full surgical attire. Open the glove packaging slowly. Avoid fanning the wrapping or touching the gloves. Put the first glove on your dominant hand (Fig. 23-6). This is the open method of gloving.

A general rule to consider when applying the second glove is to touch glove-to-glove and skin-to-skin. The already-gloved hand may touch any of the sterile surfaces of the second glove.

Table 23-3 ➤ A Comparison of Hand Hygiene and Surgical Scrub

	HAND HYGIENE	SURGICAL SCRUB
No visible soil	Use alcohol-based handrub or soap (plain or antimicrobial) and water.	1. Perform handwashing with soap and water. 2. Then perform the surgical scrub using either an FDA-approved antimicrobial scrub product or an antiseptic handrub that is FDA-approved for surgical hand asepsis.
Hands visibly soiled	Wash with soap (plain or antimicrobial) and water.	Surgical scrub steps remain the same, even with visible soil.

Sources: AORN (2010b); Boyce & Pittet (2002); Garbutt (2011).

FIGURE 23-6 When applying the first glove, touch only the inside cuff of the glove.

The second hand may touch only the inside of the glove—the portion that will have contact with the skin. Figure 23-7 illustrates the hand positions used to apply the second glove. Although this process sounds awkward, you will develop comfort with practice. The box Highlights of Procedures 23-1 Through 23-8 contains a summary of the open method of gloving. For complete instructions,

Go to **Procedure 23-7: Sterile Gloves (Open Method),** in Volume 2.

Using Sterile Technique in Nursing Care

Healthcare providers use sterile technique to perform a variety of procedures. Some of the procedures require full surgical attire; others do not. The following procedures, for example, use both sterile technique and principles of medical asepsis: administering an injection, starting an IV line, and performing a sterile dressing change. To clarify, when administering an injection, you prepare the patient, cleanse the injection site, and remove the needle cap using standard precautions. You do not don sterile gloves, but for the rest of the procedure you observe sterile technique by taking care not to touch or otherwise contaminate the exposed needle.

FIGURE 23-7 When applying the second glove, consider this general rule: glove-to-glove, skin-to-skin.

Before performing a sterile procedure, determine what supplies you will need and whether you will need assistance. If the patient is unable to maintain a position required for the procedure, you will need a helper to hold the patient during the procedure. Wash your hands before gathering materials from the sterile supply area, and then gather the other required supplies and equipment. Check the expiration date on each package. Check the package to make sure it is intact. If it has paper or cloth wrapping, be sure there are no indications that it has ever been wet.

For guidelines related to sterile technique and preparing and maintaining sterile fields,

Go to **Clinical Insight 23-7: Guidelines for Observing Sterile Technique,** in Volume 2.

Preparing and Maintaining Sterile Fields

There are some variations in how you might set up sterile fields. Sometimes it is as simple as opening a package of supplies wrapped in a sterile disposable cover. The inside of the cover becomes your sterile field; the supplies on it are sterile, as well. At other times, you may work with a larger, reusable or disposable sterile drape (wrapped in an outer wrapping). In that situation, you open the outer wrapping, then pick up the sterile drape grasping only the corners, and allow it to fall open to create a sterile field, perhaps to entirely cover a table surface or to create a sterile field on the patient's bed.

In any sterile field, only the horizontal plane (e.g., the table top) is considered sterile. Consider nonsterile any material that drapes over the horizontal plane. A 1-inch margin around the edges of the sterile field is also considered unsterile because it is in contact with contaminated surfaces.

The box Highlights of Procedures 23-1 Through 23-8 contains a summary of how to prepare and maintain a sterile field, as well as add supplies and sterile liquids to it. For complete procedural steps,

Go to **Procedure 23-8A: Setting Up a Sterile Field,** in Volume 2.

Adding Supplies to a Sterile Field

Some supplies (e.g., urinary catheter kits) are packaged in a wrapper that can form a sterile field. The outside of these packages is considered clean, and the inside is sterile. You must open these packages in a way that does not contaminate the inside of the wrapping. Be cautious when adding supplies to the sterile field. If they are light and small, gently add them to the sterile field by separating the package flaps and allowing them to fall onto the field. If the object is large, such as an irrigation bowl, slowly unwrap the packaging and, touching only the outside wrapper, place the bowl on the field. If any object falls only partly on the field, it is no longer sterile. For detailed instructions on how to add supplies to a sterile field,

Go to **Procedure 23-8B: Adding Supplies to a Sterile Field,** in Volume 2.

Adding Sterile Solutions to a Sterile Field

Add sterile liquids to a sterile field by gently pouring them into a container on the field. Some sterile drapes contain an impermeable membrane between layers. This membrane serves as a barrier to moisture and prevents wicking. With this type of drape, you may pour sterile liquid directly on gauze pads on the field. Pour only an amount of liquid that is sufficient to make the gauze pads damp. Excess fluid may run off the field, causing the field to become contaminated—a wet field is not sterile because it does not provide a barrier to microorganisms on the unsterile surface under the drape. For step-by-step instruction in how to add sterile solutions to a sterile field,

Go to **Procedure 23-8C: Adding Sterile Solutions to a Sterile Field,** in Volume 2.

KnowledgeCheck 23-8

- When will you need to don sterile gloves using the closed method?
- (True or false) Some procedures require both standard precautions and sterile technique.
- What part(s) of a sterile field are considered to be unsterile?

INFECTION CONTROL AND PREVENTION FOR HEALTHCARE WORKERS

It is critical that you learn how to protect yourself from infections. You want not only to avoid personal illness, but also to avoid becoming a reservoir for infection. Nurses and other patient care workers are at great risk of acquiring infections because they come in contact with a large number and variety of pathogens. Skin contact, mucous membrane contact, and puncture wounds often serve as portals of entry.

Nursing assistive personnel (NAP), ancillary personnel, and housekeeping and maintenance workers are often present on nursing units. Visitors, volunteers, and family are also on the unit. It is essential that you protect them from potential hazardous exposure as well as protect yourself and patients from possible microorganisms brought into the unit. As a nurse, you need to monitor other healthcare workers, patients, and visitors for breaks in infection control and prevention.

BOX 23-3 ■ Common Breaks in Sterility

To avoid common breaks in sterility:

- Never reach across a sterile field.
- Make sure your clothing or lab coat never touches any part of the sterile field.
- Keep your fingernails short and clean. Avoid nail polish and artificial nails.
- Avoid wearing jewelry that dangles or can fall into the sterile field.
- Keep long hair pulled back, or covered by a head covering designed for sterility.
- Change your gown or reinforce with additional sterile drapes if it is soaked through.
- Avoid splashing any kind of solution onto the sterile field.
- Keep doors closed so turbulent airflow does not contaminate a sterile area with airborne microbes.
- Make sure you are opening equipment packaged with labels indicating it has been sterilized properly.
- Clean wounds and prep sterile sites from clean to dirty.
- When witnessing someone else contaminate a sterile field or object, identify the break and cover the area with sterile drapes or replace with a new sterile setup, gown, or gloves.

Source: Adapted from Simko, L. (2012). Breaking sterility: Procedural violations in healthcare. *Nursing 2012*, *42*(8), 22–26.

What Role Does the Infection Preventionist Nurse Play?

The task of the infection prevention nurse is to minimize the number of infections in the healthcare facility. Because it is not possible to provide absolute protection all the time, the nurse must balance the risks for infection with the costs of protective measures and the benefits of various strategies. Infection preventionists must keep current with information about pathogens, antibiotic resistance, and infection control. The nurse also functions as an epidemiologist, tracking down the source of HAIs and strengthening measures to prevent their recurrence. Finally, all members of the infection prevention team enforce compliance with federal, state, and local regulations related to infection control and prevention.

What Should I Do If I Am Exposed to Bloodborne Pathogens?

Exposure to blood, body secretions, or body tissues containing blood or secretions requires immediate action. See Box 23-4 for complete instructions. The first step is to minimize the exposure by washing the area thoroughly. Then notify the appropriate people, complete an injury report, and seek medical attention.

Anyone exposed to bloodborne pathogens should have baseline lab work done to check for hepatitis and HIV. If the patient source is known, the infection preventionist

BOX 23-4 ■ If You Are Exposed to Blood or Other Body Fluids

If you are stuck by a needle or other sharp, or get blood or other potentially infectious materials in your eyes, nose, mouth, or on broken skin:

1. Immediately flood the exposed area with water and clean any wound with soap and water or a skin disinfectant if available.
2. Report the exposure immediately to the appropriate person in the agency. If you are a student, also report immediately to your instructor.
3. Seek immediate medical attention. Consent to testing and follow-up treatment as advised.
4. Complete an incident or injury report.
5. Attend counseling sessions provided by the agency.

Source: Occupational Safety & Health Administration. U.S. Department of Labor. (n.d.). Bloodborne pathogens and needlestick prevention. Post-exposure evaluation. Retrieved January 21, 2013, from http://www.osha.gov/archive/SLTC/bloodbornepathogens/postexposure.html

will arrange to have the patient tested. Subsequent testing and possible preventive treatment are based on the type of exposure and what is known about the source and the injured person. To limit risks from the exposure, the infection prevention team will provide counseling and recommendations as soon as possible after the event. Chapters 24 and 26 present information on preventing needlestick injuries.

How Can I Minimize the Effects of Bioterrorism and Epidemics?

Bioterrorism is the intentional release, or threatened release, of disease-producing organisms or substances for the purpose of causing death, illness, harm, economic damage, or fear. Five diseases with recognized bioterrorism potential are anthrax, botulism, pneumonic plague, smallpox, viral hemorrhagic fevers, and tularemia. The U.S. government has recently funded development of drugs to treat three of these diseases (anthrax, plague, and tularemia).

Recognize an Outbreak Should a biological event occur, either as a result of bioterrorism or a naturally occurring epidemic, a key factor in minimizing its effects is the ability to quickly recognize unusual disease patterns and detect the presence of infectious diseases. Some electronic patient record systems include special pattern identification programs. The use of these systems supplements, but does not replace, clinical observation skills. Nurses need to assess not only the individual patient's condition, but also clusters of symptoms. Hospital, emergency department, and clinic nurses are in key positions to recognize outbreaks because they see patients from multiple primary care providers. Nurses must keep the following questions in mind:

- Am I seeing an unexpected number of infectious diseases, or diseases possibly caused by infectious organisms?
- Am I seeing similar cases that are not responding to medical treatment?
- Are healthcare workers who come in contact with infectious patients becoming ill?

Notify the Safety Officer After identifying a suspicious pattern, you should notify the institution's interventionist or safety officer as soon as possible. Appropriate cultures will be needed, and the federal and state health departments should be notified. If the infectious organism is unknown, samples must be preserved for future analysis.

Institute Appropriate Level of Standard Precautions In the event of an epidemic, the essential principles of hand hygiene and standard precautions will be the core of your infection prevention and control measures. Patients with similar symptoms should be cared for by a minimum number of healthcare personnel, and those personnel must use appropriate isolation precautions. If the etiology and transmission route of the causative organism are unknown, standard, contact, and airborne precautions should be implemented as needed. The Occupational Safety and Health Administration (OSHA) defines types of personal protective equipment and situations in which you are required to wear it (U.S. Department of Labor, n.d.).

Prepare Clients for a Pandemic Teach clients that preparing for pandemic disease is similar to preparing for other general kinds of emergency preparedness, such as power outages and natural disasters (see Self-Care: Teaching Your Patient About Preparing for a Pandemic Disease Outbreak).

Summary

After studying this chapter, you should be armed with the basic knowledge you need to protect yourself and your clients from infection. However, knowledge is not enough. Research continues to show that healthcare professionals too often fail to comply with guidelines for infection prevention, especially the seemingly simple measures such as hand hygiene and standard precautions. Although healthcare workers must wash their hands, patients do not necessarily feel comfortable asking them to do so (Ottum, Sethi, Jacobs, et al., 2012). Your role as a nurse is to integrate the best current evidence with your clinical expertise and, through your own individual performance, to minimize harm to patients and others. This includes using technology and standardized practices that support patient safety and quality.

Wash your hands! Follow standard precautions!

If you would like to know more about microbiology,

Self-Care

Teaching Your Patient About Preparing for a Pandemic Disease Outbreak

- Make a preparedness plan with your family and others in the community (e.g., school, business, church groups). Help organize local response planning and be available to help if there is an outbreak. Participate in emergency planning at work and get training if it is available.
- Talk with family members about what will be needed to care for them in your home if someone becomes ill.
- Expect that usual community services may be disrupted—for example, banks, stores, post offices, and even hospitals and public buildings may be closed
- Store a 2-week supply of bottled water and food. Keep extra nonperishable foods. Examples of food and nonperishables include:

  Ready-to-eat canned meats (e.g., ham, tuna)

  Canned fruits, vegetables, beans, soups

  Protein or fruit bars

  Dry cereals

  Peanut butter or nuts

  Dried fruit and nuts

  Crackers

  Canned juices

  Canned baby food and formula, if an infant is in the home

  Pet food, as needed
- Periodically check your regular prescription drugs to keep a continuous supply on hand.
- Have nonprescription drugs and health supplies on hand. Examples include:

  Medical supplies, such as blood pressure and glucose monitors

  Medicines for fever (e.g., acetaminophen, ibuprofen)

  Thermometer

  Soap and water or alcohol-based, antibacterial hand gel

  Antidiarrheal medication

  Vitamins

  Fluids with electrolytes
- Keep a 2-week supply of other emergency supplies on hand, such as a flashlight, batteries, portable radio, manual can opener, trash bags, tissues, toilet paper, and disposable diapers.
- Keep your family's health information up to date, organized, and accessible.
- Make sure you have more than one method to communicate (e.g., telephone and e-mail) and that you can get information from the outside world (including by battery-powered radio).
- Be sure everyone in the family washes hands frequently and properly and covers coughs and sneezes with tissues.
- Teach family members to stay away from others as much as possible if they are sick. Stay home from work and school if sick.
- Get an annual seasonal influenza vaccination.
- Explore the possibility of working by telecommuting during a pandemic to avoid unnecessary exposure.

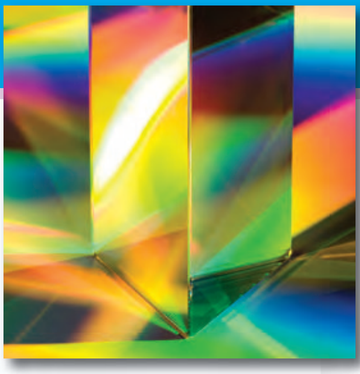
CHAPTER 24



Promoting Safety

Learning Outcomes

After completing this chapter, you should be able to:

- List the three leading causes of accidental death in the United States.
- Discuss developmental and individual factors that create safety risks.
- Identify at least five safety hazards in the home environment and interventions to prevent injury from them.
- Discuss the steps to follow when you suspect that a client has ingested a poisonous substance.
- Describe the choking rescue maneuver, and identify instances when it is appropriate to use it.
- Describe the four main physical hazards that are found in the community and interventions to prevent injury from them.
- Describe and give examples of hazards that we encounter in the healthcare agency.
- Identify four interventions to prevent falls in the healthcare agency.
- Discuss the appropriate use of siderails in the healthcare agency.
- Properly apply restraints and discuss measures to prevent injury in clients who are restrained.
- Discuss at least one data collection instrument that is used to assess the client who is at risk for falls.
- Formulate a nursing diagnosis in relation to preventing injury in the environment.
- Write an individualized goal for clients with a nursing diagnosis of Risk for Falls.

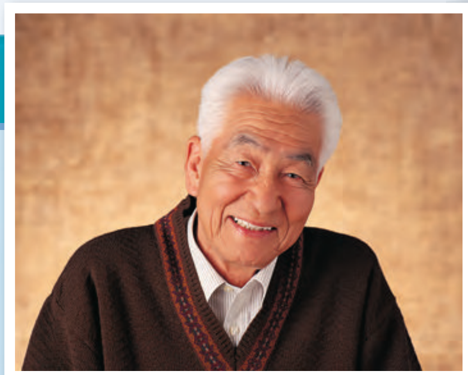
Example Problem

Falls

Meet Your Patient



1. **Alvin Lin.** Alvin Lin is a 79-year-old man who was just transferred from a long-term care facility to your medical unit. His admitting diagnosis is dehydration and pneumonia. In the morning report you were told that he had rested well during the night and was alert and oriented. When you enter his room, he is confused and does not know where he is. He is becoming combative and is trying to get out of bed. How should you respond to the situation?
2. **Teresa.** Suppose you are a nurse making a home visit to Teresa, who lives in a rural area. Teresa is 20 years old and has a 2-year-old daughter. She is also responsible for caring for her elderly grandmother, who is recovering from a hip fracture. Teresa states that it is getting more difficult to keep up with her toddler, who is "into everything," and to care for the needs of her grandmother. Her grandmother has a fear of falling and is reluctant to do anything for herself.

Theoretical Knowledge knowing why

This chapter will increase your ability to recognize safety hazards in the home, community, and healthcare facility, and to plan interventions that promote safety for clients of all ages, such as the two in the Meet Your Patients scenario. Many accidental injuries can be prevented by being aware of hazards and taking reasonable precautions.

ABOUT THE KEY CONCEPTS

Safety is a basic human need, second only to survival needs such as oxygen, nutrition, and fluids. As a nurse, the concept of safety is fundamental to providing high-quality care to your clients. A contribution of nursing to **patient safety**, in any setting, is the ability to coordinate and integrate the multiple aspects of quality within the care directly provided by nursing, and across the care delivered by others in the setting. You must also be concerned with your own safety and the safety of other care providers. Many accidental injuries can be prevented by being aware of hazards and taking reasonable precautions.

IMPORTANCE OF SAFETY

According to the National Safety Council (NSC), accidents, or unintentional injuries, are the fifth leading cause of deaths in the United States. More than 118,000 people die each year as a result of accidents (NSC, 2011). Expressed another way, one person dies from an accident every 5 minutes. Poisoning is now listed as the number one cause of unintentional death, followed by motor vehicle accidents, firearms, falls, drowning, and fires. Of course, the death rate is not the only significant number: In 2008, approximately 26 million people received injuries that disabled them beyond the day of injury (NSC, 2010) (see Table 24-1). Many healthcare organizations are campaigning for safer patient care in an effort to reduce the cost of healthcare and the burden of suffering. The following are examples:

- **The Joint Commission**, the accrediting body for healthcare facilities, each year publishes National Patient Safety Goals. For example, in 2013 the goals included improving the accuracy of patient identification, improving the safety of medication use, reducing the risk of healthcare-associated infections, and preventing mistakes in surgery. For a link to the 2013 National Patient Safety Goals,

Go to Chapter 24, **Resources for Caregivers and Healthcare Professionals,** on Davis*Plus*.

- **Institute of Medicine's (IOM)** report, *To Err Is Human: Building a Safer Health System,* brought public attention to patient safety. It stated that it is simply not acceptable for patients to be harmed by the same healthcare system that is supposed to offer healing and comfort. The report identified five critical principles to ensure safe healthcare systems: provide leadership, recognize human limits in process design, promote effective team functioning, anticipate the unexpected, and create a learning environment (IOM, 2001). To learn what is meant by a "culture of safety" in the healthcare setting, read the accompanying QSEN box.
- **American Nurses Association (ANA). The** ANA's *Health System Reform Agenda* (2010) recommends six major public policy changes that can raise the quality of healthcare. Quality Aim 1 is safe healthcare.
- **Quality and Safety Education for Nurses (QSEN Institute)**. This task force to improve nursing education identified and described six competencies that all nursing students should have by graduation. Safety is one of those competencies (Cronenwett, Sherwood, Barnsteiner, et al., 2007; Cronenwett, Sherwood, & Gelmon, 2009). For a list of the essential features that demonstrate the safety competence,

Go to Chapter 24, **ESG Table 24-1, QSEN Safety Competency,** on Davis*Plus*.

- **Medicare.** This federal agency has identified "**never events**" or hospital-acquired conditions (HAC): costly errors that cause serious injury or death, and that are mostly preventable (e.g., falls, injury from restraints). Medicare will no longer pay institutions for care required to treat the effects of such errors (Centers for Medicare & Medicaid Services, 2006a, modified 2011).

Table 24-1 ➤ Leading Causes of Unintentional Deaths in the United States.

MECHANISM OF INJURY	TOTAL ANNUAL DEATHS, ALL AGE GROUPS
Poisoning and exposure to noxious substances	41,592
Motor vehicles	34,485
Firearms	31,347
Falls	25,562
Drowning	3,517
Fires, flames, and smoke	2,756

WHAT FACTORS AFFECT SAFETY?

To promote client safety, you will need theoretical knowledge about developmental stages and individual risk factors that affect clients' ability to avoid accidental

Quality and Safety Education for Nurses

Creating a Culture of Safety

Chapter Key Concept: *Safety*

Competency: *Safety (Knowledge, Skills, Attitudes)**

Background: Until recently the healthcare industry assumed that correct (safe) actions would be performed by all dedicated practitioners and that people who made mistakes were "bad apples" to be fired. Mistakes were hushed up. This culture of secrecy and blame still exists, with a high cost to society and a huge impact of medical mistakes on patients and their families.

The Institute of Medicine (IOM) has called for healthcare organizations to work to dismantle the culture of secrecy and blame and to create a culture of safety. It calls for nurses to be leaders in these efforts. The Quality and Safety Education for Nurses (QSEN) competencies were created specifically to help prepare nurses for these roles.

Think about it: Although people make the mistakes, it is system factors that create a mistake-prone environment. Understanding the types of errors that occur in your facility should suggest baseline knowledge and skills you need to acquire. It is equally important to determine what systems need to be in place to build the culture of safety. Some critical features include:

- All staff members providing care are formally encouraged to communicate their concerns to the team. ***Why do you think nurses or junior doctors might not communicate concerns?***
- All information needed to appropriately manage the patient across shifts, units, facilities or after other handoffs is available at all times. ***What types of errors can occur during handoffs?***
- Facility adopts a nonpunitive response to error and uses strategies such as root cause analysis to identify system issues. ***What effect might a punitive culture have on error reporting?***
- Facility recognizes both individual and system causes of error but emphasizes a systems approach to error reduction. ***Describe one system that can break down and make error more likely.***
- Each person providing care acknowledges own potential for error and values own role in preventing errors. ***What can you do to help prevent errors?***

Sources: IOM (Institute of Medicine (IOM) (2001, 2011).

***To learn about specific QSEN Safety Knowledge, Skills, and Attitudes,**

Go to the QSEN web site **at http://qsen.org/competencies/pre-licensure-ksas/**

injury. This chapter discusses specific risk factors and describes hazards in three environments: the home, the community, and the healthcare agency.

Developmental Factors

The type and incidence of accidents vary among age groups. You will find interventions for all age groups integrated into the topics throughout this chapter. Keep in mind that the descriptions given for each age group are characteristics common to most people in that group. However, individuals progress through developmental stages at their own pace, so there will always be some people who do not fit the group description closely. For supplemental discussion of safety needs during different developmental stages, review Chapter 9.

Infant/Toddler Drowning is the leading cause of death for children ages 1 to 4, followed by motor vehicle accidents (*Morbidity and Mortality Weekly Report*, April 16, 2012). Falls, choking, sudden infant death syndrome (SIDS), and ingesting poisons are other critical safety concerns. Infants and toddlers are completely dependent on others for their care. They are able to walk and manipulate objects before they have the judgment to recognize dangers such as falling. In addition, infants and toddlers are curious and tend to explore the environment by putting objects in their mouth. This is why the incidence of choking is highest between 6 months and 3 years of age. As mobility continues to improve, toddlers gain more freedom, and their curiosity leads them to explore cupboards, stairs, open windows, swimming pools, and other hazards (Centers for Disease Control and Prevention [CDC], 2012).

Preschooler Motor vehicle injuries are a major cause of accidental death, along with drowning, fires, and poisoning. Falls are the primary cause of nonfatal injuries. After age 3, children are a little less prone to falls because their gross and fine motor skills, coordination, and balance have improved. However, as they begin to play more outside (playgrounds, pools, front yards, and so on) there are additional safety concerns. Although preschoolers are more aware of dangers and limitations, adult supervision continues to be essential.

School-Age Child Motor vehicles continue to be the leading cause of accidental death in this age group. Falls are the leading cause of nonfatal injuries. School-age children have developed more refined muscle coordination and control, and improved decision-making skills. However, because they become more involved in activities outside the home, bone and muscle injuries are common. Injuries are often related to sports, skateboarding, bicycle riding, and playground injuries. Most school-age children are less fearful than are toddlers, and are ready to try any new skill with or without practice or training. Exposure to the wider school and neighborhood environment also increases the risk for injury inflicted by people outside the home (e.g., abduction).

Adolescent The leading cause of death in this age group is motor vehicle accidents, followed by homicide—both frequently associated with alcohol and drug use. Sports and recreational injuries, including diving and drowning incidents are also common, especially when drinking and drug use are involved. Peak physical, sensory, and psychomotor abilities give teenagers a feeling of strength and confidence, yet they lack the wisdom and judgment of adults. This combination, along with feelings of being indestructible, makes them more likely to participate in risk-taking behavior, and in turn, more prone to injury.

Adult Among people 35 to 64 years old, unintentional poisoning causes more deaths than motor vehicle accidents (CDC, 2010a). Workplace injury may also be a significant concern. Other injuries to adults are related to lifestyle (e.g., excessive alcohol use), stress, carelessness, abuse, and decline in strength and stamina. For many, work and family responsibilities often leave little time for regular physical activity, increasing the risk of musculoskeletal injury in the so-called weekend athlete.

Older Adult Although many older adults have intact senses that enable them to continue to enjoy life as they age, physiological changes do occur (e.g., reduced muscle strength and joint mobility; slowing of reflexes; decreased ability to respond to multiple stimuli; and sensory losses, particularly hearing and vision). These changes increase the older adult's risk for falls, burns, car accidents, and other injury. Falls are the most common cause of accidental death for adults age 65 and older (CDC, n.d.a).

Individual Risk Factors

In addition to developmental stage, individual factors also influence a person's risk for unintentional injury. These include lifestyle, cognitive awareness, sensoriperceptual status, ability to communicate, mobility status, physical and emotional health, and awareness of safety measures (Table 24-2).

KnowledgeCheck 24-1

- What are some important developmental considerations when providing a safe environment for a preschool child?
- What is the main cause of injuries during the adolescent period?
- What are some ways that the aging process makes the older adult more prone to injury?
- Based on your theoretical knowledge and the scant patient data you have, why do you think Teresa's toddler (Meet Your Patients) is at risk for accidents? What about Teresa's grandmother?

SAFETY HAZARDS IN THE HOME

What safety issues in the home environment would you need to assess with regard to Teresa's toddler and grandmother (see Meet Your Patient)? If you cannot already answer the question about Teresa's family and home, you should be able to do so after reading this section which provides an overview of safety hazards in the home.

Except for motor vehicle accidents, most fatal accidents occur in the home. The leading causes of death in the home are poisonings, falls, fires and burns, and choking. For children, having older siblings, maternal age, financial difficulties, and maternal mental health problems are associated with less safe homes (Myhre, Thoresen, Grøgaard, et al., 2012).

Poisoning

Poisoning death rates have more than quadrupled in the past 20 years. Although young children are frequent victims, the increase has been mainly among adults. In many cases, the person does not die but becomes ill or suffers other effects. Poisoning exposure accounts for about 2,000 emergency department visits per day (CDC, 2010b).

- ***Young children*** are poisoned mostly because of improper storage of household chemicals, medicines and vitamins, and cosmetics. Box 24-1 lists poisonous agents commonly ingested by children.

Table 24-2 ➤ Individual Risk Factors for Injury

RISK FACTORS	BEHAVIOR MANIFESTATION
Lifestyle	Smoking, alcohol abuse, risk-taking behaviors
Cognitive awareness	Confusion due to stress and loss of short-term memory
Sensory and perceptual status	Loss of senses (e.g., vision, hearing, pain), which provide first line of defense
Impaired communication	Language barriers and hearing and speech impairment related to disease processes
Impaired mobility	Impaired strength with accompanying problems in mobility, balance, and endurance
Physical and emotional well-being	Reduced physical stamina and depression, with feelings of loss of control and helplessness
Safety awareness	Reduced cognitive awareness (e.g., of older adult) and immature development of the child

BOX 24-1 ■ Poisonous Agents Commonly Ingested by Children

- Household cleansers, including oven cleaner, drain cleaner, toilet bowl cleaner, and furniture polish
- Medicines, including cough and cold preparations, vitamins, pain medications, antidepressants, anticonvulsants, and iron tablets, which to children may look like candies
- Indoor house plants, including poinsettia, Dieffenbachia, philodendron, and many others
- Cosmetics, hair relaxer, nail products, mouthwash
- Pesticides
- Kerosene, gasoline, lighter fluid, paint thinner, lamp oil, antifreeze, windshield washer fluid, lighter fluid, and other chemicals
- Alcoholic beverages
- Wild plants and mushrooms
- Pesticides, rodent poisons

The use of lead in paint has been banned since 1978, but lead-based paint can still be found in older homes and toys produced in some foreign countries. Some soil (which young children often put in their mouth) contains high levels of lead. In the United States, poor, urban, and immigrant populations are at higher risk for lead exposure than other groups.

- ***Older children and adolescents*** may attempt suicide by overdosing with medicines or be poisoned accidentally when experimenting with recreational or prescription drugs intended for adults. In adults, most poisonings occur as a result of illegal drug use or misuse or abuse of prescription drugs, especially narcotic medications, tranquilizers, and antidepressants.
- ***Deaths from prescription painkillers*** have reached epidemic levels in the past decade, now greater than deaths from heroin and cocaine combined. A big part of the problem is nonmedical use of prescription painkillers—using drugs without a prescription, or using drugs just for the "high" they cause. In 2010, about 12 million Americans (age 12 or older) reported nonmedical use of prescription painkillers in the past year (CDC, 2011a).
- ***Treatment choice*** depends on the poison ingested. For most poisonings, the most effective intervention is professional administration of activated charcoal orally or via gastric tube. However, charcoal is not effective for ethanol, alkali, iron, boric acid, lithium, methanol, or cyanide. Depending on the situation, other options for medical treatment include gastric lavage, dialysis, administration of antidotes, and forced diuresis. For a list of medical treatments for commonly ingested poisons,

Go to Chapter 24, **Tables, Boxes, Figures: ESG Table 24-2,** on Davis*Plus*.

Never induce vomiting when the ingested material is acidic or caustic to the esophagus. Although the American Academy of Pediatrics no longer recommends inducing emesis (e.g., with syrup of ipecac), some practitioners may still do so. The National Capitol Poison Center does not support the routine stocking of ipecac in households with young children. The organization states that it should be given only on specific recommendation from a poison center or qualified medical personnel (National Capitol Poison Center, n.d.).

Carbon Monoxide Exposure

Carbon monoxide (CO) is a colorless, tasteless, odorless toxic gas. Exposure can cause headaches, weakness, nausea, and vomiting; prolonged exposure leads to seizures, dysrhythmias, unconsciousness, brain damage, and death. Each year in the United States, CO poisoning causes approximately 500 unintentional deaths (Bronstein, 2011). Most CO exposures occur at home and most often involve females, children under age 17 years, and adults aged 18 to 44 years. It accounts for a majority of deaths at the scene of fires, and is also a relatively common method of suicide. Many CO deaths occur during cold weather among older adults and the poor who seek nonconventional heat sources (e.g., gas ranges and ovens) to stay warm.

Scalds and Burns

The following are common causes of scalds and burns:

- ***Scald injuries*** (e.g., from hot water, steam, or grease) are the most common cause of burns in children younger than age 3. Scalding burns (especially on both feet or both hands) and cigarette burns in children and vulnerable older adults should always prompt you to assess for abuse (see Procedure 9-1).
- ***Warming food or formula in the microwave*** may cause the food to become hotter than intended, leading to burns in infants and young children.
- ***Sunburn*** can cause a first- or second-degree burn.
- ***Contact burns*** may occur from contact with metal surfaces and vinyl seats when cars are parked in the sun. The risk of contact burns in all age groups is greater in the presence of such heating devices as kerosene heaters, wood-burning stoves, and home sauna heating elements. People may use these as heat sources when they cannot afford the cost of traditional furnace fuels.
- ***Chemical agents***, such as acid, alkali, or other organic compounds, can also cause localized burns.

Fires

Home fires are a major cause of death and injury. Older adults and children younger than age 5 years have the greatest risk of fire death. Most *fatal* home fires occur while people are asleep, and most fire-related deaths occur from smoke inhalation. The following are common causes of fire in the home:

- *Cooking fires* are the number one cause of home fires and home fire injuries.
- *Smoking* (e.g., cigarettes) is the leading cause of fatal home fires, but during the winter months, *heating equipment* is equally responsible.
- *Home oxygen administration equipment* is also a hazard. In 75% of the home fires involving oxygen, smoking materials are the ignition source; cooking and candles are other common factors. When more oxygen is in the air, items such as hair, plastic, skin oils, clothing, and furniture catch fire at lower temperatures, so any fire that starts will burn hotter and faster. Other causes of fire include unsupervised children playing with matches, improper use of candles, and faulty wiring.

Example Problem: Falls

Falls are the third leading cause of injury-related deaths—the leading cause for older adults. An average of 4 in 100 people experience a nonfatal fall for which they seek medical advice. The rate triples for adults older than age 75 (Adams, Martinez, Vickerie, et al., 2011). More than half of all falls occur in the home, and about 80% of home falls involve people age 65 years and older. Health issues that increase the risk for falls include poor vision, hypotension (low blood pressure), a history of falls, dizziness, pain, alcohol use, cognitive impairment, polypharmacy, arthritis, gait or balance deficits, and age greater than 80 years (Akyol, 2007; Malafarina, Úriz-Otano, Iniesta, et al., 2012).

Firearm Injuries

Gun ownership is a controversial issue. Some people keep guns in the home for protection and/or recreation (e.g., hunting, target shooting). However, guns are a source of unintentional injury and death. Gun safety and security are especially important when there are children in the home or someone with a substance abuse problem. Household access to firearms has been implicated as a risk factor for youth suicide and domestic homicide, as well as unintentional injury (Hizel, Ozcebe, Sanli, et al., 2008; Lewiecki & Miller, 2013). Because of the frequency and severity of unintentional firearm injuries involving children, the American Academy of Pediatrics and other groups have mounted efforts to educate parents about firearm safety.

ThinkLike a Nurse 24-1

- What are some initial questions you might ask Teresa regarding her home environment?
- What are some basic interventions you might suggest to Teresa to help child-proof her home? To answer this question, you will need to recall information about:
  Safety hazards that we encounter in the home
  Developmental and lifestyle factors that affect safety
  Specific nursing activities that can be used to prevent accidents or injuries related to the environmental hazards (e.g., firearms)

Suffocation/Asphyxiation

Suffocation by smothering is the leading cause of death for infants younger than 1 year. Suffocation may also be caused by drowning, choking on a foreign object, or inhaling gas or smoke. Suffocation of infants is often related to bed or crib hazards, such as excess bedding or pillows, or toys hung from long ribbons inside the infant's crib. Infants can become entangled in cords from window blinds or in the ribbon or string used to hang a pacifier around an infant's neck.

Drowning is an important cause of accidental death in children 1 to 18 years old. **Key Point:** ***Children up to age 4 are especially at risk for drowning and should never be left unattended in or near a bathtub, hot tub, swimming pool, or other source of water. Even wading pools, toilets, and mop buckets hold enough water to drown a small child.***

Food items, including hot dogs, raw vegetables, popcorn, hard candies, nuts, and grapes, are responsible for most nonfatal choking incidents. Nonfood items, such as latex balloons and plastic bags, cause the majority of suffocation deaths in young children.

KnowledgeCheck 24-2

- What are the most common poisonous agents ingested by children?
- Name one source of carbon monoxide (CO) poisoning.

Take-Home Toxins

Take-home toxins are hazardous substances transported from the workplace to the home. The National Institute for Occupational Safety and Health (NIOSH) reports that pathogenic microorganisms, asbestos, lead, mercury, arsenic, pesticides, caustic farm products, and dozens of other agents cause significant morbidity and mortality in workers' homes (NIOSH, 2004). These toxins are most likely transported to workers' homes on the workers themselves, on their clothing, or on objects brought from the workplace. In the home, contamination occurs via any of three sources:

- Direct skin-to-skin contact, or direct contact with contaminated clothing
- Arthropod vectors, such as ticks that are responsible for Lyme disease
- Transmission on dust particles that are inhaled (e.g., anthrax spores, arsenic in mine and smelter dust)

SAFETY HAZARDS IN THE COMMUNITY

Hazardous agents in the community are a major contributor to illness, disability, and death worldwide. This section discusses four major topics of concern: motor vehicle accidents, pathogens, pollution, and electrical storms.

Motor Vehicle Accidents

Motor vehicle accidents (MVAs) are a leading cause of accidental death in American adults and children older than 1 year of age. They account for about 34% of all accidental deaths (CDC, n.d.b). The risk of being injured or killed in a car crash increases for older drivers. Every day, on average, 500 people over age 65 are injured in an automobile accident.

Failure to use seat belts and proper child car seats continues to be the major contributing factor. Severe injuries and death also occur from air bag deployment when young children are improperly placed in the front passenger seat. Other risk factors for MVAs and related injuries and deaths include speed, alcohol, and nonuse of helmets. More recently, driver distraction, particularly due to cell phone use, has become an emerging concern. Although laws exist curtailing or banning their use in almost all states, a recent survey of drivers reported cell phone use while driving at least once in the past 30 days ranged from 21% in the UK to 69% in the United States; the prevalence of drivers who had read or sent text or e-mail messages while driving at least once in the past 30 days ranged from 15% in Spain to 31% in Portugal and the United States (*Morbidity and Mortality Weekly Report*, March 15, 2013).

Pathogens

A **pathogen** is any microorganism capable of causing an illness. Pathogens can enter the body through several sources in the environment: food, mosquitoes and other insects, rodents and other animals, and unclean water.

Foodborne Pathogens

Food poisoning is a nonspecific term that describes illness caused by ingesting bacteria and other microorganisms, or their toxins, in food. Improper food storage and preparation are a major cause of food poisoning. Raw foods are commonly associated with foodborne illness, for example, raw meat, poultry, eggs, shellfish, raw fruits and vegetables, and unpasteurized milk and fruit juice. Poisonous chemicals in the environment, such as mercury, arsenic, zinc, and potassium chlorate, may also contaminate foods. Education is an important intervention for preventing food poisoning. See the section Intervention: Teaching for Safety Self-Care in the Community, and the Self-Care box Food Safety, later in the chapter.

Vectorborne Pathogens

Vectors are organisms that transmit pathogenic bacteria, viruses, and protozoa from one host to another. The following are examples:

Mosquitoes The severity of the reaction to a mosquito bite depends on the degree of allergy to the mosquito's saliva. In addition to the discomfort caused by their bites, infected mosquitoes can transmit diseases, such as West Nile virus and malaria. They can also transmit parasites to domestic animals (e.g., dog heartworm, equine encephalitis).

Other Insects Other insects, such as roaches, fleas, sand flies, lice, and ticks (which are, technically, arachnids and not insects) can also transmit serious diseases and produce a wide variety of allergens. Allergic sensitivity to cockroaches, for example, is a predictive factor for asthma severity (Page, 2012).

Animals Rodents and other animals can also act as vectors and allergens. For example, rabies can be spread through the bite of a rabid animal, some fungal diseases can spread via the inhalation of bird droppings, and mouse proteins have been implicated in the occurrence of asthma. Structural defects in a building (e.g., roofs and walls) permit entry of birds, rodents, and other small animals, and dead spaces in walls permit their circulation among apartments in multiunit dwellings (Berg, McConnell, Milam, et al., 2008; Holt, Theall, & Rabito, 2012).

Waterborne Pathogens

Sanitation refers to measures to promote and establish favorable health conditions, especially those related to the community's water supply. People who live in substandard housing may not have safe drinking water, hot water for washing, or adequate methods of waste disposal. People in rural areas often depend on private wells, which may not be adequately maintained and tested for pathogens such as *Giardia lamblia*, *Cryptosporidium*, and *Escherichia coli*. These are primarily community health problems.

Pollution

Pollution is any harmful chemical or waste material discharged into the air, water, or soil. Examples of pollutants are gaseous fumes, asbestos, carbon monoxide, and cigarette smoke. Each year Americans generate millions of tons of waste in their homes and communities (U.S. Environmental Protection Agency [EPA], 2008).

Air Pollution Motor vehicle emissions are a major cause of *outdoor air pollution* in the United States. Other toxic air pollutants include asbestos; toluene; metals such as mercury, chromium, and lead compounds; and other emissions from factories and power plants. *Indoor pollutants* include radon; carbon monoxide; and allergens from dust mites, cockroaches, mold, rodents, and pets. Passive exposure to tobacco smoke is associated with respiratory disease and cancer; and environmental air pollution is linked to cardiovascular disease and respiratory viral infection (Kit, Simon, Brody, et al., 2013; National Cancer Institute, n.d.; Pope, Burnett, Turner, et al., 2012; U.S. Department of Health and Human Services [USDHHS], 2006).

Water Contamination Contamination in lakes, rivers, and streams ultimately affects both recreation and food production. Pollution occurs when inadequately treated or inappropriate quantities of human, industrial, or agricultural wastes are released into the water systems. If the pollution is severe enough, the water may become unsafe for human consumption.

Noise Substantial exposure to noise has been associated with a range of adverse health effects, including hearing loss, stress, elevated blood pressure, and loss of sleep. Noise is pervasive in our society—for example, from road traffic, jet planes, garbage trucks, construction equipment, lawn mowers, and loud music. People who live or work near major roads, bus depots, airports, and trucking routes are at greater risk, as are those in certain work environments (e.g., railroad workers).

Soil Improper waste disposal and excessive use of pesticides can contaminate soil. Agricultural, industrial, and manufacturing processes create solid and toxic waste. Animal, radioactive, and medical wastes pose special problems. Household products, such as paints, cleaners, oils, batteries, and pesticides, contain corrosive or toxic ingredients that contaminate the environment when disposed of improperly (e.g., in household trash or poured down the drain, on the ground, or into storm sewers).

Electrical Storms

According to the National Weather Service, deaths from lightning strikes lead all other categories of weather-related fatalities, exceeded in some years only by floods (Cooper & Kulkarni, 2011). Weather conditions play a major role in outdoor recreation programming. It is important for professionals, participants, and outdoor recreation providers to understand severe weather conditions, specifically thunderstorms and lightning, and the dangers associated with them.

KnowledgeCheck 24-3

SAFETY HAZARDS IN THE HEALTHCARE FACILITY

As many as 98,000 people die from medical injuries each year in U.S. hospitals (Pham, Aswani, Rosen, et al., 2012). Several characteristics of healthcare facilities pose safety hazards for residents and workers. We have discussed the hazard of infection in Chapter 23. Box 24-2 lists The Joint Commission's National Patient Safety Goals for 2013, which should give you an idea of the types of accidents that occur in healthcare agencies. If you would like to see a full explanation of the patient safety goals,

Go to The Joint Commission Web site, at http://www.jointcommission.org/assets/1/6/2011_NPSGs_HAP.pdf

BOX 24-2 ■ The Joint Commission 2013 Patient Safety Goals

Goal 1. Improve the accuracy of patient identification.

Goal 2. Improve effectiveness of communication among caregivers.

Goal 3. Improve the safety of using medications (including anticoagulants)

Goal 7. Reduce the risk of healthcare associated infections (including hand hygiene, multidrug-resistant organisms, central-line bloodstream infections, catheter associated urinary tract infections and surgical site infections).

Goal 8. Accurately and completely reconcile medications across the continuum of care.

Goal 15. The organization identifies safety risks inherent in its patient population.

Universal Protocol: The organization meets the expectations of the Universal Protocol. (This is a preprocedure verification process to make sure that all documents, information, and equipment are available, and that the correct procedure is performed on the correct person and site.)

Source: Adapted from The Joint Commission (2013).

In its report *To Err Is Human: Building a Safer Health System*, the Institute of Medicine (IOM) estimated that as many as 98,000 hospitalized Americans die each year—not as a result of their illness or disease, but as a result of errors in their care (IOM, 2000). This figure does not reflect the many patients who survive but sustain serious injuries. Organizational factors contribute to errors and to safety problems in healthcare, including poor design, maintenance failures, unworkable procedures, shortfalls in training, less than adequate tools and equipment, and inadequate staffing. Disruptive behaviors, intimidation in the workplace, and a culture of disrespect among healthcare professionals have also been reported as significant barriers to patient safety.

Healthcare has traditionally had a hierarchical nature with the physician at the top. In addition, healthcare professionals have been taught to practice with autonomy. This combination of factors set the stage for a culture that does not respond well to questions about possible problems with patient care, particularly from subordinates. It is clear that such a culture needs to be repaired, and many healthcare organizations are working to address disrespectful behavior, staff reluctance to speak up about risks and errors, and blatant disregard of expressed concerns.

Key Point: ***Since nurses are the healthcare professionals who spend the greatest amount of time with patients, research is beginning to document what physicians, patients, and nurses themselves have long known: How well clients are cared for by nurses affects their health and outcomes, and sometimes can be a matter of life or death.***

Studies have shown that greater numbers of patient deaths are associated with fewer nurses to provide care

(Aiken, Clarke, Sloane, et al., 2001), and less nursing time provided to patients is associated with higher rates of infection, gastrointestinal bleeding, pneumonia, cardiac arrest, and death from these and other causes (Kalisch, Tschannen, & Lee, 2012; Stimpfel & Aiken, 2013; Unruh & Zhang, 2012). In providing quality care to patients, nurses are indispensable to their safety.

What Are Never Events?

Never events can cause serious injury or death to a patient, and should *never* happen in a hospital. The list of never events has been expanded over time to mean events that are clearly identifiable and measurable, serious, and usually prevented. You can also gain insight into healthcare facility hazards by examining the following list of never events (Centers for Medicare & Medicaid Services, 2008; Watson, 2010):

- Foreign object (such as a sponge) left in patients after surgery
- Air embolism
- Administering the wrong type of blood
- Severe pressure ulcers
- Falls and trauma
- Injuries from burns, restraints, or bedrails
- Infections associated with urinary catheters
- Infections associated with intravenous catheters
- Symptoms resulting from poorly controlled blood sugar levels
- Surgical site infections following certain elective procedures (e.g., certain orthopedic surgeries, bariatric surgery for obesity)
- Deep vein thrombosis or pulmonary embolism following total knee and total hip replacement procedures.

The Institute for Healthcare Improvement (IHI), an independent, not-for-profit organization, launched the 100,000 Lives Campaign to recommend changes to reduce morbidity and death in American healthcare. At least three of the 100,000 Lives goals support the list of never events: Prevent adverse drug events, prevent central line infections, and prevent surgical site infections. To read the entire list of recommendations,

Go to Chapter 24, **ESG Box 24-1, The 100,000 Lives Campaign,** on Davis*Plus*.

ThinkLike a Nurse 24-3

Many never events can be reduced by good nursing care. By preventing complications and maximizing reimbursement, nurses can prove their value to an organization and make the case for better staffing. Over which of the never events do you think nurses have the most control? Explain your thinking.

Understanding Errors in Healthcare—Root Cause Analysis

Root Cause Analysis (RCA) practice tries to solve problems by identifying and correcting the underlying cause(s) of events, as opposed to simply addressing their symptoms. By focusing correction on root causes, problem recurrence can be prevented. A **root cause** is typically a finding related to a process or system that has a potential for redesign to reduce risk, rather than an individual error. RCA provides an organized structure for analysis of errors and is designed to answer three basic questions:

1. What happened?
2. Why did it happen?
3. What can be done to prevent it from happening again?

The Joint Commission requires healthcare agencies to perform RCA for all unexpected occurrence involving death or serious physical or psychological injury, also known as **sentinel events**.

Example Problem: Falls

Although most falls occur in the home, they are a major concern in healthcare facilities as well. Falls are by far the most common incident reported in hospitals and long-term care facilities, occurring at one for every 2,000 patient stays (CDC, n.d.a; Centers for Medicare & Medicaid Services, 2011). Infants and older adults are especially at risk for injury from falls. Many patients have risk factors, such as poor vision, cognitive impairment, difficulty with walking or balance, orthostatic hypotension, weakness or dizziness from disease or therapy, and drowsiness from medications. Many cases involve falling from a bed, and falls occur more frequently on nights, weekends, and holidays. Most agencies have established procedures and safety features to prevent falls.

Equipment-Related Accidents

Equipment-related accidents usually occur when equipment malfunctions or is used improperly, for example when bed alarms fail to work or are set up incorrectly, when suction devices and infusion pumps are not working properly, oxygen cylinders are transported incorrectly, or wheelchairs and beds are not locked during transfer activities.

Fires and Electrical Hazards

Because most institutions promote a smoke-free environment, fire in a healthcare agency is more often related to anesthesia or improperly grounded or malfunctioning electrical equipment. Most healthcare agencies have policies for preventing electrical hazards. Nevertheless, patients and visitors do break the rules, so smoking cannot be discounted as a hazard.

When a fire occurs in a public building, an announcement is made over the communication system. Often words such as “Code Red” or “Code Yellow” are used in an effort to prevent panic among patients and visitors.

Depending on the situation, the announcement may ask visitors to leave the building. All personnel must know the fire escape route and follow hospital policy regarding fires. If you discover a fire, your first instinct may be to contain or put out the fire. Fight that instinct! Your first action is to rescue the patient—that is, move the patient(s) away from the area. Only then should you sound the alarm and attempt to confine the fire.

Restraints

A **restraint** is a device or method used for the purpose of restricting a patient's freedom of movement or access to his body, with or without his permission. The most obvious form of restraint is the use of physical force by another person. A restraint may also be (1) a mechanical device, material, or equipment, such as a cloth vest or siderails, or (2) a chemical restraint (medication) given to control disruptive behavior, such as sedatives and psychotropic agents.

- Devices such as casts and traction are not considered restraints (Centers for Medicare & Medicaid Services, 2008; The Joint Commission, 2009).
- Physical holding of a patient is not always considered restraint. Sometimes it is necessary to use devices or methods that involve the physical holding of a patient for routine physical examinations or tests.
- Restraints are classified according to the reason for their use: Medical-surgical restraints or restraints used for behavior management. Medicare has specific guidelines for each circumstance. Guidelines are more restrictive when restraints are used for behavior management.

As a safety measure, nurses traditionally restrained highly dependent older adults, patients with poor mobility, those with impaired cognitive status, and those they judged to be at risk for falls. However, it has been found that restraints make care more time consuming and do not reduce falls. Restraints are themselves a safety hazard, and actually increase the likelihood of injury. A restrained person has a natural tendency to struggle and try to remove the restraint, and as a result can become entangled and suffer nerve damage, circulatory impairment, and even suffocation. Restraint-imposed immobility can cause pressure ulcers, contractures, loss of strength, and other hazards of immobility. Emotionally, the person may suffer anger, fear, humiliation, and diminished self-esteem.

Avoid Restraints When Possible

Research indicates that less restraint use saves time and money, and reduces patient injuries (Chan, LeBel, & Webber, 2012; Tilly & Reed, 2008). The American Nurses Association along with other healthcare organizations have established evidence-based guidelines to show that a restraint-free environment is the standard of care (Said, A. & Kautz, D., 2013). For those reasons, healthcare facilities are trying to achieve that goal. When the decision is made to avoid restraints, it is essential to provide alternatives for keeping the patient safe. Multiple approaches are needed, including careful and ongoing assessment and surveillance, finding ways to communicate with the patient, and tailoring exercise programs, medication reviews, and environmental modifications to the needs of individual patients. **Key Point:** ***Restraints never resolve the underlying problem; addressing the reason behind the patient's behavior is key to calming the patient (Said, A. & Kautz, D., 2013).***

To provide the safest possible care environment, The Joint Commission encourages healthcare facilities to:

- Promote a commitment to reduce the use of restraints and seclusion among all direct-care staff.
- Educate caregivers before they take part in any restraint-related activity.
- Document restraint episodes specifically, in detail.
- Maintain one-on-one viewing of patients in restraint and seclusion.
- Include staff members when deciding whether to explore new technology that is considered a safe alternative to traditional restraint devices.
- Budget for an adequate number of qualified staff to attend to patients.

Restraint Is Sometimes Necessary

Guidelines are slightly different depending on whether restraints are used to directly support medical healing or for a behavioral health reason (e.g., when a patient is irrational and pulling out his IV lines). Use restraints only as a last resort. As much as possible, use technology (such as bed alarms) and better anticipation of patient needs instead of restraints.

If you must use restraints, Medicare, The Joint Commission, and other regulators require that restraints be medically prescribed and that you first try all less restrictive interventions.

Do Not Depend on Siderails

Based on the Centers for Medicare & Medicaid Services (CMS) standards siderails can be viewed as a restraint. A full-length siderail is a restraint when it is used to prevent the patient from getting out of bed regardless of whether he is able to do so safely. A half- or quarter-length upper siderail can be an aid to independence if it is used by the patient for the purpose of getting into and out of bed. Similarly, split rails are not considered restraints if a client requests them in order to feel more secure (Talerico & Capezuti, 2001).

Remember that older or cognitively impaired adults may regard siderails as a barrier rather than as a reminder that they need assistance. Several studies have shown that siderails may lead to serious falls and injuries. These findings have led healthcare providers to reevaluate the use of restraints and to recommend that siderails not be used routinely (Evans & Cotter, 2008; Sharkey, Van Leuven, & Radovich, 2012).

KnowledgeCheck 24-4

- What is a typical cause of fire in healthcare facilities?
- What measures should you take, and in what order, if a fire occurs in the hospital?

Mercury Exposure

Mercury is a heavy, odorless, silver-white liquid metal. Mercury is toxic in both acute and chronic exposure. It can be inhaled, ingested, or absorbed through the skin. It accumulates in muscle tissue and can cause renal and neurological disorders, especially in fetuses and neonates. Because of its shiny color and ability to form beads or balls, mercury is appealing to curious children. See Table 24-3 for potential health effects.

Products that may contain mercury include thermometers, thermostats, batteries, fluorescent light bulbs, blood pressure devices, and electrical equipment and switches. For more information about products and devices that may contain mercury,

Go to Chapter 24, **Tables, Boxes, Figures; ESG Box 24-2, Products and Devices That May Contain Mercury,** on Davis*Plus*.

In 1998, the American Hospital Association (AHA) and the Environmental Protection Agency (EPA) launched a program to eliminate mercury-containing waste in the healthcare industry and prevent it from entering the environment via incinerators, landfills, and wastewater. Mercury thermometers are no longer being made in the United States. However, some people may still have them in their homes. Most, but not all, healthcare facilities have eliminated mercury thermometers and sphygmomanometers. You can help prevent mercury poisoning by taking an active role in eliminating mercury-containing items from your workplace. Some hospitals conduct thermometer exchanges, providing free or low-cost nonmercury thermometers to anyone who brings in a mercury thermometer.

Healthcare facilities must have policies and procedures for hazardous waste spills (e.g., mercury). These are required by The Joint Commission and federal agencies such as the EPA and the Occupational Safety and Health Administration (OSHA). You are not likely to encounter mercury exposure in acute care and ambulatory agencies.

Biological Hazards

As a nurse, you will place a high priority on the biological safety of patients. Institutionalized patients are at especially high risk from infectious microorganisms, some of which are highly resistant to antibiotics. To learn about or review healthcare-related infections, asepsis, and infection control, refer to Chapter 23.

Hazards to Healthcare Workers

Nursing is an active profession, and workplace injuries are all too common. Nurses sometimes hesitate to report they have been injured because they fear being labeled a complainer or troublemaker or being denied opportunities for promotion and other consequences. However, OSHA requires that employers show employees how to report a workplace injury and prohibits discrimination against employees who make such reports. You should always report an injury. By doing so, you help (1) pinpoint trends and areas of need in safety, and (2) ensure you will receive necessary treatment and follow-up. Common accidents include back injuries, needlestick injuries, radiation injury, and violence.

Table 24-3 ➤ Potential Health Effects of Mercury

PRIMARY ROUTE	POTENTIAL HEALTH EFFECTS
Acute Effects	
Toxicity	Symptoms of chills, nausea, malaise, chest tightness and pain, dyspnea, coughing, stomatitis, gingivitis, excess salivation, and diarrhea. High levels can cause severe respiratory irritation, digestive disturbances, and severe renal damage.
Inhalation	Respiratory damage, wakefulness, muscle weakness, anorexia, headache, ringing in the ears, chest pain, inflammation of the mouth, and pneumonitis
Eye	Irritation and corrosion
Skin	Irritation and allergic dermatitis
Ingestion	Intestinal obstruction
Chronic Effects	
Primarily central nervous system	Numbness or tingling of the hands, lips, and feet; behavior and personality changes
Other	Fatigue, weakness, anorexia, weight loss, and gastrointestinal disturbances

Back Injury

Nursing personnel are consistently listed in the top 10 occupations for work-related musculoskeletal disorders (MSDs). Most often the MSD involves the shoulders and back (Bureau of Labor Statistics, 2012). The American Nurses Association (ANA) reports that 52% of nurses report chronic back pain (ANA, 2013), likely because many nursing tasks require bending and twisting of the torso, activities that can cause injury when the nurse does not use correct body mechanics. Among the most stressful activities are transferring patients (e.g., from toilet to chair), weighing patients, lifting a patient in bed, repositioning patients in beds or chairs, and changing bed linens.

Currently 10 states have laws requiring safe patient handling and the Veteran's Administration has guidelines that have been successful in decreasing work-related MSDs. However, healthcare facilities have not consistently implemented safe patient handling guidelines. In response, the ANA (2013) has developed national standards to guide healthcare facilities in this regard. The standards strive to create a culture of safety by requiring employers to develop a safe handling and moving program with policies, appropriate equipment, training, and accommodations for injured employees. Another critical element of the program is empowering nurses to (1) actively participate in creating and implementing safe handling measures and (2) promptly report hazards, incidents, and injuries in a "blame-free" environment.

Refer to Chapter 32 for information about body mechanics and how to safely lift and move patients. For more information about ANA's campaign to prevent musculoskeletal injuries,

ANA's **Safe Patient Handling Web site,** at http://nursingworld.org/MainMenuCategories/WorkplaceSafety/SafePatient

or

Go to Student Resources, Chapter 24, **Resources for Caregivers and Health Professionals,** on Davis*Plus.*

Needlestick Injury

Healthcare workers, mostly nurses and housekeeping staff, suffer up to 1 million injuries per year from needles and other "sharps," putting them at risk for infectious diseases such as hepatitis B and AIDS. The operating room is a high-risk area; surgeons experience about a quarter of all "sharps" injuries (Waljee, Sunitha, & Chung, 2013).

The federal Needlestick Safety and Prevention Act and OSHA standards required employers to maintain a log of sharps injuries and to purchase needleless systems and safer needle devices. Needlestick injury rates declined by more than 36% during the 3-year period following passage of that law. Nevertheless, a recent survey found that 26% of nurses still report having had at least one injury from a sharp, usually a needle, contaminated with a patient's blood (Delahanty & Myers, 2007). The risk of needlestick injury increases for nurses who:

- Work in stressful environments
- Work varying or long shifts (longer than 12 consecutive hours)
- Have a low skill level, based on education level or experience.

Other risk factors include a lack of protective equipment, recapping needles and working in an area that requires higher than average use of needles. Although OSHA has fined hospitals for noncompliance, some employers still have not complied completely with the regulations. For suggestions about how you can prevent needlestick injuries,

Go to Chapter 24, **Clinical Insight 24-1: Preventing Needlestick Injury,** in Volume 2.

For more discussion on how to handle needles safely,

Go to Chapter 26, **Procedure 26-10B: Recapping Sterile Needles,** in Volume 2.

Radiation Injury

Radiation is the process of emitting radiant energy in the form of waves or particles. Ionizing radiation is used in computerized tomography (CT scans) in diagnostic radiology, linear accelerators in radiotherapy, and positron emission tomography (PET scans) in nuclear medicine. Patients are deliberately exposed to radiation during diagnostic tests and certain medical treatments. Healthcare workers who care for these patients are unavoidably exposed to small doses of radiation.

Take precautions to avoid excessive radiation exposure for the patient and yourself during x-ray procedures. **Key Point:** ***Follow the principles of time, distance, and shielding when caring for a patient who is being treated with an internal radioactive implant:***

- *Time:* Organize nursing care to limit the amount of time with the patient.
- *Distance:* Perform near the patient only the nursing care that is absolutely necessary.
- *Shielding:* Wear protective shielding (e.g., a lead apron), if available, and wear a film badge if you deliver care that exposes you to radiation regularly. The film badge will indicate any radiation exposure.

Violence

The impact of violent acts on healthcare workers is widespread and includes injuries, higher-than-average staff turnover, increased requests for medical leaves, unusually high time-off and attendance issues, and stress-related illnesses (Papa & Venella, 2013). Hospital security may not be sufficient to protect you from injury if violence breaks out among patients, visitors, and/or staff. This is especially true in the emergency department (ED), which has 24-hour accessibility and may sometimes be crowded and chaotic. Under the stress of an acute illness, patients and family members alike may become anxious and angry and act out in ways that are unpredictable and atypical for them.

Violence typically begins with anxiety and escalates in stages through verbal aggression and then physical aggression. If you can relieve a patient's anxiety, you may be able to halt the progression to physical violence. Certain emotional and physical conditions increase the risk for patient aggression (refer to Assessing the Risk for Violence, in the following Practical Knowledge section).

Gang activity, which is widespread in U.S. cities, is another potential source of violence. As gangs spread, so does the likelihood that gang members will be treated in the ED or admitted to the hospital (Gillespie, Gates, & Berry, 2013; Taylor & Rew, 2011).

KnowledgeCheck 24-5

- What measures can healthcare workers use to reduce exposure to radiation?
- What safety measures help reduce equipment-related injuries in the healthcare facility?
- As a nurse, what can you do to help prevent injuring your back?

PracticalKnowledge knowing how

This section provides focused assessments for certain safety risks; standardized nursing language for nursing diagnoses, patient outcomes, and general interventions for addressing patient safety; and specific nursing interventions for safety hazards discussed in the preceding Theoretical Knowledge section.

ASSESSMENT

It is important to assess the client's immediate environment, developmental stage, and individual risk factors. The following will help you to perform focused assessments for falls risk, home safety, and risk for violence.

Assessing for Example Problem: Falls

Assess all inpatients for falls risk when they are admitted to the healthcare setting. For clients at risk for falls, repeat the risk assessment every 8 hours, and increase the frequency of monitoring. Also identify medications that increase the risk for falling (e.g., opioid analgesics, sedatives, and antihypertensives). Most institutions have policies and guidelines for assessing risk for falls. The following are some examples of methods you might use.

Morse Fall Scale

The Morse Fall Scale uses the following questions to assess a person's risk for falls:

1. Does the patient have a history of falling?
2. Does the person have more than one medical diagnosis?
3. Does the person use ambulatory aids, such as crutches or a walker?
4. Does the person have an IV line or a saline lock?
5. Is the person's gait normal or stooped or otherwise impaired?
6. What is the person's mental status (e.g., disoriented, forgetful)?

You can easily score, tally, and record those six variables on the patient's chart. The risk of falling varies greatly with different patient populations, different times of day, and different stages of the patient's illness. Age alone is not a predictor of falls, but the items scored by the scale are more common in older adults (Morse, 2001). Ideally, the Morse Fall Scale should be calibrated for each particular unit so that fall prevention strategies are targeted to those most at risk. Institutions implementing the Morse Scale should train personnel in the proper use of the scale (Morse, 2008, 2009). To see the complete Morse Fall Scale,

Go to Chapter 24, **Tables, Boxes, Figures: ESG Figure 24-1,** on Davis*Plus*.

Assessing Older Adults for Falls

For a flowchart summarizing falls assessment for older adults, refer to Figure 24-1.

Get Up and Go As a part of the routine assessment of all older adults, ask the patient (or caregivers) about falls. If they report a single fall or risk factors, conduct the Get Up and Go test to identify whether the patient is presently at risk for falls or needs further evaluation.

Timed Up & Go If the patient is seeking care because of a fall or if you observe any difficulty with ambulation, refer him to a practitioner with advanced skills and experience for a Timed Up & Go Test and a comprehensive fall evaluation. This is a version of the Get Up and Go test, in which the patient is asked to get up and walk 8 feet in 8.5 seconds or less. Primary care providers should annually perform a Timed Up & Go test for fall risk assessment for all patients over age 65 (American Academy of Neurology, 2008a, 2008b; Hendrich, 2007; Kenny, Rubenstein, Tinetti, et al., 2011; Podsiadlo & Richardson, 1991). To use the Get Up and Go test and the Timed Up & Go Test,

Go to Chapter 24, **Assessment Guidelines and Tools, Get Up and Go Test** and the **Timed Up & Go Test,** in Volume 2.

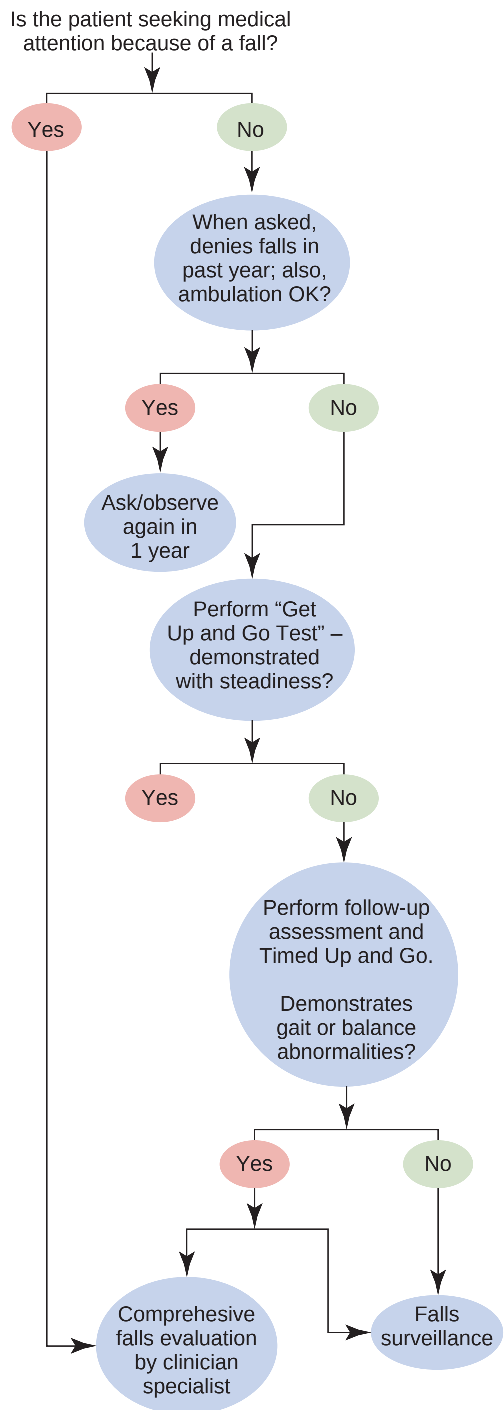

FIGURE 24-1 Falls assessment flowchart.

Assessing for Home Safety

As you know, many accidents occur in the home (e.g., fire, poisoning). Everyone should take a few minutes to check for environmental safety hazards.

- A **home safety checklist** is a convenient way for clients to identify potential hazards. For an extensive checklist you can print and use in a home assessment,

Go to Chapter Resources, Chapter 24, **ESG Figure 24-2, Home Safety Checklist,** on Davis*Plus*.

- **The safety assessment scale (SAS)** is an objective way to evaluate the dangers incurred by people with memory and cognitive deficits who live alone at home. You can use the short version of the SAS to assess the individual's risk status and decide whether she should have an in-depth evaluation. In addition to assessing for injury, this scale evaluates whether the cognitively impaired person is capable of cooking, taking medications independently, shopping, and performing other activities of daily living. To see this scale,

Go to **Assessment Guidelines and Tools, S.A.S. Safety Assessment Scale,** in Volume 2.

Assessing the Risk for Violence

You can be prepared to intervene and perhaps even prevent violence if you recognize risk factors and early warning signs (Flores, 2008; Woodrow & Guest, 2012).

1. Assess for factors that increase the risk for aggression:
   - Mental disorders, such as dementia, delirium, schizophrenia, and bipolar disorder
   - Being under the influence of alcohol or other drugs
   - Withdrawal from alcohol or other drugs
   - History of violence
   - Clinical conditions such as high fever, epilepsy, head trauma, and hypoglycemia

2. Assess for anxiety:
   - Agitation and restlessness
   - Pacing
   - Talking loudly, speaking rapidly
   - Gesturing widely
   - Be alert for verbal aggression, such as threats, sarcasm, and swearing.

KnowledgeCheck 24-6

- Which assessment tool would you use for a slightly confused home care client to assess her ability to safely live alone and perform activities of daily living?
- List the six risk factors that are assessed on the Morse Fall Scale.
- How should you screen older adults to see if they need a comprehensive falls evaluation?

ANALYSIS/NURSING DIAGNOSIS

How would your interventions differ for the following two diagnoses?

Risk for Falls related to poor vision secondary to cataracts

Risk for Falls related to muscle weakness, joint instability, and poor sense of balance

Etiologies The nursing diagnoses listed above illustrate that diagnosis etiologies are important because they affect your choice of interventions. Etiologies may include environmental hazards as well as the developmental and individual risk factors discussed in the preceding sections. Keep in mind that you must state *specific* etiologies for each individual—not just general ones such as "environmental hazards." For example:

Correct: Risk for Falls related to cluttered home environment and joint instability

Incorrect: Risk for Falls related to environmental and physical factors

NANDA-I Labels For NANDA-I labels to use in describing safety problems,

Go to ESG, Chapter 24, **Standardized Language, NANDA-I Diagnoses and NOC Outcomes for Safety Problems,** on Davis*Plus.*

A few examples are: Risk for Contamination, Risk for Aspiration, and Risk for Poisoning. **Key Point:** ***Use the diagnosis Risk for Injury only when the risk cannot be described by one of the more specific nursing diagnoses.***

PLANNING OUTCOMES/EVALUATION

The *NOC standardized outcomes* you use will depend on the nursing diagnosis. For some examples (e.g., Fall Prevention Behavior),

Go to Chapter Resources, Chapter 24, **Standardized Language, NANDA-I Diagnoses and NOC Outcomes for Safety Problems,** on Davis*Plus.*

Individualized goals/outcome statements you might write for a client's safety diagnoses include the following:

- The child will be free of injury.
- (Client) will experience no physical injury due to environmental hazards.
- Falls will not occur.
- Family members will describe their planned escape routes in case of fire.

PLANNING INTERVENIONS/IMPLEMENTATION

NIC standardized interventions will be determined by the nursing diagnosis you use. To see the more than 50 interventions in the NIC domain (category) of Safety, and some interventions from other NIC domains that are applicable to safety needs,

Go to Chapter 24, **Standardized Language, Examples of NIC Interventions Related to Safety,** on Davis*Plus.*

General Interventions Related to Safety

Specific nursing activities are designed to monitor and manipulate the physical environment to promote safety. The following are some general activities that provide an overview of your role in patient safety in all types of settings and circumstances.

- Assess and continually monitor the safety needs of patients, based on their level of physical and cognitive function and past history of behavior.
- Assess and continually monitor safety hazards in the environment (i.e., physical, biological, and chemical).
- Remove hazards from the environment, when possible.
- Provide clients with emergency phone numbers.
- Modify the environment to minimize hazards and risk.
- Teach clients about specific safety measures.
- If an accident or injury occurs in the healthcare setting, file an incident report according to agency policy. See Chapter 18 for more information on this topic.
- Urge patients to be active members of the healthcare team (Box 24-3).

The QSEN Safety Competencies should also help you to understand your role in keeping patients safe. To review those competencies,

Go to Chapter 24, **ESG Table 24-1, QSEN Safety Competency,** on Davis*Plus.*

BOX 24-3 ■ Speak Up

Speak up if you have questions or concerns, and if you don't understand, ask again. It's your body and you have a right to know.

Pay attention to the care you are receiving. Make sure you're getting the right treatments and medications by the right healthcare professionals. Don't assume anything.

Educate yourself about your diagnosis, the medical tests you are undergoing, and your treatment plan.

Ask a trusted family member or friend to be your advocate.

Know your medications and why you take them. Medication errors are the most common healthcare errors.

Use a hospital, clinic, surgery center, or other type of healthcare organization that has undergone a rigorous on-site evaluation against established state-of-the-art quality and safety standards, such as that provided by The Joint Commission.

Participate in all decisions about your treatment. You are the center of the healthcare team.

The Joint Commission encourages patients to become active, involved, and informed participants on the healthcare team, and for parents to do the same to help protect their children from medical errors. The preceding steps are based on research that shows that patients who take part in decisions about their healthcare are more likely to have better outcomes.

Home Care Safety Interventions

Specific interventions follow for promoting safety related to particular hazards in home care. In this section, you will find boxes containing specific home safety interventions.

Prevent Poisoning in the Home

In all cases of suspected poisoning, Call 911 or the local emergency number right away. Even if the person is having no symptoms, call the poison control center (PCC) as soon as possible. **The national PCC number is (800) 222-1222; they will connect you to a local PCC.**

Unintentional poisoning can affect people at all ages and from all walks of life. However, it may surprise you that middle-aged adults have the highest unintentional poisoning death rates.

For Children Nursing interventions focus on teaching parents how to childproof the home and what to do if someone ingests a poisonous substance. All homes should be equipped to handle an emergency if poisoning occurs. Teach parents to keep the telephone number for the nearest PCC easily accessible. If they suspect a child has ingested a poisonous substance, it is crucial to obtain help immediately so there is less time for the substance to enter the child's system.

For Adults Advise clients of the following:

- Take only prescription medications prescribed by a healthcare professional.
- Never take larger or more frequent doses of medications, particularly prescription pain medications, to try to get faster or more powerful effects.
- Never share or sell your prescription drugs.
- Be sure to follow directions on the label when taking medications, and read all warning labels.

Advise families with older adults to prevent accidental overdose or misuse of prescribed medications by using a medication organizer that may be filled once a week by the patient or family member (Fig. 24-2).

FIGURE 24-2 Medication organizer.

For steps to prevent poisoning, see Home Care: Preventing Poisoning in the Home. For actions to take if poisoning occurs at home,

Go to Chapter 24, **Tables, Boxes, Figures; ESG Box 24-3, Home Care: If Poisoning Occurs at Home,** on Davis*Plus*.

Prevent Carbon Monoxide Poisoning

If CO intoxication is suspected, the person should be treated with 100% humidified oxygen. A simple blood test may be done to confirm CO levels in the blood. Nursing interventions include teaching prevention measures, such as the following:

- Buy, install, and maintain a home CO detector.
- Ensure that gas or wood-burning appliances are adequately vented to the outside.
- Repair rust holes or defects in vehicles that could allow exhaust fumes to enter the passenger compartment.
- Never use a kerosene heater, gas oven, or gas range to heat a house, even for a short time.
- Never operate gasoline-powered engines, such as automobiles, generators, or lawn mowers, in confined spaces, such as garages or basements, or near open doors or windows.
- Never burn charcoal inside a home, cabin, recreational vehicle, or tent—not even in a fireplace.

Prevent Home Fires

Nursing interventions include teaching families how to prevent fires and measures to take should a fire occur. Stress the following measures:

Have a Warning System Have working smoke alarms and change batteries every 6 months or more often. Keep a phone near the bed or chair for people who have limited mobility.

Have an Escape Plan Develop a home fire escape plan and practice it at least twice a year. Keep a rope or other type of ladder for escape from rooms above ground level. Have a fire extinguisher in the home, and know where it is located and how to use it. Check fire extinguishers regularly and replace them when they become outdated.

Have a Preventive Frame of Mind For example, when decorating Christmas trees and the exterior of your home, always use fire-safe lights. Do not leave old light sets hung on the outside of your home year after year. Always unplug Christmas tree lights before leaving home, and remove the Christmas tree from the home when it becomes dry. Other fire precautions include the following:

- Never leave burning candles unattended. Do not use candles near curtains or other flammable materials.
- With charcoal grills, use only charcoal starter fluids designed for barbecue grills.

Home Care

Preventing Poisoning in the Home

Young children will eat and drink almost anything. Most victims of accidental poisoning are children younger than the age of 5. Tips to prevent poisoning include the following:

Careful Words and Actions

- Never leave a small child unattended near household cleaning supplies or medicines, even for a moment. If you must answer the phone or doorbell, take the child with you.
- Children act fast; it takes only a moment for them to swallow something.
- Avoid taking medicines in front of children; children tend to imitate adults.
- Never call medicines or vitamins "candy." Instead, use the correct name ("cough medicine," and so on).

Careful Storage

- Store medicines or household chemicals on high shelves or in locked cabinets and drawers. Never leave them on kitchen or bathroom counters.
- Store all household chemicals away from food.
- Keep medicines and household chemicals in their original containers. Leave the original labels on. Do NOT store chemicals in containers that normally hold food.
- Use child-resistant packaging for medicines and household chemicals. Close the container securely after each use.
- Do not assume your child is safe around substances in child-resistant containers; research has shown that many toddlers and preschoolers can open them.

Careful Disposal

- Teach clients to take advantage of any community programs that take back unwanted medications for safe disposal (e.g., call the local trash service or a local pharmacy for options in your area).
- Teach clients how to safely dispose of outdated prescription medications:

  Crush the medication or add water to dissolve it.

  Mix the drugs with an undesirable substance such as kitty litter or used cooking grease to make it less desirable for pets and children to eat.

  Place the mixture in an empty can or resealable bag and put it in the trash.
- Remove all identifying information from prescription labels before throwing containers in the trash or recycling them.
- It is not safe to dispose of drugs down the toilet or sink. Wastewater treatment plants are not fully designed to deal with medications, and small amounts have shown up in surface waters. Although there is no evidence of harm to humans or the environment, the long-term effects on people, animals, and the environment are unknown.

Careful Environment Checks

- Before purchasing a houseplant, verify that it is nontoxic.
- Examples of toxic plants are rhododendron, philodendron, English ivy, holly, mistletoe, and lily of the valley.
- Find out whether any plants growing in your yard are poisonous, and, if so, remove them.
- Teach children that they must never eat berries, wild mushrooms, or other edible-looking plants in yards, fields, and forests.
- A wide variety of plants can cause illness and even death in young children.
- Warn parents to keep children from chewing on windowsills, and so on, and to carefully clean up flakes of paint. Advocate for clients who need to have lead-based paint replaced in their homes.
- Lead-based paint can still be found in older homes, and some soil contains a high lead content. Young children often put dirt in their mouths and chew on furniture and window sills, especially when they are teething.

- With gas grills, be sure that the hose connection is tight, and check hoses for leaks.
- Store flammable materials (e.g., oil-soaked rags) in appropriate containers (e.g., metal container with a tight lid.
- Do not smoke, especially in bed—and especially in a home where oxygen is in use.
- Never use an open flame when oxygen is in use.

Promote Electrical Safety in the Home Make sure electrical outlets have covers. Routinely inspect electrical appliances for damaged cords; replace frayed cords. Do not place electrical cords under carpets, and make sure cords do not hang off of tables and countertops.

Know What to Do If a Fire Occurs The actions you take to extinguish a small fire depend on the source of the fire. For example, never pour water on a grease fire, and never discharge a fire extinguisher onto a pan fire. If there is an oven fire, turn off the heat and keep the door closed. If there is a microwave fire, keep the door closed, and unplug the microwave.

Key Point: ***If the house is on fire, follow your escape plan. Crawl or stay low to the floor to avoid the smoke as much as possible.***

Prevent Scalds and Burns in the Home

Fire is not the only cause of thermal injuries. Teach clients how to avoid scalds and burns from other causes:

- Turn pot handles toward the back of the stove so that children cannot tip them over.
- Never wear loose-fitting clothing when cooking.

- **Key Point:** ***Avoid warming infant formula and food in the microwave. Many parents ignore this advice, so also tell them to always check the temperature of formula and food carefully before giving it to the child.***
- Remove lids or other coverings from microwaved food carefully.
- Do not smoke, use matches, or drink hot liquids while holding an infant. Do not leave burning cigarettes unattended.
- Always check bath water temperature for children and older adults, and set water heater temperature low enough to prevent scalds.
- Place guardrails in front of radiators and fireplaces.
- Wear protective clothing and sunscreen when outside.

KnowledgeCheck 24-7

- Identify four safety measures that decrease the risk of scalds or burns in the child.
- What are some specific activities that reduce the possibility of fires in the home?

Example Problem Interventions: Prevent Falls at Home

Fall prevention may not seem like a lively topic, but it's important. Falls are a leading cause of injury among older adults. Nevertheless, fear of falling should not inhibit a person from living an active life. Instead, teach clients, especially older adults, measures for increasing the safety of their home environment (see the box, Home Care: Preventing Falls in the Home).

Teach clients, if they do fall at home, to take the following actions:

- Do not panic.
- Stay still for a few minutes to get over the shock.
- If you think you are okay, then slide over to a sturdy piece of furniture, get in a kneeling position, and push yourself up; then sit down until you recover.
- If you cannot move, try to cover yourself with something to keep warm until help arrives.

Prevent Firearm Injuries

Education is an essential intervention because of the frequency and severity of unintentional firearm injuries involving children. The American Academy of Pediatrics and other groups have mounted efforts to educate parents so that they will be able to make smart choices related to gun safety. You can help by teaching gun owners that it is important to store firearms unloaded and in a secure, locked container when not in use, and to store ammunition in a different location from the firearm. Suggest that they participate in gun safety courses and know the following rules for safe gun handling (The National Rifle Association Headquarters, 2011):

- Always keep the gun pointed in a safe direction so that even if it were to go off it would not cause injury or damage.
- Never put your finger on the trigger until you are ready to shoot.
- Always keep the gun unloaded until ready to use it.
- Before cleaning a gun, make absolutely sure that it is unloaded. If you do not know how to open the gun and inspect the chamber(s), leave it alone and get help from someone who does.

Teaching Children Even if parents avoid having guns in their own home, it is possible that children will encounter them in other places. Urge parents to teach children safe behavior around firearms, and to be sure children know what to do if they see a gun (e.g., at a friend's house or in school) (The National Rifle Association Headquarters, n.d.):

1. Stop.
2. Don't touch it.
3. Leave the area.
4. Tell an adult.

Prevent Suffocation

Clients should recognize and teach children the universal sign for choking: grasping the neck between the thumb and index finger or clutching the neck with both hands (Fig. 24-3). It is also important to teach clients the following measures to prevent suffocation or asphyxiation:

- Inspect toys for small, removable parts.
- Do not attach pacifiers, rattles, or other infant toys to ribbons or strings.
- Do not use sweatshirts or jackets with neck tie strings.
- Position mobiles well above the crib, out of the infant's reach.
- Keep window blind cords out of the child's reach.
- Store plastic bags away from young children in a secure place.
- Ensure that the crib is designed to meet federal regulations: Crib slats must be less than 2⅜ inches (6 cm) apart, and the mattress must fit snugly.
- When feeding children meat, cheese, or other firm foods, cut the food into very tiny pieces.
- Do not give a young child hard candy, chewing gum, nuts, popcorn, grapes, or marshmallows.
- Supervise children's balloon play, and dispose of burst balloons promptly.

Prevent Drowning

Drowning is a form of suffocation, but is discussed separately here for convenience. Teach clients the following water safety measures:

- Supervise activity when the child is near any source of water.

Home Care

Preventing Falls in the Home

Exercise Regularly

- Exercise at least 30 minutes every day. The amount of activity depends on age, physical condition, and the intensity of the exercise. Any activity is better than none (see Chapter 32 for more specific information). Tai chi, yoga, exercise classes, and weight training are helpful ways to improve balance, coordination, flexibility, and strength.
- Learn to use assistive devices, such as walkers and canes safely. Be sure rubber tips are not worn. Keep the walking aid by the bed at night.

Take Your Time

- You are more likely to fall when you are tired, sick, rushed, or emotionally upset.
- Walk and go up stairs carefully without hurrying; be careful not to be distracted while walking about.
- Do one thing at a time; complete it before going on to the next task.
- When getting out of bed or a chair, get up slowly and check your balance before standing or walking. Postural hypotension and dizziness on rising are a problem for some people taking medications for high blood pressure and other conditions.

Lighten Loads—Brighten Paths

- Carry things in several small loads instead of one very large load so you are able to see over them, especially on stairs.
- Use bags with handles instead of large boxes or laundry baskets to carry items.
- Make sure rooms are adequately lighted, use dim light (e.g., a night light) at night, and turn on the lights before entering a room.
- Have your eyes checked at least once a year.
- Clean eyeglasses frequently.

Don't Trip Yourself Up

- Ensure that shoes fit properly, and wear slippers with nonskid soles. Do not go barefoot.
- Avoid loose, trailing clothes. Keep hems of clothing at a length to prevent tripping.
- Older adults with leg or hip stiffness and pain may shuffle when walking; use of a cane or walker may help.
- Check tips of assistive devices, such as canes, walkers, and crutches, for the presence of intact nonskid covers.
- Use a ladder or step stool; do not stand on the top step of a stepladder; never climb on a chair.

Clear the Floor

- Tape or otherwise fasten phone and electrical equipment cords to the baseboard.
- Arrange furniture to provide wide walking areas.
- Keep clutter (e.g., toys, magazines, clothing) out of the walkways.
- Remove all scatter or throw rugs (or at least be sure they have nonskid padding under them).
- Wipe up all foods and fluids from the floor immediately.
- Apply an ice-melt product, salt, or sand to icy sidewalks, steps, and porches.

Use Caution on Stairs

- Keep stairs well lit.
- Keep stairs free of clutter.
- Install sturdy handrails and slip-resistant floor coverings on staircases. Fasten any stair coverings securely.
- For older adults and those with vision problems, paint the top and bottom steps white or put white stripes on the front edges of steps.

Minimize Bathroom Hazards

- Use shower chairs and raised toilet seats.
- Install grab bars and use a nonskid mat in the shower and tub.
- Install handheld shower attachments to make it easier to sit while showering and minimize the need to move and turn.

Childproof the Home

- Install window guards; never leave a window wide open.
- Use gates at the top and bottom of stairways for small children.
- Never leave a child alone on a changing table, even for a moment. Supervise young walkers to protect from falls.
- Remove chairs near counters or other areas where young children would be likely to climb. Push chairs all the way under dining table tops.
- Teach children to pick up their toys.
- Be sure that children wear helmets and other appropriate protective gear for bicycling, skateboarding, and other active sports.

For Older Adults or Those With Limited Mobility:

- Use beds that are low to the floor.
- Keep a cordless phone in each room and by the bedside to make it easier to call for help if needed.
- Ask your doctor or pharmacist to review your medicines—both prescription and over-the-counter—to reduce side effects and interactions. This is especially important for psychotropic medications.
- Get treatment for postural hypotension and cardiovascular disorders, including dysrhythmias.

FIGURE 24-3 The universal sign for choking.

- Children up to age 4 are especially at risk for drowning and should never be left unattended in or near a bathtub, hot tub, swimming pool, or other source of water. Even wading pools, toilets, and mop buckets hold enough water to drown a small child.
- Do not allow children to run around a pool or to dive in shallow areas.
- If you have a pool, be sure it has a barrier (e.g., tall fence) to prevent children from gaining access.
- Insist that children use personal flotation devices (e.g., lifejackets, not float toys). (This is controversial. Some authorities regard flotation devices as toys that provide false security; others say anything that reduces a child's fear of the water is positive, because it is the fear reaction that leads to drowning.)

Choking Rescue

Teach adults the universal sign for choking (see Fig. 24-3) and basic first aid for choking, but explain that choking rescue is a skill that is best taught using supervised practice with a mannequin. Recommend that clients attend classes presented by organizations such as the Red Cross or the American Heart Association. The most important thing to remember when someone is choking is to have someone call 911 immediately.

The **choking rescue maneuver** is an emergency procedure for removing a foreign object lodged in the airway. It lifts the diaphragm and forces enough air from the lungs to create an artificial cough. The cough should move and expel the obstruction from the airway. The **Heimlich maneuver** makes use of abdominal thrusts only, whereas the American Red Cross (2008) alternates five back blows with five abdominal thrusts until the blockage is dislodged.

If you suspect airway obstruction in an adult, determine whether the victim is able to speak or cough forcefully (other signs include noisy breathing, loss of consciousness, and dusky skin, lips, and nail beds). Ask, "Are you choking?" If the person cannot speak or indicates he is choking, perform the Heimlich or choking rescue maneuver. Note that management of choking is different for adults and children. Do not use the Heimlich maneuver for infants under 1 year of age.

For more detailed instructions about the choking rescue procedure,

Go to Chapter 24, **Tables, Boxes, Figures; ESG Box 24-4, Rescue Maneuver for Choking: Infant Under 12 Months,** and **ESG Box 24-5, Rescue Maneuver for Choking: Adult or Child Over Age 12 Months,** on Davis*Plus*.

Prevent Take-Home Toxins

Most preventive measures apply to the workplace. However, you can teach clients who are at risk to remove work clothing and to shower, preferably in an open-air shower, before leaving work. If facilities for showering are not available, patient advocacy may be appropriate. (To learn about advocacy, see Chapter 42.) Before entering their homes, exposed workers who have not showered should remove their clothing, then shower immediately. When handling contaminated clothes or objects, they should wear gloves to reduce the risk of skin transmission. Laundering may not be effective in removing certain toxins from clothes.

Think**Like a Nurse** 24-4

You are having dinner in a restaurant and notice that the guest at the table beside you seems to be choking.

- What is the universal sign for choking?
- What is the first action you should take?

KnowledgeCheck 24-8

- List two things a person who works around workplace toxins can do to prevent bringing them into the home.
- What specific safety measures would you discuss with a mother to prevent choking in her 9-month-old child?

Intervention: Teaching for Safety Self-Care in the Community

In addition to teaching home safety to clients, you should also teach to promote safety self-care related to particular hazards in the community and environment. Some specific interventions follow for community hazards.

Motor Vehicle Safety

Anticipatory guidance and educational programs are important measures for improving motor vehicle safety for all age groups. You may also wish to become politically active on the issue of motor vehicle safety. For instance, you might petition your city council for a stop sign at a particularly dangerous intersection or a reduced speed limit on a highway in your area.

Also teach clients the following measures for avoiding motor vehicle injuries:

- Be cautious when walking or bicycling on the roadway, and observe the laws.

- Do not drink alcohol or take unprescribed or recreational drugs and drive. Have a designated driver.
- Do not engage in distracting activities while driving (e.g., using cell phones, texting, changing the music, applying cosmetics).
- Observe the speed limits.
- Always wear seat belts while driving, and periodically check belts to ensure safe operation.
- Make certain children are properly buckled in age-appropriate safety seats in the back seat of the car. If in doubt about the appropriateness or use of safety seats, ask the local police department to check the installation of your child safety seat. See Table 24-4 for types of car safety seats.

Older Adults: Age-related changes increase the risk for injury or death in a car crash, especially after age 70. But driving helps older adults maintain mobility and independence. Urge them to have regular vision checks, and to leave a large distance between their car and the vehicle in front of them.

Food Safety

Teach clients safe food handling and other preventive measures, such as the "4Cs of food safety": **C**lean, **C**ook, **C**ombat cross-contamination, **C**hill. For further explanation of the 4Cs, refer to the Home Care box, Food Safety.

Fighting Vectorborne Pathogens

This section provides points you can use to teach clients about strategies to combat the vectors mosquitoes, ticks, and rodents (CDC, 2011c; EPA, 2007).

Mosquitoes Public strategies to control mosquitoes include spraying programs and digging ditches to promote drainage from stagnant areas. Individuals can help by taking the following actions.

- **Remove sources of stagnant water.** Empty standing water in old tires, buckets, toys, or other outdoor containers. Change water in birdbaths, fountains, wading pools, and potted plant trays at least once a week to destroy mosquito habitats. Keep rain gutters unclogged. Treat swimming pools with the proper chemicals and keep the water circulating.
- **Kill or repel mosquitoes.** Use EPA-registered mosquito repellents when necessary, and follow label directions carefully. All repellents and pesticides, whether used by an agency or the consumer, should have the name and amount of active ingredient on the label. No pesticide is 100% safe, so people must use them cautiously. Use "bug zappers" or citronella candles for evening outdoor activities.
- **Avoid mosquitoes, if you can.** Repair holes in window and door screens. Replace outdoor lights with yellow "bug" lights. They will attract fewer mosquitoes, but are not repellents. If you go into areas with high mosquito populations (e.g., salt marshes, deep woods), wear head nets, long sleeves, and long pants. If there is a mosquito-borne disease alert, stay indoors during the evening when mosquitoes are active.
- **Consult the experts.** Contact your local health department if you have questions about mosquitoes or about a spraying program.

Ticks When walking in tick-infested areas:

- Use DEET-containing insect repellant. Reapply it every few hours (or according to the label). DEET formulations as high as 50% are recommended for adults and children over 2 months of age. Use with caution for children. Wash off repellent at night before going to bed.
- When wearing sunscreen, apply sunscreen first and then repellent.
- Treat clothing with permethrin-containing or other insect repellents.
- Wear light-colored clothing. Ticks are attracted to dark colors; also, it is easier to see a tick on light-colored clothing.
- Wear long-sleeved shirts, tucked in. Pull socks up over pant legs.
- Check your body visually after walking in wooded areas, especially in the hair and skin folds. Use a mirror to view all parts of your body.
- Remove ticks right away. This can prevent some infections, such as Lyme disease or Rocky Mountain spotted fever. For instructions on how to remove attached ticks,

Go to the CDC Web site in Chapter 24, **Resources for Caregivers and Health Professionals, Web Sites,** on Davis*Plus*.

Rodents and Other Animals To control rodents, raccoons, and other small animals, remove as many food and water sources as possible. Advise clients to:

- Cover food and clean up immediately after meals.
- Remove unwashed dishes from counters and in sinks.
- Keep garbage in closed containers that cannot be overturned.
- Repair holes and cracks in the exterior structure of the home, as well as interior walls, closets, attic, and around sinks and cabinets.
- Use commercial traps or hire professional exterminators.
- Participate in neighborhood cleanup projects.

Keep in mind that rat and mice poisons and baits can be fatal and should not be used in areas accessible to children and pets.

Reducing Pollution

Teach families they can help to reduce pollution solid and hazardous wastes, as well as air and noise pollution of the environment. Refer to the following tips.

Table 24-4 ➤ TYPES OF CAR SAFETY SEATS

AGE	TYPE OF SEAT	GUIDELINES
Infants younger than 1 year old  **FIGURE 24-4** Infant car seat with infant in rear-facing position in the middle of the back seat.	"Infant-only" (These are small, may have carrying handles or be part of a stroller system.)	Use rear-facing seats until the infant is 1 year old and weighs at least 20 lb (Fig. 24-4).
Toddlers and preschoolers	"Convertible" (can be used rear-facing, then converted to forward-facing) or "forward facing"	Rear-facing seats are safer for toddlers until they are age 2 yr. It is best to ride rear-facing as long as possible (until they reach the height and weight maximum specified by the seat manufacturer).
School-age children	Booster seats	After outgrowing their car safety seat, children should stay in a booster seat until the car seat belts fit properly (usually at about 4 ft 9 in. tall and between 8 and 12 years old). Booster seats are safer than a seat belt alone.
Older children	Car lap and shoulder belts	Children who have outgrown their booster seats should ride in the back seat until 13 years of age. Some experts recommend that anyone weighing <110 lb, regardless of age, ride in the back seat. Riding in the back seat is associated with a 40% reduction in the risk of fatal injury, and up to 46% in cars with airbags.

Note: These are guidelines, not legal requirements. Some states may also have laws governing types and use of car safety seats. You should be familiar with the laws in your area.

For in-depth information about child safety seats,

Go to the **American Academy of Pediatrics Web site** at http://www.aap.org/healthtopics/carseatsafety.cfm

Sources: American Academy of Pediatrics (AAP) (2011, updated 2013); CDC, National Center for Injury Prevention and Control (2006, updated 2013, and 2010d); NGC (2010); O'Keefe, L. (2009).

Self-Care

Food Safety

Clean

- Wash hands and surfaces often. Always wash your hands with soap and water before handling or preparing food and before eating.
- Don't be a source of foodborne illness yourself:
  - Avoid preparing food for others if you have a diarrheal illness.
  - Avoid changing a baby's diaper while preparing food.
- Wash produce. Rinse fresh fruits and vegetables in running tap water to remove visible dirt.
- Remove and discard the outermost leaves of a head of lettuce or cabbage.
- Never use a cutting board, knife, or other object that was used to prepare meat, poultry, or fish for any other purpose until it has been thoroughly washed in hot, soapy water.
- Be careful not to contaminate foods while slicing them up on the cutting board. Bacteria grow well on the cut surface of fruits or vegetables.
- Wash hands with soap after handling reptiles, birds, or baby chicks, and after contact with pet feces.

Cook

- Use a thermometer to measure the internal temperature of meat.
- Cook to temperatures sufficient to kill bacteria.

  Ground beef to an internal temperature of 160°F (71°C).

  Leftovers and casseroles, 165°F (74°C)

  Beef, lamb, and veal, 145°F (63°C)

  Pork and ground beef, 160°F (71°C)

  Whole poultry and thighs, 180°F (82°C)

  Poultry breasts, 170°F (77°C)

  Ground chicken or ground beef, 165°F (74°C)

  Stuffed fish, 165°F (74°C)

  Roast meats at an oven temperature of 300°F (149°C) or above
- Cook eggs until the yolk is firm. Do not eat raw or partially cooked eggs.
- Hold hot food above 140°F (60°C) and for no more than 2 hours.

Combat (Separate)

- Wash hands, utensils, and cutting boards after they have been in contact with raw meat or poultry and before they touch another food (to avoid cross-contamination).
- Put cooked meat on a clean platter, rather than back on one that held the raw meat.

Chill

- Refrigerate leftovers within 4 hours. Bacteria multiply quickly at room temperature.
- Avoid leaving cut produce (e.g., fruits, vegetables) at room temperature for a prolonged time.
- Chill cooked foods rapidly in a shallow (2-inch-deep) container. Large volumes of food will cool more quickly if they are divided into several shallow containers for refrigeration.
- Do not buy partially thawed items. Be sure they are frozen solid.
- Use a cooler to transport foods when the temperature is above 80°F (27°C).
- Store deli meat for only 1 or 2 days.
- Use thermometers in the refrigerator and freezer.

  Keep freezer temperature at 0°F (–18°C) or below.

  Keep refrigerator temperature at 40°F (4°C) or below.
- Thaw foods in the refrigerator or under cold running water. Use the microwave to thaw foods only if you are going to continue cooking them at that time.
- Pack lunches in insulated containers. You can refrigerate or freeze sandwiches before packing, to keep them cold.

Store

- Cover and date food.
- Store vegetables and fruit separately from uncooked meats.
- Do not store food in decorative containers unless they are labeled safe for food. Some crystal and pottery, for example, have high lead content.
- Store cleaning supplies away from food.

Report

Report suspected foodborne illnesses to your local health department. The local public health department is an important part of the food safety system. Often calls from concerned citizens are how outbreaks are first detected.

Other

- Never eat any food that has an odor or that might be spoiled.
- Be aware that some imported folk remedies, such as *greta* (which is used by some Hispanic patients for colic), may be contaminated with lead.
- Observe sanitation reports for selecting eating establishments in the community.

Sources: CDC (2005); FoodSafety.gov (n.d.); U.S. Food and Drug Administration (n.d.).

Hazardous Waste The following are tips for safe disposal:

- **Information.** Contact the local refuse disposal company for instructions about proper disposal of hazardous waste (e.g., paints, solvents, pesticides, cleaners, rechargeable batteries).
- **Products.** Use the least hazardous products available, and use only the amount necessary for a project. Share leftover materials with neighbors.
- **Motor oil.** Never dump motor oil into storm drains. For old oil and tires, call your local waste management company or a local quick-lube or tire dealer, for recommendations regarding disposal. You can also,

Go to http://nextgen.valvoline.com/nextgen_why_recycle.html

- **Batteries.** Talk to an automotive dealer or repair service about recycling or trading in car and other batteries.

Solid Waste Proper disposal and recycling of solid wastes helps to prevent pollution. Remember the 4-Rs: Reduce, Reuse, Recycle, and Respond

Reduce the amount of trash discarded (e.g., don't buy products that have unnecessary packaging).
Reuse containers, bags, and products; sell or donate instead of throwing items out.
Recycle. Use and buy recyclable and recycled products; compost yard trimmings.
Respond by educating others, expressing preferences for less waste (e.g., to manufacturers, merchants).

Also,

Go to Chapter 24, **Supplemental Materials, The Consumer's Handbook for Reducing Solid Waste,** on Davis*Plus*, or go to http://www.epa.gov/waste/wycd/catbook/index.htm

Air Pollution To help reduce air pollution, pay attention to air quality warnings, and restrict time spent in high-traffic areas. You might also participate in car pools or use public transportation whenever possible.

Noise Pollution There are many interventions you can teach clients to help prevent irreversible hearing loss. Two specific interventions include avoiding exposure to continuous high noise levels and to wearing protective devices (e.g., ear plugs) in environments with a high noise level.

Electrical Storm Safety Measures

Another safety self-care intervention is to teach clients about safety in electrical storms. They should know that where there is thunder, there is also lightning. Advise clients to seek shelter when they are outside and hear thunder, in a large building if possible. Tell them to also stay away from open vehicles, including bicycles and motorcycles. If they cannot find shelter during a thunderstorm, they should stay away from tall objects, particularly a single tree in an open area; and crouch or sit in the lowest spot possible.

When inside during an electrical storm, stay away from plumbing outlets, and do not use corded telephones, computers, or other electrical equipment. As preventive measures, install ground fault interrupt switches and use surge protectors for electrical equipment.

Intervention: Promoting Safety in the Healthcare Facility

The following interventions will help you to prevent common accidents in the healthcare setting.

Interventions for Example Problem: Preventing Falls

Nursing interventions to prevent falls depend, of course, on the risk factors that were identified at the initial assessment.

Key Point: ***Perhaps the single most important thing you can do to prevent falls is to identify those who are at risk for them.***

You will find other interventions in Box 24-4. For a care plan for Risk for Falls,

Go to Chapter 24, **Care Plan: Risk for Falls,** on Davis*Plus*.

Reducing Electrical Hazards

Electrical hazards are a major cause of fires in healthcare agencies. The following interventions help reduce electrical hazards:

- Before use, have all electrically powered equipment and accessory equipment evaluated by facilities management.
- Participate in education and training programs for electrical safety are mandatory for all employees as established by The Joint Commission standards.
- If an electrical safety hazard is suspected, clearly label the malfunctioning equipment and send it for inspection.
- Use three-pronged electrical plugs whenever possible.
- Observe for breaks or frays in electrical cords.

Preventing and Responding to Fires

You must know your agency's procedures for responding to a fire, including how to evacuate patients from the building. Remember: **R-A-C-E.**

- **Rescue the patient**—Remove the patient from immediate danger. Move patient(s) into the corridor, and close doors to the affected area.
- **Activate the alarm—**Report the location and kind of fire, and identify yourself. Activate the nearest alarm.
- **Confine the fire—**Close all doors and windows. Turn off all oxygen valves after coordinating with the charge nurse.
- **Extinguish the fire—**Use the proper extinguisher. Stay between the fire and the path to safety. Keep low.

BOX 24-4 ■ Preventing Falls in Healthcare Facilities

Provide a Safe Environment

- Determine the appropriate use of siderails based on the patient's cognitive and functional status. *Recent research performed in nursing homes suggests that removing or lowering siderails may help to prevent falls that occur when patients climb over them (Capezuti, Wagner, Brush, et al., 2007).*
- Keep the bed in a low position, except when giving care, with wheels locked (Fig. 24-5A).
- Make sure to lock wheels of wheelchairs, especially during transfer activities (Fig. 24-5B).
- Provide nonskid slippers (Fig. 24-5C).
- Keep water, urinal, bedpan, and tissues within easy reach of the patient.
- Place the call light within reach. Have the patient demonstrate the ability to call for the nurse.
- Provide a night light.
- Keep floors dry and free of clutter.
- For patients at risk for falls, place a warning sticker on the chart or door.

Assess, Teach, and Support

- Provide review and modification of medications, especially psychotropic medications.
- Provide gait training and advice on the use of assistive devices.
- Orient the person to surroundings (e.g., bathroom, chairs; you may need to label items).
- Offer to assist with toileting and transfer activities.
- Educate the patient and family regarding fall prevention strategies.

Policies, Procedures, Routines

- Consider instituting hourly rounds on your unit. *This has proven effective in reducing the number of falls.*
- Place disoriented patients in rooms near the nurses' station.
- Provide regular nursing surveillance of hospitalized older adults. *Research suggests that this can reduce their falls rate by about 50% (Shever, Titler, Kerr, et al., 2008)*
- Ask patients at risk for falling to wear red or brightly colored socks to alert caregivers.
- Communicate falls risk status during handover and transfer reports.
- Document changes in the patient's condition in the patient record.

Toward Evidence-Based Practice

Compton, J., Copeland, K., Flanders, S., et al. (2012). Implementing SBAR across a large multihospital health system. *Joint Commission Journal on Quality and Patient Safety, 38*(6), 261–268.

Researchers assessed by survey (1) nurses' use of the SBAR (situation, background, assessment, and recommendations) standardized communication tool and (2) physician perception of communication quality after SBAR implementation. Findings indicated that more than half of nurses who participated in the study already used SBAR for critical communication. Findings indicated that:

- 72.6% of nurses demonstrated good or high proficiency with SBAR.
- Of 155 physicians, 78.1% said that the last report they received was adequate to make clinical decisions.
- Of the 27 physicians who indicated that the last report was not adequate, 25 had not received the report in SBAR format.
- Challenges included inconsistent use across facilities, lack of physician education about SBAR, and a tendency to view SBAR as a document rather than a verbal technique.

Vardaman, J., Cornell, P., Gondo, M., et al. (2012). Beyond communication: The role of standardized protocols in a changing health care environment. *Health Care Management Review, 37*(1), 88.

A qualitative case study of two hospitals collected data from 80 interviews with nurses, nurse managers, and physicians. Results indicated that SBAR in addition to standardizing communication among nurses and physicians, SBAR may:

- Aid in rapid decision making by nurses, leading to better patient outcomes
- Provide a tool for less-tenured nurses to feel confident in communication
- Reinforce a move toward standardization in the nursing profession

Findings further suggest that standardized protocols may be a cost-effective method for hospital managers and administrators to accelerate the socialization of nurses, particularly new hires.

1. Identify a recent interaction you have had in which communication was difficult. What issues specific to the healthcare setting may encourage communication difficulties?

2. Communication problems among healthcare personnel can jeopardize patient safety. SBAR, a structured communication technique, has been adapted from aviation and the military as a strategy for clear communication based on a statement of the situation, background, assessment, and recommendations related to a clinical issue. Based on the findings from each of the studies, identify specific way that the use of SBAR can impact patient safety

Go to Chapter 24, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

Key Point: ***You should try to extinguish the fire only* after *you complete the R-A-C steps, and only a* small *fire that is contained to one area, such as a trash can. If the fire gets out of control, leave the area immediately.***

Extinguisher Classifications You should know where the extinguishers are located in your facility and know how to use them.

Most agencies use multipurpose (Class ABC) extinguishers.

Class A	Wood, paper, rubber, textiles, plastics
Class B	Flammable liquids, gases, oils, solvents, paints, or greases
Class C	Live electrical wires or equipment
Class D	Combustible metals (e.g., potassium, magnesium, titanium)
Class K	Kitchen fires involving cooking oils and fats

If you would like to read journal articles about evacuating patients,

Go to Chapter 24, **Reading More About Safety,** on Davis*Plus*.

Preventing the Need for Restraints

Sometimes restraints are necessary: They may be needed to ensure the immediate physical safety of the patient or others, for instance. When that occurs, follow organization policies and always use the least restrictive restraint that ensures safety. To learn about applying and using restraints, see the Procedure Highlights box summary and

Go to **Procedure 24-2, Using Restraints,** and **Clinical Insight 24-2, What You Should Know About Using Restraints,** in Volume 2.

Key Point: ***Restraints are a last resort. The current standard of care is restraint-free.***

The following nursing interventions provide less restrictive alternatives to using restraints for patients who are confused or otherwise cognitively impaired.

Provide Consistency Keep the environment and the caregivers as consistent as possible. Family members may be able to interpret a patient's gestures or understand what is bothering him. To help relieve anxiety, encourage family and friends to remain with the patient around the clock for a few days after admission. Also encourage family and friends to help with care and to bring familiar objects from home.

Review the Patient's Medications Some may affect mental status or balance.

Provide Relaxation and Relieve Anxiety You may wish to try some of the following measures.

- Orient patients and families to their surroundings; reorient as often as necessary. This helps to relieve anxiety and prevent wandering.
- Have family and friends help with activities of daily living (ADLs). This also provides consistency.
- Use therapeutic touch and relaxation techniques, such as massage.
- Use the least invasive and most comfortable method to deliver care. For example, use a toileting schedule or provide a bedpan instead of inserting a urinary catheter; or encourage and provide oral fluids to avoid inserting an IV for hydration.
- Discontinue treatments that cause discomfort or agitation as soon as possible. For example, some patients become agitated and pull at or try to escape sensations from indwelling catheters, intravenous catheters, and nasogastric tubes.

Provide Frequent Assessment and Surveillance Use one-to-one supervision as needed—encourage family members and friends to stay or to hire sitters for clients who need supervision. Place patients with cognitive deficits or who need supervision for other reasons near the nursing station, and check on them frequently. Assess all patients regularly for cognitive changes.

Find Ways to Communicate It is important to communicate with patients who have cognitive deficits. Assess the patient's communication abilities to determine whether he can communicate what he needs and wants. You will need to be especially alert for body language, such as gestures, nods, and eye contact, as these may be the patient's only way of communicating. Speak clearly, calmly, and slowly. Smile, and face the patient. Ask the patient directly what she needs, for example, "Do you need the bathroom?" Word the question so the patient can answer with a yes or no.

Modify the Environment Some simple ways to prevent agitation and confusion are to reduce noise on the unit and provide adequate light. Music therapy is also calming to many patients. Use wedge cushions and body props for patients sitting in chairs to help them maintain good posture in the chair; these help keep them from slumping and falling out of the chair.

Use low beds for patients who are likely to fall or wander. In some situations it is best to remove bed rails. Keep doors to the unit locked if this is feasible and acceptable; in long-term care facilities, also lock outside doors. Have a staff member at main entrances and exits.

Ambularms and bed alarms are another alternative for restraints with patients who climb out of bed and are in danger of falling. The Ambularm is worn on the leg and signals when the leg is in a dependent position, such as over the siderail or on the floor. Another type of alarm is an integral bed alarm, which beeps if the patient's weight is off the mattress for more than a few seconds. For specific instructions about using alarms, see Procedure 24-1.

Anticipate Unmet Needs Often patients try to get out of bed because they have a need they cannot express. The best way to achieve restraint-free care is to individualize care to avoid the risky behavior. Look for the meaning of disruptive behaviors (e.g., wandering). Is the behavior a way of expressing an unmet need (e.g., is the patient thirsty or in pain)? The following are examples of actions to anticipate patient needs:

- Plan an elimination routine based on the patient's history. Patients often try to get out of bed because they need to go to the toilet.
- Provide pain relief and other comfort measures to decrease agitation.
- Provide diversional activities.

Sometimes restraints are necessary to ensure the immediate physical safety of the patient or others. When that occurs, follow organization policies and always use the least restrictive restraint that ensures safety. Also see Procedure 24-2 and Clinical Insight 24-2.

Responding to Mercury Spills

If a mercury spill is not properly cleaned, the mercury can remain in cracks and crevices for long periods of time and cause continuous exposure to mercury vapors. Large spills usually must be cleaned by a pollution control agency and can be very costly. It is especially difficult to remove mercury spills from carpets, so they usually have to be disposed of as hazardous waste. If you must clean mercury spills of 25 mL or less (e.g., from a broken, glass thermometer), consult Box 24-5.

Keeping Equipment Safe

The following interventions help ensure safe use of equipment:

- Seek advice if you are unsure how to operate the equipment.
- Make sure medical equipment has been properly inspected.
- Be alert to signs that the equipment is not functioning properly.
- Make sure that rooms are not cluttered with equipment.
- Follow agency policies regarding equipment brought from the patient's home (e.g., hair dryers, electric shavers, radios); usually these should be inspected for proper grounding and safe cords.

Coping With Violence

Some agencies have a "public safety room." Patients who have been arrested and brought to the hospital for

BOX 24-5 ■ What to Do If There Is a Mercury Spill

Do not touch mercury droplets. Mercury vaporizes; the toxic vapors can be inhaled or absorbed through the skin.

In the Healthcare Agency

If you are not trained in the procedure, do not attempt to clean up a mercury spill. Notify the environmental services department.

- Keep people and animals away from the area.
- Clean the spill promptly.
- If you are trained, use a commercially made mercury spill kit. All healthcare facilities should have them. Spill kits should contain gloves, protective glasses, mercury-absorbing powder, special mercury sponges, and a disposal bag. Some kits have filtered vacuum equipment.
- Follow agency guidelines and instructions in the kit.
- Clean beads off skin, clothing, and disposable items. Place cleaning materials and disposable items in the disposal bag and seal. Follow agency policy for laundering clothing.
- On hard surfaces, use a flashlight to search for beads.
- Change clothing that has been contaminated.
- Wash well. Shower and wash your hair as soon as possible so you do not unknowingly carry mercury home.
- Ventilate the area well to reduce the concentration of mercury vapors. Promote exhaust ventilation if possible.
- Complete an occurrence report.

In the Home and Community

- If you do not have a spill kit, wear rubber gloves and eye protection; use paper towels for cleanup and a plastic bag for disposal.
- Keep people and pets away from the area.
- Wipe beads off skin, clothing, and disposable items. Place disposable items in the plastic bag and seal with tape.
- On hard surfaces, use cardboard to scrape up the beads and pour them into a can or jar with a lid. Then wash the area.
- Shower or wash well.
- Keep the area well ventilated for several days.
- Do not use a broom or vacuum cleaner. These will just spread the mercury around and be contaminated by it.
- Do not flush mercury or cleaning materials down a toilet or drain.
- Do not wash and reuse contaminated materials.

blood and urine testing for alcohol and drug levels or any hostile patient who has risk factors for violence should receive care in the public safety room. The following are other interventions for preventing and protecting yourself from violence (Ackley & Ladwig, 2010; Bulechek, Butcher, Dochterman, et al., 2012; Doenges, Moorhouse, & Geissler-Murr, 2010; Flores, 2008; Wilkinson, 2013):

- Intervene to relieve anxiety. Anxiety often precedes violent behavior.
- Treat underlying medical conditions. For example, give medications or check blood glucose levels.
- Administer sedatives such as diazepam or lorazepam. There may be standing prescriptions for these.
- Use a calm, reassuring approach.
- Avoid using threatening, aggressive body language.
- Don't respond to anger with anger.
- Don't defend when the patient is verbally aggressive.
- Don't wear a stethoscope around your neck, dangling jewelry, or anything a patient might use to hurt you.
- If you know you will be receiving an angry patient, remove from the room objects that could be used as a weapon.
- Don't go into a room alone with an angry patient.
- Keep the room door open; do not let the patient get between you and the door.
- Remain at least an arm's length away from the angry patient.
- Do not turn your back on an angry patient.
- Do not touch the patient without permission, unless you intend to physically restrain him.
- Protect others in the environment. Follow the department's safety guidelines.
- As a last resort, use mechanical restraints if ordered and as necessary.
- Your priority must be your own safety and the safety of others in the area.

If you would like some guidelines for coping with the presence of gang members in the hospital,

Go to Chapter 24, **Tables, Boxes, Figures; ESG Box 24-6, Guidelines for Coping With the Presence of Gang Members in the Hospital,** on Davis*Plus*.

Which Safety Interventions Can I Delegate?

As nurse manager on a clinical unit or as a primary care nurse, you may need to delegate safety promotion interventions to nursing assistive personnel (NAP). Which safety interventions would you delegate?

For all delegation decisions, refer to the discussion and guidelines in Chapter 7. One safety activity you might delegate is applying restraints. As in all delegation, you must first be sure that the NAP is competent to perform the skill. You may delegate the application of the restraints; however, you may *not* delegate the assessment of the patient's status nor the evaluation of the patient's response to the restraints. You may assign the NAP to (1) remove and reapply restraints to provide skin care and allow for supervised movement and (2) observe for skin excoriation under or around restraint location and report it to you.

You should be sure assistive personnel are aware of and follow all safety measures and institutional procedures. For example, you can expect the NAPs to remove clutter and spills in patient rooms, to provide patients with nonskid slippers, and to lock beds and wheelchairs.

Highlights of Procedures 24-1 and 24-2

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 24-1: Using a Bed Monitoring Device

- Select the correct type of alarm for your patient.
- Explain to the patient and family that the device alerts the staff when the patient tries to get out of the chair or bed.
- Apply or place the device; connect the control unit to the sensor pad.
- Connect the control unit to the nurse call system, if possible.
- Explain that the patient will need to call for assistance when she wants to get up.
- Disconnect or turn off the alarm before assisting the patient out of the bed or chair.
- Reactivate the alarm after assisting the patient back to the bed or chair.
- Understand that bed alarms do not prevent falls by themselves; they are used to improve the timeliness of staff response. Patients who are at risk for falls require increased observation and surveillance.

Procedure 24-2: Using Restraints

- Follow agency policy, state laws, and professional guidelines.
- Try alternative interventions, such as the following, first:

  Bed/chair alarms

  Patient sitters (nonprofessional staff hired to watch the patient)
- Use the least-invasive method among the various types of restraints:

  Verbal restraints

  Chemical restraints (e.g., antipsychotic or sedative medication)

  Seclusion (safe containment to deescalate)

  Physical restraints (4-point devices, tie-on, Velcro, leather)
- Use restraints only as a last resort to protect a patient and/or caregiver from injury; not for the convenience of the caregiver or as a punishment.
- Obtain the required consent form.
- Obtain a medical order before restraining, except in an emergency.
- Secure restraints in a way that allows for quick release.
- Ensure that restraints do not impair circulation or tissue integrity.
- Check restraints every 30 minutes.
- A prescriber must reassess and reorder the restraints every 24 hours.
- Release restraints and assess every 2 hours (more often for behavioral restraints).

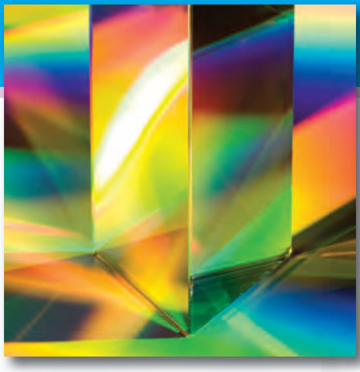
CHAPTER 25



Facilitating Hygiene

Learning Outcomes

After completing this chapter, you should be able to:

- Explain how personal hygiene relates to health and well-being.
- Identify factors influencing personal hygiene practices.
- Discuss delegation of hygiene activities to nursing assistive personnel (NAP).
- Discuss the nurse's role in determining a client's self-care ability.
- Identify nursing diagnoses related to self-care ability and hygiene practices.
- Describe assessments to make when providing hygiene care of the skin, feet, nails, mouth, hair, eyes, ears, and nose.
- Describe the following types of baths: complete, assist, partial, towel, bag, shower, tub, and therapeutic.
- Apply the nursing process to common hygiene-related problems of the skin, feet, nails, mouth, hair, eyes, ears, and nose.
- Demonstrate nursing skills to promote patient hygiene (such as bathing, foot care, and bed making).
- Demonstrate care of the eyes, ears, and teeth, including glasses, contacts, hearing aids, and dentures.
- Discuss the relationship between a patient's overall well-being and the immediate environment.

Key Concepts

Activities of daily living
Hygiene
Self-care ability

Related Concepts

See the Concept Map on Davis*Plus*.

Meet Your Patients

You and a NAP (nursing assistive personnel) are to assist the following patients with their hygiene.

The first patient is Mrs. Williams, a 76-year-old woman of Indian heritage who was admitted yesterday after suffering a stroke that paralyzed her right side. Since the stroke, she has been unable to speak clearly and becomes frustrated as she attempts to communicate her needs. Her daughter says Mrs. Williams is a proud, independent, and tidy woman who has been living alone and caring for herself since her husband's death last year, even maintaining the yard and garden. She wears eyeglasses for reading and driving and has a hearing aid.

Your second patient is Mr. Gold, a 68-year-old Orthodox Jewish man admitted last week after a massive heart attack. Although his eyes are open, he does not respond to external stimuli. Because of Impaired Swallowing, Mr. Gold is unable to take food or fluid orally. A feeding tube was placed to ensure adequate nutrition and hydration. His oral mucous membranes and lips are dry and crusty. He is incontinent of urine and stool. Mr. Gold's son, Ira, tells you that throughout his life Mr. Gold adhered to Orthodox Jewish law and requests that, in honor of his father, certain aspects of these laws be included in the care plan.

Think about the following questions now, then again after you have read the chapter. What immediate concerns come to your mind about each of these patients? How will you ensure that their hygiene needs are met? Are there any safety issues? Which parts of their hygiene care can you delegate, if any?

Theoretical Knowledge knowing why

This chapter provides the theoretical knowledge you need to answer the preceding questions, as well as others that will arise as you care for patients. It begins first with an explanation of the concepts of hygiene, activities of daily living, and self-care.

ABOUT THE KEY CONCEPTS

The concept of hygiene is the broadest of the key concepts because everything in the chapter is related to **hygiene**. However, the concepts of **activities of daily living** and **self-care ability** must also be considered key concepts because every aspect of hygiene must include consideration of these two ideas. That is, you need to know the patient's ability to perform an activity of daily living in order to know how to give appropriate hygiene care (e.g., can he wash his entire body, or just his hands and face?).

HYGIENE AND SELF-CARE

Hygiene describes activities involved in maintaining personal cleanliness and grooming. **Activities of daily living (ADLs)**, such as taking a bath or shower, washing hair, or brushing and flossing teeth promote comfort, improve self-image, and decrease infection and disease. Healthy people perform their own personal hygiene; however, some patients need assistance because of illness or injury. As a nurse, you are responsible for providing the necessary assistance and, at the same time, encouraging as much self-care as possible to promote activity, independence, and self-esteem.

What Factors Influence Hygiene Practices?

Every patient is unique, so as you would expect, personal hygiene practices vary greatly. To reflect caring, expand your understanding of the concept of hygiene to respect and accommodate each person's preferences and differences whenever possible.

Personal Preferences Some people prefer a shower, others a bath. One person may shower in the morning to wake up and feel clean for the day, whereas another bathes in the evening to relax before going to sleep. Choice of soaps and shampoos varies as well.

Culture and Religion or Spirituality Cultural and family values and beliefs about hygiene form the foundation for our beliefs as adults. Generally, people in North America consider daily bathing, use of deodorant, and brushing the teeth necessary to eliminate body odors. However, people in some cultures may find a weekly bath sufficient. Some religious or spiritual beliefs also influence hygiene practices. For example, Orthodox Judaism prohibits receiving personal care from a member of the opposite sex.

Economic Status or Living Environment Inadequate bathing facilities or lack of money for hygiene supplies (e.g., lack of access to running water or soap) can influence how often a person bathes. People living in poverty must focus on meeting basic needs for food and shelter before they can spend money and energy on hygiene.

Developmental Level Parents and other caregivers perform hygiene care for infants and young children. Older children learn practices that become habits, such as brushing and flossing the teeth. As older children begin to perform their own hygiene independently, they are influenced by media and societal norms. For example, some preteens may avoid water and bathe only under parental duress, but teenagers, who are typically very self-conscious, may begin to take several showers a day. Many teenagers have oily skin and can tolerate frequent bathing, but as we age, the oil-producing sebaceous glands become less active. For adults, frequent bathing and the use of deodorant soap further dries the skin. Older adults may find it necessary to bathe only every 2 or 3 days, use less soap, and increase the use of skin moisturizers.

Knowledge and Cognitive Levels Not everyone has the knowledge needed to make appropriate decisions. For example, some people may not know the importance of flossing. Some women may not be aware of the importance of cleansing the perineum from front to back after using the toilet. Patient teaching is an important part of your hygiene care because most people will, eventually, be responsible for their own personal hygiene.

ThinkLike a Nurse 25-1

Think about Mrs. Williams and Mr. Gold (Meet Your Patients). After reviewing each of the factors presented, determine the following for each patient:

- Which factor(s) will have the most influence on the hygiene practices of this patient?
- Why do you think so?
- How will this factor affect the individual plan of care?

How Does Health Status Affect Self-Care Ability?

Both physiological and emotional factors can interfere with a person's ability or willingness to perform hygiene measures.

Pain Pain severely limits the person's ability and motivation to perform ADLs. The pain itself, limited mobility caused by the pain, and drowsiness from analgesics used to manage the pain may all contribute to a self-care deficit.

Limited Mobility Limited mobility (e.g., from joint and muscle problems, injury, weakness, fatigue, surgery, prescribed bedrest, or pain) makes it difficult to perform hygiene activities. For example, a patient may be unable to bend over to wash her lower legs and feet, cut her toenails, or even raise her arms to wash and dry her hair. A patient who is weak or "lightheaded" may be afraid of falling and be reluctant to move about. Such a person needs help, especially getting into the bathtub or shower. Obstacles, such as IV lines, oxygen tubing, nasogastric tubes, indwelling urinary catheters, or casts, may also interfere with the patient's ability to perform self-care.

Sensory Deficits Sensory deficits diminish a person's ability to perform hygiene measures safely and independently. Safety is a priority for patients with sensory deficits. Consider these examples:

- A patient with macular degeneration (a visual deficit) is admitted to the hospital. Because he is unfamiliar with the new surroundings, he is unable to gather necessary supplies for grooming. You would need to provide direction, assistance, and understanding.
- A patient with a hearing loss is taking an anticoagulant (a medication to delay blood clotting). You may need to provide explicit written instructions about the importance of using an electric razor instead of his preferred double-edged razor.

Cognitive Impairment Cognitive impairment, such as is found in patients with dementia, delirium, psychoses, stroke, Alzheimer's disease, or traumatic brain injury, may make it impossible for the person to initiate his own grooming. The patient may be unable to determine the need for hygiene, much less know how to accomplish related tasks. For example, a patient with advanced Alzheimer's disease may actually forget how to care for himself and will need step-by-step direction. Because the person may also have difficulty interpreting stimuli in the environment, he may be fearful and resistant to hygiene measures performed by the nurse. Such cognitive deficits may require new or modified hygiene plans.

Emotional or Other Mental Health Disturbances These may diminish a person's ability to perform hygiene measures. Patients experiencing altered reality states, such as psychoses, delusions, or hallucinations, may dress inappropriately for the weather or the situation and have poor hygiene practices. Some are unable to make decisions about "what to do next" when bathing, dressing, and so on. A person who is depressed may neglect his grooming and hygiene because of a profound lack of energy or motivation.

KnowledgeCheck 25-1

- What are the benefits of personal hygiene?
- Why should you respect and accommodate your patients' hygiene preferences?
- Identify two economic or living environmental factors that may influence how frequently person bathes.
- Identify one example of a cognitive impairment that may make independent initiation of grooming impossible.
- Why may people experiencing depression neglect their grooming and hygiene?

PracticalKnowledge knowing how

This section of the chapter will assist you to assess for and promote self-care abilities and to plan care for patients with Self-Care Deficits. Plan hygiene care around the patient's needs, not facility routines or staff convenience.

ASSESSMENT (SELF-CARE)

Assess your patient's functional status regularly. This enables you to identify the need to modify the care plan and set achievable goals for self-care. Focus on the patient's *ability* to perform hygiene measures and the need for assistance, not necessarily on the *quality* of these measures. For a focused hygiene assessment guide that includes assessment of self-care abilities, as well as the skin, feet, nails, oral cavity, hair, and eyes,

Go to Chapter 25: **Assessment Guidelines and Tools, Assessment Guidelines: Hygiene,** in Volume 2.

For thorough assessment of those body systems, you can also refer to Volume 2 of Chapter 22, Health Assessment.

Assess Overall Self-Care Abilities

To describe a patient's self-care abilities, use a standardized functional status rating scale to assign a score to each response. Various scales are available, or you can create your own (see Box 25-1). Begin your assessment of self-care ability by conducting an initial interview with the patient and/or family, which includes the following:

Obtain a Health History Identify underlying illness, injury, or disease that might contribute to a self-care deficit or affect tolerance of hygiene procedures. *Cognitive impairment*, such as is found in patients with dementia, delirium, stroke, or traumatic brain injury, may make it impossible for the person to determine the need for hygiene, much less know how to accomplish related tasks. *Depression*, *psychoses*, or *delusions* may cause a profound lack of energy or motivation, causing patients to have poor hygiene and dress inappropriately for the *situation*.

BOX 25-1 ■ Functional Level Classification

1 Can do alone
2 Needs equipment or device; or someone to supervise
3 Needs hands on help; may also need an assistive device
4 Totally dependent; unable to assist

Assess Cognitive Ability and Physical Functioning Determine overall grooming and cleanliness, level of consciousness, short- and long-term memory, ability to follow instructions, range of motion (ROM) and mobility, level of knowledge, and energy level.

Assess for Sensory Disturbances Assess for auditory, visual, tactile, or olfactory disturbances that interfere with the ability to perform hygiene care safely and independently. For example, a person who has decreased tactile sensation (sense of touch) may be at risk for burns because he is not able to determine the temperature of the bath water.

Assess Mobility Limited mobility (e.g., from IV lines, joint and muscle problems) makes it difficult to perform hygiene activities such as bathing.

Assess Pain Pain and analgesic side effects can severely limit the ability and motivation to perform ADLs.

Assess for Other Factors Identify other factors (e.g., cultural, religious) that may influence hygiene practices and preferences.

Determine Preferences and Practices Identify the patient's previous hygiene measures, normal routines, preferences, need for assistive devices, or any other existing problem areas.

ThinkLike a Nurse 25-2

Answer the following questions for Mrs. Williams (Meet Your Patients):

- What factor(s) may interfere with Mrs. Williams's self-care ability?
- How can you ensure maximum independence with hygiene for her?
- How might you encourage her to strive toward optimal functioning?

ANALYSIS/NURSING DIAGNOSIS (SELF-CARE)

When a person is unable to perform one or more ADLs, a self-care deficit exists. NANDA International (2012) Self-Care diagnoses related to hygiene are Bathing, Dressing, Toileting, and Feeding, and sometimes Self-Neglect. Except for Feeding Self-Care Deficit, which is included in Chapter 27, you can find definitions and defining characteristics for each diagnosis if you

Go to Chapter 25, **Standardized Language, NANDA-I Diagnoses to Describe Self-Care Abilities,** on Davis*Plus*.

Common Etiologies Common etiologies for Self-Care Deficit diagnoses include such factors as Activity Intolerance, Fatigue, decreased strength or endurance (e.g., as in emphysema, pneumonia, heart failure), and lack of motivation. Other etiologies were discussed in the Theoretical Knowledge section preceding (e.g., limited mobility; pain; developmental, knowledge and cognitive levels; and personal, cultural, and religious preferences).

The following are examples of nursing diagnoses:

Self-Care Deficit (Bathing, Dressing) related to Activity Intolerance secondary to heart failure

Self-Care Deficit (Bathing) related to cognitive and emotional effects of substance abuse

When writing self-care diagnoses, classify the patient's functional level if you have access to a standardized scale, such as the one found in Box 25-1. Otherwise, use descriptive terms such as *mild*, *moderate*, *severe*, and *total*. The following are examples of diagnostic statements you might write:

Using a scale: Bathing Self-Care Deficit **(2)** related to severe knee pain secondary to degenerative joint disease

Using descriptive words: Toileting Self-Care Deficit **(severe)** related to inability to walk to the bathroom secondary to muscle weakness

ThinkLike a Nurse 25-3

- Which of the preceding NANDA-I self-care diagnoses apply to Mrs. Williams and Mr. Gold (Meet Your Patients)?
- Explain the reasoning for your choices.
- For each patient, what are the related factors for his or her Self-Care Deficit?
- Write a self-care diagnostic statement for Mrs. Williams and Mr. Gold.

PLANNING OUTCOMES/EVALUATION (SELF-CARE)

To see a bathing plan of care and care map,

Go to Chapter 25, **Care Plan: Bathing Self-Care Deficit,** on Davis*Plus*.

The NOC standardized outcome Self-Care: Activities of Daily Living (ADLs) is appropriate for all of the Self-Care Deficit diagnoses. For outcomes for specific diagnoses,

Go to Chapter 25, **Standardized Language, Selected Standardized Outcomes and Interventions for Self-Care Deficit Diagnoses,** on Davis*Plus*.

Individualized goals/outcome statements you might write for Self-Care Deficits include the following examples:

- Verbalizes satisfaction with body cleanliness and oral hygiene after a.m. care.
- Accepts assistance with ADLs or total care, if needed.

You will use the outcomes developed in the planning outcomes phase of the nursing process as the criteria for evaluating patient responses to self-care interventions.

PLANNING INTERVENTIONS/IMPLEMENTATION (SELF-CARE)

Although cleanliness can contribute to well-being, comfort, and health, it can also be stressful—for example, to critically ill patients, the frail elderly, and those with dementia. Adverse events may include decreased oxygenation or ventilation, hypertension, hypotension, intracranial hypertension, or even cardiorespiratory arrest (Robles, Corcoles, Torres, et al., 2002). This does not mean you should avoid hygiene care for such patients, but you may need to modify it and evaluate patient responses constantly as you work.

Even when a patient needs assistance with hygiene measures, the overall goal is to promote eventual self-care. Even if the patient is able to perform self-care, you might sometimes need to allow him to rest while you perform part of the care, for example, washing his feet and legs.

NIC standardized interventions for Self-Care Deficit diagnoses include Energy Management, Bathing, and Hair and Scalp Care. For other NIC interventions for self-care needs,

Go to Chapter 25, **Standardized Language, Selected Standardized Outcomes and Interventions for Self-Care Deficit Diagnoses,** on Davis*Plus*.

Individualized interventions depend on the extent of the client's Self-Care Deficit, as well as the etiology of the problem. The following are some examples:

- Demonstrate the use of assistive devices (e.g., to help patient grasp and pull on socks).
- Use hook and loop (e.g., Velcro) fasteners instead of buttons and zippers.
- Allow sufficient time for all ADLs to prevent fatigue and frustration.
- Offer pain medication before ADLs.

You will find a thorough discussion of specific hygiene-care activities (e.g., care of the skin, oral hygiene) in the remainder of this chapter.

Types of Scheduled Hygiene Care

The following types of scheduled hygiene care are provided in most inpatient facilities (e.g., hospitals and long-term care settings). Although they are scheduled routinely, you should individualize these activities and involve the patient as much as possible.

Hourly Rounding (Comfort Rounds or Safety Rounds) consists of seeing the patient every hour, on schedule. They are done to offer help with self-care needs such as pain relief, positioning, and toileting. Hourly rounding improves patient safety and greatly reduces call light use (Meade, Bursell, & Ketelson, 2007).

Early Morning Care is provided soon after the patient awakens. It includes preparing the patient for breakfast or other activities, such as diagnostic tests. As needed, assist with toileting, washing the face and hands, giving mouth care, and providing comfort measures.

A.M. (Morning) Care is hygiene care that occurs after breakfast. Depending on the patient's self-care ability, assist with toileting, bathing, oral hygiene, skin care, hair care (including shaving if needed), dressing, and positioning or helping the patient transfer to a chair. You or the nursing assistive personnel (NAP) will also change or straighten bed linens, according to agency policy, and tidy the room.

P.M. (Afternoon) Care consists of preparing patients to receive visitors or afternoon rest. You may assist nonambulatory patients with toileting, handwashing, and oral care; straighten bed linens; reposition the patient; and offer other comfort measures (e.g., pain medications).

H.S. (Hour of Sleep) Care is given before the patient goes to sleep. You should offer the same care as given in the afternoon, adding a back massage to help relax the patient. Also place within easy reach the call light, water glass, urinal, or anything else the patient may need during the night. Turn off lights and TV, and close the door before leaving the room (according to patient needs and preferences). For a back massage procedure,

Go to Chapter 34, **Procedure 34-1,** in Volume 2.

Delegating Hygiene Care

In many institutions NAPs perform most of the hygiene care. However, you will need to carefully assess patients to ensure that it is safe to delegate their care. If the patient is unstable or the NAP is inexperienced or unfamiliar with the patient's limitations, you must assist or perform the care yourself. Read What Should I Know About Delegation and Supervision? in Chapter 7 for a review of making delegation decisions.

Before assigning a NAP to assist with a bath, shower, or toileting, give instructions about the following:

- Patient's limitations and restrictions, and the amount of assistance necessary
- Use of any assistive devices (e.g., cane, walker, or gait belt)
- Specific safety precautions to follow (e.g., use of gait belt or shower chair)
- Any obstacles present, such as drainage tubes, catheters, IV tubing, or bandages, and how to maintain them during bathing or toileting
- Observations to make during the procedure and why the observations are important (e.g., skin condition; presence of lesions; areas of special concern over bony prominences and under abdominal folds and breasts; presence, appearance, and amount of urine or stool; or the need to collect a specimen)

Remember, as the professional nurse, you are responsible for determining the meaning of the data reported to you by the NAP. Assisting with or supervising care (especially a bath) is an excellent opportunity for you to assess the patient's level of consciousness, short- and long-term memory, ability to follow instructions, ROM, skin condition, activity tolerance, and overall self-care ability.

ThinkLike a Nurse 25-4

Think of Mrs. Williams (Meet Your Patients). You have delegated her bathing and oral hygiene to a NAP.

- What information do you need to share with the NAP about this patient's needs, limitations, or preferences?
- What, if any, specific observations will you ask the NAP to make for Mrs. Williams?
- What, if any, specific observations will *you* need to make for Mrs. Williams?
- What action will you take if you determine that the patient's needs and preferences were not met by the NAP?

CARE OF THE SKIN

The preceding sections introduced you to the broad topic of hygiene and ADLs The rest of the chapter will deal with specific topics, such as care of the skin.

Quality and Safety Education for Nurses

Promoting Health and Safety Through Self-Care Management

Chapter Key Concept: *Hygiene, Self-Care Ability*

Competency: *Patient-Centered Care (Knowledge, Skills, Attitudes)**

Background. To promote patient health and safety requires patient-engagement and patient-provider partnership. An active partnership between the patient and healthcare provider establishes trust and encourages self-care management. Hand hygiene is considered the most significant action in breaking the chain of infection. Best practice regarding hand hygiene has primarily targeted healthcare workers without consideration of the role of the patient in the chain of infection (Landers, Abusalem, Coty, et al., 2012). Salcido (2012) reported an increase in hand hygiene compliance in healthcare workers (HCW) when engaging patients and having them ask the HCW, "Did you wash/sanitize your hands?" (p. 342).

Scenario: The student is caring for a patient with a surgical incision. A nurse enters the room and begins to remove the dressing without initiating hand hygiene.

Think about it: In this situation what are the implications for the student nurse in maintaining safe and effective care and prevention of infection?

- Identify specific strategies to engage the patient in self-care management to reduce the risk of infection.
- Debate the value of utilizing the patient-engagement strategy, "Did you wash/sanitize your hands?" as reported by Salcido (2012).

Go to the QSEN Web site at **http://qsen.org/competencies/pre-licensure-ksas/**

*The QSEN, KSA that is most pertinent is: *Engage patients or designated surrogates in active partnerships that promote health, safety and well-being, and self-care management.*

TheoreticalKnowledge knowing why

To assist patients with skin care, you must have theoretical knowledge about personal hygiene measures and the structure and function of the **integument** (skin).

Anatomy and Physiology of the Skin

The **integumentary system** consists of the skin, the subcutaneous layer directly under the skin, the hair, nails, and the sweat and sebaceous glands. The skin has two distinct layers, the epidermis and the dermis (see Fig. 35-1). The **epidermis** (the thicker, outer layer) consists of stratified squamous epithelial tissue composed of keratinized (dead) cells, which are fused to make the skin waterproof. The epidermis continually sheds (**desquamates**) and is completely replaced every 3 to 4 weeks. The epidermis contains melanin**,** a pigment that provides protection against the ultraviolet rays of the sun and that together with circulating blood gives skin its color. The **dermis** (the thinner, second layer) contains blood and lymphatic vessels, nerves, bases of hair follicles, and sebaceous and sweat glands.

Functions of the Skin

The skin has the following five main functions:

1. ***Protection.*** Intact skin is the body's first line of defense against bacteria and other microorganisms that can enter the body and cause infection. It also provides protection from thermal, chemical, and mechanical injury to underlying tissues. **Sebaceous glands** secrete an oily substance called *sebum*, which helps to waterproof and lubricate the skin and decrease bacterial growth.
2. ***Sensation.*** The skin contains sensory organs or receptors for heat, cold, pressure, touch, and pain.
3. ***Regulation.*** The skin helps maintain fluid and electrolyte balance by preventing the escape of excess water and electrolytes from the body. It helps to regulate body temperature through the processes of dilating and constricting blood vessels and activating or inactivating sweat glands. **Sweat glands,** concentrated in the axillae and external genitalia, excrete water in the form of perspiration; evaporation produces a cooling effect on the skin.
4. ***Secretion/excretion.*** The sweat glands secrete fatty acids and proteins and excrete nitrogenous wastes (*urea*), sodium chloride, and water in perspiration.
5. ***Vitamin D formation.*** The skin contains a form of cholesterol that is changed to vitamin D on exposure to ultraviolet light from the sun.

See Chapter 35 for more information about the structure and functions of the skin.

Factors Affecting the Skin

In addition to a person's hygiene practices, health status and developmental stage also affect skin condition.

Health Status

Anything that interferes with the hydration, circulation, and nutrition of the skin creates a risk to skin integrity. As you read each of the following factors, think whether it would be present for Mr. Gold (Meet Your Patients)?

- **Dampness.** Excessive perspiration (e.g., in fever and certain illnesses) and incontinence of urine or bowel cause the skin to become damp. The skin breaks down more easily when it is damp, especially in the skinfolds. This is called **maceration**.
- **Dehydration.** Fluid loss (e.g., from vomiting, diarrhea, or fever) and insufficient fluid intake can cause dehydration. This causes the skin to become dry and to crack easily.
- **Nutritional status.** People who are very thin or very obese are more likely to experience skin irritation and injury. *Morbid obesity* makes it physically difficult to reach all areas of the body, and can lead to development of odor and fungal conditions.
- **Insufficient circulation.** Immobility, vascular disease, and overall inadequate nutritional status may compromise circulation. This predisposes the patient to local tissue death and ulceration when skin cells do not receive enough oxygen.
- **Skin diseases.** Skin diseases such as impetigo (a bacterial infection of the skin) and *systemic diseases*, such as measles and chickenpox, cause lesions that create discomfort and require special hygiene care.
- **Jaundice.** A yellow discoloration of the skin can be caused by accumulation of bile pigments and is a symptom of certain diseases. Jaundice causes the skin to be itchy and dry.
- **Lifestyle and personal choices.** Some people damage their skin by exposure to ultraviolet rays because they want to be tan. Some use sunscreen; some do not. As another example, many people have skin tattoos or piercings, creating the risk for systemic and local infection and scarring.

Developmental Stage

Infants have fragile, easily injured skin. As a child matures, the skin becomes more resistant to injury and infection, but children need adults to provide or supervise the cleanliness of their skin. In adolescence, the sebaceous glands enlarge, and secretions increase. The skin becomes oily and susceptible to acne.

With aging, the skin changes in numerous visible ways, increasing the older adult's risk for skin problems, such as ulcers and reduced ability to heal. Refer to Table 25-1 for a description of normal skin changes in older adults.

KnowledgeCheck 25-2

- What are five functions of the skin?
- How does the skin help regulate body temperature?
- What changes take place in the skin as a person ages?

Table 25-1 ➤ Normal Skin Changes in Older Adults

STRUCTURE	CHANGE IN STRUCTURE AND ACTIVITY	CLINICAL EFFECTS
Epidermis	Thinner; decreased rate of cell turnover	Skin appears pale and somewhat translucent; slower healing.
Subcutaneous tissues	Thinner and more fragile, less fat	Decreased protection of bony prominences and thermoregulation
Collagen and elastin fibers in the dermis	Weaken and become less elastic	Skin becomes wrinkled.
Sebaceous and sweat glands	Activity decreases.	Skin becomes dry, scaly, and itchy. Temperature regulation in hot weather becomes more difficult.
Hormones (estrogen and progesterone)	Production decreases.	Contributes to drying and thinning of the skin.
Skin	Vascularity decreases.	Skin becomes cool and pale.
Hair follicles	Diminish in number and activity.	Hair becomes thin, grows more slowly.
Melanocytes (pigment cells)	Numbers decrease.	Hair turns gray or white; skin may become unevenly pigmented.
Nails	Thicken, become softer, growth rate diminishes.	Nails tear easily.
Skin growths	Become more common (e.g., warts, "liver spots," "age spots").	Most are caused by years of sun exposure; most are harmless (except for skin cancers, which are fairly common but not normal changes).

PracticalKnowledge knowing how

ASSESSMENT (SKIN)

For a thorough discussion of skin assessment, including how to describe and document your observations, see Chapter 22. However, as you provide skin hygiene you should routinely assess the skin. For focused questions and observations,

Go to **Assessment Guidelines and Tools, Focused Assessment: Guidelines for Assessing Hygiene** (section entitled Skin), in Volume 2.

Patients may be sensitive about skin problems or poor hygiene practices, so as you interview and examine the patient, do so in a nonjudgmental, respectful manner. Protect the patient's privacy by closing the curtain and exposing only the area being bathed or examined. Be mindful of the room temperature, and try to reduce drafts to avoid chilling the patient.

Subjective Data Ask the patient about his usual bathing and skin care practices and preferences, as well as the following:

- Past and current skin problems, including their effects on the patient's life
- Prescription and over-the-counter (OTC) or herbal remedies used to treat any skin problems
- Allergic skin reactions to food, medications, plants, skin care products, or other substances
- History of diseases or other factors that are known to cause skin problems, for example, decreased mobility, decreased circulation, incontinence, inadequate nutrition, or deficient knowledge

Objective Data Inspect each area of the skin in an orderly, head-to-toe manner, noting overall cleanliness, condition, color, texture, turgor, hydration, and temperature. Also look for rashes, lumps, lesions, and cracking. Look for drainage from wounds or around tubes. Observe for the following changes in skin color:

- **Pallor** in a light-skinned person may appear as pale skin without underlying pink tones. In a dark-skinned person, observe for an ashen gray or yellow color.
- **Erythema** is redness of the skin. It is related to vasodilation and inflammation. It is difficult to see in dark-skinned people, so you may discover it by palpating the skin for areas of increased warmth.
- **Jaundice,** a yellow discoloration of the skin, occurs in patients with impaired liver function. It is best seen in the sclerae of the eyes.
- **Cyanosis,** a bluish coloring of the skin, is caused by decreased peripheral circulation or decreased oxygenation of the blood. It may be related to cardiac, pulmonary, or peripheral vascular problems (e.g., arteriosclerosis). In dark-skinned patients, you can best see cyanosis by examining the conjunctivae, tongue, buccal mucosa, and palms and soles for a dull dark color.

KnowledgeCheck 25-3

- True or False: The professional nurse is responsible for making assessments.
- True or False: Assisting with the bath is an excellent time to assess the patient.
- To inspect for pallor in a dark-skinned person, which areas would you assess for an ashen gray or yellow color?
- What is the term that means "a bluish color of the skin"?
- Name two physiological causes of erythema.
- Where can you best see jaundice?

ANALYSIS/NURSING DIAGNOSIS (SKIN)

You should be familiar with the following common skin problems and observe for them as you provide skin care:

- **Pruritus** (itching) may lead to scratching and breaks in the skin and skin.
- **Dry skin** tends to crack, burn, or itch.
- **Maceration** is softening of the skin from prolonged moisture (e.g., urinary incontinence). It makes the epidermis more susceptible to injury.
- **Excoriation** is a loss of the superficial layers of the skin caused, for example, by scratching and by the digestive enzymes in feces.
- **Abrasion,** a rubbing away of the epidermal layer of the skin, especially over bony areas or prominences, is often caused by friction or shearing forces that occur when a patient moves or is moved in bed.
- **Pressure ulcers** are lesions caused by tissue compression and inadequate perfusion. See Chapter 35.
- **Acne** is an inflammation of the sebaceous glands that is common among adolescents and young adults.
- **Burns** are a type of traumatic injury caused by thermal, electrical, chemical, or radioactive agents.

To see illustrations of most of those skin problems,

Go to Chapter 22, **Procedure 22-2** and the **Abnormal Atlas** at the end of the chapter, in Volume 2.

Impaired Skin Integrity as the Problem

When you wish to focus on prevention or treatment of the *skin condition,* use the following NANDA-I (2012) diagnostic labels.

- **Risk for Impaired Skin Integrity.** *Definition:* At risk for alteration in epidermis and/or dermis.
  Risk factors: NANDA-I lists about 20 specific risk factors (e.g., radiation, extremes of age). It may be easier for you to remember the general conditions that affect the skin: dampness, dehydration, insufficient circulation, nutritional status (thin or obese), skin diseases, systemic diseases, and jaundice.
  Example: Risk for Impaired Skin Integrity related to immobility secondary to casts and traction
- **Impaired Skin Integrity.** *Definition:* Altered epidermis and/or dermis.
  Defining characteristics: Invasion of body structures, destruction of skin layers (dermis), disruption of skin surface (epidermis).
  Example: Impaired Skin Integrity related to decreased peripheral circulation secondary to arteriosclerosis

Impaired Skin Integrity as the Etiology

Impaired Skin Integrity may be the etiology of other nursing diagnoses. Certain skin problems place the patient at risk for infection by causing cracks or breaks in the skin. Others may contribute to discomfort and low self-esteem. The following are examples:

Risk for Infection related to skin lacerations and abrasions

Situational Low Self-Esteem related to appearance and self-consciousness about skin lesions secondary to severe eczema

ThinkLike a Nurse 25-5

- Why are Mrs. Williams and Mr. Gold (Meet Your Patients) at risk for Impaired Skin Integrity?
- What are the specific kinds of skin integrity problems that pose an increased risk to both patients?

PLANNING OUTCOMES/EVALUATION (SKIN)

For *NOC standardized outcomes* for problems of the skin, feet, nails, mouth, teeth, hair, eyes, ears, and nose,

Go to Chapter 25, **Standardized Language, Selected Standardized Outcomes and Interventions for Hygiene Diagnoses,** on Davis*Plus*.

Two examples of NOC skin outcomes are Tissue Integrity: Skin and Mucous Membranes, and Self-Care: Hygiene.

Individualized goals/outcome statements you might write for a patient with skin problems include the following:

- Skin will remain intact and free of secretions.
- Skin will remain free of lesions.
- Patient will follow regimen to improve skin dryness.

PLANNING INTERVENTIONS/IMPLEMENTATION (SKIN)

Some examples of *NIC standardized interventions* for skin integrity and skin care are Bathing, Perineal Care, and Wound Care. For others,

Go to Chapter 25, **Standardized Language, Standardized Outcomes and Interventions for Hygiene Problems,** on Davis*Plus*.

Individualized nursing activities for patients with Impaired Skin Integrity include bathing and massage, which are presented in this section. You will usually delegate patient bathing to NAPs (Fig. 25-1). Therefore, your most important interventions may be to be certain that the patient actually gets a bath.

Bathing Bathing serves three purposes: health, social interaction, and pleasure or relaxation. Bathing removes perspiration and bacteria from the skin surface, helping to prevent body odor. The warmth from the warm water or bath wipes and the friction of bathing dilate the blood vessels near the surface of the skin, increasing the circulation. Bathing stimulates depth of respirations and provides sensory input. It can also be a time to strengthen the nurse–patient relationship, promote relaxation and comfort, enhance well-being, and improve self-image.

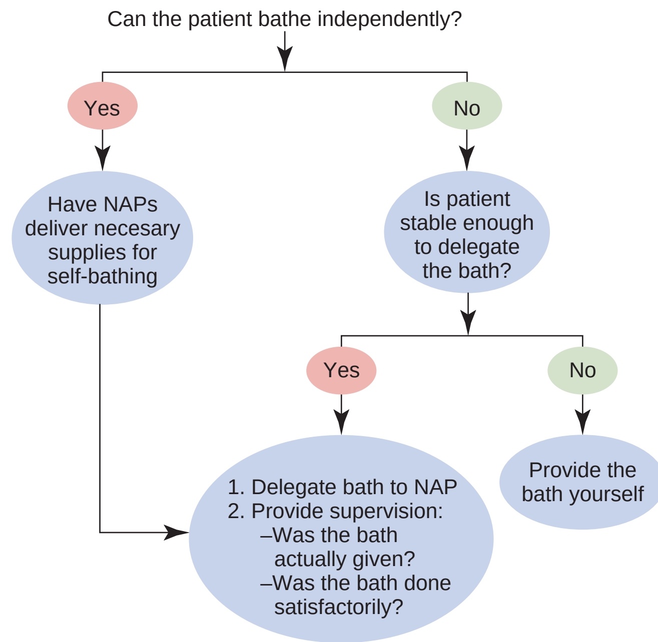


FIGURE 25-1 The RN should assess the patient, delegate bathing as appropriate, and provide supervision.

Back Massage Regardless of the type of bath used, when possible end the bath with a back massage to provide relaxation and stimulate circulation. As with all procedures, be sure there are no contraindications to massage (e.g., fractured ribs, burns, recent heart surgery). To learn a procedure for giving a back massage,

Go to Chapter 34, **Procedure 34-1,** in Volume 2.

Choosing the Type of Bath to Meet Patient Needs

The type of bath you give depends on your nursing judgment; the patient's preference, self-care ability, and endurance; and the medical plan of care. **"Assist" bath** is a term commonly used to indicate that the nurse helps the patient with areas that may be difficult to reach, such as the back, feet, and legs. If a complete bath would be stressful to the patient, you may sometimes give a **partial bath**; that is, you will cleanse only the areas that may cause odor or discomfort, such as the axillae and perineum. A **complete bath** means you will wash the patient's entire body without assistance from the patient. For complete instructions,

Go to **Procedure 25-1: Bathing: Providing a Complete Bed Bath Using a Prepackaged Bathing Product,** in Volume 2.

The following sections discuss other types of baths in detail.

Bed Baths and Modified Bed Baths

A **bed bath** is for patients who must remain in bed but who are able to bathe themselves. You will assist by placing the bath supplies on the bedside stand or overbed table.

Recent evidence supports the now widespread use of **prepackaged bathing products** (Clark & John, 2006). Prepackaged bathing products are a set of commercially prepared and packaged, premoistened, disposable washcloths that are warmed prior to use. Recent guidelines recommend the use of prepackaged bathing products. Studies suggest the following benefits:

- Helps assure consistency of bathing technique among caregivers
- Prevents inconsistent applications of emollients (moisturizers)
- Decreases the skin damage due to rough washcloths
- Decreases the potential for colonization of the skin and the spread of microorganisms with the use of tap water and basins. This is especially true of products containing chlorhexadine (Johnson, Lineweaver, & Maze, 2009; Ritz, Pashnik, Padula, et al., 2012; Rubin, Louthan, Wessels, et al., 2013; Sievert, Armola, & Halm, 2011).

Be certain the patient knows what the packaged bath is for and how to use it. Provide privacy, and place the call device within reach. If the patient cannot bathe all areas of his body, complete the bath for him.

The following are three modified types of bed bath:

- A **towel bath** is a type of bed bath in which you place a large towel and a bath blanket in a plastic bag, saturate them with a warmed, commercially prepared mixture, and use them to bathe the patient. Because the solution dries rapidly, there is no need to towel-dry the patient. Patients find towel baths satisfactory, and some agencies prefer towel baths because they take less time than a traditional bed bath. This is a preferred method for patients who have mild to moderate Impaired Skin Integrity or Activity Intolerance and for patients with dementia (e.g., Alzheimer's disease). See Procedure 25-2.
- A **bag bath** is a modification of the towel bath, in which you use 8 to 10 washcloths instead of a towel and bath blanket. They are moistened with water (preferably sterile, filtered, or distilled) or a pH-balanced no-rinse soap. They are then warmed and each part of the patient's body is cleansed with a fresh cloth.
- A **basin and water bath** is a type of bed bath, in which you use a disposable basin with water; washcloths; lotion; and a pH-balanced, no-rinse soap or a chlorhexidine-and-water solution. This may be done, for instance, if a patient refuses the prepackaged bath or if the patient is grossly soiled (i.e., large amounts of blood or feces). When you use a basin and water bath, you must be aware of the potential for healthcare-acquired infections (HAIs) related to (1) reusable basins and (2) the presence of biofilm in hospital waterlines and plumbing.
- Keep in mind that the potential exists for a bath basin to become a reservoir for microorganisms, leading to cross-contamination of the immediate environment and healthcare personnel. Therefore, if you must provide this type of bath, most recommendations are to use a disposable basin and not to re-use it.
    - **Bath water**. Depending on the agency and the patient's condition, it may be safer to use of distilled, sterile, or filtered water in place of tap water to prevent skin contamination with bacteria biofilm. Some agencies have a serious problem with biofilm, whereas others do not; and some agencies have filtering systems that make the water safe to use. You must know the situation and the policy in your institution. When using tap water, it is a good idea to bathe the patient with a solution of chlorhexadine and water to combat any bacteria that may be present (Rubin, Louthan, Wessels, et al., 2013; Rutala, Weber, & HICPAC, 2008).

Key Point. ***One size does not fit all! The more vulnerable the patient, the more caution you must exercise regarding basin and water bathing.***

Examples of patients who need special measures include the frail elderly, newborns, the critically ill, those who are immunocompromised, those having recent surgery or other loss of skin integrity, and patients requiring mechanical ventilation.

For the AACN guidelines for bathing adults, see Box 25-2.

Key Point: ***Guidelines change frequently; be alert for practice changes.***

Shower

Most ambulatory patients prefer a shower. It is a time-saver and refreshing as well as cleansing. In a hospital or long-term care facility, some clients can manage a shower mostly on their own. You may need to prepare the client's bathing supplies, assist her to the shower, and help with areas of her body that she cannot reach. For complete information,

Go to Chapter 25, **Clinical Insight 25-1: Assisting With a Shower or Tub Bath,** in Volume 2.

You will need to be sure the shower is clean and safe and that the water system is monitored as required by the healthcare agency. Primary prevention measures for nosocomial infections includes ensuring that the water system is designed and maintained in accordance with national standards, including the following:

- The hot water is maintained above 55°C (131°F).
- Routine sampling for bacteria is done.

Avoid showering and exposure to faucet water in patients who are immunocompromised or at high risk of infection. Use sponge baths instead.

Most hospitals and long-term care facilities have safety grab bars and handrails in the bathrooms, but these may need to be installed in the home.

BOX 25-2 ■ Guidelines for Bathing the Adult Patient

Bathing Frequency

For patients who are unable to provide self-care, assist with or provide a bath:

- daily or more frequently for comfort purposes (on patient request)
- to respond to diaphoresis
- to address a significant incontinence episode

Privacy and Timing of the Bath

Maintain patient privacy throughout the procedure.

Bath time should be determined based on:

- patient preference
- clinical stability
- patient's physiological tolerance to activity
- sleep pattern (uninterrupted sleep is essential to the healing process)

Bath Supplies and Products

Prepackaged bath products should be used in place of basin and tap water for regular bathing:

- Remove reusable basins from the environment to encourage use of prepackaged bathing products.
- If using a basin, use sterile or distilled water in place of tap water, unless the hospital has a filtering system that prevents biofilm in the waterlines.
- No-rinse pH-balanced cleansers with emollients help to protect the barrier function of the skin and reduce the risk of dry skin.
- Chlorhexidine gluconate (CHG) 2% prepackaged cloths are recommended to decrease the colonization of bacteria on the skin.
- Do not rinse; retain 2% CHG on the skin at all times.
- Do not use on mucous membranes (face or perineal area).

Adapted from: American Association of Critical-Care Nurses (AACN). (2013). AACN practice alert. Bathing the adult patient. Retrieved April 28, 2013, from http://www.aacn.org/wd/practice/content/practicealerts/bathing-adult-patient-practice-alert.pcms?menu=practice

Tub Bath

If a client is ambulatory but requires much assistance with bathing (e.g., because of pain and stiffness in the hands and arms) you may prefer a tub bath (see Clinical Insight 25-1 in Volume 2). It will be easier for you to wash and rinse the patient, and you will not get as wet as when you help with a shower. Immersion in the water also helps to soak areas that are crusty, scaly, or soiled and relaxes stiff, sore muscles and joints. Overall, tub baths are thought to be of greater benefit than a sponge or bed bath. Evidence suggests that hospital water supplies may serve as a reservoir for pathogens and play a role in their spread, so prevention of nosocomial infections related to the use of tubs should include a stringent maintenance and cleaning according to facility policy.

The tub should have handrails and a nonskid surface to prevent falls. Some patients need assistance getting into and out of a tub. Some kneel or squat first and then sit in the tub. For completely dependent patients, there are specially designed tubs that reduce the effort necessary to lift patients into and out of the tub. You can also use a hydraulic lift and a regular tub (Fig. 25-2).

Therapeutic Bath

The primary care provider may prescribe **therapeutic baths** for some patients. Given that current research suggests that hospital water supplies may serve as a reservoir for pathogens and play a role in HAIs, use of distilled, specially filtered, or sterile water would seem preferable, if in accord with provider prescription and facility policy. It is your responsibility to add the medically ordered substance, ensure appropriate temperature, and assist the patient into the tub. Oatmeal or coal tar baths are examples of therapeutic baths used to treat specific skin conditions, such as chickenpox lesions or psoriasis. A warm sitz bath is another type of therapeutic bath; it helps to cleanse the perineum and soothe inflammation of perineal, vaginal, or rectal tissues. Use a disposable sitz tub if one is available. If a disposable tub is not available, clean the tub thoroughly at the end of the bath, preferably with a chlorhexidine-based product.

Perineal Care

The **perineum** (the area between the anus and vulva in a female, or the anus and scrotum in a male) is a dark, warm, moist area that supports bacterial growth. Perineal care promotes comfort and prevents odor, skin excoriation, and infection. You will usually give perineal care (including the external genitalia) along with a complete bed bath, but it may be needed at other times as well. Give perineal care more frequently if the patient is incontinent of urine or feces or has drainage from the area.

Because of personal, cultural, or religious beliefs, some patients may wish to have a same-sex caregiver provide the bath, or at least be present in the room. Whether you and the patient are of the same or opposite sex, perineal care may be embarrassing for you both. Perform care in a professional manner, and provide the patient with privacy (e.g., shut the door, pull bed curtains, drape properly). A matter-of-fact, sensitive approach puts most patients at ease. For information about providing perineal care refer to the Highlights of Procedures box and,

Go to Chapter 25, **Procedure 25-4: Providing Perineal Care,** in Volume 2.

FIGURE 25-2 *A*, A hydraulic lift allows you to transport a patient to a bath or shower. *B*, A tub with a side-opening door enables patients to safely and easily enter the tub. (Courtesy of Carroll Health Care, London, Ontario, Canada.)

KnowledgeCheck 25-4

- What causes body odor?
- What is the best intervention to rid the skin of body odor?
- What is the rationale for providing perineal care?
- How can you protect patient privacy during perineal care?

ThinkLike a Nurse 25-6

- Which of your patients (Meet Your Patients) will require nurse-assisted perineal care? Explain your reasoning.
- Which patient, if you are a woman, is most likely to be embarrassed by perineal care? Explain your reasoning.
- If you need more theoretical knowledge to answer these questions, what is it? Where could you find the information?

Bathing Patients With Dementia

Bathing should be a pleasant experience, not a stressful one. But patients with dementia tend to become agitated when told it is time to bathe, and often yell, scream, pinch, or hit their caregivers (Rasin & Barrick, 2004). The reason for the patients' agitation is usually that they experience pain, cold, fear, and loss of control. When the nurse meets patient comfort needs, (e.g., by maintaining the temperature of the prepackaged wipes or taking special care when washing arthritic joints), the patient becomes less agitated and aggressive behavior declines significantly. Nurses and NAPs sometimes focus, mistakenly, on the need to give a daily tub bath or shower. You can significantly reduce aggressive behaviors by giving a towel bath or bag bath instead (Konno, Stern, & Gibbs, 2013). Despite the common myths about bathing, keep in mind that:

- It does not take a large amount of water (e.g., a shower) to get a person clean. Prepackaged bathing products resulted in the use of significantly less product, a reduction in time to gather supplies and perform the bath, lower cost, and higher nurse satisfaction.
- The bath does not have to be performed at the same time every day, nor in the way "we have always done it here." You can educate families that a shower or tub bath is not the only ways to get clean.
- The patient will not be at more risk for skin problems or infections if a towel bath is used.
- It is not necessary to bathe a person who is resisting. You can adapt the approach, method, and time.
- Patients who are forced to bathe do not "just forget about it"; many stay upset and agitated for hours.

For more discussion of bathing myths and for instructions about providing a towel bath for a person with dementia,

Go to Chapter 25, **Clinical Insight 25-2, Bathing a Patient With Dementia,** in Volume 2.

ThinkLike a Nurse 25-7

Suppose you have been providing towel baths to a patient who has mild dementia. One day a visiting family member says, "My father tells me he has not had a bath all week. What's going on here?" What would you do? How could you help to prevent this misunderstanding in the future?

Bathing Morbidly Obese Patients

Obesity is traditionally defined as a body mass index of 30 or higher (about 20% to 40% above one's ideal weight). Severe, or **morbid**, obesity exists when the body mass index (BMI) is 40 or higher (or body weight is 50% more than ideal weight). For the morbidly obese person, thorough skin assessment is essential, but it is difficult. Be sure to obtain adequate assistance to reposition the patient during the skin exam, so that you do not miss any areas. Pay special attention to skinfolds. Refer to Table 25-2 for etiologies of skin problems in morbidly obese clients, and for interventions to use when providing skin care for severely obese patients. Teach these interventions to NAPs and to patients who bathe independently.

Table 25-2 ➤ Skin Care for Morbidly Obese Clients

PROBLEM ETIOLOGY	INTERVENTIONS
Hygiene	
Morbidly obese clients find it physically difficult to reach all areas of the body. In addition, they may have limited mobility. Inability to maintain good hygiene may lead to odor and fungal infections.	Ask how the patient handles skin care at home. Use the same adaptations, if possible. Provide a trapeze to assist the patient to lift and reach difficult areas. Provide a handheld shower and long-handled brushes. Experts vary on the use of soap. Certainly the skin should be rinsed and dried well.
Moisture	
Skin in skinfolds stays damp because perspiration cannot evaporate. Moisture contributes to the development of fungal and other skin infections.	Use moisture barrier creams, particularly in skinfolds. Use fans, if permitted. Change linens often. Manage incontinence, including petrolatum barrier creams. If fungal infections occur, you may need a medical prescription for antifungal powders, sprays, cream, or ointment.
Pressure	
Pressure can be caused by limited mobility, by skin folds where skin rubs on skin, by tight clothing, catheters, and so on.	Reposition the patient frequently to redistribute the pressure of the skinfolds. Reposition catheters and tubes often; use tube holders to prevent rubbing. Separate the skin folds with towels.
Shear and Friction	
The patient is at risk for friction and shearing injury from pulling skin across the linens when moving in the bed and chair.	The ANA's (2013) position is that you should use specialized lifts and other equipment to move patients safely and avoid injury to yourself. If in an emergency you must move the patient, obtain sufficient help to avoid pulling the skin across the sheet or other surfaces. Do not use sheepskins. Use a waterproof and breathable mattress cover. Keep linens wrinkle-free. Provide a trapeze.
Nutrition	
Morbidly obese patients may have poor nutritional status because of lifestyle factors (e.g., fast-food intake and other poor dietary habits) and lack of exercise or mobility.	Recommend evaluation by a nutritionist. Monitor blood sugar. Encourage adequate protein intake.

Source: Beitz, J. M. (2014).

Bathing Older Adults

For older adults, especially the bed-bound and frail elderly, you must provide proper skin care and bathing techniques to prevent skin breakdown. At the same time, you should promote comfort and encourage independence in ADLs. Goals are to prevent drying of and injury to the skin. Bag baths adequately address the problems of skin dryness, itching, and irritation. They also improve skin integrity, and are far less distressing to frail older adults (White-Chu, & Reddy, 2011). Use a no-rinse pH-balanced cleanser to further protect the barrier function of the skin. Other interventions include avoiding use of soap, being sure to clean the skin immediately after soiling, and applying skin moisturizer. For further guidelines, see What If . . . Your Patient is an Older Adult, when you

Go to Chapter 25, **Procedure 25-1: Bathing: Providing a Complete Bed Bath Using a Prepackaged Bathing Product,** in Volume 2.

KnowledgeCheck 25-5

- A nurse has given a bath in which he washed a bedridden patient's entire body without assistance from the patient. What is the term for this bath?
- What are the advantages of a towel or bag bath?
- For which type of bath will you most likely have a medical prescription?

ThinkLike a Nurse 25-8

Which type of bath would be most appropriate for each of your patients (Meet Your Patients)? Provide rationales for your choices.

CARE OF THE FEET

Foot care is a necessary part of hygiene and essential at any age for tissue health, proper posture, and ambulation.

TheoreticalKnowledge knowing why

When providing foot care, you will need theoretical knowledge about the structure of the feet, life span variations, and common foot problems. The feet provide support for the weight of the entire body and absorb a significant amount of shock during walking. Their musculoskeletal structure is complex, consisting of 26 bones and many muscles, tendons, and ligaments. The feet can be affected by congenital malformations, injuries, improper footwear, and medical conditions.

Developmental Variations

Foot problems tend to increase with aging. Because of diseases such as arteriosclerosis and peripheral vascular insufficiency, older adults often have decreased circulation to the lower extremities. This increases their risk for foot ulcers and infection. The incidence of diabetes is high among older adults, further increasing the risk for infection secondary to delayed healing. In addition, the skin becomes dry, predisposing the older adult to cracking of the skin.

Common Foot Problems

In a recent survey in the United States, 83% of adults age 21 and older reported their foot health to be good to excellent. However, 78% reported that they had had at least one foot problem (e.g., pain, blisters, and athlete's foot) (Institute for Preventive Foot Health, 2012). Many foot problems are the result of improperly fitting shoes.

- A **corn** is a cone-shaped thickening of the epidermis caused by continuous pressure (e.g., from improperly fitting shoes) over bony prominences, such as the toe joints. Corns are often painful.
- **Calluses** are usually found over bony prominences in the weight-bearing part of the foot: the heels, soles, or plantar surfaces of the feet. They are similar to corns but cover a wider area and are not painful.
- **Tinea pedis**, or athlete's foot, is a fungal infection of the skin. It is aggravated by moisture accumulation in unventilated shoes. Symptoms include itching and burning skin with blisters, scaling, and cracking, especially between the toes. Athlete's foot may be contracted by walking barefoot in public showers.
- An **ingrown toenail** may result from improperly trimming the toenails and wearing poorly fitting shoes. The toenail grows inward into the soft tissues around it and the tissue at the nail border becomes swollen, inflamed, and painful. The nail may need to be surgically removed.
- **Foot odor** is produced when microorganisms growing on the feet interact with perspiration. The warm, moist environment created by shoes encourages both perspiration and bacterial growth.
- **Plantar warts** are painful growths caused by a virus. They may occur on any part of the sole of the foot but often develop under pressure points, such as the heel or ball of the foot.
- **Pressure ulcers** are lesions caused by unrelieved pressure that impairs the circulation, which usually occurs over a bony prominence. In patients who are immobile, the back of the heels, the ankles, and the great toes are common locations; but pressure ulcers do, of course, occur over other bony prominences.
- A **bunion** (hallux valgus) is a progressive disorder that begins at the enlargement of the first metatarsal joint at the base of the great toe and then progresses to leaning of the big toe, gradually changing the angle of the bones over time. A characteristic bump occurs slowly and continues to become increasingly prominent with aging. Tight-fitting shoes (particularly with high heels) are thought to be the cause of bunions in the large majority of patients. Genetics also play a role as do some diseases, such as arthritis. For illustrations and more information about bunions,

Go to the URL of the American College of Foot and Ankle Surgeons, at the link provided in **Resources for Caregivers and Health Professionals,** in Chapter 25 on Davis*Plus*.

PracticalKnowledge knowing how

The nursing focus for foot care is on prevention and early identification of problems. For associated *NOC standardized outcomes* and *NIC interventions* for patients with common foot problems,

Go to Chapter 25, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Hygiene Problems,** on Davis*Plus*.

ASSESSMENT (FEET)

Careful assessment of the feet allows for early detection of common foot problems. This chapter describes routine observations that you can make when giving foot care. For a thorough discussion of foot assessment, see Chapter 22 and,

Go to Chapter 25, **Procedure 25-5, Pre-Procedure Assessments; and Assessment Guidelines and Tools, Guidelines for Assessing Hygiene,** in Volume 2.

The color and temperature of the feet provide data about circulation and oxygenation. For example, cold, dusky, or pale feet may indicate impaired circulation or tissue perfusion secondary to peripheral vascular disease.

ANALYSIS/NURSING DIAGNOSIS (FEET)

The following are examples of nursing diagnoses related to the feet:

- Impaired Skin (or Tissue) Integrity (feet) related to mechanical pressure from wearing shoes that do not fit properly
- Risk for Impaired Skin Integrity (feet) related to (1) decreased sensation secondary to diabetes mellitus and (2) decreased circulation to the feet secondary to arteriosclerosis
- Impaired Walking related to foot pain secondary to arthritis
- Risk for Injury (to feet) related to deficient knowledge of foot hygiene

PLANNING OUTCOMES/EVALUATION (FEET)

NOC outcomes for foot care are the same as for other areas of the body, as they relate to circulation, infection, tissue integrity, and wound healing. For example, Tissue Integrity: Skin and Mucous Membranes is useful for any area of the body.

Individualized goals/outcome statements you might write for a patient with foot problems include the following:

- Demonstrates proper cleansing, rinsing, and drying of the feet.
- Avoids trimming calluses.
- Wears shoes that fit properly.
- Inspects feet regularly.

PLANNING INTERVENTIONS/IMPLEMENTATION (FEET)

Examples of *NIC standardized interventions* include Foot Care, Skin Surveillance, and Circulatory Care: Arterial Insufficiency.

Individualized nursing activities related to care of the feet are those that prevent infection, odor, and trauma to the soft tissues of the feet. While performing foot care, teach the patient about self-care measures for care of the feet (see Self-Care: Teaching Your Client About Foot Care). To learn how to administer foot care,

Go to Chapter 25, **Procedure 25-5: Providing Foot Care,** in Volume 2.

Diabetic Foot Care Because of impaired circulation and increased risk for infection, people who have diabetes are at high risk for problems with their feet. If they have neuropathy, they may not experience pain with a foot injury, so treatment may be delayed. If untreated, a seemingly minor foot lesion can progress to gangrene and require amputation. The instructions in the box Self-Care: Teaching Your Client About Foot Care are especially important for people with diabetes as well as for those with impaired peripheral circulation.

KnowledgeCheck 25-6

- What are some causes of ingrown toenails?
- What is the cause of foot odor?
- Why should you *not* apply lotion between the toes?

CARE OF THE NAILS

The nails are part of the integumentary system. They are composed of epithelial tissue. Healthy nailbeds are usually clean, pink, smooth, convex, and evenly curved. Present at birth, the nails change very little throughout life; however, as one ages, nails thicken, become ridged, and may yellow or become concave in shape.

Other changes are caused by certain pathological conditions. For example, trauma to the nail can lead to nail bruising or falling out; and inadequate diet or metabolic changes can cause the nails to become brittle. Also, patients with diabetes mellitus are much more prone to infection and must be vigilant about toenail care.

For NANDA-I diagnoses, *NOC standardized outcomes*, and *NIC interventions* for patients with common nail problems,

Go to Chapter 25, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Hygiene Problems,** on Davis*Plus*.

Self-Care

Teaching Your Client About Foot Care

Use the time during foot care to teach your client the following self-care activities. These measures are good advice for most people, but they are especially important for people who have diabetes or poor peripheral circulation.

Daily Foot Inspection

- Inspect the feet daily, using a mirror to view all surfaces. Check between the toes for cracks or redness. Look for calluses, blisters, wounds and lesions, or dry areas. If you cannot check your own feet, have someone else do it.
- If you have diabetes, have your feet checked regularly by a professional.
- Seek professional help for foot problems, such as poor circulation, corns, and ingrown toenails, and for trimming very thick nails—especially if you have diabetes.

Hygiene for Feet and Nails

- Wash, rinse, and dry the feet well.
- Avoid soaking the feet (if you are diabetic, or if there is decreased circulation to the feet).
- Apply a water-soluble lotion to feet, but do not use lotion between the toes, because it may cause maceration.
- Use an antifungal powder, if necessary, for athlete's foot.
- Do not cut or file callused areas.
- Cut and file toenails straight across. Do not use a razor blade on the nails or feet.

Shoes and Stockings

- Wear cotton or wool socks, which absorb perspiration.
- Wear well-fitted, sturdy shoes with nonskid soles and arch support. Natural materials, such as canvas and leather, are best because they allow air to circulate and perspiration to evaporate. Shoes should allow 1/2 to 3/4 inch of toe room.
- Avoid open-toed shoes, sandals, high heels, and flip flops. They do not protect the feet.
- Before putting on shoes, check for foreign objects; check that the inside of the shoe is smooth.

Protecting the Feet

- Avoid measures that impair circulation to the feet, such as wearing tight garters or knee stockings, or crossing the legs.
- Do not go barefoot, even when getting out of bed at night. Wear slippers.
- Do not put tape or over-the-counter corn medicines or pads or other medications (e.g., hydrogen peroxide) on the feet.
- Do not smoke. This further decreases circulation to the feet.

Seek Medical Attention for the Following:

- Pain in the feet or legs. This may be a sign of loss of circulation, serious infection, or nerve damage (neuropathy).
- Wounds or ulcers on the feet, especially if they don't seem to be healing
- A cut to the feet or lower legs that extends deep into the skin and bleeds significantly
- Generalized redness or red streaks surrounding a wound or ulcer on the feet or lower legs. This might be a sign of infection of the tissue (cellulitis).
- Fever greater than 101°F (38.5°C).
- Confusion. This can be a sign of that a wound infection has entered the bloodstream (septicemia). A change in mental status might indicate low blood sugar, which occurs with serious infection, or if the patient is diabetic.
- Foot problems, such as numbness or tingling, decreased sensation, cold skin temperature, corns, ingrown toenails, and for trimming very thick nails—especially if you have diabetes.

ASSESSMENT (NAILS)

When assessing the nails, you should obtain *subjective data* about the patient's usual nail care practices, any history of nail problems, and their treatments. To obtain *objective data*, inspect the nails for shape, contour, and cleanliness. Look for redness or swelling of the skin around the nails, and observe whether they are neatly manicured and trimmed appropriately, straight across. Unclean or rough fingernails may scratch or abrade the skin and create a risk for infection. Other nail changes may reflect an underlying disease process. In addition, the area under the nail can harbor direct and bacteria, which can be another source for transmitting microbes.

For more information about physical assessment of the nails, see Chapter 22, and

Go to Chapter 25, **Assessment Guidelines and Tools, Guidelines for Assessing Hygiene,** in Volume 2.

ANALYSIS/NURSING DIAGNOSIS (NAILS)

There are no NANDA-I labels to describe nail problems. However, the following are examples of nursing diagnoses related to nail care:

- Risk for Impaired Tissue Integrity related to ingrown nails secondary to trimming too close to the cuticle
- Risk for Infection related to loss of skin integrity secondary to hangnails, cracked cuticles, or trauma from using sharp scissors or nail clippers

PLANNING OUTCOMES/EVALUATION (NAILS)

There are no *NOC outcomes* that relate especially to nail care, but you can use outcomes that relate more generally to circulation, infection, tissue integrity, wound healing.

Individualized goals/outcome statements you might write for a patient with problems related to the care of the nails may include the following:

- Demonstrates proper care of the nails.
- Trims fingernails with supervision.
- Seeks care of a **podiatrist** (physician who specializes in foot care) for toenail care.

PLANNING INTERVENTIONS/IMPLEMENTATION (NAILS)

Individualized nursing activities related to proper care of the nails include the following:

- Teaching for self-care (see the box Self-Care: Teaching Your Client About Nail Care)
- Providing nail care for dependent patients (the procedure for care of the fingernails is the same as for care of the toenails). Also,

Go to Chapter 25, **Procedure 25-5: Providing Foot Care,** in Volume 2.

KnowledgeCheck 25-7

- True or False: Healthy nails are usually clean, smooth, and convexly curved.
- List at least three nail changes that occur with aging.
- List at least four things you should teach clients about self-care of their nails.

Self-Care

Teaching Your Client About Nail Care

- Inspect the nails daily.
- Trim nails with a nail clipper. (People with diabetes or circulatory problems should file only, because cutting poses a risk for injury to the tissues.)
- File the nails straight across, rounding the corners slightly to prevent scratching. Do not cut deeply into the lateral corners because this may cause ingrown nails.
- Remove hangnails by carefully removing them with cuticle clipper.
- Clean under the nails with an orangewood stick or other blunt instrument.
- Push back the cuticles gently.
- Use a moisturizing lotion to soften cuticles.
- Avoid biting nails.
- Consult a podiatrist for ingrown toenails or other nail problems.
- Recommend to patients with diabetes, circulatory insufficiency, or nail problems that they seek nail care from a podiatrist.

ORAL HYGIENE

To maintain the integrity of the mucous membranes, teeth, and gums, and to prevent tooth loss and gum disease, it is important to have (1) routine dental checkups, (2) adequate nutrition, and (3) daily mouth care (oral hygiene). Mouth care removes food particles and secretions. In addition, a clean mouth helps to promote a better appetite. It also reduces the incidence of healthcare-acquired pneumonia in older adults and critically ill patients in acute care settings.

TheoreticalKnowledge knowing why

Digestion of food begins in the mouth (oral cavity). The tongue and teeth begin digestion by breaking up food and mixing it with saliva. Front teeth, also called **incisors**, are for biting and tearing while the teeth in the back of the mouth, known as **molars**, are used for chewing. Saliva, produced by three pairs of salivary glands in the mouth, also acts as a mechanical cleaner of the mouth. The structures of the mouth pertinent to oral hygiene include the tongue, **gingiva** (gums), and teeth.

Developmental Variations

The first set of teeth (the **deciduous teeth**) erupts between 6 months and 2 years of age. By age 2, a child usually has 20 teeth (Fig. 25-3). Between the ages of 6 and 12 years, the deciduous teeth loosen, fall out, and are eventually replaced with 32 permanent teeth (Fig. 25-4). **Wisdom teeth** are the very back molars on either side of each jawbone.

The tooth surface wears away with aging and the gums may begin to recede, resulting in bone and tooth loss and necessitating the use of dentures (false teeth). Other changes that may occur with aging are a brownish pigmentation of the gums and dryness of the oral mucosa, which is caused by decreased saliva production.

Risk Factors for Oral Problems

Oral health is influenced by heredity, nutrition, and oral hygiene. Therefore, any condition that prevents good oral hygiene can lead to oral problems. Such risk factors include the following:

- ***History of periodontal disease***
- ***Lack of money or insurance*** for dental care
- ***Pregnancy.*** Increased estrogen during pregnancy increases the vascularity of the gingiva, so the gums may bleed easily and become puffy and tender. Good hygiene is needed to prevent infection.
- ***Poor nutrition or eating habits.*** Adequate intake of calcium, phosphorus, and vitamin D is essential for

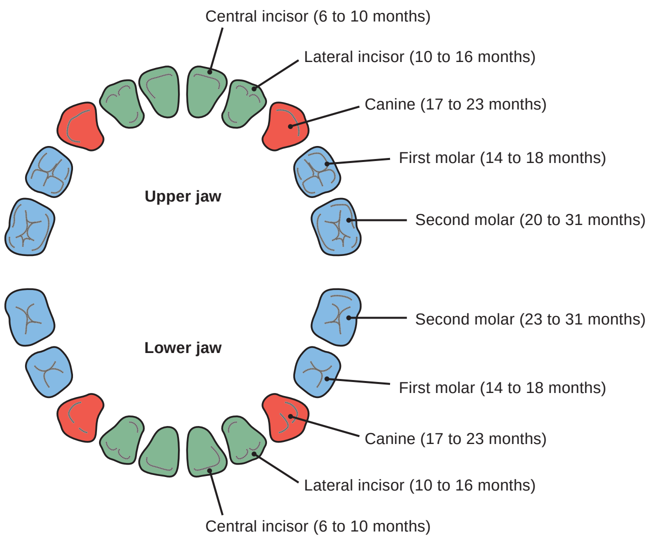

FIGURE 25-3 **The 20 deciduous teeth.** (Courtesy of P. Dillon (2007). *Nursing health assessment* (2nd ed.). Philadelphia: F. A. Davis.)

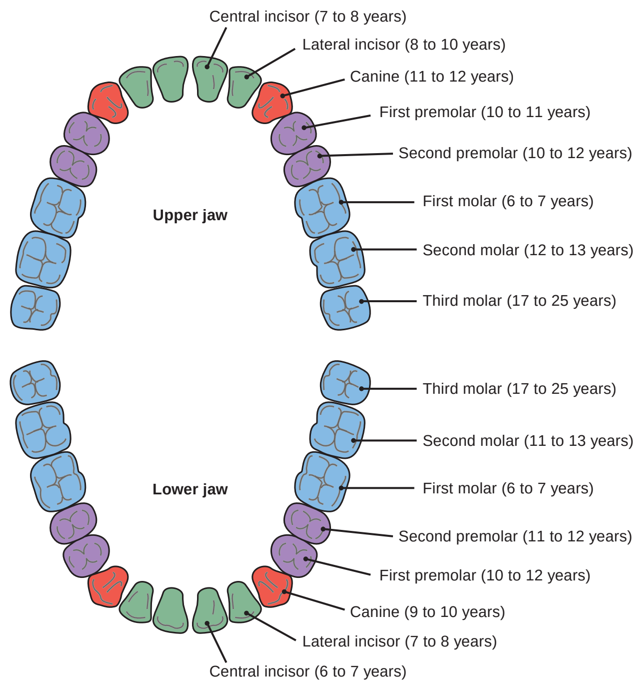

FIGURE 25-4 **Most adults have 32 permanent teeth.** (Courtesy of P. Dillon (2007). *Nursing health assessment* (2nd ed.). Philadelphia: F. A. Davis.)

healthy teeth and gums. Excessive intake of refined sugars leads to dental decay. One example of this is **baby-bottle tooth decay**, which occurs when parents put an infant or toddler to bed with a bottle or sippy cup of milk, fruit juice, or other sugary beverages. Carbohydrates in the fluid cause demineralization of the tooth enamel, leading to major decay of the upper and lower teeth.

- ***Medications.*** The anticonvulsant phenytoin (Dilantin) causes gingival **hyperplasia** (excessive growth of cells). Other medications cause dryness of the mouth (e.g., diuretics, medications used to treat cancer, numerous calcium channel blocker agents [especially nifedipine], and tranquilizers such as chlorpromazine [Thorazine] and diazepam [Valium]).
- ***Medical treatments affecting the oral cavity include the following:***
  - Jaw surgery, which requires scrupulous oral hygiene to prevent infection
  - Radiation treatments of the head and neck, which can damage teeth and jaw structure and permanently damage the salivary glands.
  - Oxygen therapy, which dries the oral mucosa
- ***Any situation that causes dry mouth*** predisposes to cracking of the mucosa, including heavy cigarette smoking, excessive alcohol use, inadequate fluid intake (e.g., being NPO), dehydration, and mouth breathing
- Compromised self-care abilities may be caused by:
  - Decreased level of consciousness (e.g., a person who is comatose or heavily sedated), serious illness or injury, weakness, activity intolerance, or paralysis
  - Cognitive impairment (e.g., developmental delay, dementia)
  - Depression
  - Lack of knowledge or motivation to perform self-care

KnowledgeCheck 25-8

- How do the teeth aid in digesting food?
- How many deciduous teeth does a child usually have?
- List at least three factors that cause dry mouth.
- List at least two medications or medical treatments that can cause oral problems.
- Name four situations that can compromise self-care ability for oral hygiene.

ThinkLike a Nurse 25-9

- For which of your patients, Mrs. Williams or Mr. Gold, does the Meet Your Patients scenario provide *actual data* to indicate that the patient is at risk for oral problems? What are the data?
- Why is the patient's nursing diagnosis Risk for Impaired Oral Mucous Membrane instead of Impaired Oral Mucous Membrane?

Common Problems of the Mouth

Dental **caries** (cavities) and periodontal disease are the two most frequent problems affecting the teeth. They are discussed here along with other common mouth problems:

- **Halitosis.** Also known as bad breath, halitosis results from poor oral hygiene, eating certain foods (e.g., garlic, onions), tobacco use, dental caries, infections, or even systemic diseases, such as uncontrolled diabetes or liver disease.
- **Dental caries.** Failure to remove plaque is the primary cause of dental caries. **Plaque**, an invisible, destructive

bacterial film that builds up on the teeth eventually leads to destruction of the tooth enamel. Untreated plaque can result in tooth loss. The plaque builds up with dead bacteria and forms hard deposits at the gumlines (**tartar**). The tartar causes deterioration of the supporting structures that hold the teeth in the gums and also attacks the bone tissue, causing the teeth to become loose. Other factors that contribute to the formation of cavities include excessive intake of refined sugars, a lack of brushing and flossing, and infrequent visits to the dentist.

- **Gingivitis** is inflammation of the gum tissue surrounding the teeth. If untreated, may progress to periodontal disease.
- **Periodontal disease (pyorrhea)** is the major cause of tooth loss in adults 35 years and older. It is an inflammation characterized by bleeding and receding gums and destruction of the surrounding bone structure. The patient experiences halitosis and complains of a bad taste in the mouth. When pyorrhea is advanced, the gums become infected, and the teeth loosen and may fall out or need to be removed.
- **Stomatitis**, an inflammation of the oral mucosa, has numerous causes, including bacteria, mechanical trauma, irritants, nutritional deficiencies, and systemic infection. Symptoms may include pain, halitosis, and increased salivation.
- **Glossitis**, an inflammation of the tongue, is caused by deficiencies of vitamin B_{12}, folic acid, and iron.
- **Cheilosis** is a cracking and/or ulceration of the lips, in the form of reddened fissures at the angles of the mouth. It is usually caused by vitamin B complex deficiencies.
- **Oral malignancies** must be detected as early as possible. Teach patients to see a dentist immediately if any of the following are present in the mouth: lumps, ulcers, white or red patches, bleeding, pain, persistent sores, or numbness.

KnowledgeCheck 25-9

- Identify and define several causes of halitosis.
- What are the two most common problems affecting the teeth?
- What is the end result of severe periodontal disease?

PracticalKnowledge knowing how

You should assess the patient's oral cavity when performing or assisting with oral hygiene. This is particularly important for older adults because of the association between oral health and systemic disease. For *NANDA-I diagnoses*, *NOC standardized outcomes*, and *NIC interventions* for patients with problems of the mouth,

Go to Chapter 25, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Hygiene Problems,** on Davis*Plus*.

ASSESSMENT (ORAL CAVITY)

You might begin your subjective assessment by asking the patient about his usual hygiene practices. You should also interview the patient or examine his records for the risk factors for oral problems discussed in the preceding section (i.e., history of oral problems, nutritional status, access to dental care, medications such as anticonvulsants or diuretics, radiation therapy, oxygen therapy, NPO status, dehydration, and nasogastric tubes). Ask about tobacco and alcohol use.

As part of your objective assessment during hygiene care, inspect the lips, oral mucosa, gums, and tongue. Mucosa and gums should be pink and moist without lesions or bleeding. Look for loose, missing, or decaying teeth; tartar; stomatitis; and note any unusual odors or halitosis. Check to be sure the tongue is normal in color and without lesions.

The Kayser–Jones Brief Oral Health Status Examination (BOHSE) is used to assess the oral cavity of older adults. It was specifically designed for nursing home residents who have either normal or impaired cognitive functioning, and can be used by a variety of nursing personnel. The tool assigns a numerical rating to findings for: the lymph nodes, lips, tongue, tissue inside the mouth, gums, saliva, condition of natural teeth, condition of artificial teeth, pairs of teeth in chewing position, and oral cleanliness.

For a copy of the BOHSE assessment,

Go to Chapter 25, **ESG Table 25-2,** on Davis*Plus*.

To learn more about physical assessment of the oral cavity, refer to Chapter 22. Also,

Go to Chapter 25, **Assessment Guidelines and Tools, Guidelines for Assessing Hygiene,** in Volume 2.

ANALYSIS/NURSING DIAGNOSIS (ORAL CAVITY)

In addition to Self-Care Deficit, discussed in the first part of the chapter, the following are examples of nursing diagnoses that may be useful in describing problems of the mouth:

- Risk for Infection related to mouth lesions
- Impaired Dentition (caries) related to inability to afford dental care
- Impaired Oral Mucous Membrane related to inability to manage mouth care secondary to impaired mobility

Oral and dental problems can be the etiology of other nursing diagnoses, for example:

- Deficient Knowledge related to lack of interest in learning about oral hygiene
- Imbalanced Nutrition related to lack of teeth for mastication
- Pain related to mouth lesions

PLANNING OUTCOMES/EVALUATION (ORAL CAVITY)

NOC standardized outcomes for oral problems include Oral Hygiene, Self-Care: Oral Hygiene, and Knowledge: Health Behavior.

Individualized goals/outcome statements you might write for mouth problems include the following:

- Oral mucous membranes will remain pink, moist, and intact.
- Demonstrates correct technique for brushing and flossing.
- Makes preventive dental visits every 6 months.

PLANNING INTERVENTIONS/IMPLEMENTATION (ORAL CAVITY)

For some clients, you may need only to provide the necessary supplies for mouth care. For others, you will need to assist or even completely provide care as often as necessary to keep the mouth clean and moist. Rinsing with mouthwash is not a substitute for a thorough cleaning of the teeth and mouth.

NIC standardized interventions for mouth care include Oral Health Maintenance, Self-Care Assistance, and Teaching: Individual.

Individualized nursing activities related to oral hygiene include (1) teaching for self-care (see the box Self-Care: Teaching Your Client About Oral Hygiene) and (2) assisting with and providing oral hygiene for dependent patients.

Denture Care

A patient may have a complete set of removable dentures or just an upper or lower plate. A **bridge**, or partial plate, consists of one or more artificial teeth. A bridge may be permanently fastened to other teeth, or it may be removable. Artificial teeth are fitted to the individual and should not be used by anyone else. If the person leaves the prosthesis out of his mouth for long periods, the shape of the gums will change, and it will no longer fit properly. Poorly fitted or loose dentures can lead to chewing difficulties and even nutritional deficiencies. The nurse's role is to ensure cleanliness by teaching for self-care (see the box Self-Care: Teaching Your Client About Oral Hygiene) or to provide denture care for dependent clients,

Chapter 25, **Procedure 25-7: Providing Denture Care,** in Volume 2.

Oral Care for Critically Ill Patients

Patients in long-term care settings and critically ill patients in acute care settings are at high risk for healthcare-associated pneumonia. This is especially true for those dependent on a ventilator. Ventilator-associated pneumonia (VAP) is the most common hospital-acquired infection in critically ill patients. The teeth may be an

Self-Care

Teaching Your Client About Oral Hygiene

Measures to promote oral health and prevent periodontal disease and caries include the following:

Preventing Caries and Periodontal Disease

- Eliminate high sugar snacks between meals (ice cream, soft drinks, candy, gum, jams and jellies).
- Include in the diet cleansing, fibrous foods, such as raw fruits and vegetables.
- Include an adequate intake of calcium, phosphorus, and vitamins A, C, and D.
- Have regular dental checkups every 6 months.
- Brush teeth with a soft brush and toothpaste after each meal and at bedtime (some dentists say twice a day). Bacteria do the most damage to the teeth in the first 24 hours after eating.
- Floss between the teeth daily to remove food debris and stimulate the blood flow to the gingiva.
- Use a fluoride toothpaste to strengthen tooth enamel.
- You can make your own cleanser by combining one part baking soda with two parts salt.
- Follow the dentist's recommendations for topical applications of fluoride.

Flossing between the teeth is an essential part of oral hygiene.

Brushing and Flossing

- Make sure the brush is small enough to reach all teeth. If it is too firm, it can injure enamel and gum tissue.
- Electric toothbrushes are effective; however, you should consult your dentist about using waterspray units, because they can force debris into pockets of the gums.

Continued

Self-Care

- Brush at a 45° angle, from the gum to the tooth crown, using small circular or vibrating motions.
- When flossing: (1) Wrap one end of the floss around each of your middle fingers. (2) Hold about 1 to 2 inches of floss tightly between the fingers. (3) Insert floss between the teeth by gently moving it back and forth; do not force it. (4) Floss adjacent sides of both teeth to the gum tissue, but not into the gum, because you may injure the tissue. (5) Use a fresh section of floss when it becomes soiled or frayed. (6) Rinse your mouth well when you are finished. A variety of convenient flossing devices are available as an alternative to this method.

Oral Hygiene for Children

- Begin oral hygiene when the first tooth erupts. Use a washcloth, cotton ball, or gauze pad moistened with water.
- Do not put the child to bed with a bottle or sippy cup. Milk, juice, or any other liquid with sugar can lead to dental caries in the young child when the liquid sits on the teeth at night or for naps.
- Begin brushing the child's teeth with a soft toothbrush when she is about 18 months old. Start first using water only. Later, switch to a fluoride-containing toothpaste.
- Follow your dentist's instructions for giving a fluoride supplement.
- Schedule a visit to the dentist when all 20 deciduous teeth have erupted.
- See your dentist if you notice any problems, such as chipping, redness or swelling, caries, or misalignment.
- For school-age children, parents may need to supervise mouth care to be sure it is done adequately.

Care of Dentures

- If you have dentures or other removable prostheses ("bridges"), wear them. If you do not, the gums are likely to shrink, and you will have further gum loss.
- Clean dentures and bridges at least once a day, preferably after each meal.
- Remove dentures from the mouth to clean them.
- Use regular toothpaste or special denture-cleaning compounds.
- Do not use hot water on dentures; it may damage them.
- If the dentures have metal parts, do not soak them overnight in cleaning solutions.
- Store dentures in a denture cup, in distilled, sterile, or filtered water, to prevent drying. Do not wrap them in tissues because they may accidentally be thrown away.
- Clean dentures over a plastic pan or towel in the sink. They are fragile and may break if dropped.

Dentures must be cleaned thoroughly as a part of daily oral hygiene.

important reservoir for bacteria that cause pneumonia. A simple and inexpensive way to reduce the risk of pneumonia for these patients is to keep their teeth clean, thus reducing the numbers of bacteria (AACN, 2007). The regimen includes the following:

- Brush the teeth twice a day.
- Use a soft toothbrush.
- Moisturize oral mucosa and lips every 2 to 4 hours.
- Use a chlorhexidine gluconate (0.12%) rinse twice a day during the perioperative period for patients who undergo cardiac surgery (adult patients).
- Use mouthwash inside the mouth twice a day for adult patients who are on a ventilator.

Oral Care for Unconscious Patients

Oral care for unconscious patients is particularly important because they often breathe through the mouth. If the patient is receiving oxygen per cannula or has a nasogastric or feeding tube inserted, the mucous membranes dry out even more.

An unconscious patient often responds to oral stimulation by biting down, so use a padded tongue blade instead of your fingers to hold the mouth open. Also use a padded tongue blade when providing oral care for a patient with seizures to avoid the patient biting you.

Follow agency practices for the type and frequency of special mouth care. Some patients may need it every hour or two. You may use commercially packaged applicators or foam swabs to clean the mouth. Do not use lemon-glycerine swabs because they are drying to the mucosa and may cause changes in tooth enamel. Likewise, do not use hydrogen peroxide because it is irritating to oral mucosa and may alter the balance of normal flora of the mouth. To learn more about how to provide oral care for unconscious patients,

Toward Evidence-Based Practice

American Association of Critical-Care Nurses (AACN). (2007). AACN practice alert. Oral care in the critically ill. Retrieved April 20, 2013, from http://www.aacn.org/WD/Practice/Docs/PracticeAlerts/oral%20care%2004-2010%20final.pdf

This evidence report reviewed 14 references and graded the evidence for the conclusions they drew. They used a I to VI scale (Level VI = strongest support, Level I = weakest [manufacturer's recommendations only]). The following are two AACN recommendations for oral care in the critically ill:

- Use oral chlorhexidine gluconate (0.12%) rinse twice a day for adult patients undergoing cardiac surgery; not routinely for all patients. (Level V)
- Brush teeth, gums, and tongue at least twice a day. (Level II)

Yao, L.Y., Chang, C. K., Maa, S. H., et al. (2011). Brushing teeth with purified water to reduce ventilator-associated pneumonia. *Journal of Nursing Research, 19*(4), 289–297.

Researchers examined the effects of an oral care protocol on ventilator-associated pneumonia (VAP) rates on ventilator patients in an intensive care unit. The experimental group received a twice-daily oral care protocol of toothbrushing with purified water, elevating the head of the bed, and before-and-after hypopharyngeal suctioning. The control group received twice-daily mock oral care that was similar but did not include toothbrushing. After 7 days of toothbrushing with purified water, researchers found that cumulative VAP rates were significantly lower in the experimental group.

Lorente, L., Lecuona, M., Jiménez, A., et al. (2012). Ventilator-associated pneumonia with or without toothbrushing: A randomized controlled trial. *European Journal of Clinical Microbiology & Infectious Diseases, 31*(10), 2621–2629.

Patients in a medical-surgical intensive care unit (ICU) who were undergoing mechanical ventilation for more than 24 hours received regular oral care with 0.12% chlorhexidine digluconate. Patients were randomly assigned to receive toothbrushing in addition to regular oral care. Others did not receive toothbrushing. No statistically significant differences were found between the groups regarding the incidence of VAP with toothbrushing versus without toothbrushing. They concluded that adding manual toothbrushing to chlorhexidine oral care does not help to prevent VAP in critical care patients on mechanical ventilation.

1. Suppose you are a critical care nurse, using the AACN Practice Alert guidelines. For which of the two AACN recommendations would you most want to have further research evidence?

2. Which of the two studies above provides additional support for the AACN guideline? Explain your thinking.

3. How are the patients in the two studies alike or different from the patients for whom the AACN Practice Alert was designed?

Go to Chapter 25, **Toward Evidence-Based Practice Suggested Responses,** on the Electronic Study Guide or Davis*Plus*.

Go to Chapter 25, **Procedure 25-6: Brushing and Flossing the Teeth; Procedure 25-7: Providing Denture Care;** and **Procedure 25-8: Providing Oral Care for an Unconscious Patient,** in Volume 2.

Oral Care for Patients With Dementia

Poor oral health and dental pain affect general well-being and quality of life—specifically, on the ability to eat, type of diet, weight changes, speech, hydration, appearance, and social interactions. This is especially true for older adults with dementia, who have a high level of oral diseases and dental problems. Dental disease and pain may be the source of some of the behavior problems in this population. Because it is a challenge to provide oral hygiene for patients with dementia, staff sometimes neglect care. Residents may be uncooperative: refusing care, refusing to open the mouth, biting the toothbrush, and so on. Research is needed to identify the best interventions (Joanna Briggs Institute, 2004; Weening-Verbree, Huisman-de Waal, van Dusseldorp, et al., 2013). Meanwhile, for experts' suggestions for ways to provide oral care to patients with dementia, see the What if . . . ? section,

In Chapter 25, **Procedure 25-6: Brushing and Flossing the Teeth,** in Volume 2.

KnowledgeCheck 25-10

How would you position Mr. Gold (Meet Your Patients) to perform his oral hygiene?

CARE OF THE HAIR

Hair is an accessory structure of the skin. The hair helps to maintain body temperature, serves as a receptor for tactile sensation, and influences a person's self-image. **Vellus hair** is the short, fine hair present over much of the body. **Terminal hair**, which is coarser, darker, and longer, is found on the scalp, eyebrows, axillae, perineum, and legs. Sebaceous glands found at the base of the hair follicle secrete sebum, or oil, to lubricate hair and scalp. The condition of the hair is a measure of a person's overall health. See Chapter 22 for more information about changes in hair that occur through the life span and as a result of illness.

For *NOC standardized outcomes* and *NIC standardized interventions* for patients with problems related to care of the hair,

Go to Chapter 25, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Hygiene Problems,** on Davis*Plus*.

ASSESSMENT (HAIR)

For the purposes of hygiene, you will need information about the patient's history of hair problems or current conditions needing treatment (e.g., pediculosis), diseases or therapy that affect the hair (e.g., chemotherapy), and factors influencing the patient's ability to manage her hair and scalp care (e.g., Impaired Mobility). Ask the patient about special products she uses and about her preference for styling her hair. Inspect the condition and cleanliness of the hair, and inspect the scalp for dandruff, lesions, and so forth. For more complete information about assessing the hair, see Chapter 22. Also,

Go to Chapter 25, **Assessment Guidelines: Hygiene,** in Volume 2.

ANALYSIS/NURSING DIAGNOSIS (HAIR)

Common problems associated with the hair and scalp include the following (also see Chapter 22):

- **Dandruff** is a condition in which there is excessive shedding of the epidermal layer of the scalp. Primary symptoms include itching and flaking of the scalp, which may be caused by fungal infection.
- **Pediculosis** is an infestation of head lice. Though frequently associated with poor hygiene practices, it knows no socioeconomic boundaries. Head lice spread through sharing of combs, brushes, hair ornaments, hats, and caps.
- **Alopecia**, or hair loss, can be very stressful and affect self-image. Abnormal hair loss, which may be gradual or sudden, can be caused by an autoimmune disorder, hormonal imbalance, thyroid disease, stress, fever, certain medications, or chemotherapy.

There are no NANDA-I labels that apply specifically to the hair. When the difficulty lies with self-care ability, you can, of course, use Dressing/Grooming Self-Care Deficit and Bathing/Hygiene Self-Care Deficit. Examples of other nursing diagnoses that may apply include the following:

- Risk for Impaired Skin Integrity related to secretions on the scalp
- Situational Low Self-Esteem related to alopecia secondary to chemotherapy

KnowledgeCheck 25-11

- List at least four assessments you should make of a patient's hair.
- What is pediculosis?
- What is alopecia?

PLANNING OUTCOMES/EVALUATION (HAIR)

As always, select outcomes based on the client's nursing diagnoses. *Individualized goals/outcome statements* you might write for a patient with problems related to the hair include the following:

- Scalp and hair are clean.
- By 9/18, brushes own hair.
- Hair and scalp are free from infestation, infection, irritation, or dryness.
- Verbalizes improved comfort and self-esteem.

PLANNING INTERVENTIONS/IMPLEMENTATION (HAIR)

Individualized nursing activities related to the care of the hair include daily brushing and combing of the hair, shampooing, and, for men, shaving and beard.

Providing Hair Care

Brush the hair daily to remove tangles, massage the scalp, stimulate the circulation, and distribute oil down the hair shaft. Use a stiff-bristled brush, but be sure the bristles are not sharp enough to injure the patient's scalp. Likewise, a comb with broken or uneven teeth or one that is too fine can break or snarl the hair or scrape the scalp. Comb tightly curled hair with a wide-toothed comb or pick. Encourage patients to brush and comb their own hair, if they are able to do so. Encouraging family members to assist with hair care will involve them in the patient's care and reduce feelings of helplessness. Do not cut a patient's hair unless he or she consents to the haircut. For a summary of a procedure for shampooing the hair, see the Highlights of Procedures box. For complete steps,

Go to Chapter 25, **Procedure 25-9: Shampooing the Hair,** in Volume 2.

Shampooing the Hair Shampooing cleans the hair and scalp. It is soothing and relaxing to many patients. Hair can be shampooed while the person is in the shower, standing or sitting over a sink, or in bed. Protect the patient's eyes with a dry washcloth, and make sure the water temperature is appropriate for the patient. For patients who are unable to tolerate a standard shampoo procedure, you can use a dry shampoo as an alternative. However, it is not as effective as shampooing with water. Commercially prepared shampoo caps are available and have, in most institutions, replaced the dry shampoo method.

Hair Care for African Americans Hair care is equally important for all patients, so if a patient's hair requires special care, you must learn how to do it. The hair of African Americans varies in texture from some other ethnicities—it may be long or short, straight or kinky, thick or thin. Worn naturally, very curly hair can easily become entangled or matted, and it tends to be fragile and easily broken. The scalp also tends to be dry. The hair requires careful handling, especially if it has been chemically straightened, relaxed, or curled. Shampoo and groom the hair according to the person's preference, of course. In general, though, you should comb and brush the hair daily and apply a light oil to the scalp (e.g., mineral oil or a light moisturizing cream). Ask a family member to bring from home the product the patient prefers to use. Do not apply chemical relaxers to a patient's hair. Only a licensed beautician should do this.

Beard and Mustache Care

Beards and mustaches tend to collect food particles. They should be washed daily during a bath or shower and combed and trimmed as necessary. Do not shave a patient's mustache or beard without permission to do so. For details of beard and mustache care,

Go to Chapter 25, **Procedure 25-10: Providing Beard and Mustache Care,** in Volume 2.

Shaving

Depending on the culture, shaving is an important part of grooming and helps patients feel better about their appearance. Many men shave their facial hair every day. Women may shave to remove axillary and leg hair. If the patient has a bleeding disorder or is taking anticoagulant medication, you should use an electric razor. For important points about shaving,

Go to Chapter 25, **Procedure 25-11: Shaving a Patient,** in Volume 2.

Some dark-haired men (e.g., African Americans and Italians) have tightly curled facial hair, which curls back into the skin when shaved. An inflammatory reaction may occur, resulting in the formation of papules and pustules. In such cases, the man may wish to use a **depilatory** (hair-removing agent) instead of shaving. If you apply a depilatory, be sure to keep the chemical from contacting the patient's eyes, nose, mouth, and ears. Do not use a straight or safety razor to remove the depilatory, because it will irritate the skin. Some men with this condition prefer to grow a beard, especially when they are ill and unable to care for themselves.

CARE OF THE EYES

Usually you will not need to provide special hygiene care for the eyes. The eyelids and lashes keep dust and debris from entering the eyes, and tears continually cleanse and lubricate them. When necessary, you may gently cleanse the eyes, from the inner to the outer canthus, with a moistened washcloth (but with no soap). If there is drainage or crusting, use a different cloth for each eye to prevent cross-contamination.

ASSESSMENT (EYES)

When performing hygiene care, inspect the eyes for redness, lesions, swelling, crusting, excessive tearing, or discharge. Also check the color of the conjunctivae. You should also ask the patient or check his records to see whether he wears glasses or contact lenses. If the patient wears glasses, ask when he uses them (e.g., for reading, for driving), and ask how well he sees without them. If the patient wears contact lenses, determine:

- The type of lens (hard, soft, long-wearing, disposable)
- How often he wears them (daily, occasionally) and for how long at a time
- Whether they are worn during sleep
- History of or current problems with lens usage (e.g., cleaning, removal)
- Usual practices for cleaning and storage
- History of or current problems with the eyes (e.g., redness, tearing, irritation, dryness, or "scratchy feeling")

These should be adequate data for hygiene care. However, it is not a complete eye assessment. For detailed information about assessing the eyes, see Chapter 22.

ANALYSIS/NURSING DIAGNOSIS (EYES)

Other than Bathing Self-Care Deficit, there is only one NANDA-I label specific to the eyes: Disturbed Sensory Perception: Visual. This label is of limited use for hygiene care. Other diagnoses that might occur include:

- Risk for Infection related to improper hand washing and improper lens cleaning
- Risk for Injury (to eyes) related to wearing lenses longer than recommended

PLANNING OUTCOMES/EVALUATION (EYES)

The only *NOC standardized outcome* specific to the eyes is Sensory Function: Vision. Its use is limited with regard to hygiene care; instead, you would use it if the client has a diagnosis of Disturbed Sensory Perception: Visual.

Individualized goals you might write for eye care include these examples:

- Demonstrates proper cleaning and storage of contact lenses.
- Eyes appear clean and without redness or drainage.

PLANNING INTERVENTIONS/IMPLEMENTATION (EYES)

For *NIC standardized interventions* related to eye care,

Go to Chapter 25, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Hygiene Problems,** on Davis*Plus*.

Individualized nursing activities related to the care of the eyes include providing eye care to unconscious clients, caring for eyeglasses and contact lenses, and caring for artificial eyes.

Eye Care for the Unconscious Patient

Having lost the blink (corneal) reflex, comatose or critically ill patients need more frequent eye care (every 2 to 4 hours). Keep their eyes lubricated with saline or artificial tears to protect them from corneal abrasions and drying. You may also need to use a protective eye shield to keep the patient's eyes closed. Instill eye ointment or drops in the lower lids as ordered.

To review a procedure for administering eye medications,

Go to Chapter 26, **Procedure 26-2: Administering Ophthalmic Medications,** in Volume 2.

Caring for Eyeglasses and Contact Lenses

Eyeglasses need to be cleaned at least once a day. Using warm water and a soft cloth, clean gently to prevent scratching of the lens. Ask the patient whether the lenses require a special cleaning solution; some patients bring their own.

Key Point: ***Label each patient's glasses, and store them in a safe place within the patient's reach, preferably in a glasses case in the drawer of the bedside table. They are expensive, so take care that they are not lost or damaged.***

An alternative to glasses, contact lenses are plastic discs worn on the cornea over the pupil. They float on the tears of the eye and stay in place because of surface tension. The cornea is nourished mainly by oxygen from the atmosphere and from tears, so in order to ensure an optimal supply of oxygen, contact lenses must be removed periodically. Wearing time varies from daily wear to up to around 30 days, depending on the type of lens. If you want more information about several different types of contact lenses:

Go to Chapter 25, **Supplemental Materials, Types of Contact Lenses,** on Davis*Plus*.

People usually care for their own contact lenses. Contact lens users must be careful to keep them free of microorganisms that could cause eye infections and to be careful to avoid eye irritation. Teach cleaning and disinfecting measures clients as needed (see the box Self-Care: Teaching Your Clients About Cleaning and Storing Contact Lenses), and follow those measures when you must care for a client's lenses.

If you need to remove a patient's lenses during an emergency, follow universal precautions and handle the lenses as you would any other valuable patient property.

Never use your fingernails to remove a lens, as you may scratch the eye or damage the lens.

Self-Care

Teaching Your Clients About Cleaning and Storing Contact Lenses

- Cleaning and disinfecting procedures and solutions vary among manufacturers. Depending on the type of lens, use saline solutions or special rinsing and soaking solutions.
- Use a special container for the lenses, with a cup labeled for the left and right lens. Some lenses are stored in a solution; others are stored dry. Follow manufacturer's instructions.
- Always wash your hands before touching the eyes or the lenses.
- Be careful not to allow the lenses to come in contact with soaps, hair sprays, or cosmetics.
- Do not wear soft lenses while using eye drops or ointment (wait 1 hour after using drops and at least 4 hours for ointment).
- Be aware of the risk for eye irritation when in the presence of smoke or chemical vapors.

To avoid placing a contact lens in the wrong eye, lens cases are marked for the left and right eyes.

For more detailed instructions,

Go to Chapter 25, **Procedure 25-12: Removing and Caring for Contact Lenses,** in Volume 2.

Caring for Artificial Eyes

An artificial eye is made to look like a natural eye. It can be made of glass or plastic. Some artificial eyes are permanently implanted in the socket, but others must be removed daily for cleaning of the prosthesis and the eye socket. If the patient is not able to perform his own eye care, ask about and follow his usual routines, when possible. To remove an artificial eye, wear procedure gloves. Using your dominant hand, raise the upper eyelid and depress the lower lid. Apply slight pressure below the eye to release the suction holding it in place (Fig. 22-5). Alternatively, you can use a small bulb syringe, place it directly on the eye, and squeeze to create suction and lift the eye from the socket. For details about removing, cleaning, and replacing an artificial eye, see the Procedures Highlights box and

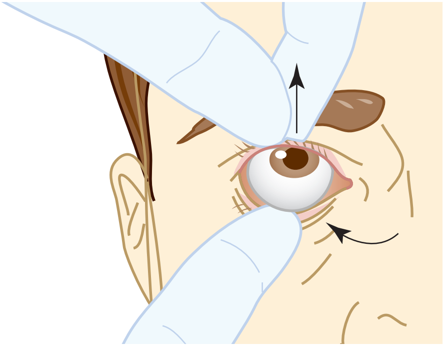

FIGURE 25-5 To remove a prosthetic eye, apply pressure just below the eye.

Go to Chapter 25, **Procedure 25-15: Caring for Artificial Eyes,** in Volume 2.

KnowledgeCheck 25-12

- True or False: Eyes should be cleansed from the outer to the inner canthus.
- How can a contact lens wearer help prevent eye infections?
- After you have cleaned a prosthetic eye, should you dry it before reinserting it, or leave it wet? To answer this question, you may need to refer to Procedure 22-15, in the Highlights of Procedures box.

CARE OF THE EARS

Healthy ears require minimal care. However, you will need to help patients who have limited self-care abilities and teach others about self-care.

For example, **cerumen** (wax) impaction is a common cause of hearing loss, especially in older adults. People sometimes believe hearing loss is a normal part of aging and fail to seek treatment. Encourage them to see their primary care provider whenever hearing loss occurs.

Teach patients to avoid using rigid objects, such as bobby pins or toothpicks to clean their ears. Such instruments can traumatize the ear canal and may rupture the **tympanic membrane** (eardrum). Likewise, never use cotton-tipped applicators; they will push the cerumen further into the ear, causing a blockage.

For dependent patients, assess for drainage, excess cerumen, and hearing loss during the bath. Clean the auricle, and remove wax from the canal with the tip of the moistened washcloth. If cleansing with a washcloth does not effectively remove excess cerumen buildup, obtain a prescription for **cerumenolytic** drops and water irrigation. You can delegate ear cleaning and hearing aid care to the NAP if you are sure that the NAP knows how to perform these tasks. Describe what you want the NAP to observe and report to you. See Chapter 30 for information about ear irrigations.

Care of Hearing Aids A hearing aid is a battery-powered device that amplifies sound. Three types of hearing aids are shown in Figure 25-6. Also, some patients wear a hearing aid in the temple pieces of their eyeglasses. People with severe hearing loss may wear a body hearing aid that clips onto the clothing or a harness-type carrier that connects by a cord to the earpiece. Digital hearing aids are rapidly replacing the analog models.

Hearing aids are expensive, so handle and store them properly. They require regular cleaning and replacement of batteries. Even with good care, they usually need to be replaced every 5 to 10 years, and earmolds usually need adjustment more often than that. Never place a hearing aid in water. For guidelines to remove, clean, and replace a hearing aid,

Go to Chapter 25, **Procedure 25-16: Caring for Hearing Aids,** in Volume 2.

CARE OF THE NOSE

Usually the nose requires no special care. Have the patient remove excess secretions by gently blowing into a tissue with both nostrils open. Holding one nostril

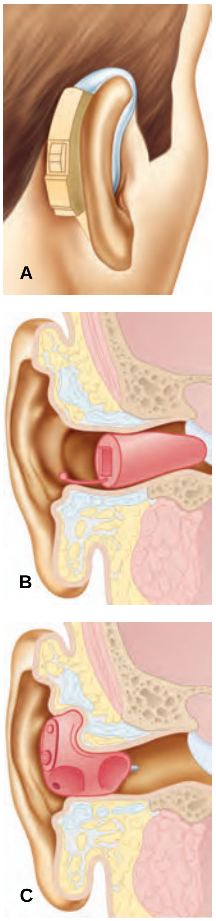

FIGURE 25-6 Hearing aids. *A*, The postaural (behind-the-ear) aid is the most widely used. A plastic tube connects it to an earmold. *B*, An in-the-canal aid is the least visible. *C*, The in-the-ear aid is made in one piece; all components are in the earmold.

shut can force secretions into the eustachian tubes. In debilitated or unconscious patients, dried secretions can interfere with respirations. Remove secretions by gently inserting a moistened cotton-tipped applicator into the nostrils. Occasionally you may need to instill saline into the nares and suction secretions to keep the airway patent. If the patient has a nasogastric (NG) tube, the constant pressure on the skin may cause breakdown. Provide special skin care and a lubricant at the point where the tube touches the nares.

Highlights of Procedures 25-1 to 25-16

For steps to follow in *all* procedures, refer to the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these Procedure Highlights later to help you review key points.

Procedures 25-1, 25-2, and 25-3: Bathing: Providing a Complete Bed Bath Using a Prepackaged Bathing Product, Bathing: Providing a Towel Bath, and Bathing: Using a Basin and Water

- Use prepackaged bathing products.
- Check the temperature of the packaged bath wipes after microwaving.
- Avoid chilling or tiring the patient.
- Bathe the patient following the principles of "head to toe" and "clean to dirty."
- For extremities, cleanse from distal to proximal.
- Use a new wipe for cleansing the perineum and whenever the wipe becomes soiled.
- Perform hand hygiene when moving from a contaminated body part to cleanse a clean body part.
- If performing a basin and water bath, use a disposable basin and distilled, filtered, or sterile water, according to agency requirements. Use a CHG and water solution to bathe the patient and clean the pan. Store the basin upside down.
- Chlorhexidine gluconate (CHG) 2% prepackaged cloths decrease the colonization of bacteria on the skin and should not be rinsed.

Procedure 25-4: Providing Perineal Care

- Provide privacy; keep the patient covered as much as possible.
- Place waterproof underpad to protect the bed linens.
- Use warmed prepackaged wipes.
- Perform perineal care following the principle of "clean to dirty" (front to back).

Procedure 25-5: Providing Foot Care

- Inspect the feet thoroughly for skin integrity, circulation, and edema.
- Clean the feet with warmed prepackaged wipes; clean the toenails; rinse; and dry well.
- Trim the nails straight across, unless contraindicated. Check institutional policy; many institutions do not allow nurses to trim nails.
- File the nails with an emery board.
- Lightly apply lotion, except between the toes.
- Ensure that footwear or bedding is not irritating to the feet.

Procedure 25-6: Brushing and Flossing the Teeth

- Assess the teeth, mucous membranes, and swallowing ability.
- Position the patient to prevent aspiration (sitting or side-lying position).
- Hold the brush at a 45° angle, and brush the patient's teeth (or assist).
- Floss and rinse, using sterile, filtered, or distilled water according to agency policy.
- If the patient is at risk for choking, suction secretions as needed.

Procedure 25-7: Providing Denture Care

- Refer to Procedure 25-6, Brushing and Flossing the Teeth.
- Remove (and replace) the top denture before the lower denture.
- Tilt dentures slightly when removing and replacing.
- Handle dentures carefully, and place a towel in the sink to avoid breaking the dentures if you drop them.
- Use cool, agency-approved water and a stiff-bristled brush.

Procedure 25-8: Providing Oral Care for an Unconscious Patient

- Assess the condition of the teeth (or dentures), gums, and mucous membranes.
- Assess for the gag reflex.
- Position the patient to prevent aspiration.
- Brush and floss the patient's teeth.
- Suction secretions as needed

Procedure 25-9: Shampooing the Hair

- Determine the type of procedure needed. Assess the patient's ability to help and the condition of the hair and scalp.
- Identify hair care products needed for the procedure.
- Wash the hair with no-rinse shampoo or no-rinse shampoo cap.
- If basin and water are used, protect the bed from getting wet.
- Protect the patient's eyes and ears from soap and water.
- Towel-dry the hair.
- Take care not to burn the patient with the hair dryer, if one is used.

Procedure 25-10: Providing Beard and Mustache Care

- Assess the skin for redness, dry areas, or lesions.
- Trim the beard and mustache to the desired length with a comb and scissors or beard trimmer.
- Shampoo the beard and mustache.
- Apply conditioner, if desired.
- Towel-dry the beard and mustache, and comb and style as desired.

Highlights of Procedures 25-1 to 25-16

Procedure 25-11: Shaving a Patient

- Wear procedure gloves.
- Assess the skin for redness or dry areas.
- To soften the beard and moisten the skin:
  - Apply a warm, damp towel to the face.
  - Apply shaving cream or soap.
- To prevent skin irritation:
  - Hold the skin taut, and shave the face and neck.
  - If using a safety razor, hold the blade at a 45° angle to the skin.
  - Apply after-shave product, if desired.

Procedure 25-12: Removing and Caring for Contact Lenses

- Instill one or two drops of wetting solution.
- Gently remove contact lenses; use your finger pads, not your fingernails.
- Clean and store contact lenses in sterile solution.
- Mark the containers "L" and "R" to identify the correct eye.

Procedure 25-13: Making an Unoccupied Bed

- Remove soiled linens without cross-contaminating other items in the room.
- Remake the bed with clean linens.
- Do not "shake" or "fan" linens.
- Work efficiently and safely.
- Ensure that there are no wrinkles in the bottom sheet or drawsheet.

Procedure 25-14: Making an Occupied Bed

- Maintain patient safety during the procedure.
- Assess the patient's ability to move and need for assistive equipment and patient-handling devices.
- Position the patient laterally near the far siderail, and roll soiled linens under him.
- Place clean linens on the side nearest you, and then tuck under the soiled linens.
- Roll the patient over the "hump," and position him on his other side, near you. Raise the near siderail.
- Move to the other side of the bed; pull soiled and clean linens through, and complete the linen change as in Procedure 25-13: Making an Unoccupied Bed.
- Place the bed in a low position, raise the siderails, and fasten the call light to the pillow.

Procedure 25-15: Caring for Artificial Eyes

- Have the patient lie down.
- Remove the artificial eye: Raise the upper eyelid; with dominant hand, depress the lower lid and apply slight pressure below the eye (or use a small bulb syringe).
- Clean the eye: Clean the eye with saline; store in saline or distilled, sterile or filtered water (per agency policy); label the container.
- Clean the edge of the eye socket with a moistened cotton ball.
- Reinsert the eye: Be sure the prosthesis is wet. Hold it with your dominant hand. Spread the patient's eyelids apart with nondominant hand, and guide prosthesis into the eye socket.

Procedure 25-16: Caring for Hearing Aids

- Keep hearing aids away from heat and moisture.
- Clean hearing aids with a damp cloth only.
- Avoid hairspray and other hair care products.
- Turn off hearing aids when not in use.
- Replace dead batteries immediately.
- Store hearing aids in a case with the battery compartment open.
- Keep hearing aids and batteries away from children and pets.
- To clean a hearing aid: Turn it off, remove it from the ear, cleanse the outer ear and the hearing aid, check the battery, reinsert it, turn it on, and check the volume with the patient.

THE CLIENT'S ENVIRONMENT

A comfortable environment contributes to the client's well-being. It is your responsibility, as a nurse, to see that the bedside unit and surroundings are clean, safe, and comfortable.

ASSESSMENT (SCANNING THE ENVIRONMENT)

Each time you enter a patient's room, you should scan the environment to see whether you need to make adjustments to ensure patient safety and comfort:

- Is the room temperature comfortable?
- Are the siderails up, when indicated?
- Is the bed in low position, and the wheels locked?
- Are bed linens clean and free of wrinkles?
- Is the patient's call device within reach?
- Is the overbed table clean and uncluttered?
- Is there uncluttered walking space?
- Are there unpleasant odors?

Each time you leave the room, ask, "What else can I do for you?" This ensures that you have not overlooked anything.

PLANNING INTERVENTIONS/IMPLEMENTATION (THE ENVIRONMENT)

Adequate ventilation; proper room temperature; low noise level; and neat, clean surroundings are important to ensure the patient's comfort.

Promoting Ventilation

Body secretions such as urine, feces, vomitus, or draining wounds cause odors in both inpatient facilities and the home. Odors can be offensive, and patients often feel embarrassed by them, so work quickly to free the environment of any sources of odors. Cleanliness is the best way to prevent odors. Other suggestions include the following:

- Provide good ventilation, if this is under your control. For example, open a window or use a fan.
- Empty and clean urinals, bedpans, or emesis basins promptly.
- Dispose of soiled dressings or other malodorous items in appropriate containers, and immediately remove them from the room.
- Unless contraindicated by the patient's illness, you can use a room deodorizer to help eliminate odors.
- Most institutions ban smoking in patient rooms, in part because of the odor.

Control Room Temperature

Although preferences may vary, a room temperature between 68°F and 74°F (20°C and 23°C) is usually comfortable for most patients. Those who are very ill, very young, or very old may need a higher than normal room temperature. If there is no thermostat in the room, you may need to provide blankets, open a window, provide a fan, and so on to adjust the room temperature.

Limit Noise

People who are ill are often sensitive to various environmental noises, such as an ice machine, suction equipment, paging systems, loud talking, and laughter. In addition, sleeping in a new and strange environment or in the presence of pain may be difficult. Make it a priority to control noise. Keep unnecessary conversations to a minimum, and speak quietly. Some hospitals have instituted a "quiet hour" to promote better rest. Others have installed decibel meters to help nurses be mindful of noise escalation during activity in the nurses' station.

Standard Bedside Equipment

In a hospital, standard bedside equipment usually includes a bed, bedside stand (end table), overbed table, and one or two chairs. The wall unit may consist of a call light, oxygen, suction and electrical outlets, and light fixtures and switches. The patient's personal items are usually kept in the bedside stand. Therefore, you should request permission from the patient before opening the stand. Personal hygiene items, bedpan, and urinal may also be kept in the lower cabinet of this stand.

Hospital Beds

Hospitalized patients spend a significant amount of time in bed. Hospital beds can be uncomfortable and may contribute to restlessness and poor sleep. Memory foam and moisture control mattresses are available and provide more comfort. However, they are expensive and not used routinely. Hospital beds are generally standard in size and higher and narrower than a home bed. This allows you to reach the patient more easily and safely.

Hospital beds are usually electronically controlled, so the patient and nurse can raise and lower the head and foot separately by the push of a button (see Fig. 25-7 for bed positions).

Patient safety is your priority, so although you should raise the entire bed to a working level that is comfortable for you, be sure to place the bed in the lowest position before leaving the bedside. Long-term care settings usually have low beds to make it easier for ambulatory patients to transfer into and out of bed. As a part of the admission procedure, you will teach patients how to use the bed controls.

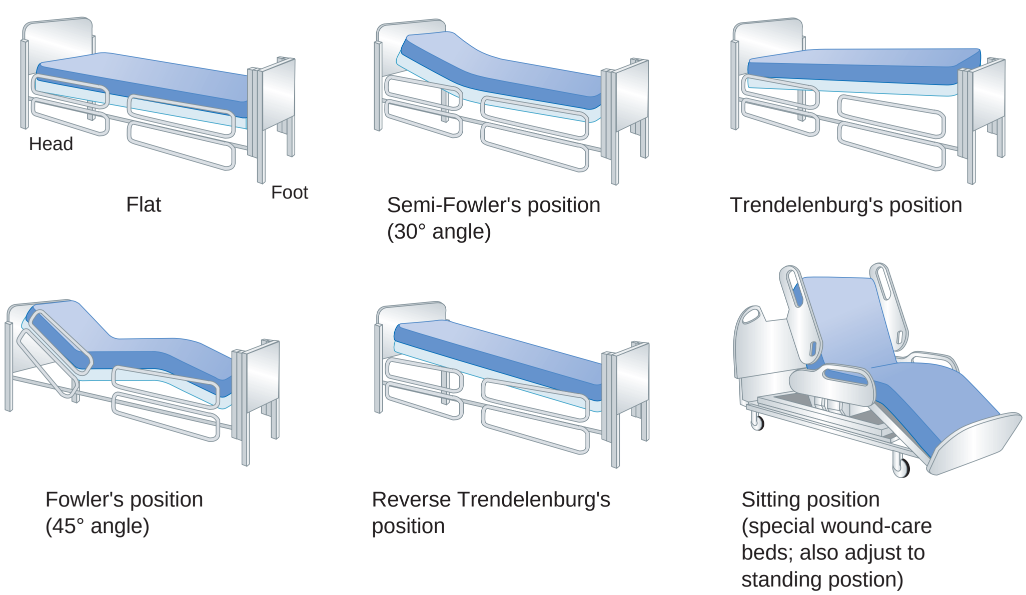

FIGURE 25-7 Hospital beds adjust to several positions.

Go to Chapter 11, **Procedure 11-1: Admitting a Patient to a Nursing Unit,** in Volume 2.

Patients may use siderails when moving into and out of bed. Siderails may help to prevent falls by patients with decreased consciousness. However, siderails are considered a passive restraint and may pose risk to a patient with a cognitive impairment. See Chapter 24 for additional information about the safe use of siderails and other equipment.

Always lock the wheels on a hospital bed when it is stationary. For example, an unlocked bed could roll out from under an ambulatory patient who is moving from the bed to a chair. Ensure that the wheels are locked when you are helping the patient to a sitting position on the side of the bed or assisting with a transfer to a chair or stretcher.

Mattresses and Linens

Mattresses are usually firm and covered in a water-repellant material that resists staining and soiling and may be easily wiped down with a germicidal cleaner. A variety of special therapeutic mattresses are available to help reduce the effects of pressure over the bony prominences (e.g., sacrum, heels). See Chapter 35 for further discussion of special mattresses.

Using a mattress cover and/or pad promotes patient comfort and prevents soiling of the mattress. Plastic covers, however, do not allow moisture to escape, and contribute to skin maceration for patients who are incontinent or diaphoretic. Bed mattress covers, whether water-resistant, waterproof, or water-repellent, may lose their effectiveness over time, allowing moisture, blood, or bacteria to penetrate the mattress. Regularly check each medical bed mattress cover. If any visible signs of damage or wear such as cuts, tears, cracks, pinholes, snags, or stains are found, the cover should be immediately replaced to reduce the risk of infection (U.S. Food and Drug Administration, 2013).

Sheets may be fitted or flat. Other linens include drawsheets, washable incontinence pads, pillowcases, blankets, bedspreads, and gowns. If a plastic surface lies directly under the sheet, you should place a cloth or other absorbent pad between the patient and the sheet.

Bed Making

Clean, wrinkle-free bed linens help to promote comfort and a sense of well-being. In contrast, wrinkled and soiled linen can contribute to skin breakdown and pressure areas. Linens are generally changed daily after the bath and when soiled. If patients are up and about during the day, such as on a rehabilitation unit, beds are made daily, but bed linen may be changed weekly or only when soiled. If the patient is immobile or on bedrest, the bed is made while the patient occupies it. You or the NAP may make an unoccupied bed or an occupied bed. For more information about bed making,

Go to Chapter 25, **Procedure 25-13: Making an Unoccupied Bed** and **Procedure 25-14: Making an Occupied Bed,** in Volume 2.

Think**Like a Nurse** 25-10

For which of your patients (Meet Your Patients) will you most surely need to make an occupied bed? Why?

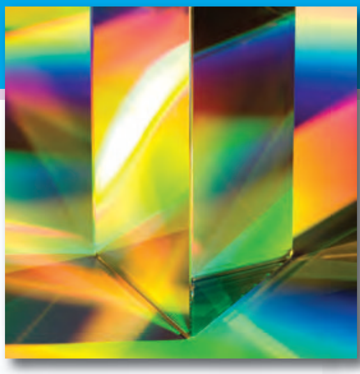
CHAPTER 26



Administering Medications

Learning Outcomes

After completing this chapter, you should be able to:

- Name at least five sources of medication information.
- Distinguish among various nomenclature systems for naming and classifying drugs.
- Discuss the concepts and processes of pharmacokinetics, including drug absorption, distribution, metabolism, and excretion.
- Define onset, peak, and duration of drug action; therapeutic level, peak level, and trough level; and biological half-life.
- Compare and contrast primary, secondary, cumulative, and side effects; and adverse, toxic, allergic, anaphylactic, and idiosyncratic reactions.
- Define drug-drug interaction, antagonistic drug relationship, synergistic drug relationship, drug incompatibility, and medication contraindications.
- Correctly calculate drug dosages, including (1) conversion among the metric, apothecary, and household measurement systems and (2) working with units and milliequivalents (mEq).
- List the types of medication prescriptions, including the methods for communicating them.
- Discuss the agencies and legislation that help to ensure drug quality and safety.
- Describe nursing assessment before, during, and following the administration of a drug.
- Plan care for clients with problems of Risk for Injury and Noncompliance related to medications.
- Administer medications using the "three checks" and "rights of medication."
- Describe appropriate steps to take when communicating a medication error.
- Demonstrate the correct procedure for administering medications by the oral, enteral, inhalant, and parenteral routes.
- Demonstrate the intramuscular injection procedure at the following sites: ventrogluteal, deltoid, and vastus lateralis.
- Explain why the dorsogluteal site is no longer recommended for intramuscular injections.
- List five steps to incorporate in your practice to ensure safe medication administration and prevent a medication error.

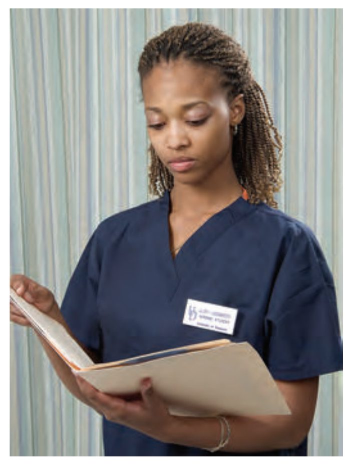
Key Concepts

Medication administration
Medication safety
Pharmacology

Related Concepts

See the Concept Map on Davis*Plus*.

Meet Your Patients



As a new nurse, you are scheduled to administer medications to five patients on the medical-surgical unit today for the first time. Your preceptor will be available as a resource. Your patients are:

- Margaret Marks, an 82-year-old woman who has a fractured hip and experiences periods of confusion.
- Cary Pearson, a 70-year-old man with feeding and swallowing difficulties who receives his medications through a gastrostomy tube.
- Cyndi Early, a 32-year-old woman with diabetes who is scheduled for surgery at 1000 today.
- James Bigler, a 44-year-old man who has had a repair of a compound fracture of the right arm and is receiving intravenous fluids and medications.
- Rebecca Jones, an 84-year-old woman with compression fractures of two lumbar vertebrae resulting from a fall.

You have reviewed your assignment but are unsure of where to begin. Should you visit your patients first and perform an assessment? Should you review the charts first? What should you do with the medication administration records (MARs)? There are so many questions running through your head, and you are a little nervous being on your own. Perhaps you could use the model of full-spectrum nursing (Chapter 2) to focus your thinking. In general, any time you give a medication, you will need to incorporate the following:

1. *Theoretical Knowledge:* Find out about the actions and expected effects of the medications you are to give.
2. *Patient Situation:* Assess the health status (e.g., disease process) of each patient as it relates to his medications.
3. *Critical Thinking:* Why is the drug being given? Is there anything about the patient's physiology that may alter his responses to the drug? Do you need to modify the administration procedure in any way?
4. *Practical Knowledge:* Be sure that you know the procedures for administering each medication safely.

By the time you complete this chapter, you will have the information you need to make those kinds of judgments. And remember that while you are a student, your instructor and the staff nurses will be there for support.

Theoretical Knowledge knowing why

Pharmacology is the science of drug effects. It deals with all drugs used in society, legal and illegal, prescription and nonprescription, and "street" drugs. Because of their potential for harm as well as benefit, you should thoroughly understand the medications you administer.

ABOUT THE KEY CONCEPTS

The broadest concept identified in this chapter is **medication administration**. The concept of **medication safety** is intimately related to it. In order to administer medications without causing harm to patients, you will need theoretical knowledge of **pharmacology** (another key concept), as well as practical knowledge about safe procedures. You will identify many related concepts as you read this chapter (e.g., pharmacodynamics, pharmacokinetics). Try to understand how they relate to the three key concepts. If you can organize information this way in your mind, you are likely to remember it better.

HOW ARE DRUGS NAMED AND CLASSIFIED?

A **drug** is a chemical that interacts with a living organism and alters its activity. In healthcare, drugs are used in diagnosing, treating, or preventing a disease or other medical condition. The term *drug* is used interchangeably with *medication,* although some people think of the term *drug* as meaning an illegal substance.

Drug Names

A drug may have multiple names.

- **Chemical name** is the exact description of the drug's chemical composition and molecular structure. For example, *2-(p-isobutylphenyl) propionic acid* is the chemical name of the anti-inflammatory drug ibuprofen. The chemical name is rarely used in nursing practice.
- **Generic (nonproprietary) name** is assigned by the United States Adopted Name Council (USAN Council) when the developing manufacturer is ready to market the drug. This is usually similar to the chemical name, but in a simpler form.

- **Official name** is also the generic name that is listed in publications such as the *United States Pharmacopeia (USP)* and *National Formulary (NF)*. For example, *ibuprofen* is both a generic and an official name.
- **Brand (trade** or **proprietary) name** is what the drug is sold as in stores. The brand name is easily recognized because it begins with a capital letter and sometimes has a registration mark (®) at the upper right of the name. Different manufacturers of the same medication may give the medication different brand names. For example, Advil, Nuprin, and Motrin are all brand names for ibuprofen.

Prescription drugs require a written order from a healthcare provider (e.g., physician or advanced practice nurse) who is licensed by the state to prescribe or dispense drugs. **Nonprescription**, or **over-the-counter (OTC)**, drugs may be purchased without a prescription and are assumed to be safe for the general population if consumers follow the manufacturer's directions. Some drugs are nonprescription at low doses but require a prescription for the consumer to purchase in a higher dose. For example, naproxen sodium 200 mg is sold over the counter as Aleve, whereas naproxen 500 mg is sold as Naprosyn and requires a prescription. Some drugs once available only by prescription may become OTC, such as with loratadine (Claritin).

Drug Classifications

It is not realistic to know everything about every drug, so "looking it up" must become second nature. If you learn the common characteristics for a drug classification, then when you encounter a new drug, you will be able to associate it with its classification and make inferences about its basic characteristics.

- By usage—why the drug is used
- By body system—where the drug works
- By chemical or pharmacological class—what the drug is made of

To see an explanation and examples of those classifications methods,

Go to **ESG Table 26-1, Drug Classification System,** on Davis*Plus*.

A drug can be placed in more than one category in a classification system. Classified by usage, for example, ibuprofen (Motrin) can be an analgesic, anti-inflammatory, and an antipyretic agent. A drug can act on more than one body system, as well; in fact, most do. For example, diazepam (Valium) is used for its anti-anxiety effects, but it also decreases the activity of the intestinal system and other smooth muscles.

KnowledgeCheck 26-1

- Name three ways a drug may be classified.
- List at least four ways a drug could be named.

WHAT MECHANISMS PROMOTE DRUG QUALITY AND SAFETY?

Before the 20th century, the United States did not have mechanisms for publishing drug ingredients, regulations to govern the contents of drugs, or limitations regarding drug sales. People could buy medicines containing potent and dangerous ingredients, such as opium and alcohol. Now, reliable sources of drug information, state and federal regulations and standards controlling drug administration, and a variety of systems for storing and distributing medications in healthcare agencies all work together to protect consumers.

Drug Listings and Directories

Key Point: ***When in doubt, look it up!*** As a nurse, you are professionally, ethically, legally, and personally responsible for every dose of medication you administer. Always use current information when researching a medication. The following references have become the official standards for the healthcare industry:

Pharmacopoeia and Formularies The ***United States Pharmacopoeia (USP)*** is a directory of drugs approved by the Food and Drug Administration (FDA) that lists the physical and chemical composition of each drug. Any drug included in this book has met rigorous standards of quality, strength, and purity and the manufacturer is permitted to use the letters "USP" after the drug name. The ***National Formulary (NF)*** is another official resource for medication information in the United States. It identifies the therapeutic value of drugs as well as their formulas and prescriptions.

Nursing Drug Handbooks Available from textbook and other publishers, handbooks serve as a quick resource for dosage, side effects and nursing interventions associated with a drug.

Physician's Desk Reference (PDR) This book, commercially compiled by the pharmaceutical companies, lists manufacturers' prescribing information and is a standard resource for professionals prescribing and administering medication. The *PDR* does not include nursing interventions, but does contain information on dosing, routes of administration, and side effects.

Pharmacology Texts A textbook provides more information about physiology, pathophysiology, mechanism of action, and drug classifications than the drug formulary or a handbook. However, it may or may not have detailed information about the specific drug you are administering.

Electronic and Internet-Based Formularies The Internet, computer software, PDAs, and other handheld devices offer convenient access to formulary databases.

Pharmacist A clinical pharmacist can assist you with medication-related concerns (e.g., dosage calculations, compatibility).

Medication Package Inserts Most medications are packaged with an insert that provides information identical to that found in the drug formulary and specific for that particular drug.

Institutional Medication Policies and Procedures You should know the policies and protocols for medication administration for each institution in which you practice.

ThinkLike a Nurse 26-1

Mr. Pearson (Meet Your Patients) has a medication, metoprolol (Lopressor), due at 0800. You are not familiar with this medication.

- What do you need to know before giving the drug?
- What resources might you use to learn about this medication?
- Which is the generic and which is the brand name of this medication?
- Select a nursing drug handbook and research this medication. What kinds of information are available to you in the book?
- Now look up the drug in a pharmacology text. How is that information similar to and different from the information in the handbook?

Legal Considerations

In the United States, drug administration is controlled by federal, state, and local laws. Standards of nursing care, state nurse practice acts, and organizational policies and procedures define your role and responsibilities in administering medications. You must be familiar with them to know what you can and cannot do. In addition, you must recognize the limits of your own experience, skills, and knowledge.

The Food and Drug Administration (FDA) of the U.S. Department of Health and Human Services regulates the testing, manufacture, and sale of all medications. This agency also monitors the safety and effectiveness of medications available to consumers. This process helps to ensure that ineffective or unsafe drugs are not marketed or are recalled, if later found unsafe. However, many medicinal products are *not* regulated by the FDA. For example, herbal remedies and some naturopathic supplements are considered "food products" and are not regulated, yet they are advertised as having health benefits.

Nurse Practice Acts

In most states, a nurse cannot prescribe or administer medications without an authorized provider's (e.g., advanced practice nurse, physician) order. The Board of Nursing also regulates the types and routes of medications that can be administered by the various levels of nurses. For example, a licensed practical nurse (LPN) in some states cannot administer intravenous medications, whereas other states requires additional education and experiences before LPNs can perform this skill. You should refer to your state's nurse practice act for your scope of practice. If you violate the state's nurse practice act by giving medications without an order/prescription, your state's nursing board could revoke your license to practice nursing.

ThinkLike a Nurse 26-2

Obtain a copy of your nurse practice act for the state in which you work. To find a copy,

Go to the **National Council of State Boards of Nursing** Web site at https://www.ncsbn.org/contactbon.htm

What does your state's nurse practice act tell you about administering medications?

U.S. Drug Legislation

Various state and federal agencies regulate the manufacture and sale of medications. Each state must conform to federal regulations concerning medications. The states may, however, institute additional controls. Local governments may enact regulations for the use of alcohol and tobacco. For a historical list of U.S. laws regulating drug quality and safety,

Go to Chapter 26, **ESG Table 26-2, U.S. Legislation for Drug Quality and Safety,** on Davis*Plus*.

For a history of additional activities to protect consumers and ensure drug safety,

Chapter 26, Chapter Resources, **Resources for Caregivers & Professionals,** on Davis*Plus*.

Regulation of Controlled Substances

Controlled substances are drugs considered to have either limited medical use or high potential for abuse or addiction. Under the Controlled Substances Act (CSA) of the Comprehensive Drug Abuse Prevention and Control Act of 1970, it is illegal to possess a controlled substance without a valid prescription. For a summary of categories of controlled substances,

Go to Chapter 26, **Tables, Boxes, Figures: ESG Table 26-3, Schedules for Controlled Substances,** on Davis*Plus*.

Controlled substances must be stored, handled, disposed of, and administered according to regulations established by the U.S. Drug Enforcement Agency (DEA). Only prescribers with a *national provider identification number* have the authority to prescribe controlled substances. Controlled substances must be stored in locked drawers within a second locked area. (This process is known as **double locking**.) The facility must also keep a record of every dose administered. A count of all controlled substances is performed at specified times, usually at change of shift. To facilitate counting and tracking inventory, drug manufacturers package many narcotics in sectioned containers, with each tablet separately and consecutively numbered (Fig. 26-1).

FIGURE 26-1 To facilitate counting, many narcotics are packaged in sectioned containers with each tablet numbered consecutively.

ThinkLike a Nurse 26-3

Locate the controlled substance area on your nursing unit.

- Is a double-locking system in place?
- Who is responsible for "carrying" the narcotics keys?
- What is done if there is a discrepancy between a narcotic sign-out sheet and the actual number of narcotic doses present?

Systems for Storing and Distributing Medications

Most inpatient healthcare facilities have specific areas designed for preparation of medications. Usually this is a central room ("medication room") or mobile cart. Some nursing units store drugs and supplies in a locked cabinet in or near patient rooms. Whatever the method, all drugs are secured in designated areas accessible only to nurses.

Stock Supply

Medications used most frequently may be kept in **stock supply** (bulk quantity), labeled, and in a central location. For example, acetaminophen elixir and cough syrups may be kept in large multidose bottles from which you measure doses for more than one patient. Stock supplies require you to measure the dose each time a patient needs it, so the potential for measurement error occurs more frequently. However, a bulk supply of medication is often very cost-effective.

Unit-Dose System

A locked, mobile cart is used, with drawers containing separate compartments for each patient's medications (Fig. 26-2). Extra drawers contain supplies, such as medication cups, syringes, and alcohol swabs. The pharmacy staff refills the drawers each shift or every 24 hours. Limited amounts of **prn** (give according to patient need) medications and stock medications are also kept in the mobile cart.

FIGURE 26-2 Medications may be kept in locked, mobile carts, with a drawer for each patient. Mobile (portable) medication carts are linked to the automated dispensing unit.

A **unit dose** is the prescribed amount of drug the patient receives at a single time. For example, if 800 mg of ibuprofen (Motrin) is prescribed to be given every 8 hours, the unit dose is 800 mg. Each unit dose (usually one tablet) is individually packaged and labeled with the drug name, dose, and expiration date. The pharmacist checks each unit dose before sending the drug to the nursing unit. You must recheck the drug and dose when preparing it for administration. The unit-dose system not only saves nursing time, but also is the safest method because of the double-check system.

Automated Dispensing System

An automated dispensing system is a computerized system similar to a unit-dose system. The locked cart contains all the medications frequently used on a particular nursing unit, and the computer database contains records and counts of the medications, as well as the medication prescriptions for each patient on the unit. Each nurse uses a password to access the machine and enters the data about the needed drug, after which the machine dispenses the medication. The medications are usually packaged in unit doses, but some bulk medications may also be kept on the cart. This method allows for immediate administration of newly prescribed medications, prn medications, controlled substances, and emergency medications because the nurse does not need to wait for the pharmacy to fill a prescription.

Self-Administration

At times while in the hospital, patients may self-administer medications. For example, sublingual nitroglycerin (used for chest pain) is self-administered in the outpatient setting, and some patients can continue self-administration of the drug while in the hospital. The drugs prescribed for self-administration are supplied in individual containers and stored at the bedside. Remind the patient to tell you when he takes a dose. This method promotes independence and allows you to evaluate the patient's ability to manage medications safely and accurately before she is discharged. Check the policy in your institution regarding self-administration of drugs.

KnowledgeCheck 26-2

- What legislation defines controlled substances in the United States?
- How is medication quality managed?

WHAT IS PHARMACOKINETICS?

Pharmacokinetics refers to the absorption, distribution, metabolism, and excretion of a drug (Fig. 26-3). These four processes determine the intensity and duration of a drug's actions. Each drug has unique pharmacokinetic characteristics. As you study these concepts, think how they relate to each other and to the key concepts pharmacology, medication administration, and medication safety.

What Factors Affect Drug Absorption?

Absorption refers to the movement of the drug from the administration site into the bloodstream. The rate of absorption determines when a drug can begin to exert its action; thus, absorption also influences metabolism and excretion. Absorption depends on the administration route, drug form, drug solubility, pH, blood flow to the area, and body surface area.

Route of Administration

Drugs are manufactured for a specific route of administration: oral, sublingual, buccal, inhalant, topical, enteral, and parenteral. They are absorbed at different rates for each route. Medications are available in a variety of forms.

Drugs are given for either local or systemic effect. The **local effects** of a drug occur at the site of application (e.g., certain topical applications of drugs to the skin), so no or limited absorption occurs. When given for a **systemic effect**, the drug must be absorbed into the bloodstream before it can be distributed to a distant location. A drug may enter the circulation either by injection into a vein or by absorption from other areas (e.g., muscle, stomach, mucous membranes).

Table 26-1 summarizes the preparations and the advantages and disadvantages of the various routes of administration. The choice of route is crucial in determining the suitability of the drug for a particular patient. For example, if your patient is vomiting, an

(Text continued on page 614)

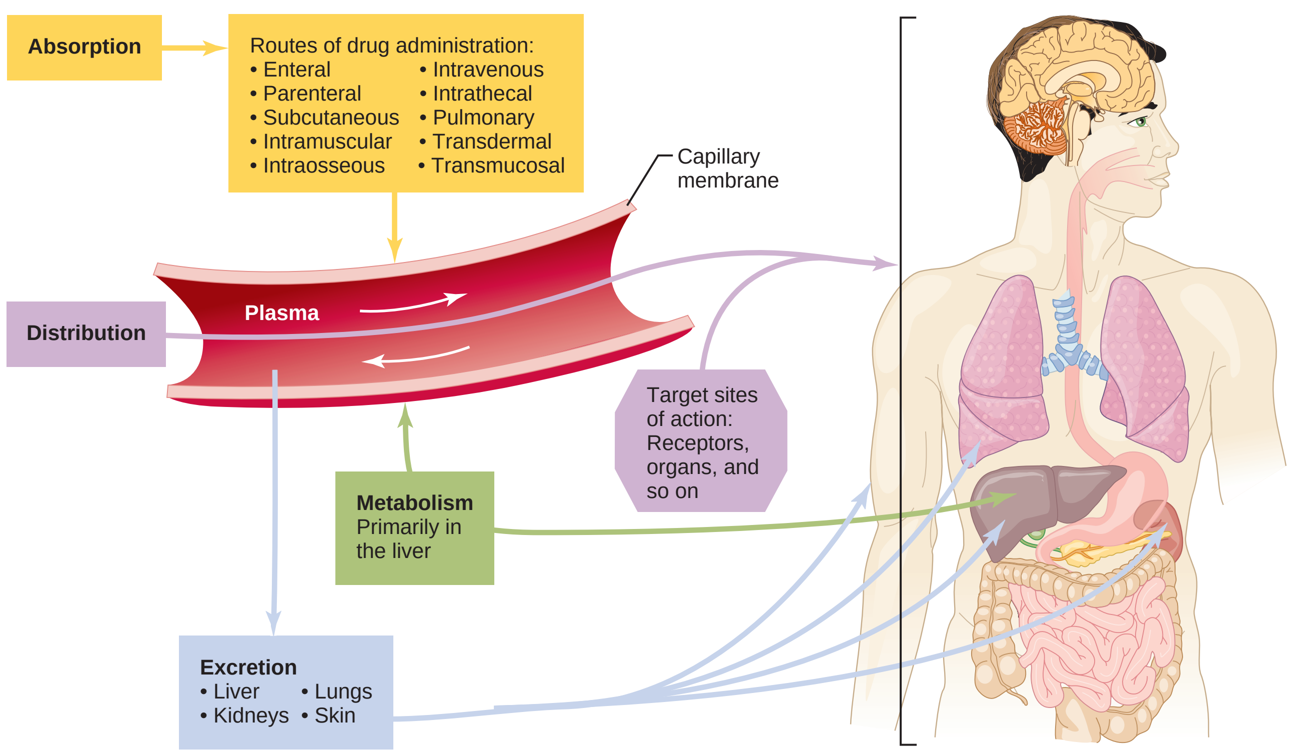


FIGURE 26-3 Pharmacokinetics is the study of drug absorption, distribution, metabolism, and excretion, which determine the intensity and duration of a drug's actions in the body.

Table 26-1 ➤ Advantages and Disadvantages of Routes of Administration

ROUTE: ORAL The drug is swallowed and absorbed from the stomach or small intestines.

Preparation types

- **Capsule**—A gelatinous container that holds the liquid, powder, or oil form of the drug. When swallowed, the gelatin container dissolves in the gastric juices.
- **Pill**—This term is rarely used now. *Tablet* is the preferred term.
- **Tablet**—A powdered drug is compressed into a hard, compact form (e.g., round, oval) that is easy to swallow and then breaks up into a fine powder in the stomach. The tablet is the most common oral preparation. *Enteric-coated tablets* have an acid-insoluble coating to keep them from dissolving in the stomach; they disintegrate in the alkaline secretions of the small intestine.
- **Time-released tablet or capsule**—A tablet or capsule formulated so that it does not dissolve all at once, but gradually releases medication over a few hours
- **Elixir**—A liquid containing water and about 25% alcohol that is sweetened with volatile oils (e.g., aromatic elixir); not as sticky or as sweet as syrups
- **Extract**—A very concentrated form of a drug made from animals or vegetables; may be a syrupy liquid or a powder
- **Fluid extract**—An alcohol-based solution of a drug from a vegetable source (e.g., belladonna); the most concentrated of the fluid preparations
- **Spirits—**A concentrated alcohol-based solution of a volatile (easily evaporated) substance or oil (e.g., ammonia, peppermint oil, orange oil); contains larger amounts of the substance than can be dissolved in water
- **Syrup**—An aqueous solution of sugar, used to disguise unpleasant taste of drugs
- **Tincture**—An alcohol or water-and-alcohol (with a high percentage of alcohol) solution made by extracting potent plants; may also be used externally (e.g., tincture of iodine)
- **Powder**—Finely ground drug(s), usually mixed with a liquid before ingesting; some are used internally, others externally. (Some are mixed with diluents for parenteral injection.)
- **Solution**—Drug(s) dissolved in a liquid carrier. *Aqueous solutions* are medications dissolved in water. (May be used orally, externally, and parenterally.)
- **Suspension**—Drug(s) that are suspended (not completely dissolved) in a liquid. *Aqueous suspensions* are suspended in water. *Never* used for IV or intra-arterial routes

Advantages	Disadvantages
■ Convenient ■ Sterility is not needed for oral use. ■ Economical ■ Noninvasive, low-risk procedure ■ Easy to administer, good for self-administration ■ Capsule can mask unpleasant taste of a drug. ■ Capsule can be time-release ■ Unpleasant taste may cause noncompliance.	■ May irritate gastric mucosa. ■ Patient must be conscious. ■ Digestive juices may destroy drug. ■ Cannot use if patient has nausea and vomiting or decreased gastric motility. ■ Cannot use if patient has difficulty swallowing. ■ Potential for aspiration ■ May be harmful to teeth. ■ Onset of action is slow.

ROUTE: ENTERAL The drug is given directly into the stomach or intestine (e.g., through a nasogastric (NG) or gastrostomy tube).

Preparation types

Same as for oral medications

Advantages	Disadvantages
■ Can be used for patients with Impaired Swallowing as an alternative to parenteral administration.	■ Not all tablets or capsules can be crushed; medications can clog the NG tube. ■ NG tube itself presents some risk of aspiration.

Table 26-1 ➤ Advantages and Disadvantages of Routes of Administration—cont'd

ROUTE: SUBLINGUAL (a variation of transmucosal administration)—The drug is held under the tongue and absorbed across the sublingual mucous membrane.

Preparation types

Lipid-soluble lozenge (troche)—A flat, round preparation that dissolves when held in the mouth. May act locally or be absorbed through mucosa for systemic effect.

Tablet (See oral route.)

Advantages	Disadvantages
■ Used for local or systemic effects ■ Convenient ■ Sterility not needed ■ Quick delivery to general circulation ■ Bypasses stomach and intestines; absorbed directly into bloodstream	■ May inadvertently be swallowed in the saliva. ■ Not useful for drugs with unpleasant taste ■ May irritate the oral mucosa. ■ Patient must be conscious. ■ Useful only for highly lipid-soluble drugs ■ Patient must hold the drug in place until it is dissolved, which may take a few minutes. ■ Limited period of effectiveness, requiring frequent redosing

ROUTE: BUCCAL/TRANSMUCOSAL ADMINISTRATION Medication is held against the mucous membrane of cheek until it dissolves.

Preparation types

Lipid-soluble lozenge or tablet (See oral and sublingual routes.)

Spray—Can be dispersed to the nasal or pharyngeal mucosa for rapid absorption.

Advantages	Disadvantages
■ Same as sublingual ■ Rapid, convenient, portable	■ Same as sublingual

ROUTE: TOPICAL (SKIN) The drug acts locally or is absorbed directly through skin (transdermal or percutaneous absorption).

Preparation types

Gel or jelly—A clear or translucent semisolid substance that liquefies when applied to the skin

Liniment—An oily liquid to rub into the skin

Lotion—An *emollient* (softening or soothing agent) for use on the skin; may be a clear solution, suspension, or emulsion

Ointment—A semisolid, fatty (usually petroleum jelly or lanolin based) substance for skin or mucous membranes; usually not water soluble

Paste—Similar to an ointment, but thicker and stiffer

Tincture (see oral route).

Transdermal patch—Releases constant, controlled amounts of medication, for systemic effect.

Aerosol spray or foam—A liquid or foam that is sprayed by air pressure onto the skin

Cream—A non-oily, semisolid substance applied to the skin

Advantages	Disadvantages
■ Continuous dosing ■ Sterility is not needed. ■ For local or systemic effects ■ Long-acting systemic effect ■ Useful if patient is unable to take oral medications ■ Acceptable to most patients	■ Effective only for lipid-soluble drugs and must be specially formulated. ■ May cause local irritation, especially if the patient is allergic to latex or tape. ■ Discarded patches may pose danger of poisoning. ■ Leaves residue on skin. ■ Accurate doses can be difficult to obtain when the drug is in a tube or jar.

Continued

Table 26-1 ➤ Advantages and Disadvantages of Routes of Administration—cont'd

ROUTE: TOPICAL: INSTILLATIONS The drug is placed into a body cavity (e.g., urinary bladder, rectum, vagina, ears, nose, eye).

Preparation types

Solutions (for nose, ears, and eyes; enemas per rectum)—Drug(s) dissolved in a liquid carrier

Suppositories (for bladder, vagina, rectum)—Drug(s) mixed with a glycerin-gelatin or cocoa butter base and shaped for insertion into the body. They dissolve gradually at body temperature.

Jellies, creams (for vagina and rectum)—See skin route.

Advantages	Disadvantages
▪ Continuous dosing ▪ Sterility is not needed ▪ Useful if patient is unable to take oral medications, when the oral drug has an unacceptable taste or odor. ▪ Preferred when the patient is vomiting or unconscious. ▪ May be used for local or systemic effects	▪ May be embarrassing for the patient. ▪ Absorption from the rectum is slow and if stool is present, there is local irritation, or if the patient defecates before the suppository melts. ▪ Pain, if the patient has hemorrhoids. ▪ As a rule, contraindicated when there is active rectal bleeding.

ROUTE: TOPICAL: INHALATION A device (e.g., nebulizer, face mask) breaks the drug into finely dispersed particles, which are breathed into the respiratory passages. Some drugs are intended for local effects in the respiratory passages; others (e.g., anesthetic gases) are for systemic effects, especially in the brain.

Preparation types

Aerosols—Aerosols are liquids in very fine particles that can be inhaled into the lungs; they are sprayed under air pressure.

Gases—Gas is a basic form of matter (i.e., solid, liquid, and gas). A gas must be kept in a closed container; otherwise, the fast-moving molecules escape into the air. Examples are oxygen, nitrogen, carbon dioxide, and anesthetic gases.

Advantages	Disadvantages
▪ Quick and efficient local and systemic route through the lungs ▪ May be given to unconscious patient. ▪ Allows continuous dosing, and dosage can be easily modified.	▪ Requires special equipment. ▪ May irritate lung mucosa. ▪ Useful only for drugs that are gases at room temperature. ▪ May have unexpected systemic effect when only local effect is desired.

ROUTE: ALL PARENTERAL ROUTES Drug taken into the body other than through the digestive system.

Preparation types

Depends on route.

Advantages	Disadvantages
Patient may be conscious or unconscious.	▪ Requires sterile procedures. ▪ Poses risk for infection because skin is broken. ▪ Requires skill. ▪ May cause some pain. ▪ Produces anxiety. ▪ More expensive than oral administration

ROUTE: PARENTERAL: INTRAVENOUS The drug is injected directly into the vein, either by bolus or slow infusion.

Preparation types

Aqueous solutions—Drug(s) dissolved in water

Table 26-1 ➤ Advantages and Disadvantages of Routes of Administration—cont'd

Advantages	Disadvantages
■ Rapid effect because absorption is bypassed; therefore, good for emergency situations ■ Patient needs only one needlestick, even for multiple doses.	■ Poses risk of transient drug concentrations if drug is injected too rapidly. ■ Limited to highly soluble medications. ■ Poses risk for sepsis because pathogens may be introduced directly into the bloodstream. ■ The patient must have usable veins. ■ Cost of supplies and medications
ROUTE: PARENTERAL: INTRAMUSCULAR The drug is injected into the muscle mass.	
Preparation types	
Primarily aqueous solutions (see intravenous route), although some preparations (e.g., penicillin) are suspensions	
Advantages	**Disadvantages**
■ Rapid absorption, except for oily preparations or suspensions ■ Allows use of drugs that are not stable in solution. ■ Causes less pain (than do subcutaneous injections) from irritating drugs because they are deep in the muscle. ■ Allows administration of a larger volume than does subcutaneous administration. ■ Allows more rapid absorption than does subcutaneous or oral administration.	■ May cause irritation and local reactions. ■ Poses risk for tissue and nerve damage if site is improperly located. ■ Cannot be used where tissue is damaged (e.g., bruised) or peripheral circulation is decreased.
ROUTE: PARENTERAL: SUBCUTANEOUS The drug is injected into the subcutaneous tissue under the skin	
Preparation types	
Primarily solutions—Drugs dissolved in a liquid carrier	
Advantages	**Disadvantages**
■ Allows faster action than does oral administration. ■ Allows better absorption of lipid-soluble drugs than does intramuscular administration.	■ Only very small amounts can be given. ■ Absorption is relatively slow and often confined to the injected area.
ROUTE: PARENTERAL: INTRADERMAL The drug is injected under the skin, into the dermis. Most commonly used for diagnostic testing or screening or for injecting local anesthetic.	
ROUTE: PARENTERAL: OTHER	
Preparation types	
Intraspinal—Injection of drug into the spinal canal **Intrathecal**—Injection of drug into the subarachnoid space around the spinal cord **Epidural**—Injection of drug between the vertebral spines into the extradural space. Most commonly used for regional anesthesia and pain control.	
Advantages	**Disadvantages**
Most rapid absorption Highly effective	Some patients may be anxious about administration method. Spinal route can produce hypotension, nausea, urinary retention, or headache.

oral drug will not be absorbed effectively in the stomach and would likely be expelled during vomiting. If the patient has diarrhea, rapid motility of the gastrointestinal (GI) tract would decrease absorption. If your patient Cary Pearson (Meet Your Patient) has a prescription for an oral medication, would you question the route? Why or why not?

Solubility of the Drug

Solubility refers to the ability of a medication to be transformed into a liquid form that can be absorbed into the bloodstream. Typically, absorption occurs more rapidly with highly soluble drugs. *Oral medications* must be water soluble and at least partially lipid soluble to be absorbed in the GI tract. Liquids (e.g., suspensions or solutions) are absorbed faster than tablets or capsules because the liquids are already dissolved.

- *Water-soluble drugs.* Drugs must be water soluble in order to dissolve in the *aqueous* (watery) contents of the GI tract. These drugs are more rapidly absorbed from the GI tract and take effect faster.
- *Lipid-soluble drugs.* Lipid solubility depends partly on the drug's chemical structure and partly on the environment at the site of absorption. Lipid-soluble drugs can penetrate lipid-rich cell membranes and enter the cells; whereas, water-soluble drugs (e.g., penicillin) cannot. That is why a highly fat-soluble drug (e.g., nitrous oxide) can easily pass through the blood brain barrier and effect sedation. Lipid-soluble drugs are preferred when a much longer acting effect is desired, since they are more slowly released into the circulatory system.

Solubility Factors Some drugs have been designed for delayed breakdown. **Enteric-coated** drugs cannot be broken down by gastric acids because the coating prevents the medication from being diluted before it reaches the intestines. In this way, the coating delays the action of the drug, which decreases the irritating effects on the stomach. **Timed-release (sustained-release)** medications are formulated to dissolve slowly, releasing small amounts for absorption over several hours.

You should never crush or break enteric-coated and time-released medications; to do so would destroy their protective coatings.

Which of your patients (Meet Your Patient) is most likely to receive a water-soluble medication?

Effects of pH and Ionization

The **pH** (relative acidity or alkalinity) of the local environment also affects the absorption of a drug. The acid content of the stomach aids in transporting the medication across the mucous membranes, so *acidic* medications, such as aspirin, are more readily absorbed in the stomach than are *basic* (alkaline) medications, such as sodium bicarbonate, which are readily absorbed in the more alkaline small intestine. For best absorption, should Mr. Pearson's (Meet Your Patient) medications be acidic or alkaline preparations?

In solution, some of a drug's molecules are in **ionized** (electrically charged) form, and others in a **nonionized** (neutral or noncharged) form. The ionized molecules are lipid insoluble and thus cannot pass easily through the phospholipid layer of cell membranes. Drug molecules can be easily converted easily from one form to the other, depending primarily on the pH of the environment. For example, when aspirin is dissolved in the stomach acid, most of its molecules remain nonionized because of the low pH, so they easily pass through the membranes of the gastric mucosa and enter the bloodstream. If the person ingests an antacid before taking aspirin, the pH increases and the aspirin becomes more ionized, and will likely reduce the absorption and effects of the aspirin.

Blood Flow to the Area

Medications are absorbed rapidly in areas where blood flow to the tissue is greatest (e.g., oral mucous membranes). Areas with poor vascular supply (e.g., the skin, scarred areas) experience delayed absorption. Consider the following examples:

- Excessive exercise draws blood away from the stomach and intestines to the muscles. Which route would promote absorption for a person who has just exercised heavily: oral or intramuscular (IM)? Why?
- A person in shock has poor peripheral circulation. Which route would promote faster absorption: intramuscular or intravenous (IV)? Why?

For the first question, the IM route would be better for the person who has recently engaged in heavy activity. This is because medication injected deep into the muscle where there is a rich blood supply would be absorbed more readily, whereas medication administered orally must first dissolve and be absorbed in the GI tract. For the second question, the IV route would be more efficient for the person with poor circulation because drugs act more rapidly, even in healthy people, when they are injected directly into the bloodstream and do not have to be absorbed.

KnowledgeCheck 26-3

- Define *absorption.*
- How are drugs absorbed?
- What factors affect absorption?

How Are Drugs Distributed Throughout the Body?

Distribution is the transportation of a drug in body fluids (usually the bloodstream) to the various tissues and organs of the body. Because blood goes to all parts of the body, theoretically a drug can produce effects (intended or unintended) anywhere. The rate of distribution depends on adequate local blood flow in the **target area** (the site where the drug effects occur). It is also influenced by the permeability of capillaries to the drug's molecules as well as the protein-binding capacity of the drug. For a visual description,

Go to Student Resources, **Pharmacokinetic Animation: Medication Absorption, Distribution, Metabolism, and Excretion,** on Davis*Plus*.

Local Blood Flow The blood supply of the target site affects distribution of a drug. For example, it is difficult to deliver a systemic medication to the skin and toes, where the blood vessels are very small. Factors that cause vasodilation in an area (e.g., application of warmth to an injection site, fever, and rest) increase circulation to area tissues. Factors that cause vasoconstriction (e.g., shock and chilling of the body) decrease circulation to the target tissue.

Membrane Permeability Drug molecules must leave the blood and cross capillary membranes to reach their sites of action. The capillary networks in some organs consist of tightly packed endothelial cells that prevent some drugs from crossing them. For example, the blood–brain barrier allows distribution into the brain and cerebrospinal fluid of only those drugs that are (1) lipid soluble (e.g., anesthetics and barbiturates) and (2) not tightly bound to plasma proteins. This barrier can be bypassed by injecting medications intrathecally (via the spinal canal) into the cerebrospinal fluid.

Protein-Binding Capacity For a given amount of a drug, some molecules bind to plasma proteins, and the remainder will be "free." Only free (unbound) drug molecules can produce pharmacological effects because only free molecules can be metabolized or excreted. For example, nearly all acetaminophen (Tylenol) molecules are free in the bloodstream and are therefore pharmacologically active. By contrast, about 99% of the anticoagulant warfarin (Coumadin) is bound in the blood; its effects are produced by only the 1% of warfarin molecules that are free. A drug's tendency to bind to plasma proteins depends mostly on its chemical structure. Some medical conditions also affect protein binding. For example, malnourishment and liver disease reduce the amount of protein (serum albumin) available for binding.

KnowledgeCheck 26-4

- Define *distribution*.
- What factors affect distribution of drugs in the body?

How Are Drugs Metabolized in the Body?

Metabolism (or **biotransformation**) is the chemical inactivation of a drug through its conversion into a more water-soluble compound or into metabolites that can be excreted from the body. Once a medication reaches its site of action, it is metabolized (changed into the inactive form) in preparation for excretion.

Metabolism takes place mainly in the liver, but medications can be detoxified also in the kidneys, blood plasma, intestinal mucosa, and lungs. If liver function is impaired (e.g., due to liver disease or aging), the drug will be eliminated more slowly, and toxic levels may accumulate. Disease states also affect drug metabolism. For example, patients with diabetes do not metabolize sugar effectively, so they should not take elixirs, which are high in sugar content.

Oral medications are absorbed from the GI tract and circulate through the liver before they reach the systemic circulation. Many oral medications can be almost completely inactivated in passing through the liver. This inactivation is known as the **first-pass effect**. For this reason, oral medications are formulated with a higher concentration of the drug than are parenteral medications. Alternatively, some medications can be given parenterally, allowing the drug to be distributed directly to target sites. For example, nitroglycerin undergoes this first-pass effect when taken orally; therefore, it is given sublingually or intravenously so that it bypasses the stomach and liver and reaches therapeutic levels in the blood.

KnowledgeCheck 26-5

- Define drug *metabolism*.
- Where are drugs metabolized?
- What factors affect drug metabolism?

How Are Drugs Excreted From the Body?

A drug continues to act in the body until it is excreted. For **excretion** to occur, drug molecules must be removed from their sites of action and eliminated from the body. Drugs may be metabolized completely, partially, or not at all when they are excreted. The following are common organs of excretion.

Kidneys The kidneys are the primary site of excretion. Adequate fluid intake facilitates renal excretion. If your patient has decreased renal function (e.g., as indicated by an elevated creatinine level), you should monitor for medication toxicity. Obtain a prescription for adjusted dosing if signs of toxicity are present.

Liver and GI Tract Some drugs broken down by the liver are excreted into the GI tract and eliminated in the feces. Others (e.g., fat-soluble agents) are reabsorbed by the bloodstream, distributed to the target site, and returned to the liver. This is called **enterohepatic recirculation**. The kidneys later excrete these compounds. Anything that increases peristalsis (e.g., diarrhea, laxatives, enemas, chronic bowel disease) accelerates drug excretion via feces. Inactivity, poor diet, and decreased peristalsis delay excretion, increasing the effects of a drug.

Lungs Most drugs removed by the lungs are not metabolized first. Gases and volatile liquids (e.g., general anesthetics) administered by inhalation usually are removed through exhalation. Other volatile substances, such as ethyl alcohol and paraldehyde, are highly soluble in blood and are excreted in limited amounts by the lungs. Strenuous exercise and deep breathing increase pulmonary blood flow and thereby promote excretion. By contrast, decreased cardiac output (as in shock) and hypoventilation (as can happen when a patient is in pain) prolong the period of time for drug elimination.

Exocrine Glands Drug excretion through the **exocrine** (sweat and salivary) **glands** is limited. The elimination of metabolites in sweat is frequently responsible for such side effects as dermatitis. Drugs excreted in the saliva are usually swallowed and absorbed as other orally administered agents.

Think**Like a Nurse** 26-4

You are notified of a patient being transferred from the ICU to your unit. The patient is 79-year-old Hattie Banks, admitted 2 days ago to the ICU for digoxin toxicity.

- What theoretical knowledge do you have about the metabolism and excretion of digoxin (Lanoxin)?
- What assessments are important to make for Ms. Banks?

Concepts Relevant to Drug Effectiveness

In addition to the processes of absorption, distribution, metabolism, and excretion, you need to understand four other concepts related to a drug's effectiveness: (1) onset, peak, and duration of drug action; (2) therapeutic range; (3) bioavailability of the drug; and (4) concentration of the drug at target sites. As you read about them, try to relate these concepts to the key concepts of medication administration and medication safety.

Onset, Peak, and Duration of Action

Before reading on, think for a moment how the subconcepts *onset, peak,* and *duration* of action relate to the chapter key concept, *medication safety.* The **onset of action** is the time needed for drug concentration to reach a high enough blood level for its effects to appear. This is the **minimum effective concentration**. When the concentration of medication is highest in the blood, the medication has reached its **peak action**. The **duration of action** is that period of time in which the medication has a pharmacological effect (before it is metabolized and excreted) (Fig. 26-4). If the serum level of a medication falls below the minimum effective concentration, then the drug is not effective during that time. If the drug level exceeds the peak level, toxicity occurs.

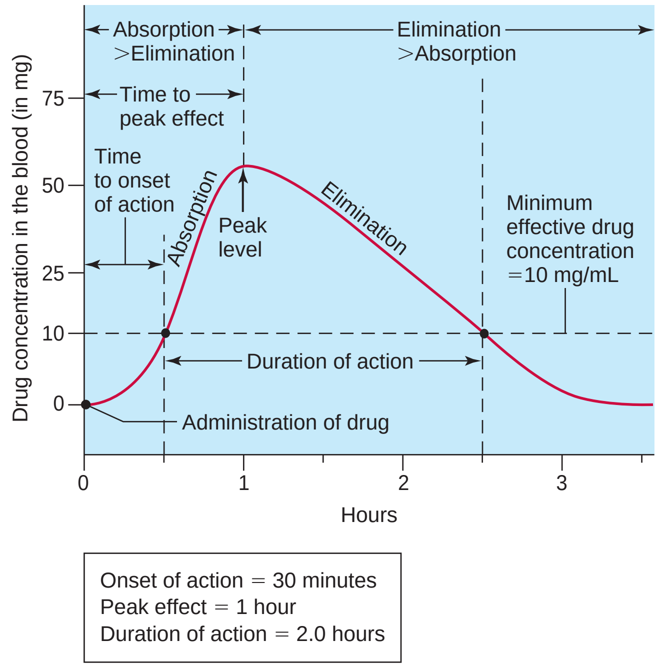

FIGURE 26-4 Once the drug is administered and absorption begins, blood levels begin to rise. When the *minimum effective concentration* is reached, drug effects begin (*onset of action*). *Maximum effect* occurs at peak blood level.

Think**Like a Nurse** 26-5

Refer to Table 26-1. James Bigler (Meet Your Patient) is having right arm pain and needs relief quickly.

- Would it be better to give him oral acetaminophen with codeine (Tylenol #3) or an IM injection of a similar-strength medication? Why?
- Do you have enough information to be completely sure your choice of route will bring the quickest onset of action? Explain.

Therapeutic Range

Even after absorption stops, distribution, metabolism, and excretion continue. When giving multidose medication (e.g., an antibiotic), the goal is to achieve a constant, therapeutic blood level. Because a fraction of the drug is constantly being excreted, repeated doses of the medication are given to achieve and maintain a constant therapeutic concentration.

Therapeutic range of a drug is a range of therapeutic concentrations. At onset of action, serum drug level is minimal.

Therapeutic level is the concentration of a drug in the blood serum that produces the desired effect without toxicity.

Peak level occurs when the drug is at its highest concentration (when the rate of absorption is equal to the rate of elimination). After that, metabolic and excretory processes begin to remove the drug from the tissues and blood.

Trough level occurs when the drug is at its lowest concentration, right before the next dose is due.

A test called a *peak and trough level* helps to ensure the safety and effectiveness of certain drugs. The peak level must be measured when absorption is complete. This, of course, depends on all the factors that affect absorption. The trough level is typically measured about 30 minutes before the next dose of the drug is due. The drug's half-life and the time between doses affect the trough level. You will sometimes need to monitor serum drug levels so the primary care provider can adjust the dose and timing of a medication as needed. For a graphic illustration of peak, trough, and therapeutic levels,

Go to Chapter 26, **Tables, Boxes, Figures: ESG Figure 26-1, Peak and Trough,** on Davis*Plus*.

Biological Half-Life

A medication's **biological half-life** is the amount of time it takes for half of the drug to be eliminated. For example, tramadol (Ultram), a narcotic-like pain reliever, has a half-life of approximately 6 hours. This means if you take a 50-mg dose at 0800, by 1400 half of that dose (25 mg) will still be left in your body. In 12 hours, one-fourth of the initial dose (12.5 mg) will be left in your body. Liver and kidney disease, aging, absence of food, and slowed metabolic rate prolong half-life because of their effects on metabolism and excretion. Drug composition and distribution also affect half-life.

ThinkLike a Nurse 26-6

Rebecca Jones (Meet Your Patients) received tramadol (Ultram) 50 mg for pain at 0800. The prescription allows the patient to have the drug every 6 hours. At 1400, you give her another 50 mg. Ultram is metabolized in the liver and excreted mainly in the urine.

- When this medication reaches onset of action, about how much tramadol does Ms. Jones now have in her body?
- If the normal half-life of tramadol is 6 hours, you would expect that Ms. Jones would still have about 25 mg of her first dose left in her body at the time of the second dose. Given her age, though, do you think she probably has more or less than 25 mg left at 6 hours? Why?

Concentration of Active Drug at Target Sites

The effectiveness of a medication depends ultimately on its concentration at the intended site. For example, a medication such as nitrofurantoin (Macrodantin) may be prescribed to treat a urinary tract infection. This drug is used because it is highly soluble in urine, and therefore tends to accumulate and concentrate in the bladder and kidneys, where the infection exists.

What Factors Affect Pharmacokinetics?

A drug's pharmacokinetics and therefore its effectiveness and safety are affected by the following factors:

- **Age.** Infants and young children need smaller doses because of their smaller body mass and immature body systems.

Older adults may have declining liver and kidney function and are therefore at higher risk for drug toxicity.

Table 26-2 summarizes life span variations in pharmacokinetics.

- **Body Mass (Weight).** The final concentration of a drug in the body depends on the patient's body mass. The average adult dose is based on the drug quantity that will produce a particular effect in 50% of people 18 to 65 years of age and weighing 150 lb. Obviously, a person who is much larger or smaller than this "average" requires an adjusted dose.
- **Sex.** Men and women absorb drugs differently because women usually have lower muscle mass, a different hormone profile, and different fat and water distribution.
- **Pregnancy.** Most drugs are contraindicated during pregnancy because of their possible adverse effects on the embryo or fetus. Drugs known to cause developmental defects are called **teratogenic** drugs (e.g., alcohol; the anticonvulsant phenytoin [Dilantin]).
- **Environment.** Heat and cold affect peripheral circulation. A noisy environment may interfere with a person's response to anti-anxiety, sedative, or pain medications.
- **Route of Administration.** The route of administration influences the amount of a drug absorbed into the circulatory system and the distribution to the sites of action.
- **Timing of Administration.** The presence or absence of food in the GI tract affects an oral drug's pharmacokinetics. Biorhythms and cycles (e.g., drug-metabolizing enzyme rhythms, blood pressure cycles) also influence drug action.
- **Fluids.** Insufficient fluid intake affects the absorption of solid dosage forms.
- **Pathological States.** Intense pain decreases the effect of opioids; diseases causing circulatory, hepatic, or renal dysfunction interfere with pharmacokinetic processes.
- **Genetic Factors.** Abnormal susceptibility to certain chemicals is genetically determined. Enzyme deficiencies and altered metabolism change a patient's responses to a drug. For example, African Americans usually respond better to diuretics for blood pressure control than do other racial groups; and people of Asian descent metabolize some opioids at a slower rate. Use your critical thinking now. What important nursing intervention should you perform after you administer an opiate to an Asian patient?[1]
- **Psychological Factors.** Some patients have the same response to a placebo—a pharmacologically inactive substance—as they do to the active drug. If a person has faith that a drug will help him, a *placebo effect* similar to the effect of an active drug may occur. Emotional states, such as anxiety, may cause resistance

[1]How did you answer the question? If you said that you would need to observe closely for unexpected side effects, good thinking!

Table 26-2 ➤ Drug Therapy Across the Life Span

PHARMACOKINETIC PROCESS	CHILDREN	OLDER ADULTS
Absorption	■ Exaggerated in infants as a result of lack of gastric acidity and shorter intestines ■ More complete topical absorption results from a larger body surface and thinner epidermis. ■ Enteral route is unpredictable. ■ Decreased muscle tone makes absorption of parenteral drugs unpredictable. ■ Gastric pH is higher, so that medications absorbed in acid environments are absorbed much more slowly.	■ Delayed but more complete ■ Gastric pH is less acidic because of decreased acid production in the stomach. ■ Decreased gastric pH delays absorption of medications absorbed in acid environments. ■ Because of decreased intestinal motility, drugs remain in the system longer, allowing for more absorption.
Distribution	■ Protein binding may be a problem. ■ Greater chance of toxicity because of low albumin levels. ■ Water content in the child's body is higher than in adults, so water-soluble drugs are less concentrated in the child and fat-soluble drugs are more highly concentrated.	■ Low albumin level could create a problem with plasma protein binding. ■ Increased risk of toxicity owing to multiorgan slowdown. ■ Altered because of less lean mass ■ Less body water, greater body fat ■ Dehydration, poor nutrition, and electrolyte imbalances decrease absorption.
Metabolism	■ Metabolism may be altered because of immature liver. ■ Best to base dosage on body weight to avoid toxicity.	■ Presence of diseases may decrease metabolism of the drug. ■ Changes from age, higher blood concentration, and less excretion cause greater chances of toxicity. ■ Some drugs interfere with the liver's ability to metabolize another drug.
Excretion	■ Excretion is delayed as a result of immature kidneys. ■ Repeat dosing may cause problems.	■ Decreased glomerular filtration rate inhibits excretion from the kidneys. ■ Diminished renal function inhibits excretion, thereby increasing the risk of toxicity.

to tranquilizing drugs. Hostility toward or mistrust of medicine or health personnel can also interfere with a drug's effectiveness.

WHAT IS PHARMACODYNAMICS?

Pharmacodynamics, another subconcept of pharmacology, is the study of *how* medications achieve their effects at various sites in the body—how specific drug molecules interact with target cells and how biological responses occur. You will use knowledge of pharmacodynamics concepts to help you administer medications safely and to evaluate patient outcomes.

What Are Primary Effects?

Primary or **therapeutic effects** of medications are effects that are predicted, intended, and desired. The primary effects, in short, are the reason the drug was prescribed. All other consequences are **secondary effects** (unintended, nontherapeutic). Both primary and secondary effects are dose related, so increasing the dose increases the effects. Medications are given for the following effects:

- **Palliative effects** relieve the signs and symptoms of a disease but have no effect on the disease itself. For example, morphine sulfate may be given to a patient with cancer to manage pain, but it does not destroy cancer cells. The goal of palliative therapy is to make the patient as comfortable as possible when treatment options have been exhausted.
- **Supportive effects** support the integrity of body functions until other medications or treatments can become effective. For a patient with a bacterial infection, you may give acetaminophen (Tylenol) to control fever until blood levels of the prescribed antibiotic are effective in combating the infection causing the fever.
- **Substitutive effects** replace either body fluids or a chemical required by the body for improved functioning. You may, for example, administer insulin to

a diabetic patient to replace the insulin no longer produced by the pancreas.

- **Chemotherapeutic effects** destroy disease-producing microorganisms or body cells. Two examples are (1) antibiotics, used to treat infections by killing or limiting the reproduction of certain bacteria and (2) antineoplastic drugs, used to treat cancer by limiting cell reproduction and destroying malignant cells.
- **Restorative effects** return the body to or maintain the body at optimal levels of health. For example, vitamin and mineral supplements are administered to many patients recovering from surgery.

KnowledgeCheck 26-6

- Name and define the four pharmacokinetic processes.
- How does absorption differ in children and older adults?
- What factors affect excretion?
- You are to administer the following drugs to Cyndi Early (Meet Your Patients): (1) insulin for her diabetes, administered subcutaneously, and (2) morphine to relieve her pain, administered intravenously. For which primary effect is each of these drugs being given?

What Are Secondary Effects?

All medications can cause secondary effects (e.g., side effects, adverse reactions, allergic reactions), which can either be harmless or cause injury and which can sometimes be predicted.

Side Effects

Side effects are unintended, often predictable, physiological effects of the medication to which patients usually adapt. They occur at the usual prescribed dose and may be immediate (e.g., dizziness) or delayed (e.g., constipation). For hospitalized patients, you will most often see side effects caused by analgesics, antibiotics, antipsychotics, and sedatives. The most common side effects are nausea, vomiting, diarrhea, dizziness, drowsiness, dry mouth, abdominal distention or distress, and constipation.

If side effects are significant, the medication may be discontinued. For example, digoxin (Lanoxin), which is given to regulate and strengthen the heartbeat, can cause cardiac irregularities, a side effect that can be life threatening. Persistent or undesired side effects may require symptom management with laxatives, antidiarrheals, and antiemetics. For example, levofloxacin (Levaquin), an antibiotic, may cause diarrhea, which is treated with antidiarrheal medication (e.g., loperamide [Imodium]).

Key Point: ***As a primary nurse, your role includes teaching the patient what side effects to anticipate and how to manage them.***

Adverse Reactions

Adverse reactions are harmful, unintended, usually unpredicted reactions to a drug administered at the normal dosage. They are more severe than side effects and often require discontinuation of the drug.

- *Dose-related* adverse reactions result from the known pharmacological effects of the medication. For example, a diabetic patient treated with insulin may develop a very low blood sugar if too much insulin is administered.
- *Patient sensitivity* adverse reactions occur because the patient is unusually susceptible to the effects of the drug. Box 26-1 lists patients at high risk for adverse reactions.

The FDA defines **severe adverse reactions** as those that (1) are life threatening; (2) require intervention to prevent permanent impairment or death; or (3) lead to congenital anomaly, disability, hospitalization, or death. Health professionals must document serious adverse reactions according to agency policy and report them to the FDA MedWatch program. To make a report, contact the FDA by calling 1-800-332-1088, or

Go to the **FDA Medwatch** Web site at http://www.fda.gov/medwatch/

You can also contact the Institute for Safe Medication Practices (ISMP) to report errors, close calls, or hazardous conditions. ISMP guarantees the confidentiality and security of the information received. For information on where and how to report errors,

Chapter 26, Chapter Resources, **Resources for Caregivers and Health Professionals,** on Davis*Plus*.

BOX 26-1 ■ Risk Factors for Adverse Drug Reactions

Behavioral and Situational Factors

- History of allergies or previous adverse drug reactions
- Receiving treatment from two or more providers at the same time
- Taking multiple prescription drugs in addition to over-the-counter preparations and herbal remedies and supplements. This is also called polypharmacy.
- Taking a drug inconsistently
- Long-term use of a drug (may promote accumulation, leading to toxicity)

Physical Factors

- Concurrent illnesses (e.g., diabetes and renal failure)
- A change in the ability to absorb, metabolize, or excrete the drug (e.g., impaired hepatic or renal function)
- Confusion/cognitive impairment
- Very old or very young age
- Obesity or extreme thinness
- Dehydration or rapid change in hydration status

Toxic Reactions

Toxic reactions are dangerous, damaging effects to an organ or tissue. They are more severe than adverse reactions, sometimes even causing permanent damage or death. It may help to think of toxicity as poisoning. Antidotes are available for some medications; for example, naloxone (Narcan) is given for opiate toxicity. Toxicity may be caused by any of the following:

- *Overdosing* (administrating a dose that exceeds the prescribed amount). Examples are respiratory depression from excessive morphine and hypoglycemia from too much insulin.
- *Accumulation* of the drug in the tissues (related to long-term use or incomplete metabolism/excretion)
- *Abnormal sensitivity* or allergic response to the drug

Toxic reactions are usually localized, reversible, and immediate. However, they can be:

- Localized to a particular tissue or organ, or they can also affect several organ systems.
- Reversible (e.g., tinnitus caused by aspirin) or permanent (e.g., hearing loss caused by aminoglycoside antibiotics).
- Evident soon after administration; although, some toxic reactions take months or even years to develop (e.g., drug-induced cancers).

Think**Like a Nurse** 26-7

- You have just looked up the antihypertensive drug lisinopril (Zestril) and found the following side effects:
  neutropenia, dizziness, headache, fatigue, depression, somnolence, paresthesia, hypotension, orthostasis, chest pain, nasal congestion, diarrhea, nausea, dyspepsia, impotence, rash, cough, muscle cramps, angioedema, lethargy, hypokalemia, decreased libido
  What strategy could you use to help you remember all the above side effects?
- You have checked the MAR for Margaret Marks (Meet Your Patients) and prepared her next dose of antibiotic for intravenous administration. The MAR also indicates that she is receiving morphine for pain and that her last dose was given 1 hour ago. When you enter the room, you find her apparently sleeping. You are not able to awaken her to verify her identity. What do you suspect is happening, and how should you respond? (If you need information about antibiotics and morphine, look it up in an appropriate reference.)

Allergic Reactions

In an **allergic reaction,** the immune system identifies a medication as a foreign substance that should be neutralized or destroyed. The patient experiences no problems with the first dose of the medication, but it acts as an antigen, activating the formation of antibodies against the drug. When the drug is again administered, the antigen–antibody binding complex prompts an allergic reaction.

Allergic reactions range from minor to serious; however, even a small amount of a medication can cause a severe reaction. Urticaria (hives), pruritus (itching), edema of soft tissue and mucosa, and rhinitis (inflammation of the nasal mucosa) usually occur within minutes to 2 weeks after exposure and are considered mild. Such reactions often disappear after the medication is discontinued and the blood level of the drug falls. Medications most frequently implicated in allergic reactions are antibiotics, biological agents, and diagnostic agents. For a list of specific drugs you can print and use,

Go to Chapter 26, **Tables, Boxes, Figures: ESG Table 26-4, Medications Frequently Triggering Allergic Reactions,** on Davis*Plus*.

An **anaphylactic reaction** is a life-threatening allergic reaction that occurs immediately after administration. Anaphylaxis produces sudden constriction of bronchioles, edema of the larynx and pharynx, severe shortness of breath, wheezing, and severe hypotension (low blood pressure). Immediate treatment includes discontinuing the medication and giving epinephrine, IV fluids, steroids, and antihistamines. Respiratory support (e.g., oxygen, intubation, ventilation) may also be required.

A patient who is allergic to one drug may also be allergic to other medications in the same class. For example, many patients who are allergic to penicillin are also allergic to cephalexin (Keflex), a synthetic penicillin.

Always explore the patient's allergy history and the patient's reaction to the medication. Remember to document allergies in the patient's chart, care plan, and MAR.

People with severe allergic reactions should wear a Medic Alert bracelet (Fig. 26-5) that identifies the person and the allergen, and carry epinephrine for emergency injection.

Think**Like a Nurse** 26-8

You are administering medications to your assigned patients (Meet Your Patients). What should you do in each of the following situations? Which patient should you attend to first? Explain your thinking.

- Ms. Jones has ibuprofen (Motrin) prescribed for back pain. She tells you she cannot take this medication because it makes her feel nauseated.
- Mr. Bigler had an open reduction internal fixation of his arm performed yesterday and is receiving an antibiotic, cefazolin (Ancef) 500 mg IV every 8 hours. He has already received three doses of this medication, and you initiated his 0800 dose about 10 minutes ago. He tells you that he thinks his throat is closing shut.

Idiosyncratic Reactions

An **idiosyncratic** reaction is an unexpected, abnormal, or peculiar response to a medication. Idiosyncratic reactions may take the form of extreme sensitivity to a medication, lack of response, or a paradoxical (opposite of

FIGURE 26-5 People with severe allergies to a medication should wear a Medic Alert bracelet.

expected) response, such as agitation in response to a sedative.

Cumulative Effect

A **cumulative effect** is the increased response to repeated doses of a drug that occurs when the rate of administration is greater than the rate of metabolism and excretion. This happens when (1) the body cannot metabolize a dose of the medication before the next dose is given, (2) excretion is slowed but absorption is normal or rapid, or (3) absorption is slowed. Unless the dose is changed, the medication accumulates in the system until a toxic level is reached. Opiates and barbiturates are known for their cumulative effects.

KnowledgeCheck 26-7

- Differentiate between primary and secondary effects of medications.
- List one adverse reaction for each of the following systems: blood, gastrointestinal, neurological, cardiovascular, hepatic, renal.
- What are some of the symptoms you will see in an anaphylactic reaction?
- What type of patient is most likely to experience an allergic reaction?

How Do Medications Interact?

When one drug alters or modifies the action of another, a **drug interaction** occurs. In an **antagonistic drug relationship**, one drug interferes with the actions of another and decreases the resultant drug effect—that is, the combined effect is less than that of one drug given alone. In a **synergistic drug relationship**, there is an additive effect; that is, the effect of both drugs together is greater than the individual effects. **Drug incompatibilities** occur when multiple drugs are mixed together, causing a chemical deterioration of one or both drugs. The result is an incompatible solution that should not be administered.

You can usually recognize an incompatibility when the mixed solution takes on a changed appearance. However, you should always consult medication resources and compatibility charts *before* mixing medications. Then, after mixing, double-check the medication for changes in appearance.

As a nurse, you must know about drug interactions and monitor your patients for them. For a list of common drug-drug and drug-food interactions,

Go to Chapter 26, **Tables, Boxes, Figures: ESG Table 26-5, Drug-Drug and Food-Drug Interactions,** on Davis*Plus*.

The more drugs a patient takes, the higher will be the risk of a drug interaction. Other variables influence drug interactions: intestinal absorption, competition for protein binding, drug metabolism, renal excretion, and alteration of electrolyte imbalance. Drugs may also interact with certain foods. For example,

High-fat foods and those low in fiber will delay stomach emptying and medication absorption by up to 2 hours.

Acidic citrus fruits and juices enhance absorption of iron. Some citrus fruits, such as grapefruit, interact with medication in an antagonistic manner.

Carbonated soft drinks can cause medications to dissolve faster, be neutralized, or experience a change in absorption rate in the stomach.

Dairy products taken with an antibiotic such as tetracycline decrease the absorption of the drug in the stomach.

Foods containing tyramine (e.g., aged, dried, or fermented products), when consumed while taking monoamine oxidase (MAO) inhibitors, may produce a hypertensive crisis.

To print and use a list of several medications that should be taken with food and those that should be taken on an empty stomach,

Go to Chapter 26, **Tables, Boxes, Figures: ESG Box 26-1,** on Davis*Plus*.

KnowledgeCheck 26-8

- What type of interaction occurs when one drug interferes with the action of another?
- What interactions occur when one drug has an additive effect on another drug?
- What is drug incompatibility?

What Should I Know About Drug Abuse or Misuse?

You should be able to differentiate between the concepts that describe nontherapeutic use or effects of drugs.

- **Tolerance** is a decreasing response to repeated doses of a medication. The person then requires more of the drug to achieve the desired effect.

- **Dependence** is a person's reliance on, or need for the drug. Dependence leads to compulsive patterns of drug use wherein the user's lifestyle centers on procuring and taking the drug.
- Drug misuse is the nonspecific, indiscriminate, or improper use of drugs, including alcohol, over-the-counter (OTC), and prescription drugs. In performing self-care, people frequently misuse laxatives, aspirin, acetaminophen, ibuprofen, cough and cold remedies, and sleep-inducing drugs.

Older adults are especially prone to misuse of laxatives in the self-treatment of constipation. Continued use of laxatives can led to dependence and other medical problems.

- **Drug abuse** is the inappropriate intake of a substance by amount, type, or situation, continuously or periodically. For example, consuming alcohol at work is considered abuse, but having a glass of wine with dinner is not. Drug abuse may or may not lead to drug dependence.
- **Illicit drugs**, also known as street drugs, are drugs sold illegally. Many are prescription drugs (e.g., hydrocodone [OxyContin or Vicodin]) sought for their mood-altering effects. Prescription drugs can be abused when taken for purposes other than medically intended.

HOW DO I MEASURE AND CALCULATE DOSAGE?

Medications are not always available in the exact dosage the patient needs. Therefore, you must be proficient in calculating drug dosages to be sure your patients receive the correct amount of medication.

Medication Measurement Systems

Medications are usually prescribed and measured using the metric system; however, a few are still dispensed using the apothecary and household systems. You will sometimes need to make conversions from one measurement system to another. To learn about how to convert medications doses within one system and between systems,

Go to Chapter 26, **Measuring and Calculating Dosage,** in Volume 2.

Metric System The metric system is the preferred system because it promotes accuracy by allowing for calculation of small drug dosages. A disadvantage of this system in the United States is that many people outside the healthcare system are not familiar with it.

Apothecary System The British apothecary system of measurement has been used in the United States since colonial times. Only a few medications (e.g., aspirin) are measured using this system because it is less convenient and less precise. Apothecary measurements are usually written using Roman numerals, but you may also see them in Arabic numerals. For example, *5 grains* might be written as *grains V* or *gr V.*

To avoid a dosage error, write out the intended unit of measurement (grains) so gr (grains) is not mistaken for gm (grams). (The Joint Commission, 2012)

Household System Because most people are familiar with the household system, it is easier to teach a patient about home medications using this system. However, nurses do not often use it because dosages measured in this system are less precise (e.g., teaspoons, ounces, cups) and can lead to medication dosing error.

Special Measurements: Units and Milliequivalents

Units Insulin, a drug used by diabetics to help control blood sugar, is measured in **units**, with 100 international units (U100) being the standard strength preparation. In this strength, 1 mL of the fluid medication contains 100 units of insulin. The following is a medication prescription using units: "NPH insulin 14 units subcutaneously every morning." Heparin, an anticoagulant, and penicillin are also prescribed in units.

Not all units are the same. For example, 1 mL of heparin does *not* contain 100 units of heparin. You must always read the container label to know the number of units per milliliter.

Milliequivalents (mEq) indicate the strength of the ion concentration in a drug. A milliequivalent is the number of grams of a solid contained in 1 mL of a solution. Electrolytes, such as potassium chloride (KCl), are measured in mEq. The following is a prescription using mEq: "D_5W 1000 mL with KCl 40 mEq every 8 hours."

Key Point: ***Note that units and mEq cannot be directly converted to the apothecary, metric, or household system.***

Calculating Dosages

You should be able to calculate accurately using several different methods and formulas. Inaccurate calculations result in incorrect dosages and could harm the patient. For expanded instructions on calculating dosages for adults and children,

Go to Chapter 26, **Measuring and Calculating Dosage,** in Volume 2.

Several practice problems are available on Davis*Plus*. To use them,

Go to Chapter Resources, Chapter 26, **Dosage Calculation Problems,** on Davis*Plus*.

WHAT MUST I KNOW ABOUT MEDICATION PRESCRIPTIONS?

Before administering any medication you must obtain a medication prescription from the care provider and verify that it is complete, correct, and legible.

- *For inpatients*, prescriptions for medications are either entered into an electronic health record for automated dispensing or printed in the medical orders section of the paper chart. This was traditionally referred to as an "order."
- *For outpatients* and for medications that will be filled by the patient (instead of the agency pharmacy). See Figure 26-6 for an example of a prescription that might be written and given to the patient or family. This is what was traditionally called a "prescription."

The term *prescription* is now used to refer to both the traditional inpatient *order* and the outpatient *prescription*. A written or printed outpatient medication prescription should contain the following essential elements:

- Patient's full name (some agencies and some states require the address of the patient)
- Name, address, and telephone number of the prescriber, including relevant credentials and legal registration number, such as the National Provider Identification (NPI) in the United States. Providers who are prescribing controlled substances must register with the federal Drug Enforcement Agency (DEA). The prescriber's DEA number must be included on the prescription. The NPI number is needed for Medicaid, Medicare, and durable medical equipment prescriptions.
- Date and time prescription was written
- Name of medication
- Dosage (including amount, frequency, and number of doses)
- Route of administration
- Signature of prescriber

FIGURE 26-6 Example of a prescription.

Verifying Prescriptions

To verify a medication prescription, ask yourself the following questions:

- Is the prescription legible enough for me to read with certainty?
- Is the prescribed dose within the normally prescribed dosage range and comparable to any previously prescribed dose?
- Is the prescribed route appropriate?
- Is the drug appropriate for the patient? (For example, you would question an antihypertensive drug prescribed for a patient with hypotension.)
- Is the patient allergic to the prescribed medication?
- Are the administration times appropriate (for example, an antibiotic prescribed for every 6 hours, when the drug formulary indicates it should be taken every 24 hours)?

For outpatient prescriptions (to be obtained by the patient), ask yourself the following questions:

- What is the address and National Provider Identification (NPI) of the person prescribing?
- Is a DEA number included on prescriptions for controlled substances?
- How many doses are there before the prescription needs to be refilled?
- How many refills are prescribed?

KnowledgeCheck 26-9

- What are the essential parts of a medication prescription?
- How does an inpatient prescription (order) differ from an outpatient prescription?

What Abbreviations Are Used in Medication Prescriptions?

For a list of medication-related abbreviations you may see used when prescribing and documenting medications,

Go to Chapter 26, **Tables, Common Medication-Related Abbreviations,** in Volume 2.

You should write out drug names in full. Abbreviations can be easily confused and many are not universally understood. However, you will see and use some abbreviations when administering and documenting medications (e.g., mL, mEq). Always do so carefully because some may be similar and confusing. Consult The

Joint Commission's official Do Not Use list (Table 18-1) and know the acceptable abbreviations used in your facility. Also,

Go to Chapter 26, **Tables, Institute for Safe Medication Practices (ISMP): List of Error-Prone Abbreviations, Symbols, and Dose Designations,** in Volume 2.

Types of Medication Prescriptions

Common types of medication prescriptions are based on the duration, frequency, and/or urgency of the prescription.

- **Standard written prescriptions** apply without a renewal date until the prescriber writes a prescription to alter or discontinue the medication or indicates on the original prescription a specific stop date. For example, "Give furosemide (Lasix) 20 mg IV-Push twice a day for 5 days." After 5 days, the prescription is discontinued, unless the provider renews it.
- **Automatic stop dates** are protocols that hospitals use for discontinuing medications after a certain length of time. Most narcotic prescriptions are in effect only for 7 days. If the medication is needed after the automatic stop date, the care provider must write another prescription.
- **STAT** prescription means that a single dose of medication is to be given immediately and only once. The word *STAT* or *now* should appear in the prescription, for example, "Give furosemide (Lasix) 20 mg IV push STAT," or "Give lorazepam (Activan) 1 mg IV push now."
- **Single** prescription, or *one-time prescription*, indicates that the medication is to be given only once at a specified time. Preoperative medications, given before surgery or diagnostic procedures or treatments, are an example of a single prescription. For example:

  Versed 25 mg intramuscularly on call for when surgical staff requests premedication to be administered

  Tetanus toxoid 0.5 mL intramuscularly before discharge
- **Standing orders.** When a unit has a standard population of patients—for example, coronary care patients or knee replacement patients—the primary care provider may develop a set of *standing orders*. These are officially accepted sets of prescriptions for this population of patient to be applied routinely by nurses for the care of patients. They establish guidelines for treating a particular disease or set of symptoms. For example:

  Coronary care or intensive care units (CCUs or ICUs) may have standing orders for the administration of nitroglycerin for chest pain (e.g., "Give nitroglycerin 0.4 mg sublingually q3–5 min for chest pain, to a maximum of 3 doses in 15 min").

  Many postoperative patients receive a prescribed number of injectable analgesic medications for pain relief. So, for all the postoperative patients on a unit, standing orders would include, "ketorolac (Toradol) 30 mg IV push q12hr for 2 days."
- **prn prescription.** The care provider may prescribe a medication to be given whenever the patient requires (prn), within the established parameters. A prn prescription requires the nurse to determine, in collaboration with the patient, when the medication is to be given. The prescription specifies (1) the condition for which the medication is to be given and (2) the minimum time intervals between doses.

Key Point: ***The medication cannot be given more frequently than prescribed, even if symptoms persist.***

Pain medications, antiemetics (antinausea medications), and laxatives are usually given prn. For example:

Morphine 10 mg intramuscularly q3–4hr prn incisional pain.

Acetaminophen 650 mg PO q4hr prn for temp > 101°F.

How Are Medication Prescriptions Communicated?

Providers communicate medication prescriptions either in writing or verbally. The nursing implications are slightly different for each. The provider usually must cosign verbal and telephone prescriptions within 24 hours.

Written Prescriptions You will find **written prescriptions** either handwritten on a prescription form or preprinted standard medication orders and protocols. Some agencies accept medication orders or prescriptions transmitted electronically or via facsimile from the prescriber to the nurse, with the original copy provided later. To reduce the risk of errors with faxes and electronic transmission, always ensure that the content is legible.

Verbal Prescription A prescriber may sometimes give a **verbal prescription**, which is an oral order spoken to the nurse. When you receive a verbal prescription, you, as the RN, will write the prescription and sign it with the provider's name followed by your name and credentials. Medication names that sound the same can be confusing and lead to administering the wrong drug (Box 26-2). Repeat the prescription to the provider and spell the medication name to ensure accuracy—many drug names sound the same. Avoid taking verbal prescriptions, and use them only in urgent situations because they increase the risk for miscommunication and errors.

Telephone Prescription Prescribers may also give medication prescriptions via telephone. Usually this will be in response to a call you have placed to report a change in the patient's condition or the results of laboratory or other tests.

What Should I Do If I Think a Prescription Is Incorrect?

Key Point: ***As a nurse, you are legally responsible for medications you administer.***

BOX 26-2 ■ Medications With Similar-Sounding Names

Alprazolam—lorazepam	NovoLog—Humalog
Baclofen—Bactroban	NovoLog—Novalin R
Cefzil, Keflin—Keflex	Ophthalgan—Auralgan
Celebrex—Celexa, Cerebyx	Percocet—Percodan
Cytoxan—Ciloxan	Phenergan—Phenaphen
Demerol—dicumarol	Procardia—Procardia XL
Digoxin—digitoxin	Quinine—quinidine
Glyburide—glipizide	Ranitidine—amantadine
Humalog—Humulin R	Serzone—Seroquel
Keflex—Kantrex	Taxotere—Taxol
Lamictal—Lamisil	Zantac—Xanax
Lodine—iodine	Zantac—Zyrtec
Morphine—meperidine	Zostrix—Zestril

If you believe a prescription is incorrect, do the following:

- Ask another nurse or physician to check the prescription.
- Look up the medication in a reliable resource (e.g., drug formulary) to verify spelling, usage, dosages, and routes.
- Contact the prescriber for clarifications, concerns, or questions.
- Do not assume you are correctly interpreting the prescription if you have any question at all.

Use your knowledge, common sense, and intuition when administering medications. To avoid errors, you must know and understand the procedures at your facility, be familiar with the medications you give, and always check the prescription. Each agency will have a policy specifying the procedure for checking medication prescriptions. For example, a unit secretary may copy the original prescription onto a MAR, but the nurse must check to be sure the transcription is correct.

Most medication errors occur during the prescribing process; however, 50% are detected before these errors reach the patient (Mckay, 2012). Thus, this double check system is imperative.

ThinkLike a Nurse 26-9

Find the errors in these medication prescriptions. Use a drug formulary or nursing drug handbook to check dosages, spelling, and so on.

- Ancef 10 g q6hr IV
- Capatril 25 mg orally twice a day
- Digoxin 0.125 mg daily
- Lasix 400 mg by mouth
- NTG gr 1/150 prn chest pain
- Tylenol orally prn fever

MEDICATION ERRORS

A **medication error** is any preventable event that may cause or lead to inappropriate medication use or harm to a patient. Medication errors occur with surprising frequency. They are among the most common adverse events that occur in hospitalized patients. The National Coordinating Council for Medication Error Reporting and Prevention (2012) estimates that 98,000 hospitalized patients die annually from medication errors.

The most common medication errors made by nurses are related to confusion caused by similar drug names, lack of knowledge of the drug (e.g., incorrect dosages, incorrect mixing), and lack of information about the patient (e.g., allergies, lab results, medical condition). Box 26-3 describes several causes of medication errors by nurses. For a list of drugs that can have devastating consequences when erroneously administered,

Chapter Resources, Chapter 26, ISMP Web site, in **Resources for Caregivers and Health Professionals,** on Davis*Plus.*

How Can I Avoid Errors?

To ensure patient safety, begin by following the "three checks" and the six-plus "rights" found in the section Ensuring Safe Medication Administration for Inpatients, later in this chapter. You also must be familiar with and follow the variety of system-wide measures designed to prevent medication errors in your healthcare agency. For example, The Joint Commission recommends standardizing protocols for prescribing, administering, and documenting medication. Errors can be reduced in the home setting if the patient is prescribed the same dose at home as in the hospital.

Critical thinking may be your best way to avoid errors and improve patient care and safety. You need to learn from your mistakes and the mistakes of others, and you also need to think defensively. Ask "are we," "what if," and "why" questions: "Are we following standardized protocols for prescribing, administering, and documenting medication? What will happen if I don't do something or if I do something wrong? What assessments are required before and after I give this medication? Why am I hanging this IV or giving this medication?"

Error-Prevention Technology

Computers can decrease errors by improving access to information and communication among health professionals. Some healthcare agencies provide nurses with laptops and handheld mobile devices, putting at their fingertips detailed information about diseases, similar-sounding drugs, interactions, and side effects. A variety of error-prevention technologies can reduce the likelihood of medication errors.

BOX 26-3 ■ Why Do Medication Errors Occur?

The following are several factors associated with medication errors:

Lack of Knowledge or Information

- Lack of knowledge of the drug (e.g., incorrect dosages, incorrect mixing, overly rapid infusion, drug interaction, adverse effects) is the most common factor contributing to medication errors.
- Lack of information about the patient (e.g., allergies, other medications, lab results, medical condition for which the medication is contraindicated). This is the second most frequent cause of errors.
- A drug is given by the wrong route.

Faulty Communication

- The written prescription is unclear, illegible, or transcribed incorrectly, resulting in administering the wrong drug or dosage (e.g., confusion between drugs with similar names).
- The telephone prescription is taken incorrectly.
- Protocol is not understood or is violated.
- A drug prescription is written on the wrong patient's chart.
- The wrong dosage is prescribed (e.g., by misplacing a zero or decimal point).
- Abbreviations are misunderstood.
- Poor, or no, documentation can result in error. For example, a nurse administers a medication yet fails to record it immediately afterward. A second nurse checking the patient's chart thinks the drug has not been given so administers a dose. The patient receives a double dose.

Equipment Errors

- Wrong equipment is used to administer the drug.
- Equipment malfunctions or is not used properly.

Calculation and Measurement Errors

- An error in calculating the dosage is made so the patient receives the wrong dose.
- There is confusion in the unit of measurement; for example, a drug is prescribed based on kilograms and dispensed or administered based on pounds (and vice versa).

Other

- Medication is improperly handled or stored.
- The patient's identity is not checked, and the wrong patient receives the medication.
- Lighting is inadequate.
- The nurse is fatigued, distracted, or interrupted.

PICOT

Medication Safety

Situation: The student is preparing to administer medications to two clients in the subacute nursing setting. There are several medications to be administered to each client. The student has researched the medications, and knows that there are oral, subcutaneous, and intravenous medications to administer. Prior to preparing the medication the student reviews the medications, and calculates the doses to ensure accuracy.

PICOT Components:

P	Population/client	=	Nursing students
I	Intervention/indicator	=	Medication administration simulation
C	Comparator/control	=	Math testing only
O	Outcome	=	Safe medication administration skills
T	Time	=	Initial practice after graduation

Searchable Question: Do __________ (P) who receive __________ (I) demonstrate __________ (O) as compared to __________ (C) during __________ (T)

Example of Evidence: Medication errors have been identified as a cause of 6% of all sentinel events from 2004 through 2010 (The Joint Commission, 2010). Nursing students are often tested on medication calculation skills separately from the skill of administering medications. Shanks (2011) noted that psychomotor and cognitive skills needed to be integrated. Simulations that included calculating a pediatric dosage (mg/kg/day), administration of the medication, documentation, and evaluation of the efficacy allow the skills to be practiced in an environment that does not expose clients to harm. During the debriefing or reflection session that follows the simulation, the factors that contributed to an error or near miss can be identified, and further remediation can be utilized.

Practice Change. While this method may not be fail-safe, it allows students and new graduates to gain the knowledge and confidence to work through medication problems and arrive at accurate results (Shanks, 2011).

References: The Joint Commission (2010). *Summary data of sentinel events reviewed by The Joint Commission.* Oakbrook Terrace, IL: Author; Shanks, L. (2011). Medication calculation competency. *American Journal of Nursing, 111*(10), 67–69.

Technology cannot substitute for the need to adhere to all guidelines in medication administration. Rubin, Nash, and Safran (2012) present a case scenario that resulted in the death of a premature infant and a pretrial settlement of $8.25 million. The numerous systems in place failed to detect human error that caused the infant to receive an IV that contained 60 times the normal dose of sodium.

Computerized Prescriber Order Entry (CPOE) CPOE helps prevent errors in reading and transcribing orders, particularly when handwritten orders are illegible. Electronic prescribing systems are safer when combined with decision-support tools that automatically alert prescribers to possible interactions, allergies, and other potential problems.

Barcoding Medications Barcode medication administration, especially when combined with CPOE, provides a highly effective system for identifying the right patient. It also transfers data electronically, eliminating the error-prone paper transcription process. When used correctly, barcoding at the unit-dose level prevents nurses from selecting an incorrect medication.

Smart Pumps IV infusion technologies, called smart pumps, used at the point of care can help you avoid programming the wrong dose into the pump and ensure the correct dose is delivered. Once they are programmed, the delivery rate does not change. An alarm will sound or the pump will stop if:

- A nurse attempts to program outside dosing limits.
- The flow is interrupted (e.g., a blocked line).

You must adhere to standard operating guidelines to use these pumps effectively to reduce errors (Cummings & McGowan, 2011). For more information on smart pump technologies, cases involving medication errors, and risk management strategies,

Chapter Resources, Chapter 26, the FDA Web site, in **Resources for Caregivers and Health Professionals,** on Davis*Plus*.

Automated Dispensing Cabinets (ADCs) Most healthcare institutions use ADCs. These systems are known to reduce medication errors when the built-in safety features are used, and the collaboration between pharmacy and nursing is ongoing (Mandrack, Cohen, Featherling, et al., 2012). ADCs in the pharmacy minimize human handling, which can also reduce error.

See the QSEN box for examples of errors that can occur when technologies for administering medication are misused.

Quality and Safety Education for Nurses

Understanding the Limitations of Technologies for Medication Safety

Chapter Key Concept: *Medication Safety*

Competencies: *Safety (Knowledge); Informatics (Knowledge, Skills, Attitudes)**

It is important to understand the limitations of safety enhancing technologies so that you can apply the technologies correctly (Informatics) and reduce the risk of patient harm (Safety).

Computerized physician order entry (CPOE). CPOE was hailed as the answer to prescribing errors and it has had many positive effects. However, several studies have reported mixed results: One documented 22 new types of errors, and one reported an *increase* in mortality after CPOE implementation. Factors contributing CPOE errors include:

- "Alert fatigue": the tendency for users to ignore frequent interruptions from warning messages
- Rigid programs that take users through multiple unnecessary screens or force unnecessary decisions. These encourage users to bypass decision points.
- False sense of security generated by the belief that automated systems prevent errors

Bar-code-assisted medication administration (BCMA). A high rate of false-positive alerts has led to practitioner overrides and work-around actions. Of particular concern is the practice of "back scanning" in which the patient's bar code is scanned *after* medication administration. This greatly increases the risk of error and constitutes negligence.

Smart pump problems. These include software limitations and practitioner misuse (e.g., turning off the pump's dose-checking feature and bypassing alerts). Such actions are ethically and legally indefensible, and do not meet standards of care.

Think about it. How does Informatics competency relate to the Safety competency? How can you avoid risky behaviors, contribute to the redesign of safety technologies, and put patient safety first when administering medications?

(2005); Poon, E. G., Keohane, C. A., Yoon, C. S., et al. (2010); Sittig, D. F., & Singh, H. (2011); Trbovich, P. L., Pinkney, S., Cafazzo, J. A., et al. (2010).

* For specific Knowledge, Skills, and Attitudes,

Go to the QSEN Web site **at http://qsen.org/competencies/pre-licensure-ksas/**

Pediatric Considerations

Confusion between pounds and kilograms is a source of dosing error. You should weigh patients in kilograms when possible, because it is the standard measurement for pediatric prescriptions, medical records, and staff communication. Medication prescriptions should be written with the dose per kilogram of body weight so that the intended dosage can be easily double-checked by nurses and pharmacists. Pediatric-specific medication formulations and concentrations should be used when available, because they are safer than medications dispensed for adults.

What Should I Do If I Commit a Medication Error?

As a nurse, you have a duty to do no harm. With that said, if you make a medication error, even though you might be anxious about having put your patient at risk, embarrassed to admit that you made a mistake, or fear you could lose your job, you must immediately assess the patient's vital signs and physical status. Report your findings to the patient's primary care provider. Then follow the detailed guidelines about actions to take if you commit a medication error, which you will find when you,

Go to **Clinical Insight 26-7: Taking Action After a Medication Error,** in Volume 2.

Follow your institution's policy regarding incident reports and other actions. Although an error does not actually occur until the patient has *taken* a medication, you may be required to file a report for an averted error or "near miss" (e.g., if you discover that the pharmacy has sent the wrong medication for a patient). **Near misses** are errors detected during the checking procedure before drug administration.

PracticalKnowledge knowing **how**

Regardless of the type of medication or the route of administration, when administering a medication you should perform a medication-focused assessment, follow procedures for safe administration, and perform related interventions (e.g., explaining that a certain drug should be taken with food). The rest of this chapter explains these activities to you. Also be certain to become familiar with the guidelines, and

Go to Chapter 26, **Medication Guidelines: Steps to Follow for All Medications (Regardless of Type or Route),** in Volume 2.

Think**Like a Nurse** 26-10

Mr. Pearson (Meet Your Patients) refuses his 1400 dose of antibiotic, stating that he had just taken it. What actions do you take to ensure sound decision making and maintain patient safety?

ASSESSMENT

During your initial patient assessment, you will gather data needed to administer medications safely. The following are highlights of medication-related assessments.

Before Medicating Patients do the following:

- Measure vital signs
- Assess whether the patient's general condition is appropriate for the medication
- Evaluate your knowledge of the medication
- Identify biological factors that affect drug metabolism. Also,

Go to Chapter 15, **Clinical Insight 15-1: Assessing for Biological Variations,** in Volume 2.

While Administering Medications assess the patient's:

- Mental status
- Coordination
- Ability to self-administer the drug
- Swallowing (for oral medications)

After Medicating Patients assess for:

- Effectiveness of the drug
- Side effects
- Signs of toxicity or adverse reactions

Medication History

When taking a medication history, explore the patient's allergy history. Allergic reactions occur with 5% to 10% of all prescriptions. You should also ask about the patient's history of illness, medications, attitudes toward medications, learning needs, and whether the patient (if a woman) is pregnant or breastfeeding. Also check relevant laboratory test results. For more discussion of the components to include in a medication history, and to print out a tool you can use for a full medication history and physical,

Go to Chapter 26, **Supplemental Materials: Components of a Medication History,** on Davis*Plus*.

Physical Examination

The physical examination helps you to identify potential problems and the need for adapting medication administration procedures. For example, you will assess relevant body systems to confirm the need for the drug and to provide a baseline for evaluating the patient's responses. For oral medications, assess the patient's ability to swallow; for intramuscular medications, assess muscle mass. For more complete information about the physical examination related to medications,

Go to Chapter 26, **Supplemental Materials: Physical Examination Related to Medications,** on Davis*Plus*.

ANALYSIS/NURSING DIAGNOSIS

The following are some examples of nursing diagnoses associated with patient medications:

Deficient Knowledge related to lack of motivation to learn about medications

Ineffective Family Therapeutic Regimen Management related to anxiety over child's health status
Risk for Aspiration related to Impaired Swallowing

For examples of other nursing diagnoses,

Go to Chapter 26, **Standardized Language; Standardized Diagnoses, Outcomes, and Interventions Related to Medication Administration,** on Davis*Plus*.

A few nursing diagnoses represent medication side effects; however, because a wide range of adverse effects is possible, no attempt was made to include them all. The following sections discuss Risk for Injury and Noncompliance.

Risk for Injury

Risk for Injury may be related to polypharmacy, misuse, overuse, or underuse of medications.

Polypharmacy Many people self-prescribe or rely on OTC medications for relief of symptoms such as insomnia, headaches, joint pains, and indigestion. They may continue taking them in combination with prescribed medications. This practice is **polypharmacy**: the ingestion of numerous medications in an attempt to treat many conditions simultaneously. Polypharmacy increases the potential for adverse reactions and dangerous drug and food interactions.

Older adults are especially prone to polypharmacy. They typically take several medications prescribed for chronic diseases, and may self-medicate for symptoms related to the aging process (e.g., constipation). The likelihood of increased sensitivity to medications, drug interactions, and adverse drug effects increases as the number of medications taken by older adults increases (Perry, 2011). You should carefully assess the older adults' medication history to identify combinations that can be especially dangerous to them.

Misuse, Overuse, Underuse Some patients misuse, overuse, underuse, or use drugs inconsistently. They may even use them when contraindicated. For example, a person takes an antibiotic, "feels better" after a few days of the medication, and then stops taking it or takes it erratically as symptoms come and go. Such an inconsistent dosage schedule hinders the body's ability to achieve a blood level high enough to treat the infection or disease. Some drugs, for instance beta blockers, when taken inconsistently can be dangerous, even life threatening.

Noncompliance

Noncompliance (nonadherence) is failure to follow the treatment plan (e.g., not taking a prescribed medication, or skipping doses). You cannot assume that the reason a patient may be noncompliant is because he hasn't been taught the importance of following the treatment plan. Prescription medications are expensive. Faced with choosing between food and medicines, people on a limited budget or without health insurance often simply do not buy the more costly medications, or they may take only partial doses of maintenance medications (e.g., thyroid medications, oral hypoglycemics for diabetes). Some patients, particularly older adults, have visual and motor deficits that limit their ability to read labels and manipulate access (e.g., bottle caps, syringes). Other reasons for noncompliance include lack of symptoms, inability to tolerate side effects, lack of belief in the medication regimen, forgetfulness, and impaired mental capacity. Always investigate the patient's reasons for nonadherence so you can take the appropriate actions.

KnowledgeCheck 26-10

- What are the risks involved for patients who engage in polypharmacy?
- List at least three reasons for noncompliance with a medication regimen.

PLANNING OUTCOMES/EVALUATION

NOC standardized outcomes depend on the specific nursing diagnoses you choose. For NOC outcomes for selected nursing diagnoses,

Go to Chapter 26, **Standardized Language; Standardized Diagnoses, Outcomes, and Interventions Related to Medication Administration,** on Davis*Plus*.

Individualized goals/outcome statements you might write should be stated so their achievement reflects resolution of the problem (NANDA-I label). The following are some examples:

After explanation, and within 1 week, describes the expected actions and side effects of his medications.
Self-administers his medications in the correct amounts and on the prescribed schedule.
After demonstration and practice, and within 1 week, correctly draws up and self-administers insulin.

PLANNING INTERVENTIONS/IMPLEMENTATION

NIC standardized interventions depend on the patient's nursing diagnoses, especially on the etiologies.

Go to Chapter 26, **Standardized Language; Standardized Diagnoses, Outcomes, and Interventions Related to Medication Administration,** on Davis*Plus*.

Specific individualized nursing activities include preparing and administering medications and teaching clients to self-administer their medications. You will use specific, step-by-step procedures in Volume 2 for preparing and giving medications. Only the general principles are included in the Highlights of Procedures box in this volume. For specific, step-by-step procedures,

Go to Chapter 26, **Procedures 26-1 through 26-18,** in Volume 2.

TEACHING PATIENTS ABOUT MEDICATION SELF-ADMINISTRATION

Teach the following information to patients to help them safely administer their own medications.

Know and Understand What You Are Taking You need to know and understand your drugs in order to take them safely and effectively.

- **When you are prescribed a new medication**, ask why you are taking it, how long you should take it, what side effects to expect, whether you should take it with food, and whether there are any special precautions.
- **Ask what each drug is for and what it does.** This can prevent taking two medications that do the same thing, as can occur when you are seeing multiple providers (e.g., a podiatrist and an internist may both prescribe a medication to treat toenail fungus).
- **Keep a list of your medications**, including doses and times taken. Take this list with you when you visit any healthcare provider or emergency department.

Take the Drug as Prescribed to achieve maximum safety and effectiveness.

- **Take the drug for the prescribed length of time** to make certain you receive its full benefit (e.g., some patients may take only part of an expensive antibiotic, hoping to "save it for later." However, if you do not take all of the medication, the infection may recur. Or antibiotic resistance may develop, leading to "superinfection," such as methicillin-resistant *Staphylococcus aureus* (MRSA).
- **Older adults may forget to take their medications.** A simple plan you can follow at home, such as a written schedule or a meds calendar, might help, especially if the drugs are taken other than at mealtimes and bedtime.
- **If you cannot see well**, ask a family member to write the schedule in large, black letters. Display it in a highly visible place.
- **Some older adults may take the medication, only to forget shortly thereafter that they did so.** Use a divided pill container or a small glass filled with the medications for each dosage time during the day. If the a.m. container is empty, you will know you have taken the morning drugs and won't accidentally repeat them.

Communicate With Your Prescriber Notify your prescriber if you have side effects, adverse reactions, or questions. If you become pregnant, notify your primary care provider as soon as possible so your medications can be discontinued or adjusted.

Think About Safety Be aware of your safety and the safety of others.

- **Wear a Medic Alert bracelet** or necklace if you are a diabetic, take anticoagulants, or have allergies to any medication.
- **Do not take medications prescribed to others**, and do not share your medications with others.
- **If you take a variety of medications**, post a list of them in a prominent place that is easy to see in the event of an emergency.
- **Use childproof caps** if children have access to your medications. If no children are in the home, replace with simple closure cap for elderly patients who might have difficulty opening the containers.

Families with young children visiting the homes of older adults need to be alert to the risk of accidental ingestion of medication.

- **Dispose of expired medications safely.** Do not place them in the trash within the reach of children. Disposing of drugs in the sink or toilet is not environmentally sound (e.g., they can appear in the community water supply). Your community may sponsor an "old medications discard day" or provide a place to discard drugs to avoid contamination. Some local pharmacies may offer medication disposal as a community service.

Administer Your Drugs Correctly, as follows:

- **Read the label carefully on the bottle each time** you take the medication so that you take the correct medication. Many pills look alike.
- **Take only the amount and dose prescribed.** If you have questions, call your prescriber.
- **To measure liquids, use kitchen measuring spoons** rather than tableware, which can vary in volume.
- **If you have difficulty opening containers and administering your medications** because of pain or stiffness in the hands and fingers, ask family members and friends to help you. Ask the pharmacy and the primary care provider *not* to put childproof safety lids on containers for easier handling. Older adults are allowed to sign a release with their pharmacy to do this.

Store Your Drugs Safely Do not store a drug in a different container from the one it came in. The medication may lose its strength, or you may take the wrong medication. Store all your medications in a dry place out of the sunlight and away from the heat. If a medication requires a cold storage, be sure you return it to the refrigerator immediately after use.

Maintain Your Supply Your drugs need to be up to date and available when you need them.

- **Monitor your prescription amounts, and get refills before you run out.** If you get medications by mail, be sure you order them in plenty of time.
- **Check expiration dates**, and discard any **outdated** medications.
- **Do not take expired medications**; they may have lost their strength.

ENSURING SAFE MEDICATION ADMINISTRATION FOR INPATIENTS

Medication mistakes are the most common type of healthcare error. Errors include giving the dose at the wrong time, omitting doses, giving the wrong dose, and giving the dose without authorization. One safeguard is to develop a set routine for medication administration.

Many errors occur as a result of interruption or distraction. It is best not to stop what you are doing when preparing or giving medication. One recommendation is to create a "sterile cockpit environment" (similar to takeoffs and landings in which the flight attendants are not disturbed) when preparing your medications (ISMP, 2008). You can do this by putting up "do not disturb" signs or wearing a bright yellow sash/apron to alert people not to disturb you when you are preparing or giving medication.

Specifically, to help prevent errors when giving medications, perform "three checks" and "rights of medication" discussed following.

Each time you administer a medication, be sure to follow the guidelines you will find,

In Chapter 26, **Medication Guidelines: Steps to Follow for All Medications (Regardless of Type or Route),** in Volume 2.

Three Checks

Check each medication three times:

1. *BEFORE you pour, mix, or draw up a medication,* check its label against the entry on the MAR. Be sure that the name, route, dose, and time match the MAR entry.
2. *AFTER you prepare the medication,* and before returning the container to the medication cart or discarding anything, check the label against the MAR entry again.
3. *AT THE BEDSIDE, check the medication again* before actually administering it.

Observing the "three checks" rule will help you to practice the "rights of medication."

Rights of Medication

Following the **rights of medication** means that you will give the (1) right medication to the (2) right patient in the (3) right dose using the (4) right route at the (5) right time with the (6) right documentation of the medication administration. This system helps you prevent medication errors.

Right Drug

Obviously, you must always administer the correct medication. That is one reason for reading each label three times (see the "three checks"). Other ways to ensure giving the correct drug are to:

1. Think Critically.

- If you must take a verbal prescription, always repeat it back to the prescriber to be sure you have heard correctly. Spell the medication name. Many medication names sound the same when you hear them but are actually very different drugs (e.g., Isordil, Isuprel; see Box 26-2 for more examples).
- Be familiar with the drugs you administer. If you don't know, look it up.
- Always check the prescription to see whether there have been changes in the medication dosage, route, and so forth—especially after days off, after working a different shift, and after a break.
- Ask yourself whether the medication prescription is suitable for the patient's condition. If not, question the prescriber.
- Participate in daily patient rounds so you will be better informed about your patient's plan of care and why the medications are prescribed.

2. Be aware of the pitfalls in abbreviations, units of measurement, and handwriting.

- Double-check all prescriptions transcribed by hand to the MAR, especially when decimal points are involved.
- Do not attempt to decipher illegible handwriting, confusing abbreviations, or units of measurement (e.g., mg and mL, or IU and IV). When in doubt, ask the prescriber to clarify.
- Be alert for names that look very similar (e.g., Keflex and Keflin). It may be impossible to differentiate them when they are handwritten. Do not administer a drug prescribed by a nickname; be sure it is written out in full.

3. Perform the "three checks" of the label against the MAR.

- Read the label before and after you prepare the medication, and again at the bedside to verify that you selected the correct product name and strength.
- Select the prescribed medication from the patient's drug drawer (unless it is a stock drug). Do not "borrow" from another patient's drawer.
- Do not substitute one medication for another.
- Even when using a unit dose, read the label. Avoid selecting medications based on size and color because many medications are the same size, shape, and color as others.
- Be alert for similar-looking labels. If you are accustomed to withdrawing oxytocin (given IV to stimulate uterine contractions) from a small vial with a green label, you might be surprised to find that the small, green-label vial in your hand is actually hydroxyzine (Vistaril), which would harm the patient if given IV.
- If a label is hard to read or comes off the container, return the container to the pharmacy. Never give a

medication from such a container. Also, do not transfer medications from one pharmacy container to another.

- **Heparin.** Physically separate the highly concentrated heparin sodium (10,000 units/mL in 1-mL vials) from the more diluted 1-mL vials for flushing heparin locks. There is a risk for fatal hemorrhage if the highly concentrated heparin solution is mistakenly used to flush an IV line. FDA-approved labeling now includes new color and design in order to distinguish various heparin concentrations in the vials. Be extremely careful when administering heparin to infants and children.

Right Dose

The right dose is the dose prescribed for the particular patient. Be sure the dose is within the recommended range for the patient's age, weight, and condition. The following are suggestions for avoiding dose errors:

- Perform the "three checks" of the container against the MAR. If the pharmacist has sent a dose different from the one prescribed, you may need to calculate how much of it to give. It is a good idea to have another nurse check your dosage calculations.
- For IV medications, use smart infusion pumps to help ensure the correct dose is delivered.
- How you prepare medications can affect the dose. When you must break a tablet, use a knife or a cutting device. If the tablet does not break evenly, discard and account for it. Also, when crushing a tablet to mix with liquid or food, clean the crushing device completely before and after using it to remove any pieces of a previously crushed drug.
- Read and write measurements carefully. It is easy to misread "mg" instead of "mL." There is a significant difference between 1 mg and 1 mL of IV morphine.
- Write out "international units" instead of abbreviating as "IU." IU can be confused with IV.
- Know how and when to use a zero. Always write a zero *before* a decimal point. It is easy to mistake .15 for 115 if the decimal point is written large or the 1 is written small (e.g., write "Lanoxin 0.125 mg," not "Lanoxin .125 mg"). Conversely, never write a decimal point and a zero *after* a whole number. The decimal point may be mistaken for a 1 (e.g., write "5 mg," not "5.0 mg").
- Question prescriptions for multiple tablets or vials as a single dose; most doses are one or two tablets or one single-dose vial.
- Question abrupt and excessive increases in dosage; most dosages increase gradually.
- Question prescriptions that are not consistent with the standard (protocol) dosage range for the patient's age, weight, and condition.
- Examine the standards of care and practice in your institution to see if they comply with the intent of The Joint Commission's National Patient Safety Goal related to safe dosing with anticoagulation therapy.

Right Time

- Check the prescription against the time to give the drug, and document the exact time of administration on the MAR.

If the drug is not charted, never assume the patient received it as scheduled. If you do, the patient may not receive an essential medication; if you assume it has not been given and give it, the patient may receive an overdose.

- Medications are designed to be given at specific times to maintain constant therapeutic blood levels. However, you can give scheduled medications within a "window" of one-half hour before and one-half hour after the scheduled time, as a rule.
- Time oral medications in relation to meals. Give drugs that are irritating to the stomach (e.g., potassium, aspirin) with food; give drugs that absorb better on an empty stomach (e.g., tetracycline, iron supplement) before meals.
- Determine whether your patient is scheduled for any diagnostic procedures, surgery, or blood tests that require him to remain NPO. If so, you may need to hold oral or enteral medications, or have them changed to another route.
- If a drug has been delayed (e.g., for a diagnostic text), have the prescriber clarify when to administer the next dose in order to maintain constant therapeutic blood levels.

Right Route

Recall that drug absorption is highly dependent on the route of administration. The following are suggestions for ensuring the right route:

- Perform the "three checks," and be sure that the drug is in the proper form for the route prescribed, especially for time-released drugs.
- If the prescription does not specify a route, do not guess; clarify with the prescriber.
- Be sure the drug is in the proper form for the route prescribed. Many medications are available in multiple forms; others are made for one specific route. For example, cephalexin (Keflex), an antibiotic, comes in capsules, suspensions for oral use, and injectable forms for intramuscular and IV administration. By contrast, the antibiotic penicillin G procaine (Crysticillin) is prepared for IM injection and is *not* to be given intravenously.
- The right route also includes **right site**. If an intramuscular injection is prescribed, be sure the site is appropriate considering the age of the patient (child, adult, elderly) and the medical condition (e.g., if the site is traumatized or with compromised circulation, you would not use that site).

- As an additional safety measure, draw up oral liquids only into an oral syringe to avoid inadvertent IV administration.

Right Patient

- Just before giving the medication, always double-check the patient's identification (ID) bracelet. The Joint Commission's (2011) National Patient Safety Goals recommend using two methods of patient identification, so also ask the patient to state his name. It is best to say, "Please tell me your name," because patients with hearing impairment or confusion might respond "yes" incorrectly when asked, for example, "Are you Mary Smith?" Never skip this step, even if you are familiar with the patient. If you are busy and distracted, it is possible to enter the wrong room. Also, patients, especially when they are confused or emotionally disturbed, may move about. You may enter room 214 with a medication for Mr. Jones but discover an entirely different person in Mr. Jones's bed!
- Do not leave medications at the bedside. Suppose you are taking an oral tablet to a patient's room. He is in the bathroom and says, "Just leave it; I'll take it when I come out." If you leave the tablet, how would you know whether he really took it? And what might happen if another, confused patient (or a visiting child) wandered into the room and took the tablet?
- Be alert for patients with the same last name. It is common to have two patients with same or similar last names (e.g., Williamson, Wilkinson, Wilson, Wilkerson). Look for and place special alerts on charts and MARs to call attention to names that look or sound similar.
- Computerized prescriber order entry (CPOE) and bar code medication administration transfer data electronically and provide a nearly foolproof system for identifying the right patient. However, you must still ensure order entry is made in the correct patient record.

Right Documentation

Most nurses consider documentation the sixth right. After administering a medication, document it immediately on the patient's MAR, as in Figure 26-7. To see an electronic MAR, go to Chapter 18. Be sure to document the following information:

- Name of medication given
- Dose of medication given
- Route of administration and injection site for parenteral medications
- Date and time administered
- Your name or initials as administering nurse

Most MARs are preprinted with the patient's name, name of the medication, dosage, and route administered

FIGURE 26-7 After administering a medication, immediately document the date, time, dose, route, and person administering the medication on the MAR.

(e.g., intramuscular, oral, or intravenous). If so, you need only to write the time you actually gave the medication, initial each medication, and sign the form one time. Write legibly in ink.

If for some reason (e.g., patient refusal, NPO for tests or procedures) you do not administer a prescribed medication, document that information on the MAR and write a nurse's note explaining why it was not given. For example:

06/20/15 0800—Pt NPO for surgery this a.m. 0800 meds held as prescribed. ____________________ Janet King, RN

When giving a PRN medication, in addition to recording on the MAR, write a nursing note describing your assessment and the time the drug was given. Then, after allowing time for the medication to be absorbed and take effect, evaluate and document the patient's responses. For example:

06/20/15 0800—Pt reports abdominal pain at incision site rated as a #6 on a scale of 1–10. Active bowel sounds auscultated. Resp 16 breaths/min, HR 88 beats/min, BP 130/84. Denies N/V. Morphine 10 mg given intramuscularly in right vastus lateralis. No injection-related complaints (see MAR). ____________________ Janet King, RN

06/20/15 0900-States pain relieved; "about 3" (scale of 1–10). Resp 14 breaths/min, HR 68 beats/min. BP 126/80. ____________________ J. King, RN

You are responsible for documenting the client's responses to all medications, including therapeutic effects, side effects, and unexpected or adverse reactions. Never document a drug before you give it; never document a medication given by someone else; and do not ask someone else to document medications you administer.

Other Rights

In addition to the six "rights" already discussed, patients also have the following rights about medications they receive:

- **Right Reason.** This includes the right to not receive unnecessary medications. For example, a tranquilizer or sleeping pill should be given because the patient is very anxious or cannot sleep, not for the convenience of caregivers who are weary of his incessant demands.
- **Right to Know.** This means that you tell the patient the name of the medication, why it is being given, its actions, and potential side effects.
- **Right to Refuse.** The patient has the right to refuse a medication regardless of her reasons and regardless of the consequences, except under certain circumstances (e.g., incompetency).

Some have advocated adding three additional rights: right form (of medication), right actions, and right response (Elliott & Liu, 2010).

KnowledgeCheck 26-11

- What are the rights of medication?
- Give an example of each one.
- How many times, and when, should you check the medication against the MAR?

ADMINISTERING ORAL MEDICATIONS

The oral route is the one most commonly used for medications. Recall what you already know about oral medications: Where are they absorbed? What are their advantages and disadvantages? What assessments should you make? If you cannot answer these questions, review Table 26-1 and the discussions of drug preparations and routes of administration. For an overview of administering various types of oral medications, see the Highlights of Procedures box. To see complete procedural steps,

Go to Chapter 26, **Procedure 26-1: Administering Oral Medication,** in Volume 2.

Pouring Liquid Medications

Liquid medications are frequently used for children and older adults. They usually come in multidose bottles, so you will need to pour individual doses into a disposable, calibrated cup, as in Figure 26-8. When pouring, hold the bottle with the label inside your palm, so the liquid does not run over the label, making it difficult to read.

Buccal and Sublingual Medications

Buccal and sublingual medications, although placed in the mouth, are intended for absorption in the mucous membranes rather than in the GI tract. Some soluble forms of medications and enzyme preparations are

FIGURE 26-8 When pouring a liquid medication, measure the dose while holding the calibrated cup at eye level.

administered by this route and are rapidly absorbed, some within seconds. **Buccal medications** are held between the cheek and the gums; **sublingual medications** are held under the tongue.

Enteral (Nasogastric and Gastrostomy) Medications

For patients who cannot swallow or who have feeding tubes, you can give oral medications through nasogastric (NG), gastrostomy, or jejunal tubes. As with all routes of administration, check for drug interactions. Observe the following special considerations when administering enteral medications:

- *Hydrophilic medications*, such as psyllium (Metamucil)—Do not administer these through feeding tubes because they attract water and will solidify in the tube.
- *Crushing tablets*—Some tablets (e.g., enteric-coated or extended-release medications) should not be crushed, because crushing can change their action. Always check.
- *Continuous tube feedings*—Disconnect before giving medications.
- *Enteral tube suction*—Discontinue the suction for 30 minutes after administration and keep the tube clamped to allow time for the drug to be absorbed, if applicable.

For other procedures related to gastric and enteral tubes,

Go to Chapter 27, **Procedure 27–2: Inserting Nasogastric and Nasoenteric Tubes, Procedure 27-3: Administering Feedings Through Gastric and Enteric Tubes, and Procedure 27-4: Removing a Nasogastric or Nasoenteric Tube,** in Volume 2.

Special Situations

Some oral medications can discolor or damage tooth enamel, have an objectionable taste, are difficult to swallow, or cause the patient to gag. Offer oral hygiene immediately after giving the medication. The following may also be helpful:

- **Medications that discolor the teeth.** Mix such drugs with liquid, have the patient drink the solution through a straw, and drink water afterward. Unless contraindicated, encourage the patient to drink a liberal amount of flavored liquid (e.g., juice) or water to dilute the medication.
- **Medications with an objectionable taste.**
  Have the patient suck on ice chips for several minutes before taking the medication. Ice numbs the taste buds.
  Store the medication in the refrigerator, unless contraindicated. The smell and taste are less objectionable when chilled, especially for oily liquids.
  Use a syringe to place the medication on the back of the patient's tongue. There are fewer taste buds there.
  Some medications can be constituted with flavored additive to make the elixir more appealing, particularly for children.
- **Contraindications to oral medications.** In the following situations, do not give the drug. Obtain a prescription for an alternative route or, if the patient is NPO, permission to give the medication with small sips of water. Patients who:
  Cannot swallow fluids. The risk for aspiration is too great.
  Have nausea or vomiting; the medication would be lost in the emesis.
  Are NPO.
  Are not coherent or are comatose.
- **Patients who have difficulty swallowing medications.** Some patients may gag, or the pills become "stuck" in their throat. It may help to crush soluble tablets and place them in liquids or in a small amount of applesauce or pudding. Remember that some forms (e.g., time-released tablets) should *not* be crushed, so check your drug reference sources to be certain. To learn more about which medication to take with or without food,

Go to **ESG Box 26-1, Oral Medications Taken With or Without Food,** on Davis*Plus*.

KnowledgeCheck 26-12

- Describe two ways to ensure an accurate dosage when pouring liquid medications.
- What instructions should you give to a patient who is taking a sublingual medication?
- Explain the special steps required when administering enteral medications to a patient who is receiving continuous tube feedings.
- Describe three methods to use when administering objectionable-tasting drugs.
- For which patients are oral medications contraindicated?

Medicating Children Orally

Children are not motivated by logic. They do not grasp the cause and effect of "Take this, it will make you feel better." If they do not like the taste, they simply will not swallow it. Another challenge is that before the age of 5 years, a child may not be able to swallow tablets and capsules; therefore, most oral medications for children are prepared as sweetened and flavored liquids or chewable tablets. For very young children and infants, you must take care to prevent choking and aspiration. Parents can often suggest the best methods for getting their child to take medicines. For other parents, you may need to teach techniques for administering medications at home (see Self-Care: Teaching Parents About Medicating Children).

Self-Care

Teaching Parents About Medicating Children

1. Mark each bottle or syringe containing medication with a different color of tape or adhesive label. This makes each clearly distinguishable since many medication bottles look alike.
2. You can reuse syringes for oral medications until the markings or tape begins to wear off or the plunger becomes difficult to move. Wash syringes with warm, soapy water, rinse well, and allow to air dry.
3. Take your time when giving medication, and find a quiet environment. Don't rush the process. It can be frustrating to struggle with a young child who is resisting taking a medication, especially if your time is limited.
4. Give the medication at the same time each day so it becomes a matter of routine. It is easier to remember when a pattern is established.
5. If the child is old enough to understand, warn him when a medication has an unpleasant taste (e.g., "John, this doesn't taste very good, but you can have a big drink of juice as soon as you swallow it."). You may lose his trust if you surprise him with a bad taste.
6. Give the child a frozen fruit bar or frozen flavored ice pop just before the medication. This helps to numb the taste buds to weaken the taste of the medication.
7. To mask bad-tasting medicines, you can crush tablets or empty the contents of a capsule and mix with soft foods, such as applesauce, hot cereal, or pudding. This is helpful for children who might aspirate liquids, as well. (***Caution:*** Check a drug reference book or with the prescriber before crushing a tablet or emptying a capsule. Some medications should not be crushed.)
8. Do not use essential foods in the child's diet (e.g., milk or orange juice) to mask the taste of medications. The child may later refuse a food he associates with the medicine.
9. To prevent choking or aspiration when giving liquids to infants and toddlers, hold the child in a sitting or semi-sitting position. Use a medicine dropper or syringe to place the medication between the gum and cheek. Instill the medication; avoid giving too much, too fast.
10. Always praise the child after she swallows the medication.

Medicating Older Adults Orally

Many interventions for older adults are the same as for patients of all ages (e.g., actions to facilitate swallowing, the content of the teaching). For those, review preceding section on Teaching Patients About Medication Self-Administration.

In Chapter 26, **Procedure 26-1, Administering Oral Medication,** in Volume 2.

However, because of physiological changes associated with aging (see Table 26-2), certain problems occur more frequently in older adults. For example, older adults usually require smaller dosages of drugs, and physical responses to some medications are unpredictable. Therefore, interventions such as carefully observing for both therapeutic and undesired effects become even more important. The following interventions are for nurse-administered drugs (also see Box 26-4) and are not described in the self-administration discussion.

- **Address swallowing difficulties.** As the desire to drink decreases with age, the mouth often becomes drier, making it difficult to take large tablets. Crush tablets (if acceptable) or give drugs in liquid form. Try gently massaging the area just below the chin to initiate swallowing. For other strategies, collaborate with an occupational or speech therapist.
- **Accommodate slower reflexes and reasoning ability.** Allow more time to explain and administer medications. When teaching, keep instructions simple and repeat them often. Also reinforce the need to take the medication as prescribed. Some patients may think, "I don't feel any better when I take all this stuff." In the hospital, they may refuse to take medications, or they may put the tablets in their mouths but spit them out when you leave the room. Stay with the patient until you see that he has swallowed the medications.

KnowledgeCheck 26-13

- What is the chief danger when administering oral medications to children?
- How can you help a person who has some difficulty swallowing oral medications?
- Keeping in mind that patients do have the right to refuse medications, how can you be sure that they are actually taking them and not spitting them out after you leave the room?

ADMINISTERING TOPICAL MEDICATIONS

Topical medications are applied directly to the skin or placed in body cavities by irrigation or instillation. Most must be applied two or three times per day for maximum effect. They have local or systemic effects, depending on how the drug is prepared, as in the following examples:

- *Local effects*—Zinc oxide ointment to protect the skin against irritation associated with bowel and bladder incontinence; corticosteroid creams for itching.
- *Systemic effects*—These are absorbed through the skin and mucous membrane (e.g., estrogen patches; also see Transdermal Medications, following).

Lotions, Creams, and Ointments

Before applying medications to the skin, assess for contraindications (e.g., skin irritation, open lesions, hypersensitivity). Use a cotton swab, tongue blade, or gloved

BOX 26-4 ■ Reducing Risk for Medication Errors for Older Adults

- **Be alert to unnecessary drug therapy.** It is not unusual for prescribers to be reluctant to stop a medication or simply forget to do so. The likelihood of a poor outcome increases as the number of drugs prescribed increases.
- **Request the indication for use** on all medication prescriptions.
- **Suggest primary care provider trials of nonpharmacological interventions** (such as warm massage and guided imagery) before prescribing medication for new symptoms.
- **Consider the "snowball effect."** This occurs when symptoms result as a side effect of prescribed medication, and the care provider then prescribes another drug to deal with the side effect. This results in yet another side effect, another drug, and so on. To interrupt this phenomenon, the prescriber can discontinue the medication, reduce the dose, or substitute one that the patient tolerates better.
- **Verify that a newly prescribed medication** does not have a documented drug-drug interaction. Check that the prescribed dosage is correct within the desired range.
- **When titrating drug doses, start low and go slow.** It's best to start with the lowest possible dose when starting a medication because adverse drug effects are dose related and older adults tend to be more sensitive.
- **Assess urinary status.** Many drugs are cleared through the renal system. Some have toxic effects on the kidneys, particularly for older adults.
- **Recommend safer drugs** if the prescriber initiates medication associated with adverse outcomes for older adults. The benefit must exceed the risk to the patient (Zwicker & Fulmer, 2008; Zwicker & Fulmer, updated 2012).

finger to apply lotions, creams, and other ointments so that your skin does not absorb them. The Highlights of Procedures box summarizes key points for applying skin medications, including powders and aerosols. For the step-by-step procedure,

Go to Chapter 26, **Procedure 26-7A: Applying Lotion, Cream, and Ointment,** in Volume 2.

Transdermal Medications

Designed to be absorbed through the skin, transdermal medications are prepared as patches made of a special membrane. Patches allow constant, controlled amounts of medications to be released over 24 hours or more, giving a prolonged systemic effect. Examples of drugs administered by patch include nitroglycerin (used to control angina or chest pain), scopolamine (used to treat motion sickness), nicotine (used to control smoking urges), and fentanyl (used to treat chronic pain).

FIGURE 26-9 Patches allow constant, controlled amounts of medications to be released over a 24- to 72-hour period, giving a prolonged systemic effect. Wear gloves when removing and applying them.

Most patches are prepared with the correct dose already applied and should not be cut. Some gel patches can be cut and are self-adherent (e.g., lidocaine and diclofenac). Check the package insert or ask a pharmacist about proper handling, application, and disposal of patches. Wear gloves when applying, removing, and discarding transdermal patches (Fig. 26-9). See the Highlights of Procedures box and,

Go to Chapter 26, **Procedure 26-7D: Applying Transdermal Medication,** in Volume 2.

PERFORMING IRRIGATIONS AND INSTILLATIONS

Washing out a body cavity with a steady stream of fluid or water is called **irrigation**. Sterile water, saline, or antiseptic solutions are flushed into the eyes, ears, throat,

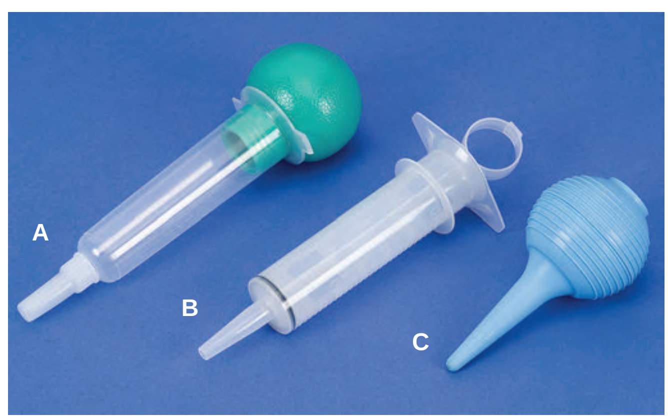

FIGURE 26-10 Syringes for administering enteral medications and performing irrigations and instillations. *A*, Asepto syringe: Plastic syringe with rubber bulb. *B*, Toomey (piston) syringe: Calibrated plastic syringe with removable tip that fits into the end of a tube (e.g., urinary catheter or enteral tube). For deep wound and bladder irrigations, and administration of enteral medications. *C*, Rubber bulb syringe, for ear irrigations.

vagina, rectum, or urinary tract to wash out the cavity. **Instillation** is the insertion of medication into a body cavity (e.g., eye drops) so the medication can be retained or absorbed through that body cavity. Some medications need to remain in the body cavity for a period of time for maximum absorption and effect.

Irrigations and instillations are performed to remove discharge or foreign bodies (e.g., from the eye or ear); to apply heat and cold to an area; to apply medications (e.g., antiseptics); and to prepare an area for surgery (e.g., an enema for cleansing the bowels). You will usually not use sterile technique unless there are breaks in the skin. Several types of syringes are used for irrigating and instilling medications and fluids. Each is calibrated to allow you to control the amount and speed of solution delivered into the cavity (Fig. 26-10).

Ophthalmic Medications

Ophthalmic ointments or solutions are used for their local effects, for example, to treat eye irritations, infections, and glaucoma or to lubricate the eye. During an eye examination, eye medications may be used to anesthetize the eye, dilate the pupil, or temporarily stain the cornea to identify abraded areas. Eye irrigation may be performed to remove foreign bodies, secretions, or harmful chemicals.

Ophthalmic medications are packaged in small bottles or tubes with a label that states, *"For ophthalmic use only."* Do not place any medication in the eye unless that statement appears on the container. Damage to the eye can result in permanent blindness.

The **cornea** (the transparent part of the sclera in front of the iris and pupil) is easily injured, so you should not place medications directly onto the eyeball. Take care to not touch the tip of the dropper or tube to the eye or conjunctiva; doing so may lead to bacterial growth on the container or damage the eye.

See Chapters 22 and 30 for information about the structure and function of the eyes. The Highlights of Procedures box summarizes key points in performing ophthalmic instillations. For the step-by-step procedure,

Go to Chapter 26, **Procedure 26-2: Administering Ophthalmic Medication,** in Volume 2.

Otic Medications

Medications or solutions may be dropped into the ear to treat internal and external ear infections, to apply heat to the area, and to soften and remove earwax. Use solutions at body temperature because a solution that is too hot or too cold may cause vertigo, nausea, and pain. You will use clean technique when administering otic medications.

To prevent infection, use sterile technique if the tympanic membrane (eardrum) has been ruptured or a surgical procedure has been done.

See Chapters 22 and 30 for information about the structure and function of the ear. The Highlights of Procedures box provides guidelines for performing otic instillations. For the complete procedure,

Go to Chapter 26, **Procedure 26-3: Administering Otic Medication,** in Volume 2.

Nasal Medications

Clients usually self-administer nasal drops and sprays, many of which are available without a prescription. The most common nasal medications are used in the treatment of nasal congestion from colds, sinus infections, and so on. Nasal decongestants shrink swollen mucous membranes and allow for better airflow and drainage of mucus. Caution your patient that long-term use of decongestants may cause a **rebound effect**. This occurs when the medication is effective immediately after administration, but nasal congestion often recurs and even increases when the effects of the drug wear off. Thus, continual use of the drug becomes necessary to achieve nasal decongestion. Frequent use of or swallowing excess decongestant can also cause systemic side effects (e.g., increased heart rate, increased blood pressure). These effects can be serious in children; saline drops are safer for them.

See Chapters 22 and 30 for information about the structure and function of the nose. The Highlights of Procedures box provides guidelines for performing nasal instillations. For the complete procedure,

Go to Chapter 26, **Procedure 26-4: Administering Nasal Medication,** in Volume 2.

Vaginal Medications

Vaginal medications come in various forms: foams, jellies, liquids (douches), creams, tablets, and suppositories. They may be used for contraception; to destroy bacteria in the vagina before gynecological surgery; to reduce vaginal dryness related to menopause; to treat vaginal itching or infection; or to induce labor. To keep suppositories firm enough to insert, store them in the refrigerator. After insertion, the body temperature causes the suppository to melt. Foams and jellies are inserted using an applicator or inserter. Apply a clean perineal pad if there is heavy drainage or if the woman is ambulatory (the medication may melt and drain from the vagina by gravity).

A **douche** is a vaginal irrigation using low pressure. Vaginal irrigations are used to administer antimicrobial solutions to prevent infection (e.g., before surgery), to remove irritating discharge, and to apply heat or cold (e.g., to reduce inflammation). In the acute care setting, you will usually use sterile supplies. However, this is not usually necessary when the irrigation is self-administered at home because people usually have some resistance to the microorganisms in their daily environment.

The Highlights of Procedures box provides guidelines for administering vaginal medications. For the complete procedure,

Go to Chapter 26, **Procedure 26-5: Administering Vaginal Medication,** in Volume 2.

Rectal Medications

Rectal suppositories and liquid instillations (**enemas**) are used to encourage bowel movements or to treat systemic complaints. For example, antiemetic suppositories are often used to treat nausea. The rectal route may provide for higher blood levels of the medication than does the oral route because the venous blood from the rectum does not pass through the liver before entering the general circulation (review the discussion of the first-pass effect as needed). They can also be given in a colostomy stoma in certain patients. For advantages and disadvantages, see Table 26-1.

The Highlights of Procedures box provides guidelines for administering rectal medication. For the complete procedure,

Go to Chapter 26, **Procedure 26-6: Inserting a Rectal Suppository, and Chapter 29, Procedure 29-3: Administering an Enema,** in Volume 2.

ADMINISTERING RESPIRATORY INHALATIONS

Nebulization is the production of a fine spray, fog, powder, or mist from a liquid drug. The patient inhales the medication mixture by breathing deeply through a mouthpiece attached to the nebulizer. Absorption is rapid because of the vascularity of the airways and alveoli.

Types of Nebulizers

The following are four types of devices for achieving nebulization:

- *Atomizers* disperse the medication in the form of large droplets.
- *Aerosol sprayers* suspend the droplets of medication in a gas (e.g., oxygen).
- *An ultrasonic (handheld) nebulizer* mixes a small volume of medication, usually less than 1 mL, with 3 mL of normal saline. The device forces air through the nebulizer and delivers medication and humidity as a fine mist. Because the particles are so small, the mist can be inhaled deep into the lungs.
- *A metered-dose inhaler (MDI)* (Fig. 26-11) is a type of nebulizer that delivers measured doses of a nebulized drug.

No matter which device is used, the smaller the droplets, the farther the medication can be inhaled into the respiratory tract.

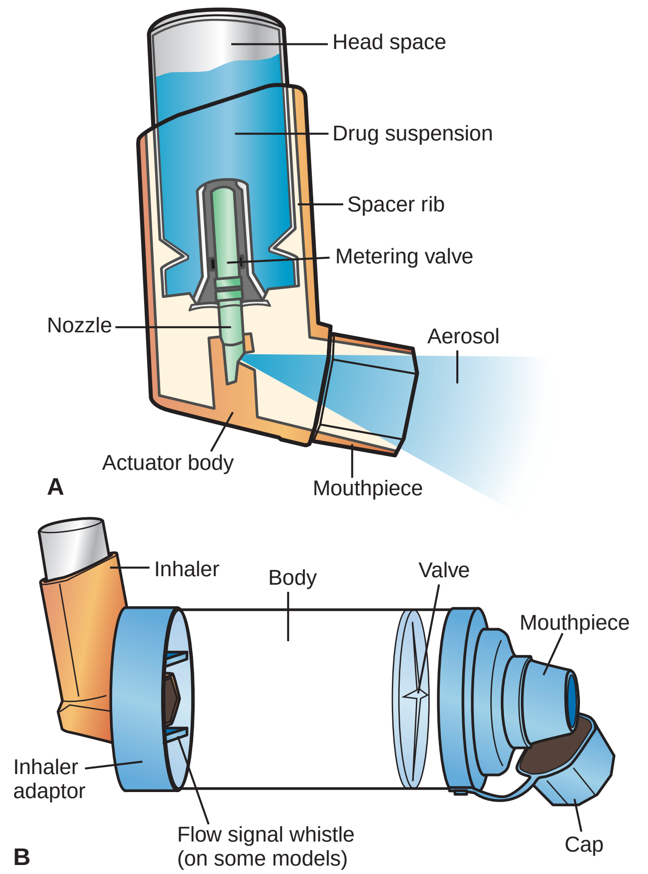

FIGURE 26-11 Inhalers. *A*, Metered-dose inhaler. *B*, Inhaler with a spacer.

Metered-Dose and Dry Powder Inhalers

A metered-dose inhaler (MDI) is a pressurized container prefilled with several doses of a drug and an eco-friendly substance, called hydrofluoroalkane, or HFA, for propelling the medication forward. The patient inhales while pushing the canister's pump to release a measured dose of medication through a mouthpiece (Fig. 26-11A). Sometimes an extender (spacer) is attached to the mouthpiece to enhance the delivery of medication into the respiratory tract (Fig. 26-11B). Medication is pumped into the extender instead of directly into the patient's mouth. The patient inhales the drug from the chamber.

A **dry powder inhaler (DPI)** is similar to an MDI. The medication is activated by a pump rather than by inhalation. Each powdered dose is in a blister pack that is activated according to the manufacturer's instructions. Once the dose is loaded, the patient simply takes a deep breath. DPIs are not designed to be used with a spacer.

The advantage of MDIs is that high doses of medication can be rapidly instilled in the lungs, producing local effects directly into the airway, while avoiding systemic side effects. Disadvantages are the need for manual dexterity, which is often compromised in older adults and young children; skill in coordinating the inhalation of the medication and the pushing of the canister to administer the dose; and the ability to inhale and exhale

FIGURE 26-12 Child using a metered-dose inhaler with an extender.

deeply enough to allow penetration of the medication in the more distal bronchioles.

Patients frequently self-administer inhalations (most often bronchodilators or steroids) using an MDI. You may need to teach your patients how to use the device correctly (Fig. 26-12). Keeping track of how many puffs have been used is problematic for some users, which can lead to a canister being unexpectedly empty when needed. For this information, see the Highlights of Procedures box. Also,

Go to Chapter 26, **Procedure 26-8: Administering Metered-Dose Inhaler (MDI) Medication,** in Volume 2.

KnowledgeCheck 26-14

ADMINISTERING PARENTERAL MEDICATIONS

Parenteral medications are those that are injected or infused into body tissues or into the bloodstream via various routes, including intradermal, subcutaneous, intramuscular, or intravenous routes. Parenteral injections are absorbed faster and more completely than drugs given by other routes; therefore, the results are more predictable and the dosage can be measured more accurately. In addition, they can be used for patients who cannot take oral medications. However, tissue damage may result if the pH, osmotic pressure, or solubility of the medication is not appropriate to the tissue where the medication is given. For example, medications intended for injection into muscle may damage subcutaneous tissue. You must prepare and administer parenteral medications accurately, because the medications, once given, cannot be retrieved.

Equipment for Parenteral Medications

When administering injectable (parenteral) medications, you must know about various kinds of needles and syringes. You will also need to decide, based on each situation, what size and type of needle and syringe to use. For a summary of the sites and equipment used for parenteral administration,

Go to Chapter 26, **Tables, Boxes, Figures: ESG Table 26-6, Parenteral Injections: Comparison of Sites and Equipment,** on Davis*Plus*.

Reusing Equipment at Home Many people (e.g., those who have diabetes) must give themselves repeated injections, perhaps several each day. Supplies for home use are expensive. Insurance may or may not cover the cost, or the person may not have insurance. Therefore, although health professionals and manufacturers recommend that disposable syringes and needles be used only once, some people find it practical to reuse them. If they do, you can help them to do it more safely by teaching them the content in

Chapter 26, **Clinical Insight 26-1: Reusing Needles and Syringes: Home Care,** in Volume 2.

Needles

Needles are disposable, stainless steel sheaths that attach to a syringe. Figure 26-13 shows the parts of a needle. Needles are made in various lengths and gauges and with different bevel sizes.

Gauge refers to the inside diameter of the needle lumen. Needle gauges are numbered 14 through 30: the smaller the gauge, the larger the diameter (i.e., a 16-gauge needle has a larger diameter than a 20-gauge needle). Choose the gauge based on the patient's size and skin condition, the viscosity of medication used, and the speed of administration desired. Smaller needles (25- to 30-gauge) cause less pain and trauma to the tissue, so they are useful for patients who must have frequent or long-term injections (e.g., insulin and heparin). Larger needles, 14- to 18-gauge (or needleless systems), are used to infuse blood and more viscous medications or for rapid infusion of IV medications.

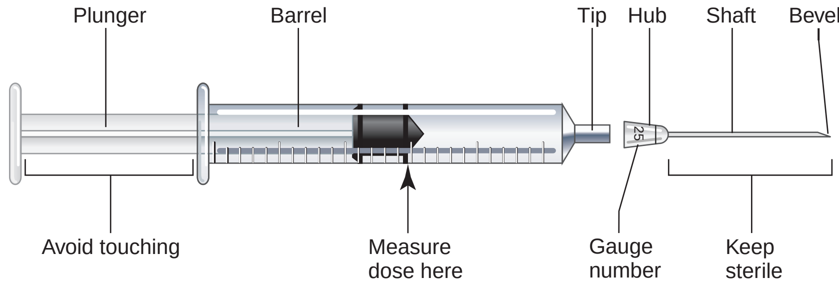

FIGURE 26-13 Parts of a needle and syringe.

Bevel is the slanted tip with a narrow slit. The slant of the tip creates an opening that will close quickly to prevent leakage of medication, blood, and serum. A long bevel tip is sharper and narrower and therefore causes less discomfort during injection. Long bevels are usually used for subcutaneous and intramuscular injections. Short bevels are used for intradermal or IV injections. For an illustration of a bevel,

Go to **Procedure 26-11: Administering Intradermal Medication,** in Volume 2.

Needle Length is the distance from the tip to the hub (bottom) of the needle. Common needle lengths range from $\frac{3}{8}$ inch to 3 inches. Choose the length according to the thickness of the patient's muscle and adipose tissue and the site in which the drug is to be injected. For example, use a longer needle for intramuscular injections, and a shorter one for intradermal injections. A $1\frac{1}{2}$-inch needle is common for intramuscular injections, but you would use a shorter one for a child or a very thin person.

Think**Like a Nurse** 26-11

- You are to give repeated intramuscular injections to a patient who is frail and has very little muscle mass (5 ft 5 in. tall and weighing 96 lb). You are to give 1 mL of a thin, watery medication. You have these needle sizes available: 16-gauge, 20-gauge, 25-gauge. Which would you use, and why?
- For the same patient, you have needles available in 1-inch and $1\frac{1}{2}$-inch lengths. Which would you use, and why?

Filter Needles and Filter Straws are used to trap rubber or glass fragments when drawing up a medication from a vial or an ampule. You must replace the filter needle with a regular needle before injecting the medication into the patient or into the IV solution.

Safety Needles Many safety needle devices are available. Examples include a resheathing system with a sliding barrel that shields the needle, syringes with retractable needles, and needles with attached covers that reduce the risk of accidental puncture with contaminated needles (Fig. 26-14). Wing-tipped safety needles are also available for clinical use. To see some types of safety needles,

Go to Student Resources, **Animations: Self-Resheathing Needle, Syringe With Retractable Needle, Winged Steel Needle, and "Add-On" Safety Feature for Needle,** on Davis*Plus*.

Syringes

A syringe consists of a barrel, plunger, and syringe tip (see Fig. 26-13). Because injections require strict sterile technique, you may touch the outside of the barrel and end of the plunger but not the inside of the barrel, hub, shaft of the plunger, or needle.

Syringes are usually made of plastic and are disposable. Some have the needle attached; others do not. The syringe tip, either **luer-lock** (twist on) or **non-luer-lock** (slip on), fits into the needle hub (Fig. 26-15). Syringes are made in various sizes, from 0.5 mL to 60 mL. The larger sizes are used for adding medications to IV solutions and for instillations and irrigations. You will usually use a 2-mL or 3-mL syringe for intramuscular injections. Three syringes are shown in Figure 26-16. For interactive exercises to familiarize yourself with syringe markings,

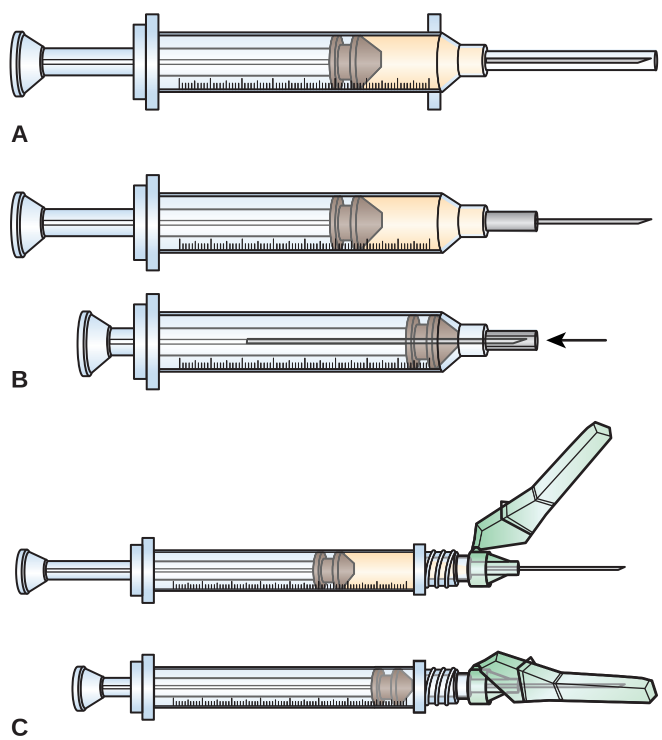

FIGURE 26-14 Needle safety features. *A*, Self-sheathing safety feature: Sliding needle shields attached to disposable syringes and vacuum tube holders. *B*, Syringe with retractable needle. *C*, Needles with covers.

FIGURE 26-15 Syringe tips. *A*, Luer-lock (twist-on) tip. *B*, Non-luer-lock (slip-on) tip.

Go to **Animations: Syringe Exercises,** on Davis*Plus.*

- **Standard syringes** are supplied in 3-, 5-, and 10-mL sizes. They are commonly supplied without needles or with 18-, 21-, 23-, or 25-gauge needles that are 0.5 to 3 inches long. They are calibrated and marked in 0.1-mL and 1- or 2-mL increments so that drugs can be measured accurately.
- **Tuberculin syringes** have a 1-mL capacity and are calibrated in 0.01-mL increments; they come with a small (usually 25- to 28-) gauge, short ($\frac{1}{2}$- to $\frac{5}{8}$-in.) needle. Use tuberculin syringes to administer small, precise doses of medication (e.g., when medicating infants or children, for allergy tests, or when administering potentially dangerous medications, such as heparin).
- **Insulin syringes** are calibrated in units and are used to administer insulin. Insulin syringes are marked in 100 units per milliliter. They are made in 0.3-, 0.5-, or 1-mL sizes with very small-gauge needles (26- to 30-gauge).
- **Prefilled unit-dose systems** are reusable syringe holders that hold disposable, single-dose, prefilled medication cartridges. No medication preparation is necessary, but you must check each cartridge and dose carefully because all of the cartridges look alike. You simply insert the cartridge into the holder and lock it in place. An auto-retractable needle on the syringe is intended to decrease the chance of needle stick. Prefilled syringes for intravenous use have a luer-lock system or a blunt cannula to connect with the port. After administering the medication, dispose of the cartridge; keep the holder for reuse.
- **Disposable prefilled, self-contained systems** are available for hospitals, office practices, nursing homes, and self-administration. The injection plunger is attached to the medication barrel and twists in directly. This ready-to-use syringe reduces the risk of constituting or dosing errors. Because you do not need to remove the cartridge from the holder after using it, the risk of a needlestick injury is reduced (Fig. 26-17). To learn more about using prefilled systems,

Go to Chapter 26, **Clinical Insight 26-2: Using Prefilled Unit-Dose Systems,** in Volume 2.

- **Safety syringes.** Many safety syringe devices are available. Examples include a resheathing system with a sliding barrel that shields the needle (Fig. 26-18), syringes with retractable needles that spring back into

FIGURE 26-17 (*Left*) Prefilled unit-dose system. (*Right*) Disposable, prefilled, self-contained system.

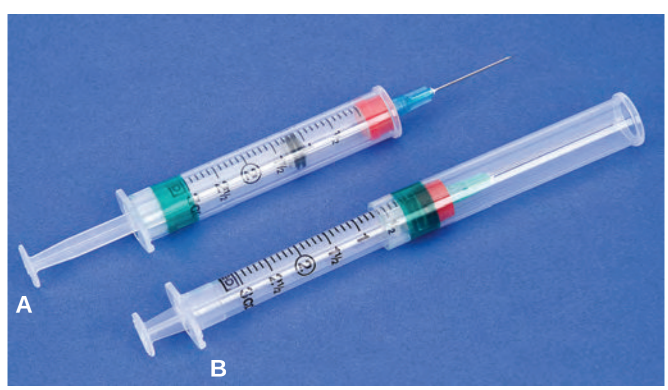

FIGURE 26-18 Special safety syringe. *A*, Needle guard position before injection. *B*, Needle guard position after injection.

the barrel of the syringe, and needles with attached covers that reduce the risk of accidental puncture with contaminated needles.

KnowledgeCheck 26-15

- What does the term *parenteral* mean?
- What are two disadvantages of the parenteral route?
- To maintain sterile technique, which part of a syringe must you *not* touch?
- You need to irrigate a wound. Which syringe size do you need: 0.5 mL, 3 mL, 5 mL, or 50 mL?
- Which syringe would you use for an intramuscular injection, as a rule: tuberculin, 50 mL, 5 mL, or 3 mL?

Drawing Up and Mixing Medications

Most injectable medications are packaged in single-dose or multidose ampules and vials. You will use slightly different techniques, depending on the container.

Drawing Up Medications From an Ampule

An **ampule** is a thin-walled, disposable glass container with a narrow neck that you must snap off to access the medication. To prevent injuries, use an ampule opener to snap the glass (Fig. 26-19). Each ampule holds a single dose of a liquid medication, usually 1 mL to 10 mL, although some hold 50 mL. Because glass fragments may be introduced into the medication, most agencies require you to use a filter needle or filter straw to draw up the medication. See the Highlights of Procedures box. Also,

Go to Chapter 26, **Procedure 26-9A: Drawing Up Medication From Ampules,** in Volume 2.

FIGURE 26-19 Safety device for opening glass ampules.
(Courtesy of Medi-Dose, Inc. EPS, Inc., Ivyland, PA.)

Drawing Up Medications From a Vial

A **vial** is a single-dose or multidose plastic or glass container with a rubber stopper that reseals the top after each needle introduction. A plastic or metal cap covers the rubber stopper to protect it until it is used (Fig. 26-20). Because the vial is a closed system, you must inject air into it to withdraw the solution. Otherwise, a vacuum is created in the vial that makes withdrawal difficult. See the Highlights of Procedures box. Also,

Go to Chapter 26, **Procedure 26-9B: Drawing Up Medication From Vials,** in Volume 2.

Nurses traditionally wipe the rubber stopper with alcohol after removing the cap, even on a single-dose vial; however, there is conflicting scientific justification for this practice as an infection control measure. The practice does remove dust and rubber particles from the top of the vial; however, using a filter needle or straw achieves that purpose as well. You will need to follow the policy of the institution in which you work.

Reconstituting Medications

Medications that are not stable in solution are dispensed as powders in vials. You must add a diluent or solvent to the powder to create a solution for injection. The diluent is usually sterile water or saline; however, each packaged vial includes the manufacturer's instructions for the amount and kind of solvent to add. For safety, use a plastic vial access cannula instead of a needle when possible. For guidelines,

Go to Chapter 26, **Clinical Insight 26-3: Reconstituting Medication,** in Volume 2.

Mixing Medications in the Same Syringe

You can mix two medications in the same syringe (1) if they are compatible, (2) if the total dose is within accepted limits, and (3) if they are both to be given by the same route. This technique allows for efficient use of supplies and allows the patient to receive fewer injections.

Medications are *compatible* if they can be mixed without affecting their constituents or actions. Package inserts and medication references usually include compatibility information.

FIGURE 26-20 Vials containing medications.

Always check the compatibility before mixing medications together. If the contents of the syringe become discolored, there are visible particles in the solution, or there is a change in consistency, do not administer the medications.

When mixing medications in one syringe, you must follow these principles:

- Maintain sterile technique (as with all parenteral medications).
- Do not contaminate one container with medication from the other container. You must use a separate needle to withdraw from each vial (exceptions: when both are single-dose vials, and in the case of different types of insulin).
- Ensure the total, final dosage is correct by adding the volumes of the two medicines together and ensuring that this is the amount you have in the syringe.
- If you draw up too much of the second drug, or if your final measurement of the total for both drugs is incorrect, you cannot eject medication, because you cannot know how much of either drug you are ejecting. You must discard the syringe and medication and begin again.

Never reuse a needle or syringe for drawing up a later dose of medication. A single-use vial contains only one dose of medication. Even if you do not administer the entire dose, the remaining amount must be discarded.

Key Point: ***A single-dose vial should only be used one time for one patient, using a sterile needle and sterile syringe.***

See the Highlights of Procedures box for guidelines. For the complete steps,

Go to Chapter 26, **Procedure 26-9C: Mixing Medication From Two Vials,** in Volume 2.

Accounting for Needle "Dead Space"

Some nurses believe a small amount of the patient's medication remains in the needle when an injection is given. Therefore, they recommended adding 0.2 mL of air to the syringe after measuring a medication for IM injection. Nurses are not in agreement regarding this practice and, unfortunately, there is scant research to provide evidenced-based guidance. Theoretically, on injection the air clears the needle of medication, ensuring that the patient receives the entire dose. However, because syringes are calibrated to account for medication left in the needle, and because the medication left in the needle after injection is the same amount as before the injection, many believe that air should not be added. We recommend that you add air only in the following situations:

1. *When the medication is irritating to subcutaneous tissues,* add 0.2 mL of air after measuring the proper dose. The air drives the medication deep into the subcutaneous tissue and creates an air lock above the medication, preventing it from tracking through subcutaneous tissue.
2. *When you change needles after drawing up the medication (e.g., replace a filter needle).* The new needle has air in it instead of medication. If you push the plunger until you see a drop of medication at the tip of the needle, you will see that you no longer have a complete dose in the syringe. Pulling in 0.2 mL air before changing the needle and then pushing the plunger until you see a drop of medication at the tip of the new needle will prevent the loss of medication with the needle change.

Go to Chapter 26, **Clinical Insight 26-4: Measuring Dosage When Changing Needles,** in Volume 2.

Preventing Needlestick Injuries

Workplace injuries occur from needles and other "sharps," putting healthcare workers at risk for bloodborne diseases, such as hepatitis B, hepatitis C, and HIV (see Chapter 24). For this reason, special safety devices have been designed to reduce the risk of needlestick injuries through blunting, shielding, retracting needles, wing-tipped needles, and needles with attached covers as in Figure 26-14A, B, and C. Figure 26-18 is a photo of a safety syringe with a guard that pulls forward to cover the needle immediately after it is withdrawn from the skin to reduce the risk of accidental punctures with contaminated needles. You then dispose of both needle and sheath in a "sharps" container. Needles with attached covers reduce the risk of accidental punctures with contaminated needles.

The Centers for Disease Control and Prevention (CDC) and the Occupational Safety and Health Administration (OSHA) recommend the use of "needleless" systems. Most systems involve adapters that can be used with regular intravenous tubing and medication vials, permitting access through a valve system without a needle. Figure 26-21 shows three such devices.

Another needle-free system is the jet injection most often used for immunizations. The jet injectors drive liquid medication into the intradermal, subcutaneous, or intramuscular tissues by creating a narrow stream under high pressure that penetrates the skin. However, local reactions or injury, such as redness, bruising, and pain, occur more often with jet injectors than by use of a needle.

Always dispose of needles, glass, and other "sharps" in clearly marked, usually red, puncture-proof containers (Fig. 26-22). Never force a needle into an already full container; you may be injured by sharps protruding from the top. Never put a needle or other sharp in a wastebasket, in your pocket, or leave it at the patient's bedside.

For tips to prevent needlestick injury,

Go to Chapter 24, Promoting Safety, **Clinical Insight 24-2: Preventing Needlestick Injuries,** in Volume 2.

Recapping Contaminated Needles You should never recap a contaminated needle (e.g., after giving an

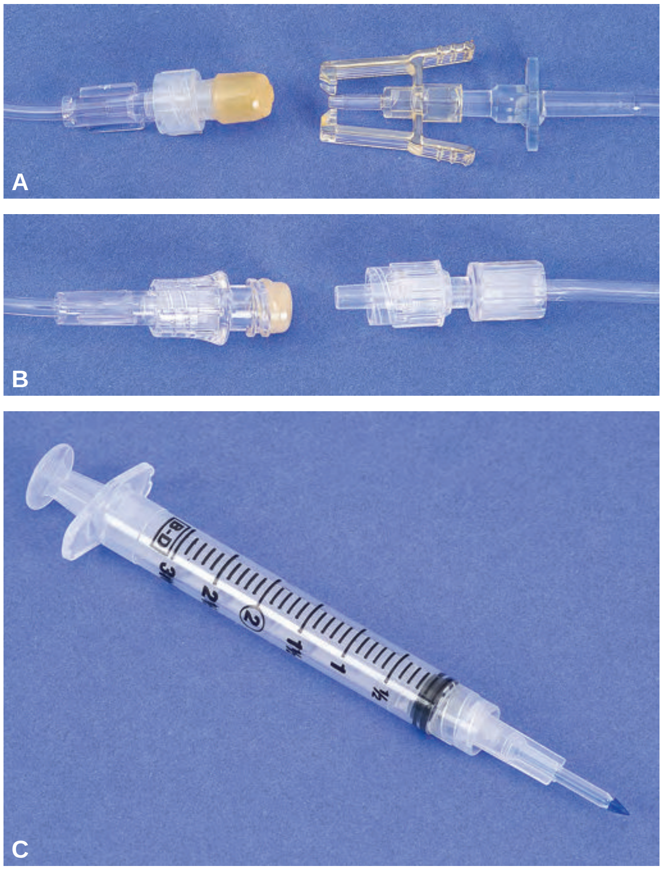

FIGURE 26-21 Needleless systems. *A*, Lever-lock cannula. *B*, Threaded lock cannula. *C*, Blunt-tipped syringe for drawing up medication.

FIGURE 26-22 Disposal system for sharp objects, such as needles and glass. The container must be clearly marked, usually red, and puncture-proof.

injection); place it uncapped, needle pointing downward, directly into a sharps disposal container. However, you may occasionally find that you must recap a contaminated needle. The OSHA Fact Sheet (2012) requires bending, recapping, or needle removal using a mechanical device or a one-handed technique. For step-by-step instructions,

Go to Chapter 26, **Procedure 26-10: Recapping Needles Using a One-Handed Technique,** in Volume 2.

Recapping Sterile Needles OSHA and the National Institute of Occupational Safety and Health (NIOSH) (U.S. Department of Health and Human Services [USDHHS], NIOSH, 2012) do not advise against recapping sterile needles (e.g., after drawing up a medication), except to recommend needleless systems and safety systems. We suggest that you not use the one-handed "scoop" technique to recap a sterile needle because the risk of contaminating it is high. Consider one of the other methods described in Procedure 26-10.

Comfort and Safety Considerations

Parenteral techniques are invasive. They carry the potential for tissue trauma and provide a portal of entry for pathogens through the skin. You must, of course, maintain strict aseptic (sterile) technique to minimize the risk of infection. Moreover, your injection technique and choice of injection site are critical to patient comfort and safety. When choosing a site, consider the type, viscosity, and volume of the medication to be administered; the anatomical landmarks underlying injection sites; and the patient's situation (e.g., the condition of the tissues at the injection site, the accessibility of certain sites). The following are examples of judgment and technique errors and their consequences:

- Injecting a large volume of medication into a small muscle causes pain and may damage the tissues.
- Injecting into the wrong tissue (e.g., giving an intramuscular medication too shallowly into the subcutaneous tissue) may (1) accelerate or delay the rate of absorption and (2) cause tissue injury and pain.
- Incorrectly locating an injection site may result in bone or nerve injury when you insert the needle.
- An unsteady needle and syringe while injecting the drug could lead to pain and tissue trauma.
- Forgetting to aspirate before injecting risks administration of medication into an artery or vein instead of the muscle. This could result in an adverse, even fatal, effect.

Minimizing Discomfort

The discomfort associated with an injection comes from three sources: the prick of the needle, the pressure of the volume of the drug in the tissues, and chemical irritation caused by some drugs. Fear and anxiety magnify discomfort. Use the following techniques to reduce discomfort:

- Use the smallest needle suited for the site and medication.
- Use two needles when drawing up medications: one to withdraw the medication from the container, and the

second one for the injection. If the needle is not free of medication, it may irritate tissues as it is inserted.

- Do not administer too much solution into an injection site. If the total volume is more than the recommended amount, give it in two injections and at two sites.
- For intramuscular injections, help the patient assume a position that reduces muscle tension.
- For intramuscular injections, use the Z-track technique, discussed later in this chapter, to minimize pain and tissue irritation.
- Pull the skin taut, and insert the needle quickly to avoid pulling the tissues. Remove the needle quickly and at the same angle you inserted it.
- Steady the syringe with one hand while injecting the medication.
- Inject the medication slowly.
- Distract the patient from the procedure by talking to her.
- Apply gentle pressure (not massage) after injection unless contraindicated.
- Especially with children, acknowledge that they will feel some pain (e.g., "This may hurt a little bit."). If you deny or minimize the pain, the patient might lose trust in you and be even more anxious about future injections.
- After injecting a child, pat or hug him, speak softly to him, and perhaps play with him, so that he does not associate you only with pain.
- Other methods for decreasing pain can be cooling the skin (e.g., applying ice) or flicking or tapping over the injection area before injecting. Both send distracting signals to the brain so that when the needle comes, it can't process the stimulus as easily.

Developmental Stage

Because older adults may experience muscle atrophy or have decreased muscle mass, you may need to use a shorter needle.

Infants and children also require shorter, thinner needles. Also, you should ask a parent or another caregiver to immobilize an infant or young child to prevent injury during the injection.

The preferred intramuscular site for infants is the vastus lateralis muscle, because there are no major nerves or blood vessels in the area and the gluteal muscles have not yet been developed by walking. For children who are walking, the site of choice is the ventrogluteal muscle because the muscle is more developed.

Do not use the dorsogluteal site for patients of any age, including older children and adults, because of its location to major blood vessels and the sciatic nerve.

Intradermal Injections

Intradermal injections are given into the **dermis**, which is the layer of the skin located beneath the skin surface. The intradermal route is commonly used for allergy or tuberculosis (TB) testing. Most nurses use the patient's nondominant arm for TB screening and the dominant arm, chest, or upper back for all other tests (Fig. 26-23). Give only small amounts of medication by this route—about 0.1 mL. Use a 1-mL syringe and a short, small (26- to 28-gauge) needle, and insert at an angle of 5° to 15° (see Fig. 26-24).

Do not apply pressure or massage the injection site, because the capillaries in the dermal tissue will quickly absorb the medication.

Refer to the Highlights of Procedures box for critical elements of intradermal injections. Also,

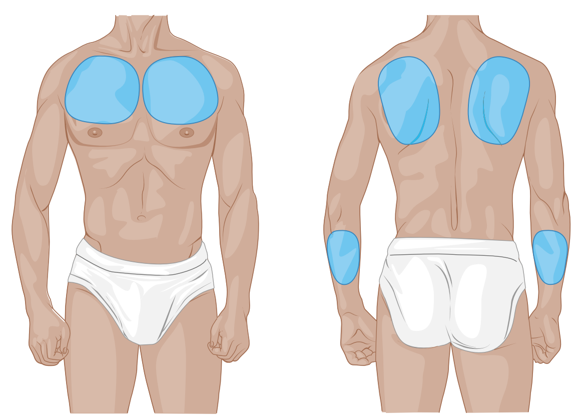

FIGURE 26-23 Sites commonly used for intradermal injection.

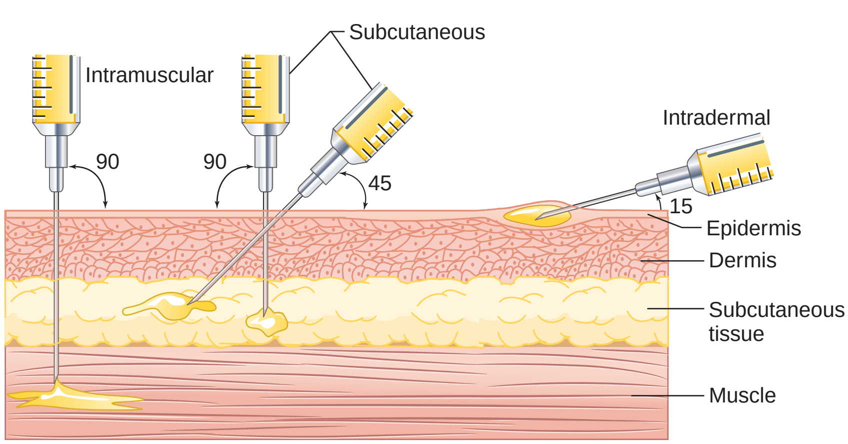

FIGURE 26-24 Standard angles of insertion for intramuscular, subcutaneous, and intradermal injections.

Toward Evidence-Based Practice

Agac, E., & Gunes, U. (2011). Effect on pain of changing the needle prior to administering medicine intramuscularly: A randomized controlled trial. *Journal of Advanced Nursing, 67*(3), 563–568.

One hundred patients rated the pain associated with two IM injections:

- One-needle technique—The same needle was used to both withdraw the medication and inject it.
- Two-needle technique—The needle was changed before administering the IM injection.

In both injections, air was pushed from the barrel after changing the needle, and the same investigator performed the actions. On a pain scale of 0 to 10, the overall pain score was 5.53 for the two-needle technique and 6.43 for the one-needle technique. Researchers recommended using a two-needle technique to promote patient comfort.

Zaybak, A., & Khorshid, L. (2008). A study on the effect of the duration of subcutaneous heparin injection on bruising and pain. *Journal of Clinical Nursing, 17*(3), 378–385.

Researchers studied the differences in bruising or pain when subcutaneous injections of heparin were given quickly or slowly in 50 patients who required treatment with heparin. Injections on the right abdomen were given over 10 seconds; on the left abdomen, over 30 seconds. Bruising occurred in 64% of patients who received the rapid injection and 42% of those receiving the slower injection. Pain intensity and pain duration were statistically significantly lower for the slower injection group, and the size of the bruising was smaller.

Ipp, M., Taddio, A., Sam, J., et al. (2007). Vaccine-related pain: Randomized controlled trial of two injection techniques. *Archives of Disease in Childhood, 92*(12), 1105–1108.

This study compared pain during a routine DPTaP-Hib immunization using a slow injection versus a rapid technique. Subjects were 113 healthy infants aged 4 to 6 months.

- Technique 1—One group received the IM dose using slow aspiration before injection, slow injection, and slow withdrawal.
- Technique 2—The other group's technique involved no aspiration, rapid injection, and rapid withdrawal.

Infants receiving the slower injection technique cried twice as often, cried longer, and took more time to have the vaccine injected. Researchers concluded that for the study participants, using a rapid injection technique is less painful than a slower technique and should be recommended for routine intramuscular immunization.

1. You are providing care to an older adult patient who is receiving heparin therapy via subcutaneous injection. Based on the Zaybak study, would you give subcutaneous doses over 10 seconds or 30 seconds?

2. You are working in a pediatric clinic. You want to administer IM medication and immunizations to children in as pain-free a way as possible. Would you give IM injection slowly or more rapidly? Why would you choose that technique?

3. Why do you think changing the needle after withdrawal of medication but prior to administration would be less painful?

Also go to Student Resources, **Animations: Angle of Injection,** on Davis*Plus*.

Subcutaneous Injections

Subcutaneous (subQ) injections are given into the subcutaneous tissue, the layer of fat located below the dermis and above the muscle tissue. Absorption is slower than it is through the intramuscular route because subcutaneous tissue does not have as rich a blood supply as muscle. However, speed of absorption varies with the subcutaneous site selected. Absorption is fastest in sites on the abdomen and arms; it is slower on the thigh and upper buttocks. Medication is absorbed more evenly from the abdomen than from the thighs and buttocks because it is affected less by activity.

You do not need to aspirate for blood return when giving a subcutaneous injection because of the shallow depth of the needle into the subcutaneous layer under the skin. The Highlights of Procedures box contains critical elements of the procedure. For the full procedure,

Go to Chapter 26, **Procedure 26-12: Administering Subcutaneous Medication,** in Volume 2.

Choosing a Subcutaneous Site Avoid sites in which the subcutaneous tissue lies beneath burns, birthmarks, inflamed tissue, or scars. Do not use sites with lesions or sites over bony prominences, large underlying vessels, or nerves. When using the abdominal site, do not inject any closer than 5 cm (2 in. horizontally and vertically) from the umbilicus. For repeated injections, each injection should be at least an inch apart. It is important to rotate sites for repeated injections to minimize scarring and hardening of fatty tissue that will interfere with the absorption of medication. See Figure 26-25 for sites to use for subcutaneous injections.

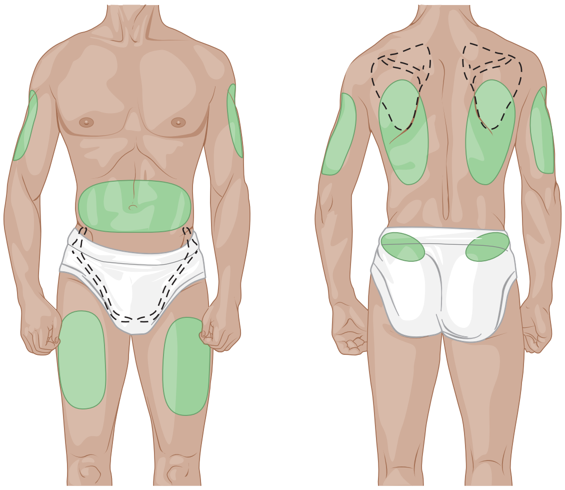

FIGURE 26-25 Sites used for subcutaneous injections.

Choosing a Subcutaneous Needle As a general rule, use a syringe with a small-gauge, short needle for subcutaneous injection—that is, long enough to penetrate beyond the skin into the fatty subcutaneous layer and yet not into the muscle. The needle length will vary depending on the amount of adipose the patient has and the type of injection that is needed (e.g., insulin, immunization, or other medication). For most subcutaneous injections, a 3/8- to 5/8-inch needle is preferred. However, shorter needles (e.g., 3/16 to 5/16 inch) are more comfortable for some insulin users.

The needle **gauge** for subcutaneous injection is typically 25- to 27-gauge; however, finer needles are preferred by many insulin users (e.g., 28- to 31-gauge). For children and persons with little or average subcutaneous fat, insert a standard length needle (5/8 in.) at a 45° angle; however, when using a shorter needle, inject at a 90° angle. Obese patients will need a longer needle (e.g., 1-inch) and a 90° angle for injection (Fig. 26-24), and the nurse needs to spread the skin taut rather than pinching.

Inject only small amounts (0.5 to 1 mL) of water-soluble medication subcutaneously to avoid creating sterile abscesses (hardened, painful lumps under the skin).

Administering Insulin

Insulin must be administered subcutaneously or intravenously because it is a protein and would be destroyed in the gastrointestinal tract. Insulin is administered using a special insulin syringe. Insulin vials contain 100 units/mL. The prescriber will specify the number of units (**not** milliliters or milligrams) to administer. Insulin may be routinely prescribed in specific dosages at specific times or on a **sliding scale**, in which the amount of insulin prescribed is based on the patient's blood glucose level. However, some view the sliding scale as a reaction to hyperglycemia rather than preventing its occurrence and a practice that may be dangerous (DeYoung, Bauer, Brady, et al., 2011). Others believe that when appropriately used, it is an effective type of correction insulin therapy (Magaji & Johnston, 2011). Sliding scale is used less now because basal insulin is available to stabilize blood sugar with fewer fluctuations, and because insulin pumps are in more common use. However, it can be useful when initiating insulin therapy and during times of physical stress (e.g., illness, surgery, trauma). Follow your institution's policy and the prescriber's guidance regarding the sliding scale.

People with diabetes usually administer their own insulin injections. Teach them to rotate injection sites to promote absorption and minimize tissue damage. Insulin is absorbed at different rates from different parts of the body. For hospitalized patients, you should document site rotation (usually on a diagram of the body) to prevent repeated use of the same site.

Categories of Insulin

To prevent errors and give insulin safely, you need to understand the categories of insulin and how they are used for blood sugar control.

- **Basal insulin** is given to cover the body's energy needs without taking the diet into account. Common basal insulins are NPH, insulin glargine (Lantus), and insulin detemir (Levemir).
- **Prandial** (mealtime) and **preprandial insulins**, such as regular insulin (e.g., Humulin R, Novolin R), are given to prevent high blood sugar after eating a meal. However, analogs with a more rapid acting onset than regular insulin (e.g., insulin lispro [Humalog], insulin aspart [NovoLog/NovoRapid], and insulin glulisine [Apidra]) are being added to the medication regime (Magaji & Johnston, 2011).
- **Correction insulin** is given to reduce an elevated blood sugar level that is not controlled by mealtime insulin. When a part of the patient's total daily dose requirements, this type of sliding scale blood sugar management may be effective. When used alone, it can create unpredictable glucose levels that may be dangerous.

Using two types of insulin can help keep blood sugar level in a target range. By mixing it in the same insulin syringe, your patient will need only one injection. For guidelines for mixing insulins,

Go to Chapter 26, **Clinical Insight 26-5: Mixing Two Kinds of Insulin in One Syringe,** in Volume 2.

Appearance of Insulin

Regular (unmodified) insulin is rapid acting. It is a clear solution. If a vial of regular insulin is cloudy, you should discard it. Other types of insulin (e.g., modified, such as Lente, insulin glargine [Lantus], and neutral protamine Hagedorn [NPH]) are cloudy because of the addition of proteins, which slow the absorption of the drug, giving the insulin an intermediate to long duration of action. As a rule, remember "clear before cloudy"; that is, draw up the regular (clear) insulin first, and then draw up the modified (cloudy) insulin. In practice, though, you may rarely need to mix insulins because stable premixed insulins are available.

Storing Insulin

The length of time insulin can be stored depends on whether it is refrigerated or stored at room temperature. Discuss with your pharmacist or check the package insert to know how long the insulin will remain effective after the vial is opened. Also,

Go to Chapter 26, **Supplemental Materials, Insulin Administration,** on Davis*Plus*.

Insulin Equipment

Insulin can be administered using a variety of tools. Regardless of the device, correct technique is essential for both nurses and patients who self-administer.

- **Disposable syringes** for subcutaneous injection are the most common.
- **Automatic injectors** are used by some patients for subcutaneous dosing. By pressing a button on the device, the injector releases the needle into the skin, releasing the insulin dose.
- **Insulin pumps** are becoming more common as a way to maintain glycemic control because of the benefit of fine-tuning the dosing. The pump consists of a tube with a needle on the end of it that is taped to the abdomen, and a computerized device that is worn at the waist. Insulin is received continuously from the pump. A button is pressed at mealtime to release an extra insulin dose.
- **Insulin pen devices** contain a cartridge and disposable needles to deliver certain doses with each injection. They are convenient and may help patients to avoid certain medication errors. However, the Institute for Safe Medication Practices (ISMP, 2013) strongly suggests that hospitals consider transitioning away from using them because of the risk of cross-contamination.
- **Nondisposable syringes** (glass syringe and metal needle) may be used repeatedly if they are sterilized after each use.
- **Spray injectors** forcefully spray the insulin dose into the skin. This involves a wider area of skin than would a regular injection.

- How are they different?

Administering Heparin

Heparin is a fast-acting medication that interrupts the blood-clotting process. It may be used for patients at risk for thrombus formation, for example, those who are immobile after major surgery, have undergone vascular surgery, or have problems related to blood clotting, such as cerebrovascular accident (stroke, brain attack) or myocardial infarction (heart attack). Because heparin is absorbed poorly from the gastrointestinal tract, it is given intravenously or subcutaneously. If mistakenly given intramuscularly, it will cause hematoma and pain.

Heparin dosage is based on the patient's weight and results of blood coagulation studies, so always check laboratory values for coagulation studies before giving.

Give the injection deep into the subcutaneous tissue of the abdomen, at least 5 cm (2 in.) away from the umbilicus. Rotate sites. Because of the anticoagulant properties of heparin, you will need to modify your injection technique. For detailed guidelines,

Go to Chapter 26, **Clinical Insight 26-6: Administering Anticoagulant Medication Subcutaneously,** in Volume 2.

Intramuscular Injections

Intramuscular (IM) injections (injections into muscle tissue) are absorbed faster than subcutaneous medications because of the rich blood supply in the muscles. Muscles can also tolerate more fluid—you can give as much as 3 or 4 mL of liquid in the large vastus lateralis and ventrogluteal muscles. The smaller the muscle, the less fluid it can tolerate. For example, you should usually give no more than 0.5 to 1 mL in the average deltoid muscle.

Conventional techniques require you to **aspirate** (pull back on the plunger of the syringe) before injecting medication intramuscularly to be sure the needle tip is not in a blood vessel. If there is no blood return, you are confident that the medication will not be injected into a blood vessel. However, there are insufficient evidence-based studies to support this conclusion. The CDC does not recommend aspiration before giving IM vaccines using the vastus lateralis and deltoid muscles *for vaccine administration* because there are no large blood vessels at these sites (CDC, n.d.). Others would limit the practice of aspiration to IM injections of large molecule medications such as penicillin (Crawford & Johnson, 2012). To promote better outcomes and less pain when administering IM injections to children, the practice of aspiration is not recommended (Walden & Vangilder, 2013). Since this has been a conventional practice and no evidence exists that aspirating for blood poses a risk to the patient, you should follow your institution's policies and procedures for IM injections.

Choosing an Intramuscular Site

When selecting an IM site, you should look for a site that is:

- A safe distance from nerves, large blood vessels, and bones
- Free from injury, abscesses, tenderness, necrosis, abrasion, or other pathology
- Large enough to accommodate the volume of medication to be given

Muscles commonly used are the vastus lateralis, ventrogluteal, and deltoid. Because of their proximity to major nerves and vessels, the rectus femoris and dorsogluteal are no longer recommended sites (Greenway, 2004; Walsh & Brophy, 2011). For a summary description of IM injection sites, refer to the Highlights of Procedures box. For the complete procedure,

Go to Chapter 26, **Procedure 26-13: Locating Intramuscular Injection Sites,** in Volume 2.

Ventrogluteal Site—Site of Choice Whenever possible, use the ventrogluteal site for IM injections; it is the site of choice for adults and young children who are walking. The ventrogluteal site, located on the lateral hip, involves the gluteus medius and gluteus minimus muscles (Fig. 26-26). Because it is located away from major blood vessels and nerves, it is the safest and least painful site for IM injections. Be aware, though, that some medications and immunizations, such as those used to treat influenza/pneumonia, are normally given in the deltoid; be sure to check the package insert.

When learning to locate this site, many students notice that it feels "hard" when they palpate it. They worry the needle will hit the bone. In part, the muscle feels hard because there is little subcutaneous tissue over it. To reassure yourself it is safe, examine a skeleton model with the muscles attached. Notice that the ilium is concave (curves in) and the muscle lies deep down in the "cup" it forms. If you are sure you have located the anterosuperior iliac spine and if you follow the procedure steps, you will not hit a bone. In fact, you are less likely to do so than were you to use other sites. For guidelines in locating the ventrogluteal site, refer to the Highlights of Procedures box and Procedure 26-13A (in Volume 2).

Dorsogluteal Site—Site to Avoid The dorsogluteal site consists of the gluteal muscles of the buttocks.

Avoid using the dorsogluteal site for IM injections because its close proximity to the sciatic nerve and superior gluteal artery increases the risk of (1) injection into a major blood vessel and (2) damage to the sciatic nerve. Furthermore, the site is difficult to identify accurately in older adults or in people with flabby skin.

Research found that nurses continue to use the dorsogluteal site, even though they are aware of its potential for complications, because of tradition, ease of mapping, and comfort level (Walsh & Brophy, 2010). **Key Point.** ***Your avoidance of the dorsogluteal site gives you the opportunity to role model patient safety by demonstrating correct technique for locating the preferred site.***

Deltoid Site The deltoid site is located in the middle third of the upper arm (Fig. 26-27). The area has a small muscle mass with little subcutaneous tissue, so medications are absorbed rapidly. This muscle is easily accessible but is not well developed in many older adults. You should use it only for small amounts of up to 1 mL or when other sites are inaccessible. Avoid using the deltoid site in infants and assess children for adequate muscle mass before using it. However, the anterolateral thigh is preferred for children.

The deltoid muscle is small and lies close to the radial nerve and brachial artery. When locating this site, do not

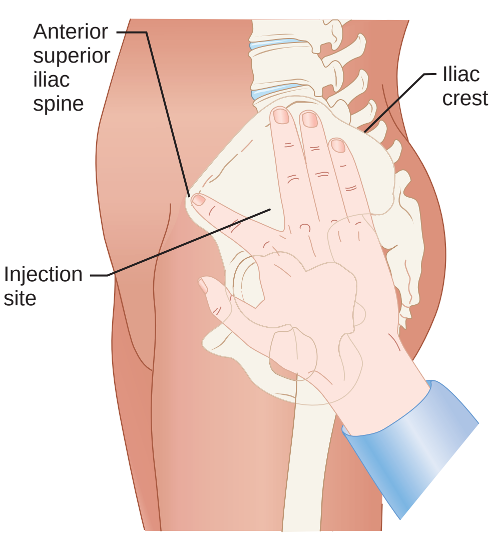

FIGURE 26-26 Locating the ventrogluteal site.

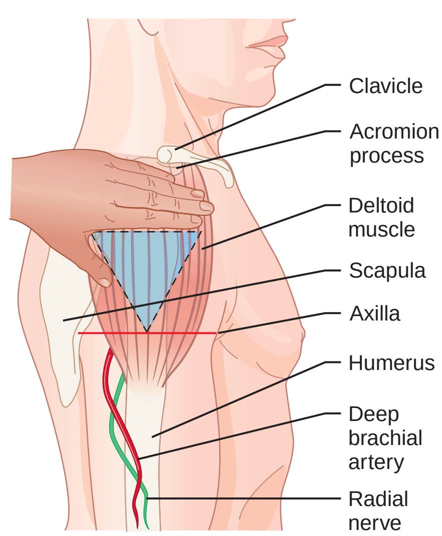

FIGURE 27-27 Locating the deltoid site.

merely roll up the sleeve; fully expose the entire upper arm and shoulder. Otherwise, you may miss the muscle mass and injure a nerve or blood vessel. For a guide to locating the deltoid site, see the Highlights of Procedures box and Procedure 26-13B (in Volume 2).

Vastus Lateralis Site The vastus lateralis muscle, located in the anterolateral thigh (Fig. 26-28), is the preferred site for young infants, particularly before walking age (Bartley, 2012; Jackson, Peterson, Nelson, et al., 2013) because it's usually the best developed and contains no large nerves or blood vessels, minimizing the risk for injury. Other advantages are that (1) drugs are rapidly absorbed from this area, (2) it can accommodate a larger volume of medication than can the deltoid, and (3) it is a convenient site for those who self-administer injections. A disadvantage is that the patient can see you administer the injection, and the psychological effect may create some discomfort. Also, because this muscle is used in walking, an ambulatory patient may notice more residual soreness than in another site.

To relax this muscle for injection, have the patient sit or lie flat with his knee slightly flexed. For children and adult patients with small muscle mass, you should grasp ("pinch up") the body of the muscle during injection to be sure that the medication reaches muscle tissue and the needle does not penetrate to the underlying bone. For a guide to locating the vastus lateralis site, refer to the Highlights of Procedures box and Procedure 26-13C (in Volume 2).

Rectus Femoris Site—For Adults Only The rectus femoris site, located in the anterior thigh, is no longer recommended for infants and children. In addition, you may rarely use it for adults, only when other sites are inaccessible or rapid absorption is needed. It is often used by patients who self-administer their IM injections because it is easy for them to reach. A disadvantage is that it is usually painful. Use a shorter needle when injecting this site. For a guide to locating the rectus femoris site, refer to the Highlights of Procedures box and Procedure 26-13D (in Volume 2).

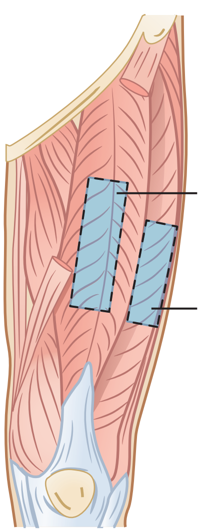

FIGURE 26-28 Locating the vastus lateralis.

Choosing an Intramuscular Needle

Although a 1½-inch needle is considered "standard" for IM injections, you should choose the needle gauge and length based on the site, the size of the muscle, the amount of medication to be given, and the amount of adipose tissue over the muscle. In the deltoid muscle, for example, you might use a 23- or 25-gauge, 1-inch needle. But if the solution is viscous, you would need a larger-bore needle (e.g., 20-gauge). For a very thin person, you could use a 1-inch needle, even when injecting into the larger muscles. For an obese person, you might need a needle as long as 3 inches to penetrate adipose tissue and reach the muscle (long needles may not be available in many settings). As a rule, the angle of insertion for an IM injection is 90° (see Fig. 26-24). See Table 26-3 for needle length recommendations based on age and site for immunizations and vaccinations. The Highlights of Procedures box presents the key elements for IM injections. For the complete steps,

Go to Chapter 26, **Procedure 26-14: Administering an Intramuscular Injection,** in Volume 2.

Z-Track Technique

The Z-track technique seals the needle track and prevents medication from leaking out of the muscle up through the needle track and into the subcutaneous tissues after the needle is withdrawn. The Z-track method is recommended for all IM injections, because it is less painful and helps to prevent irritation of subcutaneous tissues. It is particularly useful for irritating medications, such as iron preparations, that irritate or discolor subcutaneous tissue and for older adults who have reduced muscle mass. Procedure 26-14B, in Volume 2, describes the procedure for using the Z-track technique for intramuscular injections.

For this technique, it is best to use the larger muscles: the ventrogluteal and vastus lateralis sites.

To see an animation of this method,

Go to Student Resources, **Administering Animations, Z-track Injection,** on Davis*Plus*.

KnowledgeCheck 26-17

- Name three sites for giving IM injections.
- What is the preferred IM injection site for adults? Why?
- From which route is medication absorbed more rapidly: subcutaneous or IM? Why?
- For an "average" adult, what is the standard needle length for IM injections?
- Why is the dorsogluteal site *not* recommended?
- What are the disadvantages of the deltoid site?

Table 26-3 ➤ Appropriate Needle Size Based on Age and Site for Vaccinations and Immunizations

AGE		NEEDLE LENGTH	SITE
Newborns (first 28 days)		5/8″*	Anterolateral thigh
Infants (1–12 months)		1″	Anterolateral thigh
Toddlers (1–2 years)		1–1 1/4″ 5/8–1″*	Anterolateral thigh Deltoid
Children and Teens (3–18 Years)		5/8–1″* 1–1 1/4″	Deltoid Anterolateral thigh
Adults (19 years and older)			
Male or Female	Less than 130 lb	5/8–1*″	Deltoid
Male	130–260 lb	1–1 1/2″	Deltoid
Female	130–200 lb	1–1 1/2″	Deltoid
Male	260+ lb	1 1/2″	Deltoid
Female	200+ lb	1 1/2″	Deltoid

*A 5/8″ needle may be used with the skin stretched tight and injection given at a 90° angle.
Source: Adapted from Centers for Disease Control and Prevention (2010a, updated 2012). Administering vaccines: Dose, route, site, and needle size. Retrieved June 23, 2013, from http://www.immunize.org/catg.d/p3085.pdf

- When using the vastus lateralis to give an IM medication to a person with small muscle mass, how can you ensure the medication reaches muscle tissue and the needle does not penetrate to the underlying bone?

Intravenous Medications

Intravenous (IV) medications are given through a catheter, or cannula, inserted into a vein. The onset of medication action takes place within seconds, so IV administration is especially useful in emergencies. However, because an IV drug begins to act immediately, there is no way for you to stop its action if an adverse reaction occurs (unless there is a known antidote). Review Table 26-1 for advantages and disadvantages of using the IV route. IV medications may be administered by a variety of programmable electronic pumps and infusers. These are discussed in Chapter 38.

Many IV push medications are irritating to vein walls and tissues around the vein. If the drug is accidentally injected into tissues, sloughing, pain, and abscesses may occur. To prevent complications, when administering IV medications, you should:

- Assess the patient before, during and after giving the medication.
- Determine whether the drug is compatible with the IV fluid that is infusing. Consult a pharmacist as needed.
- Determine whether the drug is compatible with the plastic IV bag and tubing. You may occasionally need to use a glass IV bottle and special tubing.
- Use sterile technique.
- Observe the insertion site often and check to be sure the cannula is in the vein before administering a medication. Figure 26-29 provides an example of damage that can occur when certain IV medications escape from the vein into surrounding tissues.
- Administer the medication slowly.
- Observe the patient carefully for signs of adverse reactions.
- Have an antidote on hand if the drug has potentially serious side effects. Be aware, though, that many drugs do not have an antidote.
- If your patient shows signs of serious allergic reaction, you will need to prepare to support the patient's airway, deliver oxygen, and administer medication to reduce the reaction.

The following sections explain how to administer IV medications by (1) adding medication to the large-volume primary or maintenance fluids, (2) IV push or bolus, (3) intermittent infusion (piggyback setup), (4) volume-control infusion sets, and (5) central venous access devices. You will find the procedures for initiating and maintaining intravenous fluids and using intermittent injection ports in Chapter 38.

Adding Medications to Large-Volume (Primary) Infusions

The safest way to administer a drug intravenously is to mix it into a bag of fluid that is already infusing (e.g., normal saline, lactated Ringer's solution, glucose). Vitamins, potassium chloride, oxytocin, and several blood pressure and cardiovascular drugs are commonly given

FIGURE 26-29 Tissue and skin injury after intravenous medication leaks into an infiltrated site. (Used by permission of the National Extravasation Information Service (UK). www.extravasation.org.uk)

this way. This method is useful when the drug can be infused continuously over a long period of time or when it must be given continuously to achieve the desired effect. The main disadvantage is the danger of infusing too much fluid, especially for children, older adults, and people with cardiac or renal disease. The drug may be premixed with the IV fluid in the pharmacy or you may occasionally need to add a drug to a bag of IV fluids.

A safe method for mixing medication from multidose IV vials while providing sterile air filtration is to use a **reconstitution device**—designed with a sharp, thin, piercing spike to minimize coring and permit easy penetration of rubber top vials (Fig. 26-30). The luer-lock port maintains a secure closure between the device and the syringe. The hinged cap and the sheath over the spike help maintain sterility before use, minimize "touch" contamination, and ensure a closed system for disposal.

A safe method for adding medications to an IV container is to use a **transfer needle** or **cannula**—a blunted plastic needle with a double beveled tip (Fig. 26-31). One end is inserted into the powdered or liquid medication and the other end is inserted into a port of the IV bag. Solution is transferred from the IV bag into the medication vial, which you shake lightly to mix the medication. Then the medication is transferred back into the IV bag for administration.

Refer to the Highlights of Procedures box. Also,

Go to Chapter 26, **Procedure 26-15: Adding Medications to IV Fluid,** in Volume 2.

IV Push Medications

IV push (bolus) medications are injected directly into a vein and enter systemic circulation immediately. IV push drugs are usually administered incrementally over a 1- to 10-minute time period. Read the package insert or ask the prescriber for specific guidelines on how fast the drug can be pushed. One minute can seem like a very

FIGURE 26-30 A reconstitution device is used to add medication from multidose IV vials while providing sterile air filtration. (Courtesy of Medi-Dose Inc./ EPS Inc., Ivyland, PA.)

long time when you are pushing a medication, so don't guess—look at your watch!

"IV push" does not mean the same thing as "give rapidly." If given too rapidly, IV drugs—particularly potassium—can be quite dangerous. Because you cannot retrieve the medication once it is injected, there is no margin for error.

To learn how to administer IV push drugs, refer to the Highlights of Procedures box, and

Go to Chapter 26, **Procedure 26-16: Administering IV Push Medication,** in Volume 2.

Intermittent Infusion

Many medications, such as antibiotics, are administered intravenously by intermittent infusion. Intermittent infusions may be given through the port of an infusing IV line or, if the patient does not need the additional fluids, through an intermittent injection port, also called a saline or heparin lock (Fig. 26-32).

Infusion Setup Most intermittent infusion medications are supplied in bags containing 50 to 250 mL of 5% dextrose in water (D_5W) or normal saline. The drug is given over a period of time, usually 30 to 60 minutes, and at regular intervals (e.g., every 6 hours). The small bag of diluted medication (the "secondary" bag) is attached to the primary IV infusion line for administration, usually

FIGURE 26-31 Transfer needles. (Courtesy of PFM Medical Ag.)

FIGURE 26-32 Intermittent injection port.

with a piggyback setup. With an **IV piggyback** setup, the smaller (secondary) container is connected to the primary (continuous) infusion line at the upper (primary) port (Fig. 26-33). This setup allows for intermittent use only and the infusion of one solution at a time.

A **tandem setup** allows for the simultaneous infusion of two IV bags, but is less commonly used than is a piggyback setup. For safety, most healthcare facilities require tandem infusions to be regulated via an IV pump.

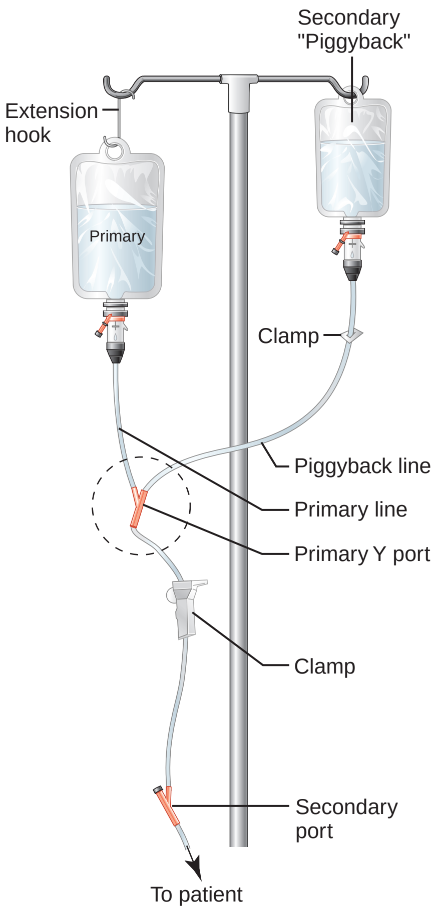

FIGURE 26-33 Piggyback setup is attached to the primary (continuous infusion) IV line at the upper port, allowing for intermittent infusion only.

Needleless Connections Traditionally, the secondary tubing was attached to the primary set tubing by inserting a needle into the port and taping it in place. However, most agencies now have needleless systems (see Fig. 26-21), which use a threaded or lever-type lock to make the connection. In addition to decreasing needlestick injuries, a needleless system prevents contact contamination at the IV connection site.

Key Point: ***You can help prevent catheter-related bloodstream infections by scrubbing the needleless IV connector for 15 seconds. Remember: "Scrub the Hub."***

When the secondary tubing is no longer needed, a disinfection cap containing either alcohol or chlorhexidine/alcohol solution is placed over the port (Fig. 26-34).

The Highlights of Procedures box provides guidelines for administering intermittent infusions. Also,

Go to Chapter 26, **Procedure 26-17B: Using a Piggyback Administration Set With a Gravity Infusion,** in Volume 2.

Volume-Control Infusion Sets

To effectively control the infusion of smaller amounts of solutions, particularly with pediatric patients, a volume-control infusion set (e.g., Buretrol, Soluset, Volutrol, or Pediatrol) may be used (Fig. 26-35). These are small fluid containers (100 to 150 mL) that are attached directly below the primary fluid container. The medication and the desired amount of IV fluid are added to the volume-control container and administered through the primary line. This system decreases the risk of overhydration because the amount of fluid that can infuse into the patient is limited to the amount that you place in the small container.

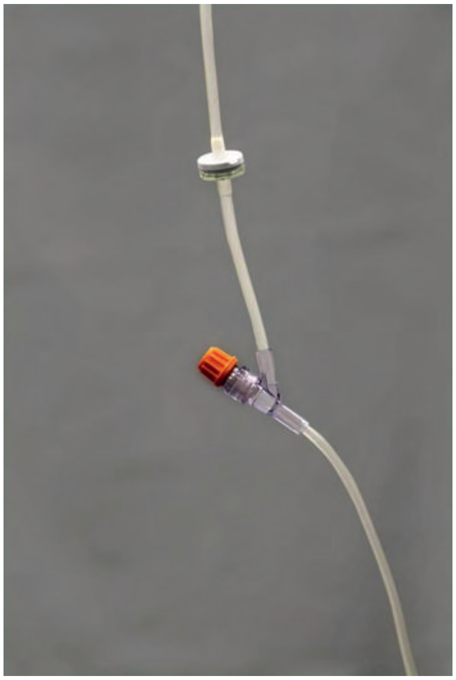

FIGURE 26-34 Disinfection cap for luer-lock needleless hubs. (Courtesy of Dr. Donna Clarren and Dr. Brian Oxhorn, Roseman College of Nursing.)

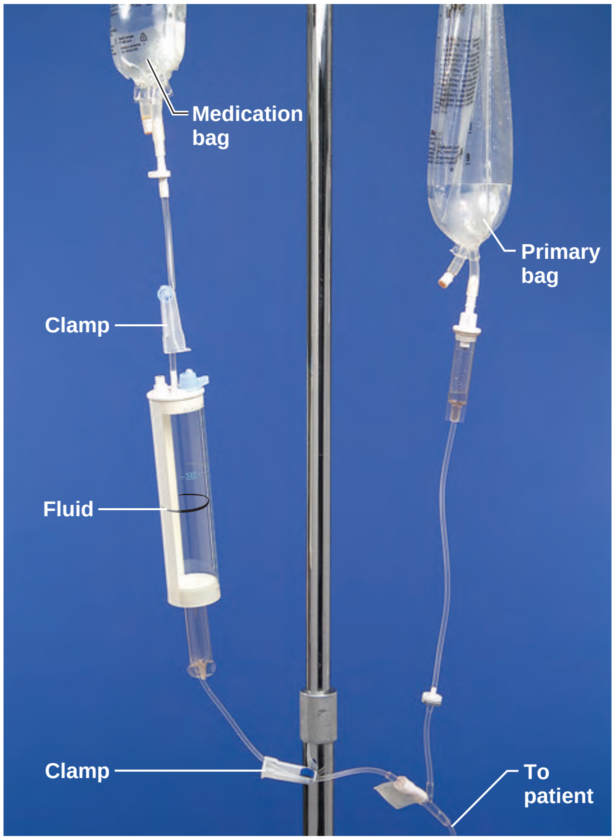

FIGURE 26-35 Volume-control infusion set for intermittent infusion administration; used when the fluid volume is critical and must be carefully monitored.

Central Venous Access Devices

Intravenous medication can be delivered through a central or peripheral vein. The most common reasons for a patient to have a **central venous access device (CVAD)** are to:

- Give long-term IV therapy
- Provide total parenteral nutrition when the patient cannot eat normally
- Have blood drawn without the trauma and complications of repeated venipuncture
- Provide vascular access when peripheral IV placement is difficult

External CVADs can be either tunneled or nontunneled. The ***tunneled devices*** are surgically implanted peripherally and tunneled to a central vein, typically the superior vena cava. ***Nontunneled catheters*** are inserted near the destination site. These catheters can be single- or multilumen. This category includes peripherally inserted central catheters (PICCs), which are inserted into the central circulation via a peripheral vein and can remain in place for months. For short-term use, the nontunneled central catheter can be inserted into the jugular, subclavian, or femoral veins.

An **internal**, or **implantable, port** is a CVAD that can remain in place and be functional for years. Access is gained through the skin via a hollow port with a self-sealing silicone cap. These devices are inserted when long-term IV medication is needed or the medication is too irritating for a peripheral site. See Figure 26-36A for an example of a port for injecting medication into the subclavian vein.

Catheters for central venous delivery can be single- or multilumen (Fig. 26-36B). Although they are more convenient for administering different medications and fluid, some types of multilumen catheters have a higher infection rate than single-lumen catheters.

To learn how to administer medications through a CVAD, see the summary in the Highlights of Procedures box. Also,

Go to Chapter 26, **Procedure 26-18: Administering Medication Through a Central Venous Access Device,** in Volume 2.

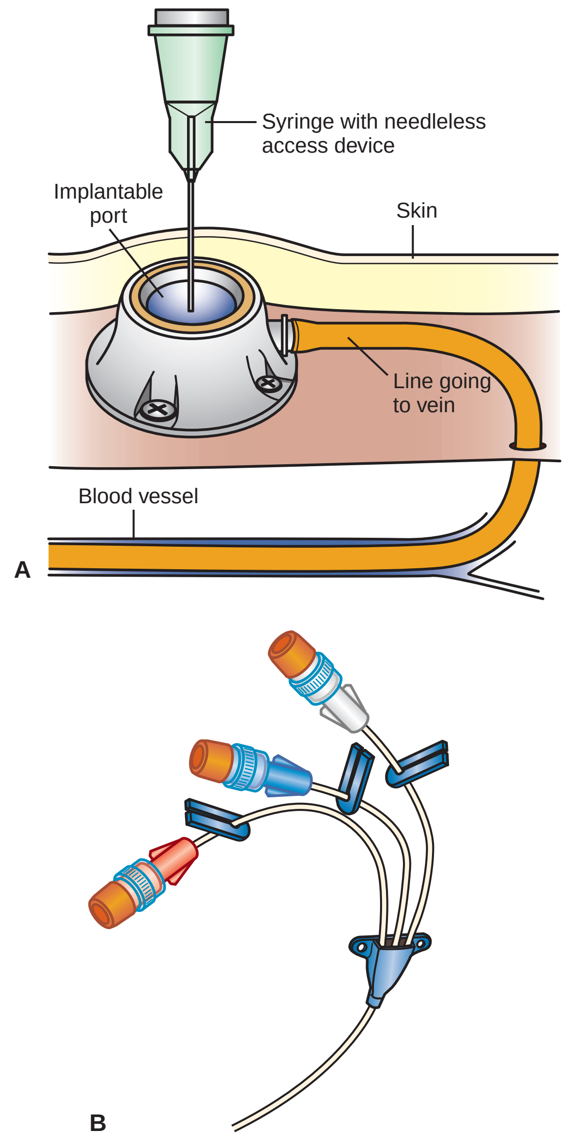

FIGURE 26-36 Central vascular access device: *A*, Implantable device. *B*, Multilumen catheter with blunt cannula, split septum, needleless access device.

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 26-1: Administering Oral Medication

- Observe the "three checks" and the "rights of medication": right patient, drug, dose, time, route, and documentation.
- *Tablets and capsules:* Pour the correct number into the medication cup.
- *Liquids:* Hold the plastic medication cup at eye level to measure the dose.
- Assist the patient to a high-Fowler's position, if possible.
- *Enterically administered medications:* Check for correct placement of the nasogastric or gastric tube.
- Correctly administer the medication.

  Powder: Mix with liquid, and give the mixture to the patient to drink.

  Lozenge: Instruct the patient not to chew or swallow it before dissolving it in his mouth.

  Tablet or capsule: Place the tablet or medication cup in the patient's hand or mouth, and instruct the patient to swallow with sips of liquid.

  Sublingual: Have the patient place the tablet under the tongue and hold it there until it is completely dissolved.

  Buccal: Instruct the patient to place the tablet between the cheek and gums and hold it there until it is completely dissolved.
- Stay with the patient until medications have been swallowed or dissolved.

Procedure 26-2: Administering Ophthalmic Medication

For instillations

- Use a high-Fowler's position, with the head slightly tilted back.
- Work from the inner to outer canthus when cleansing or instilling medication.
- Apply the medication into the conjunctival sac.
- Do not apply the medication to the cornea.
- Do not let the dropper or tube touch the eye.
- For eye drops, press gently against the same side of the nose for 1 to 2 minutes to close the lacrimal ducts. For an eye ointment, ask the patient to gently close his eyes for 2 to 3 minutes.

For irrigations

- Use a low-Fowler's position, with head tilted toward the affected eye, if possible.
- Check the pH in the conjunctival sac, if indicated.
- Use a Morgan lens or IV tubing to irrigate the eyes.
- For direct-flow irrigation, irrigate from the inner canthus to the outer canthus.
- Irrigate for 20 minutes or until the desired pH is reached.

Procedure 26-3: Administering Otic Medication

- Warm the solution to be instilled to body temperature.
- Assist the patient to a side-lying position, with the appropriate ear facing up.
- Straighten the ear canal. For an adult patient, pull the pinna up and back; for a child younger than 3 years, pull it down and back.
- Instill the prescribed number of drops into the ear canal.
- Do not force the solution into the ear or occlude the ear canal with the dropper.
- Instruct the patient to remain on his side for 5 to 10 minutes.

Procedure 26-4: Administering Nasal Medication

- Determine head position: Consider the indication for the medication and the patient's ability to assume the position.
- Explain to the patient that the medication may cause some burning, tingling, or unusual taste.
- Have the patient gently blow his nose and wash his hands afterward.
- Position the patient with the head down and forward for nasal sprays. Remember: "To spray your nose, look at your toes." For drops, assist the patient to a supine position with the head back.
- Place the tip of the sprayer into the right nostril, pointing the tip toward the outside of the nose (toward the outside corner of the right eye). Never point the tip toward the middle of the nose (the septum) or straight up (toward the sinus).
- Squirt the spray into the nose while patient inhales.
- Have the patient breath out through his mouth.
- Repeat for the other nostril.
- If the patient tastes the medicine, the head was not down or he did not inhale long enough. Advise him to put his head back down and sniff again without the medicine.
- If nose drops are used, ask the patient to stay in the same position for 1 to 5 minutes (depending on manufacturer's guidelines).

Procedure 26-5: Administering Vaginal Medication

For instillation

- Position the patient in a dorsal recumbent or Sims' position.
- Inspect and cleanse the vaginal area before administering the medication.
- Use a water-soluble lubricant.
- Insert the suppository or applicator along the posterior vaginal wall about 8 cm (3 in.).
- Instruct the patient to maintain the position for 5 to 15 minutes after the medication is inserted.

For irrigation (douche)

- Warm the irrigation solution to approximately 105°F (40.6°C).
- Hang the irrigation solution approximately 30 to 60 cm (1 to 2 ft) above the level of the patient's vagina.
- Position the patient in a dorsal recumbent position on a waterproof pad and bedpan.
- Lubricate the end of the irrigation nozzle.
- Insert the nozzle approximately 8 cm (3 in.) into the vagina, and start the flow of irrigation solution.

Procedure 26-6: Inserting a Rectal Suppository

- Before inserting the suppository, assess for contraindications, such as rectal surgery, rectal bleeding, or cardiac disease.
- Don gloves.
- Position the patient in the Sims' position.
- Lubricate the suppository.
- Insert the suppository past the internal sphincter about ½ to 1 inch in infants and 1 to 3 inches in adults. Never force the suppository during insertion.
- Instruct the patient to stay on his side for 5 to 10 minutes and retain (not expel) the suppository for about 30 minutes.

Procedure 26-7: Applying Medication to the Skin

- Wear gloves to avoid absorbing the medication through your own skin and to avoid cross-contamination.
- Before applying topical medication, cleanse the skin with soap and water.
- Do not apply medication to skin with open lesions, irritation, or known hypersensitivity.
- Avoid exposure to UV light/sunlight after applying medication.
- Assess for adverse skin reactions (e.g., hypersensitivity, redness, itching, or local irritation).
- Use gentle technique when applying topical medication to fragile skin, which is typical in older adults.
- Take care to not over-apply the medication.
- For transdermal patches, wear gloves when applying and removing; dispose of the patch in an appropriate receptacle, away from children and pets.

Procedure 26-8: Administering Metered-Dose Inhaler (MDI) Medication

- Identify the number of remaining inhalations in the canister. The "float method" is no longer recommended.
- Assist the patient to a seated position. Shake the inhaler. Remove the mouthpiece cap of the inhaler and insert the mouthpiece into the spacer while holding the canister upright.
- Remove the cap from the spacer.
- Ask the patient to breathe out slowly and completely.
- If a patient is unable to use the metered-dose inhaler independently, time the use of the device with the patient's own respirations.
- Place the spacer's mouthpiece into the patient's mouth and ask him to seal his lips around the mouthpiece. Press down on the inhaler canister to discharge one puff of medication into the spacer.
- Ask the patient to slowly inhale, and then hold his breath for as long as possible.
- If a second puff is needed, wait at least 1 minute and repeat.

Procedure 26-9: Preparing, Drawing Up, and Mixing Medication

- Maintain sterile technique.
- Recap the needle or vial access device (VAD) using a needle safety device or the one-handed method.
- Change the needle, if indicated.

Procedure 26-9A: Drawing Up Medication From Ampules

- Tap the ampule to remove medication trapped in the top of the ampule or shake it with a quick snap of the wrist.
- Use an ampule opener to break the ampule neck. Or wrap gauze or an alcohol swab in its wrapper around the neck of the ampule, and snap the ampule away from you.
- Use a filter needle or filter straw to withdraw the medication.
- Withdraw all of the medication from the ampule by inverting or tipping the ampule.
- Remove the filter needle and replace it with an appropriate size needle.
- Dispose of the broken ampule and filter needle in a sharps container.

Procedure 26-9B: Drawing Up Medication From Vials

- Scrub the rubber top of the vial with an alcohol prep pad or chlorhexadine gluconate (CHG)–alcohol product (for a multidose vial only).
- Draw air into the syringe equal to the amount of medication to be withdrawn.
- When inserting the needle or VAD through the rubber top of the vial, insert at a 45° to 60° angle, bevel up. Puncture the rubber top at that angle, but immediately raise to 90° as you insert the needle.
- Keeping the needle above the fluid line, inject air into the vial before inverting the vial and withdrawing the medication.
- Remove bubbles from the syringe, hold the vial at eye level, and check that the dose is correct before removing the needle.

Procedures 26-9C, D, and E: Mixing Medication From Two Vials, Mixing Medication From One Ampule and One Vial, and Using a Prefilled Cartridge and Single-Dose Vial—For Intravenous Administration

- Make sure the medications are compatible.

Continued

- Before beginning, determine the total volume of all medications to be put in the syringe and whether that volume is appropriate for the administration site.
- Maintain the sterility of the needles and medication.
- Avoid contaminating a multidose vial with a second medication.
- Carefully expel air bubbles.
- Withdraw the second medication very carefully because the medications are mixed as you pull back the plunger; therefore, you must withdraw the *exact* amount. If there is any excess, you must discard the contents of the syringe and start over.
- When opening ampules, protect yourself from injury.
- Use a filter needle or straw to withdraw medication from ampules; change to a needle of the proper length and gauge for administering the medication.
- When drawing up from a single-dose vial and ampule, draw up from the vial first.
- Do not use prefilled cartridges unless they have a safety needle; transfer the medication to a syringe with a safety device before administering.
- Always recap a sterile needle using a safety capping process or the one-handed scoop method.

Procedure 26-10: Recapping Needles Using One-Handed Technique

Procedure 26-10A: Recapping Contaminated Needles

- Recap a contaminated needle only if you cannot avoid it.
- Do not place your nondominant hand near the needle cap when recapping the needle or engaging the safety mechanism.
- If you are using a safety needle, engage the safety mechanism to cover the needle.
- Place the needle cap in a mechanical recapping device if one is available.
- If recapping devices are not available and you must recap the needle for your own and/or the patient's safety, use the one-handed scoop technique or one of the methods in Procedure 26-10B.

Procedure 26-10B: Recapping Sterile Needles

- Be sure to keep the needle and cap sterile.
- Do not place your nondominant hand near the needle cap when recapping the needle or engaging the safety mechanism.
- Use one of the following methods:
  - Place the needle cap in a medication cup, and insert the needle into the cap.
  - Place the cap on a clean surface so that the end of the needle cap protrudes over the edge of the counter or shelf, and scoop with the needle.
  - Use a hard syringe cover: Stand it on end; insert the needle cap into the cover, and then insert the needle.
  - Place the needle cap on a sterile surface, such as on open alcohol prep pad, and use the one-handed scoop technique. This is the least desirable method.

Procedure 26-11: Administering Intradermal Medication

- Have appropriate antidotes for certain injections readily available before beginning the procedure.
- Know the location of resuscitation equipment in case of a life-threatening adverse reaction.
- Maintain sterile technique and standard precautions.
- Use a 1-mL syringe and a 25- to 28-gauge, $\frac{1}{4}$- to $\frac{5}{8}$-inch needle with a short bevel.
- Be aware that an intradermal dose is small, usually about 0.01 to 0.1 mL.
- Administer the injection on the ventral surface of the forearm, upper back, or upper chest.
- Hold the syringe parallel to the skin at a 5° to 15° angle, with the bevel up.
- Stretch the skin taut to insert the needle.
- Do not aspirate.
- Inject slowly, and create a wheal or bleb.
- Do not wipe the site with alcohol, massage, or bandage the site.

Procedure 26-12: Administering Subcutaneous Medication

- Maintain sterile technique and standard precautions.
- Use a 1-mL syringe and a 25- to 27-gauge needle that is less than 1 inch long (usually $\frac{3}{8}$ to $\frac{5}{8}$ in.).
- A subcutaneous dose is typically no more than 1 mL.
- Most common injection sites: Use the outer aspects of the upper arms, abdomen, and anterior aspects of the thighs.
- Pinch the skin to inject, as a general rule.
- For an average-weight or thin patient, pinch up the skin and inject at a 45° angle. For an obese patient, inject at a 90° angle, if the adipose tissue pinches 2 inches or more, as a general rule. Use a longer needle and spread the skin taut instead of pinching.
- Do not aspirate when injecting heparin or insulin.
- Do not massage the site.

Procedure 26-13: Locating Intramuscular Injection Sites

- Always palpate the landmarks and the muscle mass to ensure correct placement.

Procedure 26-13A: Locating the Ventrogluteal Site

- On adults, a triangle is formed between your fingers when you place your palm on the head of the trochanter, index finger on the anterior superior iliac spine, and middle finger pointing toward or on the iliac crest. This is the preferred site for adults and children older than 7 to 12 months.

Procedure 26-13B: Locating the Deltoid Site

- The injection site is an inverted triangle on the upper arm. The base is the lower edge of the acromion process, and the tip is even with the top of the axilla. This is a good site in healthy adults for small-volume injection, especially when other sites aren't easily accessible because of drains or dressings.

Procedure 26-13C: Locating the Vastus Lateralis Site

- Midlateral thigh: On adults, one handbreadth below the head of the trochanter and one handbreadth above the knee. The site is the middle third of this area. This is the preferred site for infants who are not walking.

Procedure 26-13D: Locating the Rectus Femoris Site

- Middle third of the anterior thigh: Use this site only if no others are accessible. It is more painful than other sites.

Procedure 26-14: Administering an Intramuscular Injection

- Maintain sterile technique and standard precautions.
- Use a 1- to 5-mL syringe and a 21- to 25-gauge, 1-inch needle for deltoid site; 1½-inch needle for adults; 3-inch needle if the patient is obese.
- The usual volume is no more than 3 mL per injection. If the volume for injection is more than 3 to 5 mL, divide the dose into separate injections.
- Select an appropriate injection site, and identify the site using anatomical landmarks:
  - The ventrogluteal site is preferred except in special circumstances (e.g., for many adult immunizations).
  - The deltoid site is acceptable for IM doses of 1 mL or less.
- Inject at a 90° angle.
- Follow agency procedure regarding aspiration. If appropriate, aspirate before injecting. If blood appears, withdraw the needle, discard it, and start over.
- Press the plunger slowly to inject the medication (5 to 10 sec/mL).
- Z-track technique is recommended. Mnemonic:

Deliver	**D**isplace
All	**A**spirate
Injections	**I**nject (wait 5–10 seconds)
With	**W**ithdraw
Responsibility	**R**elease

Procedure 26-15: Adding Medications to IV Fluid

- Check the compatibility of the IV solution and medication.
- Refer to agency policy regarding maximum number of meds that can be added to one IV solution.
- Assess the patency of the IV site.
- Maintain the sterility of IV fluids and medication admixture.
- Affix the medication label to the bag, with the name and amount of medication, date and time administered, and your name or initials.

Procedure 26-16: Administering IV Push Medication

- Determine the type and amount of dilution needed for the medication.
- Determine the amount of time needed to administer the medication.
- Ensure the patency of the line before administration.
- Flush the line before and after administering the medication with normal saline. Flushing peripheral venous catheters with heparin 100 U/mL rather than with saline solution is recommended (Bertolino, Pitassi, Tinelli, et al., 2012).
- Maintain sterility.

Procedure 26-17: Administering Medications by Intermittent Infusion

- Ensure the compatibility of the IV solution and medication —both the solution in the primary IV system and in the secondary system.
- Assess the IV site and the patency of the line.
- Calculate the amount of medication to add to the solution.
- Use the correct amount and type of diluent solution.
- Use the correct rate of administration.
- Determine the correct primary line port in which to infuse the medication.
- Affix the correct label to the secondary bag identifying the infusate, patient name, start date and hour, discard date and hour, and your initials.

Procedure 26-18: Administering Medication Through a Central Venous Access Device

- First verify the medication can safely be administered through a central site.
- Scrub all surfaces of the catheter port, including the extension "tail," using an alcohol or CHG-alcohol combination product every time you enter the line.
- Flush the line before and after administering medication. Use saline, heparinized flush solution, or solution from the infusing IV line, according to agency policy.
- For multilumen catheters, flush all lumens.
- Clamp the line between the IV infusion set and the medication port. Open the clamp after medication is administered.

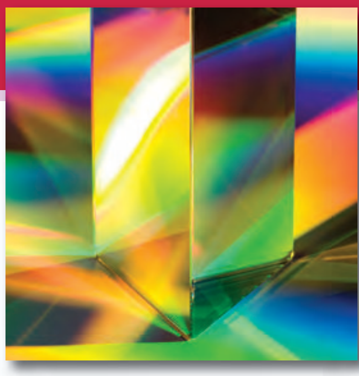
Supporting Physiological Functioning

CHAPTER 27



Nutrition

Learning Outcomes

After completing this chapter, you should be able to:

- Identify the types, functions, metabolism, and major food sources of (1) the energy nutrients, (2) vitamins, (3) minerals, and (4) water.
- Differentiate among the various sources of nutritional information (e.g., USDA dietary guidelines, food guide ChooseMyPlate, DRIs, Nutrition Facts labels).
- Calculate a client's basal metabolic rate.
- Identify the primary nutritional considerations for various developmental stages.
- Discuss how each of the following affects and is affected by nutritional status: lifestyle choices, vegetarianism, dieting for weight loss, culture and religion, disease processes, functional limitations, and special diets.
- Describe tools and techniques for gathering subjective data about nutritional status.
- Compare the effectiveness of various anthropometric measurements.
- Calculate the body mass index for a client.
- Explain the significance of body mass index.
- List at least five physical assessment findings that indicate nutritional imbalance.
- Identify laboratory values that are indicators of nutritional status.
- Discuss the need for and advisability of vitamin and mineral supplementation.
- Describe nursing interventions for patients with special needs: Impaired Swallowing, NPO, older adults, and Nausea.
- Describe techniques for assisting patients with meals.
- Identify and discuss six nursing interventions for Imbalanced Nutrition: Less Than Body Requirements and six interventions for Imbalanced Nutrition: More Than Body Requirements.
- Safely provide enteral and parenteral nutrition for patients.

Example Problems

Overweight/Obesity
Underweight/Malnutrition

Meet Your Patients

As part of a class assignment, you are to assist a local business with its wellness program. You will be completing health risk appraisals and gathering the following data on each of the employees: height, weight, medical and nutritional history, and lifestyle practices. Today you will screen two employees, and then each will have blood drawn for a complete blood count (CBC), comprehensive metabolic panel, and lipid panel:

- ***Isaac Schwartz***, a 65-year-old accountant, works long hours. He describes a sedentary lifestyle, no tobacco use, infrequent alcohol use, no medical problems, and a nutritional history of skipping meals and daily consumption of restaurant food. You measure his height as 69 in. and weight as 245 lb.
- ***Sujing Lee***, a 29-year-old project manager, regularly works 65 hours per week. Sujing is 30 weeks pregnant. She does not smoke or drink and has never been hospitalized or had surgery. She has gained a total of 25 lb since becoming pregnant. Her diet consists mainly of traditional Chinese food. She eats three meals a day and always brings lunch from home. Lately she has felt "tired all the time." At the screening, she weighs 126 lb and measures 63 in. tall.

At the end of your clinical day, you need to compile a report on the clients you have seen. How would you interpret the data on height, weight, and nutrition? What, if any, additional information do you need to help you evaluate their nutritional status? In this chapter, you will read about dietary recommendations, energy balance, and nutritional concerns across the life span. You will gain the theoretical knowledge to answer these questions, as well as practical knowledge about managing nutritional problems.

Theoretical Knowledge knowing **why**

Organic, natural, low-fat, sugar-free, reduced-calorie, low-sodium, calcium-enriched . . . these are just a few of the hundreds of claims you find on packaged foods. Television and print ads hype nutritional supplements, weight-loss pills, and new diets, while the media carries conflicting reports on the benefits and dangers of phytochemicals, antioxidants, and *trans*-fatty acids. With so many options and different recommendations about what's healthy or not, it's no wonder that many people are confused about what to eat.

ABOUT THE KEY CONCEPTS

Nutrition is the study of food: how it affects the human body and influences health, and **metabolism**—specifically, how the body metabolizes food for **energy**. Good nutrition is essential to wellness, and poor nutrition contributes to disease, so clients need accurate, current, and appropriate nutritional information. Before you can give effective individualized advice, you need to know about the nutrients found in foods. In this chapter you will learn about concepts related to **energy**, for example, energy balance, nutrients, micronutrients, and factors that influence nutritional status.

WHAT ARE SOME RELIABLE SOURCES OF NUTRITION INFORMATION?

Standards and guides provide credible nutrition information. **Standards** are a reference for nutrient intake thought to meet the nutritional needs of most healthy population groups. They list nutrient amounts in measurements, such as grams and milligrams, and are not intended to indicate individual requirements or therapeutic needs. **Food guides** are more practical tools that you can use to educate patients and families. They specify the number of servings of foods needed daily so nonprofessionals can use them in making healthful meal choices. In general, standards and guides provide recommendations to healthy individuals but they are not sensitive to the needs of people experiencing metabolic or other medical problems.

Dietary Reference Intakes

The National Academy of Sciences, in a collaborative effort by the United States and Canada, has established standards, the **Dietary Reference Intakes (DRIs),** to promote the consumption of healthful nutrient levels. For carbohydrates and lipids, the *acceptable macronutrient distribution range (AMDR)* is used. To view the DRIs and AMDRs for males and females in various age groups, Go to Chapter 27, **Supplemental Materials, Dietary Reference Intakes: Vitamins; Dietary Reference Intakes: Electrolytes** and **Water; Dietary Reference Intakes: Elements; and Dietary Reference Intakes: Macronutrients,** on Davis*Plus*.

The DRIs are a revision of the older Recommended Dietary Allowances (RDAs) for vitamins and minerals, protein, and total kcal that are thought to meet the needs of about 98% of individuals in a group. For vitamins and minerals, the DRI tables include RDAs and Adequate Intakes (AIs). AIs are the intakes adequate to meet the needs of all individuals in a group. For files you can download,

Go to Browse by Subject, **U.S. Department of Agriculture, National Agricultural Library, Food and Nutrition Information Center,** a government Web site, at http://fnic.nal.usda.gov/

USDA Dietary Guidelines

In 1980, the U.S. Department of Agriculture (USDA) developed dietary guidelines for Americans. The guidelines are revised every 5 years. Box 27-1 presents the 2010 guidelines to help people evaluate their food habits and work toward general improvement in their diet. The guidelines do not specify daily amounts of food and nutrients.

The USDA intends this document to be a primary source of dietary health information for nutrition educators, policy makers, and healthcare providers. It is based on the latest scientific evidence and provides information about choosing a nutritious diet, maintaining healthy weight, achieving adequate exercise, and food safety to avoid food-borne illness. The dietary guidelines are updated every 5 years, so the new ones should be available after this book is published. To see the complete 2010 guidelines and the new guidelines when they are available,

Go to the **USDA Dietary Guidelines** Web site, at http://www.cnpp.usda.gov/dietaryguidelines.htm

MyPlate

MyPlate is a colorful, four-part food guide for use as a dietary-teaching tool (Fig. 27-1) Based on USDA 2010 dietary guidelines, it visually illustrates a healthy meal—red for fruits, green for vegetables, orange for grains, and purple for protein with a separate blue section for dairy on the side.

MyPlate stresses the following concepts for healthy eating:

- Balancing calories by avoiding oversize portions.
- Eating more healthy food. That means making half the plate fruit and vegetables and making half of the grains whole grains.
- Eat less unhealthy food, for example, processed and high-sodium, high-sugar, and high-fat foods and snacks, and sugary and high-caffeine beverages.

BOX 27-1 ■ Dietary Guidelines for Americans 2010—Key Points

- Consume a variety of nutrient-rich foods and beverages daily.
- Adopt a balanced eating pattern (e.g., the USDA Food Guide) to meet recommended intakes.
- Limit the intake of saturated fats, *trans* fats, and cholesterol to less than 10% of calories. Replace them with mono- and polyunsaturated fats. Consume less than 300 mg of dietary cholesterol per day. Most fats should come from foods such as fish, nuts, and vegetable oils.
- Limit your intake of refined sugars, salt, and alcohol. Those aged 14 to 50 should limit their daily salt intake to 2,300 mg. However, those who are 51 and older; blacks; and people with hypertension, diabetes, or chronic kidney disease should reduce salt intake to 1,500 mg per day.
- Replace higher-fat protein foods with leaner meat, poultry, seafood, eggs, beans, unsalted nuts, and seeds.
- Increase the intake of fat-free or low-fat milk products, such as skim milk and cheese, cottage cheese, and yogurt.
- Achieve and maintain a healthy weight.
- Be physically active each day.
- Balance calorie intake with increase or decrease in activity.
- Choose a variety of fruits and vegetables each day, especially dark green, orange, red, and yellow vegetables and beans.
- Choose fiber-rich fruit, vegetables, and whole grains often. At least half the grains should come from whole grains.
- Women capable of becoming pregnant should consume iron-rich food and supplement with 400 micrograms (mcg) of folic acid.
- People 50 years and older should eat foods fortified with vitamin B_{12}.
- Cook, chill, and store foods to keep them safe from microorganisms.
- Clean hands, food contact surfaces, and fruits and vegetables. Do not wash or rinse meat and poultry. (Also see Chapter 24 for food safety.)

Retrieved from http://www.cnpp.usda.gov/DGAs2010-PolicyDocument.htm; and CDC. (2009). Application of lower sodium intake recommendations to adults—United States, 1999–2006. *Morbidity and Mortality Weekly Report, 58*(11), 281–283. Retrieved from http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5811a2.htm

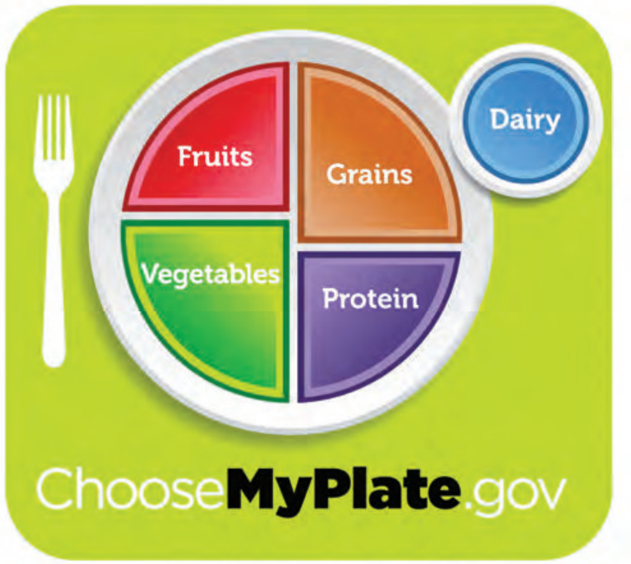

FIGURE 27-1 USDA Choose MyPlate. (From U.S. Department of Agriculture, www.choosemyplate.gov.)

MyPlate does not specify number of servings per day; it specifies measurable amounts, such as ounces and cups. For access to MyPlate,

Go to the **MyPlate** Web site at http://www.ChooseMyPlate.gov

MyPlate is also provided in Spanish, with the same foods as the English MyPlate. For the Spanish version,

Go to http://www.choosemyplate.gov/en-espanol.html

MyPlate promotes healthy eating:

- *Activity.* MyPlate partners with Let'sMove to emphasize the importance of activity and exercise.
- *Choices.* MyPlate illustrates a meal that consists of 50% fruits and vegetable, as well as changing to fruit, vegetables, or unsalted nuts as snacks.
- *Personalization.* Eat the right amount of calories for you (one size does *not* fit all). To find the kinds and amounts of food you need to eat each day, based on personal factors, check the MyPlate Web site.
- *Proportionality.* Notice that the food group wedges are of slightly different sizes. The wedges are a general guide to how much food you should choose from each group. For example, the Vegetable group is a very large area, and the Protein area is slightly smaller. This gives you a general idea that you should eat many more servings of grains than of oils.
- *Variety.* Four different colors represent food groups. This illustrates the importance of variety in your diet; you need foods from all groups each day.
- *Tools for Success.* The SuperTracker, Daily food plans and sample menus are a few of the tools included on the site.

For information about serving sizes and nutrients provided by each food group when assisting patients with nutritional choices,

Go to **Clinical Insight 27-1: 10 Tips for Building Healthy Meals,** in Volume 2,

or

Go to Chapter 27, **Tables, Boxes, Figures: ESG Table 27-1, Serving Sizes for Daily Food Choices,** on Davis*Plus*.

For Asian, Latin American, Vegetarian, and Mediterranean diets, which include some of the traditional foods of those cultural groups,

Go to the **Oldways Preservation and Exchange Trust** Web site at http://www.oldwayspt.org

For the Diabetes Food Plate,

Go to the **American Diabetes Association** Web site at http://www.diabetes.org/food-and-fitness/food/planning-meals/create-your-plate/

The Diabetes Food Plate, unlike MyPlate, groups foods based on their carbohydrate and protein content. For example, you will find the plate divided into three sections, and the types of vegetables encouraged are non-starchy, such as spinach and green beans.

Food Guides for Older Adults

For an updated (2011) MyPlate for Older Adults,

Go to the **Tufts University Friedman School of Nutrition Science and Policy** Web site at http://www.nutrition.tufts.edu/research/myplate-older-adults

The Tufts University MyPlate for Older Adults is consistent with the federal government's 2010 Dietary Guidelines for Americans, which recommend limiting foods high in *trans* and saturated fats, salt, and added sugars, and emphasize whole grains. The model also emphasizes whole fruits and vegetables in a range of colors. The MyPlate for Older Adults emphasizes nutrient-dense foods and stresses the importance of fluids by showing a circle representing glasses for fluids. It shows packaged fruits and vegetables in addition to fresh because they are easier to prepare and have a longer shelf life. This is important to consider when it is difficult for an older adult to make frequent trips to the grocery store. It also promotes physical activity with icons showing active adults.

Nutrition Facts Label

You are likely familiar with the **Nutrition Facts label** shown in Figure 27-2, because the U.S. Food and Drug Administration (FDA) requires this label on all packaged foods sold in the United States. The Nutrition Facts panel contains important information about serving

Toward Evidence-Based Practice

Scarmeas, N., Luchsinger, J., Mayeux, R., et al. (2007). Mediterranean diet and Alzheimer disease mortality. *Neurology, 69,* 1084–1093.

A Mediterranean diet (MeDi) consists of an average of nine servings of fruits and vegetables daily, whole grains, fish once or twice a week, and up to 5 ounces of red wine daily. It limits red meat and avoids *trans* fats and saturated fats, using instead olive oil for its antioxidant effect and canola oil and nuts to provide omega-3 fatty acids.

Researchers followed 192 community-based individuals diagnosed with Alzheimer's disease (AD) for 4.4 years. Eighty-five of the AD patients died during that period. Researchers concluded that adherence to the MeDi may reduce not only risk for AD but also subsequent disease course: Higher adherence to the MeDi is associated with lower mortality in AD.

Barberger-Gateau, P., Raffaitin, C., Letenneur, L., et al. (2007). Dietary patterns and risk of dementia. *Neurology, 69,* 191–193.

This study included 8,085 nondemented participants aged 65 and older in three cities in France. An independent committee validated 281 cases of dementia (including 183 AD). Daily consumption of fruits and vegetables was associated with a decreased risk of all-cause dementia; weekly consumption of fish was associated with a reduced risk of AD, but only among people carrying a high-risk AD gene; regular use of omega-3–rich oils was associated with a decreased risk for all-cause dementia. Researchers concluded that frequent consumption of fruits and vegetables, fish, and omega-3 rich oils may decrease the risk of dementia and AD, especially among those who do not carry the high-risk AD gene.

Vogiatzoglou, A., Refsum, H., Johnston, C., et al. (2008). Vitamin B_{12} status and rate of brain volume loss in community-dwelling elderly. *Neurology, 71*(11), 826–832.

This was a 5-year study of 107 community-dwelling elders aged 61 to 87 years with no cognitive impairment at the beginning of the study. They were assessed yearly by magnetic resonance imaging (MRI) scans, cognitive tests, and blood studies. The decrease in brain volume over the 5-year period was greater for those with lower vitamin B_{12} levels. Researchers concluded that low vitamin B_{12} status should be further researched as a cause of brain atrophy and likely cognitive impairment in the elderly.

1. Suppose you are a manager in a long-term care facility that specializes in treating residents with AD. You are planning nutritional interventions for these residents. Which of these three studies is best suited to your patients, and why?

2. How was the cognitive status of the subjects different in all three studies?

3. Based on the third study, vitamin B_{12} supplementation would most likely be of benefit to which of the following groups? Explain your thinking.
   a. People who have AD and want to extend their life expectancy
   b. Older adults who wish to prevent getting AD
   c. Older adults who want to avoid cognitive impairment from brain changes other than AD.

Go to Chapter 27, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*

Go to Chapter 27, **Resources for Caregivers and Health Professionals,** on Davis*Plus*

size, number of servings per package, total calories and calories from fat per serving, a list and amounts of the key nutrients in the food, and the *percent daily values* (% DV) for the nutrients listed on the panel. The % DV identifies the percentage that a serving of the food contributes to a consumer's overall intake of the nutrient listed. Updates to the label will reflect more typical serving sizes, listing added sugars when present, removing the "calories from fat" information, and proposed changes to the Daily Values.

Teaching your patients how to read these labels will help them to make wiser dietary choices. If you need a more thorough explanation of how to use Nutrition Facts labels,

Go to the **USDA** Web site at http://www.fda.gov/downloads/Food/ResourcesForYou/Consumers/UCM079504.pdf

ThinkLike a Nurse 27-1

How might you use the various sources of nutritional information to evaluate the nutritional status of the clients introduced in the Meet Your Patients scenario?

WHAT ARE THE ENERGY NUTRIENTS?

The cells and tissues of the body depend for their functioning on building blocks called **nutrients**. Any one food may contain a variety of nutrients; for instance, cheese contains carbohydrates, protein, lipids, sodium, vitamins, and minerals. Some nutrients, called *macronutrients,* supply the body with energy (kilocalories),

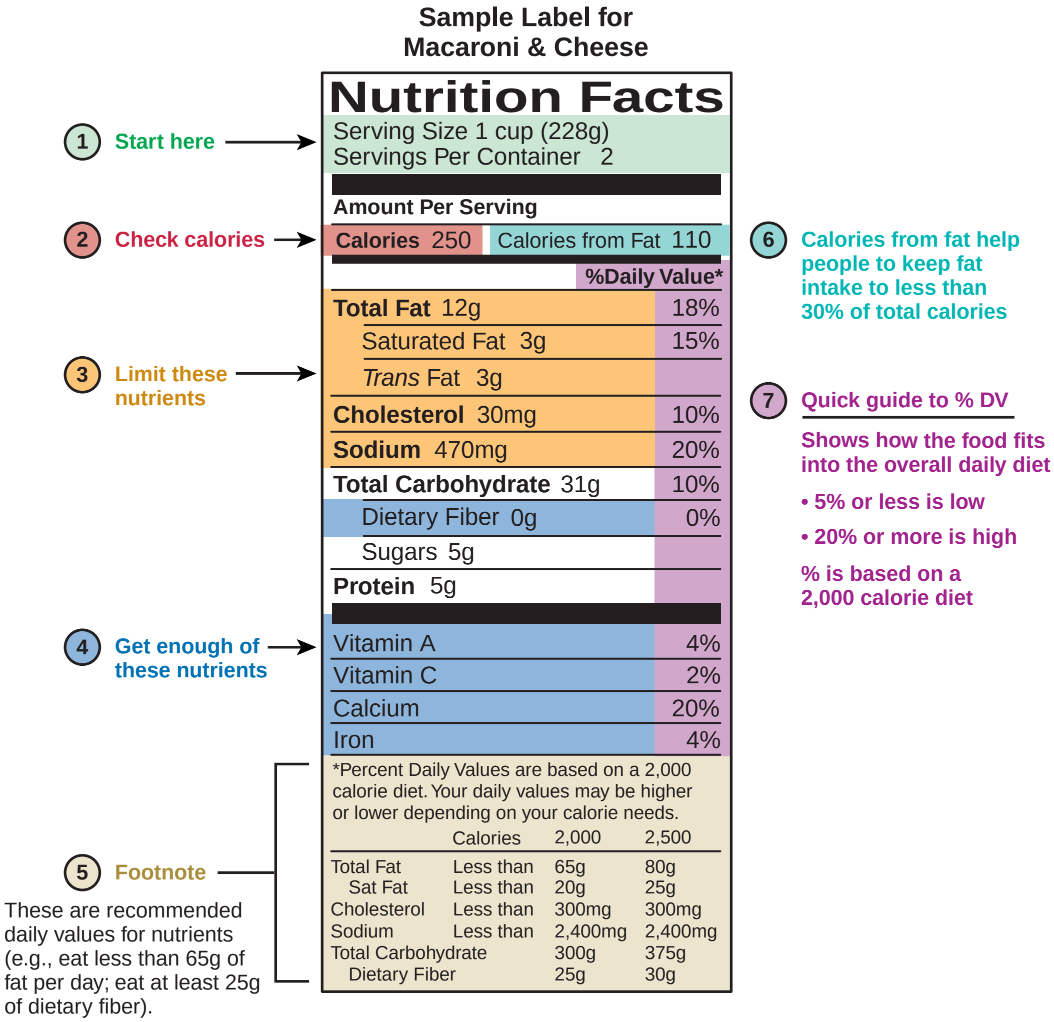

FIGURE 27-2 A Nutrition Facts panel. (From U.S. Food and Drug Administration, 2007a).

whereas others, called *micronutrients*, help manufacture, repair, and maintain cells. In this section, we discuss the three classes of nutrients that provide the body with energy: carbohydrates, proteins, and lipids. Table 27-1 lists the sources of and requirements for macronutrients.

The body requires a constant supply of energy. Physiological mechanisms constantly convert stores of more complex forms of chemical energy into usable energy, which is then carried to individual cells. The term **metabolism** encompasses all the ways in which the body changes and uses nutrients. Two types of metabolic reaction, anabolism and catabolism, occur continually and are adjusted according to the needs of the body. **Anabolism** involves the formation of larger molecules from smaller ones. For example, if protein is needed for tissue repair, amino acids are recombined to form proteins. This process requires energy. **Catabolism** involves the breakdown of larger molecules into smaller components. One of the results of this separation is the release of energy. Most metabolic reactions, including metabolism of nutrients, are catalyzed by enzymes; each is specific and catalyzes only one type of reaction.

Carbohydrates

Carbohydrates (CHOs) are the primary energy source for the body. **Simple carbohydrates**, commonly called *sugars*, are named according to the number of sugar (or *saccharide*) units making up their chemical structure. **Monosaccharides** (simple sugars) consist of a single unit; **disaccharides** are molecules made up of two saccharides. **Complex carbohydrates** consist of long chains of saccharides, called **polysaccharides**. **Dietary fiber**, a polysaccharide, is the indigestible "fibrous skeleton" of plant foods. Humans do not have the enzymes to digest fiber; thus, it provides no usable glucose. Carbohydrates perform several functions:

1. *Supply energy for muscle and organ function.* Carbohydrates, which are more easily and quickly digested than proteins and lipids, fuel strenuous short-term skeleton muscle activity and provide nearly all the energy for the brain. Humans store glucose in liver and skeletal muscle tissue as **glycogen**. Glycogen is

Table 27-1 ➤ Energy Nutrients

NUTRIENT	SOURCES	ENZYMES INVOLVED IN DIGESTION	REQUIREMENTS
Carbohydrates	*Simple sugars* occur mainly in corn syrup, honey, milk, table sugar, molasses, sugar cane, sugar beets, and fruits. *Complex carbohydrates* occur in vegetables, breads, cereals, pasta, grains, and legumes.	Salivary amylase (mouth) Ptyalin (mouth and stomach) Pancreatic amylopsin Intestinal: sucrase, lactase, maltase	There is debate about the amount of carbohydrate needed in the diet. Many popular diet plans alter carbohydrate intake: The Atkins diet is a low-carbohydrate plan, whereas the Pritikin and Ornish diets recommend high intake of complex carbohydrates. Body size and activity level affect the amount of carbohydrate used by the body. The 2002/2005 DRIs specify that adults should get 45%–65% of their calories from CHOs, or 130 grams per day (g/day).
Proteins	*Complete proteins* come mostly from animal sources: meat, poultry, fish, eggs, and milk products. *Incomplete proteins* are supplied by plant sources (e.g., grains, nuts, legumes, seeds, vegetables). They can be combined to make complete proteins.	Stomach: Pepsin Pancreas: Trypsin, chymotrypsin, carboxypeptidase Intestine: Aminopeptidase, dipeptidase	Protein needs depend on age, body size, and physical state. Needs are increased during growth periods, such as childhood and pregnancy. The average adult needs about 1 gram of protein per kilogram of body weight per day. The 2002/2005 DRIs specify that adults should get 10%–35% of their calories from protein, or 0.8 g/kg of body weight (46–56 g/day for an "average" person).
Lipids	*Saturated fats* occur in pork, beef, poultry, seafood, egg yolk, and dairy; coconut oil and palm oil. *Unsaturated fats (from plants)* occur in olives, olive oil, vegetable oils (peanut, soybean, cottonseed, corn, safflower), nuts, and avocados *Essential fatty acids (linoleic acid [omega-6] and alpha-linolenic acid [omega-3])* occur in polyunsaturated vegetable oils and in fatty fish (e.g., salmon). *Trans* fats occur in hydrogenated oils, some margarines, packaged baked goods, and many processed foods	Lingual: Lipase Gastric: Lipase, tributyrinase, bile salts Pancreatic lipase (steapsin)	There is debate about the appropriate amount of fat in the diet. The American Heart Association recommends that people obtain <30% of their calories from fat; <7% of calories should come from saturated fats, and <1% from *trans* fat. Clients with increased risk for heart disease may need stricter control. The 2002/2005 DRIs specify that adults should get 20%–35% of their calories from fat; children, 25%–40%.

Sources: Adapted from U.S. Department of Agriculture, Food and Nutrition Center (2002–2005). *Dietary guidance. DRI Tables. Dietary Reference Intakes: Macronutrients.* National Academy of Sciences. Institute of Medicine. Food and Nutrition Board. Retrieved from http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables; and American Heart Association (n.d.a) Fats 101. AHA recommendation. Retrieved from http://www.heart.org/HEARTORG/GettingHealthy/FatsAndOils/Fats101/Fats-101_UCM_304494_Article.jsp converted back into glucose to meet energy needs. This process is called **glycogenolysis**. If carbohydrates are not available, proteins and lipids (fats) can also be used for energy.

2. *Spare protein.* If glycogen stores are low (for instance, in a person who is undernourished), physical activity causes the breakdown of body stores of protein (**gluconeogenesis**) and lipids (fats) to use for energy. But when proteins are used for energy, they are not available for their primary functions of tissue growth, maintenance, and repair. Fats are converted directly into an alternative fuel called **ketones**; ketones raise the acidity of the blood and can lead to acid–base imbalance. Fats are used for fuel in persons with diabetes, whose cells cannot use glucose for energy.
3. *Other physiological functions.* Carbohydrates enhance insulin secretion, increase satiety (feeling of fullness and satisfaction), and improve absorption of sodium and excretion of calcium. **Insulin** is a pancreatic hormone that promotes the movement of glucose into the cells for use.

To see the basic chemical structure of four types of carbohydrates,

Go to Chapter 27, **Tables, Boxes, Figures: ESG Figure 27-1, Carbohydrates,** on Davis*Plus*.

Proteins

Proteins are complex molecules made up of *amino acids.* Every amino acid consists of a central carbon atom connected to a hydrogen atom, an acid, an *amine* (a region of the molecule containing nitrogen), and a side chain. Only the side chain varies from one amino acid to another. Just 20 different amino acids are the building blocks of most of the proteins in the human body (Table 27-2). The **essential amino acids** are significant in our diets because the body cannot manufacture them. They must be supplied by food or nutritional supplements. In contrast, the body can synthesize the 10 **nonessential amino acids,** so we do not need to obtain them from food. To see the basic structural formula for an amino acid and a polypeptide,

Go to Chapter 27, **Tables, Boxes, Figures: ESG Figure 27-2, Amino Acids,** on Davis*Plus*.

For protein synthesis to occur, every amino acid necessary to build that protein must be available. **Complete protein** foods contain all of the essential amino acids necessary for protein synthesis. These usually come from animal sources. **Incomplete protein** foods (e.g., nuts, grains) do not provide all of the essential amino acids. However, by combining two incomplete proteins, a complete protein can be made. For instance, lentils (legumes) and rice (grain) with yellow peppers makes a healthy meal using complementary proteins; or almonds (nuts) with black beans (legumes) in a salad is another good choice. Yogurt (dairy) combined with sunflower and flax seeds (seeds) creates complementary proteins for a healthful vegetarian diet.

Protein Metabolism and Storage

Refer to Table 27-1: How many servings of protein did you eat yesterday? How many were complete proteins? How many were incomplete proteins? Do you think that protein foods accounted for more than 10% of your food intake yesterday?

Although protein digestion begins in the stomach, it occurs mostly in the small intestine, where enzymes break it down into amino acids. The body continually breaks down and resynthesizes protein into tissues, adjusting as needed to maintain overall protein balance. The body also maintains a balance between tissue protein and plasma protein. When amino acids are catabolized, the nitrogen-containing part is converted to ammonia (NH_3) and excreted in the urine as urea. Therefore, nitrogen balance reflects how well body tissues are being maintained.

Table 27-2 ➤ Amino Acids

TYPE	DESCRIPTION	EXAMPLES
Essential	Must be obtained from the diet; cannot be made in the body.	Arginine,* histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine
Nonessential	Easily synthesized by the body.	Alanine, asparagine, aspartic acid, cysteine,† glutamic acid, glutamine, glycine, proline, serine, and tyrosine**

*Considered by some to be "semiessential" because it cannot be synthesized at a rate that will support growth. Therefore, it is essential for children, but not for most adults.

†Considered conditionally essential. That is, essential in some situations (e.g., in immaturity, during severe stress).

Sources: American Heart Association (AHA). (n.d.a, updated 2011, June 29). Fats and oils: AHA recommendation. Retrieved March 4, 2014, from http://www.heart.org/HEARTORG/GettingHealthy/FatsAndOils/Fats101/Fats-and-Oils-AHA-Recommendation_UCM_316375_Article.jsp; Guyton, A. C., & Hall, J. E. (2011). *Textbook of medical physiology* (12th ed.), Philadelphia: W. B. Saunders; Lutz, C., & Przytulski, K. (2010). *Nutrition and diet therapy*, (5th ed.). Philadelphia, F.A. Davis; U.S. Department of Agriculture, Food and Nutrition Center (2002/2005). *Dietary Guidance. DRI Tables. Dietary Reference Intakes: Macronutrients.* National Academy of Sciences. Institute of Medicine. Food and Nutrition Board. Retrieved March 6, 2014, from http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables

Nitrogen balance occurs when intake and output of nitrogen are equal. A **positive nitrogen balance** exists when nitrogen intake exceeds output, making a pool of amino acids available for growth, pregnancy, and tissue maintenance and repair. **Negative nitrogen balance** exists when nitrogen intake is lower than nitrogen loss. This occurs in illness, injury (e.g., burns), and malnutrition.

Functions of Protein

Dietary proteins perform the following functions:

1. *Tissue building.* Protein is the structural material of every cell in the body. In fact, except for water, protein makes up the biggest part of the body. It is essential for growth, maintenance, and repair of body cells and tissues.
2. *Metabolism.* Proteins are essential for building body tissue. For example, proteins are precursors to digestive enzymes and hormones (e.g., thyroxine). **Enzymes** facilitate cellular reactions throughout the body. In addition, proteins combine with iron to form hemoglobin, the oxygen carrier in red blood cells.
3. *Immune system function.* **Lymphocytes** (specialized white blood cells) and antibodies (components of our immune system that defend against foreign invaders) are proteins.
4. *Fluid balance.* Because they attract water, proteins in cells and the bloodstream help regulate fluid balance.
5. *Acid–base balance.* Blood proteins function as buffers, helping to regulate acid–base balance.
6. *Secondary energy source.* As noted earlier, proteins can be broken down to provide energy when stores of the other energy nutrients are inadequate (Thompson & Manore, 2012).

Protein needs vary according to age, sex, weight, and health. Lean meat is nourishing and healthy as long as it is consumed in modest amounts and is not processed. Most North Americans eat more protein than they need, especially in the form of meat. There is no health benefit from eating more than the recommended amount of protein. In fact, there may be health risks in eating a diet that is high in animal protein. Animal proteins are high in saturated fat, which increases the risk for certain cancers and coronary artery disease, and which has been associated with kidney stones and calcium loss through the urinary system.

Lipids

Lipids are organic (carbon-containing) substances that are insoluble in water. They are made up of carbon, hydrogen, and oxygen—the same basic elements that make up carbohydrates. The term *lipid* comes from *lipos*, the Greek word for "fat." Lipids that are solid at room temperature are called ***fats***, whereas those that are liquid at room temperature are called ***oils***. For example, butter is a fat even when it is melted, because it would be solid at room temperature. You will hear the terms *lipids* and *fats* used interchangeably.

People in developed countries typically eat a diet relatively high in fat. In the United States about 45% of our total kcal consumption comes from fat. Fat is an essential nutrient, but certain types when consumed in excess can also be a health hazard.

Lipid metabolism occurs in the small intestine, where bile and pancreatic enzymes begin splitting the fatty acids from their glycerol backbone. Lipids are stored as adipose tissue. Because lipids are insoluble in water, and because blood is primarily water, lipid absorption requires a solvent carrier.

Types and Sources of Lipids

The three types of lipids found in foods are glycerides, sterols, and phospholipids (Box 27-2). **Glycerides** (also called **true fats**) consist of one molecule of glycerol attached to one, two, or three fatty acid chains. *Glycerol* is an alcohol composed of three carbon atoms. *Fatty acids* are long chains of carbon and hydrogen atoms ending in an acid. Most glycerides found in foods are *triglycerides*, which are compounds consisting of a glycerol molecule attached to three fatty acids.

Go to Chapter 27, **Tables, Boxes, Figures: ESG Figure 27-3, Lipids,** on Davis*Plus*.

Sterols are lipids, but they are not made of fatty acids. They consist of rings of carbon and hydrogen. The most important sterol in the body is **cholesterol**, a wax-like substance needed for the formation of cell membranes, vitamin D, estrogen, and testosterone. Cholesterol is synthesized in the liver, and it is also found in animal foods.

Phospholipids (which contain a phosphate group) are soluble in water. They are a key component of **lipoproteins**, which consist of phospholipids and a protein. Because they are water soluble, lipoproteins are the major transport vehicles for lipids in the bloodstream. By "wrapping" triglycerides with water-soluble phosphates and proteins, lipoproteins deliver these substances to body cells.

- **Low-density lipoproteins (LDLs)** transport cholesterol to body cells. Diets high in saturated fats increase

BOX 27-2 ■ Types of Lipids

Glycerides	Fatty Acid Molecules	(bonded to)	Glycerol Molecules
Monoglycerides	1		1
Diglycerides	1		2
Triglycerides	1		3
Sterols	0		0
Phospholipids	1		2 + a phosphate group

LDLs circulating in the bloodstream and may result in fatty deposits on vessel walls, causing cardiovascular disease. As a result, LDL is often known as the "bad cholesterol."

- **High-density lipoproteins (HDLs)** remove cholesterol from the bloodstream, returning it to the liver, where it is used to produce bile; thus, a high blood level of HDL is considered protective against cardiovascular disease. It is often known as the "good cholesterol."

Saturated and Unsaturated Fatty Acids

Fatty acids are classified as saturated, unsaturated, or *trans* fats (Table 27-3). **Saturation** means that a substance is holding all that it is capable of holding (e.g., think of a wound dressing saturated with blood).

- An **unsaturated fatty acid** is one that is not completely filled with all the hydrogen it can hold. Therefore, it is lighter and less dense. Fats made up primarily of unsaturated fatty acids are called **unsaturated fats**. Molecules of **monounsaturated fats** have one unfilled spot where hydrogen is not attached. **Polyunsaturated fatty acids** contain two or more unfilled spots for hydrogen. At the spot(s) where the molecule does not have hydrogen attached, it becomes kinked and does not pack together. This is why these fats are liquid at room temperature. Replacing saturated fats in the diet with mono- and polyunsaturated fats reduces the risk of heart disease and stroke. Dietary fat should mainly be polyunsaturated and unsaturated, from food sources, such as fish and nuts.
- **Saturated fatty acids** are those in which every carbon atom is fully bound to (or "saturated" with) hydrogen. The molecules pack tightly together at room temperature and are dense, solid, and heavy. A fat made up mostly of saturated fatty acids is called a **saturated fat**. Animal fats are the primary source of saturated fats in the North American diet; however, many processed foods contain saturated fats.

Table 27-3 ➤ Dietary Fats

TYPE OF FAT	SOURCES	EFFECT ON BLOOD CHOLESTEROL
Monounsaturated	Olives; olive oil, canola oil, peanut oil; cashews, almonds, peanuts, some legumes, and most other nuts; avocados	Lowers LDL and raises HDL.
Polyunsaturated	Corn, soybean, safflower, sesame, sunflower, and cottonseed oils; fish, nuts, and seeds	Lowers LDL and raises HDL.
Saturated	Whole milk, butter, cheese, and ice cream; lard; red meat; chocolate; coconuts, coconut milk, and coconut oil; palm oils; cocoa butter	Raises LDL and HDL.
Trans fats	Most margarines; vegetable shortening; partially hydrogenated vegetable oil; deep-fried chips; many fast foods (e.g., French fries, donuts); most commercial baked goods	Raises LDL.
Dietary Cholesterol	Foods from animals: meats, egg yolks, dairy products, organ meats (e.g., heart, liver), fish, and poultry	Raises cholesterol.

American Heart Association Recommendations

Limit foods high in saturated fat, *trans* fat, and/or cholesterol. Instead choose foods low in saturated fat, *trans* fat and cholesterol. Here are some helpful tips (AHA, n.d.a):

- Limit intake of whole-milk dairy products, fatty meats, tropical oils, partially hydrogenated vegetable oils, and egg yolks.
- Include a variety of fruits and vegetables in the diet: at least 4.5 cups/day
- Eat a variety of grain products; include whole grains: at least three 1-oz servings/day.
- Eat fish, particularly fatty fish, at least twice a week, 3.5-oz servings.
- Limit sodium intake to less than 1,500 mg/day.
- Include fat-free and low-fat milk products and legumes.
- Choose skinless poultry and lean meats.
- Choose fats and oils with 2 grams or less saturated fat per tablespoon (e.g., liquid and tub margarines, canola oil). Reduce saturated fat intake to less than 7% of total calories.
- Limit sugar-sweetened beverages to no more than 450 calories (36 oz) a week.
- Eat nuts, legumes, and seeds, at least four servings a week.

- ***Trans*-fatty acids** are saturated fats created when food manufacturers add hydrogen to polyunsaturated plant oils, such as corn oil, to break the double carbon bonds and straighten out the molecules. This process solidifies the fat and extends the shelf life of the food. *Trans* fats are found in many margarines and other processed foods containing *hydrogenated vegetable oils.*

Saturated fats and *trans* fats are the main dietary factors in increasing blood cholesterol levels. They raise LDL cholesterol levels. The FDA mandates that *trans* fat content be listed on all food labels. Intake of saturated fats and *trans* fats should be limited.

Refer to Table 26-3: How many servings of fat did you eat yesterday? How many were saturated fats; how many were unsaturated?

Essential and Nonessential Fatty Acids

A fatty acid is considered **essential** if (1) the body cannot manufacture it and (2) its absence creates a deficiency disease. The essential fatty acids, **linoleic acid (omega-6)** and **alpha-linolenic acid (omega-3)**, help protect against heart disease. Omega-6 fatty acid is found mainly in polyunsaturated vegetable oils, nuts, and seeds. Omega-3 fatty acid can be obtained in adequate amounts by eating fatty fish (e.g., tuna, shellfish) twice a week (American Heart Association [AHA], last updated 2014).

Functions of Lipids

Lipids perform the following functions:

1. *Supply essential nutrients.* Food fats supply the essential fatty acids and aid in the absorption of fat-soluble vitamins.
2. *Energy source.* Although carbohydrates are the primary energy source during strenuous physical activity, our bodies burn fat for energy when we are engaging in sustained light activity, such as walking or mowing the lawn, and when we are at rest. The body also burns fat for energy when glycogen stores are exhausted.
3. *Flavor and satiety.* Lipids give food its creamy taste and texture and promote our sense of satiety (being "full"). Fats are digested more slowly than carbohydrates, so stomach emptying time is slower.
4. *Other functions of lipids.* Body fat provides insulation, protects vital organs, aids in thermoregulation, and enables accurate nerve-impulse transmission. In addition, lipids are a component of every cell membrane and are essential to cell metabolism.
5. *Cholesterol functions.* Cholesterol is a component of every cell in the body, where it lends suppleness and support. It is also an ingredient of bile, which helps digest fats, and serves as a precursor to all steroid hormones, including sex hormones. When lipid metabolism is "disordered," cholesterol contributes to atherosclerosis.

ThinkLike a Nurse 27-2

Review the information you collected on the two employees (Meet Your Patients).

- What conclusions, if any, can you make about their intake of carbohydrates, protein, and fats?
- How might you gather additional data on their intake of the energy nutrients?

WHAT ARE THE MICRONUTRIENTS?

Vitamins and minerals are called **micronutrients** because they are required by the body in only very small amounts. Although they provide no energy, they are critical in regulating a variety of body functions.

Vitamins

Vitamins are organic substances that are necessary for metabolism or preventing a particular deficiency disease. Because the body cannot make vitamins, they must be supplied by the foods we eat. Vitamins are critical in building and maintaining body tissues, supporting our immune system so we can fight disease, and ensuring healthy vision. They also help our bodies to break down and use the energy found in carbohydrates, proteins, and lipids. Vitamins are especially critical during periods of rapid growth, pregnancy, lactation, and healing. Some evidence supports the claim that certain vitamins prevent chronic illness.

Table 27-4 summarizes information about vitamins, including specific functions and Dietary Reference Intakes (DRIs). Recommended Daily Allowances (RDAs) represent the daily dietary intake that is adequate to meet the needs of about 98% of all healthy individuals in a group, such as men, women, or infants. The American Academy of Pediatrics recommends that infants, children, and adolescents have a minimum daily intake of 400 international units (IU),* or 10 micrograms, of vitamin D (Wagner, Greer, & the Section on Breastfeeding and Committee on Nutrition, 2008). All breastfed, breast and bottlefed, and formula-fed infants who consume less than a liter of formula per day should receive oral vitamin D supplementation (American Academy of Pediatrics, 2008).

Fat-Soluble Vitamins The fat-soluble vitamins are A, D, E, and K. They are stored primarily in the liver and adipose tissues, although vitamin E is deposited in all body tissue. Because the body can store these vitamins, we do not need to consume them every day if we are consuming them in adequate amounts; however, diets extremely low in fat and disorders affecting fat digestion and absorption can lead to deficiency of fat-soluble vitamins. Because they are not readily excreted, excessive supplementation with the fat-soluble vitamins can lead to toxicity.

The USDA (2011g) now recommends 600 IU of vitamin D every day for most healthy adults age 70 and younger, and 800 IU for healthy people age 71 and older (Ross, Taylor, Yaktine, et al., 2011). This is sufficient for

*Although The Joint Commission includes the abbreviation *IU* on its "do not use" list, the abbreviation is used in other settings (e.g., on vitamin labels).

Table 27-4 ➤ Vitamins: Adult Dietary Reference Intakes (DRIs)*

VITAMIN	FUNCTION	RDA[†]	SOURCES	EFFECTS OF DEFICIENCY	SYMPTOMS OF EXCESS
Fat-Soluble Vitamins					
A	Night and color vision Cellular growth and maturity Maintaining healthy skin and mucous membranes Growth of skeletal and soft tissues Reproduction	Women: 700 mcg/day Men: 900 mcg/day	Fish liver oil, liver, butter, cream, egg yolk, yellow fruit, green leafy vegetables, fortified milk	Night blindness, xerosis, xerophthalmia, keratomalacia, skin lesions	GI upset, headache, blurred vision, poor muscle coordination, fetal defects
D[‡]	Regulates blood calcium levels. Regulates rate of deposit and resorption of calcium in bone.	15 mcg/day to age 70; then 20 mcg/day (AI), after age 71	Fish liver oil, fish, fortified milk, sunlight exposure	Bone and muscle pain, weakness, softening of bone, fractures, rickets	Fatigue, weakness, loss of appetite, headache, mental confusion, mental retardation in infants
E	Antioxidant Protects red blood cells and muscle tissue cells	15 mg/day, age 14+	Vegetable oils, nuts, milk, eggs, muscle meats, fish, wheat and rice germ, green leafy vegetables	Hyporeflexia, ataxia, hemolytic anemia, myopathy	Insufficient blood clotting, impaired immune system
K	Synthesis of clotting factors Bone development	Women age 19+: 90 mcg/day (AI) Men age 19+: 120 mcg/day (AI)	Green leafy vegetables, liver (Intestinal bacteria synthesize a form of vitamin K, so deficiency is unlikely.)	Increased bleeding	Jaundice and hemolytic anemia in infants
Water-Soluble Vitamins					
Thiamin	Cellular metabolism (producing energy from glucose and storing energy as fat) Nervous system function GI system function Cardiovascular system function	Women: 1.1 mg/day Men: 1.2 mg/day	Whole grains, enriched cereal, beef, pork, liver, peas, beans, nuts	Peripheral neuritis, loss of muscle strength, depression, memory loss, anorexia, constipation, dyspnea, decreased alertness and reflexes, fatigue, irritability, beriberi	Unlikely; readily excreted
Riboflavin	Cellular metabolism Antioxidant Tissue health and growth	Women: 1.1 mg/day Men: 1.3 mg/day	Milk, cheese, eggs, green vegetables, whole grains, enriched grains, bread, organ meats, poultry, fish	Tissue inflammation and breakdown: Sore throat, stomatitis, swollen tongue, facial dermatitis, anemia; poor wound healing	Unlikely; readily excreted

Table 27-4 ➤ Vitamins: Adult Dietary Reference Intakes (DRIs)*—cont'd

VITAMIN	FUNCTION	RDA†	SOURCES	EFFECTS OF DEFICIENCY	SYMPTOMS OF EXCESS
Niacin	Cellular metabolism to produce energy	Women: 14 mg/day Men: 16 mg/day	Enriched breads and cereals, chicken, tuna, liver, peanuts, dairy products	Weakness, poor appetite, indigestion, dermatitis, diarrhea, headache, dizziness, insomnia. Chronic: Central nervous system (CNS) damage (confusion, neuritis, dementia), pellagra	Facial flushing, itching, nausea, liver damage
B_6 (Pyridoxine)	Protein (and some carbohydrate) metabolism RBC production Neurotransmitter synthesis	Men and women through age 50: 1.3 mg/day Women 50+: 1.5 mg/day Men 50+: 1.7 mg/day	Meats, poultry, fish, beans, nuts, seeds, dairy products, enriched cereals	Rash, stomatitis, seizure, peripheral neuritis, depression	Irreversible nerve damage (i.e., extremity numbness, walking difficulties)
Pantothenic acid	Cell metabolism of fat and cholesterol Amino acid activation Heme formation	All adults: 5 mg/day (AI)	Occurs widely in most foods. Best sources: Meats, whole grain cereals, legumes	Deficiency is unknown.	Unlikely; readily excreted
Folacin (folate, folic acid)	Cellular metabolism Neurotransmitter synthesis Cell division DNA synthesis Hemoglobin formation	400 mcg/day (folic acid); 600 mcg/day when pregnant Women capable of becoming pregnant should take a daily supplement of 400–800 mcg	Green leafy vegetables, asparagus, liver, yeast, eggs, beans, fruits, enriched cereals	Megaloblastic anemia, neural tube defects	Increased seizure activity, hives, respiratory distress, itching, rash
B_{12} (Cyanocobalamin)	Metabolic reactions Maintain myelin sheath Hemoglobin synthesis	2.4 mcg/day	Dairy products, meat, poultry, fish, liver, milk, cheese, eggs	Classic triad of glossitis (inflamed tongue), weakness, and ascending paresthesia; pernicious anemia, irreversible nerve damage, memory loss, dementia	Unlikely; readily excreted

Table 27-4 ➤ Vitamins: Adult Dietary Reference Intakes (DRIs)*—cont'd

VITAMIN	FUNCTION	RDA†	SOURCES	EFFECTS OF DEFICIENCY	SYMPTOMS OF EXCESS
C	Collagen synthesis "Cementing" substance for capillary walls Antioxidant Iron absorption Immune function	Women: 75 mg/day Men (age 19+): 90 mg/day Additional 35 mg/day for those who smoke	Citrus fruits, tomatoes, potatoes, green vegetables, cauliflower	Anemia, tissue bleeding, easy bone fracture, gingivitis, petechiae, poor wound healing, joint pain, scurvy	Stomach inflammation, diarrhea, oxalate kidney stones

Note: 1 mcg = 40 International Units.
*Values in the table are RDAs unless marked (AI). Dietary Reference Intakes (DRIs) represent:
- Recommended Dietary Allowances (RDAs)—Intake set to meet the needs of 97%–98% of healthy individuals in a group.
- Adequate Intakes (AIs)—Believed to cover the needs of all individuals in the group.
- Upper Intake Levels (Uls)—The maximum daily intake likely to pose no risk of adverse effects.

†RDAs are usually less than adult values for infants and children, more for pregnant women, and highest for lactating women. RDAs for some vitamins (e.g., vitamin A) are higher for older adults and higher for men than for women.
‡The American Academy of Pediatrics recommends 10 mcg/day of vitamin D for infancy through adolescence (Wagner, Greer, & the Section on Breastfeeding and Committee on Nutrition, 2008). Other clinicians and researchers have suggested that the RDA for adults should be dramatically increased as well, to 20–25 mcg (800–1000 IU) for adults aged 50 and older (Jockers, 2007).

Go to Chapter 27, **Supplemental Materials, Dietary Reference Intakes: Vitamins,** on Davis*Plus*.

Sources: Adapted from U.S. Department of Agriculture. (2011f) Dietary Reference Intakes (DRIs): Tolerable upper intake levels, vitamins. Food and Nutrition Board, Institute of Medicine, National Academies. Retrieved March 9, 2014, from http://iom.edu/Activities/Nutrition/SummaryDRIs/~/media/Files/Activity%20Files/Nutrition/DRIs/ULs%20for%20Vitamins%20and%20Elements.pdf; Complete reports are available at http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables; Lutz, C., & Przytulski, K. (2011). *Nutrition and diet therapy: Evidence-based applications* (5th ed.). Philadelphia: F.A. Davis.

most healthy adults; however, some adults may need more. These include those with very little sun exposure (or who consistently wear sun screen or protective clothing), dark skin, osteoporosis, impaired ability to absorb dietary fat, or who are taking medicines that interfere with vitamin D.

New research has revealed that women with very low levels of vitamin D are more likely to have cognitive impairment and higher risk of mental decline (Annweiler, Rolland, Schott, et al., 2012; Slinin, Paudel, Taylor, et al., 2012). Vitamin D is unique in that the body can synthesize it from a cholesterol compound in the skin when we receive adequate exposure to sunlight. However, adequate exposure is difficult in winter months for anyone living at a latitude of 40° or more north or south of the equator (e.g., in Canada and the northern United States). Newest recommendations are that adults age 50 years and older should receive 20 to 25 mcg (800 to 1,000 IU) of vitamin D per day.

Water-Soluble Vitamins The water-soluble vitamins include vitamin C and the B-complex vitamins: thiamine, riboflavin, niacin, pyridoxine (vitamin B_6), folic acid, pantothenic acid, biotin, and cyanocobalamin (vitamin B_{12}). Because these vitamins are soluble in water, excess amounts are regularly excreted by the kidneys in the urine. Thus, toxicity is rare except in people with renal disease. However, because excess amounts are excreted, the body cannot store these vitamins; so they need to be consumed every day.

Minerals

Minerals are inorganic elements found in nature. They occur in foods either naturally or as additives, as well as in supplements. **Major minerals (macrominerals)** are minerals that the body needs in amounts of 100 mg/day or greater. **Trace minerals** are essential, but in a lower concentration. In the United States, calcium deficiency is one of the most common mineral deficiencies (Table 27-5).

Minerals assist in fluid regulation, nerve impulse transmission, and energy production; they are essential to the health of bones and blood and help rid the body of by-products of metabolism. Evidence also shows that minerals play key roles in disease prevention and treatment. For example:

1. Adequate *calcium* intake throughout the life span decreases the likelihood of osteoporosis (a condition marked by porous bones). The recommended daily intake of 1,200 mg for adults aged 50 years and older is difficult to achieve by diet alone (Food and Nutrition Board, Institute of Medicine, National Academies, 1997–2011; Lim, Hoeksema, Sherin, et al., 2009; National Guideline Clearinghouse [NGC], 2009; Ross, Taylor, Yaktine, et al., 2011).

Table 27-5 ➤ Minerals: Adult Dietary Reference Intakes*

MINERAL	FUNCTION	RDA†	SOURCES	EFFECTS OF DEFICIENCY	SYMPTOMS OF EXCESS
Macrominerals					
Calcium (Ca)	Bone and teeth formation, blood clotting, nerve conduction, muscle contraction, cellular metabolism, heart action	1,000 mg/day (AI), ages 19–50 1,200 mg/day (AI) ages 51+ 1,300 mg/day (AI), ages 9–18	Dairy products, sardines, green leafy vegetables, broccoli, whole grains, egg yolks, legumes, nuts, fortified products	Bone loss, tetany, rickets, osteoporosis	Kidney stones, constipation, intestinal gas
Magnesium (Mg)	Aids thyroid hormone secretion, maintains normal basal metabolic rate, activates enzymes for carbohydrate and protein metabolism, nerve and muscle function, cardiac function	*Men:* 400 mg/day (AI), ages 19–30; 420 mg/day, age 31+ *Women:* 310 mg/day (AI), age 19+	Whole grains, nuts, legumes, green leafy vegetables, lima beans, broccoli, squash, potatoes	Tremor, spasm, convulsions, weakness, muscle pain, poor cardiac function	Weakness, nausea, malaise
Phosphorus (P)	Bone and tooth strength, overall metabolism, formation of enzymes, acid–base balance	700 mg/day (AI), age 19+	Dairy products, beef, pork, beans, sardines, eggs, chicken, wheat bran, chocolate	Bone loss, poor growth	Tetany, convulsions
Potassium (K)	Intracellular fluid control, acid–base balance, nerve transmission, muscle contraction, glycogen formation, protein synthesis, energy metabolism, blood pressure regulation	4.7 g/day (AI)	Unprocessed foods, especially fruits, any vegetables, meats, potatoes, avocados, legumes, milk, molasses, shellfish, dates, figs	Muscle weakness (including weakness of heart and respiratory muscles), weak pulse, fatigue, abdominal distention. (Rarely occurs as a result of inadequate dietary intake. More likely due to losses from prolonged vomiting, diarrhea, or some diuretic drugs.)	Cardiac dysrhythmias, cardiac arrest, weakness, abdominal cramps, diarrhea, anxiety, paresthesia
Sodium (Na)	Water balance, acid–base balance, muscle action, nerve transmission, convulsions	1.5 g/day (AI), ages 19–50; 1.3 g/day, age 51–70; 1.2 g/day, age 70+	Table salt (NaCl), milk, meat, eggs, baking soda, baking powder, celery, spinach, carrots, beets	Dizziness, abdominal cramping, nausea, vomiting, diarrhea, tachycardia, convulsions, coma. (Rarely occurs except in heavy exercise and sweating.)	Thirst, fever, dry and sticky tongue and mucous membranes, restlessness, irritability, convulsion

Continued

Table 27-5 ➤ Minerals: Adult Dietary Reference Intakes*—cont'd

MINERAL	FUNCTION	RDA†	SOURCES	EFFECTS OF DEFICIENCY	SYMPTOMS OF EXCESS
Trace Minerals					
Copper	Aids in iron metabolism, works with many enzymes in protein metabolism and hormone synthesis	900 mcg/day (AI)	Liver, seafood, cocoa, legumes, nuts, whole grains	Rarely occurs: anemia, low WBC count, poor growth	Vomiting, nervous system disorders
Fluoride	Increases resistance to dental caries	*Women:* 3 mg/day (AI) *Men:* 4 mg/day (AI)	Fluorinated water, toothpaste, dental treatment, seaweed, fish, tea	Increased dental caries	Stomach upset, staining of teeth, bone pain
Iodine	Synthesis of the thyroid hormone, thyroxine	150 mcg/day	Iodized salt, salt water fish, dairy products, enriched white bread	Goiter, poor infancy growth, cretinism, hypothyroidism	Skin lesions, thyroid malfunction
Iron	Synthesis of hemoglobin, general metabolism (e.g., of glucose), antibody production, drug detoxification in the liver	*Women:* 18 mg/day, ages 19–50; 8 mg/day, age 50+ *Men age 19+:* 8 mg/day	Meats, eggs, spinach, seafood, broccoli, peas, bran, enriched breads, fortified cereals	Small, pale RBCs, anemia	Hemochromatosis
Zinc	Cofactor for many enzymes involved in growth, insulin storage immunity, alcohol metabolism, sexual development and reproduction	*Men:* 8 mg/day *Women:* 11 mg/day	Primarily meats and seafood; also legumes, peas, and whole grains	Skin rash, diarrhea, decreased appetite, hair loss, poor growth and development, poor wound healing	Reduced copper absorption, diarrhea, cramps, depressed immune function

*Dietary Reference Intakes (DRIs) represent:

- Recommended Dietary Allowances (RDAs)—Intake set to meet the needs of 97%–98% of individuals in a group.
- Adequate Intakes (AIs)—Believed to cover the needs of all individuals in the group.
- Upper Intake Levels (ULs)—The maximum daily intake likely to pose no risk of adverse effects.

Values in table are RDAs unless marked (AI).

†RDAs are usually less than adult values for infants and children, more for pregnant women, and highest for lactating women. RDAs for some minerals are higher for older adults and different for men and women.

Sources: Adapted from National Institutes of Health, Office of Dietary Supplements, National Institutes of Health. (Last modified 2010). *Dietary Reference Intakes: Vitamins*. Retrieved March 9, 2014, from http://books.nap.edu/openbook.php?record_id=5776. Complete reports are available at http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes/dri-tables. Institute of Medicine of the National Academies, Food and Nutrition Board, Standing Committee on the Scientific Evaluation of Dietary Reference Intakes. (2010). DRIs for calcium, phosphorous, magnesium, vitamin D, and fluoride. Retrieved on March 9, 2014, from http://iom.edu/Activities/Nutrition/SummaryDRIs/~/media/Files/Activity%20Files/Nutrition/DRIs/ULs%20for%20Vitamins%20and%20Elements.pdf

2. *Iron* deficiency causes anemia, the most common nutritional problem worldwide.
3. *Magnesium* may decrease the risk of hypertension and coronary artery disease in women.
4. *Sodium*, consumed in high amounts (>2,500 mg/day), increases the risk for high blood pressure, heart attacks, and stroke.

Minerals are absorbed mostly in the small intestine. Salt and potassium are absorbed in the large intestine, however. If the body is deficient in a mineral, it absorbs more; if the body has enough, it absorbs less and excretes more in the feces. Minerals interact with other minerals, vitamins, and other substances to accomplish absorption and metabolism and perform their functions.

For example, iron absorption is enhanced in the presence of vitamin C, and vitamin D deficiency inhibits calcium absorption.

WHY IS WATER AN ESSENTIAL NUTRIENT?

Water is made up of hydrogen and oxygen. Water makes up about half of total body weight (55% to 65% in men and 50% to 55% in women). Men have greater muscle mass; muscle contains a relatively large amount of water. Water is distributed in two body compartments. **Intracellular fluid** is the water contained within each living cell. It makes up about 40% of the total body weight. **Extracellular fluid** is external to the cell membrane (e.g., in the fluid portion of blood and lymph and in the gastrointestinal [GI] tract); it accounts for 20% of body weight. Water is critical to the body because its functions are essential to life:

1. *Solvent.* Water is the basic solvent for the body's chemical processes.
2. *Transport.* Circulating as a component of blood, water serves as a medium for transporting oxygen, nutrients, and metabolic wastes.
3. *Body structure and form.* Water "fills in the spaces" in body tissues (e.g., in muscle).
4. *Temperature.* Water helps maintain body temperature. When body temperature rises, evaporation of sweat helps cool the body.

The amount of water a person requires varies according to the environmental humidity and temperature, activity level, age, and metabolic needs. The average AI for adult women is about 2.7 liters of water per day and 3.7 liters for men. Eighty percent of those amounts should come from fluids. We also obtain water in the foods we eat (Lutz & Przytulski, 2011). What foods can you think of that are high in water content?

Overall fluid balance is maintained when fluid intake in liquids, foods, and metabolic reactions matches fluid output through urine, feces, respiration, and sweat. Fluid and electrolyte balance is discussed in Chapter 38.

KnowledgeCheck 27-2

- What is the body's most usable energy source?
- Which nutrient's primary function is growth and repair of tissue?
- Identify five functions of adipose tissue (body fat).
- Which type of vitamin requires daily consumption to maintain appropriate levels?
- What distinguishes a major mineral from a trace mineral?
- Identify at least four functions of water.

WHAT MUST I KNOW ABOUT ENERGY BALANCE?

The energy in carbohydrates, proteins, and lipids is measured in terms of **calories**, or, more precisely, **kilocalories (kcal)**. A kcal is the amount of heat required to raise the temperature of 1 kg of water 1° centigrade. To maintain a stable weight, the number of kcal we consume must equal the number of kcal we burn. Any deviation results in weight loss or weight gain. Below is the amount of energy liberated from the metabolism of 1 gram of energy nutrients:

- Carbohydrates = 4 kcal/g
- Protein = 4 kcal/g
- Fat = 9 kcal/g

PICOT

Situation: The nurse is reviewing a client's intake and output (I&O) with him. The I&O are out of balance. The nurse begins to question the client further about other potential consequences of dehydration.

Searchable Question: Do __________ (P) who are __________ (I) demonstrate __________ (O) as compared to __________ (C) during __________ (T)

PICOT Components

P	Population/patient	= Elderly inpatients
I	Intervention/indicator	= Dehydration
C	Comparator/control	= Elderly community dwellers
O	Outcome	= Complications of dehydration
T	Time	= During hospitalization

Searching for the Evidence: Overall fluid balance is affected by diet, exercise, temperature, illness, and medication. Older people are also more susceptible to dehydration because of cognitive, sensory, motor impairments, which affect their activities of daily living (ADLs). They tend to take more medications and have more illness that can increase the risk for fluid imbalance. For example, the frail older person with exercise intolerance related to chronic pain may not be able to stay hydrated. If that person becomes ill, it is even more likely that the client will be unable to independently take in sufficient amounts of fluid. It is important to encourage all elderly people, inpatient and in the community, to consume small amounts of fluids throughout the day in order to maintain adequate fluid balance. Assessment questions that might point to a fluid imbalance would include those regarding intake, activity, and elimination patterns.

Source: Schold, J. M., De Groot, C., van de Cammen, T., et al. (2009). Preventing and treating dehydration in the elderly during periods of illness and warm weather. *Journal of Nutritional Health Aging, 13*(2), 150–157.

KnowledgeCheck 27-3

Imagine that you have just eaten a food consisting of 4 grams of protein, 18 grams of carbohydrate, and 1 gram of fat.

- What would your total kcal intake be?
- What percentage of your kcal is from carbohydrates? Protein? Fat?

A diet of too few kcal is likely also to lack essential nutrients. People who are undernourished may experience weakened immunity, stunted growth, and hormonal disruption. Too many kcal can cause obesity, which increases the risk for chronic diseases, such as diabetes, arteriosclerosis, hypertension, hyperlipidemia, and cancers. In determining total energy (kilocalorie) needs, consider two factors: the client's basal metabolic rate and the duration and intensity of daily physical activity.

What Is Basal Metabolic Rate?

The **basal metabolic rate (BMR)** is a measure of the energy used while at rest in a neutral temperature environment—the energy required for vital organs such as the heart, liver, and brain to function. *Direct measurement* of BMR requires use of a calorimeter: an insulated unit that measures temperature changes of water that are produced by exposure to a fasting individual at rest. Although it is very accurate, it is rarely used because most institutions do not have calorimeters and because the test requires a controlled environment and a 12-hour fast. Direct measurement of BMR is used primarily by researchers. *Indirect calculation* of BMR, sometimes called the resting energy expenditure (REE), includes the following:

- Measuring oxygen uptake per unit of time. This can be done in an exercise lab or with portable machines at the bedside. This is most often done for patients in intensive care units. Not all facilities have this capability.
- Serum thyroxine levels (a blood test).
- A formula for calculating BMR when precise measurement is not required (Box 27-3).

BOX 27-3 ■ Calculating Basal Metabolic Rate (BMR)

Women:	0.9 kcal/kg of body weight per hour
Men:	1.0 kcal/kg body weight per hour
Example:	Isaac Schwartz (Meet Your Patients) weighs 245 lb.

1 kilogram = 2.2 pounds.

Divide 245 by 2.2 to convert pounds to kilograms:

$245 \div 2.2 = 111.3$

Now complete the calculation:

$1.0 \times 111.3 \times 24 \text{ hours} = 2671.2$

What Factors Affect Basal Metabolic Rate?

When interpreting test results, consider the following factors that influence BMR:

- *Body composition*. Lean body tissue has greater metabolic activity than do fat and bones. This explains why women, who have on average more adipose tissue than men, also have lower BMRs.
- *Growth periods*. BMR increases during periods of growth, such as the first 5 years of life, adolescence, pregnancy, and lactation.
- *Body temperature.* The BMR increases 7% for each 1°F (0.83°C) rise in body temperature.
- *Environmental temperature.* Cold weather, especially temperatures below freezing, causes a slight rise in the BMR to generate body heat and maintain normal body temperature.
- *Disease processes.* Diseases involving increased cellular activity, such as cancer, anemia, cardiac failure, hypertension, and asthma, result in BMR elevation. For the same reason, systemic injury (e.g., severe burns, traumatic injury) increases BMR.
- *Prolonged physical exertion.* Metabolic demands are also elevated during prolonged physical exertion (e.g., chopping wood, running).

How Do I Calculate a Client's Total Energy Needs?

The amount of energy required varies according to the intensity of the activity (Table 27-6). A person's total daily energy requirement is the number of kcal necessary to replace those used for basic metabolism plus those used in physical activities. The following are simple estimates based on activity level and age:

- Sedentary women and older adults need 1,600 kcal/day.
- Children, teenage girls, active women, and most men need 2,200 kcal/day.
- Teenage boys, active men, and very active women need 2,800 kcal/day.

However, these estimates have limited usefulness. For instance, is a woman who works a desk job but walks for 30 minutes a day sedentary, active, or somewhere in between? To calculate energy use more precisely, you need to know the person's age, weight, and physical activity, including the intensity and duration of the activity. See Table 27-7.

Heightened emotional states may also increase energy needs, not because they directly increase metabolic activity, but because they increase muscular activity in the form of muscle tension, restlessness, and agitated movements.

KnowledgeCheck 27-4

You have already calculated the expected BMR for Mr. Schwartz (Meet Your Patients) for a 24-hour period.

- If Mr. Schwartz describes himself as working at a desk 8 to 10 hours per day, lawn mowing manually every other week

Table 27-6 ➤ Levels of Physical Activity: Energy Expended and Examples*

INTENSITY LEVEL	LIGHT	LIGHT TO MODERATE	MODERATE	HIGH
Energy Expended	120–150 kcal/hr	150–300 kcal/hr	300–420 kcal/hr	420–700+ kcal/hr
Examples of Activities	Dressing Showering Shaving Rocking Writing Typing Standing	Housework (e.g., sweeping) Light gardening Mowing lawn (motorized) Painting Walking 2–3 mph Bicycling 5½ mph Canoeing 2–3 mph	Digging Mowing lawn (manually) Walking 3½–4 mph Ballet Ballroom dancing Golf (no cart) Tennis (doubles)	Shoveling snow Walking 5 mph Climbing Bicycling 15–25 mph Cross-country skiing Jogging 5 mph or 1 mile in 10 min Swimming Aerobic dancing

*Precise energy use varies with body weight. For example, an individual weighing 200 lb burns about 740 calories per hour during aerobic dance, whereas an individual weighing 125 lb burns about 470 during the same activity.

Table 27-7 ➤ Energy Needs Based on Weight and Activity

For *each pound of body weight*, a person needs the following per day:

ACTIVITY LEVEL	UNDERWEIGHT	NORMAL WEIGHT	OVERWEIGHT
Sedentary	13 kcal	13 kcal	9–11 kcal
Moderately active	18 kcal	16 kcal	13 kcal
Active	18–23 kcal	18 kcal	16 kcal

during the summer, and playing an occasional game of golf, how would you classify his general activity level?

- After interviewing Mr. Schwartz, you estimate his average caloric intake to be approximately 3,000 kcal per day. Determine whether his kcal intake is sufficient or insufficient to maintain his present activity level.

What Are Some Body Weight Standards?

Weight standards have been established to correlate weight with good health and longevity and to help determine a client's ideal body weight. The **general ideal weight guide** uses a formula to determine a reasonable weight based on height:

Men: 106 lb (47.7 kg) for the first 5 ft (150 cm), then add 6 lb/in. (2.7 kg/2.5 cm)

Women: 100 lb (45 kg) for the first 5 ft (150 cm), then add 5 lb/in. (2.25 kg/2.5 cm)

Add 10% for large body frame; subtract 10% for small body frame.

Various **height–weight tables** have been developed over the years (beginning as long ago as 1943). Height–weight tables are based on statistical estimates and often include variations for age, sex, and body frame. Use standards and standardized tables with caution because they are based on limited samples and may create unrealistic expectations, especially at the low weight ranges. Consider the following example: You have two male clients; each weighs 200 lb. Mason is 72 in. tall, works out vigorously 5 days per week, and has 18% body fat. Travis is 72 in. tall, rarely exercises, and has 35% body fat. Which of these clients requires more kcal to maintain his present weight? Which of these clients is at lower risk for cardiovascular disease?

If you answered Mason, you are correct. Although both men have the same height and weight, Mason has more lean body mass. He will burn energy more rapidly and be able to eat more without gaining weight. Height–weight tables cannot replace a thorough assessment and analysis of body composition when attempting to determine a client's overall fitness.

To see the World Health Organization (WHO) (2006b) child growth standards (e.g., length and height-for-age, weight-for-age), Go to http://www.who.int/childgrowth/standards/en/

Body composition analysis attempts to quantify lean body mass versus percentage body fat. Lean body mass includes muscle, bone, and connective tissue. Lean tissue weighs more than fat; thus, a person who engages in regular weight-bearing exercise and is physically fit may actually weigh more than an individual of similar appearance who is sedentary and unfit. Various methods to assess body composition, known as *anthropometric measurements*, are provided in the Assessment section later in the chapter.

Think**Like a Nurse** 27-3

Examine your dietary intake for the next 3 days to determine how balanced your diet is. Use the form on Davis*Plus* and record all intake.

- How does your diet compare to the USDA MyPlate or Canada's Food Guide in terms of:
  a. Servings of bread, cereal, rice, and pasta?
  b. Servings of vegetables?
  c. Servings of fruits?
  d. Servings of milk, yogurt, and cheese?
  e. Servings of meat, poultry, fish, dry beans, eggs, and nuts?
  f. Servings of fats, oils, and sweets?
- From what you have learned from this activity, what habits could you change in patterns of eating in order to achieve optimal nutrition?

WHAT FACTORS AFFECT NUTRITION?

Several factors influence nutritional needs and choices. Some can be modified; some cannot. The most influential factors are development, knowledge, lifestyle, culture, disease processes, and functional limitations. Parents and caregivers are the most important influences on the eating habits of children. For tips about how to be a role model for children and set good examples for healthy eating for life,

Go to the **USDA** Web site at http://www.choosemyplate.gov/food-groups/downloads/TenTips/DGTipsheet12BeAHealthyRoleModel.pdf

For more tips on how to encourage healthy eating in children,

Go to Chapter 27, **Tables, Boxes, Figures: ESG Box 27-1, Healthy Eating for Children,** on Davis*Plus*.

Developmental Stage

At specific developmental stages, nutritional needs and eating patterns vary according to physiological growth, activity level, metabolic processes, disease prevention, and other factors.

Infants to One Year

Humans grow most rapidly during the first year of life. Birth weight doubles by 5 months of age and triples during the first year, with length increasing by 50%. A baby 20 inches long at birth grows to about 30 inches by age 1 year. Nutritional needs per unit of body weight are greater during this period than at any other time.

Calories and Protein The infant needs adequate protein for tissue building and enough carbohydrates to furnish energy and "spare" the protein. The period from conception into the second year of life is most critical to brain development. For maximum brain growth, the baby needs optimal nutrition. Severe protein-calorie deficiency in the last trimester of pregnancy or the first 6 months of life may decrease the number of brain cells by 20%.

Vitamins and Minerals Fetal iron stores are depleted at 4 to 6 months, so intake of iron becomes important. The infant needs calcium for bone growth and development of teeth, calcium and vitamin C for iron absorption, and vitamin D for calcium regulation.

Fluids Compared to adults, infants have a higher metabolic rate. They also have greater water loss through the skin, which makes up a greater proportion of the body. These factors, along with immature kidneys, mean that infants need proportionately more fluid than adults. To meet nutritional and fluid needs, the infant requires 1.5 to 2 ounces of breast milk or formula per pound of body weight per day.

Infant Feedings The only safe choices for meeting fluid and nutrient needs in the first months of life are breast milk and commercially prepared formulas. Breast milk is the ideal food for infants because it is matched to their nutritional requirements. It contains enzymes to digest fats, protein, and carbohydrates. In addition, it enhances maturation of the infant's immune system and provides passive immunity against a number of infections, including pneumonia, acute otitis media, and gastroenteritis. The American Academy of Pediatrics (AAP) supports the benefit of breastfeeding because of numerous other health benefits to infants, such as lower risk of sudden infant death syndrome (SIDS). Infants receiving breast milk in the first six months of life may also have less risk of developing diabetes mellitus later in life, obesity, asthma, and childhood leukemia (AAP, 2008; Ip, Chung, Raman, et al., 2007; Owen, Martin, Whincup, et al., 2007; Rosenbauer, Herzig, Kaiser, et al., 2007; Yamakawa, Yorifuji, Inoue, et al., 2013).

When breastfeeding is contraindicated or the mother chooses not to breastfeed, numerous commercial formulas are available. The most commonly used formula is modified cow's milk available in powder, liquid concentrate, or ready-to-use liquid. Other types include iron-fortified, soy, and hypoallergenic formulas.

Infants younger than 1 year should not receive cow's milk because it may cause gastrointestinal bleeding and may place too much strain on the infant's kidneys. It also can contribute to iron-deficiency anemia.

Honey and corn syrup should not be used as a source of carbohydrates in preparing infant formula. They are potential sources of botulism toxin, which can be fatal in children younger than 1 year old (Schlenker & Roth, 2010).

Boiling water prior to constituting infant formula depends on the water quality of the tap supply. When in doubt, consult the local health department. If unsure, the FAD recommends boiling rapidly for a minimum of 1 full minute and cooling completely before adding it to infant formula.*

At 4 to 6 months, infants may be started on solid foods, beginning with iron-fortified infant rice cereal. They progress to eating table food by 1 year of age. If solid foods are begun too early, they may trigger food allergies.

Healthy infants born at term have sufficient iron for their first 4 months. Iron supplements are usually given beginning at 4 to 6 months (depending on whether breast- or formula-fed), and they may continue after 12 months if iron needs are not being met (AAP, 2010). Fluoride might also be prescribed for infants without a fluoridated water supply.

Toddlers and Preschoolers

Toddlers grow more slowly in comparison to infants, and have fewer energy demands. Toddlers require about 900 to 1,800 kcal and 1,250 mL of fluid per day, depending on body weight. As the GI system matures, they are able to eat most foods and adjust to the adult pattern of three meals a day. By age 3, most children have all of their deciduous teeth and can chew adult food.

Cut food into small pieces to avoid choking in toddlers who sometimes are "too busy" to chew food sufficiently. Sometimes young children "chipmunk" their food and can later choke on it. Do not give food when the child is in a car seat or bouncy chair, where choking is more likely and can occur without a parent noticing.

Toddlers Toddlers' diets are sometimes deficient in fat and meat. One- and 2-year-old children should drink reduced-fat (2%) milk or in some cases whole milk to provide adequate fat for the still-growing brain. Deficiencies in iron, calcium, and vitamins A and C are also common during this period. Parents need to offer a variety of foods to provide these essential nutrients. This can be a challenge, because toddlers assert their autonomy and manipulate their parents by refusing foods. They may take a long time to eat or refuse to eat at all. Parents should not turn mealtime into a battle of wills or use foods to punish or reward; such reactions may affect the child's attitude toward food. To encourage the child to eat, you may offer parents the suggestions in the accompanying Home Care box.

Preschoolers Preschoolers' growth and nutritional needs are similar to those of toddlers; however, their eating patterns typically improve. They begin to form responses to specific foods, such as refusing all green vegetables or drinking less milk. They often refuse casseroles and foods with sauces, and they might also eat only one particular food for several days. Because they are active, preschoolers require nutritious between-meal snacks. Lifelong food habits are developed during this stage, so encourage families to widen the variety of foods offered to preschoolers and to investigate the diet provided by their child's day care or preschool. Between ages 2 and 5 fat should provide only about 30% of the child's intake.

School-Age Children

In the school-age period, growth and body changes occur gradually. Permanent teeth erupt, and the digestive system matures. School-age children need about 2,400 kcal and 1,750 mL of fluid per day. An adequate supply of vitamins and minerals is critical because the body is still growing and preparing for the demands of adolescence.

Parental control over food intake declines during these years. Peers and advertisers influence the child's food choices. The child eats away from home and may buy junk food with his lunch money or choose less nutritious foods in the school cafeteria. Even if the child brings lunch from home, he may trade his food or not eat lunch at all. Parents should encourage their children to eat breakfast to provide nutrients and energy to fuel problem-solving skills, memory, and sports and playground activities.

Home Care

Tips for Encouraging Toddlers to Eat

- Keep only nutritious foods in the house to avoid battles over nutrient-poor snacks.
- Serve foods in a "child-friendly" way; for example, arrange tortillas, cheese, tomato slices, and beans in a smiling face.
- Allow the child to "graze" throughout the day on healthful foods rather than insisting that she sit for formal meals at the table.
- Avoid "combined" foods, such as casseroles and stews.
- Limit consumption of sweets and snack foods.
- Do not use dessert as a reward for eating other foods (e.g., "You can't have cookies until you eat your meat").
- Offer healthy foods that are easy to eat (e.g., "finger foods" or those easily chewed)

*Water that is purified or bottled for use in infant formulas does not contain fluoride.

Poor eating habits may lead to obesity. Thirty-two percent of U.S. children are overweight: 18% of boys, and 15% of girls (Centers for Disease Control and Prevention [CDC], 2008). Leading causes of childhood obesity include the following:

- Routine consumption of high-fat, high-sugar fast foods, nutrient-poor foods, and high-calorie snacks and beverages
- Loss of family mealtime
- Eating in front of a TV, computer, or video game
- Lack of regular physical activity to burn the kcal consumed (Berkowitz & Borchard, 2009)

Adolescents

Adolescence is a time of dramatic growth and the development of the reproductive system. Boys experience an increase in muscle tissue and bone length and density. At menstruation, girls experience fat deposition. The needs of the adolescent body for energy, vitamins, and minerals approach those of the infant. In particular, adolescents need protein, calcium, iron, and B and D vitamins. Boys in particular seem to eat constantly. Adolescents have active lifestyles and snack often, preferring ready-to-eat, eat-on-the-run foods, such as chips, pizza, cookies, and fast foods. Unfortunately, most such foods have little nutrient value. Adolescents are responsible for their own food decisions, so the best approach for parents is to keep only healthful snack foods (e.g., cheese, fruit, raw vegetables) in the home.

For girls, the need for nutrients conflicts with intense social pressure to be slim. About half of all teenage girls report that they are either dieting or that they need to be. Eating disorders are a concern in adolescence. Most people with eating disorders exhibit their first symptoms before age 20, some as early as age 10. The majority of eating disorder sufferers are female (National Association of Anorexia Nervosa and Associated Disorders, n.d.). Underweight and undernutrition are discussed more in the Practical Knowledge Section.

Adults

Young adults continue to require adequate amounts of protein, vitamins, and minerals, but not at the same levels as in adolescence. If adults continue unhealthful behaviors developed in earlier stages, repercussions will begin to show up in adulthood. Calcium, vitamin D, folic acid, and iron continue to be critical, especially in women, for bone and reproductive health. U.S. Preventive Services Task Force (USPSTF) officials recommend that women capable of becoming pregnant should take a folic acid supplement of 400 to 800 mcg per day to lower the risk for neural tube defects in the fetus (Simmons, 2013; USPSTF, 2009).

The BMR of middle adults decreases, potentially causing weight gain if dietary intake and activity level are unchanged. Individuals may begin to experience chronic illnesses such as diabetes, hypertension, obesity, and hyperlipidemia, often as a result of heredity or poor lifestyle choices. Dietary modification and exercise are essential to control these diseases. Overweight and obesity are discussed more fully in the Practical Knowledge section. For dietary strategies for preventing cancer,

Go to Chapter 27, **Tables, Boxes, Figures: ESG Box 27-2, Dietary Strategies for Preventing Cancer,** on Davis*Plus*.

Pregnant and Lactating Women

Nutritional requirements increase dramatically during pregnancy as the mother provides for the nutritional needs of the fetus. Folic acid intake is critical in the first trimester of pregnancy (the first 13 weeks) to prevent neural tube defects; a daily supplement of 600 to 800 mcg is recommended during pregnancy. Adequate protein and calcium are important for growing muscle, brain, and bone tissues; iron is essential to maintain maternal and fetal blood supplies and stores during pregnancy. It is almost impossible to consume the recommended amount of dietary iron, so supplements are commonly prescribed, as are supplements of folic acid and calcium. Pregnant women need about 300 additional kcal/day in the second and third trimesters of pregnancy.

Pregnant women also need to be screened for gestational diabetes (GDM). Complication for the mother and the fetus/infant of uncontrolled GDM include increased childhood obesity, fetal macrosomia and primary cesarean section (Agency for Healthcare Research and Quality [AHRQ], 2012).

Women who are breastfeeding need 500 additional kcal per day. They continue to need additional protein and calcium, as well as increased fluid intake to make adequate amounts of breast milk. Needs vary based on the size of the baby and the frequency of breastfeeding. The quantity of the breast milk depends on an adequate supply of fluids and nutrients. However, the nutritional quality of the milk remains the same even if dietary intake is not adequate.

KnowledgeCheck 27-5

- Why is breast milk an ideal food source for infants?
- Why are an infant's nutritional needs per unit of body weight greater than at any other period of development?
- Why is it sometimes a challenge to meet the nutritional needs of toddlers?
- What is the challenge in meeting the nutritional needs of school-age children?
- Which age group experiences a growth spurt second only to that of infants?
- Why are energy (kcal) requirements less for older adults?

Older Adults

Nutritional needs of older adults vary only slightly from middle adulthood. Lean body mass, physical activity, and BMR decrease, so older adults tend to need fewer kcal; but they still need the same or higher levels of nutrients. However, it is not unusual for older adults to lose interest in eating and for the thirst sensation to decrease.

Older adults with chronic diseases may need to adjust to therapeutic diets low in salt, simple sugars, or fat. Unfortunately, the ability to taste and smell diminishes with age, and many clients find these diets unappealing. Other sensory changes, such as diminished vision or hearing, limit mobility and interaction, making it more difficult to purchase and prepare food. Tooth loss and gum disease limit chewing ability, forcing many older adults to eat only soft food. Arthritic hands may have difficulty preparing and eating food, and when they are no longer able to drive, many older adults must rely on local markets, where food choices may be limited and expensive. Other physical problems that may affect nutrition include gastroesophageal reflux, decreased gastric secretions, decreased intestinal peristalsis, and glucose intolerance.

See Table 27-8 for dietary requirements for adults older than 70 years. Notice the main difference is that older adults require smaller quantities of most foods. In general, they require slightly more of the milk/yogurt/cheese group and slightly less of all other groups, especially the breads/cereal group. Older adults need complex carbohydrates (i.e., fiber) to maintain bowel function. They should be sure to drink at least eight glasses of water or other fluids (e.g., soups) per day and choose primarily green leafy vegetables and brightly colored fruits to help prevent constipation and dehydration. All of this, of course, assumes their medical condition allows this type of diet.

Many older adults may need supplements of calcium, vitamin D, and vitamin B_{12}. For example: (1) As bone density decreases, calcium requirements increase, especially in women at risk for *osteoporosis*; and (2) low concentrations of vitamin B_{12} have been linked to cognitive decline in older adults (Clark, Birks, Nexo, et al., 2007; Orton, 2012; Ross, Taylor, Yaktine, et al., 2011).

With advancing age, older adults face many losses. As a result, depression and social isolation are common. Both negatively affect appetite. **Adult failure to thrive** is a complex disorder seen in many institutionalized older adults. It is characterized by weight loss, decreased activity and interaction, and increasing frailty.

ThinkLike a Nurse 27-4

Make a list of all the food products you have seen advertised on television and in magazines. What are the implications for the nutritional status of the public?

Lifestyle Choices

Nutrition-related lifestyle choices include the following:

Dietary Patterns The type of food consumed is as important as the amount of food to a person's overall health. Whole foods, such as fresh fruits and vegetables, whole grains, and legumes, promote health, whereas

Table 27-8 ➤ Daily Food Requirements for Adults Older Than Age 70

FOOD GROUP	ADULTS ≥70 YEARS
Supplement of calcium, vitamin D, and vitamin B_{12}	As prescribed. Not everyone needs supplements. People should consult their healthcare providers.
Fats, oils, and sweets	Use sparingly
Milk, yogurt, and cheese group	3 servings
Meat, poultry, fish, dry beans, eggs, and nut group	2 or more servings
Vegetable group	3 or more servings
Fruit group	2 or more servings
Bread, fortified cereals, rice, and pasta group	6 or more servings
Water equivalents	8 or more servings

Source: Tufts University Nutrition. (2011). MyPlate for Older Adults. Retrieved December 23, 2012, from http://www.nutrition.tufts.edu/research/myplate-older-adults

foods high in simple sugars, saturated and *trans* fats, and sodium increase the risk for health problems.

Work Environment Physically demanding work can cause fatigue and affect the quantity and quality of food consumed. When time pressure on the job makes it difficult to prepare and eat healthy food during a short lunch break, some workers may rely on convenience foods to save time.

Cooking Methods Up to one-half of the water-soluble vitamin content (vitamins B and C) is lost in the cooking water of boiled vegetables. Keeping foods hot longer than 2 hours results in even further loss.

Oral Contraceptive Use This method of family planning lowers the serum level of vitamin C and several B vitamins. Women with marginal nutrient intake may need vitamin supplements.

Using Food to Relieve Stress Food is commonly used to cope with stress, depression, loneliness, or boredom. For example, in highly stressful work environments some workers react by consuming high-calorie snacks beverages. Skipping meals, binge eating, or consuming too much of a single food (e.g., snack foods or chocolate) can result in poor nutrition, obesity, and low self-esteem.

Smoking Smokers use vitamin C faster than nonsmokers. Vitamin C is also an antioxidant. The more a person smokes, the more vitamin is lost, and the more the body needs vitamin C to counteract the damage smoking causes to cells. Additionally, because vitamin C aids in absorption of iron, low levels of vitamin C also are linked to iron deficiency. If the person cannot quit smoking, a vitamin C supplement (2,000 mg/day) may help compensate.

Otherwise, there is some evidence suggesting folic acid found in leafy vegetables may protect against cancer in current and former smokers (National Institutes of Health, 2010).

Alcohol Alcohol contributes to obesity. A 12-oz beer contains 150 calories; a juice-based cocktail contains about 160 calories. This can add many unnecessary calories to the regular diet. In addition, alcohol significantly decreases the rate of fat metabolism. Excessive alcohol use interferes with adequate nutrition by (1) replacing the food in the person's diet, (2) suppressing the appetite, (3) decreasing the absorption of nutrients by its toxic effects on intestinal mucosa, and (4) impairing the storage of nutrients. People who use alcohol heavily need multivitamin supplements, especially B vitamins and folic acid.

Caffeine The most common sources of caffeine are coffee, soda, and energy drinks. Over the years, research reports have claimed a variety of dangers and health benefits for caffeine. Recently a privately funded group (Schardt, 2008) published an analysis of nine scientific reports in which they state that many of our accepted beliefs about coffee are myths. They report coffee does not create risk for dehydration, heart disease, or cancer, and has little or no role in hypertension. Caffeine may be associated with bone loss; however, its negative effect can be offset by as little as 2 tablespoons of milk. In high doses, caffeine can sometimes cause anxiety and stomach upset. On the positive side, caffeine can enhance mood and mental and physical performance. It aids the ability to burn fat for fuel instead of carbohydrates, and has been linked to a lower risk of Parkinson's disease, type 2 diabetes, stroke, and dementia (Schardt, 2008; van Dam, Willett, Manson, et al., 2006). So it appears that while the evidence is still mixed, caffeinated beverages in moderation are not the villains we once thought.

Vegetarianism

All vegetarian diets exclude red meat and poultry, but beyond this distinction is a wide spectrum of diets. **Semi-vegetarians** are the most inclusive, allowing fish, eggs, and dairy products as well as plant-based foods. **Ovo-lacto vegetarians** are somewhat more strict; they eat eggs and dairy products, but not fish. **Lacto-vegetarians** consume only dairy and plant-based foods. **Vegans** eat only foods of plant origin, and a **fruitarian** diet includes only fruits, nuts, honey, and vegetable oils. Soybeans, soy milk, tofu, and processed protein products can be used by all but fruitarians to enhance the nutritional value of the diet.

People choose vegetarian diets for a number of reasons. As noted in Chapter 16, some religions prohibit consumption of animal flesh or foods of animal origin. Ethical considerations related to humane treatment of animals also cause some people to adopt a vegetarian diet. However, many people adopt a vegetarian diet simply as a health choice, noting the abundant research indicating that vegetarianism reduces the risk of disease (e.g., ischemic heart disease) and promotes wellness by limiting fat intake.

Although ovo-lacto vegetarians have no higher rate of nutrient deficiencies than the meat-eating population, they must choose foods carefully to include enough of the following nutrients:

- *Vitamin B_{12}* is found only in animal products, such as eggs and milk. Vegans must eat foods fortified with B_{12} or take B_{12} supplements. Long-standing B_{12} deficiency can result in severe and irreversible neurological impairment.
- *Vitamin D* may be inadequately supplied by vegetarian diets, so vitamin D–fortified foods (e.g., soy and dairy milk are usually vitamin D fortified) should be included. Adequate sun exposure also helps to compensate for lack of dietary intake.
- *Calcium, iron, and zinc.* Vegans, fruitarians, and others who limit animal foods may need to supplement the diet with calcium, iron, and zinc. This is especially important for children and women who are pregnant or lactating.
  (a) *Iron:* The iron from plant foods is not absorbed as well as that from animal sources. However, it is easier to absorb dietary iron when it is eaten with foods containing vitamin C, so eating fruit or vegetables containing vitamin C with meals helps to compensate.
  (b) *Calcium:* Vegans, especially, may find it difficult to obtain enough dietary calcium. It is important to include fortified soy milk and calcium-rich vegetables (e.g., bok choy, broccoli, collards, Chinese cabbage, kale, mustard greens, okra, and fortified tomato juice). Calcium-fortified cereals are also available.
  (c) *Zinc:* A wide variety of foods contain zinc. Oysters contain more zinc than just about any other food. Meat and poultry also have a high zinc content. Although some grain and plant foods contain zinc, it is not as bioavailable from non-animal sources (National Institutes of Health, Office of Dietary Supplements, n.d.).
- *Protein* may be inadequate, especially in vegan children who do not care for the taste of soy milk, tofu, and other soy-based meat substitutes. For adults, a varied diet that meets normal nutrient and energy needs is also likely to supply adequate amounts of essential amino acids. Complementary proteins should be eaten throughout the day, but careful meal-by-meal balance of amino acids is usually not necessary. Review Table 27-1 and the discussion of complete and incomplete proteins earlier in the chapter.

- To ensure adequate nutrients it may be wise for vegetarians to consult a qualified nutrition professional, especially during periods of growth, breastfeeding, pregnancy, or recovery from illness. For recommended servings of vegetarian food groups, see MyVeganPlate (Fig. 27-3). This is presented in a similar manner to the ChooseMyPlate.org nutritional guidelines.

Go to Chapter 27, **Tables, Boxes, Figures: ESG Table 27-2, Recommended Daily Servings for Vegetarian Meal Planning,** on Davis*Plus*.

As a vegetarian diet can be a healthy option, the USDA also has tips for vegetarian diet.

Go to the **USDA** Web site at http://www.choosemyplate.gov/healthy-eating-tips/tips-for-vegetarian.html

Eating for Health and Athletic Performance

In recent decades the consumption of processed foods, grains, and beverages is cited as a cause of diseases, such as type 2 diabetes and obesity, heart disease, cancer, and many others. Consuming a diet high in meats and fish, fresh fruits and vegetables, nuts and seed, eggs, and other natural, whole foods is biologically healthier than the modern diet high in *trans* fats, preservatives, and chemical additives. Proponents of the paleo diet, named for the foods hunted and gathered by people of the Paleolithic era, advocate returning to a "caveman" diet for improved health and athletic performance. Foods to avoid are all processed foods, grains containing gluten, diary, refined sugar, legumes, potatoes, processed oils, and caffeine.

Dieting for Weight Loss

Many diets, including the *D*ietary *A*pproaches to *S*top *H*ypertension (DASH) diet, the American Heart Association diet, and others, are nutritionally sound, but many others are "fad diets," claiming to produce speedy, effortless, almost miraculous, weight loss. You can recognize fad diets by the following characteristics. They:

- Promise quick and dramatic weight loss, which is usually achieved only temporarily because it results from loss of body fluids.
- Limit the range of foods from which the dieter can select (e.g., only fruits and vegetables for the first week), leading to an imbalance in nutrients.
- Often recommend purchase of supplements and/or special packaged meals; in many cases, these are brands that they endorse or actually produce.
- Fail to include practical strategies that help dieters permanently change eating and activity patterns.

As soon as they achieve their weight-loss goal, fad dieters typically revert to former eating habits and regain the weight. In contrast, more moderate calorie-restriction diets, such as the American Heart Association diet:

- Describe food selection and preparation tips and other behavior modifications that can lead to slow, sustained weight loss.
- Promote a diet that includes a variety of food choices and a balance of nutrients.
- Encourage physical activity as a cornerstone of weight loss.
- Emphasize self-monitoring, cognitive strategies, and behavior modification.

Go to the **USDA ChooseMyPlate.gov, Weight Management & Calories** Web site at http://www.choosemyplate.gov/weight-management-calories.html

Ethnic, Cultural, and Religious Practices

As described in Chapters 15 and 16, religion and culture can have a major impact on diet and lifestyle. The following are examples:

- Language barriers may make it difficult for a client to understand nutritional information. For those patients, simple visual aids may be useful.
- Ethnic/cultural food choices often reflect the foods that were plentiful in the region of origin (e.g., fish in coastal communities, coffee and cocoa beans in equatorial regions), as well as foods that were readily grown in the native soil (e.g., rice in warm wetlands, potatoes in colder climates).
- Other diet choices reflect a concern for food preservation: for instance, people from various geographic regions eat salted meats and dried fruits and cook with fiery spices to combat microbes.
- Certain religions may require fasting or abstaining from certain foods. For example, Roman Catholics fast on Ash Wednesday and Good Friday; kosher dietary laws prohibit eating pork and shellfish.
- The burden of childhood obesity is not spread equally across the U.S. population. For example, obesity has been increasing faster among lower socioeconomic groups and Mexican American and black children (U.S. Department of Health and Human Services, CDC, & National Center for Health Statistics, 2012).
- Cultural beliefs, perceptions, and attitudes about weight issues may often not match those of health providers. For example, some parents may perceive their children as cute and healthy, even though their BMI indicates they are obese. A slim body is not the ideal in all cultures.

Traditional diets of many cultures are healthful and should not be discouraged; in fact, contemporary adaptations made to these diets may compromise their nutritional quality.

Mediterranean Diet This diet is rich in olive oil, fish, fruits, vegetables, and nuts and low in dairy foods, processed foods and saturated fats, and red meat, and includes a glass of red wine. It has been linked to decreased risk of death from all causes, including deaths due to cancer and coronary artery disease in a U.S. population (Estruch, Ros, Salas-Salvado, et al., 2013; Mitrou, Kipnis, Thiébaut, et al., 2007).

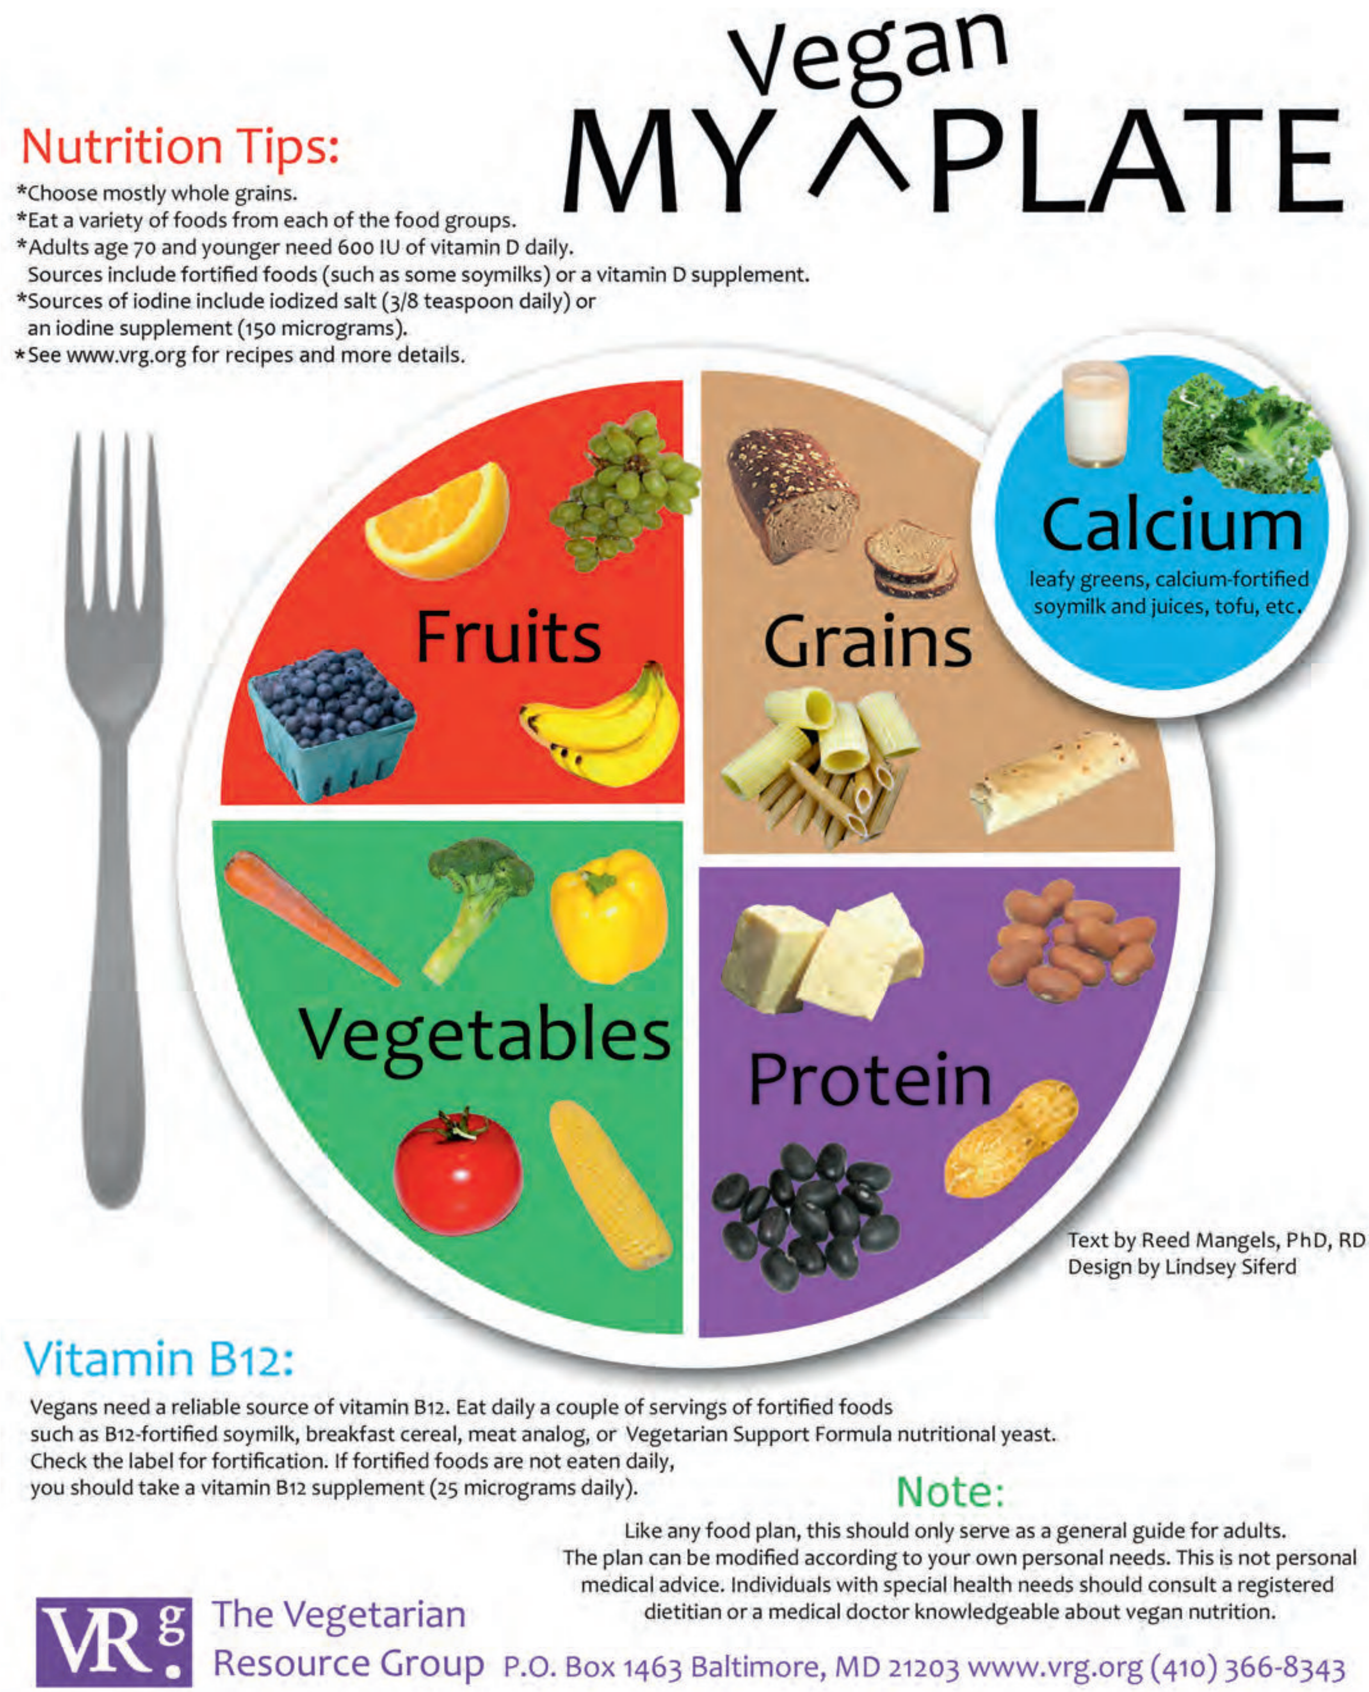

FIGURE 27-3 **MyVeganPlate.** (Source: Vegan Resource Group. www.vrg.org)

Asian Diet The traditional Asian diet is a plant-based diet with a low amount of animal products. It consists of rice, fresh fruits, and vegetables, such as melons, bananas, tangerines, bok choy, cabbage, and other green leafy vegetables. Protein intake primarily consists of beans, nuts, and seeds, and occasional poultry, shellfish, and eggs. Health benefits of this diet include lower incidence of cardiovascular disease, diabetes, colon cancer, and obesity. Green and black teas contain antioxidants that may lower the risk of cancer.

Indian Diet The traditional Indian diet contains fresh, home-cooked foods containing a wide array of spices. The selection of meat is based on religious preference (e.g., Muslims don't eat pork; Hindus aren't permitted to eat beef; Buddhists are vegetarian). People who eat a traditional Indian diet that is high in fruits, vegetables, legumes, and nuts, and low in processed foods reap the benefit of low incidence of diabetes, heart disease, and other chronic diseases.

Hispanic Diet The Hispanic diet relies heavy on grains, especially rice, and legumes (e.g., beans), and corn-based products. Beans as a staple provide a diet rich in fiber, B vitamins, calcium, phosphorus, and iron; however, when prepared with lard, the health benefits diminish. The traditional Hispanic fare includes few fresh vegetables, except for tomatoes, which are rich in vitamins A and C, as well as potassium and iron. Diabetes type 2 is more prevalent among nonwhite Hispanics, due to a high rate of obesity. Sugary fruit beverages and soda are a common part of the contemporary Hispanic diet.

Disease Processes and Functional Limitations Affecting Nutrition

Chronic diseases (e.g., diabetes mellitus, GI disorders) can alter nutrient intake, digestion, absorption, use, and excretion. Any illness, especially when accompanied by fever, increases the need for protein, water, and calories to meet the demands of increased metabolic rate. Traumatic injury (e.g., burns, surgery) requires extra protein and vitamin C for wound healing and tissue rebuilding. People with long-term insufficient calorie intake (e.g., patients with cancer) also suffer from **protein-calorie malnutrition**, which is characterized by weight loss and muscle and fat wasting. A variety of other physical and psychological disorders and/or their treatments can adversely affect a client's nutrition:

Alcoholism Poor appetite is common in alcoholism, which results in decreased intake of food and therefore of nutrients. Alcohol can also interfere with the function of some vitamins.

Cognitive Function A person with a developmental delay, severe mental illness, confusion, or memory loss may be unable to remember what, when, or whether she has eaten.

Ability to Obtain and Prepare Food Paralysis or hemiplegia (e.g., from a stroke) can cause functional limitations that affect mobility and, hence, the ability to shop for food. Social factors also limit the ability to gather or procure food. People with limited income may be forced to choose between buying food, medication, or household utilities. Homeless people and others in extreme poverty are often reduced to eating from trashcans and dumpsters or consuming nonfoods, such as paper, grass, and clay.

Preparing food takes time and energy. A person with severe dyspnea from chronic obstructive pulmonary disease (COPD), for example, may not have the stamina to prepare a nutritious meal. Instead, she may eat prepared foods that are high in sodium content. Fatigue is also caused by advanced chronic disease, severe anemia, pregnancy, depression, or excess work.

Chewing and Swallowing Decayed or missing teeth and ill-fitting dentures make chewing difficult. The person often resorts to eating only soft foods, many of which lack fiber. Acute disorders affecting the throat, such as pharyngitis, make swallowing painful. Cancer of the larynx or esophageal strictures also makes swallowing painful or difficult, and frequently leads to avoiding food.

Stomach Function Heartburn, indigestion, and other stomach disorders are common. People may eat only bland foods or avoid certain foods to prevent the pain or burning that follow eating.

Peristalsis **Peristalsis** is the wave-like action that propels food through the intestinal tract. Bowel inflammation or infection, diverticula (outpouchings of the intestine), or tumors may increase peristalsis, thereby decreasing absorption of nutrients. In addition, high stress levels may either speed or slow transit time. If peristalsis is slow, the stomach may not empty properly (gastroparesis). This could lead to early satiety, nausea, or vomiting and affect nutrient intake. This is not unusual in patients with diabetes.

Intestinal Surface Area The amount of intestinal surface area may be diminished either by surgery or disease, thereby decreasing absorption of nutrients. This may result in malnutrition despite the fact that the patient is consuming adequate calories and protein.

Enzyme Secretion Liver, gallbladder, or pancreas problems affect the secretion of enzymes involved in digesting foods. Nearly 50 million Americans lack the enzyme (lactase) needed to digest milk. Up to 80% of blacks, 80% to 100% of Native Americans, and 90% to 100% of Asian Americans are lactose intolerant (National Digestive Diseases Information Clearinghouse, 2009, updated 2012).

Bariatric Surgery alters digestion to achieve rapid weight loss. The three types are restrictive, malabsorptive, and combined restrictive/malabsorptive. Restrictive procedures (sleeve gastrectomy, adjustable gastric banding). limit the stomach's capacity to hold food and reduce the passage through the GI tract. Malabsorption surgeries (intestinal bypass) are done to impair the uptake of food nutrients and fats. A combined approach uses stomach restriction and a partial bypass of the small intestine. Bariatric weight loss procedures increase the risk of nutrient deficiency, especially iron, copper, zinc, selenium, thiamine, folate, and vitamins B_{12}, and D. (Choban, Dickerson, Malone, et al., & the American Society for Parenteral and Enteral Nutrition, 2013).

Medications In addition to the direct effects of diseases and disorders, nutrition may be affected by the drugs and therapies used to treat them, as in the following examples:

- *Decreased appetite.* Some medications directly decrease appetite, for example, amphetamine and dextroamphetamine (Adderall), aspirin, diphenhydramine (e.g., Benadryl), and lithium carbonate (e.g., Lithobid).
- *Chemotherapy and radiation therapy*. These may cause oral ulcers, intestinal bleeding, or diarrhea—which interfere with eating and absorbing nutrients from food.
- *Altered metabolism.* Certain drugs alter nutrient metabolism; others increase or decrease nutrient excretion. Medication metabolism may also alter taste, changing the overall intake.
- *Effect on Specific Nutrients*. For example, acetylsalicylic acid (aspirin) decreases folate levels and increases excretion of vitamin C; laxatives may cause calcium and potassium depletion; and thiazide diuretics decrease the absorption of vitamin B_{12}.
- *Nausea and Vomiting.* Almost all oral medications have the potential to cause nausea or vomiting, thereby decreasing appetite. Examples include acetylsalicylic acid (aspirin), antibiotics, anticonvulsants, antidepressants, anti-inflammatory agents, antineoplastic agents (chemotherapy), asthma medications (especially theophylline), birth control pills, fluoride supplements, opioids, potassium chloride, and vitamin and mineral supplements.

KnowledgeCheck 27-6

- List at least three nutrients that may be more difficult to supply through a vegetarian diet.
- When selecting a program for weight loss, what factors should a person consider?
- Why should you encourage clients from various cultures to follow their traditional diets?
- Describe the effects on nutrition of (1) smoking and (2) heavy alcohol use.

Special Diets

Many people must follow a modified diet to assist in managing their illness. In addition, all inpatients at healthcare facilities must have a diet prescribed by their primary care provider. The following are the most commonly prescribed modified diets.

Regular Diet

A regular diet, also called the "house diet," is appropriate for clients without special nutritional needs. This diet is a balanced meal plan that supplies 2,000 kcal per day. Many facilities provide vegetarian and ethnic variations (Asian menu, kosher, and so on). Inpatients choose each meal from a list of menu choices.

Have you ever eaten "hospital food"? Or have you heard someone complain that hospital food is bland and unimaginative? There is some justification for that complaint. House diets must accommodate the varied tastes of all patients, so they are usually lightly seasoned. Selections are limited to avoid unpopular items (e.g., Brussels sprouts) and restrict fatty, fried, or gassy foods, which many patients tolerate poorly. However, you should refrain from making negative comments to patients about the food.

NPO

NPO means no food or fluid (including water) by mouth. This may be ordered before surgery or an invasive procedure to limit the risk of aspiration. Common examples are "NPO after midnight," or "NPO 8 hours prior to procedure." Most well-nourished, well-hydrated patients easily tolerate short-term NPO status. However, no one can tolerate prolonged periods of NPO. Intravenous fluids may be given to provide hydration, and clients who must remain NPO for a lengthy period need enteral (through a stomach tube) or parenteral (IV) nutrition to prevent malnutrition.

Diets Modified by Consistency

Patients undergoing surgery, bowel procedures, or acute illness may, for a short period of time, need a diet modified by consistency. Patients with chronic health concerns that affect their ability to chew or swallow (e.g., Impaired Dentition and Impaired Swallowing) may need long-term changes in the consistency of their diet (Table 27-9).

Diets Modified for Disease

Some health conditions require modification of dietary intake. The following are the most common diets:

- *Calorie-restricted*. For clients requiring weight reduction
- *Sodium-restricted.* For clients with blood pressure or fluid balance problems
- *Fat-restricted.* For clients with elevated cholesterol or triglyceride levels; may also be ordered for general weight loss
- *Diabetic.* To manage calories and carbohydrate intake for clients with diabetes mellitus
- *Renal diet.* To manage electrolytes and fluid for clients with renal insufficiency
- *Protein-controlled diet.* To manage liver and kidney disease

Table 27-9 ➤ Diets Modified by Consistency

DIET DESCRIPTION AND FOODS INCLUDED	COMMENTS
Clear Liquids. Provides fluids to prevent dehydration, and supplies some simple carbohydrates to help meet energy needs. *Foods Included:* Water, tea, coffee, broth, clear juice (usually apple, grape, or cranberry juice), Popsicles, carbonated beverages, and gelatin.	▪ Does not supply adequate calories, protein, and other nutrients, so timely progression to more nutritious diets is recommended. ▪ If clear liquids are required for more than 3 days, commercial clear liquid supplements are usually prescribed.
Full Liquids. Contains all the liquids included in the clear liquid diet plus any food items that are liquid at room temperature. *Foods Included:* Add to clear liquid diet: soups, milk, milk shakes, puddings, custards, juices, some hot cereals, and yogurt.	▪ Difficult to obtain a balanced diet on a full liquid plan; use for a short time only. ▪ If needed for a longer time, a professional dietitian should be involved in planning the diet. ▪ High-calorie, high-protein supplements are often added.
Mechanical Soft Diet. The diet of choice for people with chewing difficulties resulting from missing teeth, jaw problems, or extensive fatigue. *Foods Included:* Add to the full liquid diet: soft vegetables and fruits; chopped, ground, or shredded meat; and breads, pastries, eggs, and cheese.	▪ This diet can supply a full range of nutrients but is quite low in fiber. As a result, constipation is a risk. ▪ Many food items can be added to this diet by cooking them extensively or blending or grinding to alter their texture.
Pureed Diet. A pureed diet is a blended diet. It may have some or no foods excluded.	▪ Often liquids are added to the food to create a texture that may be scooped onto serving plates.

- *Antigen-avoidance diets.* For clients allergic to or intolerant of certain foods, such as a gluten-free diet for clients with celiac disease
- *Calorie-protein push.* Used when there is a need to heal wounds, maintain or increase weight, or promote growth. If the person cannot consume enough kcal by adding fats and proteins to his regular diet, high-calorie, high-protein supplements may be used.

Analyze the following diets. Which nutrients are missing or difficult to obtain from these diets?

- Clear liquid
- Full liquid

PracticalKnowledge knowing how

Good nutrition not only is essential for health, but also is a key aspect of disease management. In the rest of this chapter, we look at assessing nutritional status and diagnosing and planning care for some nutrition problems. In addition, we discuss specifically the care of patients who are underweight/undernourished or overweight/obese.

Nutrition is a basic human need. But more than a physical necessity, it also has emotional associations. We eat when we are hungry, but we also eat for pleasure because the food tastes good! Food has become a part of most social events and activities. A certain food may symbolize one's cultural or religious affiliation or even be a political statement (e.g., refusal to eat lettuce in support of migrant workers). It is wise to keep in mind that food has different meanings to different people. Personal beliefs, habits, and preferences are as important as nutritional knowledge in determining what a person eats.

ASSESSMENT

There are two kinds of nutritional assessment: (1) screening assessments and (2) thorough, focused nutritional assessments. Usually you will perform a screening exam. If you identify nutritional risk factors, you then perform a focused nutritional assessment. For the components of a nutritional history,

Go to Chapter 27, **Focused Nutritional Assessment,** the section entitled **Nutritional History, in Volume 2.**

SCREENING FOR NUTRITIONAL PROBLEMS

All hospitalized patients, especially those with obesity and patients at risk for nutritional deficit, should be receive a nutritional screening support plan within 48 hours of inpatient admission (Choban, Dickerson, Malone, et al., & the American Society for Parenteral and Enteral Nutrition, 2013). **Cursory screening** consists of evaluation of height, weight, and BMI coupled with a brief dietary history. Clients who are found to be at risk for nutritional problems should be further evaluated.

It is especially important to assess nutritional status in elderly clients carefully to ensure that you detect marginal deficiencies before major problems occur.

- *The subjective global assessment.* This commonly used screening method makes use of information from the overall medical history and physical examination to evaluate a client's nutritional status.
- *The Nutrition Screening Initiative (NSI)* (1991), developed for older adults, identifies indicators of impaired nutritional status.
- *The Mini Nutritional Assessment (MNA)*, also developed for older adults, can be used with clients of all ages (DiMaria-Ghalili & Guenter, 2008).

To learn more about those and other screening methods and for tools to use (e.g., to screen for dementia),

Go to Chapter 27, **Screening for Nutritional Problems,** in Volume 2.

FOCUSED NUTRITIONAL ASSESSMENT

If screening reveals nutritional problems, perform a focused nutritional assessment to evaluate the client. The nutrition component of the complete physical assessment or any focused nutritional assessment includes both subjective (history) and objective (physical examination) data. To see and use a focused nutritional assessment,

Go to Chapter 27, **Focused Nutritional Assessment,** in Volume 2.

Dietary History You can obtain a dietary history during any routine assessment. When you take a **dietary history**, whether you use a self-administered form or an interview, you collect general knowledge of the client's basic eating habits, food attitudes and preferences, cultural factors, and use of dietary supplements. A dietary history creates a picture of the client's food habits and eating behaviors.

24-Hour Recall A 24-hour recall requires the client to name all food eaten within a day. Simply ask questions such as, "Yesterday, what did you eat for breakfast/lunch/dinner/snacks?" A 24-hour recall is simple, requires no equipment, and can be used as often as required. However, accuracy of the data may be questionable, because some people have difficulty remembering everything they ate the previous day, and any single day may be atypical. Sometimes, a family member can help the client recall intake more accurately (Garibalia & Forster, 2008).

Food Frequency Questionnaire A food frequency questionnaire asks the client to identify the number of times per day, week, or month a particular food group is eaten (e.g., fruits, red meats). You can modify the questions according to the client's specific issues. Food frequency questionnaires provide a more global image of the client's nutritional intake than the 24-hour recall; however, accuracy is still a problem.

Food Record A food record is the most accurate food diary. It provides information on the quantity as well as the types of foods eaten. You ask the client in advance to keep a record of measured and weighed amounts of all foods he eats in a 3-day period. From the detailed information collected, you can analyze the total kilocalories and nutrient content for the recorded period. Although the food record provides meaningful results, it requires a high level of cognitive and psychomotor functioning that not all clients have. It also requires commitment to the process for 3 days, which may be difficult for some people. You may wish to remind some patients that there are Web sites that can help them with journaling their diet and tracking nutritional intake, goals, and energy expenditure. For examples,

Go to Chapter Resources, Chapter 27, **Resources for Caregivers and Health Professionals,** on Davis*Plus*.

How Can I Assess Body Composition?

When assessing body composition (the proportion of fat in the body), you use **anthropometric measurements**. These are noninvasive physical examination techniques to determine body dimensions such as height and weight. Other examples are discussed in the following sections. Anthropometric measurements are used to assess growth rate in children; to indirectly assess adults' protein and fat stores; and to diagnose overweight, obesity, and underweight. To obtain accurate data, you must use standardized equipment and procedures and compare the data to existing reference standards for men and women.

Skinfold Measurements

Approximately half of body fat is located subcutaneously. Therefore, you will use measurement of skinfold thickness to estimate a person's body fat content. Skinfold thickness reveals information about current nutritional status as well as long-term changes in fat stores. Use a caliper to obtain the most accurate measurement. The most reliable location is the triceps for children and women and the subscapular area in men. The combined measurements of triceps skinfold and mid-upper arm circumference yield a better estimate of muscle and fat areas than a single measurement. For instructions on taking skinfold measurements,

Go to Chapter 27, **Clinical Insight 27-2: Skinfold Measurement,** in Volume 2.

Circumferences

Another method of estimating the percentage of body fat is to use girth, or circumference measurements. Waist circumference is a complement to BMI for predicting obesity risk because BMI does not account for the difference between muscle and fat accumulation. *Mid-upper arm circumference* is routinely measured as part of screening. For people who are obese, *abdominal circumference* is the preferred measurement. *The waist-to-hip ratio (WHR)* evaluates obesity by assessing abdominal fat. A WHR of greater than 1 in men and greater than 0.8 in women indicates obesity. A high level of abdominal fat is associated with increased risk for hypertension, diabetes, hyperlipidemia, and cardiovascular disease. For specific instructions on measuring mid-upper arm circumference and WHR,

Go to Chapter 27, **Clinical Insight 27-3: Measuring Circumferences to Evaluate Body Composition,** in Volume 2.

Body Mass Index

BMI can be precisely measured using scanning devices that measure *bioelectrical impedance*—the conduction of a harmless electrical charge through the client's body. Lean tissue readily conducts the charge, whereas adipose tissue does not. However, you will usually roughly estimate BMI by using the calculation formula in Box 27-4. You may also consult tables with precalculated values based on height and weight (National Heart, Lung and Blood Institute [NHLBI], n.d.). For an example of a height–weight BMI table,

Go to Chapter 22, **Procedure 22-1: Performing the General Survey,** in Volume 2.

You can also find BMI calculators on the Web. Two reliable examples are at:

Centers for Disease Control and Prevention, at http://www.cdc.gov/healthyweight/assessing/bmi/adult_bmi/english_bmi_calculator/bmi_calculator.html

and

National Heart, Lung and Blood Institute, at http://www.nhlbi.nih.gov/guidelines/obesity/BMI/bmicalc.htm

The normal BMI for adults ranges from 18.5 to 24.9 (although this may vary slightly among professional organizations). The usefulness of BMI values is limited for athletes because of their highly developed muscle mass, and for pregnant and postpartal women because their increased weight is normal. In addition, BMI values have not been specifically calculated for people older than age 65. Despite these limitations, BMI is useful in identifying underweight and obese individuals.

KnowledgeCheck 27-7

- What is the most accurate type of food diary?
- Compare and contrast four nutritional screening approaches: cursory screening, subjective global assessment, Mini Nutritional Assessment, and Nutrition Screening Initiative.
- Identify three nutritional risk factors.

BOX 27-4 ■ Calculating Body Mass Index (BMI)

BMI = weight in kilograms ÷ (height in meters)^2

Example:

Robert weighs 165 lb. Convert his weight to kilograms:

165 ÷ 2.2 = 75 kg

He is 71 inches tall. Convert his height to meters.

1 meter = 39.37 inches.

Divide 71 inches by 39.37 inches; he is 1.8 meters tall (rounded off)

His BMI is 75 kg ÷ (1.8)^2 = 23

The normal BMI for adults ranges from 18.5 to 24.9.

Classification of Body Mass Index Values

Classification	*BMI (kg/m^2)*
Severely underweight	<16
Moderately underweight	16–16.99
Mild underweight	17–18.49
Underweight	<18.5
Healthy weight	18.5–24.9
Pre-obese	25.0–29.9
Class I obesity	30.0–34.9
Class II obesity	35.0–39.9
Class III obesity	40.0 or higher

Source: Adapted from National Heart, Lung and Blood Institute (1998); and World Health Organization (2006a).

Think**Like a Nurse** 27-6

1. Calculate your WHR.
2. Use Box 27-4 to calculate your BMI. Evaluate the result.
   - How useful are these data?
   - Do you feel you need to pursue a program of weight loss? Why or why not?

Imaging Techniques

Imaging techniques are not widely used to evaluate lean body mass because they are quite expensive to perform. Imaging methods include the following:

- *Dual-energy x-ray absorptiometry (DEXA)* is used to assess bone mineral content and density. Because lean tissue has different absorptive properties than does adipose tissue, this technique shows promise for wider use because it is quick and noninvasive.
- *Computed tomography (CT)* measures volume rather than actual body tissue composition. It can provide information about the quantity of adipose tissue, particularly in body cavities.
- *Magnetic resonance imaging* (MRI) is an excellent noninvasive method for directly assessing body composition. The cost and availability of the machinery, however, make it impractical for day-to-day evaluation of clients.

Underwater Weighing

Hydrodensitometry, or underwater weighing, is another method for determining body composition. It requires total submersion of the patient in a tank of water. Because fat readily floats, the person's buoyancy will vary depending on his percentage of body fat. This method is considered the gold standard for body composition measures. However, clinical use of this method is limited because it is impractical to use with children, the elderly, or individuals who are severely ill.

KnowledgeCheck 27-8

- What are the most reliable locations for skinfold measurement?
- What are the implications of an increased WHR?

What Physical Examination Findings Are Cues to Nutrient Imbalance?

To detect nutritional abnormalities, such as diabetes, you should assess physical findings, lifestyle, nutritional and medical history, dietary intake, anthropometric measurements, and laboratory testing (Box 27-5). Refer to Chapter 22 as needed for a review of physical examination techniques. For guidelines in performing a nutrition-focused physical examination,

Go to Chapter 27, **Focused Nutritional Assessment,** in Volume 2.

BOX 27-5 ■ When to Assess for Diabetes

- Adults with BMI >25
- Physical inactivity
- High-risk ethnicity for obesity (e.g., American Indians, Alaskan Natives)
- First-degree relative with diabetes
- Women who have delivered a baby weighing more than 9 lb or diagnosed with gestational diabetes during pregnancy
- Hemoglobin A_{1c} >5.7% (test for glucose control over a 2- to 3-month period)
- HDL cholesterol <35 mg/dL and/or triglyceride >250 mg/dL
- History of cardiovascular disease and/or hypertension
- Physical signs indicating low blood sugar (sweating, shakiness, anxiety, confusion, irritability, dizziness, difficulty speaking, lethargy, or loss of consciousness)
- Physical signs indicating high blood sugar (flushed skin confusion, weakness, labored breathing, sweet or fruity breath, nausea, loss of consciousness)
- Clinical conditions associated with insulin resistance (e.g., foot ulcers that are slow to heal)

If diabetes testing is normal, the American Diabetes Association (2011) recommends repeat evaluation every 3 years or more frequently, depending on risk factors.

KnowledgeCheck 27-9

- Identify at least 10 physical examination findings that would lead you to suspect nutritional problems.
- What factors would lead to poor wound healing?

What Laboratory Values Indicate Nutritional Status?

Various laboratory or biochemical indicators provide information about nutritional status. These include blood glucose, serum protein level and associated indices, total lymphocyte count, and hemoglobin. To see the norms for these lab tests,

Go to Chapter 27, **Diagnostic Testing, Tests Reflecting Nutritional Status: Norms,** in Volume 2.

Blood Glucose

The blood glucose level indicates the amount of fuel available for cellular energy. Levels above the normal set point trigger the release of insulin, which causes the glucose to move into body cells and to be stored in the liver and muscles. A level below the normal set point triggers the release of glucagon, leading to the release of glucose from storage.

Hypoglycemia limits the fuel supply to the body, resulting in symptoms ranging from weakness to coma. Hypoglycemia is usually defined as blood glucose of less than 50 mg/dL, but some people may feel symptoms at higher levels. Often the cause is insufficient food intake, excessive physical exertion, or a disproportionate amount of hypoglycemic agents.

Hyperglycemia (blood glucose greater than 109 mg/dL fasting or greater than 127 mg/dL at random) may be a sign of diabetes mellitus, an endocrine problem, which may develop as a result of either insufficient insulin production or resistance to the existing supply of insulin. A high blood glucose level does not mean that there is more fuel available for cellular energy, though. A characteristic of diabetes is that although there is more than enough glucose in the blood, it cannot enter and be used by the cells. Repeated blood glucose measures are required before making a diagnosis of diabetes mellitus because glucose levels may be temporarily elevated as a result of excessive carbohydrate intake, growth, infection, or emotional and physical stressors.

A rise in blood sugar may produce weakness or fatigue. Prolonged elevations lead to weight loss, blurred vision, **polyphagia** (excessive hunger), **polydipsia** (excessive thirst), increased urination, **ketosis** (incomplete metabolism of fat due to inability to use carbohydrates as fuel), renal failure, and **peripheral neuropathy** (damage to nerves due to prolonged exposure to high glucose levels).

Patients with diabetes usually monitor their own blood sugar levels, but you may need to do it for some. Usually this is done by a fingerstick to obtain capillary blood for testing. Some devices can use blood from alternative sites such as upper arm, forearm, base of thumb, or thigh. Other types of monitors are available. For example, one kind uses a disposable sensor placed just under the skin. The sensor, worn like a watch, communicates with a receiver that reads the levels, and sounds if the blood sugar level is too high or too low. See the Highlights of Procedures box for a summary of the fingerstick procedure. For complete steps,

Go to Chapter 27, **Procedure 27-1: Checking Fingerstick (Capillary) Blood Glucose Levels,** in Volume 2.

Serum Protein Levels and Indices

Protein molecules dissolve in blood to form plasma proteins. Tissue proteins are a combination of albumin and globulin, so serum protein levels are indicators of *protein stores*.

- **Albumin** is synthesized in the liver and constitutes 60% of total body protein. Low levels of albumin are associated with malnutrition, malabsorption, acute and chronic liver disease, and repeated loss of protein through burns, wounds, or other sources. The half-life of albumin is 18 to 21 days. As a result, there is a lag in detecting nutritional problems based on serum albumin. Albumin is also affected by fluid status and, therefore, is not an accurate measure in the patient with fluid imbalance. For example, a patient in positive fluid balance (taking in more than excreted) will have a falsely low albumin level.
- **Prealbumin** level fluctuates daily and is considered a better marker of acute change than albumin.
- **Transferrin** is a protein that binds with iron. Because it has a half-life of only 8 to 9 days, it allows for faster detection of protein depletion than does measuring albumin. Transferrin can be measured directly or indirectly (by a total iron-binding capacity test [TIBC]). It also reflects iron status. In a person with iron deficiency, the TIBC will be increased; in a person with anemia, the TIBC will be decreased.

Other markers are used to monitor *protein metabolism*:

- **Urea** is formed in the liver as an end product of protein metabolism and is excreted through the kidneys. As such, the serum blood urea nitrogen (BUN) level is an indicator of liver and kidney function. An elevated BUN level is seen with impaired kidney function, dehydration, excessive protein breakdown (often seen with diabetes mellitus, hyperthyroidism, or starvation) or excessive dietary protein intake. Low levels are seen with impaired liver function, fluid overload, and low protein intake.
- **Creatinine**, an end product of skeletal muscle metabolism, is excreted through the kidneys and is an excellent indicator of renal function. Increased levels may indicate impaired kidney function or loss of muscle mass.
- **Lymphocytes**, or white blood cells (WBC), are the body's first line of defense against microorganisms. For a detailed discussion of the role of WBCs in infection control, as well as a discussion on the types of WBCs and their normal values, see Chapter 23. A decrease in total lymphocytes, known as **leukopenia**, is associated with malnutrition, protein deficiency, alcoholism, bone marrow depression, and anemia.
- **Hemoglobin** is composed of **heme**, an iron-rich compound, and **globulin**, a serum protein. Adequate iron intake is required to produce heme. Therefore, low hemoglobin levels may indicate inadequate iron intake or chronic blood loss. Globulin forms the backbone of hemoglobin as well as antibodies, glycoproteins, lipoproteins, clotting factors, and a variety of key enzymes. A decreased globulin level indicates insufficient protein intake or excessive protein loss.

May I Delegate Nutritional Assessments?

You may safely delegate to nursing assistive personnel (NAPs) the measurement of weight, height, and intake and output; (I&O) other nursing staff (e.g., licensed practical/vocational nurses) can collect a nutritional history. However, the registered nurse (RN) is responsible for reviewing and interpreting these findings. When delegating these tasks, you must also tell the NAP or licensed practical nurse (LPN) how often the measurements are to be made. Review Chapter 7 for making delegation decisions.

KnowledgeCheck 27-10

- What are the likely causes of hyperglycemia?
- Why is it important to identify the serum albumin level?

ThinkLike a Nurse 27-7

The Nutrition Screening Initiative (NSI) is completed for a 70-year-old.

- What major indicator on the NSI would indicate impaired nutritional status?
- What minor indicator would you likely see?
- What would malnourishment look like in the adult?
- What type of anthropometric findings would be typical of an older adult with poor nutrition patterns?
- What type of laboratory values would support impaired nutritional status?

ANALYSIS/NURSING DIAGNOSIS

For clients who have no symptoms of or risk factors for nutrition problems, use the diagnostic label Readiness for Enhanced Nutrition. NANDA-I defines this as "a pattern of nutrient intake that is sufficient for meeting metabolic needs and can be strengthened" (2012, p. 67).

Nutrition as the Problem

You can use the following NANDA-I labels to describe general nutrition problems:

- Adult Failure to Thrive
- Imbalanced Nutrition: Less Than Body Requirements
- Imbalanced Nutrition: More Than Body Requirements

- Risk for Imbalanced Nutrition: More Than Body Requirements
- Self-Care Deficit (Feeding)

As you have learned, nutrition problems have many causes. Etiologies for undernutrition include eating disorders, difficulties with chewing and swallowing, vomiting, alcoholism, food intolerances, metabolic disorders, digestive disorders, and absorption disorders. For overnutrition, etiologies include overeating, lack of exercise, and metabolic or endocrine disorders. The following nursing diagnoses may contribute to nutrition problems: Diarrhea, Health Behaviors (Nutrition), Impaired Swallowing, Nausea, Noncompliance (with prescribed diet), and Deficient Knowledge (nutrition).

The following is an example of a nutrition nursing diagnosis statement:

Imbalanced Nutrition: Less Than Body Requirements related to difficulty chewing and Impaired Swallowing

Nutrition as the Etiology

Nutritional problems can also be the etiology of problems in other functional areas, for example:

- Ineffective Breastfeeding r/t inadequate milk production 2° insufficient intake of calories and fluids
- Constipation r/t insufficient intake of fluids and fiber
- Diarrhea r/t excessive intake of alcohol and/or sugar
- Risk for Infection r/t inadequate intake of calories and protein
- Impaired (or Risk for Impaired) Skin Integrity r/t inadequate intake of protein and/or vitamin A
- Disturbed Sleep Pattern r/t excessive caffeine intake or to eating fatty and spicy foods near bedtime
- Impaired Social Interaction r/t low self-esteem 2° obesity

PLANNING OUTCOMES/EVALUATION

The overall *Healthy People 2020* nutrition goal for the United States population is to "promote health and reduce chronic disease associated with diet and weight" (U.S. Department of Health and Human Services [USDHHS], 2010, updated 2012). For specific objectives related to that goal,

Go to Chapter 27, **Tables, Boxes, Figures: ESG Box 27-3, Nutrition and Weight Status Objectives From Healthy People 2020,** on Davis*Plus*.

Also see the **Healthy People 2020** home page at www.healthypeople.gov

NOC standardized outcomes directly linked to nutritional problems include the following: Nutritional Status, Nutritional Status: Food and Fluid Intake, Nutritional Status: Nutrient Intake, and Weight Control.

You would choose other NOC outcomes based on the patient's nursing diagnosis. For example, for Situational Low Self-Esteem related to obesity, you might use Self-Esteem; for Noncompliance (prescribed diet), you could use Adherence Behavior, Compliance Behavior, or Treatment Behavior: Illness/Injury.

Individualized goals/outcome statements you might write for a patient with nutrition-related problems include the following:

Loses 1 lb per week until ideal weight is attained.
Follows the prescribed modified diet that, at a minimum, meets the DRIs.
Eats a variety of foods that provide a balanced diet.

PLANNING INTERVENTIONS/IMPLEMENTATION

NIC standardized interventions directly linked to nutrition problems include the broad interventions of Nutrition Management, Nutrition Therapy, Nutritional Counseling, and Nutritional Monitoring. These interventions could probably be used for most nutrition problems, regardless of the etiologies. The other 13 interventions grouped under Nutritional Support address specific etiologies (e.g., Swallowing Therapy).

Go to Chapter 27, **Standardized Language, NOC Outcomes and NIC Interventions Related to Nutrition,** on Davis*Plus*.

Individualized nursing actions are determined by the patient's nursing diagnosis. They may include, for example, counseling regarding vitamin and mineral supplementation, teaching clients on a limited budget how to buy nutritious foods, supporting special nutritional needs, and assisting clients with meals. These are discussed in the rest of this chapter.

Vitamin and Mineral Supplementation

Do you take a vitamin tablet every day? Do you know anyone who takes megadoses of vitamin C to prevent a cold? Or zinc to cure one? Noncredentialed nutrition "experts" recommend, and sell, megadoses of the entire alphabet of vitamin and mineral supplements to prevent cancer and heart attacks, improve your sex life, prevent aging, and work other miracles. However, conservative health professionals are often skeptical of high dose vitamin supplements, insisting that a nutritious diet supplies all the micronutrients you need. Somewhere in the middle, most likely, lies the truth. A growing body of research suggests that certain supplements provide health benefits, particularly calcium and vitamin D. Remember, too, that RDAs and AIs are for "average" needs. Individual needs for micronutrients vary. During periods of increased nutrient demands, it may be difficult to get enough nutrients from diet alone.

NIC Intervention—Nutritional Counseling

When teaching clients about supplements, keep the following principles in mind:

1. Dietary supplements may be appropriate for people whose diet does not provide the recommended

intake of specific vitamins. With a few exceptions, there is little evidence to suggest that people will be harmed by taking vitamin supplements in appropriate amounts (AHRQ, 2003).

2. Individual needs vary, and those needs should determine the specific nutrients and amounts used. For example:
   - Newborn infants are given a vitamin K injection to prevent hemorrhaging because they do not yet have bacterial flora in the gut to synthesize enough vitamin K.
   - Breastfed infants may need a vitamin D supplement (but not other vitamins) if the mother does not have an adequate diet or if the baby does not receive enough exposure to sunlight. Fetal iron stores are depleted at 4 to 6 months, so breastfed infants also need iron supplementation at that age.
   - Vegetarians who eat little or no animal products may need vitamin B_{12} or vitamin D supplementation.
   - Overweight children and those who have type 1 diabetes or hypertension, particularly Latino and African American children, are at risk for vitamin D deficiency.
   - Folic acid supplementation is recommended for people taking methotrexate (a drug used to treat certain types of cancer).
   - All women who are capable of becoming pregnant should take a daily folic acid supplement of 400 to 800 mcg in addition to the naturally occurring folate they eat in foods. Pregnant women need at least 600 mcg daily.
   - Most adults older than 50 years should obtain vitamin B_{12} from fortified foods or supplements.
   - Women age 50 and older should take calcium supplements to prevent osteoporosis; there is growing evidence that men may need to do so as well. Adults in the United States do not typically obtain adequate calcium from their diets.
   - Most calcium supplements come in combination with vitamin D to promote absorption of the calcium.
   - People who do not eat dairy products need supplemental calcium.
3. Food is the best source of nutrients. Supplements do not replace the need to eat a nutritious diet. Vitamins need carbohydrate, protein, and fat to do their work. Specific supplements for certain individual situations are more effective if the person also has an adequate diet.
4. Read supplement labels carefully. They provide information about toxicity levels, dosage, and side effects.
5. Encourage patients to ask their primary care provider's advice before taking vitamins.
6. Advise patients to follow the dosages recommended in the DRIs or RDAs.
7. Be certain that any health claims made for a supplement are based on sound research.
8. The long-term effects of most nutritional supplements have yet to be fully researched.

The same principles apply with regard to mineral supplementation. Supplements of specific minerals may be needed during growth periods (i.e., pregnancy, lactation, and adolescence), but as a rule healthy adults eating balanced diets do not need supplements. People who require mineral supplementation include those who refuse dairy products (and therefore lack calcium), and those with clinical problems such as iron-deficiency anemia, zinc deficiency (e.g., in alcoholism and long-term low-calorie diets), and treatment with certain diuretics (e.g., for hypertension).

Nutritious Foods on a Limited Budget

Hunger and malnutrition are not unusual among the poor in the United States. When your clients cannot afford to buy food, you should teach them about available assistance and make appropriate referrals to programs such as the following:

Supplemental Nutrition Assistance Program (SNAP) This is the new name for the federal Food Stamp Program. For low-income households, this program issues coupons that can be used to buy food to cover the household's needs.

Commodity Supplemental Food Program The federal government buys surplus food items to support certain agricultural products. These include both perishable and nonperishable commodities (e.g., peanut butter, cheese, green beans). The foods are made available to low-income pregnant and breastfeeding women, infants, children younger than 6 years old, and older adults at least 60 years old.

Women, Infants, and Children (WIC) This federal program provides free food to low-income women who are pregnant or breastfeeding and to children younger than age 5. Typical available foods are milk, eggs, cheese, cereals, juice, and infant formulas. They are intended to supplement the diet with protein, iron, and vitamins. They are not meant to supply all necessary food for the household.

National School Lunch and Breakfast Programs These federally assisted programs subsidize schools that provide free or reduced-rate breakfasts and/or lunches to low-income children. All students pay slightly less than the full cost of the meal. Lunches must supply about one-third of the child's DRIs for energy and nutrients.

NIC Intervention—Teaching: Individual

You can help your clients to use their food dollars creatively by teaching them to follow the suggestions in the Self-Care box.

Self-Care

Teaching Your Patients to Buy Nutritious Foods on a Limited Budget

Plan Ahead

- Look at the grocery advertisements in the paper or in their fliers, and plan meals around the sale items that are also the most nutrient dense.
- Make a list of the foods you need. This will help you to control impulse buying and extra trips to the store.
- Avoid eating at fast-food restaurants. Meals are more expensive and less nutritious than those you can prepare at home.
- If transportation is not a problem, buy fresh foods at farmers' markets, at consumer co-ops, and from neighbors who have gardens.

Buy Wisely

- Buy generic instead of more expensive and widely advertised brands.
- Watch for sales of nutrient-dense items. Stock up on and freeze them for future use if you do not need them right away.
- Buy in quantity—if it results in real savings and if you can use that amount of food before it spoils.
- Limit convenience foods (e.g., frozen dinners); they are expensive and often high in fat and sodium.
- Buy foods when they are in season; for example, fresh tomatoes are less expensive, and better tasting, in the summer than in the winter.
- Purchase oatmeal and cream of wheat instead of cold, sugared cereals. Buy in bulk rather than single-serving packages.
- Avoid shopping at convenience stores. Items are usually more expensive than in supermarkets.
- Buy inexpensive cuts of meat; avoid processed lunchmeats and hot dogs.
- Buy frozen concentrated fruit juices instead of juice in plastic jugs and cardboard boxes.
- Substitute dairy products, beans and lentils, and peanut butter for more expensive meat. Substitute powdered milk for whole milk.
- Read the Nutrition Facts panels on prepared foods to be sure you obtain the most nutrition for the money.

Supporting Special Nutritional Needs

Patients with impaired dietary intake and those who experience difficulty with swallowing, digestion, or elimination require specific nutritional interventions, such as the following.

Patients with Impaired Dietary Intake

Nutritional health is related to the type and amount of food patients consume. Physical illnesses that alter appetite, taste, and smell impair dietary intake. Medical restriction in intake, such as NPO, also affects nutritional status. Other factors leading to poor nutritional health include impaired ability to purchase and prepare nutritious food, and feed self.

Patients Who Have Nausea Nausea can cause vomiting and loss of appetite, leading to Impaired Nutrition. Nursing interventions include assessing for the cause of the nausea, and providing comfort and prevention measures. For other interventions,

Go to **Clinical Insight 27-5: Interventions for Patients Who Have Nausea,** in Volume 2.

Loss of Appetite; Diminished Sense of Smell and Taste Refer to the section Stimulating the Patient's Appetite, later in this chapter.

NPO Patients who are to receive nothing by mouth (NPO) must receive glucose and electrolytes through either intravenous (IV) fluids (e.g., ½ NS, D5W, Lactated Ringers solutions), or total parenteral nutrition (TPN) and IV lipid infusion to meet the body's fluid and nutritional needs for prolonged periods of NPO.

Remember, too, that remaining NPO for more than 3 days puts the patient at risk for malnutrition.

- Provide comfort measures for patients who cannot take food and fluids orally. Assist the patient with or provide oral hygiene. If allowed, provide ice chips, hard candy, chewing gum, or sips of water for rinsing the mouth.
- Advise family or visitors not to eat or drink around the patient, and try to schedule other activities for the patient at mealtimes.
- When older adults must be NPO for tests or procedures, schedule them early in the day to decrease the length of time the patient must be NPO. If testing must be late in the day, ask the primary care provider whether the patient can have an early breakfast.

Self-Care Deficit: Feeding You will find interventions in the section Assisting Patients With Meals.

Poor Selection of Nutritious Foods Advise clients to eat nutrient-dense foods and to eat essential foods first.

Because the sense of taste is decreased, older adults may prefer concentrated sweets; and because they may also have a poor appetite, once they eat sweets they may not be hungry enough to eat other foods.

At least one study suggests that dementia, especially Alzheimer's disease, is less common among people who eat fruits and vegetables daily, eat fish once a week, and use fats rich in omega-3 fatty acids (e.g., walnut and soy oils) (Barberger-Gateau, Raffaitin, Letenneur, et al., 2007). Although this merely suggests there may be a connection, clients can benefit from this dietary advice.

Limited Ability to Purchase Nutritional Food Adults and children living in impoverished situations may qualify for government entitlement (e.g., Food Stamps, School Lunch Program) to supplement nutritional needs. Additionally, private, religious, and other charitable agencies (e.g., Harvesters) offer meals to those in need. Meals on Wheels are directed to the seniors living independently in their homes but who may have limited ability to buy and prepare nutritious meals. Refer to the Self-Care box Teaching Your Patients to Buy Nutritious Foods on a Limited Budget.

Patients with Impaired Swallowing, Digestion, or Elimination

Nutritional health is due in part to digestive function from **mastication** (chewing) all the way through passing stool. Dysfunction of the GI tract can reduce the transport, absorption, and elimination of food nutrients.

Dry Mouth This is typically an age-associated change. Advise clients to avoid caffeine; alcohol; tobacco; and dry, bulky, spicy, salty, or highly acidic foods. Offer sugarless hard candy or chewing gum to stimulate salivation (unless the patient has dementia). Use lip moisturizer and encourage frequent sips of water.

Impaired Swallowing The NANDA-I diagnosis Impaired Swallowing may be caused by mechanical obstruction (e.g., tumor), neuromuscular impairment (e.g., facial paralysis), stroke, cerebral palsy, or a host of other anatomical or physiological defects. Nutritional support for patients with Impaired Swallowing includes activities from the NIC intervention, Swallowing Therapy (Bulecheck, Butcher, Dochterman, et al., 2012, pp. 369–370). For a list of these activities,

Go to **Clinical Insight 27-4: Interventions for Patients With Impaired Swallowing,** in Volume 2.

Gastroesophageal Reflux Advise clients not to eat just before bedtime and to elevate the head of the bed 30° to 40° to allow food to move out of the stomach before lying flat. It is also important to avoid overeating and bending over, and to take prescribed medications. They should also avoid fruit juices, fatty foods, chocolate, alcohol, and smoking; all of the stimulate reflux. If overweight, the client with reflux should lose weight.

Decreased Gastric Secretions To promote digestion for those with lessened gastric secretions, encourage regular meals, thorough chewing, and prescribed medication as needed. Food rich in vitamin D aids in calcium absorption.

Constipation To prevent problems with bowel elimination, advise patient to consume foods high in fiber. Soluble fiber allows more water to remain in the stool, which makes it softer and easier to pass. Insoluble fiber adds bulk to the stool for easier defecation. Patients should drink plenty of water—at least 64 ounces daily. Also, encourage exercise as physical activity aids GI motility needed to pass stool.

Glucose Intolerance Patients with glucose intolerance and insulin resistance should avoid concentrated, refined sugars, unless they have been told to use it to treat hypoglycemia. Complex carbohydrates (e.g., whole-grain cereals, vegetables) are better tolerated. Smaller, more frequent, nutritious meals may also be necessary.

Assisting Patients With Meals

Some patients are at risk for nutritional deficits as a result of a Self-Care Deficit (Feeding), which may be caused by loss of cognitive, musculoskeletal, or neuromuscular function; weakness; pain; or environmental barriers. Elderly patients, especially, are at risk for undernutrition or malnourishment in inpatient settings.

You should institute special nutrition interventions in patients who have one of the following:

- An involuntary weight loss of more than 5% in 30 days or 10% in 180 days.
- Leaving more than one-fourth of their food in the past 7 days or two-thirds of meals (based on a 2,000-kcal diet).
- A BMI of 19 or less.

NIC Interventions for this situation are Feeding and Self-Care Assistance: Feeding. Important nursing actions include assisting patients with meals. Other nursing activities include the following:

- Assess for functional deficits that contribute to Self-Care Deficit or Imbalanced Nutrition.
- Monitor intake for nutritional adequacy. Some patients may need liquid oral supplements of protein and calories.
- Collaborate with occupational and physical therapists in planning care.
- See that the patient has protein- and energy-enriched meals.
- Provide mid-afternoon snacks.
- Ensure the nutrition prescribed is actually implemented. Assign someone to be responsible for assisting the patient with meals as necessary. Include this in your instructions to NAPs and other assistive personnel.
- Refer the patient and family to an agency that can help them obtain a home health aide.

For guidelines more specific to assisting with meals, including care of patients with dementia,

Go to Chapter 27, **Clinical Insight 27-6: Assisting Patients With Meals,** in Volume 2.

Example Problem: Overweight and Obesity

The BMI is commonly used to define weight status. A client with a BMI greater than 25 but less than 30 is considered **overweight** (or pre-obese). **Obesity** is a BMI of 30 or higher. The CDC data for 2009–2012 indicate more than one-third of adults over 20 years old are overweight (and not obese), while almost 36% are obese. Obesity rates did not differ between men and women. Almost 17% of youth were obese in 2009–2010. (UDHHS, CDC, National Center for Health Statistics, 2012).

Obesity and overweight together affect two-thirds of our adult population, and are associated with chronic diseases such as diabetes, hypertension, coronary artery disease and stroke, gallbladder disease, gout, and obstructive sleep apnea. A person who is 40% overweight is twice as likely to die prematurely as a normal-weight person (Ogden, Carroll, Kit, et al., 2012). Therefore, as a nurse you can assist your clients to achieve and maintain a healthy weight.

Obesity in Older Adults

The proportion of obese older adults has doubled in the past 30 years. Nevertheless, most older adults lead active and healthy lives and are not obese. Obesity is more prevalent in adults younger than age 70 and becomes less prevalent after that. Still, more than 15% of older adults are obese (Newman, 2009). However, according to the BMI thresholds set by the WHO, older people considered to be overweight are not at a greater mortality risk (Flicker, McCaul, Hankey, et al., 2010).

As we age we tend to be less active physically, but our eating patterns do not usually change. In addition, aging is associated with hormonal changes and slowing metabolism that cause accumulation of fat (e.g., decreased growth hormone and serum testosterone). Many of the chronic problems associated with aging are made worse by obesity (e.g., respiratory problems, arthritis, cardiovascular disease, cancer, and diabetes). For example, maintaining a BMI of less than 25 is particularly important in reducing diabetes risk, such as damage to the eyes, heart, kidneys, and other organs (National Diabetes Education Program, 2011).

Interventions are the same as for other groups: dietary modification, exercise, and use of community supports. Older adults may require more assistance in improving physical function so that they can exercise more. To avoid injuries, exercise should start at low intensity and progress gradually over several months.

ANALYSIS/NURSING DIAGNOSIS: OVERWEIGHT AND OBESITY

NANDA-I diagnoses define overweight and obesity in the following ways:

Imbalanced Nutrition: More Than Body Requirements is used when a person consumes nutrients in excess of metabolic needs. The defining characteristics are (1) triceps skinfold greater than 15 mm in men and 25 mm in women, or (2) weight 20% over ideal for height and frame.

Risk for Imbalanced Nutrition: More Than Body Requirements identifies the potential for an individual to experience intake of nutrients in excess of metabolic needs.

Etiologies Etiologies of the two preceding NANDA-I diagnoses include the following:

- Consuming more kcal than needed for activity, gender, height, and weight
- Reducing activity level without modifying food intake
- Genetic predisposition to obesity. For example, low BMR and excess adipose tissue distribution are common in certain ethnic groups.
- Ineffective coping mechanisms—for instance, the use of binge eating to reduce anxiety or relieve boredom
- Cultural influences—some cultural norms encourage excess weight, particularly as an indication of wealth.
- Decreased levels of thyroid hormone can lower BMR, causing weight gain.
- Ineffective Health Maintenance—for example, high-fat diet, inactivity, and avoidance of health assistance
- Impaired Physical Mobility, which limits physical activity and decreases energy expenditure

Obesity as Etiology of Other Problems Being overweight may lead to the development of other nursing diagnoses. Excess weight, and especially obesity, makes activity more difficult; therefore, over time, the person becomes more sedentary, and the body becomes deconditioned (weakened). The following are examples:

- Activity Intolerance r/t deconditioned state secondary to long-term sedentary lifestyle
- Decreased Cardiac Output r/t prolonged deconditioned state
- Constipation r/t inadequate physical activity
- Risk for Injury (and/or Risk for Falls) r/t deconditioned state and generalized weakness
- Social Isolation r/t poor self-image secondary to excess weight

PLANNING OUTCOMES/EVALUATION: OVERWEIGHT AND OBESITY

A part of your nursing role will be to work with clients to help achieve the Healthy People 2020 nutrition goals. To review them,

Go to Chapter 27, **Tables, Boxes, Figures: ESG Box 27-3, Nutrition and Weight Status Objectives From Healthy People 2020,** on Davis*Plus*.

For *NOC standardized outcomes* for evaluating weight:

Go to Chapter 27, **Standardized Language, NOC Outcomes, and NIC Interventions for Overweight/Obesity and Underweight/Malnutrition,** on Davis*Plus*.

Individualized goals/outcome statements include the following examples:

States pertinent factors contributing to weight gain.
Designs dietary modifications to meet individual long-term goal of weight control.

Accomplishes desired weight loss in a reasonable time frame (1 to 2 lb/week).
Incorporates appropriate physical activities requiring energy expenditure into daily life.

PLANNING INTERVENTIONS/IMPLEMENTATION: OVERWEIGHT AND OBESITY

For the *NIC standardized interventions* for overweight and obese clients,

Go to Chapter 27, **Standardized Language, NOC Outcomes and NIC Interventions for Overweight/Obesity and Underweight/Malnutrition,** on Davis*Plus.*

Individualized nursing activities include the following:

- ***Weigh the client weekly under the same conditions.*** Weekly weighs allow the client to monitor his progress and can motivate him to follow the weight-loss regimen.
- ***Suggest keeping a food diary for a number of days or weeks.*** Research suggests that this can double diet weight loss. Analyzing the diary will provide valuable information on intake and circumstances that trigger eating. It may help to identify behavioral or coping issues. Keep in mind that many patients eat less than usual when they are keeping a food diary (Hollis, Gullion, Stevens, et al., 2008).
- ***Educate the client about a healthy diet.*** Lifestyle changes must be ongoing to maintain weight loss. For the client, the first step is to learn about a balanced diet and food quality.
- ***Encourage the client to eat more fresh fruits and vegetables and fewer fatty foods and sugar-sweetened beverages.***
- ***Discuss fat substitutes***. These are available to improve flavor and texture of low-fat foods while reducing total dietary fat. Recall that fats contain 9 kcal per gram, so reducing fat intake is an important part of most weight-loss diets. Fat substitutes are not absorbed; therefore, they contribute few kcal. The American Heart Association (n.d.b) states that fat substitutes, used appropriately, can provide flexibility in diet planning. Although the USDA (FDA) generally considers fat substitutes to be safe, long-term benefits and risks are not yet known. In addition, it is not unusual for people to experience diarrhea and stomach cramps when using fat substitutes.
- ***Encourage the client to commit to regular exercise.*** Increased physical activity will not only use up excess stores of fat but also increase the body's resting metabolic rate. Individuals should begin gradually with low-impact activities, such as walking for 20 minutes at least four times a week. The American College of Sports Medicine (ACSM) recommends 150 to 250 minutes of exercise per week to prevent weight gain. More than 250 minutes per week are needed to bring about significant weight loss—that is, 50 minutes on 5 days of the week or 40 minutes on 6 days of the week (Donnelly, Blair, Jakicic, et al., 2009; USDHHS, 2008). Although increased physical activity aids in weight control, advise your client to set realistic expectations for what exercise can achieve. A recent study concludes that overeating, more than a lack of exercise, is to blame for the American obesity epidemic (Swinburn, Sacks, Lo, et al., 2009).
- ***Be encouraging and nonjudgmental.*** Do so especially when there are setbacks.
- ***Provide weight loss tips.*** See the Self-Care box Teaching Weight Loss Tips.
- ***For children, recommend the 5-2-1-0 program*** (Marion County Children's Alliance, 2012). Children should have:
  5 – Servings of fruits and vegetables each day.
  2 – Hours or less of "screen" time per day.
  1 – Hour of physical activity per day.
  0 – Servings of sweetened beverages.

Self-Care

Teaching Weight Loss Tips

Getting Ready

Make a commitment.	➤ Promise yourself; promise others: "I will do this."
Set realistic goals.	➤ Aim to lose 1 to 2 lb/week. To do this you need to burn 500 to 1,000 calories more than you consume. Losing weight faster usually means losing water weight or muscle tissue rather than fat.
	➤ Set "process" rather than "outcome" goals. For example, "I will exercise every day" instead of "I will lose 10 pounds this month." Changing your habits (your "processes") is the key to weight loss.
	➤ Write your goals, your plan for achieving them, and your start date. This makes it reality, not just a thought.
	➤ Review your goals each week. Readjust them as needed. If you are exercising more than you thought, adjust your goal upward, for example.
Plan for setbacks.	➤ Identify situations that might trigger eating or interfere with exercise; plan specific actions you will take to overcome them.

Continued

Self-Care

Beginning New Behaviors

Eat healthier foods.

- Eat more low glycemic fruits and high fiber vegetables.
- Limit fatty foods. Grill meats and vegetables rather than fry them. Substitute non-fat Greek yogurt for mayonnaise and sour cream. Try substituting applesauce in recipes that call for vegetable oil.
- Avoid sugar-sweetened beverages and high-sugar snacks. Consume foods with whole grains instead of those with bleached, processed flour. Sweeten food with agave or honey instead of refined sugar.
- Try using natural herbs and spices, extracts, and citrus to flavor food instead of adding salt and sugar.
- Be sure to add healthy foods to your diet, such as black beans, kale, walnuts and almonds, dark chocolate, pumpkin, quinoa, red wine, Brussels sprouts, eggplant, lentils, steel-cut oats, red beets, tuna, sweet potatoes, lean meat and fish, tomatoes, chia seeds, blueberries, spinach, flax seeds, and extra virgin olive oil.
- Don't be fooled by seemingly healthy foods. For example, light microwave popcorn contains high levels of sodium and the chemical diacetyl. Use a little extra virgin olive oil and balsamic vinegar instead of "light" salad dressings. Trail mix often contains chocolate chips or candies. Granola is high in sugar. Artichoke/spinach dip is high in fat. Flavored fat-free yogurt contains added sugar and artificial flavoring. Eat whole, natural foods without chemical additives and preservatives.
- Organic foods are healthier in that they reduce exposure to pesticide residues and antibiotic-resistant bacteria. But the published literature lacks strong evidence that organic foods are significantly more nutritious (Smith-Spangler, Brandeau, Hunter, et al., 2012).

Get active and stay active.

- If you have not been exercising, start slowly and build steadily, listening to your body's natural cues signaling injury.
- Work up to at least 250 minutes per week to lose weight and maintain the loss.

Get adequate sleep.

- For most people, this is 7 to 8 hours a night.
- New research suggests that sleep deprivation can affect levels of the appetite-regulating hormones leptin and ghrelin.
- Sleep loss can affect the type of food you crave. When you are tired you are less able to cope with stress and emotional triggers for eating, and more likely to crave comfort foods such as chocolate and ice cream.

"Sticking With It"

Keep a food diary.

- Recording what you eat can double your weight loss.

Decide what and when to eat.

- Decide what foods you will eat as well as when you will eat. For example, "I will eat only at the table, 3 meals and 2 snacks daily."
- Make a conscious effort to take small bites and eat slowly.
- Serve your food on small plates.

Shop wisely.

- Shop for food on a full stomach.
- Read food labels when purchasing food (for information about calorie and fat content).

Find ways to exercise.

- Lay out your exercise clothing ahead of time (e.g., at night if you exercise in the morning).
- Use the stairs instead of the elevator; park in the back of the parking lot, as far from the door as possible.
- Walk or bike to work when possible.

Get emotional support.

- Family members can help by not offering you desserts. Weight-loss support groups let you know you are not alone. An exercise partner can help keep you motivated.

Recognize lifestyle changes must be permanent.

Key Point: *Remember: Healthy eating, physical activity, and sleep are necessities, not luxuries!*

- ***For children and adolescents,*** weight loss is more effective when it involves the child, the parents, and the community in limiting soda (deRuyter, Olthof, Seidel, et al., 2012; Ebbeling, Feldman, Chomitz, et al., 2012) and junk food consumption and limiting hours spent watching television and playing video games. Children can be taught to make "best choices" regarding activities and the foods they eat (Speroni, Early, & Atherton, 2007). To learn more about obesity in adolescents and children,

Go to Chapter 27, **Reading More About Nutrition,** on Davis*Plus*.

To see a sample care plan and care map for Imbalanced Nutrition: More than Body Requirements,

Go to Student Resources, **Care Plan, Imbalanced Nutrition: More Than Body Requirements,** and **Care Map, Imbalanced Nutrition: More Than Body Requirements,** in Chapter 27, on Davis*Plus*.

Example Problem: Underweight and Undernutrition?

A BMI of less than 18.5 is considered underweight (see Box 27-4). For patients in long-term care settings, parameters include one of the following:

1. Involuntary weight loss of more than 5% in 30 days or 10% in 180 days
2. Leaving more than one-quarter of food in the past 7 days or two-thirds of meals based on a 2,000-kcal diet
3. A BMI of 19 or less

For hospitalized patients with serious illness, increased mortality is associated with a BMI of 21 or less (CDC, n.d., updated 2011).

A person becomes underweight when he consumes fewer kcal than needed based on his activity, sex, height, and weight. Consuming too few kcal may result in serious undernutrition; that is, insufficient intake of protein, fat, vitamins, and minerals. The causes of underweight status may be psychological, social, economic, or physiological (e.g., hospitalization, self-care deficits, illness, eating disorders). A person can also be malnourished with regard to specific nutrients without being underweight.

What Are the Signs of Severe Malnutrition?

Malnutrition is a condition of impaired development or function caused by a long-term deficiency, excess, or imbalance in energy and/or nutrient intake. Malnutrition caused by deficiency of protein in a diet that is primarily starches is called **kwashiorkor**. When protein sources in food are scarce and overall caloric intake is low, **marasmus** occurs, particularly in young children. Undernourished people are prone to infections. Symptoms of undernutrition resulting from insufficient food are reduced physical activity, weight loss, reduced height, abdominal enlargement, and hair loss. Other diseases develop as a result of specific vitamin and mineral deficiency, such as beriberi (neurological deficits), scurvy (delayed wound healing and poor bone growth), and pellagra (diarrhea and dementia). See Tables 27-4 and 27-5 for specific signs of vitamin and mineral excesses and deficits.

Malnutrition is most common in underdeveloped nations and among children, older adults, and people with chronic illnesses such as cancer, HIV, and COPD. Others at risk for malnutrition include those with the following:

- Serum albumin level 3.5 g/dL or less
- Nausea or vomiting lasting 3 days or more
- Clear liquid diet or NPO for 3 days or longer
- Increased nutritional requirements (e.g., wound healing, burns)
- Recent, unplanned loss of 10% or more of patient's usual weight

To assess for malnutrition in children, compare weight, height, and head circumference to the standards (norms) for the child's age. In cases of severe malnutrition, abdominal circumference can signal worsening disease. Other indicators in children include the presence of iron deficiency anemia and, in adolescents, a delay of stages of sexual maturation.

ANALYSIS/NURSING DIAGNOSIS: UNDERWEIGHT AND UNDERNUTRITION

Undernutrition as Problem When undernutrition is the focus of the patient's problem, the following NANDA-I labels may apply:

Adult Failure to Thrive
Imbalanced Nutrition: Less than Body Requirements

When the patient is at higher than normal risk for undernutrition, you can use *Risk for Imbalanced Nutrition: Less than Body Requirements*; however, this is not a NANDA-I diagnosis.

Undernutrition as Etiology Imbalanced Nutrition: Less Than Body Requirements may be the etiology of other nursing diagnoses. Compare the two following examples:

Imbalanced Nutrition: Less Than Body Requirements r/t Impaired Swallowing 2° pain with swallowing
Risk for Disproportionate Growth r/t Imbalanced Nutrition: Less Than Body Requirements 2° anorexia nervosa

For other etiologies and related diagnoses, and for help in choosing which to use for a patient,

Go to Chapter 27, **Standardized Language, Nursing Diagnoses Associated with Undernutrition,** on Davis*Plus*.

Eating Disorders

Eating disorders stem from social pressures to be thin, fashion styled for slender body types, and even societal prejudices against people with obesity. Although all segments of society are affected, eating disorders are more common in women, and most report the onset of illness before the age of 20.

Anorexia Nervosa is a psychiatric disorder characterized by self-imposed, self-starvation. Some common physical signs include:

- Refusal to maintain body weight at or above minimally normal weight for age
- Intense preoccupation with weight and body shape
- Excessive facial or body hair (because of inadequate protein in the diet)
- Thinning, dry hair or hair loss
- Feeling cold and having a lower than normal body temperature
- Absent or irregular menstruation

Bulimia Nervosa refers to binge eating (eating an excessive amount of food in a short period of time) followed by self-induced vomiting or laxative abuse to purge food. People with bulimia people also have many of the same physical signs as anorexia as well as tooth decay or erosion of enamel resulting from repeated vomiting. Salivary glands are swollen. People with bulimia lack energy, feel bloated, and have low levels of potassium and other serum electrolytes. Feelings of guilt, anxiety, or depression are common.

Serious medical complications for anorexia and bulimia nervosa include osteoporosis and increased risk for fractures; brain damage; decreased resistance to infection; cardiac, renal, liver, and metabolic disorders; and even death. You will need to recognize the warning signs of eating disorders, such as the behavior changes described in Box 27-6.

PLANNING OUTCOMES/EVALUATION: UNDERWEIGHT AND UNDERNUTRITION

The NOC standardized outcome for assessing weight is Weight: Body Mass. If it becomes necessary to monitor nutritional status, you could use the labels of Nutritional Status: Food and Fluid Intake and Nutritional Status: Nutrient Intake.

Individualized goals/outcome statements include the following:

Progressively gains weight toward desired goal.
Verbalizes willingness to follow diet.
Body mass and weight are within normal limits.
Laboratory values (e.g., albumin, CBC) are within normal limits.
Recognizes factors contributing to underweight.

PLANNING INTERVENTIONS/IMPLEMENTATION: UNDERWEIGHT AND UNDERNUTRITION

NIC standardized interventions for undernutrition include Appetite, Nutritional Status, and Weight: Body Mass. For others,

BOX 27-6 ■ Warning Signs of an Eating Disorder

Food Behaviors

- Deliberate self-starvation with weight loss.
- Continuous dieting.
- Skips meals.
- Takes only tiny portions.
- Will not eat in front of others.
- Always has an excuse not to eat.
- Usually has a diet soda or coffee in hand.
- Eats only food that is low in fat.

Appearance and Body Image Behaviors

- Wears baggy clothes.
- Complains of being fat.
- Obsesses about clothing size.
- Spends lots of time looking in the mirror.

Exercise Behaviors

- Exercises excessively and compulsively.
- May tire easily.
- Pushes self beyond normal expectations.

Social Behaviors

- Tries to please everyone and withdraws if unsuccessful.
- Tries to care for everyone but self.
- Tries to control what and where family eats.
- Relationships tend to be superficial or dependent.

Emotional Behaviors

- Intense fear of gaining weight

Go to Chapter 27, **Standardized Language, NOC Outcomes and NIC Interventions for Adult Failure to Thrive, Overweight/Obesity and Underweight/Malnutrition,** on Davis*Plus*.

Individualized nursing activities for clients who are underweight or undernourished include the following:

- **Assess for recent changes in physiological status as underlying cause of weight loss or undernourishment** (e.g., pain, fatigue, illness, and immobility).
- **Offer high-calorie and high-protein (nutrient-dense) foods.** Serve these foods when the person is most likely to be hungry. Avoid food with little nutritional value; when intake is limited, it is essential that it not be wasted on empty calories.
- **Consult with a dietitian.** Discuss strategies to increase the nutritional content of foods.
- **Weigh the client regularly under the same conditions.** Weigh the client one to two times per week if nutritional status is severely jeopardized to assess the effectiveness of the therapeutic plan.

- **Offer high-protein supplements.** Offer nutritious high-protein supplements between meals to increase intake of protein and kcal. It may be easier for the client to drink a small amount of a supplement than to eat enough food to supply the equivalent nutrients.
- **Suggest community resources** (e.g., Meals on Wheels for clients with Adult Failure to Thrive). Additional assistance may be needed to improve access to food.
- **For eating disorders, see that the client is referred for appropriate counseling** (e.g., dietitian, mental health professional).

The following sections discuss more fully nursing interventions for improving the appetite, as well as alternative feeding methods.

Stimulating the Patient's Appetite

Illness, with its accompanying pain, anxiety, and medications, often causes appetite loss. This is especially true for institutionalized patients, who have little control over food choices and preparation. You will need to make an effort to see that hospitalized patients eat the food that is served. It is not enough merely to order meals and deliver the trays. The following measures may help improve appetite and intake and, subsequently, nutritional status:

- **Offer frequent, small meals.** This helps prevent gastric distention and improves appetite by keeping the patient from being overwhelmed with a large amount of food.
- **Suggest smokers refrain for 1 hour before a meal.**
- **Restrict liquid intake with meals** to prevent gastric distention or feeling full before the patient consumes sufficient nutrients.
- **Keep the patient's environment neat and clean** and free of unpleasant sights, odors, and medical equipment. These often trigger loss of appetite. For example, remove bedpans, urinals, and the emesis basin from the room before mealtimes.
- **Order a late food tray or warm the food** if the patient is not in his room during mealtime.
- Provide or assist with **frequent oral hygiene.**
- **Provide a pleasant eating environment.**
- **Serve foods attractively**; vary textures, colors, and flavors; arrange the tray so the person can easily reach the food.
- **Position the person comfortably** for mealtime.
- **Find out what the person likes to eat**, and encourage family and friends to bring foods from home.
- **Control pain around the clock**, and avoid painful treatments before meals.
- **If the patient receives a nutritional supplement, delay the meal for at least an hour afterward.**
- **Encourage meals with friends** for those who live alone, or meals at a senior center.
- **Provide nutrient-dense foods** (e.g., add ice cream to appropriate beverages and foods).
- **Arrange for a home health aide** to shop and prepare meals for those who are unable to leave home for groceries, or arrange for Meals-on-Wheels.

Providing Enteral Nutrition

If a patient cannot meet his nutritional needs through an enhanced diet and measures to stimulate the appetite, you may need to use an alternative feeding method. Feeding can occur through the intestinal tract as enteral nutrition, or intravenously as parenteral nutrition. **Enteral nutrition** (tube feeding) refers to the delivery of liquid nutrition into the upper intestinal tract via a tube. Tube feeding may be used in addition to or instead of oral intake. It is the preferred method of feeding for a patient who has a functioning intestinal tract but needs nutritional support (e.g., patients with high metabolic needs, such as those with trauma, burns, or severe malnutrition; neurological disorders that affect swallowing; anorexia nervosa; prematurity; failure to thrive; or specific bowel diseases). Tube feeding may be a short- or long-term therapy.

Enteral feedings are preferred to parenteral (i.e., intravenous) nutrition because they maintain peristalsis and have a lower incidence of infections (Marik & Zaloga, 2004). However, there are a number of risks associated with enteral feedings. If enteral formula is aspirated into the lungs, it can lead to infection, pneumonia, abscess formation, adult respiratory distress syndrome (ARDS), and in some cases death. The high glucose content of enteral formulas provides a medium for bacterial growth. Other complications include diarrhea, nausea and vomiting, nasopharyngeal trauma, alterations in drug absorption and metabolism, and various metabolic disturbances.

There have been some instances where enteral feedings have been mistakenly connected to intravascular (IV) lines and feeding solutions have been infused into veins. These events, termed "tubing misconnections," are potentially fatal to the patient (The Joint Commission, 2006, 2007; Millin & Brooks, 2012; U.S. Food and Drug Administration, 2005). An enteral device manufacturer and a professional organization dedicated to improving patient care by advancing the science and practice of nutrition support therapy have cooperated to develop the "BE A. L. E. R. T." safety campaign to increase the safety of patients on enteral nutrition (see Box 27-7). To reduce feeding misconnections, only use an enteral-only fitting at the proximal end of the feeding administration set. This safety device can be distinguished from a traditional Leur connector so it cannot be attached to an intravenous line or syringe (Institute for Safe Medication Practice, 2014).

Administer feedings at room temperature, and be sure to check the expiration date of any feedings before starting an infusion. In this volume, the Highlights of Procedures box summarizes a procedure for enteral feedings. For complete instructions,

Go to Chapter 27, **Procedure 27-3: Administering Feedings Through Gastric and Enteric Tubes,** in Volume 2.

Quality and Safety Education for Nurses

Safe Use of Parenteral Nutrition

Chapter Key Concept: *Nutrition*

Competency: *Quality Improvement (Knowledge, Skill, Attitudes); Evidenced-Based Practice (Skills, Attitudes); Safety (Knowledge, Skills, and Attitudes)**

Clinicians at Scripps Memorial Hospital (SMH) in La Jolla, California, theorized that their poor processes and variation in methods in the use of parenteral nutrition (PN) were producing inconsistent patient outcomes, thus increasing patient risk. The following is a description of how they set out to correct this by identifying the root causes of the problems and standardizing care.

Problems Identified: Clinicians first organized a multidisciplinary team to collect and analyze data, develop better practices, and evaluate outcomes. They found several problems: inappropriate use of PN, poor glycemic control in patients on PN, inconsistent and confusing ordering practices, insufficient calorie replacement, and insufficient laboratory monitoring.

Corrective Interventions: Implementing the American Society for Parenteral and Enteral Nutrition's (A.S.P.E.N.) guideline for PN, revising the PN order form, educating physicians and other clinicians, and establishing twice weekly PN rounds. The group measured specific quality indicators before and after implementing the new procedures. The following table shows the top four measures:

Safety Measure	Pre-Intervention (2007)	Post-Intervention (2009)
Compliance with 10 Mandatory Components of a PN Order Form (A.S.P.E.N. guideline)	20%	100%
Appropriate use of parenteral nutrition	60%	97%
Baseline labs ordered before PN starts	30%	80%
Kcal delivered are within 10% of estimated need	54%	85%

Results/Conclusions: In addition to improving compliance, the new procedures resulted in significant costs savings.

Think About It: Parenteral nutrition is a high-risk treatment associated with serious complications, including death. (1) Do the above measures mean that patient outcomes are improved? (2) In what specific ways does this QI project demonstrate the QSEN competencies of Quality Improvement, Safety, and Evidenced-Based and Practice? (3) Which specific knowledge, skills, and attitudes does it address?

BOX 27-7 ■ Be A.L.E.R.T

To reduce errors and help ensure safe enteral nutrition, use the following mnemonic:

A **Aseptic** technique------------------------------------- When preparing and delivering enteral formula, practice good hand hygiene; wear gloves when handling feeding tube; avoid touching can tops, container openings, spike, and spike port.

L **Label** enteral equipment------------------------------ with patient name and room number, formula name and rate, date and time of initiation, and nurse initials.

E **Elevate** the head of the bed------------------------- a minimum of 30° for feedings whenever clinically possible; may mitigate risk of reflux and aspiration of gastric content.

R **Right** patient, **Right** formula, **Right** tube---------- Match formula to patient's feeding order; verify **enteral** tubing set connects formula container to feeding tube.

T **Trace** all lines and tubing back to patient---------- Avoid misconnections—trace all lines from origin to patient; only enteral-to-enteral connections.

Patients may receive enteral or parenteral nutrition in the home as well as in inpatient settings. The box Home Care: Home Nutritional Support reviews teaching related to alternative feeding methods in the home. You should review these topics with the patient or caregiver.

Types of Enteric Tubes

Enteric tubes are available in various materials, lengths, diameters, and types. Choose the type of tube you need based on the intended use and the length of time you anticipate it will be left in place. This chapter focuses on the use of enteral tubes as a route for feeding; however, they are inserted for other reasons, as well:

- To lavage the stomach (e.g., when there is disease, surgery, or bleeding in the GI tract, and in cases of poisoning or medication overdose)
- To collect a specimen of stomach contents for laboratory tests
- To prevent nausea, vomiting, and gastric distention postoperatively.

These are complicated therapies to manage at home, so patients typically go home with a referral for a home care nurse to assist in the transition from hospital to home and follow-up with nutritional support service.

When a nasogastric (or orogastric) tube is placed so the stomach can be emptied (lavage), larger bore, tubes made of polyvinyl chloride (PVC), are used. These are called **Salem sump tubes** (Fig. 27-4). A Salem sump tube has a lumen for drainage and one to allow air to enter the stomach. The air port (pigtail) is usually blue. A **Levin tube**, also used for drainage, has a single lumen, with holes in the tip and along the sides.

Selecting a Feeding Tube

Short-term (<6 weeks) enteral feedings are usually delivered through a nasogastric (NG) or a nasoenteric (NE) tube. As a nurse, you may be asked to place a small-bore, **nasogastric** or a **nasojenunal (NJ) feeding tube**. The tube is inserted through one naris, passed through the nasopharynx into the esophagus, and finally into the stomach. Placing the tube through the mouth is an option (oropharyngeal), but this method is more likely to trigger gagging or unconscious chewing on the tube. The Highlights of Procedures box in this volume provides a summary of a procedure for inserting nasogastric and nasoenteric tubes. For the entire procedure,

Go to Chapter 27, **Procedure 27-2: Inserting Nasogastric and Nasoenteric Tubes,** in Volume 2.

A **nasoenteric (NE) tube** is longer than an NG tube, extending through the nose down into the duodenum or jejunum (if it extends into the jejunum, it is called an NJ tube). A small, flexible tube is preferred for feeding (Fig. 27-5). An NE tube may be used instead of an NG tube for patients at risk for aspiration. This includes patients who have a decreased level of consciousness, absent or diminished gag reflex, or severe gastroesophageal reflux.

Home Care

Home Nutritional Support

Clients frequently administer enteral and parenteral nutrition at home. To assist the client or caregiver with the management of home nutritional therapy, teach the following aspects:

- ***Formula.*** Review the type of formula the patient should receive. Enteral or IV solutions are clearly marked with their contents. Emphasize that the caregiver double-check that the correct solution is being used and that the expiration date and time have not been reached before administering any feeding.
- ***Administration.*** Carefully review how to administer the feeding. Emphasize the need for handwashing before hanging the infusion. After a period of time, the client may be able to tolerate delivering 1 to 3 L of enteral feeding at night. The rate must be increased at the beginning and decreased when ending the delivery. If parenteral nutrition is administered at home, be sure that the client or caregiver is aware of proper technique.
- ***Access device.*** Review the care required for the access device, including site care, dressing changes, and flushing.
- ***Storage.*** Stored enteral and parenteral nutrition must be refrigerated to prevent bacterial contamination.
- ***Monitoring.*** Instruct the client or caregiver to report a rise in temperature, weight loss, change in bowel movements, decrease in urine output, or change in condition.
- ***Follow-up.*** Arrange for the client to be weighed and assessed regularly to monitor the adequacy of the feedings. Often clients weigh at home and report to the primary care provider's office or the nutrition support team for ongoing monitoring of progress and review of lab work.

FIGURE 27-4 A large-bore, polyvinyl-chloride (PVC) Salem sump tube used for gastric lavage.

FIGURE 27-5 A small lumen, flexible nasoenteric feeding tube provides continuous nutrition to patients with impaired swallowing.

The **lumen** (inside diameter) of a feeding tube is measured using the **French (Fr) scale**: the larger the lumen, the larger the diameter. Most feeding tubes for adults are measured in French units (each Fr unit is about 0.33 mm), and designated as either small bore (5-12 Fr) or large bore (14 Fr or larger) tubes. Large-bore NG tubes, such as the Salem sump (Fig. 27-4), are occasionally used for feeding, but are converted to a smaller tube within the first 2 days. Smaller tubes are less flexible, less comfortable, and are more commonly used if it is necessary to empty (lavage) the stomach. Figure 27-6 shows two types of feeding tubes.

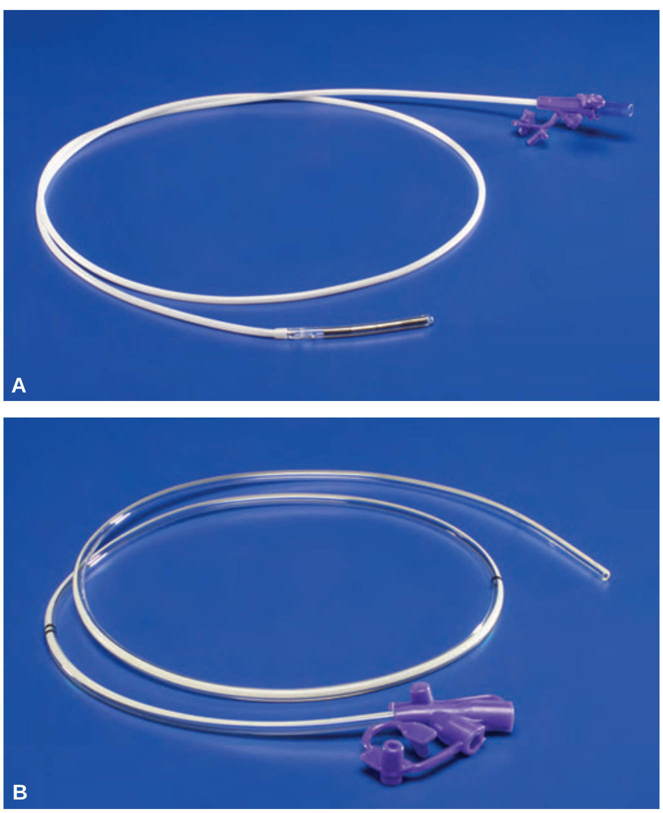

FIGURE 27-6 *A*, A double-lumen, weighted (Dobhoff) feeding tube. *B*, A nonweighted (kangaroo) feeding tube.

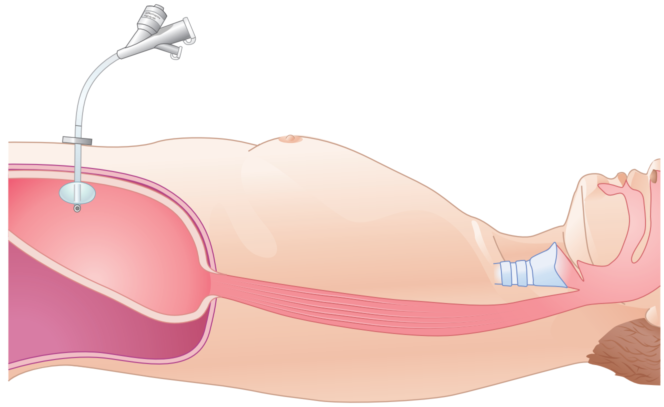

FIGURE 27-7 A percutaneous gastrostomy (PEG) tube for feeding.

For long-term feedings, a **gastrostomy tube (G-tube), percutaneous endoscopic gastrostomy tube (PEG)** (Figs. 27-7 and 27-8), **jejunostomy tube (J-tube, PEJ)**, or **gastrostomy button (G-button)** (Fig. 27-9), is preferred. These are placed surgically or laparoscopically through the skin and the abdominal wall into the stomach or jejunum. They can also be placed endoscopically. The surgical incision is sometimes sutured tightly around the tube to hold it in place and prevent leakage. You must use surgical asepsis to care for a new incision.

A gastrostomy tube can be converted to a **G-button** once healing has taken place. Historically, a PEG or PEJ was reserved for clients needing long-term nutritional support. However, that trend is changing. Patient comfort

FIGURE 27-8 A PEG feeding tube is more convenient and comfortable than a nasogastric tube.

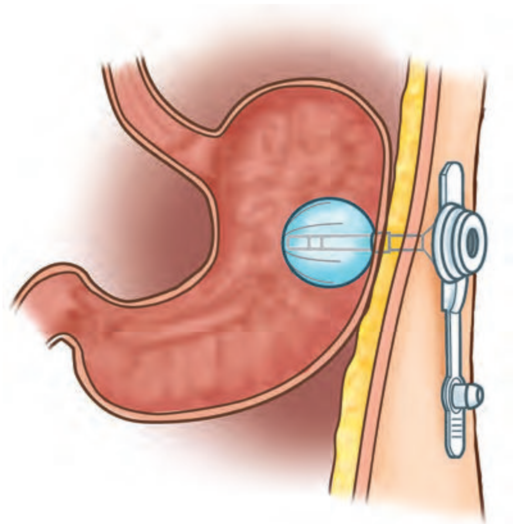

FIGURE 27-9 A gastrostomy button (G-button) in place for feeding.

and improved technology leading to ease of insertion have made PEG or PEJ an option even for short-term use. The G-tubes and G-buttons, which can be capped off flush with the abdominal wall when not in use, are the most comfortable of all for long-term use.

Checking Feeding Tube Placement

NG and NE feeding tubes are placed without direct visualization. As a result, there is risk of placing the tube into the respiratory tract. Therefore, you must check the location of the tip of the feeding tube before each enteral feeding or once per shift for continuous feedings. Failure to verify placement could be disastrous because it may result in infusion of formula into the lungs.

Radiographic Verification

Radiographic verification is the most reliable method for confirming tube placement, and must be performed before the first feeding is administered. All feeding tubes contain markings that can be detected by radiographic films. Reliable bedside assessment is necessary because even when the tube is initially placed correctly in the stomach (or intestine), it may later move upward. No other method alone reliably verifies tube placement.

Bedside Methods

No bedside method alone is reliable. Feeding tube placement can be checked by testing the pH of the aspirate in combination with other methods for bedside verification (see Clinical Insight 27-7). If in doubt, obtain a radiograph to determine tube location.

Bedside methods include the following:

- **Measuring the pH (acidity) of the aspirate and inspecting color, character, and volume.** Gastric fluid is typically clear, odorless, and green with a pH of 5.0 or less. If the tube has migrated into the lungs, the aspirate would be pale yellow and cloudy with a pH of 7.0 or higher. Testing the acidity of the gastric aspirate is currently the most reliable bedside method of checking that the tube is in the stomach. However, the following conditions can affect the accuracy of pH testing:

  If blood is present, either from epistaxis or gastric bleeding, the pH will resemble the pH of blood (7.35).

  If the patient is receiving medications to control stomach acidity (e.g., antacids, H2 blockers, or proton pump inhibitors), the gastric pH may be as high as 6.

  Because of the frequency of such situations, even the pH method should be used in combination with other verification methods (American Society for Parenteral and Enteral Nutrition [A.S.P.E.N.], 2009b).
- **Measuring the residual volume of the aspirate** and observing for unexpected changes in the volume. A dramatic increase in the residual volume may indicate that a small bowel tube has moved into the stomach. Large gastric residual volume (GRV) might also mean the patient is not digesting the feeding and may need a promotility agent (e. g., metoclopramide) to improve bowel function. The patient with large GRV is at greater risk for aspiration. Check GRV every 4 hours during the first 48 of gastric enteral feeding. After that, GRV checks can be done every 6 to 8 hours in stable patients.
- **Injecting air into the feeding tube** (the "whoosh test"). If the tube is in the stomach, injecting 5 to 30 mL of air produces a gurgling sound audible by listening with a stethoscope over the stomach. This is the least reliable method for checking placement of an NG or NE tube. Because the lungs and stomach lie close together, the sounds created by sending air through the tube can easily be transmitted to nearby areas of the body, causing you to err in determining tube placement.
- **Measuring the tube that extends outside of the body.** At the time it is placed, the feeding tube should be marked where it exits the body (e.g., the abdominal wall, the naris). If there is a change in the length of the external portion of the tube, it may have moved out of the original placement site. A consistent measurement may help to verify tube placement (Peter & Gill, 2009).
- **Capnometry** tests for carbon dioxide (CO_2). The presence of CO_2 with the placement of an NG or NE tube would indicate that the tube has been placed in the respiratory tract. This method is not yet in wide use, and is best used only at the time the tube is placed. Figure 27-10 is a CO_2 detector.
- **Measuring bilirubin, trypsin, and pepsin in the aspirate** provides a positive determination that the tube is placed in the stomach. Test devices for these three gastric components are not yet commercially available (Elpern, Killeen, Talla, et al., 2007; Peter & Gill, 2009).

FIGURE 27-10 A carbon dioxide detector for checking feeding tube placement.

No longer recommended: Adding dye to enteral feedings as a method for identifying aspiration of gastric contents is not recommended because it has been associated with several adverse effects, including gastric bacterial colonization, diarrhea, systemic dye absorption, and death (AACCN, 2005b, revise 2009).

Remember, you should not rely on any one of these methods alone. Always use them in combination. For more information and guidelines for checking enteral tube placement,

Go to Chapter 27, **Clinical Insight 27-7: Checking Feeding Tube Placement,** in Volume 2.

KnowledgeCheck 27-11

- When is enteral nutrition the preferred alternative feeding?
- Identify and describe the types of enteral nutrition tubes.
- List four tube placement verification techniques.

Administering Enteral Feedings

In a few institutions, enteral feeding formulas are blended in the kitchen, but most use one of the many commercially prepared products. The type of product selected depends on the patient's health condition. Products vary in nutritional components and caloric concentration (Box 27-8).

Feeding Schedules

Feedings may be delivered on a continuous, cyclic, or intermittent schedule. **Continuous feedings** provide a constant flow of formula and an even distribution of nutrition throughout the day. For example, an infusion of 50 mL/hr for 24 hours of a 1 kcal/mL formula provides 1,200 kcal per day. Continuous infusions are usually administered via small-bore NG, NJ, PEG, or PEJ tubes, or G-buttons, to patients in debilitated states who require intensive nutritional support. Feedings may be interrupted for periodic instillation of medications or flushing with water.

- **Pump-controlled infusions** are recommended for jejunal feedings and for gastrostomy feedings given by continuous infusion to decrease gastroesophageal reflux. A feeding pump ensures a steady flow rate.
- **Gravity feedings** can also be used, but the rate of delivery is not precise, and they increase the risk of gastroesophageal reflux, diarrhea, and aspiration. You regulate the drip rate by adjusting a clamp on the tubing, much the same as adjusting an IV rate.

Cyclic feedings are administered regularly; however, the infusion time is less than 24 hours per day. Nocturnal feedings are a form of cyclic feedings. The patient is able to eat meals and participate in activities throughout the day but receives an infusion of enteral formula at

BOX 27-8 ■ Types of Enteral Feeding Solutions

- ***Basic feeding formulas*** are used for clients who have no significant nutritional deficits but are unable to eat or drink sufficiently. They provide 1 kcal/mL of solution, and meet the needs of most clients. A standard formula contains 12%–20% of kcal from protein, 45%–60% of kcal from carbohydrates, and 30%–40% of kcal from fats. They also contain vitamins and minerals. They are usually lactose free and contain complex forms of carbohydrates, fats, and proteins. Therefore, they require digestion and absorption.
- ***High-protein formulas*** are for clients who have a substantial need for protein, such as those with burns, open wounds, or malnutrition.
- ***Elemental formulas*** do not contain complex proteins; instead, they contain amino acids or peptides. They are reserved for patients with severe small bowel absorptive dysfunction. These formulas are fiber free and highly osmotic. Their use is controversial.
- ***Diabetic formulas*** are for clients who require tube feedings to meet nutritional needs but have type 1 or type 2 diabetes mellitus. These formulas control carbohydrate intake.
- ***Renal formulas*** are for clients who require tube feedings to meet nutritional needs but have renal failure or renal insufficiency as comorbidity. These formulas limit potassium, sodium, and nitrogen intake.
- ***Pulmonary formulas*** provide 55% of the calories as fat so that less CO_2 is produced per unit of oxygen consumed. They are used, for example, for patients with lung disease.
- ***Fiber-containing formulas.*** Because fiber has a potential protective effect for multiple disease states, including diverticulosis, colon cancer, diabetes, and heart disease, fiber-containing formulas may be used for patients in long-term care facilities or patients who require enteral feedings for a prolonged period of time.

night while at rest. Another variant is a 20-hour infusion. A 4-hour break allows time for the feeding pump to be disconnected for hygiene and other activities.

Intermittent feedings are given to supplement oral intake or for patients who want greater mobility to take part in activities, such as physical therapy. Feedings are given on a regular or periodic basis several times a day, usually over 30 to 60 minutes. An example of a prescription for a *regular feeding* is, "Give 250 to 500 mL of enteral nutrition every 4 to 6 hours." *Periodic feedings* are often based on oral intake and are considered to be more physiologically similar to normal eating patterns. Consider the following periodic feeding prescription:

If the client consumes 90% to 100% of the ordered diet, give no additional feeding.
>75% but <90%, give 100 mL of formula after each meal.
>50% but <75%, give 200 mL of formula after each meal.
>25% but <50%, give 300 mL of formula after each meal.
0 to 25% of the ordered diet, give 400 mL of formula.

Intermittent feedings are sometimes given by **bolus**, if the patient can tolerate this method. In this method, you use a syringe to deliver 300 to 400 mL of formula through the tube over a 5- to 10-minute period. This is the easiest method to teach family members for home care, and it frees the patient from mechanical devices that limit activity. But because the fluid is given more rapidly by this method, it increases the risk for respiratory aspiration and for stomach distention. You can use it only with gastric tubes, never with intestinal tubes.

Open and Closed Feeding Systems

An **open system** is exposed to the environment. One example is to open cans of formula and use a syringe to inject the formula into the tube; alternatively, you can pour it into a reservoir (e.g., a plastic bag). You should flush and clean the system after each delivery. Most agencies require that an open-system feeding not hang for more than 4 hours.

A **closed system** is a prefilled system (e.g., a bag or a bottle) that functions much like IV fluid. The nurse spikes the container with tubing that is attached to the feeding pump or run through a manually controlled drip chamber. Closed systems decrease the risk of contamination. A prefilled closed-system container can safely hang for 24 to 48 hours if you use sterile technique. You can measure out the specified amount in the drip chamber, allowing the remainder of the container to be used later in the day.

Monitoring Patients Receiving Enteral Nutrition

For patients receiving enteral nutrition, you will need to monitor tube placement, skin condition, laboratory values (especially blood glucose, BUN, and electrolytes), feeding residual, and GI status. This will allow you to detect complications that affect metabolism or fluid and electrolyte balance and to assess responses to enteral feeding. Feedings may need to be increased or decreased depending on the patient's changing clinical condition. In addition, enteral feeding solutions provide an ideal medium for bacterial growth. For guidelines,

Go to Chapter 27, **Clinical Insight 27-8: Monitoring Patients Receiving Enteral Nutrition,** in Volume 2.

Also,

Go to Chapter 27, **Clinical Insight 27-9: Preventing Infection in Patients Receiving Enteral Feedings,** in Volume 2.

Removing Feeding Tubes

When a patient's condition has stabilized and she no longer requires enteral nutrition, the feeding tube may be removed. A PEG tube is usually clamped if feedings are no longer required. The Highlights of Procedures box summarizes a procedure for removing a feeding tube. For a complete set of steps to follow,

Go to Chapter 27, **Procedure 27-4: Removing a Nasogastric or Nasoenteric Tube,** in Volume 2.

Think**Like a Nurse** 27-8

Your client has dementia and is frequently agitated. She has been progressively losing weight. An interdisciplinary team recommended enteral nutrition due to poor oral intake; however, the client has repeatedly pulled out her NG tube and had an episode of aspiration pneumonia last month. What recommendations might you consider at the next meeting?

Providing Parenteral Nutrition

Parenteral nutrition (PN) is the delivery of nutrition intravenously into a large, central vein. This is the preferred method of feeding for clients who cannot be nourished through the GI tract. Some clients (e.g., those with shortened small bowel secondary to injury or disease) who are able to meet some of their nutritional needs may use PN in addition to some oral intake to meet caloric and nutrient needs. Others, such as clients who are severely malnourished, have extensive burns or trauma, or have conditions that require resting the GI system, are nourished entirely by PN.

PN solutions usually contain a 10% to 70% concentration of dextrose in water (but usually not more than 20%) along with amino acids, and can provide 20 to 30 kcal per kilogram per day, depending on the patient's calculated energy need. Note, though, that the most common concentrations of glucose provide only 200 kcal per liter. PN also contains vitamins, minerals, and trace elements. Standard PN formulas are available at many healthcare facilities; however, PN can be modified to meet individual needs.

The type of venous access device used to administer PN will depend on the components of the PN and the anticipated duration of PN. Because PN solutions

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 27-1: Checking Fingerstick (Capillary) Blood Glucose Levels

- Have the patient wash hands with warm soap and water. Dry well with a clean towel.
- Don procedure gloves.
- Cleanse the patient's finger with soap and water and let it dry thoroughly.
- Prepare the lancet and meter and obtain a clean test strip that is correct for the meter.
- Stick the side of the fingertip.
- Place the drop of blood on the test strip.
- At the indicated time, read the glucose level on the digital display. (Follow the manufacturer's instructions.)

Procedure 27-2: Inserting Nasogastric and Nasoenteric Tubes

- Place the patient in a sitting or high-Fowler's position.
- Measure the length of the tube:

  NG tubes: Measure from the tip of the nose to earlobe and from earlobe to the xiphoid process.

  Nasoenteric tubes: Add 8 to 10 cm (3 to 4 in.) to the NG measurement, as directed.
- Lubricate the tube with a water-soluble lubricant.
- Ask the patient to hyperextend the neck and breathe through the mouth.
- Insert the tube gently through the nostril; advance the tube as the patient swallows.
- Instruct the patient to tilt the head forward, drink water, and swallow.
- Withdraw the tube immediately if respiratory distress occurs during or immediately after insertion.
- Confirm tube placement initially by x-ray. Always reconfirm tube placement with a combination of bedside methods before giving feedings or medicine.
- Secure the tube to the nose and to the patient's gown.

Procedure 27-3: Administering Feedings Through Gastric and Enteric Tubes

- Check the medical prescription for the type of formula, rate, route, and frequency of feeding.
- Confirm that an x-ray of tube placement was performed.
- Confirm tube placement at the bedside before administering the feeding.
- Elevate the head of the bed at least 30° to 45° during the feedings and for an hour after administration.
- For intermittent feedings, check gastric residual volume before feeding.

  For continuous feeding: Check at least once every shift. If the residual is not within normal limits, hold the feeding and recheck in 1 hour. If still not within normal limits, notify the physician.

  For gastrostomy and PEG tubes and gastrostomy buttons (G-buttons): Check residual volume every 4 hours.

  For jejunostomy tubes: Residual volumes are not checked.
- Flush tubing with 30 mL of water before and after feeding (every 4 hours for continuous feedings), and before and after medication administration.
- Change the tube feeding administration set and other supplies a minimum of every 24 hours.
- Continuous feedings should be infused by pump.

Procedure 27-4: Removing a Nasogastric or Nasoenteric Tube

- Verify the primary provider's prescription for removal of the tube.
- Assist the patient to a sitting or high-Fowler's position.
- Inject 10 mL of air through the main lumen to clear the tube of secretions.
- Ask the patient to hold his breath, and gently, but quickly, withdraw the tube.
- Discard the equipment.
- Provide or assist with care of nose and mouth.

Procedure 27-5: Administering Parenteral Nutrition

- Perform pre-procedure assessments: Check patient record (e.g., to confirm CVC tip placement), check blood glucose, and assess patency of the line.
- Position the patient supine.
- Examine the PN solution for leaks, cloudiness, and particles. If the solution contains lipids, also look for a brown layer, oil droplets, or oil on the surface. Have a coworker verify.
- Identify the patient, using two identifiers; have a coworker verify.
- Compare the bag with the patient's ID band and with the original prescription.
- Observe meticulous sterile technique in the appropriate steps of the procedure. During all steps, observe careful aseptic (clean) technique. Or follow agency policy.
- Use a filter.
- Attach the new administration set to the new bag.
- Prime the tubing (either now or after placing in the pump).

Highlights of Procedures 27-1 through 27-6

- Place the tubing in the infusion pump; set the rate.
- Clamp the catheter and the old administration set.
- Remove gloves, perform hand hygiene, and don clean gloves.
- Observe meticulous sterile technique in the appropriate steps of the procedure. During all steps, observe careful aseptic (clean) technique.
- Scrub all surfaces of the needleless connector and luer-locking threads with an antiseptic pad.
- Determine patency of the IV line.
- Trace the tubing back to the patient, attach the new infusion tubing to the designated PN lumen (usually the largest one), and secure the luer-lock connection.
- Start the infusion.
- Label tubing.

Procedure 27-6: Administering Lipids

- Lipids require a special administration set.
- Position the patient supine.
- Be certain lipids are not cold.
- Examine the bottle for a layer of froth or separation into fat globules or layers.
- Complete the infusion within 20 hours.
- Use new tubing for each bottle of lipids.
- If infusing simultaneously with PN, use a separate port below the PN filter.
- Take vital signs before infusing, then every 10 minutes for 30 minutes, and observe for side effects.
- Begin the infusion slowly. If no reactions occur after 30 minutes, adjust to the prescribed rate.

are hypertonic, they should be administered in a large, high-flow vein through a central venous access catheter. The subclavian vein has been the site of choice; however, the jugular vein is preferred for tunneled catheters and implanted ports. Peripherally inserted central catheter (PICC) lines are also used for PN.

All PN catheters must have chest x-ray confirmation that the tip is in the lower portion of the superior vena cava adjacent to the right atrium (see Fig. 27-11) before beginning the first infusion.

High blood flow through the superior vena cava causes rapid dilution of the concentrated PN and thereby prevents vessel damage. Some types of PN solutions may be infused via a peripheral vein, but this is not usual.

Lipid emulsions contain essential fatty acids, triglycerides, and supplemental kcal. They are administered weekly for patients who rely on PN to prevent essential fatty acid deficiency. They also add calories to the PN mixture so that lower glucose concentrations can be used, thus reducing the risk of glucose fluctuations. Most IV fats are supplied by safflower or soybean oil. They provide 1.1 to 3 kcal/mL.

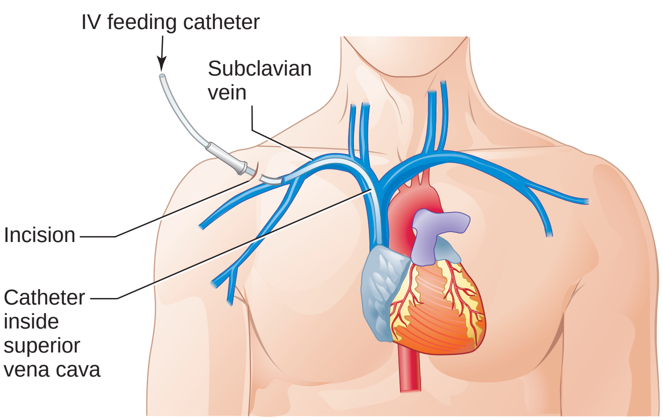

FIGURE 27-11 The subclavian vein is the site of choice for parenteral nutrition.

You may administer lipids at the same time as the PN, through a peripheral line or by Y-connector tubing through a central line. Lipids are also sometimes added to the PN solution (this is called a 3-in-1 admixture), and administered over a 24-hour period. The Highlights of Procedures box summarizes procedures for administering parenteral nutrition and lipid emulsions. For the complete procedures,

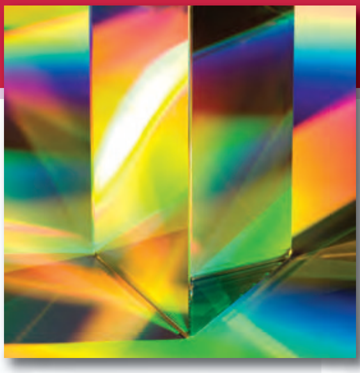
CHAPTER 28



Urinary Elimination

Learning Outcomes

After completing this chapter, you should be able to:

- Describe the normal structure and function of the organs in the urinary system.
- Describe the processes of urine formation and elimination.
- Discuss factors that affect urinary elimination.
- Describe the contents of a nursing assessment and physical examination focused on urinary elimination.
- Accurately measure urine output.
- Describe procedures for collecting various types of urine specimens.
- Describe diagnostic tests used in identification of urinary elimination problems.
- Discuss common elimination problems: urinary tract infection, urinary retention, and urinary incontinence.
- Identify nursing diagnoses associated with altered urinary elimination.
- Describe nursing interventions that promote normal urination.
- Provide care for clients experiencing urinary problems.
- Perform urinary catheterizations following accepted procedures.
- Discuss nursing care appropriate for clients who have a urinary diversion.

Key Concepts

Urinary elimination

See the Concept Map on Davis*Plus*.

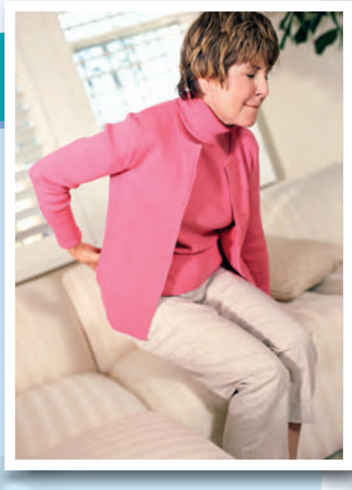
Example Problems

Urinary incontinence

Urinary retention

Urinary tract infections

Meet Your Patient



During your assigned clinical experience at University Hospital, the registered nurse (RN) asks you to complete the admission process for Marlena, a 55-year-old woman who is complaining of frequent, painful urination. As you interview her, Marlena becomes embarrassed. "I really don't enjoy talking about this," she admits. When she asks to use the bathroom, you ask her to give you a midstream clean-catch urine sample. She returns with a small specimen of pink-colored, strong-smelling urine. "I have a strong urge to go and then I hardly have any urine. It burns like crazy during my stream," she reports.

You close the door and interview Marlena in private about her usual urination pattern and current symptoms. Your calm approach and straightforward manner put her at ease. She confides that she is sexually active and that her symptoms began after spending the weekend with her new partner. You take her vital signs: oral temperature, 99.4°F (37.4°C); radial pulse, 88 beats/min; respiratory rate, 20 breaths/min; and blood pressure, 108/72 mm Hg.

The emergency department (ED) physician asks you to perform a dipstick urinalysis on the urine sample and to send the urine sample to the lab for culture and sensitivity. He says: "Well, what do you think we need to do next?" How would you answer his question?

As you gain theoretical and practical knowledge in this chapter, we will return to this case study to discuss how you might answer the physician's question and support Marlena's recovery. You will also have the opportunity to examine your feelings about giving care that patients may regard as personal or even embarrassing.

ABOUT THE KEY CONCEPTS

The key concept of **urinary elimination** is important because many of your nursing activities focus on promoting normal elimination. Your understanding of urine formation and elimination will help you will help you to choose and provide the best independent and collaborative interventions for patients with urinary elimination problems.

TheoreticalKnowledge knowing **why**

A variety of factors, including personal hygiene, age, nutrition, stress, sexual activity, and medications, play a role in urinary health. That's why it is vitally important that you take a holistic approach to patients who have altered urinary elimination patterns.

HOW DOES THE URINARY SYSTEM WORK?

The body removes from food and fluids the nutrients necessary for essential bodily functions, such as physical activity, self-repair, and mental operations. Waste products are left in the blood and in the bowel. The organs of the urinary system that help to excrete wastes and maintain a balance of chemicals and water in the body include the kidneys, ureters, bladder, and urethra (Fig. 28-1).

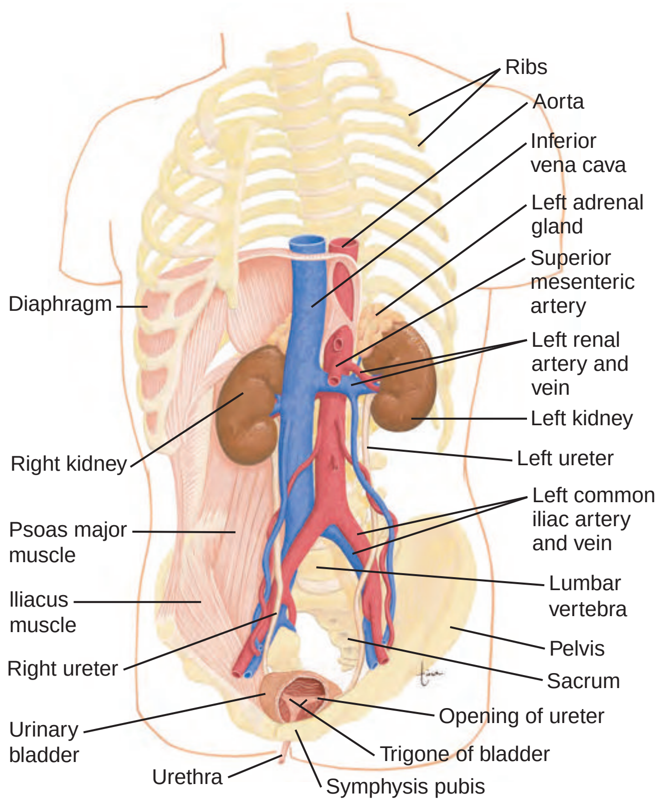


FIGURE 28-1 The organs of the urinary system include the kidneys, ureters, bladder, and urethra.

The Kidneys Filter and Regulate

The kidneys filter metabolic wastes, toxins, excess ions, and water from the bloodstream and excrete them as urine. If kidney function is impaired, these substances reach toxic levels and damage body cells. The kidneys also help to regulate blood volume, blood pressure, electrolyte levels, and acid–base balance by selectively reabsorbing water and other substances. Secondary functions of the kidneys are to produce erythropoietin, secrete the enzyme renin, and activate vitamin D_3 (calcitriol). The kidneys are located against the posterior abdominal wall behind the peritoneum (they are **retroperitoneal**). The average kidney weighs about 5 ounces and is the shape of a kidney bean (see Fig. 28-1).

The outer layer, or **cortex**, of the kidney is composed of millions of microscopic functional units, called *nephrons* (Fig. 28-2). The inner layer, or **medulla**, consists of 8 to 10 wedge-shaped cones, called the *renal pyramids*. The renal pyramids are made up of bundles of collecting tubules. The innermost area is the **renal pelvis**. Funnel-shaped extensions known as **calyces** (singular: **calyx**) enclose the central portion of each renal pyramid and direct urine into the renal pelvis.

The Nephrons Form Urine

The **nephron** is the basic structural and functional unit of the kidney (see Fig. 28-2). There are about 1 million nephrons in each kidney. Each nephron consists of:

- A double-walled hollow capsule, the **Bowman's capsule**, enclosing a **glomerulus**, a knotty ball of capillaries
- A series of filtrating tubules
- A collecting duct

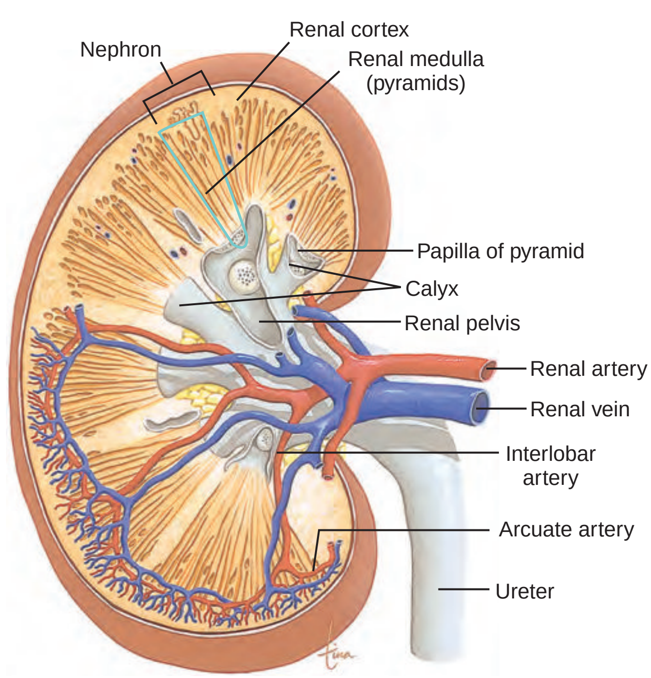

FIGURE 28-2 A cross section of the kidney, showing the renal cortex, medulla, pyramids, and calyces.

Together, these structures act as a microscopic filter, controlling the excretion and retention of fluids and solutes according to the body's moment-by-moment needs. Urine is formed by filtration, reabsorption, and secretion, as discussed next.

For a detailed view of a nephron,

Go to Chapter 28, **Tables, Boxes, Figures: ESG Figure 28-1,** on Davis*Plus*.

Glomerular Filtration

Figure 28-3 summarizes the process of urine formation. The first step, **filtration**, occurs in the glomeruli. The renal arteries bring blood to the kidneys and into the glomeruli. Blood pressure forces plasma, dissolved substances, and small proteins out of the porous glomeruli into Bowman's capsule to form a liquid called **filtrate**. The **glomerular filtration rate** is the amount of filtrate formed by the kidneys per minute. Unless the glomerular capillaries are inflamed or damaged, large molecules, such as blood cells and blood proteins, are too large to filter across their walls. Glomerular filtrate resembles blood plasma, except that it contains much less protein and no blood cells.

Renal blood flow progressively decreases with aging, primarily because of changes to the micro blood vessels to the kidney. This decline in glomerular filtration is the most important functional deficit caused by aging (Besdine, 2013).

To see an animated explanation of the processes of osmosis, diffusion, filtration, and active transport,

Go to **Animations: Osmosis, Diffusion, Filtration, and Active Transport,** on Davis*Plus*.

Tubular Reabsorption

The filtrate moves from Bowman's capsule into a highly twisted tubule (*proximal convoluted tubule*, Fig. 28-3). As the filtrate journeys through the tubule, 99% is reabsorbed into the peritubular capillaries. Approximately 1% of filtrate returns, as urine, to the *collecting tubule*, which transports it into the ureters. Wastes and toxins that remain in the blood after filtration are actively transported into the filtrate (reabsorbed) in the *distal* and *collecting tubules*. Water and sodium are reabsorbed in these structures when antidiuretic hormone (ADH) and aldosterone are secreted. For an animated explanation of urine formation and elimination,

Go to **Animations: Formation and Elimination of Urine,** on Davis*Plus*.

When the amount of fluid in the body decreases (e.g., because of low intake or blood loss), the posterior pituitary gland secretes more ADH. This causes the distal and collecting tubules to reabsorb more water into the blood. At the same time, the adrenal cortex secretes more aldosterone, which increases the reabsorption of sodium, and water follows sodium back

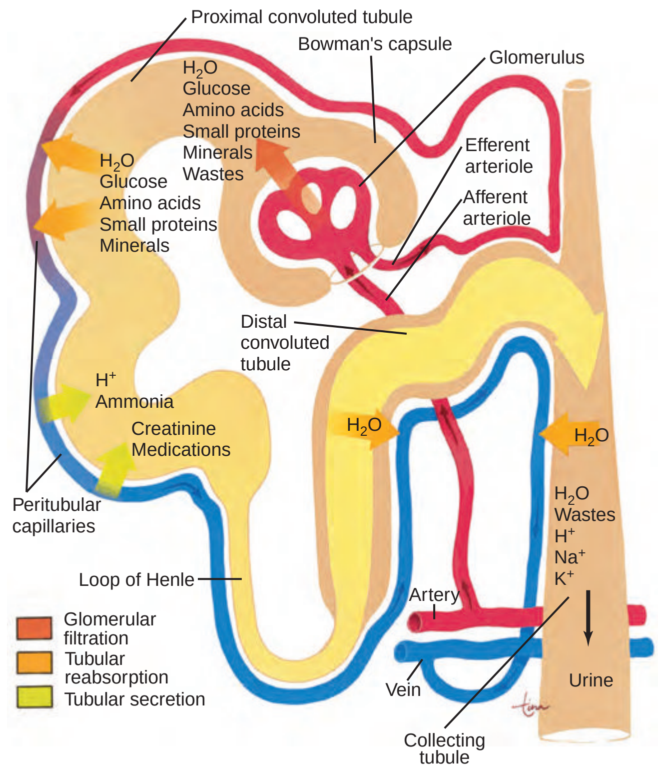

FIGURE 28-3 A schematic representation of the formation of urine.

into the blood. ADH and aldosterone thus have the effect of maintaining normal blood volume and blood pressure.

When the amount of water in the body increases (e.g., as in ingestion of excessive fluids), ADH is suppressed and the opposite effect occurs. Urine becomes dilute and water continues to be eliminated until its concentration returns to normal (Scanlon & Sanders, 2011).

Tubular Secretion

Some substances are actively secreted from the blood in the peritubular capillaries into the renal filtrate. For example, metabolic waste products, such as ammonia and creatinine, and some medications are secreted into the filtrate and then eliminated in urine. In addition, the kidneys help maintain the normal pH of blood by secreting hydrogen ions (H^+).

Think**Like a Nurse** 28-1

If a client is suffering from impaired kidney function, what signs and symptoms might you expect to see?

The Ureters Transport Urine

The remaining organs of the urinary system transport or store the urine once it is formed. From the collecting tubules, urine travels into the renal pelvis and enters the ureter. Each kidney has one ureter, approximately 26 to 30 cm (10 to 12 in.) long and 1.25 cm (0.5 in.) in diameter (see Fig. 28-1). The ureters contract in peristaltic waves to move urine toward the bladder. At the opening between the ureter and the bladder is a flap of mucous membrane that acts as a one-way valve, allowing urine to enter the bladder but preventing backflow (**reflux**) into the ureter.

The Urinary Bladder Stores Urine

The urinary bladder (see Fig. 28-1) is a sac-like organ that receives urine from the ureters and stores it until discharged from the body. The wall of the bladder consists of four layers:

- An innermost mucous membrane seals off the remaining layers from exposure to urine.
- A layer of connective tissue supports the mucous membrane.
- Three layers of longitudinal and circular smooth muscle fibers are collectively called the **detrusor muscle**.
- An outermost layer of fibrous connective tissue covers the detrusor layer.

When the bladder is empty, it shrivels and its elastic wall becomes heavily folded. As it receives newly formed urine, it expands and the wall becomes smooth. An average, normal bladder can store 500 mL (1 pint) of urine, but it may distend when needed to a capacity twice that amount. You cannot palpate an empty bladder, but a full or distended bladder extends upward to form a pear shape that you can feel in the suprapubic region.

The Urethra Transports Urine

The urethra transports urine from the bladder to the body's exterior. In women, the urethra is about 3 to 4 cm (1.5 in.) long and is anchored to the anterior wall of the vagina by connective tissue; it opens at the **urinary meatus** between the clitoris and vaginal opening. Because the female urethra is so short, women are especially prone to urinary tract infection from microorganisms residing in the vagina and rectum. In men, the urethra extends about 20 cm (8 in.) from the bladder to the urinary meatus at the distal end of the penis. As it leaves the bladder, the male urethra passes through a surrounding gland known as the **prostate**. In addition to urine, the male urethra also carries semen.

The mucous membrane of the urethra (in both men and women) is continuous with the bladder and the ureters. Therefore, infection in the urethra can easily spread through the bladder and up into the kidneys.

KnowledgeCheck 28-1

- Identify the major structures of the urinary system.
- What are the functions of the kidneys?
- Briefly describe how urine is formed.
- What role do the ureters, bladder, and urethra play in urinary elimination?

HOW DOES URINARY ELIMINATION OCCUR?

Where the bladder connects to the urethra is a thickening of smooth muscle, called the **internal urethral sphincter**. When closed, the internal sphincter keeps urine in the bladder from entering the urethra. When the bladder contains 200 to 450 mL of urine (50 to 200 mL in children), the distention activates stretch receptors in the bladder wall. The stretch receptors send sensory impulses to the *voiding reflex center* in the spinal cord, triggering motor impulses that cause the detrusor muscle to contract and the internal sphincter to relax. The internal urethral sphincter is not under voluntary control.

Voiding (also called **urination** or **micturition**) occurs when contraction of the detrusor muscle pushes stored urine through the relaxed internal urethral sphincter into the urethra. This triggers the conscious urge to void. However, voiding may be voluntarily delayed by inhibiting release of a second, **external urethral sphincter**. When the person is ready to urinate, the brain signals the external sphincter to relax, and urine flows through the urethra. Further contraction of the detrusor muscle normally forces out any urine remaining in the bladder. After the detrusor muscle relaxes, the bladder begins to fill with urine again.

As you can see, voiding and control of urination require that, in addition to normal functioning of the bladder and urethra, the brain, spinal cord, and nerves supplying the bladder and urethra be intact. The person must be aware of the need to urinate and able to respond by either inhibiting the reflex or by emptying the bladder.

Normal Urination Patterns

The kidneys produce urine at a rate of about 50 to 60 mL per hour, or 1,500 mL per day. However, output may fluctuate by 1,000 mL to 2,000 mL depending on various factors discussed in the next section. Most people void about five or six times per day, even eight times is normal—typically after awakening, after each meal, and just before bedtime. When fluid intake is increased, urination will be more frequent. Sometimes frequent urination is a sign of other medical problems, such as diabetes or urinary tract infection.

Characteristics of Normal Urine

Specific gravity is a measure of dissolved solutes in a solution. As the concentration of the urine solutes increases, specific gravity increases. The specific gravity of distilled water is 1.000 because there are no dissolved solutes. The normal specific gravity range for urine is 1.002 to 1.030. A very low specific gravity (e.g., 1.001) may indicate the kidney is ineffective in concentrating urine; a high specific gravity (e.g., 1.029) means the person is dehydrated. As fluid intake increases, urine becomes dilute and lighter in color to almost clear as it approaches a specific gravity of 1.000. In contrast, if fluid intake is low or there have been fluid losses, as with diarrhea or vomiting, the urine darkens as the specific gravity rises. Characteristics of urine are discussed in depth later in this chapter. Also,

ThinkLike a Nurse 28-2

- How does Marlena's (Meet Your Patient) urinary elimination pattern differ from normal?
- What would you expect to find if you measured her specific gravity?
- Marlena's symptoms suggest a urinary tract infection. How might this be related to the fact that she is sexually active?

WHAT FACTORS AFFECT URINARY ELIMINATION?

Given the complex structure and physiology of the urinary organs, it isn't surprising that many of the following variables affect their function.

Developmental Factors: Infants and Children

A newborn's kidneys produce 15 to 60 mL of urine per kilogram of body weight per day. Newborns do not concentrate urine well and, therefore, may void up to 25 times during the first 24 hours of life. The normal specific gravity of their urine is 1.008. Over the first weeks of life, the urine gradually becomes more concentrated, and the well-hydrated infant produces eight to ten wet diapers a day. Infants do not have voluntary control of voiding because neuromuscular functioning is immature.

The timing of toilet training is highly variable and is influenced by family and culture (e.g., the presence of older children who can act as role models). In the United States, most parents begin toilet training when their child is between 18 and 36 months of age. This timing can vary widely. Before toilet training can occur, toddlers must be able to control the external urethral sphincter, sense the urge to void, communicate their need to use the toilet, and remove their clothing. Toddlers usually stay dry in the daytime before they can go without a diaper all night. Occasional wetting (**enuresis**) is entirely normal in children, even in the early school years, especially when the child is intensely involved in a game, test, or other absorbing activity. Such events should be accepted calmly and not punished.

Nocturnal enuresis, or nighttime bedwetting, occurs in approximately 5% to 10% of 5-year-old children, 1.5% to 5% of 9- and 10-year-olds, and 1% of those aged 15 years and older. Males have higher prevalence rates than females at all age points (Brown, Pope, & Brown, 2011). **Primary nocturnal enuresis** is bedwetting in a child who has not achieved consistent dryness at night. **Secondary enuresis** occurs in a child who has had at least 6 months of nighttime dryness.

Developmental Factors: Older Adults

The size and functioning of the kidneys begin to decrease at about age 50, and by age 80 only about two-thirds of the functioning nephrons remain. This results in a decline in filtration rate, which affects the ability to dilute and concentrate urine, but does not normally create problems unless an illness alters fluid balance. For example, when older adults lose fluids and electrolytes through vomiting and diarrhea, it is difficult for their kidneys to maintain acid–base and electrolyte balances. Chronic diseases such as arteriosclerosis, common in older adults, can reduce blood flow and impair renal function. Decreased kidney function places older adults at risk for drug toxicity, as well.

The potential volume of the bladder decreases because of a loss of elasticity in the bladder wall; thus, older adults need to urinate more frequently, especially during the night (**nocturnal frequency**). Loss of elasticity and muscle tone also decreases the ability of the bladder to empty completely. Retention of urine after voiding then increases the risk for bladder infections. In women, childbearing may have weakened the pelvic muscles, which can lead to leakage of urine. In older men, the prostate gland may be enlarged, causing urinary frequency and hesitancy. Most older men have some degree of difficulty starting urination or reduced force of the urinary stream, and may experience dribbling.

Personal, Sociocultural, and Environmental Factors

Many people put off voiding while they are working, watching TV, or busy with other tasks. Delaying urination promotes urinary stasis and can lead to bladder infections. Other situations can inhibit voiding, as well, such as the following:

- *Anxiety*. A person who is anxious and tense cannot relax the abdominal and perineal muscles and the external urethral sphincter. It is then difficult to void.
- *Lack of Time*. Most people find it difficult to void when they feel rushed; therefore, when helping patients to void, make sure you have scheduled enough time for them to relax fully.
- *Lack of Privacy*. Many people require privacy for voiding and if they are in a restaurant or other unfamiliar environment, they may be embarrassed even to ask for directions to a bathroom. Some hospitalized clients may also avoid asking for assistance to the bathroom.

- *Loss of Dignity.* In Chapter 11, we talked about the loss of dignity that hospitalized patients experience. Patients who need assistance with toileting may be especially vulnerable to such feelings, especially if they require catheterization or a bedpan. It is important, therefore, to acknowledge such feelings and encourage the patient to participate in other aspects of self-care, such as bathing and dressing.
- *Cultural Influences.* Some patients will state personal, cultural, or religious requirements for toileting assistance to be provided by a person of the same gender, or they will wait until a visit from a family member before acknowledging their need for help with voiding.

Nutrition, Hydration, and Activity Level

Substances that contain caffeine, such as coffee, tea, cola, and chocolate, act as diuretics and increase urine production. Consuming large amounts of alcohol impairs the release of ADH, resulting in increased production of urine. In contrast, a diet high in salt causes water retention and decreases urine production.

The kidneys also conserve water when a person is dehydrated, such as after heavy exercise or when fluid intake is inadequate. This causes the urine to be concentrated and low in volume. During prolonged periods of physical activity, especially in hot weather, the body loses sodium and other electrolytes rapidly through sweat; for this reason, electrolyte replacement beverages may be more beneficial than plain water in helping to prevent dehydration for prolonged or vigorous-intensity activity (Thompson & Manore, 2012). For most adults, pale to clear urine indicates adequate hydration.

KnowledgeCheck 28-2

- What quantity of urine in the bladder will stimulate the urge to void?
- Identify at least three methods for determining whether hydration is adequate and urine output is within normal limits.

Medications

Various medications affect urination. Phenazopyridine hydrochloride (Pyridium), a bladder analgesic, turns the urine a deep orange-red color. *Diuretics*, sometimes called "water pills," treat blood pressure, fluid retention, and edema by increasing elimination of urine. Diuretics are classified as thiazide, potassium-sparing, or loop-acting diuretics (Box 28-1). In contrast, a number of medications have a side effect of urinary retention. They inhibit the free flow of urine because of *anticholinergic effects* (e.g., medications relax smooth muscle). See Box 28-2 for a listing of the most common medications associated with urinary retention.

Still other medications are **nephrotoxic** (damaging to the kidneys). These include some antibiotics, such as gentamicin (Garamycin) and amphotericin B (Amphotec, a fungicide), and high doses or long-term use of aspirin and ibuprofen.

BOX 28-1 ■ Common Diuretic Classes

Thiazide diuretics are used to treat high blood pressure by reducing the amount of sodium and water in the body. They also dilate blood vessels, thereby lowering blood pressure.

Potassium-sparing diuretics reduce the amount of water in the body. Unlike other diuretic medicines, these medicines do not cause potassium loss.

Loop-acting diuretics cause the kidneys to excrete more urine by reabsorbing less water. This reduces the amount of water in the body and lowers blood pressure.

Medications that have significant interactions with diuretics include digoxin, antihypertensives, lithium, certain antidepressants (especially when taking thiazide or loop-acting diuretics), and the immunosuppressant cyclosporine, especially when the patient is taking a potassium-sparing diuretic.

Common side effects of diuretics include weakness, muscle cramps, skin rash, increased sensitivity to sunlight (with thiazide diuretics), dizziness, lightheadedness, joint pain.

The following medications are sometimes used to treat various bladder conditions.

- **Anticholinergics** inhibit involuntary contractions of the bladder, increase capacity of the bladder, and delay the urge to void for people with urge incontinence. They may be given orally or transdermally. Transdermal medications are used to treat urge incontinence caused by overactive bladder. The patch relieves symptoms up to 4 days.
- **Antidepressants** (e.g., duloxetine or imipramine) can reduce stress incontinence by causing bladder muscles to relax. Some drugs work by stimulating the nerve that controls the urethral sphincter.
- **Antispasmodics** help to relax the bladder and prevent urge incontinence. For example, propantheline bromide (Pro-Banthine) is prescribed to stop bladder muscle contractions (overactive bladder).
- **Muscarinic receptor antagonists** (e.g., tolterodine tartrate) block nerve receptors in the smooth muscle of the bladder. These medications control bladder contraction and reduce urinary frequency for people suffering from overactive bladder and urge incontinence.
- **Estrogen** is used to improve the blood flow to the urethral tissues and increase thickness of mucosal and urethral tissues. Estrogen is not FDA-approved for treatment of stress incontinence, although may be prescribed for other reasons.
- **Botulinum toxin** injections control spasms of overactive bladder by relaxing the muscles. It has FDA approval for use in overactive bladder related to nerve damage, such as with spinal cord injury or multiple sclerosis.

Surgery and Anesthesia

Reproductive and Urinary Tract Surgeries can affect urine solutes, urine characteristics, and the ability to pass urine normally. Manipulation of the urinary tract frequently leads to trauma, bleeding, or the introduction of bacteria into a normally sterile tract. Swelling after diagnostic or invasive procedures and childbirth may cause urinary retention.

Surgery in the Pubic Area, Vagina, or Rectum is associated with a high incidence of trauma to the urinary organs, lower abdominal swelling, loss of pelvic muscle control, and increased pressure on the kidneys, ureters, or bladder. Surgery on the reproductive organs, such as hysterectomy in women or transurethral resection of the prostate in men, usually requires the use of an indwelling catheter (tube) for draining the bladder postoperatively. The urine may be red or pink-tinged after any invasive urinary tract surgery or procedure.

Anesthetic Agents can decrease blood pressure and glomerular filtration, thus decreasing urine formation. Spinal anesthesia decreases the patient's awareness of the need to void, which may lead to bladder distention.

Pathological Conditions

Disorders of the urinary system that affect urinary elimination include the following:

- *Infection or inflammation* of the bladder, ureters, or kidneys
- **Renal calculi** (kidney stones) or tumors, which obstruct the normal flow of urine
- In older men, **hypertrophy** (excessive growth) of the prostate gland due to benign or cancerous lesions, which interferes with flow of urine from the bladder into the urethra

Diseases involving other systems can indirectly affect urinary function. For example:

- *Cardiovascular and metabolic disorders* decrease blood flow through the glomeruli and thus impair filtration and urine production.
- *Nervous system* conditions that affect control of the urinary system organs will impair urinary elimination. After a stroke or spinal cord injury, for example, some patients may lose bladder control. ***Neurogenic bladder*** occurs as a result of impaired neurological function. The person cannot perceive bladder fullness or control the urinary sphincters. The bladder becomes flaccid or spastic, causing frequent involuntary loss of urine.
- *Systemic infection*, especially when accompanied by a high fever, causes the kidneys to reabsorb and retain water.
- *Immobility and impaired communication* may interfere with the ability to get to the bathroom in time or to communicate the need for assistance. This may result in urination in inappropriate settings or at inappropriate times.
- *Cognitive changes* that alter perception of the urge to void or severe psychiatric conditions involving altered perception or ability to manage activities of daily living may lead to **incontinence**, which is involuntary loss of urine.

KnowledgeCheck 28-3

- What common medications increase the amount of urine voided?
- What types of medications are associated with urinary retention?
- What types of conditions or surgeries are associated with a high incidence of altered urination?

Example Problem: Urinary Tract Infections

Normally urine is free of bacteria, viruses, and fungi. A urinary tract infection (UTI) occurs when microorganisms, usually *Escherichia coli*, which usually live harmlessly in the colon, enter the urethra and begin to multiply, overwhelming the normal flora. An infection limited to the urethra is called **urethritis**. **Cystitis** occurs when bacteria travel up the urethra into the bladder, causing a bladder infection. If not treated promptly, the infection may progress superiorly (upward) to the ureters or kidneys (**pyelonephritis**).

Several biological safeguards are in place in the urinary system to prevent UTIs. One-way valves at the junction of the ureters and bladder help prevent urine from backing up toward the kidneys. In addition, the flow of urine during urination helps wash bacteria out of the body. In men, the prostate gland produces secretions that slow bacterial growth. But despite these safeguards, infections still occur.

Risk Factors for Urinary Tract Infection

People who are more prone to UTIs include the following:

- *Sexually active women.* During sexual activity, perineal pathogens may enter the urethra. Because a woman's urethra is short, pathogens, particularly *E. coli,* can gain rapid access to the bladder.
- *Women who use spermicidal contraceptive gel.* Spermicides reduce normal flora in the vagina, allowing pathogens to multiply unrestricted.
- *Pregnant women.* Some pregnant women are more prone to UTI because of hormonal changes and because of pressure of the uterus on the bladder.
- *Older women.* The loss of estrogen associated with menopause leads to drying of the mucosa in the vagina and urethra and a decrease in protective normal flora.
- *Men with an enlarged prostate.* An enlarged prostate may develop as a result of aging or cancerous changes. Pressure from the prostate creates difficulty emptying the bladder, resulting in stagnant urine, which provides an excellent medium for the growth of bacteria.

- *People with kidney stones.* Kidney stones (*renal calculi*) obstruct the flow of urine, creating stagnation, and irritate the urinary tract as they are passed.
- *Anyone who has an indwelling catheter.* Indwelling catheters pose several risks:
  Failing to maintain a closed drainage system increases the risk for infection by allowing bacteria to enter the catheter; the catheter provides a pathway for bacteria to migrate up into the urinary system (Chenoweth, Gould, & Saint, 2014; Gould, Umscheid, Agarwal, et al., 2009; Wald, Fink, Makic, et al., 2012).
  The catheter irritates the mucosal lining of the urethra, which then creates a portal of entry for microbes. The longer the catheter is indwelling, the higher is the risk of developing UTI (Bernard, Hunter, & Moore, 2012).
  The urine collection bag is a reservoir for microorganisms.
- *People who have diabetes mellitus*. Glucose in the urine provides nutrients for bacteria to multiply.
- *Immunocompromised patients*. Susceptible hosts (e.g., neonates, elderly, those receiving immunosuppressive drugs, people with weakened immune systems) are less able to maintain a healthy balance of microbes in the urinary tract.
- *People who have a history of UTIs.* Anyone with a previous UTI is more likely to experience a recurrence. This may be related to the absence of certain antigens against bacteria that attach to the lining of the urethra (National Kidney and Urologic Diseases Information Clearinghouse, 2011).

Recognizing and Treating Urinary Tract Infections

The presence of bacteria in a symptomatic patient is used in the medical diagnosis of UTI. To assist in the diagnosis of UTI, assess for the signs and symptoms.

Back pain	Foul-smelling urine
Bladder spasms	Hematuria
Chills	Nausea and vomiting
Dysuria	Pyuria
Edema	Urgency
Fever	Urinary frequency

Key Point: ***The classic signs of UTI are urinary WBCs, pyuria, dysuria, urgency, and frequency.***

Signs of fever, bacteriuria, and abnormal blood values do not predict catheter-associated urinary tract infections (CAUTI) (Madigan & Neff, 2003) and UTIs in older adults (Rowe & Juthani-Mehta, 2014). Catheter-associated UTIs are generally assumed to be benign. Such infection in otherwise healthy patients is often asymptomatic and is likely to resolve spontaneously with the removal of the catheter (Hooton, Bradley, Cardenas, et al., 2010). Occasionally, infection persists and leads to such complications as prostatitis, epididymitis, cystitis, pyelonephritis, and gram-negative bacteremia, particularly in high risk patients (Grabe, Bjerklund-Johansen, Botto, et al., 2013; Parker, Callan, Harwood, et al., 2009a, 2009b).

Antibiotics are used to treat UTI. The length and type of treatment depends on the location and severity of infection. In general, a bladder infection may be treated with oral antibiotics for 1 to 5 days.

Elderly people and those with chronic underlying illness, such as diabetes, are often prescribed a longer course of treatment, sometimes up to 14 days.

In contrast, pyelonephritis (kidney infection) may require IV antibiotics for several days followed by a course of oral antibiotics. Preventive antibiotic treatment is not recommended for people requiring long-term urinary catheterization (Hooton, Bradley, Cardenas, et al., 2010; Grabe, Bjerklund-Johansen, Botto, et al., 2013; Lo, Nicolle, Classen, et al., 2008; Wound, Ostomy, and Continence Nurses Society [WOCN], 2008). Drug resistance develops easily; therefore, antibiotics are reserved for symptomatic infections (Muzzi-Bjornson & Macera, 2011).

ThinkLike a Nurse 28-3

As you may have concluded, Marlena (Meet Your Patient) has a UTI. What additional history questions would you like to ask Marlena?

Example Problem: Urinary Retention

Urinary retention is an inability to empty the bladder completely. Etiologies include obstruction, inflammation and swelling, neurological problems, medications, and anxiety.

Obstruction Among men, an enlarged prostate is the most common cause of obstruction in the lower urinary tract. Other obstructions include stones lodged in the urethra, strictures or scars from previous injury, tumors or blood clots in the urinary system, and fecal impaction. Impacted stool distends the rectum and causes forward pressure on the urethra, interfering with the flow of urine out of the bladder.

Inflammation and Swelling Obstruction may also occur as a result of inflammation and swelling, for example, from infection or surgery in the pelvic region. Swelling narrows the diameter of the urethra so that urine cannot flow freely.

Neurological Problems Recall that voiding requires that the brain, spinal cord, and nerves supplying the bladder and urethra must be intact. Conditions that affect innervation of the bladder include spinal cord tumors or injury, herniated disk, and viral infections involving perineal nerves (e.g., genital herpes).

Medications Anesthesia and other medications can also cause temporary problems with urination. Box 28-2 provides examples of medications with anticholinergic or alpha-adrenergic effects that may impede urine flow.

BOX 28-2 ■ Medications Associated With Urinary Retention

Class	Use	Medication
Antihistamine	Treat allergy symptoms	fexofenadine (Allegra) diphenhydramine (Benadryl) chlorpheniramine (Chlor-Trimeton) cetirizine (Zyrtec)
Anticholinergics/antispasmodics	Treat stomach cramps, muscle spasms, and urinary incontinence	hyoscyamine (Levbid, Cystospaz, Gastrosed) oxybutynin (Ditropan, Oxytrol) tolterodine (Detrol) propantheline (Pro-Banthine)
Tricyclic antidepressants	Treat anxiety and depression	imipramine (Tofranil) amitriptyline (Elavil) nortriptyline (Aventyl)

Source: National Kidney and Urologic Diseases Information Clearinghouse. (2007, updated June 29, 2012). *Retention.* NIH Publication No. 08-6089. Retrieved December 10, 2013, from http://kidney.niddk.nih.gov/kudiseases/pubs/UrinaryRetention/

Anxiety Painful urination may produce anxiety and lead to voluntary withholding of urination.

Example Problem Urinary Incontinence

Urinary incontinence (UI) is a lack of voluntary control over urination. Urinary incontinence will affect at least 1 in 4 women and 1 in 9 men at some point in their lives.

Incidence rises with age, with as many as 30% to 50% of elderly women being affected (Rainsbury, Fabricius, & McLarty, 2011). Incontinence is associated with skin impairment, obesity, UTIs, self-rated poor health, reduced mobility, depression, social isolation, and increased caregiver burden (Dowling-Castronovo, 2013).

The total number of people affected by incontinence is presumed to be greater than current estimates because healthcare providers often fail to ask specific questions about it or people are embarrassed to admit to experiencing leakage of urine. Incontinence affects people of all ages and social and economic levels. It affects both sexes, but women are twice as likely as men to have this condition. Risk factors for incontinence also include older age, neurological disease (e.g., stroke), obesity, sedentary lifestyle, depression, and diabetes.

Although incontinence is common, it is not a normal change that occurs with aging. This myth is pervasive and often leads older adults to avoid seeking treatment. Many people do not mention leakage of urine to healthcare providers because they are embarrassed, believe nothing can be done, or believe it is an inevitable condition of older age. These views may lead to restriction of activities and ultimately to loneliness, depression, and isolation (Dowling-Castronovo & Bradway, 2012).

In men, UI is most often related to benign prostatic hyperplasia (enlarged prostate) or to prostatectomy. In women, it is often related to childbirth, specifically to vaginal delivery. Incidence is even higher among those who required episiotomy or forceps- or vacuum-assisted birth. Other risk factors for UI are perimenopausal status, high body mass index (BMI), diabetes, and current cigarette smoking.

Types of Urinary Incontinence

The two major types of urinary incontinence are transient and established. **Transient incontinence**, also called acute or reversible, is characterized by a sudden onset of usually reversible signs and symptoms. Causes include urinary tract infection and medications, especially diuretics. **Established urinary incontinence** is also known as chronic or persistent incontinence (Dowling-Castronovo & Bradway, 2012).

The Agency for Healthcare Research and Quality guidelines identified the following types of UI:

- **Urge incontinence** is the involuntary loss of larger amounts of urine accompanied by a strong urge to void. It is often referred to as **overactive bladder**.
- **Stress incontinence** is an involuntary loss of small amounts of urine with activities that increase intra-abdominal pressure. Etiological factors include pregnancy, childbirth, obesity, chronic constipation, and straining at stool. Activities that produce leakage of urine also include exercise, laughing, sneezing, coughing, and lifting.
- **Mixed incontinence** is a combination of urge and stress incontinence.
- **Overflow incontinence** is the loss of urine in combination with a distended bladder. Causes of overflow incontinence include fecal impaction, neurological disorders, and enlarged prostate (NANDA-I, 2012).

- **Functional incontinence** is the untimely loss of urine when no urinary or neurological cause is involved. NANDA-I (2012) defines functional incontinence as the "inability of a usually continent person to reach the toilet in time to avoid unintentional loss of urine" (p. 193). This type of incontinence occurs because of physical disability, immobility, pain, external obstacles, or problems in thinking or communicating that prevent a person from reaching a toilet.
- **Reflex incontinence** is loss of urine when the person does not realize the bladder is full and has no urge to void. Central nervous system disorders and multisystem problems are common causes. NANDA-I (2012) defines reflex urinary incontinence as the "involuntary loss of urine at somewhat predictable intervals when a specific bladder volume is reached" (p. 195). Tissue damage from radiation, cystitis, bladder inflammation, or radical pelvic surgery can also trigger reflex incontinence.

The following are other types of incontinence.

- **Enuresis**, which tends to be familial, is involuntary urination after about 5 to 6 years of age, when control is usually established. Enuresis is *primary* if bladder training was never achieved and *secondary* if control was established and then lost. Enuresis has been associated with stress (e.g., marital discord), UTI, allergies, abnormal electroencephalographic patterns, sleep disorders, hearty laughing, and small bladder capacity; however, the cause is not always apparent.
- **Nocturnal enuresis** (bedwetting) can persist until age 10 or later. If one parent had nighttime bedwetting as a child, there is a high chance the child will also experience it. Most often children outgrow the condition. Only a small percentage of the secondary type is caused by a medical condition, such as UTI, urinary obstruction, diabetes, pressure on the bladder from extreme constipation, or neurological disorders of the spinal cord.

PracticalKnowledge knowing **how**

As a nurse, you will monitor and assist clients with urinary elimination, teach them about body functions, and work collaboratively with the healthcare team to facilitate normal urinary function. In the remainder of the chapter, we discuss these activities. Also see the Nursing Care Plan and the Care Map.

ASSESSMENT

To assess urinary elimination, you will use data from the nursing history, physical examination, and diagnostic and laboratory reports.

Nursing History

Because urination patterns vary among individuals, you will need a nursing history to determine what is normal for a particular person. As you interview the client, pay attention to her reaction to your questions. Many people are embarrassed about discussing urination. Tailor your assessment to the client's needs, and use language that makes her comfortable. For a set of interview questions,

Go to Chapter 28, **Assessment Guidelines and Tools, Urinary Elimination History Questions,** in Volume 2.

Think**Like a Nurse** 28-4

In the Meet Your Patient scenario, some assessment findings were given for Marlena. What additional physical assessments might you perform to complete this urinary tract assessment?

Physical Assessment

Physical assessment for urinary elimination includes examination of the kidneys, bladder, urethra, and skin surrounding the genitals, as appropriate. For a complete discussion of physical examination of the genitourinary system,

Go to Chapter 22, **Procedure 22-17: Assessing the Male Genitourinary System,** and **Procedure 22–18: Assessing the Female Genitourinary System,** in Volume 2.

KnowledgeCheck 28-4

- What should you discuss with your client when performing a nursing history focused on urinary elimination?
- What are the key elements of a physical assessment for a client with urination problems?

Think**Like a Nurse** 28-5

After gathering a focused nursing history pertaining to urinary elimination, you check your patient's vital signs: oral temperature, 99.4°F (37.4°C); radial pulse, 88 beats/min; respiratory rate, 20 breaths/min; and blood pressure, 108/72 mm Hg. What other physical assessment findings might you expect?

Assessing the Urine

In addition to observations already mentioned, assessment of the urine includes measuring urine output and conducting a variety of bedside tests.

Measuring Intake and Output

Measuring urine output is part of a comprehensive plan to monitor a client's fluid status. Recall that the kidneys produce urine at a rate of approximately 50 to 60 mL per hour, or 1,500 mL per day. However, urinary output fluctuates depending on the quantity of fluids the patient drinks and on other factors, such as the ability of the heart to circulate the blood, adequate kidney functioning, and the ability of the patient to void the urine.

Urine output might be low if the person is sweating excessively or has significant vomiting and diarrhea. High fever can contribute to reduced urine output.

You must know both the intake and the output (I&O) as well as relevant physical condition to interpret the meaning of the patient data. For example, if urine output is low, you cannot assume the patient's kidneys are not working properly. If his intake is also low, he may be dehydrated. But what does it mean if his intake is high and his output low? Yes, this could mean his kidneys are not working well. However, it could also mean that his kidneys are producing urine but that he has urinary retention because of something that is obstructing flow.

To measure fluid intake, record all fluids the patient drinks or receives intravenously. Include the following items as fluid intake: oral fluids, semiliquid foods, ice chips, IV fluids, tube feedings, and irrigations instilled and not withdrawn immediately. Fluid output includes the following items: urine output, gastrointestinal fluid loss (e.g., emesis), liquid feces, and drainage (e.g., from suction devices or wounds). Explain to the client, family members, and all caregivers that I&O are being monitored. Posting a sign at the bedside or on the door to the room is a helpful reminder. When possible, have the client assist you with monitoring.

You will usually total the I&O at the end of each shift, as well as for each 24-hour period. In intensive care units, you may measure I&O hourly. Most healthcare facilities have standardized I&O forms. I&O may be recorded on a separate form or be part of a flowsheet. To see examples, see Figure 18-2.

Go to Chapter 18, **Forms: Nursing Assessment Flow Sheet,** in Volume 2.

For more discussion of intake and output, go to Chapters 18 and 38.

Observe standard precautions when handling urine to prevent exposure to body fluids. Always wear disposable procedure gloves, and avoid splashing the urine and contaminating your uniform. The method you use to measure urine is dictated in part by the amount of help the client needs with urination.

Voided Urine

Many ambulatory clients need no assistance with urination. Be sure to inform them you are monitoring their I&O, and explain how they can help. Place a specimen "hat" (collection container) under the toilet seat to collect urine, or have male clients void into a urinal. Periodically measure the output and empty the urine into the toilet. For clients who can assist with recording the I&O, provide a bedside clipboard.

For the client with mobility problems, use a bedpan or urinal to collect urine output. Use a fracture pan for clients with a fracture of the pelvis, lower back, or legs or for clients who have casts, splints, or braces on their legs. Male clients may void into a urinal while remaining in bed.

Go to Chapter 29, **Procedure 29-2: Placing and Removing a Bedpan,** in Volume 2.

For complete instructions for measuring urine output from a bedpan or urinal,

Go to Chapter 28, **Procedure 28-1A: Measuring Urine Output From a Bedpan or Urinal,** in Volume 2.

Urine From a Catheter

An **indwelling urinary catheter**, also known as a Foley or a retention catheter, is a flexible tube that is inserted through the urethra into the bladder. It is held in place by a balloon that is inflated in the bladder above the detrusor muscle. Catheter insertion and ongoing care are discussed in the Planning Interventions/Implementation section of this chapter.

You will usually measure urine output from the indwelling catheter at the end of each shift unless otherwise prescribed. Clients who require close monitoring of I&O will have a special collection bag with a measuring chamber. Often this is used to assess hourly urine output.

For complete instructions for measuring urine from a catheter,

Go to Chapter 28, **Procedure 28-1B: Measuring Urine From an Indwelling Catheter,** in Volume 2.

Obtaining Samples for Urine Studies

Many disorders of the urinary system can be assessed by examining urine. You will perform some of these tests at the bedside. For others, you will collect a specimen that is analyzed in the lab. The various types of urine samples are discussed in the text that follows.

Freshly Voided Specimen

To collect a freshly voided sample, collect the urine in the same manner as when you are measuring intake and output. Pour the urine into a specimen container labeled with the patient's name, the date, and the time of collection. Many facilities require packaging the container in a moisture-proof specimen-handling bag. Follow agency policy on additional packaging. Transport the specimen to the lab as soon as possible (according to agency policies). If there is a delay in getting the specimen to the lab, most agencies recommend refrigeration.

Go to Chapter 28, **Procedures 28-1: Measuring Urine** and **28-2: Obtaining a Urine Specimen for Testing,** in Volume 2.

Clean-Catch Specimen

Many diagnostic tests require a clean-catch urine specimen. The client must cleanse the genitalia before voiding and collect the sample in midstream because the initial flow of urine may contain organisms from the urethral meatus, distal urethra, and perineum. A midstream sample is free of these contaminants. The Highlights of Procedures box in this chapter summarizes key steps in collecting a clean-catch sample. For the complete procedure,

Go to Chapter 28, **Procedure 28-2A: Collecting a Clean-Catch Urine Specimen,** in Volume 2.

Sterile Urine Specimen

A sterile urine specimen aids in determining the presence of a urinary tract infection. You can obtain a sterile urine specimen by inserting a catheter into the bladder or by withdrawing a sample from an indwelling catheter. Do not take the specimen from the collection bag because that urine may be several hours old.

Never disconnect the catheter from the drainage tube to obtain a sample. Interrupting the system creates a portal of entry for pathogens, thereby increasing the risk of contamination.

For a description of the steps involved in obtaining a sterile specimen from an indwelling catheter, see the Highlights of Procedures box and also

Go to Chapter 28, **Procedure 28-2B: Obtaining a Sterile Urine Specimen From a Catheter,** in Volume 2.

24-Hour Urine Collection

A 24-hour urine collection, may be prescribed to evaluate some renal disorders by showing kidney function at different times of the day and night. You will need to use a large container and preserve all the urine voided in the 24-hour time period. For details about how to collect this type of specimen, see the Highlights of Procedures box, and also

Go to Chapter 28, **Procedure 28-2C: Collecting a 24-Hour Urine Specimen,** in Volume 2.

Routine Urinalysis

A routine urinalysis (UA) is one of the most commonly prescribed laboratory tests. It is used as an overall screening test as well as an aid to diagnosing renal, hepatic, and other diseases. Urinalysis requires a freshly voided sample.

Urinalysis techniques include "dipstick" testing and/or microscopic analysis. Dipstick testing is commonly performed at the bedside; microscopic examination is done in the lab. Box 28-3 contains several terms used to describe urine characteristics and quantity. For the expected findings and common variants of urinalysis,

Go to Chapter 28, **Diagnostic Testing, Urinalysis,** in Volume 2.

Bedside Testing (Dipstick)

Dipstick testing can determine pH and specific gravity and the presence of protein, glucose, ketones, and occult blood in the urine. Commercially prepared kits contain a reagent designed to detect a specific substance (e.g., glucose). The reagent may be a paper test strip, a fluid, or a tablet. When contacted by the urine, a chemical reaction causes a color change that you compare to a color chart (Fig. 28-4). You will need good lighting to evaluate the test strip results. Read the kit label to be certain that you are using the correct reagent and that the kit is not past the expiration date. Follow the manufacturer's directions regarding the amount of urine needed and the time needed for the reagent to develop. For guidelines for dipstick testing and delegation,

Go to Chapter 28, **Procedure 28-3A: Dipstick Testing of Urine,** in Volume 2.

BOX 28-3 ■ Terms Associated With Urination

Acute renal failure (ARF): An acute rise in the serum creatinine level of 25% or more. May be caused by inadequate blood flow to the kidney, injury to the kidney glomeruli or tubules, or obstruction of kidney outflow.

Anuria: The absence of urine, often associated with kidney failure or congestive heart failure. This term is used when urine output is less than 100 mL in 24 hours.

Dysuria: Painful or difficult urination. May be associated with infection or partial obstruction of the urinary tract as well as medications that trigger urinary retention.

End-stage renal disease (ESRD): A chronic rise in serum creatinine levels associated with loss of kidney function that must be treated with dialysis or transplantation. Also known as chronic renal failure (CRF).

Enuresis: Involuntary loss of urine

Frequency: The need to urinate at short intervals

Hematuria: Blood in the urine. May be due to trauma, kidney stones, infection, or menstruation.

Micturition: To start the stream of urine; to urinate; release urine from the bladder

Nephropathy: A broad term meaning disease of the kidney

Nephrotoxic: A substance that damages kidney tissue. Some antibiotics (gentamicin, tobramycin, and amikacin), nonsteroidal anti-inflammatory drugs (NSAIDs), lead, and contrast media have the potential to be nephrotoxic.

Nocturia: Frequent urination after going to bed. May be caused by excessive fluid intake as well as a variety of urinary tract and cardiovascular problems.

Nocturnal enuresis: Involuntary loss of urine while asleep

Oliguria: Urine output of less than 400 mL in 24 hours. For pediatric patients, oliguria is <0.5–1.0 mL/kg per hour.

Pessary: An incontinence device that is inserted into the vagina to reduce organ prolapse or pressure on the bladder

Polyuria: Excessive urination. May be caused by excessive hydration, diabetes mellitus, diabetes insipidus, or kidney disease.

Proteinuria: The presence of protein in the urine. May be a sign of infection or kidney disease.

Pyuria: Pus in the urine. May be caused by lesions or infection in the urinary tract.

Urgency: A sudden, almost uncontrollable need to urinate.

FIGURE 28-4 Commercial testing kits contain a reagent for a specific substance. A chemical reaction with the urine causes a color change that you interpret using a color chart.

Specific Gravity

Specific gravity, an indicator of urine concentration, can be measured with a reagent strip. However, when you need to be precise and accurate, you should use a refractometer. Specific gravity is usually tested in the laboratory, but it is a nursing responsibility in some settings. For guidelines when testing urine specific gravity,

Go to Chapter 28, **Procedure 28-3B: Measuring Specific Gravity of Urine,** in Volume 2.

A **refractometer** (Fig. 28-5) measures the extent to which a beam of light changes direction when it passes through the urine (the *refractive index*). If the concentration of solids is high, the light is refracted more. The method is quick and easy to perform and requires only a few drops of urine. A refractometer is more precise, requires a much smaller specimen, is more compact, and poses less risk of spills and exposure to body fluids than does a urinometer, which for the most part is no longer used.

FIGURE 28-5 A refractometer indicates urine concentration by measuring the extent to which a beam of light is refracted ("bent") when passed through the urine. (Courtesy of Atago USA, Inc.)

KnowledgeCheck 28-5

- Explain how to collect a clean-catch urine specimen.
- You are caring for a patient on a hospital unit from 0700 to 1200. Based on the following information, calculate the I&O and comment on your findings.
  Receiving IV fluid at 125 mL/hr
  0800 breakfast—4 oz juice, toast, scrambled eggs, 8 oz coffee
  0930—3 oz water
  0700 to 1200—wound drainage: 360 mL
  0700 to 1200—urine output per indwelling catheter: 180 mL

ThinkLike a Nurse 28-6

- Why do you think the first voided urine is discarded at the start of a 24-hour urine collection?
- Below are the dipstick findings you obtained on the clean-catch specimen from Marlena (Meet Your Patient).

Urinalysis	**Result**
pH	8.0
Specific gravity	1.030
Protein	Negative
Glucose	Negative
RBCs	Trace
Nitrite	+1
WBCs	+2
Bilirubin	Negative
Ketones	Negative
Urobilinogen	Negative

  a. Identify the abnormal findings.
  b. What would you expect the findings of her urine culture and sensitivity to demonstrate?

Blood Studies

Blood urea nitrogen (BUN) and creatinine levels are commonly measured to assess renal function and hydration. For normal ranges,

Go to Chapter 28, **Diagnostic Testing, Blood Studies: BUN and Creatinine,** in Volume 2.

Common Diagnostic Procedures

A variety of diagnostic procedures may be performed on the urinary tract. These procedures are conducted in the operating room, procedure suite, or radiology department. Typically nurses are responsible for preparing the client for the procedure, assisting with specimen collection, delivering aftercare, and sometimes assisting the physician. For a discussion of urinary system studies and the nursing responsibilities associated with them,

Go to Chapter 28, **Diagnostic Testing, Studies of the Urinary System,** in Volume 2.

ANALYSIS/NURSING DIAGNOSIS

Urinary elimination problems are described by several nursing and medical diagnoses. NANDA-I diagnoses specific to urinary elimination include the following:

Functional Urinary Incontinence
Impaired Urinary Elimination
Reflex Urinary Incontinence
Risk for Urge Urinary Incontinence
Stress Urinary Incontinence
Urge Urinary Incontinence
Urinary Retention
Overflow Urinary Incontinence
Readiness for Enhanced Urinary Elimination
Risk for Infection (Urinary Tract)
Risk for Ineffective Renal Perfusion

Urinary problems may also be the etiology of other nursing diagnoses, such as the following:

Anxiety related to urinary urgency and recent episode of incontinence
Disturbed Body Image secondary to new urostomy
Acute Pain related to bladder spasms and urinary tract infection
Social Isolation related to frequent periods of incontinence

PLANNING OUTCOMES/EVALUATION

The general goal related to urinary elimination is that patients will comfortably void approximately 1,500 mL of light yellow urine in 24 hours. Because normal urine elimination patterns vary, the frequency and amount of urine are based on the individual's pattern, food and fluid intake, medications, and other factors.

NOC standardized outcomes for urinary problems, regardless of the specific problem, are the following: Kidney Function, Urinary Continence, Urinary Elimination, Self-Care: Toileting, and Tissue Integrity: Skin & Mucous Membranes (because urinary elimination problems often place the patient at Risk for Impaired Skin Integrity).

Individualized goals/outcome statements you might use to evaluate the effectiveness of interventions for urinary problems include the following:

- Will resume his normal urination pattern by (date).
- Will discuss feelings about his urostomy.
- Will have no visible blood in urine after 2 days on antibiotics.
- Responds to the urge to void in a timely manner.
- After voiding, states he feels he has emptied his bladder completely.
- Postvoiding residual volume is <150 mL.

PLANNING INTERVENTIONS/IMPLEMENTATION

For *NIC standardized interventions* for patients with urinary elimination nursing diagnoses,

Go to Chapter 28, **Standardized Language, NIC Interventions for Urinary Problems,** on Davis*Plus*.

You should select nursing activities to meet individual needs and address problem etiologies. *Specific nursing activities* for patients with elimination problems fall into the following categories: promoting normal urination, preventing urinary tract infection, managing urinary retention, managing urinary incontinence, and caring for patients who have urinary diversions. The rest of this chapter discusses those activities.

Promoting Normal Urination

As a nurse, you should have a repertoire of independent nursing activities for promoting normal urination. These include providing privacy, positioning, scheduling elimination, providing and monitoring fluid and nutrition, and assisting with hygiene.

Provide Privacy

Although urination is a normal physiological process, most people consider it a private matter. Taking a matter-of-fact approach confirms to patients that you are comfortable with this aspect of care. Provide privacy when discussing or providing care related to urination. Excuse visitors from the room, draw the dividing curtains in shared rooms, and close the door to the room. Whenever possible, give the patient time alone to void. Do not, for example, hover outside the bathroom door asking, "Are you okay?" or "Are you finished?" However, if the client is weak and frail, you may need to remain with him.

Assist With Positioning

Most men stand to void and may have difficulty voiding in other positions. Whenever possible, assist the patient to the bathroom to use the toilet and allow him to assume his preferred position. Alternatively, provide a bedside commode or urinal for the patient to use. To place a urinal, position the patient in a semi-Fowler's position with the legs slightly spread. Place the urinal on the bed between the patient's legs, and insert his penis into the urinal.

Women generally find an upright seated or squatting position to be the most comfortable position for voiding. If a female patient must remain in bed, provide a bedpan. Place her in a semi-Fowler's position to urinate unless contraindicated. Raise the siderails or provide an overhead trapeze so that the patient will have grip holds to maneuver herself onto and off the bedpan. If the patient is very weak, you may need an assistant to help you position her on the bedpan, and you may need to stay with her to help her maintain her position. For the steps involved,

Go to Chapter 28, **Procedure 29-2: Placing and Removing a Bedpan,** in Volume 2.

Quality and Safety Education for Nurses

Managing Urinary Incontinence

Chapter Key Concept: *Urinary Incontinence*

Competency: *Patient-Centered Care (Knowledge, Skills, Attitudes); Evidenced-Based Practice (Knowledge, Skills, Attitudes)**

Scenario: Dashondra Simms, RN, lives in a rural area and works in a urology practice. After participating in a radio interview to provide information about urinary incontinence, many women call the urology practice to ask for help. Dashondra asks each woman how she manages her incontinence, where she obtains information, if the condition has changed her quality of life, and if she would be willing to participate in an incontinence support group. Dashondra's notes reveal a population with unmet healthcare needs. To address this, she decides to develop a patient-centered, evidence-based program to increase participants' knowledge and confidence about managing their incontinence.

First, Dashondra accesses the National Guideline Clearinghouse Web site to obtain evidence-based guidelines for different incontinence management techniques. She searches databases such as MEDLINE and CINAHL for peer-reviewed studies that identify the psychosocial needs of patients, cultural or ethnic differences in managing incontinence. She also consults colleagues for their opinions.

Dashondra organizes a planning meeting with the women and asks them about the emotional impact of living with incontinence. The women talk about their feelings of self-worth, dignity, and confidence being affected. Self-image, sexuality, and their sense of freedom also emerged as specific psychosocial issues. The women identified that the following would be of value to them in an incontinence self-management program: education about new treatments, a monthly support group meeting, an online forum for members, and telephone or e-mail access to the nurse as desirable components of the program.

Think about it:

- How did Dashondra establish an evidence base for educating group members?
- How did she make the intervention patient centered?
- In what ways did Dashondra use information technology to help her design the program?

Source: Hayder, D., & Schnepp, W. (2010); Schröder, A., Abrams, P., Andersson, K. E., et al. (2009); Wilson (2004).

*For specific Knowledge, Skills, and Attitudes,

Go to the QSEN Web site at http://qsen.org/competencies/pre-licensure-ksas/

Facilitate Toileting Routines

Most patients void on awakening, after meals or drinking a large volume of fluid, before bedtime, or during the night for some. Identify your patient's pattern, and stick to it as much as possible. If you anticipate a change in the pattern for elimination, inform the patient. For example, if the patient is to receive a diuretic, explain that he will need to urinate more often. Similarly, if the patient is scheduled for a diagnostic procedure or activity, inform him ahead of time so that he may void before the activity begins.

Provide assistance to all patients who have mobility problems and those who use the bedpan. Discuss with all NAP the need to offer assistance so that patients experience minimal delays.

Promote Adequate Fluids and Nutrition

Adequate hydration promotes urinary tract function and flushes the system of waste products. Unfortunately, many people do not drink an adequate amount of fluid. Water is the preferred fluid because soda, coffee, and tea often contain caffeine or additives that may cause diuresis. However, the amount of fluid is more important than the type. If the patient will not or cannot drink water, provide the fluid he prefers. Most people should drink at least 8 to 10 eight-ounce glasses of fluid daily (also known as the 8-by-8 rule) unless health problems limit the fluid. See Box 28-4 for strategies to increase your patient's fluid intake.

BOX 28-4 ■ Strategies to Increase Patients' Fluid Intake

- For patients with limited mobility, keep water or other liquids in easy reach.
- You may need to remind young children or patients with cognitive or psychiatric disorders to drink fluids.
- For patients who have increased fluid needs, provide goals for intake, and frequently remind them to drink.
- Many foods have a high fluid content. If the patient requires additional fluid for hydration, consider adding soup and watery foods, such as watermelon, to the diet. In contrast, if the patient requires fluid restriction, you will have to account for these foods into the fluid balance.
- Try offering liquids with a straw. Patients tend to drink more this way.
- Chilled drinks might be more appealing, particularly if the patient's mouth is dry. Offer beverages with ice if they are to be served cold.
- Provide good mouth care. Patients will often drink more readily if their mouth feels fresh.

Assist With Hygiene

Urine is irritating to the skin. Therefore, perineal cleansing is an integral part of toileting hygiene. Many ill patients are unable to do this for themselves, so you may need to provide perineal care. If the patient can ambulate to the bathroom, you merely need to assist with her usual cleansing routines. You may assist the patient by pouring warm periwash over the genitals while she is seated on the toilet, the bedside commode, or on the bedpan. Be sure to rinse with warm water because soap may be drying to the genital mucosa. Also offer a moist washcloth or towelette for washing hands after toileting. For further information,

Go to Chapter 25, **Procedure 25-4: Providing Perineal Care,** in Volume 2.

KnowledgeCheck 28-6

- Identify activities that promote normal urination patterns.
- Write at least two nursing diagnostic statements that would be appropriate for Marlena in the Meet Your Patient scenario.

Interventions for Example Problem: Urinary Tract Infections

An important part of UTI treatment is prevention of future UTIs. The accompanying Self-Care box presents the teaching points that you should include in your sessions with patients at risk for or recovering from a UTI.

Interventions for Example Problem: Urinary Retention

Clients with a mechanical obstruction to urine flow are treated by surgical removal or repair of the obstruction (e.g., resection of the prostate gland, removal of bladder calculi). For clients who have loss of bladder tone, collaboratively you may:

- Administer cholinergic medications, such as bethanechol chloride (Urecholine), which promote bladder emptying by stimulating contraction of the detrusor muscle.
- Administer alpha-adrenergic antagonists, such as tamsulosin (Flomax), which reduce urethral resistance and improve bladder emptying.
- Use **Credé's maneuver** (apply manual pressure over the bladder to promote emptying).
- Perform urinary catheterization.

Independent nursing interventions for patients with urinary retention include the following:

- Monitor I&O.
- Assess for risk factors for urinary retention (e.g., prostatic hypertrophy; pelvic surgery; and medications with anticholinergic side effects, such as diazepam [Valium], some antidepressants, and diphenhydramine [Benadryl]).
- Inspect and palpate for bladder distention.
- Apply heat to the lower abdomen to relax the muscles near where the bladder lies.
- Run water nearby, or place the patient's hands in warm water. Hearing running water can stimulate the urge to urinate.
- Pour distilled water over the perineum, or assist the patient to take a warm sitz bath.
- Measure the urine that remains in the bladder immediately after the patient voids. This is known as **post-void residual urine (PVR)**. PVR can be measured with a portable noninvasive bladder ultrasound device (bladder scanner) or by insertion of a straight catheter.

Go to Chapter 28, **Procedure 28-1C: Measuring Post-Void Residual Urine Volume (PVR) With a Portable Bladder Scanner,** in Volume 2.

- Advise the patient to contact a medical professional:
  - If not previously evaluated for urinary hesitancy, dribbling, or weak urine stream
  - For fever, vomiting, side or back pain, shaking chills, or passing little urine for 1 to 2 days
  - For blood in the urine, cloudy urine, frequent or urgent need to urinate, or a discharge from the penis or vagina

Self-Care

Teaching Your Client About Preventing UTI

- **Drink at least 8 to 10 eight-ounce glasses of water per day** to keep urine dilute and to flush bacteria from the urinary tract. The Institute of Medicine (2006) recommends even more, particularly with heat exposure or prolonged exercise. Water is best. Some reports claim a benefit to drinking cranberry juice because cranberries contain a substance that keeps bacteria from sticking on the walls of the bladder (Jepson, Williams, & Craig, 2012). However, this practice is controversial (Guay, 2009).
- **Urinate when you first feel the urge.** Do not make a habit of postponing urination because bacteria can multiply in stagnant urine.
- **Always wipe from front to back** after urination or defecation.
- **Wear cotton underwear** because nylon or other synthetic fabrics prevent evaporation of moisture. Also avoid tight-fitting clothing in the groin area. Bacteria and other microorganisms grow well in a warm, moist environment.
- **Urinate after having intercourse** to flush away bacteria that might have entered the urethra.
- **If you have a history of UTI**, avoid using a diaphragm, spermicidal contraceptive gel, or unlubricated or spermicidal condoms.
- **Avoid bubble baths** and baking-soda baths if you have a history of UTI.
- **Promptly report any symptoms of UTI** to your healthcare provider.

Self-Catheterization Patients with spinal cord injuries or neurological disorders use intermittent catheterization to drain the bladder and limit the risk of infection. Many actually perform **intermittent self-catheterization**, although caregivers may assist. Although you will use sterile technique for catheterization, most patients who self-catheterize use clean technique. In spite of this difference, intermittent catheterization carries a lower risk of infection than does an indwelling catheter (Hooton, Bradley, Cardenas, et al., 2010). The goals of intermittent self-catheterization are to (1) completely empty the bladder and (2) prevent urinary tract infections. To teach patients the procedure for self-catheterization,

Go to Chapter 28, **Clinical Insight 28-4: Teaching Clients About Clean, Intermittent Self-Catheterization,** in Volume 2.

Urinary Catheterization

Catheterization is the introduction of a pliable tube (catheter) into the bladder to allow drainage of urine. Urinary catheterization is performed to:

- Obtain a sterile urine specimen.
- Drain the bladder for surgical or diagnostic purposes or when emptying is incomplete after urination.
- Prevent or treat bladder overdistention and urinary retention (e.g., after surgery) when other measures fail.
- Measure PVR if a portable bladder ultrasound device is unavailable or if the results are inconclusive.
- Protect excoriated skin from contact with urine.
- Reduce the need for unnecessary movement of patients who are near death.

Indwelling urinary catheterization is associated with the complications of bacteriuria and UTI. A catheter provides a connection between the external environment and a normally sterile system. In addition, when the patient has an indwelling catheter, microorganisms are no longer flushed from the urethra through voiding.

In fact, an indwelling urinary catheter is the most common cause of nosocomial infections. To reduce the risk of bacterial contamination, asepsis and maintain a closed system is critical when inserting and caring for a urinary catheter (Gould, Umscheid, Agarwal, et al., 2009). Catheterization can injure the urethra if the catheter is too large, is not well lubricated, is forced through strictures, or is inserted at an incorrect angle.

Types of Urinary Catheters

There are a variety of catheter types and materials to choose from, depending on whether the patient requires catheterization for long-term or short-term use, has product sensitivity, or is at increased risk for infection.

- **Silver-alloy** coated catheters may reduce the risk of catheter-associated urinary tract infections for up to 14 days (WOCN, 2009; Schumm & Lam, 2010). Silver-coated catheters are not, however, routinely used for short-term catheterization because they are more costly than standard catheters.
- **Silicone elastomer or Teflon-bonded** are coated latex catheters. The coating reduces friction and tissue irritation during insertion and while the catheter remains in place. These catheters must not be used in patients with latex sensitivity (WOCN, 2009).
- **Polyvinyl chloride (PVC)** catheters are inexpensive and commonly used for intermittent catheterization. They are more rigid and therefore less comfortable for indwelling use (WOCN, 2009).
- **100% silicone catheters** are used primarily for long-term catheterization. They cause less tissue irritation and prevent encrustation. They are safe for patients with latex sensitivity.
- **Hydrogel coated** catheters can be made of either latex or silicone. They cause less urethral trauma during insertion, resist encrustation, and can remain in place up to 12 weeks (Turner & Dickens, 2011). This type of ***lubricant and/or antimicrobial coating*** helps prevent infection.

Always check for latex or Teflon and iodine allergies before performing a catheterization.

Straight Catheter A **straight catheter** is a single-lumen tube that is inserted for immediate drainage of the bladder (e.g., to obtain a sterile urine specimen, to measure postvoid residual volume (PVR), or to relieve temporary bladder distention). After the bladder is empty or the sample obtained, the catheter is removed and the patient resumes voiding independently.

Indwelling Catheter An **indwelling catheter**, also known as a *Foley* or *retention catheter*, is used for continuous bladder drainage (e.g., when the bladder must be kept empty or when continuous urine measurement is needed). It is usually a double-lumen tube: one lumen is used for urine drainage, and the second lumen is used to inflate a balloon near the tip of the catheter. A triple-lumen indwelling catheter is used when the patient requires intermittent or continuous bladder irrigation. Men usually need a larger lumen (e.g., 18 Fr) than do women.

The inflated balloon holds the catheter in place at the neck of the bladder. The balloon is sized according to the volume of fluid used to inflate it. For most patients you will use a 5-mL balloon; for children 3-mL; and for achieving hemostasis after a prostatectomy, a 30-mL balloon.

Figure 28-6 illustrates the different types of catheters.

Suprapubic Catheter A **suprapubic catheter** is used for continuous urine drainage when the urethra must be bypassed (e.g., after gynecological surgery or where there is prostatic obstruction). A suprapubic catheter is inserted through an incision above the symphysis pubis (Fig. 28-7). It may be sutured in place initially. Once the stoma tract has healed, a standard indwelling catheter

Toward Evidence-Based Practice

Buchko, B. L., & Robinson, L. E. (2012). An evidence-based approach to decrease early post-operative urinary retention following urogynecologic surgery, *Urologic Nursing*, 32(5), 260–264, 283.

The purpose of this project was to identify evidence and develop a protocol to prevent postoperative urinary retention in women undergoing urogynecologic surgery. The goals were to decrease the incidence of urinary retention, reduce the frequency of intermittent catheterization, and reduce the duration of indwelling catheterization in these patients. An algorithm was developed that defined when and how to assess the patient for urinary retention using a portable bladder scanner. Treatment protocols related to intermittent catheterization, indwelling catheterization, or continued monitoring were then added. An educational program was also developed to teach nurses how to use the algorithm. Research is ongoing to measure patient outcomes and determine the effectiveness of this program.

Bernard, M. S., Hunter, K. F., & Moore, K. N. (2012). A review of strategies to decrease the duration of indwelling urethral catheters and potentially reduce the incidence of catheter-associated urinary tract infections. *Urologic Nursing*, 32(1), 29–37.

The authors evaluated current literature for research-based strategies to reduce the length of time of urinary catheter placement and the effect of these strategies on the incidence of catheter-associated urinary tract infections (CAUTI). The length of time an indwelling catheter is in place is the greatest risk factor for development of a CAUTI, yet assessment of the continuing need for the catheter is often overlooked. Both nurse-led and informatics-led interventions demonstrated a significant reduction in duration of catheterization. In both interventions, nurses played a critical role and impacted the development of CAUTI in their patients.

1. What are the benefits in reducing the duration of indwelling catheterization in postoperative patients?

2. Assessment of urinary retention has traditionally been done with either bladder palpation or straight catheterization. What are the advantages of utilizing a portable bladder scanner in assessing urinary retention?

3. In addition to reducing the likelihood of CAUTI, what other benefits may occur with early removal of an indwelling catheter?

Go to Chapter 28, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus.*

is usually used and is held in place by inflation of the balloon.

Catheter Sizing Catheters are sized by the *diameter* of the lumen; the larger the number, the larger the lumen. For example, 8- and 10-Fr catheters are used for children; they are smaller in diameter than the 14- and 16-Fr catheters typically used for adults. Catheters also come in different *lengths*: A 22-cm catheter is appropriate for women, whereas for men you will need a 40-cm catheter.

Supplies for Urinary Catheterization

The supplies used for inserting an indwelling catheter are usually prepackaged. Included in the kit are sterile gloves, swabs or cotton balls, a solution for cleansing the urethral meatus, sterile lubricant, a sterile indwelling

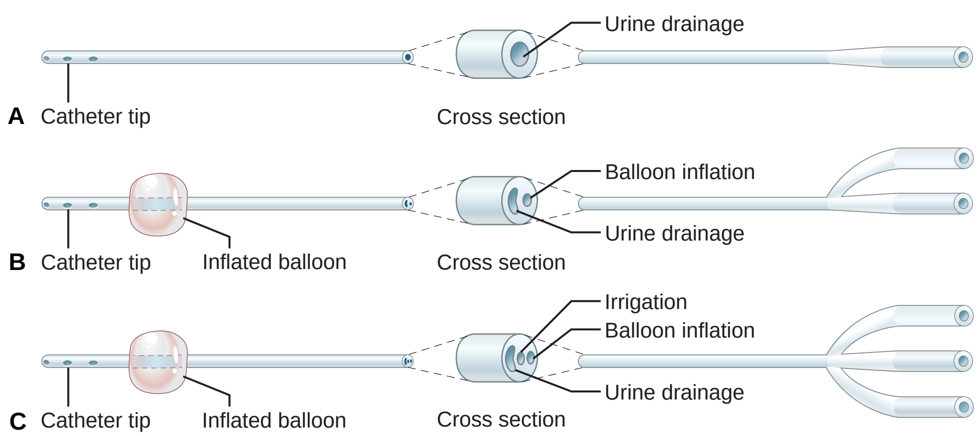

FIGURE 28-6 Types of catheters. *A*, A single-lumen catheter is used to obtain a urine sample or immediately drain the bladder. *B*, A double-lumen catheter is the most commonly used indwelling catheter. *C*, A triple-lumen catheter is inserted when the patient requires irrigation of the bladder.

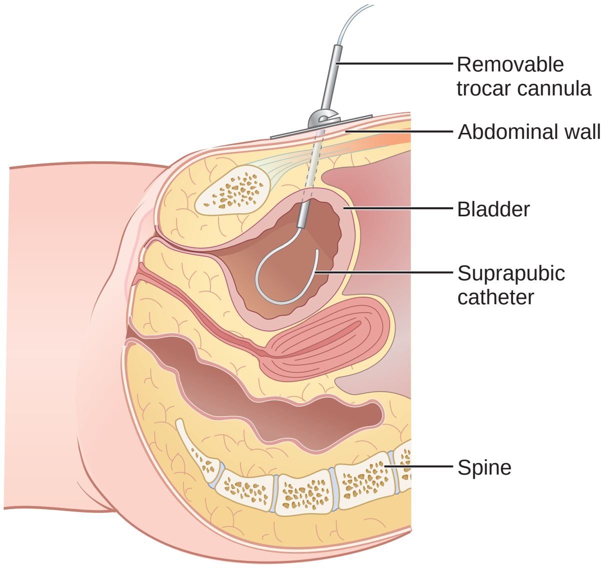

FIGURE 28-7 A suprapubic catheter drains urine from a surgically created opening into the bladder, bypassing the urethra.

catheter, a syringe filled with sterile water to inflate the retention balloon, drainage tubing, and a drainage collection bag. Kits contain the most common catheter sizes, usually 12, 14, or 16 Fr. Pediatric kits contain 8- or 10-Fr catheters. The smallest diameter catheter possible that provides proper drainage is recommended to minimize urethral trauma (Lo, Nicholle, Classen, et al., 2008).

KnowledgeCheck 28-7

- Describe the difference between a catheter used for straight catheterization and one used for ongoing drainage.
- Why is intermittent catheterization preferred for patients who must be catheterized over lengthy periods of time?

Urinary Catheter Insertion

To insert a urinary catheter, you will need to gather the appropriate supplies and prepare the patient. Explain to the patient the reason for the catheter insertion, the expected length of time the catheter will be needed, and the sensations he is likely to have. Most patients experience a sensation of pressure and some discomfort (but not pain) when a catheter is inserted. Explain that when the catheter is inserted it may feel as though he is voiding, but the urine is going into the tube, not onto the bed. If there is swelling or bleeding in the urinary tract, insertion may be painful.

Many patients feel embarrassed during this procedure. A professional approach, along with good draping and other privacy measures, helps relieve discomfort or distress. As you are draping the patient, offer to answer any further questions he may have.

Use a dorsal recumbent position for women and a supine position for men. For female patients, make sure to lower the section of the bed called the knee gatch, so that you can easily visualize the urinary meatus. You may need to place a firm cushion under the patient's buttocks to prevent her sinking into a soft mattress and obscuring visibility of the meatus. For women who are unable to assume a dorsal recumbent position, consider Sims' or a lateral position (Fig. 28-8). Cleaning around the meatus and perineum is mandatory prior to insertion of the catheter. For a brief summary, see the Highlights of Procedures box; for the complete procedure,

Go to Chapter 28, **Procedure 28-4: Inserting a Urinary Catheter,** in Volume 2.

Caring for the Patient With an Indwelling Catheter

The best practice care is always to remove a urinary catheter that is not necessary (Institute for Healthcare Improvement, 2011).

Key Point. ***Remember above all, when providing care for a patient with an indwelling catheter, keep it closed, keep it flowing, and keep it clean.***

Prevent Urinary Tract Infection UTIs are the most common healthcare-associated infection. Approximately 80% of all UTIs are associated with indwelling urinary catheters (Moola & Konno, 2010). An indwelling catheter is connected to a drainage tube and collection bag, which

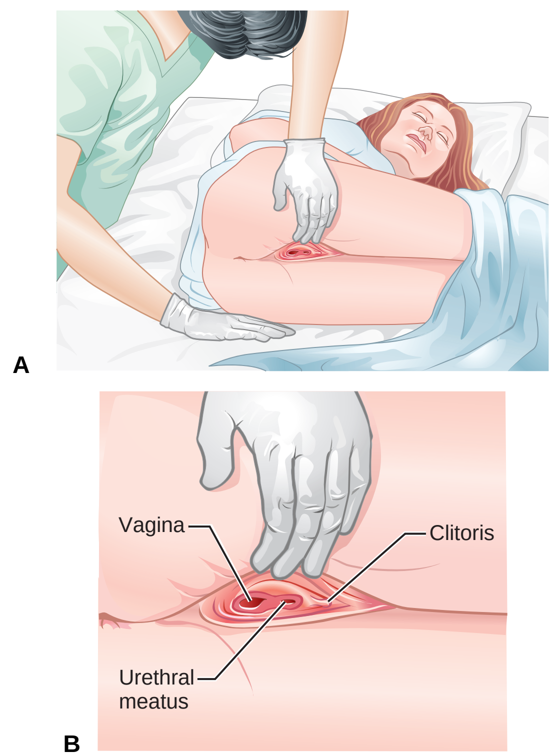

FIGURE 28-8 *A*, *B*, For women who cannot assume a dorsal recumbent position, you can use the side-lying position and lift the superior buttock to expose the urethral meatus.

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 28-1: Measuring Urine

- Don clean procedure gloves.
- Record the amount of urine on the input and output (I&O) flow sheets.

Procedure 28-1A: Measuring Urine Output From a Bedpan or Urinal

- Place the bedpan or urinal in the proper position and encourage your patient to begin voiding. Remain close by or instruct the patient to press the call light button when finished.
- Pour the urine from the bedpan or urinal into a graduated measuring device. Place on a flat, even surface and read the amount at eye level.

Procedure 28-1B: Measuring Urine From an Indwelling Catheter

- Open the drainage spout and allow urine to drain into the measuring device, being careful to avoid touching the spout to the inside of the container. Place the measuring device on a flat even surface and read the amount at eye level.

Procedure 28-1C: Measuring Post-Void Residual Urine Volume (PVR) With a Portable Bladder Scanner

- Assist the patient to a supine position. Uncover only the patient's lower abdomen and suprapubic area.
- Select the patient's gender.
- Palpate the symphysis pubis and apply ultrasound gel midline on the abdomen above the symphysis pubis.
- Position the scanner head in the gel and aim it towards the bladder and slightly downward.
- Press and release the SCAN button. Hold the scanner steady until the scan is finished.
- Read the bladder volume measurement.
- Repeat the scan several times to ensure accuracy.
- Press "DONE" when finished. Print the results by pressing PRINT.

Obtaining a Urine Specimen for Testing

Procedure 28-2: Obtaining a Urine Specimen for Testing

- Don clean procedure gloves

Procedure 28-2A: Collecting a Clean-Catch Urine Specimen

- Wash the perineum or the end of the penis first with antiseptic solution, then with an antiseptic solution. (For women, wash from front to back; for men, use a circular motion from the urethra outward.)
- Ask the patient to begin voiding. After the stream begins, collect a 30- to 60-mL specimen.
- Maintain sterility: Do not touch the inside of the container or the container lid. Avoid getting toilet paper, feces, pubic hair, or anything else in the urine sample.
- Place the lid on the container; label the container with the patient's name, the date, and the time of collection.
- Follow agency policy on additional packaging.
- Transport the specimen to the lab as soon as possible. If there is a delay in getting the specimen to the lab, most facilities recommend refrigeration.

Procedure 28-2B: Obtaining a Sterile Urine Specimen From a Catheter

- Wearing procedure gloves, empty the drainage tube of urine.
- Don clean gloves, and swab the specimen port with an antiseptic swab.
- Insert the needleless access device with a 10-mL syringe into the specimen port, and aspirate the amount of urine you need.
- Transfer the specimen into a sterile specimen container.
- Maintain sterility: Do not touch the needleless access device, the inside of the container, or the container lid.
- Label the specimen container with the correct patient identification and transport it to the lab in a timely manner.

Procedure 28-2C: Collecting a 24-Hour Urine Specimen

- Ask the patient to void. Record the time. Discard this first voiding.
- Collect all urine voided during the next 24 hours.
- Label the storage container with the patient's name, date, and time the test ended. Transport it to the lab after the collection is complete. Otherwise, place the urine in a refrigerator designated for specimen storage per agency policy.

Procedure 28-3: Testing Urine at the Bedside

- Follow the manufacturer's directions carefully regarding the amount of urine needed.

Procedure 28-3A: Dipstick Testing of Urine

- Read the kit label to be certain that you are using the correct reagent and that the kit has not passed the expiration date.
- Read the reagent strip at the exact time indicated on the label. You will need adequate lighting to evaluate the results.
- Dipstick testing is considered a preliminary test for screening.

Procedure 28-3B: Measuring Specific Gravity of Urine

- Before use, be sure the equipment is calibrated to 1.000 according to the manufacturer's instructions.
- Use fresh urine. If you cannot perform the test within 1 hour, refrigerate the specimen.
- Place a drop of urine on the glass plate and close the flap.

Continued

- Hold the refractometer up to the light when looking through the eyepiece.
- Read the specific gravity by looking for the point where the contrast line between the dark and light fields crosses the scale.
- Clean the instrument when finished.

Procedure 28-4: Urinary Catheterization

- Allow adequate time for catheterization: Experienced nurses need at least 15 minutes. You will need more time if problems arise—and even more if you are a novice.
- Take an extra pair of sterile gloves and an extra sterile catheter into the room.
- Be sure that you have good lighting.
- Work on the right side of the bed if you are right-handed and on the left side if you are left-handed.
- Drape the patient for privacy.
- Perform perineal care before the procedure; wash your hands; open the kit.
- Don sterile gloves and maintain sterile technique while manipulating the supplies in the kit and performing the procedure.
- For indwelling urinary catheterization, do not pretest the balloon by inflating it before insertion, especially with silicone catheters. The practice can cause the balloon to form cuffs, and arm the patient's urethra.
- Generously lubricate the catheter before insertion.
- Once you have touched the patient with your nondominant hand, do not remove that hand from the patient.
- Insert the catheter 5 to 7.5 cm (2 to 3 in.) for women, 17 to 22.5 cm (7 to 9 in.) for men, until urine flows.
- Drain the bladder; collect needed samples; measure urine; and then remove the catheter if it is intermittent. If the catheter is indwelling, inflate the balloon and connect the drainage bag.

Procedure 28-5: Applying an External (Condom) Catheter

- Application of a condom (external) catheter is a clean procedure.
- Clean and dry the penis before catheter application.
- When applying the condom, stabilize the penis with your nondominant hand.
- Leave a gap of 2.5 to 5 cm (1 to 2 in.) between the condom and the tip of the penis to prevent skin irritation.
- Use only the tape supplied in the application kit to secure the catheter.
- For condom catheters that contain adhesive material on the inside of the condom, grasp the penis and gently compress the condom onto the shaft.
- Be certain that the tubing from the end of the catheter to the drainage bag is free from kinks.

Procedure 28-6: Removing an Indwelling Catheter

- Use clean technique. Wash hands before and after removing the catheter. Wear clean procedure gloves.
- Be sure to remove the stabilization device or tape securing the catheter to the patient.
- Obtain a sterile specimen if needed.
- Connect a syringe to the balloon port and allow the balloon to self-deflate or withdraw the fluid slowly. Follow manufacturer's instructions. Check the balloon size on the valve port to verify that all fluid has been removed.
- If the balloon does not empty completely do not pull on the catheter. Report to the charge nurse or the primary care provider before continuing.
- Observe the first few voidings after the catheter is removed.

Procedure 28-7: Irrigating the Bladder or Catheter

Procedure 28-7A: Intermittent Bladder or Catheter Irrigation

- Drape the patient, exposing only the specimen removal port or the irrigation port on a three-way catheter.
- Because of the risk of infection, never disconnect the drainage tubing from the catheter.
- Use a sterile irrigation solution, warmed to room temperature.
- Instill the irrigation solution slowly.
- Repeat the process as necessary.

Procedure 28-7B: Continuous Bladder Irrigation

- Drape the patient, exposing only the irrigation port of the catheter.
- Using aseptic technique, attach the connecting tubing to the irrigation solution container.
- Prime the tubing.
- Don clean procedure gloves.
- Pinch the irrigation port of the catheter and connect the irrigation tubing to the port.
- Regulate the flow of the irrigant.
- Monitor urine output.

constitute a closed system. To minimize the chance for catheter-associated urinary tract infection, the system cannot be opened at any point. Meticulous hand hygiene and cleanliness of all ports using disinfectants is imperative for preventing the spread of infection (CDC, 2013)

Maintain Free Flow of Urine Free flow of urine prevents backflow of urine into the bladder, which can cause bladder distention and injury. Adequate urine production flushes pathogens out of the bladder, provides natural irrigation of the tubing, and prevents stasis of urine. Stasis of urine also provides a medium for growth of microorganisms.

Maintain Skin and Mucosal Integrity To maintain skin and mucosal integrity, secure the tubing to the leg. This prevents traction of the tubing and irritation to the urinary tract. Hygiene and perineal cleansing also reduces irritation from the encrustation of urine and feces along the tubing.

For a comprehensive list of nursing activities to help you meet the preceding goals,

Go to Chapter 28, **Clinical Insight 28-1: Caring for a Patient With an Indwelling Catheter,** in Volume 2.

Bladder Irrigation

You may perform an irrigation to maintain patency of a urinary catheter, to wash out the bladder (e.g., remove blood clots in the bladder after surgery), or to instill medications into the bladder. An intermittent irrigation is most commonly used for medication instillation, whereas a continuous irrigation is used to maintain patency when blood, clots, or debris is anticipated. Routine intermittent irrigations (e.g., every shift, every week) are sometimes prescribed to ensure patency; however, these have not shown any benefit in preventing catheter blockage and should be avoided (WOCN, 2009).

A client requiring a continuous irrigation should have a triple-lumen catheter in place: one lumen for injecting water into the balloon when the catheter is inserted, another for the irrigating solution to flow into the bladder, and a third for the solution and urine to flow out of the bladder.

A double-lumen catheter system may need to be opened for irrigation and therefore creates a high risk for infection. Although "open" irrigation was used in the past, it is no longer recommended.

The Highlights of Procedures box provides overviews of bladder irrigation. For complete procedures,

Go to Chapter 28, **Procedure 28-7A: Intermittent Bladder or Catheter Irrigation,** and **Procedure 28-7B: Continuous Bladder Irrigation,** in Volume 2.

Removing an Indwelling Catheter

Removing a urinary catheter is a simple task, but you must monitor patients carefully afterward. Gather the necessary supplies, and tell the patient what you are about to do, what she will feel, and that you will need to monitor her urination after removal. Explain that this procedure is usually painless.

Cleaning around the meatus and perineum is mandatory prior to removing the indwelling urinary catheter. After removing the catheter, ask the patient to notify you the first time she voids. Note and record the time and amount of the first voiding and the appearance of the urine. Compare the patient's intake to output for the next 8 to 12 hours, and palpate the bladder for distention. A portable bladder scanner may also be used to quantify the amount of any retained urine. The catheter may have caused some edema of the urethra, which can interfere with voiding at first. Therefore, you must assess regularly for bladder distention until normal voiding is reestablished. The same is true for patients who have had rectal, perineal, or lower abdominal surgery, which may also create perineal edema.

If a catheter is in place for several weeks and the urine has been draining continuously, the bladder does not stretch and contract as it does in normal voiding. Therefore, the muscle loses tone and the patient may require bladder retraining. Agencies have differing procedures for this. One method is to begin clamping the catheter for certain periods of time (e.g., 1 to 4 hours) to allow the bladder to fill, and then releasing the clamp to allow urine to drain from the bladder. This should stimulate the bladder muscle and improve tone. However, there is limited evidence to support a practice guideline for clamping the catheter before discontinuing it (Hadwen, 2011).

For hospitalized patients who have had a urinary catheter for a short time, it may be a good idea to time catheter removal for late at night instead of in the morning. A review of research found that when this was done, patients (on average) held urine in the bladder for a longer period of time before voiding in the morning. This led to a larger volume for the first void after the catheter was discontinued. Patients with late-night catheter removal were discharged sooner and without needing to have the urinary catheter reinserted for urine retention (Griffiths & Fernandez, 2009).

For guidelines to follow when removing a retention catheter,

Go to Chapter 28, **Procedure 28-6: Removing an Indwelling Catheter,** in Volume 2.

KnowledgeCheck 28-8

- What actions should you take before inserting a catheter?
- When caring for a client with an indwelling catheter, you notice sandy particles around the urethral meatus. What should you do?
- How often should the urine collection bag be emptied?

ThinkLike a Nurse 28-7

- You are caring for a patient who had an indwelling catheter removed 12 hours ago. The patient has not voided. What action should you take?

Interventions for Example Problem: Urinary Incontinence

Because urinary incontinence is so prevalent, you are likely to be called on to deal with this problem in your practice. Most incontinence is managed with skin care and behavioral interventions, but medications are sometimes used.

Perineal Skin Care

Normal urine is acidic. When it remains in contact with the skin, it becomes alkaline, causing dermatitis and skin excoriation. It is essential to keep the skin, clothing, and bedding clean and dry, especially after any leakage of urine. Commercially prepared perineal cleansers contain a surfactant that loosens soiling on the skin. This reduces the need for more aggressive cleansing with washcloths and tap water. Many of these preparations also do not require rinsing. Barrier creams may be used for irritated skin; antifungals may be prescribed (e.g., nystatin [Mycostatin]) to prevent or eliminate fungus growth. You may use absorbent products as an adjunct to other control measures, especially for those with intractable UI.

Behavioral Interventions

Nurses have taken the lead in investigating incontinence and treatment options. Aggressive nursing intervention can help to improve patients' quality of life, capacity for physical activity, and self-esteem. It can also help to reduce healthcare costs for the patient.

There are five categories of nonpharmacological treatment options nurses commonly provide independently: lifestyle modification, bladder training, pelvic floor muscle rehabilitation, anti-incontinence devices, and supportive interventions (Schröder, Abrams, Andersson, et al., 2009). These therapies have been proven to be effective for most patients.

Lifestyle Modification

Changes in lifestyle that can reduce incontinence. Some patients find improvement when limiting consumption of caffeine, cigarette, alcohol, and spicy and citrus foods that irritate the bladder. Timing prescribed diuretics in the morning, engaging in low impact exercise (not high impact), and avoiding constipation also improves urinary control. People with a BMI greater than 30 who suffer urinary incontinence may consider losing weight to control symptoms.

Bladder Training

The goal of bladder training is to enable the patient to hold increasingly greater volumes of urine in the bladder and to increase the interval between voidings. This involves patient teaching, scheduled voiding, and self-monitoring using a voiding diary. In addition to teaching the mechanisms of urination, teach distraction and relaxation strategies to help inhibit the urge to void. Other techniques include deep breathing and guided imagery.

Scheduled Voiding

This is a form of bladder training involving timed voiding and habit retraining. The client must be mentally and physically capable of self-toileting. Initially the patient may be scheduled to attempt voiding every 2 hours or even more often. As a pattern develops and the person gains greater control, the length of time between voiding may be increased. Scheduled voiding is usually combined with other techniques, including lifestyle adjustments and pelvic muscle exercises.

For detailed instructions for improving urinary control (e.g., bladder training, scheduled voiding, and pelvic floor muscle rehabilitation),

Go to **Clinical Insight 28-2: Caring for Patients With Urinary Incontinence,** in Volume 2.

Pelvic Floor Muscle Rehabilitation

Pelvic floor muscle exercises (PFMEs), also known as Kegel exercises, are a mainstay of UI treatment for women. PFMEs strengthen perineal muscles and help to prevent and treat stress, urge, and mixed UI. PFMEs are the most commonly used method for preventing and reversing incontinence in women for the first year after giving birth. This approach may also prevent or reduce urinary incontinence in older women and in men undergoing prostate surgery. To be successful, the patient must do the exercises correctly and practice them daily. PFMEs should include 10–15 contractions three times a day. A period of 2 to 3 months may be required before treatment is effective (Herbruck, 2008; Price, Dawood, & Jackson, 2010).

Vaginal Weight Training

Vaginal weight training may be used as an adjunct to PFMEs. A small, weighted cone is placed in the vagina and the patient is instructed to attempt to retain the weight for 15 minutes while ambulatory. This method, however, has not shown better outcomes than performing standard PFMEs (Gameiro, Moreira, Gameiro, et al., 2010).

Biofeedback

Biofeedback has been advocated by some women as an adjunct to PFMEs. Electrodes attached to the skin on the perineum provide feedback to the patient about the perineal contraction.

Supportive Interventions

Supportive interventions focus on helping the patient reach the toilet, urinate independently, and perform toileting self-care. When continence cannot be achieved, absorbent products with waterproof coverings are available. Under no circumstances should you refer to these as "diapers." To do so is disrespectful of the patient's dignity.

Key Point: ***Reassure the patient that urinary incontinence is not inevitable or shameful and that it can usually be treated effectively.***

ThinkLike a Nurse 28-8

How do you feel about instructing patients about pelvic floor muscle exercises? Do you think a woman should always provide this instruction? Explain your thinking.

Anti-incontinence Devices

Anti-incontinence devices are designed to reduce the incidence of UI or provide a pathway for urine flow. When anti-incontinence devices are used, it is important to observe for vaginal or urinary tract infection, blood in the urine, and vaginal erosion. The devices include the following:

- **An intravaginal support device** or **pessary** is a removable device inserted into the vagina. It is designed to relieve pressure of the pelvic organs on the urethra and is an effective treatment for stress incontinence. When used long term, monitor for vaginal infection and ulceration.
- An **external occlusive device** is removed before voiding. For women, a urethral meatus covering is used. For men, a penis clamp is a reusable, soft spongy rubber device used to control stress incontinence or dribbling urine, common with an enlarged prostate.
- An **internal urethral meatus plug** is a disposable, single-use device, typically used for activities that cause stress incontinence. It may be used by men and women.
- A **valved catheter** allows urine to be drained on a schedule.
- An **indwelling urethral catheter** is used as a last resort to control the flow of urine and protect the perineal skin. **Self-intermittent catheterization** can be used to drain the bladder and prevent leakage of urine, especially for those with overflow incontinence.
- A **bed alarm** can be used to wake the patient if incontinence occurs.
- An **external collection device** may also be used. Condom catheters, also known as urosheaths, are most commonly used for men who have adequate bladder emptying and intact genital skin. To learn how to apply a condom catheter, see the Highlights of Procedures box for a summary of the procedure. Also,

Go to Chapter 28, **Procedure 28-5: Applying an External (Condom) Catheter,** in Volume 2.

Complementary Alternative Methods

There are no alternative methods that have been proven to cure urinary incontinence; although some treatments show promise in reducing the symptoms (e.g., acupuncture and biofeedback). Several small-scale studies have indicated that acupuncture may be effective in relieving symptoms in urge and mixed incontinence (Engberg, Cohen, & Sereika, 2009; O'Dell & McGee, 2006). A *sacral nerve stimulator* is an electronic device used for patients who do not respond to behavioral treatment or medication for urge incontinence. The lead wire is placed near the sacral nerve and acts like a bladder pacemaker for better urinary control.

Managing Enuresis

Occasional wetting (called *enuresis*) is entirely normal in children even in the early school years, especially when the child is intensely involved in a game, test, or another absorbing activity, or when restricted from using the toilet. Parents should accept such events calmly and not punish the child (see Home Care: Managing Enuresis in Children).

Children, especially older ones, can be embarrassed by *nocturnal enuresis,* or bedwetting, not to mention the inconvenience it poses. Young children may feel anxious about using the bathroom in a clinic, hospital, or any unfamiliar environment. They may be especially anxious about using a bedpan. Also, be aware that the stress of an illness or hospitalization may cause a child to regress in his ability to toilet independently. You may need to schedule regular trips to the bathroom and to watch for nonverbal cues that the child needs to void.

ThinkLike a Nurse 28-9

What treatment options for incontinence have you seen used in your clinical experience? What options do you believe should be used more frequently? Less frequently? Explain your thinking.

Treatments for Urinary Incontinence

Behavioral interventions, such as timed voiding and pelvic floor muscle training, also known as Kegel exercises, are the first-line management options for urinary incontinence. Pelvic floor muscle exercises

Home Care

Managing Enuresis in Children

- Reassure parents that in most cases loving acceptance and passage of time provide the cure.
- Cover the mattress with plastic.
- Limit fluid intake in the evening.
- Wake the child to urinate just before the parents go to sleep.
- Use a bed alarm that wakens the child when wetting occurs. Over time, this conditioning may be effective; however, once the alarm is removed, the child may relapse into enuresis.
- If bedwetting persists into the school-age years, the child should receive a thorough medical evaluation to rule out underlying disease processes.
- Parents should plan to bathe the child in the morning rather than at bedtime to minimize urine odor.
- Medication can be effective for managing nocturnal enuresis in some children. Medication is helpful when the child is not sleeping at home.

(PFME) should be continued for at least 3 months before moving to more aggressive treatment. The following medical and surgical treatments may be used to manage UI:

- *Medications*. Although not the treatment of choice, some forms of incontinence may respond to pharmacological treatment (e.g., drugs to improve urethral sphincter muscle functioning or to relax the detrusor muscle and increase bladder capacity). Medications include topical estrogen for women who have UI associated with urogenital atrophy, and anticholinergic drugs such as oxybutynin (Ditropan) and tolterodine (Detrol), which inhibit involuntary bladder contractions.
- *Devices*. Indwelling intravaginal devices, such as pessaries, may be useful for some women with pelvic organ prolapse in reducing urinary incontinence (Herbruck, 2008). Intraurethral devices to manage incontinence are not used routinely, but instead reserved to prevent occasional leakage, for example, during exercise.
- *Sacral nerve stimulation* might be recommended for the treatment of urge incontinence in women who have not responded to conservative treatment.
- *Surgical treatment*, such as a creating a sling of muscle and tissue that holds the bladder and uterus and other pelvic organs in place to relieve the pressure that can cause discomfort and incontinence. Other surgical options include enlarging the bladder size and improving the muscular capacity for bladder emptying. However, this surgery is reserved for those who do not respond to other bladder therapies, medication, or self-catheterization.

Key Point: ***Do not use absorbent products, handheld urinals, and other toileting aids to routinely manage urinary incontinence, unless used to supplement other therapy.***

For more information about helping patients to manage urinary incontinence,

Go to Chapter 28, **Clinical Insight 28-2: Caring for Patients With Urinary Incontinence,** in Volume 2.

Caring for Patients With a Urinary Diversion

A **urinary diversion**, or **urostomy**, is a surgically created opening for elimination of urine, required when the bladder must be removed or bypassed. Diversion surgeries are used to treat patients who have conditions such as birth defects, cancer, trauma, or disease of the urinary system. Risks associated with urinary diversions are primarily infection and permanent kidney damage, which can occur from *hydronephrosis* (distention of the kidneys with urine, which results from obstruction of the ureter).

What Are the Types of Urinary Diversions?

There are four major diversion options, following:

- **Cutaneous ureterostomy.** This surgery reroutes the ureter(s) directly to the surface of the abdomen, forming a small stoma. It may be unilateral or bilateral. The procedure has limited use because it provides a pathway for pathogens on the skin to directly enter the kidney. The stomas are small and difficult to fit with a collection appliance.
- **Conventional urostomy (ileal conduit, Bricker's loop, ileal loop).** This is the most common type of urinary diversion (Fig. 28-9). A small piece of ileum is removed with blood and nerve supply intact. The remainder of the ileum is reconnected to prevent disruption of flow through the bowel. The free segment of ileum is sutured closed at one end, and the other end is brought out to the abdominal wall to create a stoma. The result is a small pouch into which the ureters are implanted. Urine, along with mucus from the ileum, drains continuously from the stoma and is collected in a pouch that the patient wears.
- **Continent Urinary Reservoir (ileal reservoir, Indiana pouch).** A continent urinary reservoir (Fig. 28-10) is a variation of the ileal conduit. Urine drains from the ureters into a surgically created ileal pouch. The stoma created on the abdomen contains a nipple valve to keep urine from leaking. Rather than having urine flow constantly, the patient inserts a catheter into the stoma to drain urine through the valve. A second valve prevents reflux of urine back into the kidneys.
- **Neobladder.** A neobladder mimics the function of a urinary bladder. A portion of intestine is made into a pouch or reservoir that is connected to the urethra. Urine is then passed through the urethra, similar to the normal passage of urine. The patient will need to void by bearing down or applying manual pressure over the bladder (Credé's maneuver), but may also need to perform intermittent self-catheterization to fully empty the bladder.

Think**Like a Nurse** 28-10

What types of challenges or problems do you think a patient with a urinary diversion might experience?

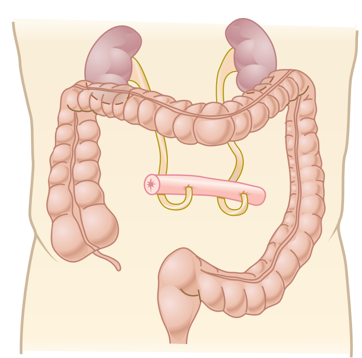

FIGURE 28-9 An ileal conduit is the most common urinary diversion.

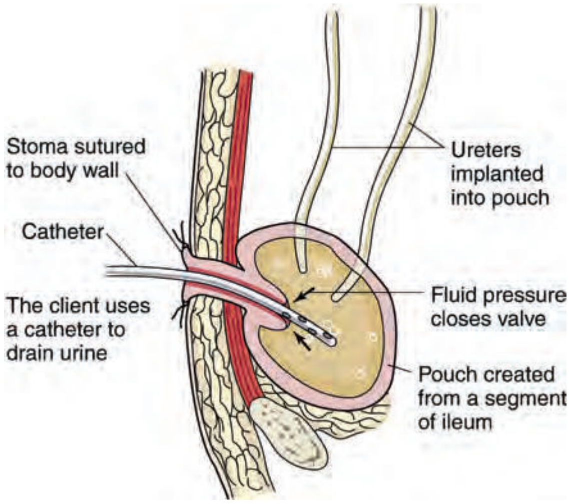

FIGURE 28-10 A continent urostomy allows the client to manage urine without the need to wear an ostomy appliance.

Interventions for Patients With Urinary Diversions

A patient with a urinary diversion requires physical and psychological care. Initially you may need to assist the patient with all aspects of his care. However, the goal is for the patient to become comfortable with his changed body and to assume self-care.

Patients with a stoma experience a variety of reactions. Patients with continent urinary reservoirs are usually more comfortable with their stoma because of the control it offers while avoiding the embarrassment, odor, and inconvenience of a conventional urostomy. Your attitude and willingness to discuss the body changes associated with an ostomy will help your patient begin his adjustment. In many communities, the local ostomy association has counselors available to visit patients, discuss the psychological changes associated with a urinary diversion, and help them with physical care of the stoma. Most counselors are adept because they too have ostomies. They are able to share practical and personal information with patients based on their own experience with similar challenges.

For guidelines specifically for caring for a patient with a urinary diversion,

Go to Chapter 28, **Clinical Insight 28-3: Caring for Patients With Urinary Diversions; Clinical Insight 28-4: Teaching Clients About Clean, Intermittent Self-Catheterization; and Procedure 29-6: Changing an Ostomy Appliance,** in Volume 2.

Patients With Neobladder or Continent Urinary Reservoir Continent urinary reservoir patients will also need instruction in inserting a catheter through the stoma to release the urine. Patients with a neobladder will need to learn to void by bearing down or applying manual pressure over the bladder, but may also need to learn clean intermittent self-catheterization.

Nursing Care Plan

Client Data

Desmond Washington, a 69-year-old man, comes to the clinic 4 weeks after having a prostatectomy for prostate cancer. He was discharged from the hospital on postoperative day 4 and went home with an indwelling urinary catheter. The catheter was removed at his last visit, 9 days after surgery.

Mr. Washington is meticulously groomed. He is friendly, greeting other patients in the clinic and chatting with the clinic personnel. When his nurse brings him to an exam room and asks how he feels, he says, "I saw the sun come up today. I appreciate that more now. The good Lord has given me a new lease on life, and I intend to use it!" His nurse continues, "That's great, Mr. Washington. How have you been doing since the catheter was removed?" Mr. Washington's smile fades. He lowers his voice and says, "You know, I think that's the worst part of this whole thing. I hate wearing these diapers—they make me feel, well, like an old man. I'm certainly not ready for this."

The nurse continues, "Do you have *any* control of your urine?" Mr. Washington explains, "I may go for hours and stay dry, and then it seems for no reason, I wet myself. Take yesterday, for example. I was sitting on the sofa watching the ball game when someone came to the door. I got up to answer the door, and all of a sudden, I felt wet. I didn't even have anything to drink so I could make it through the afternoon and stay dry. And if I cough? Forget it. Can something be done so I can hold my urine again?"

Nursing Diagnosis

Stress Urinary Incontinence related to disruption of the urinary sphincter and related pelvic muscles by surgery as evidenced by client report of involuntary loss of urine with increased intra-abdominal pressure.

NOC Outcomes	Individualized Goals/Expected Outcomes
Urinary Continence (0502) Urinary Elimination (0503)	*By the next visit, Mr. Washington will:* 1. Describe three things he can do that will help regain urinary continence. 2. Explain three interventions to cope with leaked urine. 3. Report that he is drinking adequate amounts of fluids during the day.

Nursing Interventions and Activities	Rationale
NIC Interventions Urinary Elimination Management (0590) Urinary Incontinence Care (0610)	
Nursing Activities	
1. Obtain midstream voided urine specimen for urinalysis.	Urinary tract infection can cause or worsen incontinence (Goode, Burgio, Richter, et al., 2010; Joseph, 2006).
2. Identify factors that contribute to Mr. Washington's incontinence by using an incontinence diary.	Identifying activities or other factors that cause loss of urine control can guide specific interventions. A diary facilitates monitoring over time and can identify patterns that could otherwise be missed (Rainsbury, Fabricius, & McLarty, 2011; Robinson, 2006; Shultz, 2012).

Nursing Care Plan (continued)

Nursing Interventions and Activities	Rationale
3. Teach pelvic floor muscle exercises (PFMEs).	PFMEs strengthen pelvic muscles and enhance sphincter control. They have been shown in some studies to increase urinary continence without side effects in men who have undergone prostatectomy (Glazener, Boachie, Buckley, et al., 2011; Rainsbury Fabricius, & McLarty, 2011; Sighinolfi, Rivalta, Mofferdin, et al., 2009; Van Kampen, De Weerdt, Van Poppel, et al., 2000; Vaughan, Goode, Burgio, et al., 2011).
4. Use biofeedback when needed in conjunction with PFME training to help Mr. Washington isolate pelvic floor muscles.	Biofeedback allows clients to receive auditory or visual (or both) cues when the proper muscles are contracted, so they learn what the proper muscle contraction feels like. Biofeedback also allows the nurse or therapist to objectively measure strength of contractions (Campbell, Glazener, Hunter, et al., 2012; Herderschee, Hay-Smith, Herbison, et al., 2011; Robinson, 2006).
5. Teach timed voiding. Have Mr. Washington void on a schedule of every 2 hours.	Voiding on a schedule of every 2 hours can reduce the amount of urine in the bladder, thus reducing the likelihood of leakage with activities of daily living (Shultz, 2012).
6. Explain the need to drink adequate fluids and *not* limit fluids in an effort to prevent incontinence. Help Mr. Washington identify ways to drink a minimum of 1,500–2,000 mL/day.	Adequate fluid intake is important to maintain dilute urine, which is less irritating to the bladder; to maintain systemic hydration; and to reduce the risk for constipation, which can contribute to urinary incontinence (Rainsbury, Fabricius, & McLarty, 2011; Robinson, 2006).
7. Assist the client in selecting appropriate absorbent products that collect urine strictly for temporary management while continence management is ongoing.	Proper absorbent garments and pads can collect and trap urine, keep skin clean and dry, reduce odor, and minimize the risk of soiling accidents (National Institute for Health and Clinical Excellence, 2013; Robinson, 2006).
8. Help the client develop a personal hygiene routine that will maintain skin integrity.	Proper hygiene will reduce the risk of skin irritation and infection. Use warm (not hot) water, and pat (don't scrub) the perineal area. A barrier cream will repel fluid and protect the skin from urine.
9. Offer referral to a support group.	Support groups provide a sense of community and enhance problem-solving skills of members. Mr. Washington may feel less embarrassment when he discovers that others share his problems (Robinson, 2006).
10. Explain that urinary incontinence is common after prostatectomy, but that it may be only temporary.	Urinary incontinence can be a troubling complication of prostatectomy for many men. Fortunately, it often resolves within 6 to 12 months after surgery (Yu Ko & Sawatzky, 2008).

There are other treatment recommendations that are supported by research or have been identified anecdotally to be useful for some clients (WOCN, 2003). These include reducing caffeine consumption; eliminating bladder irritants, such as artificial sweeteners, spicy foods, and citrus from the diet; losing weight; and quitting smoking. In addition, it is important for nurses to understand the pathophysiology of urinary incontinence differs between men and women and that interventions that are successful in women may or may not be equally successful in men.

(continued)

Nursing Care Plan (continued)

Evaluation

At the end of the visit, Mr. Washington said, "I didn't know there were things I could do about the leaking urine. Before surgery, all I cared about was getting rid of the cancer. I don't need a support group for me but maybe I'll lead one!" Mr. Washington had been placing folded paper towels in his underwear to collect urine because he thought absorbent products were too expensive, but with guidance from his nurse he identified products he could afford. He liked that they would not be visible through his clothing.

At Mr. Washington's next visit, the nurse will review the initial collaborative goals and stated outcomes and perform a client assessment to determine whether the goals were reached in the stated time frame.

Mr. Washington currently has a positive attitude and is focused on "beating" his cancer first and on managing complications of surgery second. As time passes, incontinence may persist and may become more frustrating for him once he is fully recovered from surgery. Mr. Washington initially declined referral to a support group, but he may be more interested in joining one in the future for help dealing with long-term consequences of prostatectomy.

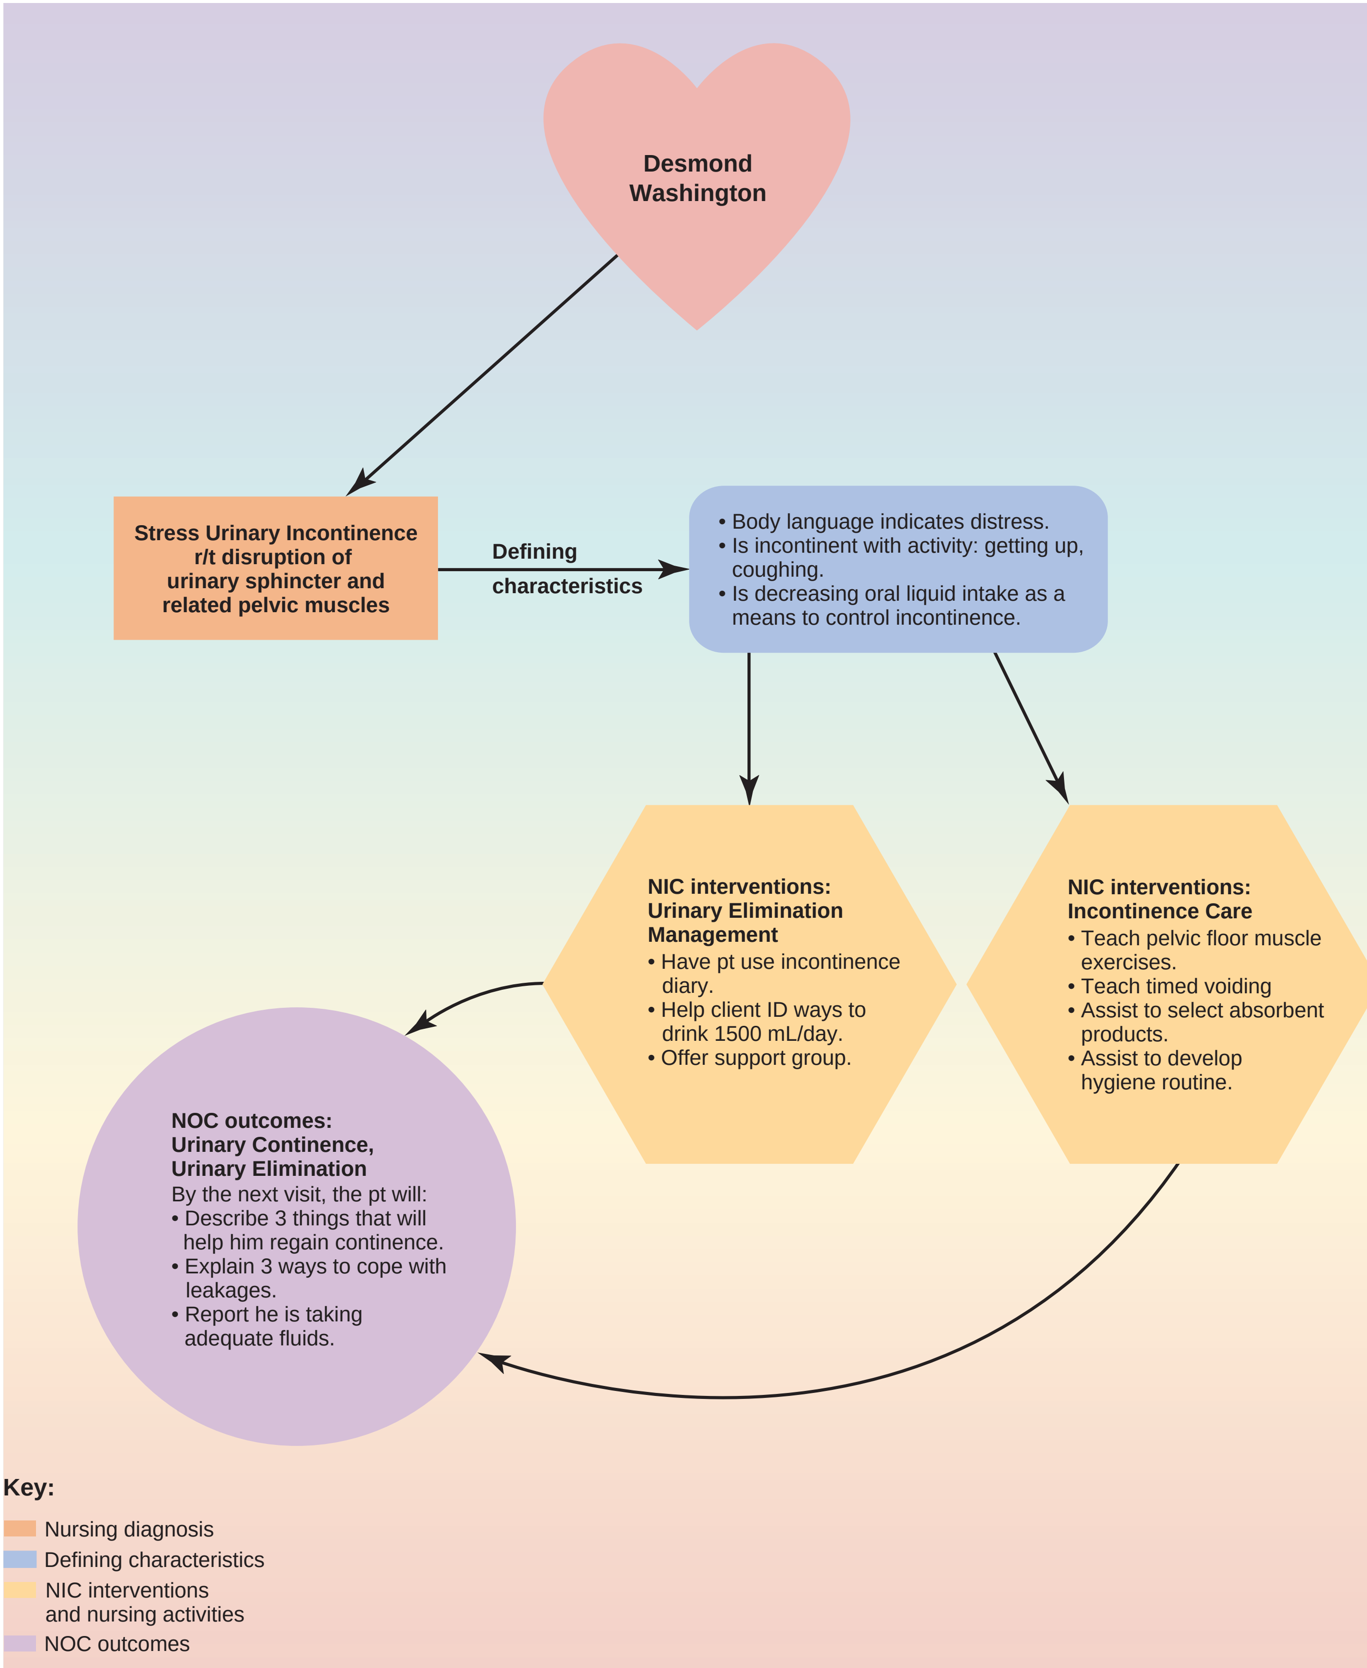
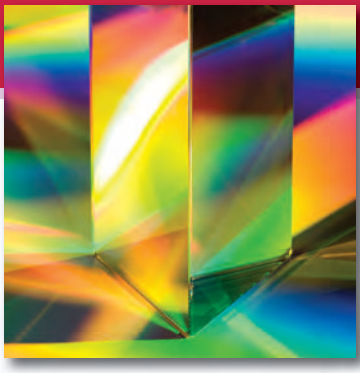
Care Map



Desmond Washington
Stress Urinary Incontinence r/t disruption of urinary sphincter and related pelvic muscles
Defining characteristics
• Body language indicates distress.
• Is incontinent with activity: getting up, coughing.
• Is decreasing oral liquid intake as a means to control incontinence.
NIC interventions: Urinary Elimination Management
• Have pt use incontinence diary.
• Help client ID ways to drink 1500 mL/day.
• Offer support group.
NIC interventions: Incontinence Care
• Teach pelvic floor muscle exercises.
• Teach timed voiding
• Assist to select absorbent products.
• Assist to develop hygiene routine.
NOC outcomes: Urinary Continence, Urinary Elimination
By the next visit, the pt will:
• Describe 3 things that will help him regain continence.
• Explain 3 ways to cope with leakages.
• Report he is taking adequate fluids.
Key:
Nursing diagnosis
Defining characteristics
NIC interventions and nursing activities
NOC outcomes

CHAPTER 29



Bowel Elimination

Learning Outcomes

After completing this chapter, you should be able to:

- Identify the basic structures and functions of the gastrointestinal system.
- Discuss factors that affect bowel elimination.
- Describe normal bowel elimination.
- Differentiate among the various types of bowel diversions.
- Discuss common bowel elimination problems.
- Identify appropriate nursing history questions to assess bowel elimination problems.
- Perform a physical examination focused on bowel elimination.
- List and describe diagnostic tests used to identify bowel elimination problems.
- Formulate nursing diagnoses associated with altered bowel elimination.
- Describe nursing interventions that promote normal bowel elimination.
- Provide care for clients experiencing alterations in bowel elimination.
- Discuss nursing care associated with the use of bowel diversions.

Key Concepts

Bowel elimination

Motility

Related Concepts

See the Concept Map on Davis*Plus*.

Example Problems

Bowel incontinence

Constipation and impaction

Diarrhea

Meet Your Patient

You are assigned to care for Mrs. Zeno, a frail 96-year-old woman who broke her hip last month after a fall at home. Mrs. Zeno was hospitalized for surgical repair of her hip and is now in a skilled nursing facility (SNF) for rehabilitation. The nursing assistive personnel (NAP) informs you that Mrs. Zeno has eaten poorly for the past week, only picking at the food on her meal trays and refusing the protein supplements that were added to her diet. Mrs. Zeno tells you she would like to go home: "I have my routine and the foods I like. I think I'd be better there." As you review the chart in preparation for clinical, you note that she has not had a bowel movement (BM) for 3 days. Her last BM was small and very hard.

What additional assessments should you perform? What, if anything, is of concern about her bowel pattern? What actions should you take with Mrs. Zeno?

In this chapter, you will gain theoretical and practical knowledge to help you answer those questions and provide care for clients with bowel elimination concerns.

Theoretical Knowledge knowing why

Bowel elimination is a normal process by which we eliminate waste products from our bodies. In this chapter you will come to understand concepts underlying the function of the gastrointestinal tract as well as factors that affect bowel elimination.

ABOUT THE KEY CONCEPTS

Bowel elimination is one of the overarching concepts in this chapter—the "hook" on which you hang your theoretical knowledge. The other key concept, **motility**, helps you to understand how normal elimination occurs and what changes take place in problems such as constipation and diarrhea. Other, more specific, concepts will flesh out your understanding of bowel elimination. For example, when you grasp the concept of bowel diversion, you will how it relates to various bowel elimination problems. As you study the chapter, identify the concepts and try to understand how they are connected. This will help you to care for clients with any medical diagnosis affecting bowel elimination.

WHAT ARE THE ANATOMICAL STRUCTURES OF THE GASTROINTESTINAL TRACT?

The gastrointestinal (GI) tract is a smooth-muscle tube approximately 10 m (30 ft) long, running through the body from the mouth to the anus. Its major functions are to digest and absorb the nutrients present in food and to eliminate food waste products as feces. The structures of the GI tract are the mouth, pharynx, esophagus, stomach, small intestine, large intestine, rectum, and anus (Fig. 29-1).

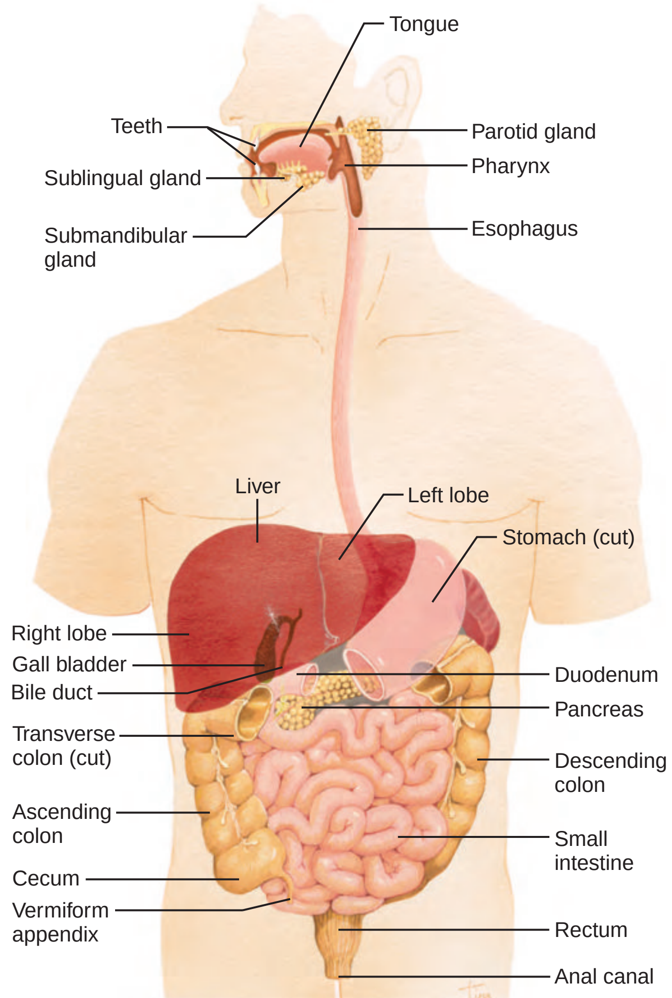


FIGURE 29-1 The gastrointestinal tract extends from the mouth to the anus. The major functions of the GI system are to digest and absorb the nutrients in food and to eliminate food waste products as feces. (*Source:* Scanlon, V., & Sanders, T. (2010). *Essentials of anatomy and physiology* (6th ed., p. 371). Philadelphia: F. A. Davis. Used with permission.)

The Upper Gastrointestinal Tract

The upper part of the GI tract consists of the mouth, pharynx, esophagus, and stomach.

Mouth Mechanical digestion begins in the mouth with **mastication**, or chewing. Food is torn into small pieces, mashed, moistened with saliva, formed into a bolus, and then swallowed into the esophagus. Glands in the mouth secrete enzymes, such as ptyalin and salivary amylase, which begin the digestion of carbohydrates.

Pharynx The pharynx is the back part of the throat where food and air pass after chewing. To prevent choking and aspiration, a flap of connective tissue, called the **epiglottis**, closes over the trachea when food is swallowed.

Esophagus The esophagus is a tube of smooth muscle, which alternately contracts and relaxes in waves of **peristalsis** to push the bolus toward the stomach. The bolus travels the length of the esophagus (about 25 cm, or 10 in.) in about 15 seconds. The *cardiac sphincter* (also called the *gastroesophageal sphincter*) relaxes to allow food to pass into the stomach. When the cardiac sphincter constricts, it prevents acidic stomach contents from flowing back into the esophagus.

The Stomach The stomach is a distensible sac that extends from the esophagus to the small intestine. The stomach stores food while it churns and mixes it, providing further mechanical breakdown. Chemical digestion continues in the stomach, which secretes hydrochloric acid (HCl), a protein-digesting enzyme called *pepsin;* and *gastric lipase*, an enzyme that begins the digestion of lipids. The stomach lining also secretes a mucous coating that protects the stomach from being corroded by HCl. Food remains in the stomach an average of 4 hours. It leaves the stomach and enters the small intestine as a liquid, called **chyme**.

The Small Intestine

The small intestine is a folded, twisted, and coiled tube that connects the stomach and the large intestine. About 2.5 cm (1 in.) in diameter and approximately 6 m (20 ft) long if fully extended, it occupies most of the abdominal cavity. Most digestion and absorption of food occurs in the small intestine. Chyme travels through it slowly, by peristalsis; peristalsis halts periodically to allow for absorption. The small intestine consists of three segments: the duodenum, jejunum, and ileum.

- The **duodenum** is the first section of the small intestine. It is a C-shaped tube that branches off from the stomach, about 30 to 60 cm (1 to 2 ft) long. The duodenum processes chyme by mixing it and adding enzymes. The bile duct and main pancreatic duct both enter the small intestine at the level of the duodenum, providing bile from the liver and gallbladder to digest lipids and pancreatic enzymes to digest lipids, proteins, and carbohydrates.
- The **jejunum** is the coiled midsection of the small intestine. It is about 1.8 to 2.4 m (6 to 8 ft) long and forms the connection between the duodenum and ileum. Its major function is to absorb carbohydrates and proteins.
- The **ileum** joins the small and large intestine. It is responsible for absorption of fats; bile salts; and some vitamins, minerals, and water. However, nutrients are absorbed mainly in the duodenum and jejunum.

As mentioned previously, the total length of the small intestine, if it were stretched out, is approximately 6 m (20 ft), but in the body it is much shorter because it is folded to provide a vast surface area for absorption. The inner wall of the small intestine is covered by millions of tiny finger-like projections called **villi** (Fig. 29-2). The villi are covered with even tinier projections, called **microvilli**. The combination of folds, villi, and microvilli increases the surface area of the small intestine greatly, facilitating absorption of nutrients.

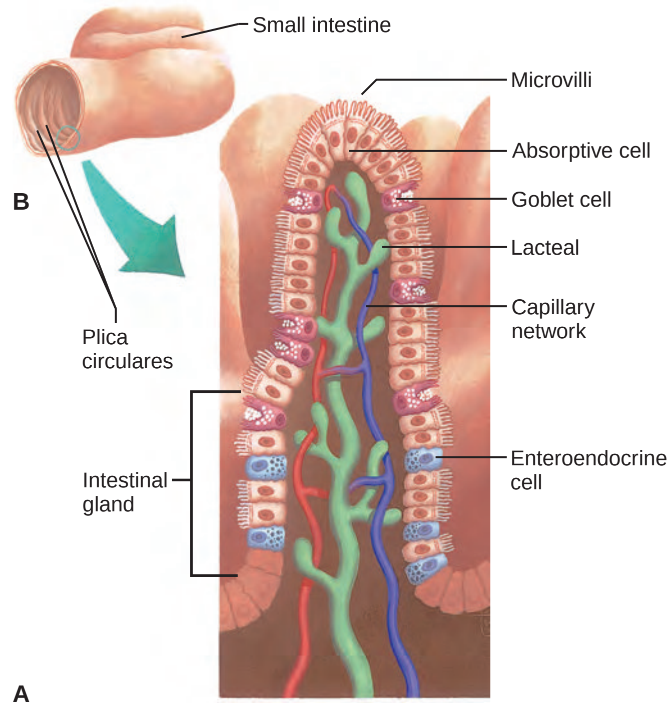

FIGURE 29-2 The small intestine is highly folded, providing a vast surface area for absorption of nutrients. The microvilli form a brush border, which is the site of most nutrient absorption. *A*, Section through the small intestine showing the plica circulares (circular folds) of the mucosa and submucosa. *B*, Microscopic view of a villus showing the internal structure. (*Source:* Scanlon, V., & Sanders, T. (2010). *Essentials of anatomy and physiology* (6th ed., p. 383). Philadelphia: F. A. Davis. Used with permission.)

The Large Intestine

The **large intestine**, also known as the **colon**, is larger in diameter than the small intestine (6.3 cm, or 2.5 in.) but shorter in length—about 1.5 to 1.8 m (5 to 6 ft). It extends from the ileum of the small intestine to the anus. It contains seven segments: the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anus (Fig. 29-3).

Undigested food entering the first portion of the large intestine, the **cecum**, consists mostly of cellulose and water. The connection of the ileum to the cecum is controlled by the **ileocecal valve**. Under most conditions, the valve prevents backflow of chyme from the colon into the small intestine. The **appendix** is a small, finger-like appendage off the cecum. It is believed to be a **vestigial organ**—one whose significance has diminished over time—however, it is lined with lymphatic tissue and may play a role in immune function.

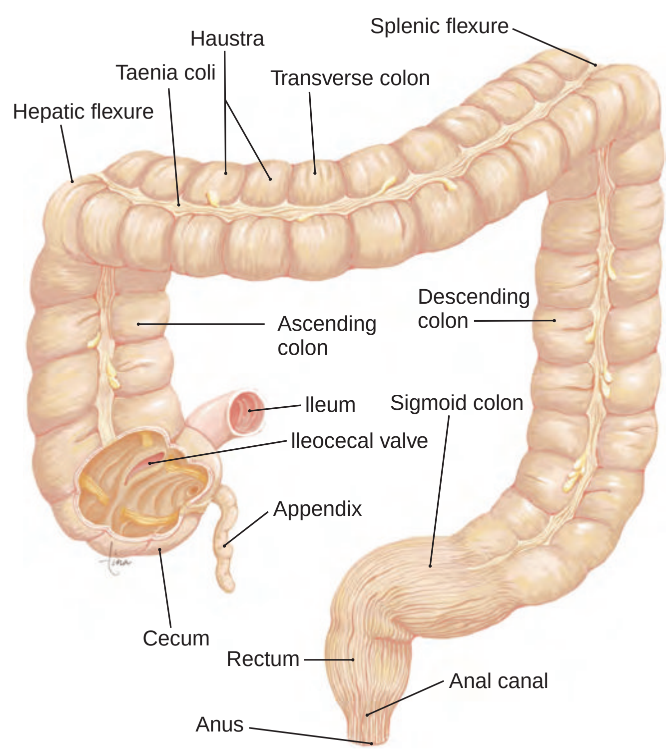

FIGURE 29-3 The large intestine shown in anterior view. The term *flexure* means a turn or bend. (*Source:* Scanlon, V., & Sanders, T. (2010). *Essentials of anatomy and physiology* (6th ed., p. 385). Philadelphia: F. A. Davis. Used with permission.)

The next three segments, the **ascending**, **transverse**, and **descending colon**, ring the small intestine. The **sigmoid colon** is a final, small segment of bowel that twists medially and downward to connect with the rectum and anus.

The colon secretes mucus, which facilitates smooth passage of stool, and absorbs water, some vitamins, and minerals. Approximately 80% of the fluid that enters the colon is reabsorbed along its passage. Normal flora in the colon aid in the digestive process. These bacteria are responsible for producing vitamin K and several of the B vitamins.

The large intestine has two sets of muscles that give it a puckered appearance. Longitudinal muscles, known as **taenia coli**, run lengthwise along the colon surface. Tension in these muscles gathers up the colon into pouched segments known as **haustra** all along its length (see Fig. 29-3). In addition, the colon wall contains circular muscles that, together with the taenia coli, cause the colon to expand and contract in length and width to achieve haustral churning, peristalsis, and mass peristalsis.

- **Haustral churning** moves digestive contents around within each haustra. This action promotes reabsorption of water.
- **Peristalsis** continues throughout the length of the large intestine, where it propels intestinal contents toward the rectum and anus.
- **Mass peristalsis** is a powerful contraction along a lengthy segment of bowel. It is facilitated by the **gastrocolic reflex**, which is triggered by food entering the stomach and small intestine. Mass movements usually occur only one to three times each day, and they are responsible for most of the propulsion of the contents in the transverse and sigmoid colon.

The Rectum and Anus

The **rectum** is approximately 15 cm (6 in.) long and is continuous with the **anus**, the last 2.5 cm (1 in.) of the colon. A highly vascular folded tube, the rectum is free of waste products until just before defecation.

The anus has two ring-like muscles that function as sphincters. The **internal sphincter** involuntarily relaxes and opens when stool is present in the rectum. The **external sphincter** is under voluntary control. Voluntary relaxation of the external sphincter allows stool to be expelled from the body (Fig. 29-4). The anus is highly vascular. Chronic pressure on the veins within the anal canal, as with prolonged sitting or retained feces, can cause **hemorrhoids** (distended blood vessels within or protruding from the anus).

KnowledgeCheck 29-1

- What are the major functions of the small intestine and large intestine?
- How do the rectum and anus control elimination of feces from the body?

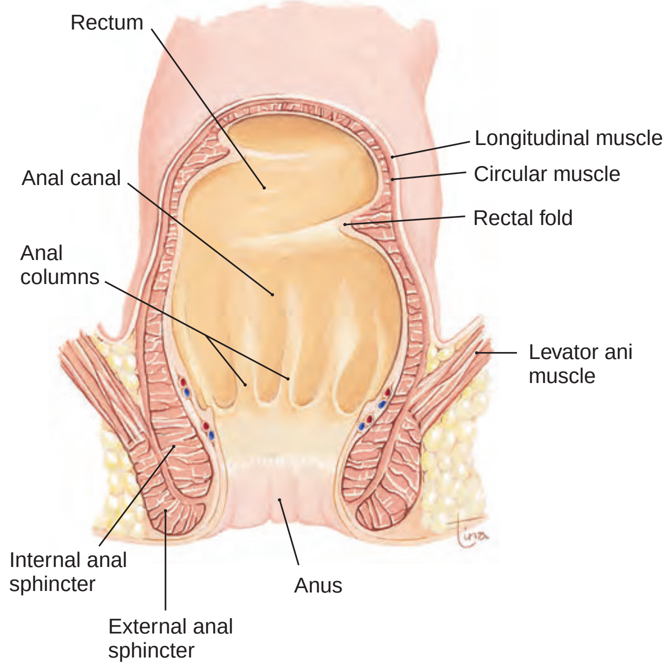

FIGURE 29-4 Internal and external anal sphincters shown in a frontal section through the lower rectum and anal canal. (*Source:* From Scanlon, V., & Sanders, T. (2010). *Essentials of anatomy and physiology* (6th ed., p. 387). Philadelphia: F. A. Davis. Used with permission.)

ThinkLike a Nurse 29-1

Based on your knowledge that hemorrhoids are dilated blood vessels in the anal canal, what symptoms would you expect a patient with hemorrhoids to exhibit?

HOW DOES THE BOWEL ELIMINATE WASTE?

As you have learned, reabsorption of water from chyme in the large intestine results in a semisolid mass known as **feces**. Feces are a mixture of fiber and undigested food, shed epithelial cells, inorganic material (e.g., calcium and phosphates), bacteria, and water. Small amounts of fat may be present. Feces are usually brown because **bile salts**, which aid in the digestion of fat, are excreted in the feces. Bile is normally golden yellow, but the action of bacteria in the GI tract changes the color to brown. Bacteria are also responsible for the odor of feces.

Flatus, or gas, is formed in the digestive process. Some is swallowed air that accompanies the intake of food. A small portion diffuses from blood into the GI tract. However, most of the gas is created by bacterial fermentation in the colon.

The Process of Defecation

The process by which the bowel eliminates waste is called **defecation**. When fecal material reaches the rectum and causes it to distend, (a) stretch receptors are stimulated to start contraction of the sigmoid colon and rectal muscles, and (b) the internal anal sphincter relaxes. At the same time, sensory impulses transmitted to the central nervous system (CNS) produce a conscious urge to defecate. We respond to this signal by voluntarily contracting our diaphragmatic and abdominal muscles to increase downward pressure, while at the same time relaxing the external anal sphincter. These actions allow feces to be propelled through the anus. If we ignore the signal to defecate, the reflexive contractions ease for a few minutes, until mass peristalsis occurs again.

A person can increase the pressure to expel feces by contracting the abdominal muscles (straining) while maintaining a closed airway (e.g., holding the breath). This is called the **Valsalva maneuver**. Although it assists with the passage of stool, you should caution clients with heart disease, glaucoma, increased intracranial pressure, or a new surgical wound to avoid the Valsalva maneuver because it increases pressure within the abdominal cavity, raises blood pressure, and is associated with an increased risk for cardiac arrhythmias.

Normal Defecation Patterns

The sheer volume of over-the-counter (OTC) products to treat "irregularity" suggests that bowel function problems are common. Nevertheless, many people avoid the topic of bowel elimination—it is not typically something they chat about with their neighbors. As a result, many patients have unanswered questions about their bowel function and may turn to you for information.

Part of the confusion about bowel function is that there is a wide range of "normal." The frequency of BMs may range from several times per day to once a week. As long as the person passes stools without excessive urgency (needing to rush to the toilet), with minimal effort and no straining, without blood loss, and without the use of laxatives, you can regard bowel function as normal.

Normally stool is approximately 75% water and 25% solid when expelled. This combination yields a soft, formed semisolid. If passage through the colon is slowed, more water is reabsorbed from the feces. The stool becomes dry and hard, requiring more effort to pass. If transit time through the colon is faster than normal, less water is reabsorbed, and stools are watery.

ThinkLike a Nurse 29-2

- Based on your knowledge of normal bowel function, how would you describe Mrs. Zeno's (Meet Your Patient) bowel function? Is it normal or abnormal?
- What additional information, if any, do you need to know to answer this question?

WHAT FACTORS AFFECT BOWEL ELIMINATION?

Each person develops an elimination pattern that is based on several factors, discussed in the sections immediately following.

Developmental Stage

Bowel elimination patterns change throughout the life span.

Infant During the first few days of life, the term newborn passes meconium through the anus. **Meconium** is green-black, tarry, sticky and odorless. It is formed by swallowed mucus, hair, and amniotic fluid. Stools transition to a yellow-green color over the next few days. After that, the appearance of the feces depends largely on the type of feeding the infant receives. Breastfed babies pass golden yellow stools, whereas formula-fed babies pass tan stools. Initially babies defecate frequently, usually after each feeding—especially when they are breastfeeding. The stools tend to be watery while the large intestine is still immature. Gradually normal flora develop in the colon, and stools become firmer and less frequent.

Children The ability to control defecation typically develops at about 2 to 3 years of age. Toilet training requires neural and muscular control as well as conscious effort. The child must be aware of the urge to defecate, be able to maintain closure of the external anal sphincter while getting to the toilet, and be able to remove clothing. When toddlers become engrossed in play, they sometimes ignore the need to move their bowels, and soiling is common. As children mature, they gradually learn to gain more control. In fact, school-age children and adolescents often delay defecation until they have come home or have completed an activity.

Adults The bowel pattern set in childhood normally continues into late adulthood if the client consumes adequate fiber and fluid and engages in regular physical activity.

However, peristalsis, intestinal smooth muscle tone, perineal muscle tone, and sphincter control normally decrease with aging. These physiological processes can contribute to bowel elimination problems among older adults, especially if they decrease their activity and fiber intake.

Personal and Sociocultural Factors

Privacy is important to most people, as is sufficient time to have a bowel movement without feeling the need to hurry. Clients working in fast-paced jobs may have difficulty even consciously recognizing the need to defecate, and some habitually ignore the need, promoting bowel dysfunction. Parents and caregivers of infants and toddlers may postpone their own toileting needs because of fear of leaving the children alone. Some clients are embarrassed by the thought that anyone might realize they are having a bowel movement and will wait until they are entirely alone before even entering the bathroom.

Have you ever heard the following phrase: "He puts his stress in his gut"? Stress does have a major influence on motility of the GI tract. It may cause diarrhea or constipation, and it is a primary risk factor in the development of *irritable bowel syndrome*, a disorder associated with bloating, pain, and altered bowel function.

Nutrition, Hydration, and Activity Level

Foods and Fiber Regular intake of food promotes peristalsis. People who eat on a regular schedule are likely to develop a regular pattern of defecation, whereas irregular eating creates irregular bowel elimination. Adequate intake of high-fiber promotes peristalsis and defecation. Bulky foods absorb fluids and increase stool mass. The increased mass stretches bowel walls, initiating peristalsis and the defecation reflex. Most people should have at least five servings of high-fiber foods each day.

Some foods have specific effects in the bowel. For example, the active bacteria in yogurt stimulate peristalsis, while at the same time promoting healing of intestinal infections. Low-fiber foods, such as pasta and other simple carbohydrates and lean meats, slow peristalsis. Foods like broccoli, onions, and beans lead to excess gas in many people. Spicy foods may also cause gas, as well as more frequent bowel movements.

Dietary Supplements Dietary supplements can also affect bowel function. For example, calcium supplements may cause constipation, whereas magnesium loosens stools. Supplemental vitamin C softens stools and, in high doses, may cause diarrhea in sensitive clients.

Fluids A minimum of six to eight 8-ounce glasses (1,500 to 2,000 mL) of fluid per day is required to promote healthful bowel function. Inadequate fluid intake or excessive fluid loss, as in diarrhea or vomiting, slows peristalsis and leads to dry, hard stools that are difficult to pass (Fritz & Pitlick, 2012). Excessive fluid intake (especially beverages with high sugar content) may lead to rapid passage through the colon and soft or watery stools. Different types of fluids have varying effects on sensitive individuals. For instance, consuming large amounts of milk may cause constipation in some people. Coffee promotes peristalsis in many clients and may even cause loose stools in sensitive clients.

Activity Physical activity seems to stimulate peristalsis and bowel elimination. In addition, sedentary people are likely to have weaker abdominal muscles. Clients with health concerns that limit activity (e.g., shortness of breath, pain, or required bedrest) often experience constipation.

Medications

Many medications may affect peristalsis. All oral medicines have the potential to affect the function of the GI tract. Examples include the following:

- ***Antacids***, often used for heartburn, neutralize stomach acid but may slow peristalsis.
- ***Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs)***, such as naproxen and ibuprofen, irritate the stomach. Repeated use can lead to ulceration of the stomach or duodenum.
- ***Antibiotics*** given to combat infection decrease the normal flora in the colon. The result is often diarrhea. Bacterial populations can be maintained with supplements of probiotics (e.g., acidophilus) or daily consumption of yogurt (Salfi & Holt, 2012).
- ***Iron***, a common mineral supplement, is available as an over-the-counter (OTC) medication and is often prescribed for the treatment of anemia. Iron has an astringent effect on the bowel and is notorious for causing constipation and changing stool color to black. It also causes nausea if taken when there is no food in the stomach.
- ***Pain medications***, particularly opioids (narcotics), slow peristalsis and are associated with a high incidence of constipation.
- ***Antimotility drugs***, such as diphenoxylate (Lomotil), may be used to treat diarrhea. They work by slowing peristalsis.
- ***Laxatives*** are used to treat constipation. In general, laxatives work by stimulating peristalsis (see Box 29-1). They are frequently abused by people who self-medicate with OTC drugs, who may become dependent on them, requiring ever-increasing dosages until the intestine fails to work properly.

BOX 29-1 ■ Types of Laxatives

- ***Stool softeners*** enable moisture and fat to penetrate the stool, thereby softening it and making it easier to pass. Example: docusate sodium. Effectiveness of stool softeners in relieving chronic constipation is being questioned, but they are still in use.
- ***Osmotic laxatives*** work by drawing water into the bowel from surrounding tissue, resulting in bowel distention. Examples: polyethylene glycol, lactulose.
- ***Lubricant laxatives*** coat the stool and the GI tract with a thin waterproof layer. Example: mineral oil. Because the lubricant coats the entire GI tract, it may interfere with the absorption of nutrients. Mineral oil is potentially dangerous in debilitated patients. Inhaled droplets can lead to a form of pneumonia.
- ***Stimulant laxatives*** are bowel irritants. They irritate the intestinal wall, stimulating intense peristalsis. Examples: senna, bisacodyl, castor oil.
- ***Bulking agents*** are high in fiber. They must be combined with sufficient fluid intake to be effective. The fiber attracts fluid into the colon, and the increased bulk of the stool stimulates the urge to evacuate. These are considered the safest form of laxative, but may interfere with absorption of some medicines. They are the drug of choice for chronic constipation. Examples: Metamucil, Citrucel, psyllium, FiberCon.
- ***Chloride channel activators*** increase intestinal fluid and motility to help stool pass.
- ***Combination laxatives*** are laxatives that contain more than one type of laxative ingredient. The most common type is a combination stimulant laxative and stool softener.

Surgery and Procedures

Clients undergoing anesthesia and surgery often experience sluggish bowel elimination. The delay in bowel elimination may be caused by a variety of circumstances:

Anesthesia General anesthesia (which renders the patient unconscious) and analgesics (administered preoperatively and postoperatively for pain) slow bowel motility. Spinal anesthesia and epidural anesthesia are less likely to cause this effect.

Stress Regardless of the type of anesthesia, most clients find surgery a stressful event. As you may recall from Chapter 12, if stress activates the general adaptation syndrome (GAS), autonomic nervous system and endocrine responses ensue. Among those responses is a slowing of peristalsis.

Manipulation of the Bowel During Surgery Abdominal or pelvic surgery in which the bowel is manipulated may result in a **paralytic ileus**, a cessation of bowel peristalsis. Although peristalsis halts, the bowel continues to produce secretions. Without peristalsis, secretions remain stagnant, causing distention and discomfort. To decrease the complications of paralytic ileus, patients who have had bowel surgery typically have a nasogastric (NG) tube with low constant or intermittent suction. The NG tube removes secretions until peristalsis returns. To review insertion of an NG tube or management of a patient with an NG tube,

Go to Chapter 27, **Procedure 27-2: Inserting Nasogastric and Nasoenteric Tubes,** in Volume 2.

Decreased Mobility After surgery, patients often experience discomfort that affects mobility. This further hinders GI motility and increases the risk for constipation.

Perineal Surgery Patients who have had surgical interventions involving the perineal region (e.g., an episiotomy after childbirth) may fear pain or that their sutures will "tear" or "break" during bowel elimination, and therefore they resist the urge to evacuate their bowel.

Anal Sphincter Surgery Patients who have had surgery that disrupts the anal sphincter may experience uncontrolled rectal drainage after surgery.

Pregnancy

In early pregnancy, many women experience fluid loss due to "morning sickness"—periods of nausea and vomiting. As the pregnancy progresses, the growing uterus crowds and displaces the intestines, and the increased level of progesterone slows intestinal motility. As a result, pregnant women often experience constipation, decreased appetite, and irregular food intake. In addition, the increasing pressure of the uterus and the increased blood volume of normal pregnancy increase the woman's risk for hemorrhoids.

PICOT

Constipation in Pregnancy

Situation: The nurse is interviewing a 27-year-old pregnant client with a history of constipation, gas, and general abdominal discomfort after eating. The client reports increasing her dietary intake of fluid and fiber, but with limited results. Focused assessment reveals hypoactive bowel sounds and a firm abdomen. She is anxious about taking medication during pregnancy. The nurse wants to learn more about nonpharmacological interventions for constipation.

PICOT Components

P	Population/client	=	Pregnant women
I	Intervention/indicator	=	Increased physical activity
C	Comparator/control	=	Fiber and liquids only
O	Outcome	=	Relief from constipation
T	Time	=	During pregnancy

Searchable Question: Do ________ (P) who receive ________ (I), as compared to ________ (C) demonstrate ________ (O) during ________ (T)?

Example of Evidence: The effect of hormones on the bowel, as well as the increased iron intake in prenatal vitamins often causes early pregnancy constipation. The increasing size of the uterus, and decreased maternal activity can further contribute to constipation. Many clients find relief with increased fiber and fluid intake. A commitment to daily exercise will also increase peristalsis, promoting fecal movement. The client on bedrest can also benefit with thigh strengthening and ROM exercises.

Application to Practice: The nurse discusses with the client ways in which she can incorporate increased physical activity into her lifestyle during pregnancy.

Think**Like a Nurse** 29-3

- Review the case of Mrs. Zeno (Meet Your Patient). What factors may be affecting her bowel elimination?
- What additional information do you need?

Pathological Conditions

Several disorders affect bowel function. Among them are neurological disorders that affect innervation of the lower GI tract, cognitive conditions that limit the ability to sense the urge to defecate, pain or immobility that leads to sluggish peristalsis, and pathological conditions of the GI tract. Constipation and diarrhea are discussed in the Nursing Diagnosis section of the chapter. Other common disorders are food allergies, food intolerances, and diverticulosis.

Food Allergies The National Institute of Allergy and Infectious Diseases (NIAID) characterizes a **food allergy**

as an adverse health effect arising from an immune response that occurs reproducibly on exposure to a given food (NIAID, 2011, updated 2013). Some common food allergens include dairy products, egg whites, shellfish, gluten, peanuts and other nuts, citrus fruits, and soy. Immune responses to foods manifest as a variety of symptoms ranging from a mild rash to anaphylactic shock. Common GI symptoms suggesting food allergy include constipation, diarrhea, a red, blistering rash around the anus, abdominal discomfort, bloating, excessive gas, and intestinal bleeding (Boyce, Assa'ad, Burks, et al., 2010).

Food Intolerances In contrast to a food allergy, a **food intolerance** is specifically linked to the GI system. It produces such symptoms as GI discomfort, pain, gas, bloating, diarrhea, or constipation after the person consumes the food. An example is *lactose intolerance*, a deficiency of the enzyme lactase, which is responsible for the breakdown of milk sugar (lactose). Such symptoms can mimic those of a food allergy, but food intolerances are not caused by immune responses.

Diverticulosis When the colon must repeatedly move highly compacted fecal material, over time the longitudinal and circular muscles enlarge. This increases force on the mucosal tissues, causing them to "balloon" out between the muscles and to form pouches in which fecal matter becomes trapped. The development of these saclike outpouchings of mucosa through the muscle layers of the colon wall is a condition called **diverticulosis**. In some cases, the pouches become infected, a condition called **diverticulitis**, and antibiotics or surgery is required. People whose diets are low in fiber or consist mainly of refined foods are especially at risk for diverticulosis. Obesity and red meat intake are also risk factors (Humes, 2012).

KnowledgeCheck 29-2

- What is a normal defecation pattern?
- Identify the factors that affect bowel elimination.

WHAT IS A BOWEL DIVERSION?

As you know, various pathologies affect the GI tract—causing motility changes, inflammation, and so on. Many can be treated with medication (e.g., laxatives, anti-inflammatory drugs). However, some conditions require surgical intervention, such as bowel diversions.

A **bowel diversion** is a surgically created opening for elimination of digestive waste products. The procedure is performed for clients with a variety of conditions, including cancer, ulcerations, trauma, or inadequate blood supply. A client with a bowel diversion does not eliminate via the anus. Instead, the **effluent** (output, fecal material) is expelled through a surgically created opening in the abdominal wall, called a **stoma** or **ostomy**. The effluent ranges from liquid to solid, depending on the part of the bowel that is being diverted.

Bowel diversions may be temporary or permanent. *Temporary bowel diversions* are common after surgical interventions for benign conditions of the bowel. They allow healing of the distal portion of the bowel. Once adequate healing has occurred, surgical **reanastomosis** (reconnection) of the bowel is performed, and the patient once again has BMs from the anus. *Permanent bowel diversions* are performed if the bowel is necrotic (dead) or cannot be salvaged because of severe disease or trauma.

Ileostomy

An **ileostomy** brings a portion of the ileum through a surgical opening in the abdomen, bypassing the large intestine entirely. Recall that most of the water is absorbed from the feces in the large intestine. Therefore, drainage at this level is liquid and continuous. The patient must wear an ostomy appliance at all times to collect the drainage. Some variations of an ileostomy are designed to control drainage more effectively and to cause less body image disturbance. However, many clients are not candidates for these procedures because of their underlying disease.

- A **Kock pouch**, or **continent ileostomy**, creates an internal pouch, or reservoir, to collect ileal drainage (Fig. 29-5A). To drain the pouch, the patient inserts a tube through the external stoma into the pouch several times per day. This alternative avoids continuous drainage and allows the patient to be free of an ostomy appliance.
- A **total colectomy with ileoanal reservoir** is a surgical procedure in which the colon is removed, a pouch is created from the ileum, and the ileum is connected to the rectum (Fig. 29-5B). The patient evacuates the bowel on

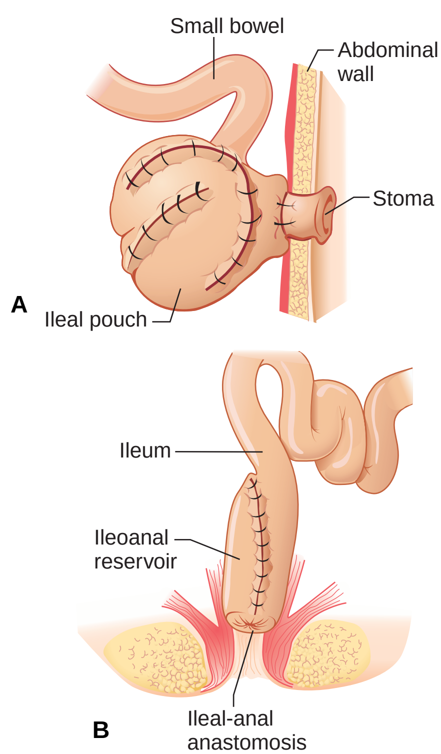

FIGURE 29-5 Ileostomy variations. *A*, Continent ileostomy (Kock pouch). *B*, Ileoanal reservoir.

the commode in the usual manner. Although this procedure should result in continence of bowel elimination, the feces will still be liquid.

Colostomy

A **colostomy** is a surgical procedure that brings a portion of the colon through a surgical opening in the abdomen. The location of the colostomy determines the consistency of the feces eliminated, as well as the need to wear an ostomy appliance (Fig. 29-6). The closer the colostomy is to the ascending colon and the ileocecal valve (between the small and large intestine) (Fig. 29-3), the more liquid and continuous the drainage will be. In contrast, a colostomy close to the sigmoid colon will produce solid feces. Colostomies near the rectum, such as sigmoid colostomies, can often be controlled by diet and irrigation. As a result, the client may not need to wear an ostomy appliance to collect drainage.

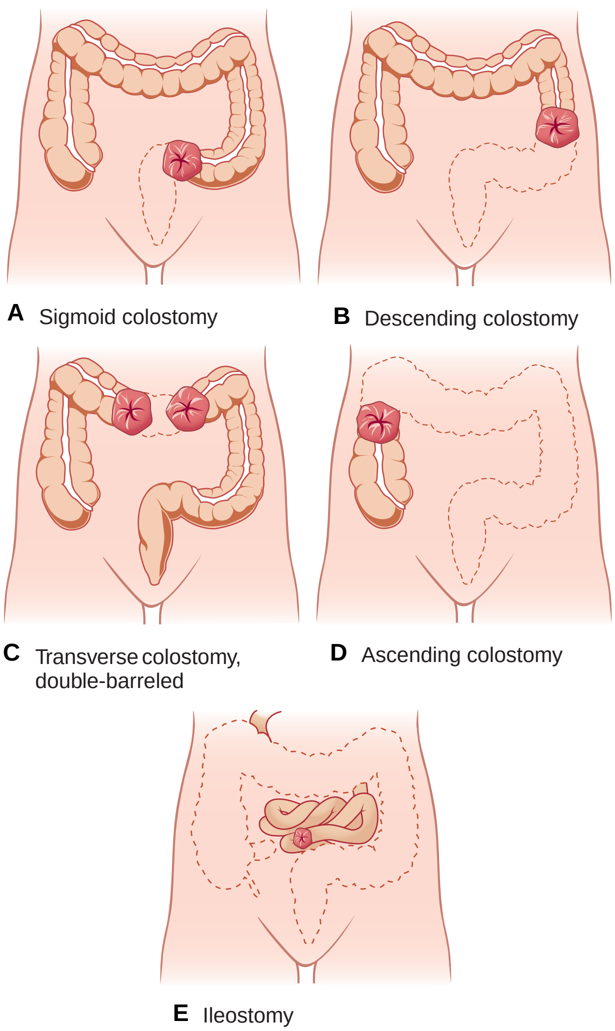

FIGURE 29-6 *A–E*, Location of various bowel diversion ostomies. Shaded areas indicate sections of the bowel that are removed or being "rested." The closer the colostomy is to the ascending colon ("higher"), the more liquid and continuous the drainage will be.

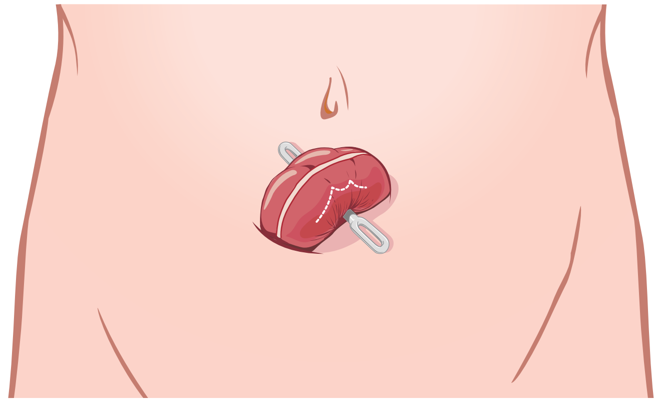

FIGURE 29-7 A loop colostomy.

A colostomy created in the transverse colon is usually temporary and may be either a double-barreled or loop colostomy.

- A **double-barreled colostomy** (see Fig. 29-6C) has two separate stomas that externalize the bowel on both sides of the portion that has been removed. The proximal stoma is the functioning end that drains fecal material. The distal stoma may drain mucus and is sometimes called a mucous fistula.
- A **loop colostomy** (Fig. 29-7) consists of a segment of bowel brought out to the abdominal wall. The posterior wall of the bowel remains intact, but a plastic rod is wedged under the bowel to keep it from slipping back into the abdomen. The anterior wall is incised, and the mucosal surface is left visible and open to air. It, too, has a functioning proximal end and limited drainage from the distal end.

You may also be interested in seeing an animation about colostomies at

Go to **Animations: Colostomy,** on Davis*Plus.*

KnowledgeCheck 29-3

- What changes in bowel elimination are associated with constipation? With diarrhea?
- Why are bowel diversions performed?
- What determines the nature of the effluent from a bowel diversion?

PracticalKnowledge knowing **how**

As a nurse, you will monitor and assist clients with bowel elimination, teach about bowel function, and work collaboratively with the healthcare team to facilitate normal bowel function in well and ill clients. In the remainder of the chapter, we discuss these activities.

ASSESSMENT

To assess bowel elimination, you must obtain a focused nursing history, perform a physical examination focused on elimination, and review diagnostic and laboratory data. For guidelines for physical examination and for a list of questions to use in a focused bowel assessment,

Go to Chapter 29, **Assessment Guidelines and Tools, Focused Assessment: Bowel Elimination,** in Volume 2.

Focused Nursing History

Because bowel patterns vary, you will need a nursing history to determine what is normal for each client. As you interview clients, pay attention to their reactions to your questions. Many people are embarrassed by discussion about bowel function. Tailor your assessment to the client's needs, and use language that makes the client comfortable. Remember to ask the client about her medications because many have the potential to cause constipation (e.g., antacids, antidiarrheals, calcium and iron supplements) (Box 29-2). For clients with a bowel diversion, you will also gather data on the client's usual care of the stoma, use of appliances, and adjustment to the ostomy.

Focused Physical Assessment

Physical assessment for bowel elimination includes examination of the abdomen, rectum, and anus, as well as characteristics of normal and abnormal stool (Table 29-1). Observe the size, shape, and contour of the abdomen, and listen to bowel sounds. You might also palpate the anus and rectum for the presence of stool or masses. When auscultated:

- *Normal bowel sounds* are high-pitched, with approximately 5 to 15 gurgles every minute.
- *Hyperactive bowel sounds* are very high-pitched and more frequent than normal. They may occur with small bowel obstruction and inflammatory disorders and may produce diarrhea.
- *Hypoactive bowel sounds* are low-pitched, infrequent, and quiet. A decrease in bowel sounds indicates decreased peristalsis, which can result in constipation.
- *Absent bowel sounds.* If after listening for 3 to 5 minutes you hear no bowel sounds, you can describe them as *absent*. Absent bowel sounds indicate a lack of intestinal activity, which may occur after abdominal surgery and indicate a paralytic ileus.

For complete details about a focused assessment of bowel function,

Go to Chapter 22, **Procedure 22-14: Assessment of the Abdomen** and **Procedure 22-19: Assessing the Rectum and Anus,** in Volume 2.

BOX 29-2 ■ Medications Associated With Constipation

- Antacids containing aluminum hydroxide or calcium carbonate
- Anticholinergic drugs (e.g., belladonna)
- Anticonvulsant drugs (e.g., phenytoin)
- Antidiarrheals (e.g., loperamide)
- Antihistamines (e.g., diphenhydramine)
- Antiparkinsonian drugs (e.g., amantadine hydrochloride)
- Antipsychotic drugs (e.g., chlorpromazine)
- Calcium channel blockers (e.g., verapamil hydrochloride)
- Calcium supplements
- Diuretics (e.g., furosemide)
- Iron supplements
- Lithium
- Nonsteroidal anti-inflammatory drugs (e.g., ibuprofen)
- Opioids (e.g., morphine, codeine)
- Sympathomimetics (e.g., ephedrine)
- Tricyclic antidepressants (e.g., nortriptyline)

KnowledgeCheck 29-4

- What should you discuss with your client when performing a nursing history focused on bowel elimination?
- Describe the physical assessment you would perform for a client with constipation.

Diagnostic Tests

Several diagnostic tests may be performed to assess for bowel elimination problems (e.g., to screen for colorectal cancer, to diagnose diverticulosis). They may be classified as indirect or direct visualization studies. **Indirect visualization studies** are radiographic views of the lower GI tract. The simplest of the tests is an abdominal flat plate, an anterior to posterior (AP) x-ray view of the abdomen used to detect gallstones, fecal impaction, and distended bowel.

Direct visualization studies are used for diagnostic and treatment purposes. They are invasive procedures and are conducted by a gastroenterologist, who inserts various instruments (e.g., *endoscopes*) to examine the interior of the GI tract. The nurse's role during these studies is to prepare the patient for the test, function as an assistant, and provide aftercare. You might need to assist the patient to the appropriate position, monitor the patient's tolerance of the procedure, provide pain medication or sedation to keep the patient comfortable during the exam, and provide reassurance to the patient as the test proceeds. For a description of the most common visualization tests,

Go to Chapter 29, **Diagnostic Testing, Direct Visualization Studies of the Gastrointestinal Tract** and **Indirect Visualization Studies of the Gastrointestinal Tract,** in Volume 2.

Table 29-1 ➤ Normal Characteristics of Feces and Variations

STOOL CHARACTERISTIC	CONDITION	AGE GROUP	DESCRIPTION
Frequency	Normal	Infants*	Bottlefed—1 to 3 stools/day; Breastfed—4 to 6 stools/day
		Adults	Daily; 2 to 3 BMs/week
	Variations (Hypermotility)	Infants*	>6 stools/day
		Adults	>3 stools/day
	Variations (Hypomotility)	Infants*	Bottle fed—<1 stool every day or 2 Breastfed—<1 stool/week
		Adults	<1 stool/week
Color	Normal	Infants*	Dark green (1st week); then yellow
		Adults	Brown
	Variations		*Bile* pigment gives feces a brown color. Infant stools are yellow because of their rapid passage. *White or clay-colored* stool may indicate absence of bile (e.g., as in bile duct obstruction) or use of some antacids. *Light brown* stool may indicate diet high in milk products and low in meat. *Pale, fatty* stool may indicate malabsorption of fat. *Black, tarry stool* (melena) may indicate use of iron medications or upper GI bleeding; eating large quantities of red meat, spinach, and dark green vegetables may cause feces to be almost black. *Red stool* may indicate bleeding in lower intestinal tract or hemorrhoids. Stool darkens the longer it is left standing after defecation.
Quantity	Normal	Adults	Approximately 150 g/day
	Variations		Quantity varies with amount of food eaten, from 100 to 400 g per day.
Shape	Normal		Approximately the diameter of the rectum: about 2.5 cm (1 in.) in diameter
	Variations		Narrow, pencil-shaped stool may indicate intestinal obstruction or constriction, or rapid peristalsis. Small, marble-shaped stool may indicate slow peristalsis, with longer time in the large intestine.
Consistency	Normal		Formed, soft, moist
	Variations		Consistency is related to gastric motility and is affected by food and fluid intake. Hard stool indicates constipation. The more time spent in the large intestine, the more water is reabsorbed, and the harder the stool. May also indicate dehydration. Liquid stool may indicate diarrhea; rapid peristalsis (e.g., from infection).
Odor	Normal		Pungent; affected by foods eaten
	Variations		Normal odor is created by putrefaction and fermentation in the lower GI tract. Odor is also influenced by the pH of the stool, which is normally neutral or slightly alkaline. Strong, foul odors may indicate blood in the stool, especially in the upper GI tract, or infection.

*All information about infant stool patterns applies after passage of meconium.

For nursing care before, during, and after each of these tests,

Go to Chapter 29, **Tables, Boxes, Figures: ESG Box 29-1, Direct Visualization Studies of the Gastrointestinal Tract,** and **ESG Box 29-2, Indirect Visualization Studies of the Gastrointestinal Tract,** on Davis*Plus*.

ThinkLike a Nurse 29-4

A client asks you why he must perform a bowel prep with a strong laxative before having a colonoscopy. How might you reply?

Laboratory Studies of Stool

Stool specimens may be analyzed to detect blood, infection, or parasitic infestation. The client must void first and then defecate into a clean, dry bedpan, bedside commode, or a special container (half hat) placed under the toilet seat. A small sample is obtained and sent to the laboratory for analysis or analyzed at the bedside. To obtain a specimen from an infant or young child, you will collect freshly passed feces from a diaper.

Handling Stool Specimens

Wear clean gloves when you handle the container or manipulate stool specimens. Use tongue blades to transfer the stool specimen to the container provided by the lab. Do not contaminate the outside of the specimen container.

In most cases you will need approximately 2.5 cm (1 in.) of formed stool or 20 to 30 mL of liquid stool. If blood, mucus, or purulent material is present, be sure to include this with the sample. Transport the specimen to the laboratory as soon as possible. If that is not possible, consult the laboratory for appropriate storage. Usually you will need to refrigerate the specimen until it can be received in the lab.

Testing for Fecal Occult Blood

Blood from the GI tract may be visible to the eye or **occult** (hidden), especially when passed through the stool from higher up in the intestine. You can perform the test for occult blood at the bedside, although some institutions require that it be done in the laboratory. The test is called a *guaiac test* or *fecal occult blood test*. It requires use of a special reagent that detects the presence of **peroxidase**, an enzyme present in hemoglobin. Only a small smear of stool is required. For home testing, remind patients to wash their hands before and after collecting stool. The Highlights of Procedures box in this chapter summarizes the skill. For the complete procedure, including medications and foods to avoid before the test,

Go to Chapter 29, **Procedure 29-1: Testing Stool for Occult Blood,** in Volume 2.

Colorectal cancer is the third most common cancer in both women and men, with African Americans having the highest incidence of colorectal cancer compared with other races (American Cancer Society, 2013). Screening can detect colorectal polyps so they can be removed before becoming cancerous. Annual guaiac-based fecal occult blood testing is recommended for all patients 50 to 75 years of age and older as one method of screening for colorectal cancer (some guidelines suggest every 2 years). The recommended age for annual testing drops to the age of 40 years for high risk adults or 10 years younger than the age at which the youngest affected relative was diagnosed with colorectal cancer (National Guideline Clearinghouse [NGC], 2012). Some suggest the cutoff age to stop screening should be age 75, or an expected remaining life span of less than 10 years. Based on 2011 data, a little more than half of adults aged 50 and older were screened for cancer at the recommended intervals (American Cancer Society, 2013).

Assessing for Pinworms

Pinworms (an intestinal parasite) are small, white, thread-like worms that spread through human-to-human transmission, by ingesting (swallowing) infectious pinworm eggs and/or by entry through the anus (e.g., when eggs attach to a person's fingers and are transferred to the anal area by scratching or touching the anus). Once present, the pinworms live in the cecum. They come to the anal area to deposit eggs during the night and migrate back up through the rectum during the day. In assessing a child, you can spread the buttocks while the child is sleeping and examine the anus to see whether any pinworms are visible to the naked eye. You can also test for the presence of the eggs with tape. In the morning, as soon as the patient awakens, press clear cellophane tape against the anal opening. Remove the tape immediately, and place it adhesive side down on a slide. Alternatively, or in addition, insert a cotton-tipped swab gently into the rectum for not more than 2.5 cm (1 in.). Smear the specimen on a slide for microscopic inspection for parasites and eggs. You may also check at night by using a flashlight. The test may need to be repeated on consecutive days.

ThinkLike a Nurse 29-5

You are reviewing a client's chart and note that the client was tested for fecal occult blood. The results are as follows:

3/10/16 negative for occult blood
3/11/16 no BM
3/12/16 no BM
3/13/16 no BM
3/14/16 positive for occult blood
3/15/16 negative for occult blood
3/16/16 negative for occult blood

What can you conclude? What questions do these findings raise?

ANALYSIS/NURSING DIAGNOSIS

Common nursing diagnoses related to bowel elimination include the following:

- *Bowel Incontinence* is a change in normal bowel habits characterized by involuntary passage of stool. It is more common among women and older adults. Other risk factors include neurological diseases, stroke, sphincter damage, and inflammatory bowel disease.
- *Constipation.* Because frequency of bowel elimination varies, constipation is usually defined as a decrease in the frequency of bowel movements resulting in the passage of hard, dry stool. Constipation can be a temporary problem wherein symptoms resolve in a short time. Nearly everyone experiences constipation at some point. *Chronic constipation* typically lasts 3 months or longer and may persist for years. Unrelieved constipation may eventually result in a **fecal impaction**, in which dry, hard stools lodged in the rectum cannot be passed.
- *Risk for Constipation* is an appropriate diagnosis for clients at increased risk because of bedrest, medications such as opioids, or surgery. You might use this diagnosis for a client with a condition or taking medications known to decrease peristalsis.
- *Perceived Constipation* is an appropriate diagnosis for a client who makes a self-diagnosis of constipation and uses laxatives, suppositories, or enemas to ensure a daily bowel movement.
- *Diarrhea* is the passage of loose, unformed, or watery stools.
- *Dysfunctional Gastrointestinal Motility* is a broad label that encompasses increased, decreased, ineffective, or absent peristaltic activity within the GI system. If you use this label, you need to specify whether the GI motility is increased, decreased.
- *Toileting Self-Care Deficit* is impaired ability to perform or complete own toileting activities.

For definitions and defining characteristics of these diagnoses, consult a nursing diagnosis handbook or

Go to Chapter 29, **Standardized Language, Nursing Diagnoses Associated With Bowel Elimination,** on Davis*Plus*.

Bowel elimination problems may also form the etiology of other nursing diagnoses and collaborative problems. Examples include the following:

- Social isolation r/t embarrassment secondary to bowel incontinence
- Potential Complication: Electrolyte imbalance secondary to diarrhea. Older adults, very young children, and infants are at especially high risk.
- Impaired Skin Integrity r/t irritating effects of feces secondary to diarrhea
- Anxiety r/t perceived need for a daily bowel movement
- Disturbed Body Image r/t bowel diversion

Think**Like a Nurse** 29-6

- What data do you have about Mrs. Zeno's (Meet Your Patient) bowel function?
- What else would you like to know about her bowel function? What other symptoms often accompany these cues?
- Which NANDA-I nursing diagnosis best describes this cue cluster?
- In addition to this nursing diagnosis, what other data in the scenario might also be contributing to her infrequent BMs?
- From the scenario data, how would you describe the etiology of Mrs. Zeno's problem?
- What questions do you still have about the etiology?

PLANNING OUTCOMES/EVALUATION

The general bowel elimination goal is that the patient will have soft, formed bowel movements regularly.

For *associated NOC standardized outcomes* for bowel elimination diagnoses,

Go to Chapter 29, **Standardized Language, Selected Standardized Outcomes and Interventions for Bowel Elimination Diagnoses,** on Davis*Plus*.

When bowel elimination is the etiology, choose outcomes linked to the problem side of the diagnosis. For example, for Impaired Skin Integrity r/t irritating effects of diarrhea stool, the NOC outcomes might fall within Tissue Integrity: Skin and Mucous Membranes.

Individualized goals/outcome statements depend on the nursing diagnosis. Because normal bowel elimination patterns are individualized, regularity is based on the individual's pattern. Examples include the following:

Will resume his normal bowel pattern by (date).
Will discuss his feelings about his colostomy.

PLANNING INTERVENTIONS/IMPLEMENTATION

Bowel elimination is a normal physiological function. It is important for you to convey an attitude of acceptance and display professionalism when providing care for patients with bowel elimination problems.

A few examples of *NIC standardized interventions and activities* for patients with bowel elimination problems include: Bowel Incontinence Care, Constipation/Impaction Management, Diarrhea Management, Bowel Management, and Teaching: Individual. For a more comprehensive list of NIC interventions for various nursing diagnoses,

Go to Chapter 29, **Standardized Language, Selected Standardized Outcomes and Interventions for Bowel Elimination Diagnoses,** on Davis*Plus*.

Specific nursing activities to promote normal bowel function and relieve elimination problems are found in the following sections. Both independent and dependent interventions are discussed.

Promoting Normal or Regular Defecation

Promoting regular defecation entails a number of independent nursing activities. These include providing privacy, positioning, timing, providing hydration and nutrition, promoting exercise, and teaching clients when they should seek medical assistance.

Provide Privacy

Try this exercise. Imagine that your class assignment for today is to stand in front of the classroom and describe to the class your normal pattern of defecation, including frequency, appearance, and other characteristics of the stool. How would you feel about that? Would you do it?

Although defecation is a normal physiological function, most patients consider it a very private matter. Taking a matter-of-fact approach confirms to patients that you are comfortable with this aspect of care. Provide privacy for your patient when discussing or providing care related to bowel elimination. For example, excuse visitors from the room, draw the dividing curtains in shared rooms, and close the door. Many patients are embarrassed by the odor of bowel movements and therefore may ignore the urge to defecate. Using an aromatic spray or other odor-reducing product may help to reduce embarrassment.

Assist With Positioning

An upright seated or squatting position is the most comfortable for defecation and decreases the need to strain. When possible, assist the patient to the bathroom to use the toilet. An alternative is to place a bedside commode next to the bed for patients who are unable to ambulate to the bathroom. A patient who must remain in bed should assume a semi-Fowler's position to use the bedpan. Patients who are unable to assume this position because of surgery, trauma, or other medical conditions must use supine or side-lying positions. These positions are unnatural for bowel elimination and place the patient at risk for constipation.

Raise the siderails or provide an overhead trapeze so that the patient can grip them to maneuver on and off the bedpan. If the patient is very weak, you may need an assistant to help you position him on the bedpan. In addition, you may need to stay with the person while he uses the bedpan to help him maintain his position. The Highlights of Procedures box in this chapter provides a summary of this skill. For the complete procedure,

Go to Chapter 29, **Procedure 29-2: Placing and Removing a Bedpan,** in Volume 2.

Consider the Timing of Defecation

Recall that food entering the duodenum triggers mass peristalsis. As a result, the urge to defecate often occurs after meals. Advise patients not to ignore this urge, because doing so may lead to constipation. For patients who are ambulatory, allow some free time after meals to use the restroom. Assist those who cannot toilet independently to ambulate to the bathroom or use the bedpan. Discuss with NAPs the need to offer help without waiting to be asked so that patients experience minimal delays.

Support Healthful Intake of Food and Fluids

Teach clients the importance of a balanced diet in promoting soft, formed, regular bowel movements. Encourage a daily intake of 25 to 30 grams of fiber to provide bulk, attract water into the stool, and promote peristalsis. The diet should be rich in fresh fruits, dried fruits, vegetables (especially raw), whole-grain foods, flaxseed, popcorn, dried beans, peas, and legumes.

Without adequate fluid intake, a high-fiber diet can actually cause constipation. Recommend a minimum intake of 1,500 mL of fluid per day to keep stool soft and aid in production of mucus to lubricate the colon. Ideally, a person should drink eight to ten 8-ounce glasses of fluid daily (2,000 to 2,400 mL). Water is the preferred fluid because soda, coffee, and tea often contain caffeine or additives that promote diuresis. However, because the diuretic effect of these fluids is minimal, they are acceptable for clients who simply will not drink enough plain water.

Key Point: ***Adding fiber does not help to relieve opioid-induced constipation unless the patient's current intake is deficient.*** In fact, excessive fiber might put the patient at risk for bowel obstruction due to the opioid-induced decreased peristalsis, delayed gastric emptying, and prolonged intestinal transit time of the feces (Pitlick & Fritz, 2013).

Encourage Exercise

Physical activity increases peristalsis and promotes defecation. Encourage patients to exercise three to five times per week and to engage in daily walking or light activity. Assist hospitalized or institutionalized patients to ambulate as soon as their condition permits. Even limited activity, such as getting out of bed or walking 10 feet, decreases the risk for constipation.

Provide range-of-motion (ROM) exercises for patients who must remain on bedrest. Even passive ROM (the joints are moved through ROM by the nurse) promotes peristalsis. Chapter 32 provides additional information about activity and ROM exercises, if you need it.

For clients who can assist with exercise, the following exercises promote abdominal and perineal strength:

- *Thigh strengthening.* Have the client slowly bring one knee up to his chest, briefly hold it, then lower the leg to the bed. Repeat this pattern alternating legs. Encourage the client to perform this exercise several times per hour while he is awake.
- *Abdominal tightening.* Have the client tighten and hold the abdominal muscles for a count of five and then relax. This core exercise works the abdominal muscles used during defecation.

Managing Flatulence

Recall that flatus is a natural by-product of digestion. When gas is excessive or leads to complaints of abdominal distention, cramping, or discomfort, it is known as **flatulence**. Some people develop flatulence after eating gas-producing foods, such as beans, cabbage, cauliflower, onions, or highly spiced foods. For others, flatulence occurs when fiber intake is increased. Clients with irritable bowel syndrome experience a cluster of symptoms that include flatulence. Constipation is often accompanied by flatulence because digestive byproducts undergo prolonged fermentation in the colon. Use the following interventions to help clients manage flatulence:

- Teach clients to be aware of and avoid foods that trigger flatulence.
- Teach clients to follow self-care strategies (identified earlier) for maintaining regular bowel movements.
- Encourage patients who have had surgery with gaseous anesthesia to ambulate and perform bed exercises to stimulate peristalsis and the passage of gas.
- In severe cases, you may need to insert a rectal tube to aid in the elimination of flatus. For a summary, see the Highlights of Procedures box. To learn the entire procedure,

Go to Chapter 29, **Procedure 29-5: Inserting a Rectal Tube,** in Volume 2.

Teach Clients When to See a Primary Care Provider

Obviously many GI symptoms are normal and do not require treatment. For example, everyone has excessive flatus and abdominal distention at some time—perhaps as a result of a high-fat, high-sugar meal. And it is common for bowel movements to occasionally become a little irregular. However, clients need to know when a symptom may be signaling a more serious condition.

Teach clients to see their primary care provider for the following if a symptom lasts longer than 3 weeks or is disabling:

- Blood in the stool (unless they have hemorrhoids and this is not an unusual occurrence for them)
- Severe stomach pain
- Change in bowel habits
- Unintended weight loss
- Constipation is not relieved after trying fiber, fluids, and exercise

KnowledgeCheck 29-5

Identify at least five independent nursing actions that you can take to encourage regular elimination in a well client.

ThinkLike a Nurse 29-7

How could you facilitate regular bowel elimination for Mrs. Zeno (Meet Your Patient)? What information do you need?

Interventions for Example Problem: Diarrhea

Diarrhea may occur as a result of contaminated food, a viral infection, or dietary change, or as a side effect of a medication. Patients with diarrhea are at risk for fluid and electrolyte imbalance, particularly potassium. Ideally, oral liquids replace the lost fluid and potassium. Infants, young children, and the frail elderly are most vulnerable and may require hospitalization and intravenous fluid replacement therapy. Ideally, oral liquids replace the lost fluid and potassium.

Nursing interventions focus on treating the diarrhea itself, as well as its associated problems (cramping, fluid and electrolyte imbalances, and Impaired Skin Integrity):

Preventive Interventions

Diarrhea can be prevented in the following ways:

- **Teach hand hygiene.** Teach patients to wash their hands often. This helps prevent diarrhea caused by viruses and other pathogens.
- **Provide information about foods that can cause diarrhea.** Highly spiced foods, high-fat foods, greasy snacks, or large quantities of raw fruits and vegetables may cause diarrhea in some patients. Tell patients to keep track of foods that trigger diarrhea and to eat them in moderation.

Monitoring Interventions

During the diarrhea episode, assess and monitor the following:

- **Monitor stools.** Assess frequency, amount, color, and consistency of stools to determine the severity of the diarrhea.
- **Monitor fluid balance.** Monitor intake and output, body weight, and vital signs to assess hydration. Also assess skin turgor and moistness of mucous membranes.
- **Monitor serum electrolyte levels.**
- **Monitor skin integrity.** Assess the perineal area for alterations in skin integrity. Clients with diarrhea may experience perianal irritation and excoriation.

Treatment Interventions

Treatments include medications, diet modification, and attention to fluid balance and skin integrity.

Medications Opiates (e.g., paregoric) and opiate derivatives (e.g., loperamide) are the primary antidiarrheal drugs prescribed. Although they slow peristalsis and inhibit diarrhea, they may cause drowsiness; advise patients, especially older adults, to use them with caution. Pepto-Bismol (bismuth subsalicylate) is a readily available OTC medication that is useful for traveler's diarrhea because it has antimicrobial and antisecretory properties.

Antidiarrheal medications are not recommended for acute diarrhea. In many cases, diarrhea is a response to infection or unusual foods and serves as a mechanism to rid the body of the pathogens or troublesome food. Although antidiarrheal medications are available without a prescription, caution patients to avoid using them unless instructed by their healthcare provider. Medication is usually reserved for use with chronic diarrhea—diarrhea that has persisted for more than 1 month.

Diet and Fluids During the acute episode, the patient may need to modify his diet to control the diarrhea.

- **Teach the patient about, or provide, a clear liquid diet**, including electrolyte replacement fluids (e.g., Pedialyte or sports drinks that have been diluted by 50% or more). Clear broth and gelatin are also good choices.
- **Encourage your patient to sip liquids** or take ice chips or Popsicles often to replace the losses.
- **Reduce the amount of fiber** in your client's diet by cutting back servings of whole grain bread and fresh fruits and vegetables.
- **Limit foods containing caffeine**, such as coffee, strong tea, and colas.
- **Avoid a sudden large intake of fluid or food** when resuming a normal diet, because this may trigger mass peristalsis.
- **Plain yogurt and other probiotic foods** consumed daily may help to prevent the diarrhea caused by antibiotics. Other medications may also cause diarrhea. A change in medications may be required.
- **Continue breast milk** for breastfed infants with acute diarrhea. There should be no need for interruption. In fact, breastfeeding has a well-known protective effect against the development of enteritis, promotes faster recovery, and provides improved nutrition.
- **Advise a BRAT diet** if a child with diarrhea has an appetite. A BRAT diet consists of bananas, (white) rice, applesauce, and toast. These are easy to digest, provide calories for energy without gastric irritation, and help offset potassium loss. Although developed for pediatric use, the BRAT diet is sometimes used for adults.

Interventions for Example Problem: Constipation

Many of the nursing strategies to prevent and treat constipation are identical to the activities that promote regular bowel elimination.

Short-Term Constipation

Short-Term Constipation is usually caused by the person's lifestyle. Clients most likely to experience constipation are those who (1) have decreased activity or are on bedrest, (2) are receiving opioids or other medications that slow peristalsis, and (3) have decreased fluid and fiber intake. The following are some interventions:

- **Increase the intake of high-fiber foods** if intake is inadequate (normal adult Recommended Dietary Allowances (RDA) and Adequate Intakes (AI) is 25 to 38 grams, depending on age and sex).
- **Increase fluid intake.**
- **Increase physical activity.**
- **Provide privacy for using the toilet.**
- **Assist the patient to a seated or squatting position** whenever possible. A semi-Fowler's position is preferred for a client on bedrest.
- **Allow the patient uninterrupted time to use the toilet**, especially after meals, when mass peristalsis occurs.
- **Encourage the patient not to ignore the urge to defecate.**
- **Assess for complications** such as impaction and hemorrhoids.

Chronic Constipation

Chronic constipation may be associated with physiological factors such as dysfunctional intestinal motility, nervous system problems, and dysfunctional anorectal musculature. Chronic constipation causes significant psychological distress and decreased quality of life for many clients, and it may result in complications, which include intestinal impaction, anal fissures, hemorrhoids, volvulus (twisted loop of the intestine), intestinal obstruction, rectal ulcers, fecal seepage, and bowel perforation.

Many laxatives are readily available without prescription and are used by clients to treat actual or perceived constipation. However, lifestyle changes and nonprescription medications do not usually prevent or adequately treat chronic constipation. Therefore, laxatives may be prescribed (Box 29-1). *Bulking agents* are the preferred medications for treating constipation. They are actually fiber in a nonfood source. Habitual laxative use, except for bulking agents, may cause reliance on medications for bowel elimination and, ironically, may lead to further constipation. See Self-Care: Teaching Your Patient About Laxative Use for key points to discuss with patients about managing constipation.

Older Adults

Screen older adults for risk factors, including a history of polypharmacy and taking laxatives. Other risk factors include impaired cognitive status, inadequate fluid intake, inadequate dietary fiber, reduced mobility, lack of privacy for toileting, and reliance on others for assistance. These are the same as risk factors for all ages, but they are more likely for older adults. Prevention measures are the same for all ages. However, for those unable to walk or who are restricted to bed, exercises such as trunk rotation, pelvic tilt, and leg lifts may be helpful. For older adults, osmotic laxatives (e.g., PEG and lactulose, bulking agents) have been found to be beneficial (The Joanna Briggs Institute, 2008).

Fecal Impaction

Fecal impaction is the presence of a hardened fecal mass in the rectum. The impaction often blocks the passage of normal stool and sets up a vicious cycle of furthering

Self-Care

Teaching Your Patient About Laxative Use

Discuss the following topics with clients who have concerns about the frequency of their bowel movements or ask about laxatives.

1. The frequency of BMs may range from several times per day to once per week. As long as stools are passed without excessive urgency, with minimal effort and no straining, and without the use of laxatives, bowel function may be regarded as normal.
2. To maintain normal bowel function:
   - Eat a well-balanced diet that includes five servings of whole grains, fresh fruits, and vegetables.
   - Drink eight to ten glasses of fluid per day.
   - Engage in daily exercise to stimulate peristalsis.
   - Set aside uninterrupted time after breakfast or dinner for using the toilet.
   - Do not ignore the urge to defecate.
   - Whenever there is a significant or prolonged change in bowel habits, report this to your healthcare provider.
3. If you are experiencing constipation, choose bulking agents, such as Metamucil or psyllium, to treat the problem rather than other OTC laxatives. Be sure to drink plenty of water when using bulking agents.

hardening. Liquid stool may leak, seeping around the hardend mass, and the patient may report feelings of fullness, bloating, constipation, diminished appetite, and a change in bowel habits. You can detect fecal impaction by digital examination of the rectum. To treat a fecal impaction, you will use enemas or digital removal of stool. Once the impaction has been removed, establish a bowel regimen to prevent recurrence of impactions.

Administering Enemas

An **enema** is the introduction of solution into the rectum to soften feces, distend the colon, and stimulate peristalsis and evacuation of feces. Some enema solutions are chosen because they irritate the mucosa of the rectum and sigmoid colon and assist with forceful evacuation of stool.

Before administering a prescribed enema, explain the purpose of the enema and what the patient can expect. For example, the patient will probably experience some cramping with a large-volume enema. Reassure the patient that you will be immediately available to help her to the restroom or onto the bedpan.

Responses to an enema are governed by the height of the solution container, the speed of flow, the concentration of the solution, and the resistance of the rectum. Hypotonic and isotonic solutions are easier to retain. Muscle tone and history of constipation or other bowel disorders determine the resistance of the rectum. A client with a long history of constipation is more likely to be able to tolerate a large-volume enema, because the rectum and colon have become distended over time.

Enemas may be classified as cleansing, retention, or return-flow. The primary care provider generally prescribes the specific type to administer to a patient. The Highlights of Procedures box summarizes the steps for administering an enema. To learn the full procedure for various types of enemas,

Go to Chapter 29, **Procedure 29-3: Administering an Enema,** in Volume 2.

Cleansing Enemas

Cleansing enemas promote removal of feces from the colon. They may be used to:

- Treat severe constipation or impaction.
- Clear the colon in preparation for visualization procedures, such as colonoscopy.
- Empty the colon when starting a bowel training program.
- Clear the colon for surgeries of the lower GI tract and for some pelvic surgeries.

A cleansing enema may be given "high" or "low." A "low" enema is given by standard procedure. A "high" enema attempts to clear as much of the large intestine as possible. With a "high" enema, the client receives initial instillation of the fluid in the left lateral position. The client then moves to the dorsal recumbent position and then the right lateral position for the remainder of the instillation. This turning process allows the fluid to follow the shape of the large intestine.

Cleansing enema solutions include hypotonic solutions and hypertonic solutions.

- ***Hypotonic solutions*** (saline, tap water, and soap). With hypotonic solutions, you introduce a large volume (500 to 1,000 mL for adults, 100 to 250 mL for infants) of fluid into the rectum. The volume distends the intestine and leads to rapid evacuation of stool.

> Large-volume solutions may be contraindicated in patients who have weakened intestinal walls.

- ***Hypertonic solutions***, in contrast, are usually smaller in volume (70 to 120 mL, or 2.5 to 4 oz, for adults). The hypertonic solution attracts water into the colon, causing distention and stimulating peristalsis and defecation (Table 29-2).

> Hypertonic solutions may be contraindicated for patients who tend to retain sodium or water (e.g., those with renal failure and congestive heart failure).

Retention Enemas

Retention enemas introduce a solution into the colon that is meant to be retained for a prolonged period. Consequently the volume is small, usually 90 to 120 mL (3 to 4 oz). The following are the most common forms of retention enemas.

Table 29-2 ➤ Solutions Commonly Used in Enemas

SOLUTION	EXAMPLES	ACTION	TIME UNTIL BM	ADVERSE EFFECTS
Hypotonic	500–1,000 mL of tap water	Large volume distends the colon, thereby stimulating peristalsis; water also softens stool.	15 minutes	Fluid and electrolyte imbalance, especially water intoxication, is possible if enema is not expelled.
Isotonic	500–1,000 mL of normal saline (0.9% NaCl solution)	Large volume distends the colon, thereby stimulating peristalsis; some softening of stool also occurs.	15 minutes	Fluid and electrolyte imbalance, especially sodium retention
Hypertonic	120–180 mL of sodium phosphate (e.g., Fleet); available as a commercially prepared solution	Attracts water into the colon, thereby causing distention.	Rapid acting: 5–10 minutes	Sodium retention
Oil	90–120 mL of mineral oil, cottonseed oil, or olive oil; available as a commercially prepared solution	Softens the feces, lubricates the rectum.	Varies widely. An oil-retention enema is often given 1–3 hours before a cleansing enema is administered.	
Soapsuds	Pure Castile soap is added to tap water or saline.	Intestinal irritation stimulates peristalsis.	Varies	Only pure Castile soap is safe. Other soaps and detergents can cause bowel inflammation.
Carminative	For example 1:2:3 "MGW" solution (e.g., 30 mL magnesium, 60 mL glycerin, and 90 mL water)	Provides relief from abdominal distention caused by flatus.		

- **Oil-retention enemas** instill 90 to 120 mL of oil into the rectum to soften stool and lubricate the rectum. This type of enema may be used to assist a client to pass hard stool or before digital removal of stool. It may also be used in conjunction with a cleansing enema—at least 1 hour before the cleansing enema.
- **Carminative enema** is a procedure in which 60 to 180 mL (2 to 6 oz) of solution are instilled into the rectum to help expel flatus and relieve bloating and distention. This procedure is used after abdominal or pelvic surgery when peristalsis is slow to return and the client experiences pressure from gas. Solutions may be commercially prepared or prepared on the unit. A common carminative enema is the "MGW" enema; a mixture of magnesium sulfate, glycerin, and water in a ratio of 1:2:3 (e.g., 15 mL of magnesium sulfate, 30 mL of glycerin, and 45 mL of water).
- **Medicated enemas** may be used to instill antibiotics to treat infections in the rectum or anus or to introduce anthelminthic agents for treatment of intestinal worms and parasites.
- **Nutritive enemas** administer fluid and nutrition through the rectum for patients who are dehydrated and frail. They are most commonly used in hospice care as a means to provide hydration for dying patients.

Return-Flow Enemas

A return-flow enema, known as a *Harris flush,* may be ordered to help a patient expel flatus and relieve abdominal distention. For adults, approximately 100 to 200 mL (3 to 7 oz) of tap water or saline is instilled into the rectum. The rectal tube and solution container are then lowered below the level of the rectum to encourage return flow of the solution. This process is repeated several times, or until distention is relieved. If the solution becomes thick, discard it and begin again with new solution.

Digital Removal of Stool

If fecal impaction does not respond to use of stool softeners and enemas, you will need to digitally remove feces from the rectum. Digital removal is accomplished by breaking up the hardened mass into pieces and manually extracting the pieces. You may administer an oil-retention enema at least 30 minutes before digital removal to soften the stool and decrease the patient's discomfort during the procedure.

Aside from discomfort, the pressure generated in the rectum may stimulate the vagus nerve, slowing the heart rate. For that reason, you must have a prescription from the primary care provider.

For a summary of this procedure, see the Highlights of Procedures box. For complete steps,

Go to Chapter 29, **Procedure 29-4: Removing Stool Digitally,** in Volume 2.

KnowledgeCheck 29-6

Identify the types of enemas available for use.

- How do hypotonic and isotonic enemas differ from hypertonic enemas?
- What actions can you take to make the patient more comfortable when he receives an enema?

ThinkLike a Nurse 29-8

Mrs. Zeno (Meet Your Patient) begins to pass liquid stool. What actions should you take? Explain your reasoning.

Interventions for Example Problem: Bowel Incontinence

Bowel incontinence (or *fecal incontinence*) is the inability to control the discharge of feces and flatulence. One study suggests that 17% of Medicare patients report fecal incontinence (FI), and that patients with FI had a greater chance of institutionalization (Shah, Chokhavatia, & Rose, 2012). Physiological conditions causing bowel incontinence include conditions that affect innervation of the rectum and anus, uncontrolled diarrhea, impaction resulting in leakage of stool, and cognitive or emotional changes that alter perception of the urge to defecate. Bowel incontinence is also created by functional limitations—for example, when a client recognizes the need to have a BM but cannot get to the toilet independently or in time to defecate in the toilet.

Clients with persistent bowel incontinence require special nursing care to prevent Impaired Skin Integrity because of the moisture and the activity of enzymes in the stool. In addition, bowel incontinence may be embarrassing. As clients worry about future episodes, anxiety escalates. Refer to the Nursing Care Plan and Care Map for a patient with fecal incontinence near the end of this chapter. In general, nursing interventions include the following:

- Monitor the pattern of BMs.
- Provide a bedpan or assist the patient to the bathroom at regular intervals and at times BMs are most likely to occur.
- Change clothing and/or bed linens as soon as possible to prevent skin irritation and embarrassment.
- Provide prompt hygiene care after any episodes of incontinence.
- Monitor skin for evidence of breakdown. Use moisture-barrier cream if redness or irritation is noted.
- Review diet, fluid intake, activity, and medicines. Work with the primary care provider to alter the above factors to encourage regular bowel movements.
- Consider a bowel training program (discussed in a following section).
- Consider using containment or indwelling methods to prevent fecal drainage from soiling clothing. Research on patient outcomes of most of these methods is limited.

Absorbent Products

You may use absorbent products to prevent fecal drainage from soiling clothing and linens. For small quantities of stool, a long, rectangular pad or a belted absorbent shield can be placed inside clothing. For larger quantities, adult incontinence garments are used. They may pull on like underwear or fasten like a diaper. Moisture-resistant pads placed under the patient help to protect bed linens. When using absorbent products, remember these important points:

Key Point: ***Never refer to incontinence pads as "diapers" when caring for adults or children who have been toilet trained. This inappropriate reference may cause embarrassment and lower the patient's self-esteem.***

Never place the plastic side of the pad next to the patient's body. This holds moisture next to the skin, which leads to irritation and breakdown.

- Use state-of-the-art skin protection products, such as perineal cleansers and skin barrier products.
- Change the pad as soon as possible after defecation. Keep the skin scrupulously clean.

External Fecal Collection Devices

You may apply an external fecal incontinence pouch to protect perianal skin or to collect large fecal samples. The pouch collects fecal drainage, keeping feces away from the skin. This is a common approach for clients with uncontrolled diarrhea. Pouch systems vary widely. Most often, a moisture-proof barrier is applied around the anus, and a plastic pouch is secured to the barrier (Fig. 29-8). The equipment may be the same as that used for patients with an ostomy, which is discussed later in the chapter.

External collection systems can prevent skin breakdown, minimize odor, track output accurately, and enhance patient comfort. However, they are not typically used for patients who are ambulatory, agitated, or active in bed because the device may be dislodged, causing skin breakdown. **Key Point:** ***External systems cannot be used effectively when the patient has Impaired Skin Integrity because they will not seal tightly.***

- Assess the system regularly to ensure that it has not become dislodged and that no leaks have occurred.
- Change the fecal pouch at least every 72 hours (per protocol) and whenever there is evidence of leakage.
- Empty the fecal pouch when it is one-third to one-half full to prevent it from getting too heavy.
- Pay close attention to the perianal skin as you perform your assessment. You may need to use moisture-barrier cream on the surrounding skin.

The Highlights of Procedures box summarizes the procedures for placing both external fecal drainage devices. To learn the procedures,

FIGURE 29-8 A fecal incontinence pouch. A skin barrier is applied around the anus and a plastic pouch is secured to the barrier. (Courtesy of Hollister Incorporated, Libertyville, IL.)

Go to Chapter 29, **Procedure 29-8: Placing Fecal Drainage Devices,** in Volume 2.

Indwelling Fecal Drainage Devices

Indwelling fecal drainage devices are used to collect liquid stool from bedbound, immobilized ill patients. They consist of a soft, latex-free catheter and a collection bag (Fig. 29-9). The tube is inserted and a balloon on the end is filled with saline or water. Internal devices protect perianal skin, protect caregivers from potentially infectious stool, and are thought to decrease urinary tract infections. They are FDA approved, but only for 29 consecutive days, and not for pediatric patients. Other contraindications include patients who have severe hemorrhoids; recent bowel, rectal, or anal surgery or injury; rectal or anal tumors; or stricture or stenosis.

You must follow the manufacturer's recommendations carefully for insertion and maintenance. When the bag is filled, empty or replace it, depending on the type. You must also monitor to confirm placement and may need to irrigate the device. To learn more about placing and caring for a patient with an indwelling fecal drainage device, see the Highlights of Procedures box and,

Go to Chapter 29, **Procedure 29-8B: Inserting an Indwelling Fecal Drainage Device,** and **Clinical Insight 29-1: Caring for a Patient With an Indwelling Fecal Drainage Device,** in Volume 2.

Bowel Training

A bowel training program assists the patient to have regular, soft, formed stools. It is appropriate for clients who have chronic constipation, impaction, or bowel

FIGURE 29-9 An indwelling fecal drainage device. (Courtesy of ConvaTec Inc., Skillman, NJ.)

incontinence. Elements of a bowel training program include the following:

- Plan the program with the patient and caregiver.
- Gradually increase fiber in the diet while monitoring consistency of the stool.
- Increase fluid intake to at least eight glasses of water per day, if not contraindicated.
- Initiate a designated uninterrupted time for defecation: usually after meals, especially in the morning.
- Provide privacy for the patient during the designated time.
- Develop a staged treatment plan if constipation develops. Usually additional fiber is added as a first measure. A stool softener is next, followed by a suppository such as bisacodyl (Dulcolax).
- Regularly modify the plan based on the patient's response.

KnowledgeCheck 29-7

- What are the major patient care concerns associated with bowel incontinence?
- What are the elements of a bowel training program?

Caring for Patients With Bowel Diversions

Patients experience a variety of reactions to a bowel diversion, and each person has unique physical and psychological needs. Initially you will care for the ostomy, but the goal is for the patient to assume self-care. For a full description of the care of an ostomy appliance, including changing and emptying,

Go to Chapter 29, **Clinical Insight 29-2: Guidelines for Ostomy Care;** also see **Procedure 29-6: Changing an Ostomy Appliance,** in Volume 2.

Ongoing Assessments

Always begin care with a thorough assessment of the stoma, the stool, and the skin.

Assess the Stoma A healthy stoma (Fig. 29-10) ranges in color from deep pink to brick red, regardless of the patient's skin color, and is shiny and moist. Pallor or a dusky blue color indicates ischemia, and a brown-black color indicates necrosis. Immediately after surgery the stoma will be swollen and enlarged. As the inflammation subsides and healing occurs, the stoma will shrink. By 6 to 8 weeks, it will be at its permanent size. Stoma size varies according to the size of the person and the part of the bowel that was externalized (Fig. 29-6). An ileostomy stoma is generally smaller than a colostomy stoma. The stoma will protrude above the level of the abdomen by approximately 1.3 to 2.5 cm (0.5 to 1 in.).

FIGURE 29-10 A healthy stoma is deep pink to brick red and is shiny and moist.

Assess the Output Monitor the amount and type of drainage from the stoma. Output from an ileostomy stoma is liquid and contains digestive enzymes. An ostomy lower in the GI tract will have more solid output and fewer enzymes. The presence of enzymes in the effluent increases the likelihood of skin breakdown.

Assess the Skin Pay close attention to the skin surrounding a stoma for signs of irritation, such as redness, tenderness, skin breakdown, and/or drainage. Skin breakdown may lead to infection, pain, and leakage.

Helping Patients Adapt to the Diversion

Patients experience a variety of reactions to a bowel diversion, and each person has unique needs. Initially you will care for the ostomy, but the goal is to have the patient assume self-care and a normal life. The first step in that direction is for the patient to adjust to the presence of an ostomy. If the patient has been sick before the surgery and the ostomy leads to less pain or discomfort, the transition may be easier. Similarly, patients with continent ostomies may adapt more easily to their stoma.

Toward Evidence-Based Practice

Li, C. C., Rew, L., & Hwang, S. L. (2012). The relationship between spiritual well-being and psychosocial adjustment in Taiwanese patients with colorectal cancer and a colostomy. *Journal of Wound Ostomy & Continence Nursing, 39*(2), 161–169.

Participants were 45 Taiwanese patients, aged 42 to 83 years, who were diagnosed with colorectal cancer and underwent colostomy surgery. They completed a questionnaire that examined relationships among demographic and clinical characteristics, spiritual well-being, and psychosocial adjustment to the colostomy. Participants reported strong family relationships but poor adjustment in sexual relationships. Spiritual well-being was significantly associated with psychosocial adjustment and was found to play an important role for patients when faced with psychosocial adjustment related to a colostomy.

Poletto, D., & Silva, D. M. (2013). Living with intestinal stoma: The construction of autonomy for care. *Revista Latino-Americana de Enfermagem, 21*(2), 531–538.

Ten people who received a stoma, and their family members, participated in two semi-structured interviews to investigate which care provided in the postoperative period played the largest role in promoting autonomy. The study identified common factors that influence the development of autonomy, including (1) the need to carry out stoma care; (2) receiving health support and care after discharge from hospital; (3) the family's support in developing autonomy; and (4) returning to daily activities and social reinsertion. The authors suggested that health professionals are fundamental to the process of developing autonomy by working as educators, supporting the achievement, and encouraging the care and the return to activities.

1. Based on these studies, write three nursing interventions you would use to help a patient accept and adapt to a stoma.

2. Suppose you wanted to know whether those interventions would be effective for patients with other medical conditions. For example, would the interventions that help clients adapt to a stoma help other clients to adapt to a different issue? Think of at least two health conditions for which you might want to perform the two studies just described. Explain your thinking.

Go to Chapter 29, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

Ostomy patients no longer have sphincter control, so they may need to modify their diet. You can promote adaptation by teaching the client about diet modifications. Box 29-3 discusses the effects of some foods on a patient with an ostomy.

With the exception of a temporary double-barreled colostomy, ostomy care is a lifelong task. Patients must learn about appliances, stoma care, and ongoing management of the ostomy. In many hospitals and large communities, you can find an enterostomal therapy nurse to assist patients with their ongoing care and to provide consultation on ostomy appliances. For more interventions to promote physical and psychological adaptation,

Go to Chapter 29, **Clinical Insight 29-2: Guidelines for Ostomy Care,** in Volume 2.

Colostomy Irrigation

Colostomy Irrigation may be indicated as an occasional intervention for constipation or in a select population of patients. Consult with the ostomy nurse and/or physician to see if colostomy irrigation is appropriate for your patient. A stoma above the descending colon usually has liquid output that cannot be controlled. Therefore, it is not irrigated. Patients with an ostomy in the descending or sigmoid colon may use colostomy irrigation as a means to control bowel evacuation and possibly eliminate the need to wear an ostomy pouch.

Colostomy irrigation is similar to an enema. The nurse or patient inserts a flexible tube into the stoma and instills a traditional enema solution. The patient may use a special plastic sleeve over the stoma or an ostomy appliance to direct the output into the toilet. After evacuation of the bowel, the client may wear a small covering over the stoma instead of a pouch. See the Highlights of Procedures box for a summary. For the complete procedure,

Go to Chapter 29, **Procedure 29-7: Irrigating a Colostomy,** in Volume 2.

KnowledgeCheck 29-8

- How can you help a patient adapt psychologically to living with a bowel diversion?
- What does a healthy stoma look like?
- Why is skin care around a stoma so important?

BOX 29-3 ■ Dietary Changes Associated With an Ostomy

Note: These are only suggestions. Each person must, by trial and error, discover what works best for him.

General Guidelines for Patients

- Initially you may be asked to follow a bland, low-residue or soft diet for a month or two to prevent obstructions and GI upsets. Advance the diet by adding one new food at a time.
- Eat three or more meals daily at regular times.
- People with ostomies may require additional fluid to compensate for the loss of the large intestine.
- Avoid chewing gum, as it may cause you to swallow air, causing a noisy stoma.
- Avoid foods that cause gas, odor, blockage, or loose stools. Eventually introduce them into your diet one at a time and be aware of their effects.
- Chew your food well to avoid blockage of the stoma.
- Avoid excessive weight gain.

Foods That May Cause Gas or Odor

Alcohol, beer, carbonated beverages

Asparagus, beans, broccoli, Brussels sprouts, cabbage, cauliflower, cucumbers, garlic, onions

Dairy, eggs

Fish, cod liver oil, nuts, peanut butter

Foods That May Help Control Gas or Odor

Buttermilk, yogurt

Cranberry juice

Parsley

High-Fiber Foods That May Cause Blockage

You can eat some of these foods (e.g., mushrooms, shrimp) if you cut them into small pieces and chew them very thoroughly. As long as blockage does not occur, these foods should not necessarily be avoided, but used carefully.

- Foods with seeds (e.g., raspberries)
- Foods with tough skins (e.g., corn, dried fruits, pears, tomatoes)
- Mushrooms
- Nuts, popcorn
- Raw or minimally cooked fruits and vegetables (e.g., coleslaw, Chinese stir-fried vegetables, oranges, apple skins)
- Shrimp, lobster
- Stringy foods (e.g., celery, coconut, spinach, bean sprouts, green beans, orange pulp)

Foods That May Cause Loose Stools

Alcohol, beer, caffeine, chocolate, licorice

Milk

Baked beans, cooked cabbage, onions

Bran cereal, whole grains

Prunes, raisins

Note: Never restrict fluids in an effort to control diarrhea.

Foods That May Alleviate Diarrhea

Bananas **R**ice (white) **A**pplesauce **T**oast (BRAT diet) and other starchy foods (e.g., rice, bread, potatoes)

Cheese and creamy peanut butter

Nursing Care Plan

Client Data

Olivia Grimaldi, 59 years old, is admitted to the orthopedic unit after having a total knee replacement. She is receiving intravenous opioid analgesics for pain. Mrs. Grimaldi's nurse sits down to talk and complete the nursing admission assessment. The conversation turns to a discussion of bowel habits.

Nurse: Mrs. Grimaldi, we pay special attention to bowel elimination because many people on this unit have problems. How often do you have a bowel movement?

Mrs. G: Not as often as I'd like. I used to be very regular, but lately everything is all mixed up.

Nurse: What has changed? Tell me what's going on.

Mrs. G: Oh, it's so embarrassing. I haven't told anyone about this.

Nurse: When did this problem start?

Mrs. G: Everything started going bad when I fell and landed on this knee a few months ago. Nothing was broken, but the pain has been just awful. I knew I had arthritis, but I never felt anything like this. I couldn't sleep, the pain was so bad. The doctor put me on some pain pills—narcotics—and they helped, but I got so constipated. I started using laxatives to go to the bathroom, but I kept needing to use more and more. Sometimes I would take a laxative and then I would have to get to the bathroom quickly. I had a couple of accidents because I couldn't get to the toilet quickly enough.

Nurse: I think this is something we'll be able to help you with, Mrs. Grimaldi.

The nurse discovers that Mrs. Grimaldi drinks about 32 to 40 ounces of fluid each day and has used several stimulant laxatives and enemas to relieve her constipation. Her mobility has been significantly impaired for the past 2 months.

Nursing Diagnosis

Bowel Incontinence related to overdistention of the rectum secondary to chronic constipation, as evidenced by client report of constipation when taking opioids and subsequent fecal incontinence with the use of laxatives.

NOC Outcomes	Individualized Goals/Expected Outcomes
Bowel Continence (0500) Bowel Elimination (0501)	*By discharge, Mrs. Grimaldi will:* 1. Be free from fecal impaction. 2. Begin to establish a regular pattern of stool evacuation. 3. Describe four actions she can take to reduce the risk of constipation. *Within 1 month, Mrs. Grimaldi will:* 1. *Control stool passage without any episodes of fecal incontinence.*

NIC Interventions

Bowel Management (0430)
Bowel Training (0440)

Nursing Activities	Rationale
1. Conduct a comprehensive assessment of all factors related to fecal incontinence and impaired bowel elimination.	Fecal incontinence has multiple possible causes. The best nursing interventions are those based on client assessment (Bliss & Norton, 2010). Constipation is attributed to immobility, weak straining ability, use of constipating drugs, neurological disorders, lack of dietary fiber, and poor fluid intake (Fritz & Pitlick, 2012).

Nursing Care Plan (continued)

Nursing Activities	Rationale
2. During physical examination, inspect the perianal skin for possible causes of fecal incontinence or skin irritation resulting from exposure to liquid stool.	Congenital abnormalities and hemorrhoids can lead to incontinence. Skin tags can make cleansing difficult and lead to minor soiling that is difficult to distinguish from actual fecal incontinence (Bliss & Norton, 2010).
3. Inquire about Mrs. Grimaldi's access to the bathroom and toileting facilities at home and work. Provide regular toileting assistance as long as the client needs it during her hospitalization.	A lack of convenient access to the toilet can precipitate fecal incontinence (Song, 2012).
4. Work with Mrs. Grimaldi to establish a bowel reeducation program, starting with bowel cleansing.	Cleansing is indicated for rectal impaction or palpable stool in the descending or sigmoid colon. Cleansing with manual disimpaction, laxatives, and/or enema removes any potential blockages to stool elimination (Jamshed, Lee, & Olden, 2011; Rao & Go, 2010).
5. Ensure that Mrs. Grimaldi drinks 30 mL/kg of fluids per day and gradually increase dietary fiber with bran or with bulking agents. Mrs. Grimaldi is drinking only about 1,200 mL of fluid per day. If she weighs 125 lb (56.7 kg), she would need to drink at least 1,700 mL of fluid per day.	Increasing fluid intake may help to normalize stool consistency in clients with constipation who do not have adequate fluid intake (Leung & Rao, 2011; Linari, Schofield, & Horrom, 2011). Increasing dietary fiber improves stool consistency and reduces fecal incontinence (Leung & Rao, 2011; Shakil, Church, & Rao, 2008); however, unless the diet is deficient in fiber, adding fiber does not necessarily alleviate constipation. Bulk should be added to the diet slowly to reduce the risk of bloating, gas, or diarrhea. Dosing of bulking agents can be increased weekly until desired results are achieved; the results are more important than the amount of fiber ingested.
6. Teach Mrs. Grimaldi about how her body works to produce stool; ways to gently signal the body to defecate; the importance of responding to the urge to defecate; and how immobility, medications, and dehydration can cause constipation.	Gaining knowledge about bodily functions allows clients to be active participants in their care. Addressing causes of constipation can reduce the risk of recurrence (Fritz & Pitlick, 2012; Rao & Go, 2010).

Evaluation

Review initial outcomes and goals. Reassess daily progress toward stated discharge goals.

The day before Mrs. Grimaldi's discharge she had no palpable stool on physical exam, and she no longer needed the intravenous analgesics; her patient-controlled analgesia (PCA) pump was discontinued. She was drinking approximately 20 mL/kg per day of fluids, she had begun taking 2 tablespoons of psyllium dissolved in water every morning, and she had a bowel movement each of the previous 2 days with stool of normal consistency for the first time in more than a month. She was able to state the actions she would take at home: Continue the bulk supplements, try to increase her fluid intake to 30 mL/kg per day, use nonconstipating analgesics, and increase her mobility each day. The nurse charted that the goals were met.

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 29-1: Testing Stool for Occult Blood

- Persons age 50 or older should be screened every 1 to 2 years for occult (hidden) blood in the stool. Some guidelines suggest annual screening. High-risk groups require initial screening at a younger age.
- Patients should avoid foods that may alter the accuracy of the test for 3 days before collecting the stool specimen.
- Review the patient's medications. If the patient is taking salicylates, NSAIDs, iron, anticoagulants, or colchicines, consult with the physician.
- Take care that the sample is not contaminated by urine or menstrual blood.
- Test two small stool samples from separate areas of the large sample.
- Following the manufacturer's directions, place the correct number and size of drops of developer solution into the "windows" of the opposite side on the Hemoccult slide.
- Record a positive result if the slide windows turn blue.

Procedure 29-2: Placing and Removing a Bedpan

- Determine whether the patient will need to use a regular bedpan or a fracture pan.
- Don clean procedure gloves.
- Help the patient to achieve a position on the bedpan that will be most helpful in facilitating elimination. Use a semi-Fowler's position whenever possible. Modify the position based on the patient's condition.
- Provide toilet tissue, clean washcloths, and towels for the patient to perform personal hygiene when elimination is complete. Assist if the patient cannot perform these tasks independently.

Procedure 29-3: Administering an Enema

- Generously lubricate and gently insert the rectal tube.
- Instill warm solution at a slow rate.
- For best results:
  - Be sure patient is properly positioned (left lateral with knee flexed, if possible).
  - Instruct her to retain the solution for 3 to 15 minutes, depending on the type of enema.
  - Assist the patient in a sitting or squatting position to promote defecation.
- Before leaving the bedside, implement fall prevention measures that are appropriate for your patient.
- Use nursing judgment to modify the procedure based on the patient's mobility and ability to follow your instructions.

Procedure 29-4: Removing Stool Digitally

- Be aware that this procedure is both painful and embarrassing to your patient.
- Trim and file your fingernails so they do not extend over the ends of your fingertips.
- Obtain baseline vital signs, and determine whether the patient has a history of cardiac problems or other contraindications.
- Determine whether the procedure will be accompanied by suppository insertion or enema administration.
- Use only one or two gloved fingers, and remove stool in small pieces.
- Allow the patient periods of rest, and monitor for signs of vagal nerve stimulation.
- Teach the patient lifestyle changes necessary to prevent stool retention.

Procedure 29-5: Inserting a Rectal Tube

- A rectal tube may be used to facilitate the passage of gas for clients experiencing intestinal distention.
- Position the patient on his left side.
- Lubricate the tip of the tube; insert 10 to 12.5 cm (4 to 5 in.).
- Attach the collecting device to the end of the tube.
- Leave the tube in place for 15 to 20 minutes.
- Assist the patient to move about in bed; the knee-chest position is ideal if tolerated.

Procedure 29-6: Changing an Ostomy Appliance

- Change the pouch every 3 to 5 days, as a general rule.
- Empty the old pouch before removing it, if possible.
- Remove the wafer or pouch, pulling down from the top with one hand while holding counter-tension with the other.
- Assess the stoma and the peristomal skin area (e.g., for discoloration, swelling, redness, irritation, excoriation, bleeding).
- Use a measuring guide to determine the size of the stoma.
- Trace the size of the opening onto the back of the wafer, and cut the wafer opening about 2 to 3 mm (1/16 to 1/8 in.) larger.
- Apply the new wafer with gentle pressure.

Note: Some pouches come with the wafer attached, some without. These instructions assume that the wafer is attached.

Procedure 29-7: Irrigating a Colostomy

- Consult with the ostomy nurse and/or physician to see if colostomy irrigation is appropriate for your patient.
- Determine the patient's normal bowel pattern before surgery.
- Prime the tubing before irrigation, using 500 to 1,000 mL, preferably 1,000 mL, of warm tap water.

Continued

Highlights of Procedures 29-1 Through 29-8—cont'd

- Position the patient in front of or on the toilet or bedside commode. If the patient is immobile, place her in left side-lying (Sims') position, and use a bedpan.
- Prepare the new appliance before removing the existing one.
- Examine the stoma and peristomal skin.
- Lubricate the cone at the end of the tubing and insert it gently.
- Allow approximately 30 minutes for evacuation.
- Remove the sleeve, and rinse, dry, and store it.

Procedure 29-8: Placing Fecal Drainage Devices

Procedure 29-8A: Applying an External Fecal Collection System

- Select the fecal management system appropriate for the patient.
- Obtain assistance as needed.
- Place the patient side-lying.
- Cleanse and dry the perineal area; clip hair as needed.
- Spread the buttocks and apply the device; avoid gaps and creases.
- Hang the drainage bag lower than the patient.

Procedure 29-8B: Inserting an Indwelling Fecal Drainage Device

- Select the fecal management system appropriate for the patient.
- Obtain assistance as needed.
- Place the patient left side-lying.
- Remove any indwelling device.
- Cleanse and dry the perineal area;
- Prepare the device according to instructions (e.g., remove residual air from the balloon).
- Lubricate the balloon generously with water-soluble lubricant.
- Spread the buttocks and gently insert the balloon end of the catheter.
- Inflate the device with water or saline.
- Remove the syringe from the inflation port; gently tug the catheter.
- Position the tubing, avoiding kinks; position the collection bag lower than the patient.

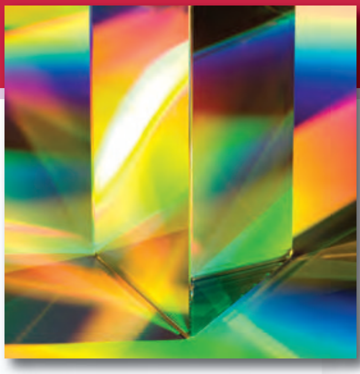
CHAPTER 30



Sensation, Perception, & Cognition

Learning Outcomes

After completing this chapter, you should be able to:

- Identify the components of the sensory experience.
- Compare and contrast sensory deprivation and sensory overload.
- List factors placing clients at risk for altered sensory perception.
- Discuss the hazards of sensory deficits in vision, hearing, taste, smell, touch, and proprioception.
- Identify factors that affect sensory stimulation.
- Assess clients for signs and symptoms of altered sensory perception.
- State nursing diagnoses and outcomes appropriate for clients with problems of sensory perception.
- Describe nursing interventions to prevent sensory deprivation and sensory overload.
- Describe nursing interventions for clients with sensory deficits.
- Discuss strategies to enhance communication with clients with sensory deficits.

Key Concepts

Perception
Reception
Sensation

Related Concepts

See the Concept Map on Davis*Plus*.

Example Problems

Sensory deprivation
Sensory overload
Sensory deficits

Meet Your Patients

- Joshua is a 28-year-old patient in the intensive care unit (ICU). He had a car accident 3 weeks ago and has had several surgeries to repair a fractured femur, ruptured spleen, and intracranial bleeding. He was ventilated mechanically for 10 days and has had numerous invasive procedures. The nurses report that he is very confused and has been hallucinating.
- Richard is a 90-year-old man who has been a resident at a skilled nursing facility for 10 years. He has no visitors, never leaves his room, has no television or radio in the room, and no longer speaks. He does not respond to verbal or tactile stimulation. He lies in bed in a fetal position. When staff members try to move him, he moans and howls.

Consider how these patients are similar and how their care might overlap. It seems hard to imagine that these patients could have much in common. What similarities can you see? What differences? As you read this chapter, follow these cases and other examples illustrating the effects of altered sensory or perceptual function.

Theoretical Knowledge knowing why

We experience the world through our senses. Vision, hearing, smell, taste, touch, and our sense of our body in space all help us to interpret and interact with our environment in a meaningful way. To grow, develop, and function, we must be able to sense and respond to sensory input.

Many patients who are being treated for one condition also have a preexisting sensory deficit (e.g., a diabetic client whom you are teaching self-injection may also be blind). Others develop alterations in sensory function as a result of their illness or of medications they are taking. The Joint Commission (2010) requires that you address the communication needs of patients with vision, speech, hearing, language, and cognitive impairments. This chapter will help you provide care for such patients.

ABOUT THE KEY CONCEPTS

Throughout your nursing career, you will care for patients with altered sensory function. To best meet their patient care needs, you will need to understand how the concepts of **sensation, reception**, and **perception** influence their sensory experience. In this section you will also learn about related concepts, including those needed to care for patients who experience sensory deprivation, overload, or deficits.

COMPONENTS OF THE SENSORY EXPERIENCE

Our senses give us information about the environment inside and outside of our bodies. The purpose of sensation is to allow the body to respond to changing situations and maintain homeostasis. A sensory experience involves four components in the nervous system: stimulus, reception, perception, and an arousal mechanism. A **stimulus** may be a sight, sound, taste, touch, pain, or anything that stimulates a nerve receptor. The brain must receive and process it to make it meaningful.

Reception

Reception is the process of receiving stimuli from nerve endings in the skin and inside the body. A receptor converts a stimulus to a nerve impulse and transmits the impulse along sensory neurons to the central nervous system (CNS). Some receptors remain activated for as long as the stimulus is applied. However, most receptors *adapt* to stimuli; that is, their response declines with time. Adaptation explains why, over time, you become unaware of an unpleasant smell or the persistent hum of an air conditioner.

Receptors usually respond to only one type of stimulus. For example, taste buds in the mouth detect sweet, sour, salty, or bitter, whereas receptors in the retina detect light rays. The following are examples of the many types of sensory receptors in the body:

- *Mechanoreceptors* in the skin and hair follicles detect touch, pressure, and vibration.
- *Hair cells* are receptors for hearing. Located in the cochlea of the ear, they detect sound waves. In the vestibular apparatus of the ear, receptors for equilibrium and balance also detect acceleration of the body and position of the head.
- *Thermoreceptors* in the skin detect variations in temperature.
- *Proprioceptors* in the skin, muscles, tendons, ligaments, and joint capsules coordinate input to enable us to sense the position of our body in space (proprioception).
- *Photoreceptors* located in the retina of the eyes detect visible light.
- *Chemoreceptors* for taste are located in our taste buds. *Olfactory receptors* (chemoreceptors for smell) are located in the epithelium of the nasal cavity.

Perception

Perception is the ability to interpret the impulses transmitted from the receptors and give meaning to the stimuli. After the receptors generate nerve impulses, the impulses travel along neural pathways to the spinal cord and brain. They are then relayed to specialized locations in the brain where perception of the stimuli occurs (Fig. 30-1). For example, vision is perceived in the occipital lobes, hearing in the temporal lobes, and touch in the somatosensory area. Perception requires functioning of the sensory receptors, the reticular activating system, neural pathways, and brain.

Perception occurs when the person becomes aware of the stimulus and receives the information. It would not be possible to process all the stimuli that constantly bombard us. The brain discards about 99% of all sensory information as irrelevant and unimportant. For example, you are usually unaware of your clothing touching your body. However, if you focus on it, you can feel it. Perception of a stimulus is affected by several factors:

- *Location* of the receptors and pathway activated
- *Number* of receptors activated
- *Frequency* of action potentials generated (which varies according to the intensity of the stimulus)
- *Changes* in location, number, and frequency

Past experiences, knowledge, and attitude also influence perception.

Arousal Mechanism

For the central nervous system to perceive, interpret, and react to incoming stimuli, it must be active. The **reticular activating system (RAS)**, located in the brainstem, controls consciousness and alertness. The neurons of the RAS make connections between the spinal cord, cerebellum, thalamus, and cerebral cortex, relaying visual, auditory,

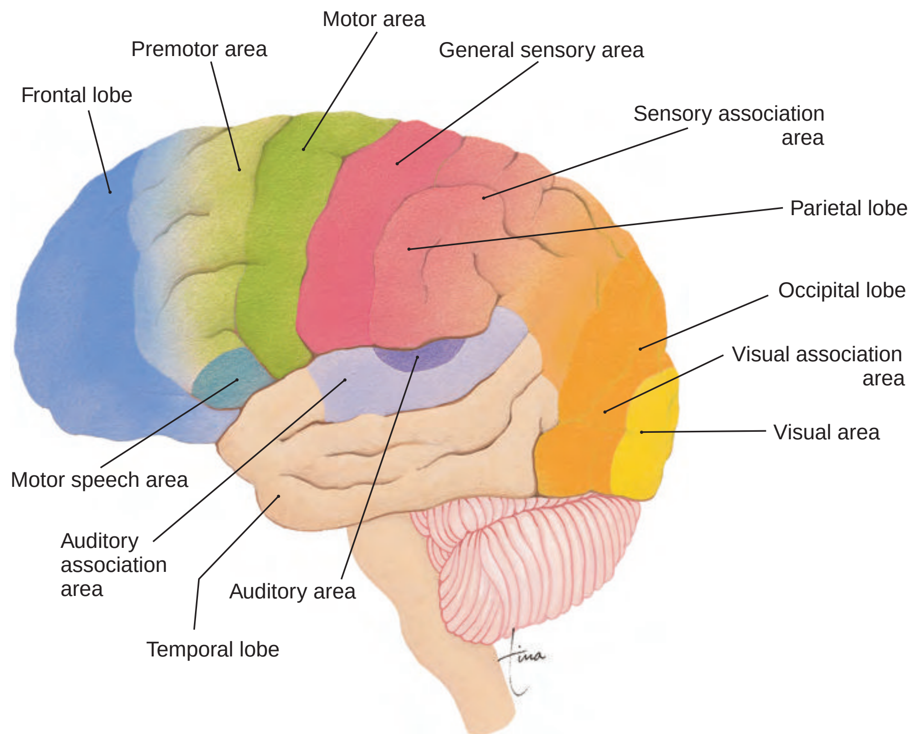


FIGURE 30-1 Special sensory areas of the brain receive and interpret stimuli from the sensory receptors. (*Source*: Scanlon, V., & Sanders, T. (2014). *Essentials of anatomy and physiology* (7th ed.). Philadelphia: F. A. Davis. Used with permission.)

and other stimuli that help keep us awake, attentive, and observant. Without such stimuli, the CNS becomes lethargic, and the person may lose consciousness. Anesthesia, sedatives, opioids, and some other drugs depress the RAS, as does a darkened, quiet environment. Not surprisingly, as you will learn in Chapter 34, sleep is regulated by the RAS.

The level of stimuli needed to maintain arousal varies: Some people feel optimally alert in bright, noisy, fast-paced environments, whereas others prefer much lower levels of stimulation. As discussed earlier, the brain adapts to constant stimuli, such as a ticking clock. Thus, to maintain arousal, some variation in stimuli is required, such as different pieces of music or an ever-changing view.

Responding to Sensations

Once a stimulus is perceived, the brain either discards it, stores it in memory, or sends impulses along motor pathways to various parts of the body (e.g., the muscles, the heart, and so on), bringing about a response. Humans respond to sensations when they are alert and receptive to stimulation. For example, a fatigued new mother may wake up to the soft cry of her infant yet sleep through the persistent ringing of the doorbell. The response to a stimulus is based on the following factors:

Intensity An intense stimulus excites more receptors, leading to a greater response. For example, a bright, glaring light can cause you to respond by squinting and shielding your eyes, whereas a dim light may cause little reaction.

Contrast Contrast is also stimulating. Imagine being outside in cold, windy weather. If you enter an unheated garage, you instantly feel warmer because the building blocks the wind. If you then go inside a room with a blazing fireplace, you will need to take off layers of clothing rapidly because the contrast in temperature will make you feel hot.

Adaptation Often we take stimuli for granted. Recall your first clinical experience. Did you notice the noise and activity on the unit? Nurses become accustomed to the noise, lights, activity, and even alarms and are able to "tune them out." These stimuli are new to many patients, so they notice them and may have difficulty resting.

Previous Experience Prior experience with a stimulus affects ongoing responses to the same stimulus. Have you ever seen a patient scrunch her eyes, grit her teeth, or turn away from an injection before you are even ready to give it? This may mean that she has memory of a prior negative experience with injections.

KnowledgeCheck 30-1

- What is the difference between reception and perception?
- What are the four components of a sensory experience?
- What is the role of the reticular activating system in the sensory experience?

FACTORS AFFECTING SENSORY FUNCTION

Among the many factors affecting sensory function are developmental stage, culture, health status, medications, stress level, personality, and lifestyle.

Developmental Variations

People have differing sensory perceptual abilities at different stages of life. In addition, the need for and use of sensory stimulation differs throughout life.

Newborns Newborns can track objects and respond to light, but their vision is far less acute than that of older children and adults. Their hearing is especially acute at low frequencies. Newborns can also discriminate between different tastes, and they prefer sweet over sour. They react to odors and seem to be able to discriminate between the smell of their own mother's breast milk and that of another woman. The sense of touch is keenly present at birth; the face, hands, and soles of the feet are the most sensitive (Polan & Taylor, 2010). In the first months of life until the autonomic nervous system matures, newborns are easily overstimulated by the loud noises, bright light, high contrast objects, and sensitive areas (back and bottom of feet), particularly when more than one sense is involved. They defend themselves from sensory overload by exhibiting avoidance behaviors, such as crying, mottling, poor feeding and sleeping, and even yawning.

Infants Infants require sensory stimulation to grow and develop normally. Tactile stimulation through cuddling, feeding, and soothing creates a bond between infant and caregivers, provides comfort and pleasure, and teaches the infant about the external environment. Exposure to voices, music, and ambient noise develops the auditory nervous system. By 1 year of age, the child can discriminate between different sounds and often recognizes the source. Lights, colors, and contrast allow the infant to observe the world in which she lives.

Children and Adolescents In early childhood, visual acuity improves; full depth perception is achieved during the preschool period. Hearing is usually fully developed in young children; however, they may experience reversible hearing loss as a result of frequent ear infections and cerumen impaction. In contrast to toddlers, who often lose their balance when walking, older children are sure and steady on their feet. During the school-age years and adolescence, children are developmentally driven toward peers, and the increased social interaction provides a wealth of sensory stimulation.

Adults and Older Adults By early adulthood, senses are at their peak, unless they are affected by illness or injury. As the adult ages, all of the senses are affected. Table 30-1 describes sensory changes associated with aging.

Table 30-1 ➤ Sensory Function Changes With Aging

SENSE	CHANGES ASSOCIATED WITH AGING
Vision	The vitreous humor becomes thinner, and "floaters" appear in the visual field. The lens becomes discolored and opaque; the pupil becomes smaller. Therefore, less light reaches the retina, limiting vision. The lens becomes less flexible and less able to focus on near objects. The ciliary body contracts and the lens thickens, bringing loss of visual acuity, decreased ability to accommodate to distance and sudden changes in illumination, and decreased night vision. Peripheral vision decreases. Tear production decreases.
Hearing	Cerumen is drier and more solid, creating hearing loss. Scarring occurs (e.g., from previous inflammation over the life span). Hearing changes commonly include presbycusis (hearing loss of high-frequency tones) and decreased speech discrimination.
Taste	Taste buds atrophy and decrease in number, so there is less ability to perceive tastes, especially sweetness. Dry mouth may alter the sense of taste.
Smell	Atrophy and loss of olfactory neurons decreases the ability to perceive smell (which may also alter the sense of taste).
Touch	Loss of sensory nerve fibers and changes in the cerebral cortex decrease the ability to perceive light touch, pain, and temperature variations.
Kinesthesia	Kinesthetic changes include a decrease in muscle fibers and diminished conduction speed of nerve fibers, resulting in slowed reaction time, decreased speed and power of muscle contractions, and impaired balance. These place older adults at increased risk for falling.

Older adults experience a generalized decrease in the number of nerve conduction fibers, resulting in slower reflexes and delayed response to stimuli. Structural changes also occur in the aging eye and ear. Sensory decline with aging may cause withdrawal, depression, social isolation, and hallucinations. Keep in mind that aging is not the only cause of sensory deficits in older adults.

Culture

Culture affects the nature, type, and amount of interaction and stimulation that people feel comfortable with. People of different cultural backgrounds tend to prefer differing amounts of eye contact, personal space, and physical touch. Compare the day-to-day experience of an older adult living in a remote farming community to someone living in an extended family home in the center of a large city. The amount of stimulation perceived as normal would be very different for each of these people. You may think your hospitalized patient needs quiet time alone to rest. However, if he is accustomed to being surrounded by a large family, he may actually rest better in the midst of what seems like chaos to you. Also, use touch advisedly. For some people it is comforting; for others, it may be offensive.

Illness and Medications

Neurological disorders, such as multiple sclerosis, slow the transmission of nerve impulses. Diseases that affect circulation (e.g., atherosclerosis) may impair function of the sensory receptors and the brain, thereby altering perception and response. Reduced or lack of oxygen (anoxia) harms and even destroys cells, causing widespread damage to the neurologic system.

Some conditions affect specific sensory organs. For example, diabetic retinopathy is the leading cause of blindness among adults ages 20 to 74. Hypertension, too, can damage the retina of the eyes.

Physiologic injury to the brain may occur from trauma, as follows:

- *Closed head injury* (e.g., acute concussion) occurs when brain tissue is compressed from bleeding, bruising, fluid, or increased pressure inside the skull, for example after a fall.
- *Penetrating injury* occurs when a foreign object enters into the brain, resulting in damage to the brain tissue or structure.

Medications that cross the blood brain barrier affect neurologic or sensory function by damaging or killing brain cells. For example, aspirin and furosemide (Lasix) become ototoxic if taken for a long period of time and impair function of the auditory nerve. CNS depressants, such as opioid analgesics and sedatives, blunt reception, and perception of stimuli.

Stress

Have you ever been under a great deal of stress? How did it feel? When you are under stress, do you find yourself looking for or avoiding stimuli? Obviously, stress provides added stimulation. As a result, a person who is bored may add stress. By setting a goal, such as running a marathon, the person undertakes a series of activities to reach that goal. In that regard, stress provides sensory stimulation at a time when the person may have been experiencing deprivation.

However, stress can cause too much stimulation. Physical illness, pain, hospitalization, tests, and surgery are all stressors that can lead to sensory overload—more stimuli than the person can handle. Jason (Meet Your Patients) has been under tremendous physical and emotional stress as a result of his injuries and surgeries. His situation is one in which you might want to limit unnecessary stimuli (e.g., noise, lights, too many visitors).

Personality and Lifestyle

Are you the kind of person who likes to have people around all the time? Do you thrive on noise and action? Or are you the kind of person who loves to curl up with a book and a cup of tea? Clients, too, vary in their personalities and lifestyles. Some people, by nature, like excitement, change, and stimulation; others prefer a more predictable and quiet life. Clients are at risk for sensory alterations if their previous level of stimuli does not match their current level. Health problems, a change of environment, or loss of a partner can each create changes in stimuli.

KnowledgeCheck 30-2

- List five major factors that affect sensory function.
- Compare and contrast the sensory changes in childhood with those in older adulthood.

SENSORY ALTERATIONS

Humans are constantly striving to achieve **sensoristasis**, a state of optimal arousal. Sensory alterations occur when the body experiences meaningless or limited stimulation (sensory deprivation), excessive stimulation (sensory overload), or sensory deficits.

Example Problem: Sensory Deprivation

Sensory deprivation is a state of RAS depression caused by a lack of meaningful stimuli. When environmental stimuli are deficient, the remaining stimuli, such as distant noises, minor pain, and cold extremities, can become overly noticeable or distorted, filling in the "sensory gap" and causing the patient a level of distress that is out of proportion to the intensity of the stimulus. Clinical manifestations include problems with perception, cognition, and emotion (Box 30-1).

PICOT

Sensory Overload in the ICU

Situation: The nurse is caring for a client with an impulse control disorder who is admitted to the ICU after sustaining traumatic injuries from motorcycle accident. The client has a history of violent outbursts; the nursing team is meeting with a psychiatric social worker to develop an appropriate plan of care.

PICOT Components

P	Population/patient	=	Hospitalized patients with impulse control disorder
I	Intervention/indicator	=	Sensory overload in ICU
C	Comparator/control	=	Patients without a psychiatric history
0	Outcome	=	Violent behavior
T	Time	=	During hospitalization

Searchable Question: Do __________ (P) who are __________ (I) demonstrate __________ (O) as compared to __________ (C) during __________ (T)

Example of Evidence: Clients with a psychiatric history who are admitted to the acute medical facility pose special challenges for the nursing staff. Priorities include ensuring safety for this client and others, including healthcare staff. Initial assessment should focus on patterns and types of violent behavior, frequency, and characteristics of targeted victims. The nurse would also assess for possible triggers to agitation. In addition to collecting the client's psychiatric and medication history, the nurse would also be alert to potential high stress situations during hospitalization, such as sensory overload, that precipitate negative behaviors.

Practice Change: Healthcare staff will modify the environment to avoid exposing clients to excess sensory stimulation.

Reference: Flannery, R. B., Jr. (2005). Precipitants to psychiatric patient assaults on staff: Review of empirical findings, 1990–2003, and risk management implications. *Psychiatric Quarterly*, 76(4), 317–326. doi:10.1007/s11126-005-4965-y

The following situations increase the risk for sensory deprivation:

- Impaired sensory reception (e.g., neurological injury, dementia, depression, sleep deprivation, sensory losses, and CNS depressant medications)
- Inability to transmit or process stimuli (e.g., nerve or brain injury)
- Restricted mobility
- Sensory deficits (e.g., vision, hearing)
- A nonstimulating, monotonous environment. Examples include children in orphanages; people in prison; homebound disabled and older people; patients in nursing homes and other institutions; and hospitalized patients in isolation, seclusion, or private rooms.
- Being from a different culture and unable to interpret received cues

Example Problem: Sensory Overload

Sensory overload develops when either environmental or internal stimuli—or a combination of both—exceed a higher level than the patient's sensory system can effectively process. This sometimes occurs in patients who, because of neurological or psychiatric disorders, are unable to adapt to continuing, nonmeaningful stimuli. Some clinical manifestations of sensory overload are similar to those of sensory deprivation (see Box 30-1).

Hospitalized patients often experience sensory overload due to a combination of physical discomfort, anxiety, separation from loved ones, and the experience of being in the unfamiliar hospital environment. Medications that stimulate the CNS may also contribute to overload, as will substances, such as caffeine. In

BOX 30-1 ■ Signs of Sensory Deprivation and Sensory Overload

Sensory Deprivation	Sensory Overload
Irritability	Irritability
Confusion	Confusion
Reduced attention span	Reduced attention span
Decreased problem-solving ability	Decreased problem-solving ability
Drowsiness	Drowsiness (due to insomnia)
Depression	Muscle tension
Preoccupation with somatic complaints (e.g., heart palpitations)	Anxiety
Delusions (misinterpretations of external stimuli)	Inability to concentrate
Hallucinations (seeing, hearing, feeling, tasting, or smelling something that is not there)	Decreased ability to perform tasks
	Restlessness
	Disorientation

addition, physical conditions that activate the CNS (e.g., hyperthyroidism, acute brain injury) contribute to sensory overload. Some mental health conditions (e.g., psychosis, sensory integration disorder, attention deficit hyperactivity disorder) are exacerbated by high intensity noise and light in the environment.

KnowledgeCheck 30-3

- How does sensory deprivation occur?
- Identify five signs of sensory deprivation.
- How does sensory overload occur?
- Identify five signs of sensory overload.

ThinkLike a Nurse 30-1

Review the stories of Joshua and Richard (Meet Your Patients). How are these patients similar? What factors may have contributed to each patient's current concerns?

Example Problem: Sensory Deficits

Sensory deficits may stem from impaired reception, perception, or both. Of the six basic sensory deficits discussed here, impaired vision and hearing are the ones you are most likely to encounter in nursing practice. Drawing on your personal experience, think how many people you know who wear glasses or contact lenses or who wear a hearing aid. How many do you know whose vision or hearing is not completely corrected by such aids? You can see that sensory deficits are common.

A sudden onset of a deficit is unnerving and may lead to disorientation and anxiety. Gradual changes allow the person to adapt, often without even realizing the extent of it. The patient who has progressively lost hearing may, over time, keep turning up the sound on his radio and telephone and not realize that others find the sound blaring. When there is a deficit in one sense, the other senses may become sharper to compensate (e.g., a person who is blind may develop more acute hearing). Six sensory deficits are discussed in the following sections.

Sensory Deficit: Impaired Vision

Vision occurs when light rays that focus on the retina trigger a nerve impulse that is transmitted to the visual area of the brain in the occipital region. Visual deficits may result from trauma or disease of the eye, microvascular problems, or CNS disorders. Common causes of visual deficits include age-related changes, refractive errors, orbital trauma, cataracts, glaucoma, diabetic or hypertensive retinopathy, macular degeneration, or loss of visual fields after a stroke (Box 30-2). Changes in vision affect all aspects of daily living and may severely limit mobility and interaction.

Sensory Deficit: Impaired Hearing

Hearing occurs when sound waves entering the ear canal are converted to vibrations and transferred from the middle ear to the inner ear. Vibrations cause the hair cells in the cochlea to bend, generating impulses that are carried by cranial nerve VIII to the brain. The auditory area in the brain is located in the temporal lobes. The auditory area interprets the sound and allows you to determine the direction from which the noise is coming. See Chapter 22, Figure 22-5, for an illustration of the structures of the ear.

Hearing deficits may result from injury or disease in structures of the ear, the nerves, or the brain (Box 30-3). Inability to hear decreases the ability to communicate and thus hampers social interaction. It may interfere with a patient's ability to understand instructions from healthcare professionals and create a safety hazard due to inability to hear warnings.

Sensory Deficit: Impaired Taste

Taste imparts flavor and interest to food. Taste deficits may decrease the pleasure associated with eating; weight loss and malnutrition may result. Taste depends on the functioning of the taste buds on the tongue and, to a lesser extent, on the soft palate. Four types of taste

BOX 30-2 ■ Common Visual Deficits

- **Myopia**, or nearsightedness, means that the patient is able to see close objects well but not distant objects. For example, a person with 20/200 vision can see an object from 20 feet away that a person with normal sight could see from a distance of 200 feet.
- **Hyperopia**, or farsightedness, implies that the eye sees distant objects well. A person with hyperopia may have 20/10 vision—he can see an object from 20 feet that a normal eye can see from 10 feet; however, near vision is impaired.
- **Presbyopia** is a change in vision associated with aging. The lens becomes less elastic and less able to accommodate to near objects. If you're older than 40 years of age, there's a good chance you may be experiencing this problem.
- **Astigmatism** is caused by an irregular curvature of the cornea or lens that scatters light rays and blurs the image on the retina. The person has blurred vision with distortion.
- **Cataracts** are a clouding of the lens, resulting in blurred vision, sensitivity to glare, and image distortion.
- **Glaucoma** is a type of vision loss caused by increased pressure in the anterior cavity of the eyeball that distorts the shape of the cornea and shifts the position of the lens, resulting in loss of peripheral vision. It can eventually lead to blindness.
- **Macular degeneration** is the loss of central vision due to damage to the *macula lutea*, the central portion of the retina. The leading cause of visual impairment in U.S. residents older than age 50, it is characterized by slow, progressive loss of central and near vision. It is usually present in both eyes.
- **Strabismus** (crossed eyes), in which one eye deviates from a fixed image, can cause permanent vision loss.

BOX 30-3 ■ Common Hearing Deficits

- **Conduction deafness** results when one of the structures that transmits vibrations is affected. It may be a temporary or permanent condition caused by infection of the middle ear, a punctured tympanic membrane, or arthritis of the auditory bones. A hearing aid may be helpful for conduction deafness.
- **Nerve deafness** occurs when there is damage to cranial nerve VIII or the receptors in the cochlea. It may result from ototoxic medications (e.g., gentamicin) or viral infections that affect cranial nerve VIII. Chronic exposure to loud noise may also lead to nerve and receptor impairment.
- **Presbycusis** is a progressive sensorineural loss associated with aging. It results from deterioration of the hair cells in the cochlea. Presbycusis leads to diminished ability to hear high-pitched sounds and to distinguish sounds in a noisy environment. Hearing aids may be of no value in sensorineural hearing loss.
- **Central deafness** results from damage to the auditory areas in the temporal lobes. Tumor, trauma, meningitis, or CVA (cerebrovascular accident, i.e., stroke) in the temporal lobe may cause this.
- **Tinnitus** is a term used to describe ringing in the ears. Most tinnitus comes from damage to the microscopic endings of the nerve in the inner ear, for example, trauma, turbulent blood flow, hypertension, ear infection, medications, otosclerosis, or arthritic changes of the bones of the ear.
- **Impacted cerumen** is a condition in which earwax becomes tightly packed in the ear canal, blocking the canal. Patients with impacted cerumen may experience a feeling of fullness or pain, decreased hearing, or tinnitus.
- **Otosclerosis** is a hardening of the bones of the middle ear, especially the stapes. The stapes becomes fixed, leading to poor sound transmission to the inner ear. The cause of this disorder is unknown.
- **Otitis media** is a middle ear infection. It is a common childhood illness that may be caused by viruses or bacteria.

buds exist: sweet, sour, salty, and bitter. A proposed fifth taste bud, glutamate, can detect savory flavors. The buds for sweet and salty tastes are primarily on the tip of the tongue; for sour taste, on the two lateral sides of the tongue; and for bitter taste, primarily on the posterior tongue and the soft palate (Fig. 30-2). When stimulated, taste buds generate nerve impulses that travel along the facial and glossopharyngeal nerves (cranial nerves VII and IX, respectively) to the taste area in the parietal–temporal cortex. Foods stimulate different combinations of taste buds. That stimulation, together with the sense of smell, produces the vast number of tastes we can perceive.

Impaired taste most commonly results from **xerostomia** (excessively dry mouth), which may be caused by medications (Box 30-4), decreased saliva production, inadequate fluid intake, poor nutrition, or poor oral hygiene. Other causes of taste deficits include the common

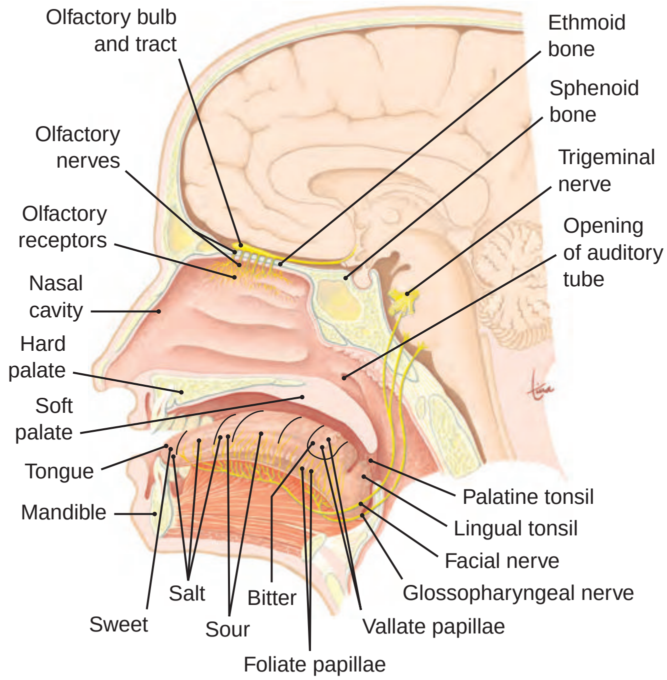

FIGURE 30-2 Structures concerned with the sense of smell and taste. (*Source*: Scanlon, V., & Sanders, T. (2014). *Essentials of anatomy and physiology* (7th ed.). Philadelphia: F. A. Davis. Used with permission.)

BOX 30-4 ■ Medications That Cause Tast Disturbance

Numerous medications can cause a foul or metallic taste. This unpleasant side effect can result from medication taken orally, IM, or IV.

- Antibiotics (metronidazole, rifampin, clarithromycin, tetracycline)
- Anticonvulsants (phenytoin and carbamazepine)
- Antihistamines and decongestants
- Antihypertensive (captopril) and cardiac medications (ACE inhibitors)
- Antiretroviral drugs (indinavir)
- Antithyroid medication
- Carbon anhydrase inhibitors, used to treat glaucoma (acetazolamide, methazolamide)
- Chemotherapy agents (procarbazine, vinblastine, vincristine, dacarbazine)
- Lithium carbonate
- Antipsychotics
- Antidepressants
- Statins
- Muscle relaxants (methocarbamol)

cold; infections of the nose, sinuses, mouth, or salivary glands; smoking; vitamin B_{12} or zinc deficiency; dental fillings and inlays; dementia; and injury to the mouth, nose, or head. A metallic taste in the mouth can occur during pregnancy due to hormonal fluctuations or from more serious causes such as cancer, peptic ulcer, and kidney disease.

Sensory Deficit: Impaired Smell

The sense of smell is triggered when chemoreceptors in the upper nasal cavities detect vaporized chemicals. Chemoreceptors generate impulses carried by the olfactory nerve (cranial nerve I) into the olfactory area in the temporal lobes (see Fig. 30-2). Vaporized molecules can be detected from a distance, so the sense of smell can serve as an early warning system for detection of smoke and noxious chemicals.

The sense of smell is vital to the sense of taste. Recall the last time you had a cold or nasal congestion. When the sense of smell is lost (**anosmia**), food does not taste the same. Patients who are unable to smell food lose their appetite, and nutritional deficits may result. Permanent anosmia may develop after cranial nerve damage, a tumor, or atherosclerosis. It may also be inherited and nonpathological. Zinc deficiency, heavy smoking, cocaine use, rhinitis, and sinusitis can cause reversible anosmia.

Nurses may make therapeutic use of a patient's sense of smell. **Aromatherapy**, the use of odors for therapeutic effect, has become one of the most widely practiced complementary therapies among nurses in the United States. Olfaction has been shown to play a role in memory, mood, and safety. See the box Complementary & Alternative Modalities (CAM): Essential Oils. Refer also to Chapter 42 for more information about aromatherapy.

Sensory Deficit: Impaired Tactile Perception

Touch is crucial to growth and development. It provides pleasure, warns us of injury, and transmits information about the external environment. The dermis of the skin contains receptors for the cutaneous sensations of light touch, pressure, heat, cold, and pain. Information from these receptors is transmitted to the sensory areas in the parietal lobes. The number of cutaneous receptors determines the sensitivity of an area and the amount of space devoted to that region in the sensory cortex area. The hands and face have the most receptors and therefore the largest area in the sensory cortex.

A person's ability to perceive touch is often measured in terms of *two-point discrimination,* that is, the ability to perceive as distinct two close but separate points pressed against the skin. On the lips and fingertips, a person can normally distinguish between points less than 4 mm apart, whereas on the torso, normal two-point discrimination is greater than 2 cm.

Loss of tactile sensitivity can be caused by a cerebrovascular accident (stroke), brain or spinal tumor or injury, or peripheral nerve damage caused by diabetes, Guillain-Barré syndrome, or chronic alcoholism.

Complementary & Alternative Modalities (CAM)

Essential Oils

Aromatherapy is the use of naturally extracted aromatic essences from plants to balance, harmonize, and promote the health of body, mind, and spirit. It is a natural, noninvasive treatment system designed to affect the whole person, not just the symptom or disease. Essential oils are thought to work by promoting the body's natural ability to balance, regulate, heal, and maintain itself. Some oils may be used topically in certain situations (e.g., minor burns). Beginning research supports the following; however, the evidence base is not strong.

- **Eucalyptus, *Eucalyptus globulus* or *Eucalyptus radiata.*** Helpful in treating respiratory problems, such as coughs, colds, and asthma. Used to treat burns, wounds, and insect bites. Also helps to boost the immune system and relieve muscle tension.
- **Ylang-Ylang, *Cananga odorata.*** Helps one to relax, and can reduce muscle tension. Good antidepressant. Used for anxiety, hypertension, and stress.
- **Geranium**, ***Pelargonium graveolens.*** Helps to balance hormones in women, good for balancing the skin. Can be both relaxing and uplifting, as well as antidepressant. Used for acne and oily skin.
- **Peppermint, *Mentha piperita.*** Used in treating headaches; sinusitis; vertigo; muscle aches; asthma; and digestive disorders such as slow digestion, indigestion, nausea, and flatulence.
- **Lavender, *Lavandula angustifolia.*** Relaxing, and also useful in treating wounds and burns, and for skin care. Also used for asthma, itching, labor pains, colic, and dysmenorrhea.
- **Lemon**, ***Citrus limonum.*** Uplifting, yet relaxing. Helpful in treating wounds and infections, and for house cleaning and deodorizing. Sometimes used for athlete's foot, colds, and warts.
- **Clary sage, *Salvia sclarea.*** Natural pain killer, helpful in treating amenorrhea and muscular aches and pains. Relaxing, and can help with insomnia. Also helpful in balancing hormones. Used to treat sore throat, stress, and exhaustion.
- **Tea tree, *Melaleuca alternifolia.*** A natural antifungal oil, good for treating all sorts of fungal infections including vaginal yeast infections, "jock itch," athlete's foot, and ringworm. Used for insect bites, itching, and migraine. Also helps to boost the immune system.
- **Roman chamomile, *Anthemis nobilis.*** Relaxing, and can help with sleeplessness and anxiety. Also good for muscle aches, arthritis, and tension. Useful in treating wounds and infection. Used for insomnia, nausea, PMS, and earache.
- **Rosemary, *Rosmarinus officinalis.*** Uplifting and promotes mental stimulation. Also stimulating to the immune, circulatory, and digestive systems. Good for muscle aches and tension.

ThinkLike a Nurse 30-2

- Why do you think a person with impaired tactile perception is at risk for injury?
- Speculate as to the possible nature of injuries that might occur.

Sensory Deficit: Impaired Kinesthetic Sense

Kinesthesia, or muscle sense, is a complex process involving **proprioceptors** that detect stretch in muscles to create a mental picture of how the body is positioned. Conscious muscle sense is perceived in the parietal lobes. Unconscious muscle sense occurs in the cerebellum, which coordinates movement.

Problems of the inner ear commonly impair kinesthesia. The vestibular apparatus of the inner ear has hair cells that detect rotation or acceleration of the body. Because the vestibular cell nuclei also receive input from neurons involved in vision, a mismatch between the position or acceleration of the head and the visual field can result in motion sickness. This is why it is not advisable to read a book while riding in a car traveling on a winding road.

Parkinson's disease, other neurological disorders, tumors, cerebrovascular accident, and even certain medications can impair kinesthesia. Kinesthetic deficits place the patient at risk for balance and coordination problems and falls. For activities that enhance proprioception, see the Home Care box Sensory Deficits—Safety and Health Measures, later in this chapter.

Seizures

A **seizure** is the abrupt onset of disturbance in electrical activity in the brain—a group of neurons fires abnormally. This results in motor symptoms, such as rhythmic jerking of the limbs. Symptoms and the duration of the seizure vary, depending on the area of the brain affected. In addition to motor symptoms, the person may have a decreased level of consciousness or a loss of consciousness. This places the patient at high risk for injury from falls. Half of the people newly diagnosed with a seizure disorder will have generalized seizures.

Seizures are not uncommon. Incidence is highest for those younger than age 10 or older than age 65. Males are more likely to have seizures than females, especially children. Three-quarters of children with seizures outgrow the events (Epilepsy Foundation of America, n.d.). Most seizures last less than 3 or 4 minutes.

In 7 out of 10 people with seizures, no identifiable cause can be found. Among adults, the most common cause is a tumor or head trauma. The most common reason for seizures in a person with epilepsy is failure to take prescribed antiseizure medication. Other common triggers are ingesting mood altering substances, sleep deprivation, stress, illness, fever, and hormone fluctuations. Additionally, high contrast patterns and flashing or flickering lights (e.g., video games, strobe lights) can provoke seizure activity.

Go to Chapter 30, **Clinical Insight 30-1: Seizure Precautions,** in Volume 2.

KnowledgeCheck 30-4

- Discuss the difference between myopia and hyperopia.
- What is the difference between conduction deafness and nerve deafness?
- Identify three factors that may impair the sense of taste.
- How is the sense of smell triggered?
- What areas of the body have the greatest number of tactile receptors?
- What type of health concerns may be generated by kinesthetic deficits?

ThinkLike a Nurse 30-3

Imagine that you are experiencing sensory deficits. Which deficits would you find most challenging?

PracticalKnowledge knowing how

As a nurse, you should always consider your client's sensory perceptual status. Sensory deficits, excess, and overload influence a person's safety and quality of life and may be especially troublesome for those in inpatient facilities.

ASSESSMENT

Assessment of sensory perception includes a history and physical exam to gather data about the following (see Chapter 22):

- Factors affecting sensory perception
- Mental status, including mood, affect, cognition, and memory
- Level of consciousness
- Recent changes in sensory stimulation
- Use of sensory aids
- The client's environment
- The support network
- Focused examination of vision, hearing, taste, smell, touch, balance, ability to respond to stimulation, muscle tone, coordination

Nursing Interview In your nursing interview, you will assess the client's usual and current state of sensory function, as well as gather a history of sensory problems and use of sensory aids. In addition to interviewing the client and family, assess the environment and client situation for factors that may alter sensory function. The rest of the Assessment section provides a brief overview of each of those items.

Physical Assessment Physical assessment of sensory function requires assessment of the six senses. For guidelines,

Go to Chapter 22, **Procedure 22-16: Assessing the Sensory Neurological System, Procedure 22-6: Assessing the Eyes,** and **Procedure 22-7: Assessing the Ears and Hearing,** in Volume 2. Also refer to Chapter 30, **Assessment Guidelines and Tools, Hearing Screening in Older Adults,** in Volume 2.

For a guide to bedside physical assessment of sensory function,

Go to Chapter 30, **Assessment Guidelines and Tools, Bedside Assessment of Sensory Function,** in Volume 2.

Assess Changes in Sensory Function

To assess changes in sensory function, you will need to obtain a history of the client's usual sensory function as well as information about the client's current status. For a list of questions you can use for this purpose,

Go to Chapter 30, **Assessment Guidelines and Tools, Nursing History: Sensory Perceptual Status,** in Volume 2.

Assess Risk Factors for Impaired Sensory Perception

You should perform a comprehensive assessment for any patient at increased risk for sensory alterations:

- Older adults
- People who are bedbound or homebound
- Patients in intensive care units
- Those with acute or chronic brain injury, limited mobility, or known sensory deficits, especially if the change has been acute.

Routinely assess developmental level, health status, medications, stress and coping mechanisms, personality, history of head trauma, and lifestyle related to sensory alterations.

Assess Mental Status

Sensory alterations may trigger changes in mental status, and altered mental status can interfere with sensory perception. A check of mental status includes assessment of behavior, appearance, response to stimuli, speech, memory, and judgment. Normal findings include an ability to express and explain realistic thoughts with clear speech, follow directions, listen, answer questions, and recall significant past events.

You can assess many of those factors as you interact with the client. For example, if you have asked the client the questions covered in your nursing interview, you have already formed an impression about his appearance, speech, ability to express himself, and other facets of mental status. In addition, you must specifically assess the client's level of orientation. Chapter 22 presents additional discussion of mental status screening and orientation.

Assess Level of Consciousness

Level of consciousness (LOC) is one indicator of cerebral function. It includes arousal (from alert to deeply comatose) and orientation (to time, place, person, and situation). An alert client will respond to auditory stimuli. If the client does not respond, progress to tactile and then painful stimuli. Remember, however, that if your client does not speak your language he may not respond to questions or commands. The Glasgow Coma Scale is commonly used to assess LOC. It assesses eye, motor, and verbal responses. The FOUR (Full Outline of UnResponsiveness) Scale adds brainstem reflexes and respirations. To use the Glasgow Coma Scale or the FOUR Scale for assessing level of consciousness,

Go to Chapter 22, **Procedure 22-16: Assessing the Sensory Neurological System,** in Volume 2.

If you are not using a coma scale, document your findings specifically and objectively in your nursing notes. Be sure to assess whether the patient is alert, confused, lethargic, obtunded, stuporous, or comatose. For explanations of those states and observations to make,

Go to Chapter 30, **Assessment Guidelines and Tools, Nursing History: Sensory Perceptual Status** (section, **Assess Mental Status),** in Volume 2.

Assess Use of Sensory Aids

Sensory aids are devices that assist with sensory function. They include glasses, contact lenses, hearing aids, canes, and walkers. For sample interview questions,

Go to Chapter 30, **Assessment Guidelines and Tools, Nursing History: Sensory Perceptual Status,** in Volume 2.

Assess the Environment

The environment is an important source of stimulation. Consider how different the environment is for Joshua and Richard (Meet Your Patients). Joshua is in a crowded space with lights and noise 24 hours per day. He has had a number of invasive procedures and is most likely receiving pain medication. In contrast, Richard is in a quiet room with little exposure to light, noise, or touch. As Joshua's and Richard's situations demonstrate, a healthcare environment can have too many or too few stimuli. As part of your assessment, observe how the client is responding to the conditions of the environment.

Compare Patient's Personality and Lifestyle With the Current Environmental Situation In healthcare facilities, patients are subjected to lights, noises, and odors that cause them anxiety. They may hear others who are crying out in pain. A patient from a small family and a quiet environment may develop sensory overload by the stimulation in a hospital setting. Even someone used to a rapid-paced lifestyle may experience overload, particularly when experiencing pain, nausea, dizziness, or other symptoms of illness. In contrast, a person used to an active lifestyle may find the hospital setting intolerable (boring).

Assess the Effect of the Environment on Sensory Deficits For a patient with age-related hearing changes, the noise of the healthcare environment may make it difficult to decipher voices. A patient with visual deficits or impaired balance will often modify his home environment to improve function in the home; however, when the patient is hospitalized or moved to a long-term care facility, these aids may no longer be feasible. To assist the patient, you must determine which environmental conditions worsen sensory deficits and which help to compensate.

Assess the Support Network

For a client with a sensory deficit, his support network may serve as a buffer or a hindrance. For example, an older adult with macular degeneration has progressive loss of vision. If he lives alone, the effect of the visual loss will be quite different than if he lived with an extended family. Support persons may help the client to adapt to deficits by assuming chores that the client can no longer perform or by providing comfort to the client so he is less distressed by the sensory losses.

A support network can also be influential when clients are experiencing sensory deprivation or overload. Recall that Richard (Meet Your Patients) has no visitors. What influence do you think frequent visits by family members would have on Richard? If you say that Richard would receive more stimulation and may have less sensory deprivation, you are correct. Family members can also help clients who are confused from sensory alterations by reorienting and calming the client.

KnowledgeCheck 30-5

- Identify six areas you should assess for a client with known or suspected sensory alterations.
- What factors must be evaluated when it is known that a client uses a sensory aid?
- Identify at least two ways that you can assess vision and hearing deficits at the bedside.

ThinkLike a Nurse 30-4

How would you assess Joshua and Richard (Meet Your Patients) for sensory alterations? You may need to review the Meet Your Patients scenario at the beginning of this chapter to answer this question.

ANALYSIS/NURSING DIAGNOSIS

NANDA International (2012) identifies the following diagnostic labels for use with sensory-perceptual problems. For definitions of the following labels,

Go to Chapter 30, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Sensory Perceptual Nursing Diagnoses,** on Davis*Plus*.

Acute Confusion
Chronic Confusion
Impaired Environmental Interpretation Syndrome
Impaired Memory
Risk for Peripheral Neurovascular Dysfunction
Unilateral Neglect

Disturbances and deficits in sensory perception may also be the etiology of other nursing diagnoses. Examples include the following:

Risk for Falls r/t visual impairment
Risk for Injury r/t reduced tactile sensation
Bathing Self-Care Deficit r/t kinesthetic impairment
Feeding Self-Care Deficit r/t visual impairment
Deficient Diversional Activity r/t reluctance to be in social situations because of hearing impairment
Imbalanced Nutrition: Less Than Body Requirements r/t loss of appetite secondary to impaired taste
Social isolation r/t embarrassment about Impaired Memory

PLANNING OUTCOMES/EVALUATION

For *NOC standardized outcomes* associated with sensory perception diagnoses,

Go to Chapter 30, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Sensory Perceptual Nursing Diagnoses,** in the Student Resources on Davis*Plus*.

Individualized goals/outcomes statements you might write for a client with Disturbed Sensory Perception include the following:

- Compensates for visual impairment by maximizing the use of touch and hearing.
- Verbalizes the importance of eating nutritious foods, despite the fact they "taste funny."
- Demonstrates proper use of her hearing aid.
- Participates in at least one unit activity daily.

As always, use the goals and outcomes you write to evaluate the client's responses to nursing interventions. The outcomes focus your data collection; comparing the new data against the outcomes allows you to determine patient progress.

PLANNING INTERVENTIONS/IMPLEMENTATION

For *NIC standardized interventions* associated with sensory perception nursing diagnoses,

Go to Chapter 30, **Standardized Language, Selected NOC Outcomes and NIC Interventions for Sensory Perceptual Nursing Diagnoses,** on Davis*Plus*.

Specific nursing activities to address sensory perception problems are based on the nursing diagnosis chosen, especially on its etiology. Common nursing activities are discussed in the following sections.

Self-Care

Teaching Your Client About Sensory Perceptual Health

Vision

- Have regular eye examinations.

  Infants and preschoolers—Screen at their routine office visits.

  Young adults—Complete eye exam at least three times between the ages of 20 and 39.

  At age 40 —Have a baseline screening, and based on that information, the ophthalmologist will determine how frequently your eyes need to be re-examined.

  Age 65 and older—Complete eye exam every 1 to 2 years to check for cataracts and other eye conditions (American Academy of Ophthalmology, 2009).

- If you are at risk for eye disease, have more frequent eye exams, regardless of your age. For example, if you: (1) take steroids; (2) are of African ancestry; (3) have a family history of eye disease, diabetes, or high blood pressure; (4) or have any symptoms. Your ophthalmologist will recommend how often you should have an exam.
- Call your healthcare provider for prompt examination if you have eye pain, discharge, a change in vision, or bleeding.
- Have your prescriptions for glasses or contact lenses reviewed at each screening and updated if needed.
- Be sure that visual screening is done at your child's elementary school. If not, consult your pediatrician or other care provider.
- Work with your primary healthcare provider to control conditions such as hypertension and diabetes.
- If you are pregnant, obtain early and adequate prenatal care to prevent the danger of premature birth and exposure of the newborn to high-volume oxygen.
- Keep sharp or pointed tools (e.g., scissors) out of reach of infants, toddlers, and preschoolers.
- Teach children to walk carefully, tool point downward, when carrying pointed tools or other objects.
- Teach children to stay away from projectile activities, such as lawn mowing.
- Keep the child away from firearms and fireworks.
- Insist that your child use eye protection when playing sports such as tennis or baseball.
- Insist that children wear helmets when skating or riding bicycles and that teenagers wear helmets when riding motorcycles.
- For children who wear glasses, be sure the lenses are made of shatterproof safety glass.

Hearing

- Auditory screening is often performed in elementary school; however, most adults do not have their hearing screened regularly. If you work in an area with a high noise level, you should have your hearing checked regularly. Early detection may prevent hearing loss.
- If you are pregnant:

  Obtain early prenatal care.

  Avoid ototoxic drugs.

  Be sure you are tested for syphilis and rubella (German measles).

  Avoid anyone you suspect may have rubella.

- Children with frequent ear infections require evaluation to determine whether hearing loss has occurred.

Middle and older adults may begin to experience difficulty distinguishing voices in a crowd or hearing the television or radio. These are indications of hearing loss and should be evaluated; you may need a hearing aid.

- Hearing loss is not a "natural part of aging.

Taste

Dental health is an important aspect of maintaining taste. Decayed teeth, gum disease, and other disorders of the mouth may affect the ability to taste. Have your teeth cleaned and examined at least yearly. You may need additional dental work to promote oral health.

Promoting Optimal Sensory Function

Optimal sensory function requires periodic health screening along with early identification and treatment of health problems. Comprehensive healthcare is the ideal approach, because sensory problems are often related to other health disorders. For example, to protect his vision, a client with hypertension needs to have periodic eye examinations and to control his blood pressure. See the Self-Care box for information to teach your clients about self-care to promote their vision and hearing. For additional information on health promotion and health screening, see Chapter 43.

Interventions for Example Problem: Sensory Deprivation

If your assessment indicates the client is at risk for sensory deprivation, include specific strategies for prevention in the nursing care plan. Be sure to communicate this information to nursing assistive personnel (NAPs) so they can participate in this aspect of care. Interventions will include (a) providing stimulation and (b) supporting the patient's ability to perceive and interpret stimuli. Ideally you will use the following as preventive actions.

Visual Stimulation For visual stimulation, help the patient with glasses to apply them whenever she is not sleeping. Make sure eyeglasses are clean and in good repair. This will allow the patient to receive available stimuli. Put artwork on the walls, furnish colorful pajamas and robes, and place pictures or flowers where the patient can see them. Unless the patient objects, open curtains during the daytime to allow sunlight to enter the room. Avoid keeping the patient in a dark room, except to promote sleep.

Auditory Stimulation To stimulate hearing, help the patient with a hearing aid to apply it whenever she is not sleeping. Check that the hearing aid has working batteries and the sound is set at the appropriate level. When possible, move the patient to a quiet area to avoid background noise when communicating.

Olfactory Stimulation Stimulate the sense of smell with fruits and flowers, or even aromatherapy. Pleasant smells may also stimulate appetite.

Tactile Stimulation Use touch carefully in your patient care activities. You may want to hold a patient's hand while talking or provide a back rub with morning and bedtime care. Gentle hand massage is sometimes effective in calming agitated patients. Another form of touch, called healing touch, using the patient's energy fields has the potential to aid in pain control and facilitate self-healing (Harwick, Pulido, & Adelson, 2012). However, people do respond differently to being touched, so adjust the amount of touch you provide according to the patient's reaction.

Audiovisual Media A television or radio in the room may provide meaningful stimulation. Teach NAPs to choose appropriate music and programs for the patient. Inappropriate choices (e.g., cartoons with laugh tracks) offer meaningless stimulation and may lead to sensory deprivation.

Social Interaction Social interaction is a type of stimulus. The following are some social interaction measures:

- Make regular contact with the patient. Introduce yourself, and address the patient by name.
- Provide continuity of care by assigning the same personnel whenever possible.
- Encourage patients to have some form of social interaction. For example, urge long-term care patients to take part in scheduled activities. Assist acute care patients out of bed for meals or visits from family and friends. Advise staff members to visit at intervals or encourage patients to leave their rooms. Children may play video games with others online.
- Avoid isolating the patient when at all possible. Ensure that any patient in isolation receives adequate stimulation from nurses, family members, or assistive personnel.

Minimizing Anxiety and Confusion Minimize anxiety and confusion so the patient can accurately perceive stimuli. For example:

- Explain all procedures and care. This will decrease anxiety and help orient confused clients.
- Hang a calendar in the room, along with a schedule of activities.
- A large clock on the wall is also helpful.
- Encourage family members to bring in familiar objects from home.
- If the patient is disoriented, provide information at each visit. For example, "Good morning, Mr. Booker. My name is Elsa. I am the nurse taking care of you this morning. It is a few minutes after 8 in the morning. I'm going to take your blood pressure and get you ready for breakfast."

Communication Develop alternative methods of communication when interacting with clients with aphasia, or who speak another language, or who have difficulty hearing. Communication boards, a magic slate, pictures, or writing may be helpful. You might also hang a message board in the room and ask family members to post photos, cards, or notes. Computers are useful if the patient has one; and texting might also be used.

Pet Therapy Consider using pet therapy. Many facilities have resident pets or can arrange to have pets visit. A singing bird may delight a resident who cannot be out of bed. In long-term care facilities, resident cats often favor bedbound clients for their frequent naps. Pet therapy can increase socialization, lower blood pressure, and decrease loneliness and pain (Braun, Stangler, Narveson, et al., 2009).

Collaboration Collaborate with other healthcare team members in caring for clients with sensory deprivation. Music therapy, activities, physical therapy, speech therapy, nutritional therapy, and occupational therapy may all be valuable in the care of the client. Carefully monitor the use of sedating medications that may contribute to sensory deprivation.

Self-Stimulation Finally, when they are able, teach patients to provide their own stimulation by counting, singing, reading, playing video games, social networking, or reciting poetry.

ThinkLike a Nurse 30-5

Which of the strategies to treat sensory deprivation would be most appropriate for Richard (Meet Your Patients)?

Interventions for Example Problem: Sensory Overload

Sensory overload is sometimes an unfortunate outcome of hospitalization. To prevent or treat sensory overload, consider the following strategies. Oddly, some of the interventions are the same as those for preventing sensory deprivation.

- **Control visual stimuli.** Minimize unnecessary light. Instruct NAPs to be aware of appropriate light levels, especially at night. Use a flashlight instead of turning on room lights, for example.

- **Control auditory stimuli.** Minimize unnecessary noise. Instruct NAPs to be aware of appropriate noise and light levels, especially at night. Speak in a moderate tone of voice, using a calm and confident manner. Do not speak about the client to others in his presence, even when he seems unresponsive. Consider the use of earplugs for the client.
- **Control olfactory stimuli.** Reduce noxious odors by promptly emptying commodes and bedpans, removing meal trays, using deodorant sprays, and keeping wounds covered.
- **Control tactile stimuli.** Some patients are overly sensitive to touch, though. In those instances, you must minimize irritating stimuli.
- **Use radio and TV appropriately.** Choose programs to meet the client's interests. Do not leave the TV or radio on 24 hours a day.
- **Minimize stress.** Stressors create internal stimuli such as anxiety. Observe for the client's reaction to environmental stimuli. Remove annoying or bothersome stimuli if possible.
  - Introduce yourself when meeting the client and address him by name.
  - Provide a calm presence; for example, do not hurry with care or speak rapidly.
  - If possible, provide a private room and limit visitors. Reduce unessential tasks by other health team members.
  - Control pain and nausea with ordered medications.
  - Teach clients about stress reduction techniques.
  - Provide relaxing music that promotes visualization and deep-breathing techniques.
- **Promote adequate sleep and rest.** Establish a schedule for care that allows for uninterrupted periods of sleep and rest. Besides preventing interruptions during rest periods, a schedule will provide the client with advance notice of what to expect during the day. Instruct NAPs and family members on the importance of allowing the client adequate rest and the need to avoid interruptions.

ThinkLike a Nurse 30-6

Review the scenario of Joshua, the young ICU patient with sensory overload (Meet Your Patients).

- Which strategies to prevent sensory overload would be most appropriate for an ICU patient?
- Which would be least likely to be successful or not feasible based on the setting?

Provide rationale for your choices. You may need to visit an ICU or talk with classmates who have been to an ICU to answer this question.

Interventions for Example Problem: Sensory Deficits

Recall that in addition to sensory deprivation and sensory overload, many clients have sensory deficits. The Joint Commission (2010) requires that you address the communication needs of patients with vision, speech, hearing, language, and cognitive impairments. Regardless of the primary medical diagnosis, you may need to modify your approach to the client or alter the environment. Describe the sensory deficits on the nursing care plan, along with strategies to deal with them. For example, if the patient recovering from an abdominal surgery has no vision in his left eye, nursing orders should specify to approach the patient from the right.

Interventions for Visual Deficits

Visual deficits range from minor problems requiring corrective lenses to complete blindness. Surgical procedures of the eye may cause temporary visual problems. Problems that limit movement of the head may limit peripheral vision but have no effect on central vision. To provide care for the client with visual deficits, you will need to describe fully the scope of the deficit on the care plan. For the client with sight, your interventions focus on enhancing vision.

- Make sure eyeglasses are clean, in good repair, and of the proper prescription. Place them within easy reach or help the client put them on if necessary.
- Offer a magnifying lens or large-print books and magazines for clients with presbyopia.
- Provide enough light, but avoid glare: (1) Use soft, diffuse lighting; (2) provide sunglasses, visors, or hats with brims when the client is outdoors.
- For information on caring for contact lenses, see Chapter 25, and

Go to Chapter 25, **Procedure 25-12: Removing and Caring for Contact Lenses,** in Volume 2.

For clients with severely limited vision:

- Be sure that all staff are aware of the client's limited vision.
- Provide an uncluttered environment, and do not rearrange furniture.
- Place the call bell, phone, and self-care items within easy reach.
- Consider books on tape or Braille for the client.
- Keep the bed in a low position.
- When helping the client walk, ask which side she prefers to have you on. Offer her your arm and allow her to grasp it.
- For safety measures, see Home Care: Sensory Deficits—Safety and Health Measures.
- If a visually impaired client uses a guide dog, do not distract the dog. A guide dog in a harness is working and should be approached only with the owner's permission.

To learn about communicating with visually impaired clients,

Go to Chapter 30, **Clinical Insight 30-2: Communicating With Visually Impaired Clients,** in Volume 2.

Interventions for Hearing Deficits

A hearing impairment can limit communication and place the client at risk for social isolation. In addition, clients with impaired hearing are unable to receive warnings. This places them at risk for injury (e.g., they may not hear a fire alarm). Your interventions should focus on supporting auditory function, improving communication, and creating a safer environment.

Support Auditory Function If the client has a hearing aid, check to make sure that it is working, the batteries are functional, and the sound is adjusted to a comfortable level. Encourage your client to wear her hearing aid as much as possible. A significant number of people with hearing impairment do not wear hearing aids. To review care of a hearing aid,

Go to Chapter 25, **Procedure 25-16: Caring for Hearing Aids,** in Volume 2.

Inspect ear canals for cerumen impaction, a common cause of conduction hearing loss. For key information about otic irrigation, see the Highlights of Procedure 30-1 box and,

Go to Chapter 30, **Procedure 30-1: Performing Otic Irrigation,** in Volume 2.

Other support measures include closed-caption television, which allows the client to read the dialogue and continue to enjoy his favorite shows or stay current with the news. For telephones, the client might want to consider sound amplification or conversion to text-telephone service. Finally, some clients may also be candidates for hearing aid dog service.

Adapt and Improve Communication For a client with hearing impairment, provide written instructions to ensure that she understands the teaching and instructions.

Highlights of Procedure 30-1

Procedure 30-1: Otic Irrigation

- Warm the irrigating solution to body temperature.
- Assist the patient into a sitting or lying position, with the head tilted slightly toward the affected ear.
- Straighten the ear canal by pulling up and back on the pinna. For a young child, pull down and back to straighten the canal.
- Instruct the patient to notify you if he experiences any pain or dizziness during the irrigation.
- Place the tip of the nozzle (or syringe) into the entrance of the ear canal, and direct the stream of irrigating solution gently along the top of the ear canal toward the back of the client's head.
- Continue irrigating until the canal is clean.
- Perform an otoscopic examination.
- Place a cotton ball loosely in the outer ear.

For additional suggestions for communicating with hearing-impaired persons,

Go to Chapter 30, **Clinical Insight 30-3: Communicating With Hearing-Impaired Clients,** in Volume 2.

Promote Safety Suggest that your client modify the home environment. For example, install blinking lights that alert the person to an incoming phone call or the ring of a doorbell. Blinking alarm clocks, burglar alarms, and smoke detectors are also available. Also refer to the accompanying Home Care box Sensory Deficits—Safety and Health Measures. For institutionalized patients, keep background noise to a minimum, and keep a call bell within easy reach of the patient.

KnowledgeCheck 30-6

- Identify three safety measures that may be used with clients with visual impairment.
- Identify three safety measures that may be used with clients with hearing impairment.

Interventions for Olfactory Deficits

An impaired sense of smell diminishes taste and denies the client the pleasure of enjoying food. This often leads to weight loss. Home safety issues are also a concern for the client who cannot smell. Measures to protect the client with olfactory impairment are found in the Home Care box Sensory Deficits—Safety and Health Measures.

Interventions for Gustatory Deficits

Many people find great pleasure from the different tastes of food. Without the gustatory sense, a client may eat less and be at risk for nutritional deficits and weight loss. If the client has lost weight, be sure to check the fit of any dentures or dental appliances. Weight changes may affect their fit and make it even harder to eat.

For hospitalized clients, provide frequent oral hygiene. Assess for sores or open areas in the mouth. These require prompt treatment because they may become infected and further damage the sense of taste. Teach clients to eat foods separately or drink water between bites to distinguish the taste of the food more readily. Seasonings, salt substitutes, spices, or lemon may improve the taste of foods and encourage the client's appetite (see the Home Care box Sensory Deficits—Safety and Health Measures).

Interventions for Tactile Deficits

Patients with peripheral vascular disease, spinal cord injury, diabetes, cerebrovascular accident, trauma, or fractures are at risk for diminished tactile sensation. They may not notice a cut or wound in an area with limited sensation. For institutionalized patients, inspect the affected area daily and teach the patient to continue this practice at home. Look for open areas, cuts, abrasions, or areas of erythema. Any of these findings requires care.

Home Care

Sensory Deficits—Safety and Health Measures

To promote safety and health, instruct clients on the following points:

Visual Deficits

- Do not use throw or area rugs on any floors.
- Keep spaces uncluttered.
- Orient the client to new surroundings, for example, "The couch is directly ahead 3 feet. There is a table next to it."
- Do not rearrange furniture.
- Keep the bed in a low position.
- Clients with significant visual impairment should be evaluated for the ability to drive. Many people resist giving up driving privileges, because this severely limits their lifestyle. However, poor vision places the driver, passengers, pedestrians, and other drivers at risk for harm.

Hearing Deficits

- Install blinking lights that alert the person to an incoming call or the ring of a doorbell.
- Install blinking alarm clocks, burglar alarms, and smoke detectors.

Olfactory Deficits

- Have gas appliances regularly inspected and maintained to prevent gas leaks.
- Check smoke detectors and replace batteries regularly.
- If you cannot detect food spoilage by smell or taste, date foods and inspect them for any evidence of spoilage. Spoilage usually causes changes in the color and consistency of canned, fresh, or leftover foods.

Gustatory Deficits

- Perform frequent oral hygiene to encourage appetite and enhance the sense of taste.
- Enhance the meal experience by concentrating on the visual appeal of the meal, the plates, and the dinner table.
- Avoid bland, overcooked food. Use spices liberally unless they are contraindicated.
- Vary food texture, color, and temperature to provide more interest.

Tactile Deficits

- Use a bath thermometer to monitor water temperature and prevent burns.
- Change position frequently to relieve pressure on bony prominences.
- Use properly fitting shoes and socks.
- Immediately report any signs of circulatory impairment (e.g., declining motor function, cool temperature, gray-blue coloration).
- Inspect daily for open areas, cuts, abrasions, or areas of redness.

Kinesthetic Deficits

Kinesthesia, or muscle sense, is enhanced by activities that tone muscles and increase coordination. These activities are helpful for individuals of any age. Examples include the following:

- Rhythmic movement (e.g., t'ai chi, dance, yoga)
- Aerobic activities, such as walking, running, or bicycling
- Strength training, such as weight-bearing exercise or use of light weights
- Flexibility activities, such as stretching
- Balance conditioning with eyes open and closed (e.g., standing on one foot)
- Putting joints through full range of motion, especially rotational movements

Also see the Home Care box Sensory Deficits—Safety and Health Measures.

If the patient consents, you can stimulate the sense of touch by brushing his hair, giving a back rub, or touching him when giving care. You may need to use firm pressure for him to feel the touch. Frequent turning and positioning may also help. Use a bed cradle, and keep bed linens loose to keep them off the skin as much as possible.

Although traditionally we have thought of touch as a caring and healing intervention, there is actually not a lot of empirical evidence that supports its use as a nursing intervention. Furthermore, there are wide differences in how touch is perceived among both patients and nurses. Use touch carefully, considering personal and cultural preferences, observing the patient's reaction, until research evidence provides clear guidelines for practice (Gleeson & Higgins, 2009; Gleeson & Timmins, 2005).

Interventions for Confused Clients

Confusion interferes with the ability to interpret stimuli accurately. It can be temporary or permanent. Confusion is an aspect of both delirium and dementia. **Delirium** is an acute, reversible state of confusion caused by medications and a variety of physiological processes, such as hypoxia, metabolic disturbances, infection, or sensory alterations. It may be accompanied by changes in the level of consciousness. In contrast, **dementia** is a chronic and progressive deterioration in mental function caused by physical changes in the brain and is not associated with changing levels of consciousness.

To promote patient orientation, use simple communication, decrease anxiety, keep the patient safe, and provide continuity of care. Notice that some of the following interventions are the same as for preventing sensory deficit.

Toward Evidence-Based Practice

Iwamoto, Y., & Hoshiyama, M. (2012, September). Time orientation during the day in the elderly with dementia. *Physical & Occupational Therapy in Geriatrics, 30*(3), 202–13. doi:10.3109/02703181.2012.713453

Researchers were interested to find out what time of day elderly patients with dementia were most lucid. Using the Mini-Mental State Examination (MMSE) and a time estimation test, they learned that time orientation was affected more in the morning than in the afternoon. Meals did not have an effect on orientation to time.

O'Keeffe, E., Mukhtar, O., & O'Keeffe, S. (2010). Orientation to time as a guide to the presence and severity of cognitive impairment in older hospital patients. *Journal of Neurology and Neurosurgical Psychiatry, 82*, 500–504. doi:10.1136/jnnp.2010.214817

Assessing orientation to time is an important part of the mental status exam. Researchers assessed a sample of 262 patients with dementia or delirium to learn what part of the time orientation is most indicative of cognitive functioning. Failure to correctly identify either the year or month was a highly sensitive measure for detecting cognitive impairment. The severity of disorientation to time was strongly associated with the severity of dementia.

1. According to the Iwamoto and Hoshiyama study about time orientation in elderly with dementia, what would the best of time of the day be for performing nursing care that requires cooperation?

2. What would the best of time of the day be for providing orientation to an elderly client with dementia?

3. Suppose you are working in a skilled nursing facility and do not know the residents yet. If you have only a brief opportunity to interact with an elderly patient, what questions might you ask to get a sense of the severity of dementia or delirium prior to planning care?

4. Other than orientation to time, what other questions might you ask the resident to assess cognitive functioning?

Go to Chapter Resources: Chapter 30; **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

Promote Orientation Introduce yourself and state the client's name each time you meet with him. Wear a readable (large, plain type) nametag to reinforce your introduction. Also identify the day, date, and time as you interact. Provide visual clues to time, such as opening the drapes during the day and closing them at night, and placing calendars and clocks where they are easy to see. Also place personal objects, photos, and mementos in the immediate environment, and discuss them with the client. Encourage the patient to participate in familiar activities, such as bathing.

Simplify Your Communications The patient cannot interpret stimuli accurately and may not understand what you say. Speak slowly and allow adequate time for the client to answer any questions you raise. Face the client and speak calmly, simply, and directly. Provide simple explanations for all care and treatments. Use short sentences with few words: "It's bath time," rather than, "Let's go have a bath and get you all nice and clean for visitors." Do not offer too many choices because this further confuses the already confused patient.

Relieve Anxiety People with dementia (a common cause of confusion) are often anxious, worried, and fearful. Find ways to make the person feel more secure and comfortable before you focus on the content of your conversations.

- Gently hold or pat the patient's hand, but use touch cautiously.
- Realize that the person is probably distressed and is doing the best he can. Be affectionate, reassuring, and calm, even when things make no sense.
- Try to respond to the person's feelings instead of the content of his words. This helps to reassure her. For example, if a woman is constantly searching for her husband, don't say, "Your husband is not here." Rather, say, "You must miss your husband," or "Tell me about your husband."
- If the person has difficulty finding the right word, supply it for him unless it upsets him. This helps control his frustration.
- If you do not understand what the patient is trying to say, ask him to point to it or describe it (e.g., "What does a zishmer look like?").
- Consider using alternative therapy, such as music therapy.

Provide for Safety Recognize that the client's decision making may be poor. Maintain a safe environment. For example, store medications away from the patient's reach, keep doors and windows closed securely, and use bed or chair monitors to prevent wandering.

Provide Continuity of Care When Possible It helps to establish a routine for care and assign the same caregivers each day.

KnowledgeCheck 30-7

- What are the major concerns associated with loss of smell and taste?
- What safety measures should be taught to a client with tactile impairment?
- How can you best assist a client who is confused?

Interventions for Unconscious Patients

The unconscious patient requires reality orientation even though he is unable to interact with you. In addition to some of the preceding suggestions, you should include the patient's support persons in the care. Teach them the necessary strategies. You can also usually incorporate more touch into the plan of care.

Safety measures are a priority for unconscious patients. Keep the bed in low position when you are not at the bedside, and keep the siderails up. If the patient's blink reflex is absent or her eyes do not close totally, you may need to give frequent eye care to keep secretions from collecting along the lid margins. The eyes may be patched to prevent corneal drying, and lubricating eye drops may be necessary. Oral care is also important because the unconscious patient does not take fluids by mouth.

Interventions for Patients at Risk for Seizures

You need to take measures to protect patients who are at risk for seizures. Pad the head, foot, and siderails of the bed and place oral suction at the bedside. If a seizure occurs, you may need to perform suctioning after the episode to prevent aspiration of oral secretions. Do not attempt to open the mouth and insert a padded tongue depressor. This can result in airway obstruction by pushing the tongue back into the pharynx. When anxious, the first responder also could break teeth trying to insert the depressor.

For a more comprehensive discussion of nursing care for patients with a seizure disorder,

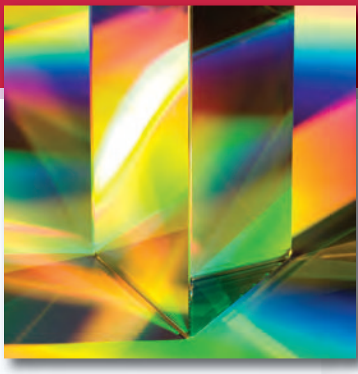
CHAPTER 31



Pain

Learning Outcomes

After completing this chapter, you should be able to:

- Define *pain*.
- Classify pain according to origin, cause, duration, and quality.
- Describe the physiological changes that occur with pain.
- Discuss two physiological mechanisms involved in pain modulation.
- Discuss factors that influence pain.
- Identify the effect of unrelieved pain on each of the body systems.
- Discuss nonpharmacological pain relief measures.
- Describe pharmacological measures, including nonopioid analgesics, opioid analgesics, and adjuvant analgesics.
- Describe chemical and surgical pain relief measures.
- Explain why pain should be considered the fifth vital sign.
- Identify the steps involved in creating a pain management program for a client.
- Individualize goals and interventions for clients with a nursing diagnosis of Acute Pain.
- Individualize goals and interventions for clients with a nursing diagnosis of Chronic Pain.
- Explain how to use a patient-controlled analgesia (PCA) system.
- Describe a method for evaluating a pain management program.

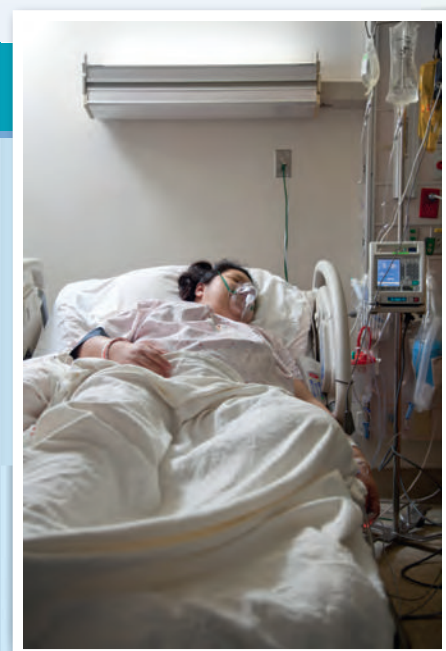
Meet Your Patient

As a special experience, your instructor has arranged for you to spend a half-day in the intensive care unit (ICU). As you enter the ICU, you are a little apprehensive. Your patient today is a 23-year-old Asian woman who was in an automobile accident yesterday and sustained chest and abdominal injuries. You walk into the room with your clinical instructor to meet your patient, Ms. Eunice Chu Ling. She was taken to the operating room during the night to have her spleen removed. She is intubated (meaning she has an endotracheal tube in her airway that is connected to a ventilator), has an intravenous line running, and a chest tube on the left side that is draining bloody fluid. Her parents and siblings are in the room sitting rigidly in the chairs, smiling at you. Ms. Chu Ling is awake and grimacing. You want to ask her if is she is in pain, but she cannot speak.



ABOUT THE KEY CONCEPTS

In this chapter, you will begin to understand the key concept of pain. Related concepts, such as transduction, transmission, perception, and modulation will help you to know what pain is and why it occurs; how to better assess it; and how to manage patients' experience of acute and chronic pain (acute and chronic pain are also related concepts you will learn in the chapter).

Theoretical Knowledge knowing why

Pain is one of the most distressing symptoms nurses deal with, and it is the most frequent reason people seek medical attention (American Academy of Pain Management, 2005, updated 2011). Most of the top 10 causes of death, such as heart disease, cancer, and chronic lower respiratory diseases, are associated with pain. As more people age and experience these chronic illnesses, you are likely to encounter more patients in pain. The following are some facts about the incidence of pain:

- More than 1 in 4 American adults experience pain lasting more than 24 hours.
- About 100 million American adults—more than the total affected by heart disease, cancer and diabetes combined—are affected by chronic pain (Institute of Medicine, 2011)
- About one-fourth to half of community-dwelling older adults report pain that interferes with normal functioning.
- An estimated 1 in 5 adults experiences pain or physical discomfort that disrupts sleep a few nights a week or more.
- In spite of measures to relieve pain, 50 percent to 75 percent of hospitalized patients die in moderate to severe pain.
- Non-Hispanic white adults reported pain more often than adults of other races. Women and men reported pain at about the same frequency.
- The most commonly reported types of pain are headaches, facial aches, joint pain, and lower back, neck pain.

WHAT IS PAIN?

The International Association for the Study of Pain (IASP) and the American Pain Society (APS) define pain as "an unpleasant sensory and emotional experience association with actual or potential tissue damage, or described in terms of such damage" (APS, 1994, p. 16; Merskey & Bogduk, 1994, p. 971). Pain is the most common reason people seek medical care in the United States. The pain experience can significantly interfere with a person's quality of life, affecting nearly every aspect of life. For instance, severe back pain can affect a patient's job performance, engagement in social activities, sexual intimacy, sleep and rest, ability to exercise, and ability to perform activities of daily living. These factors, in turn, can affect the intensity of the patient's pain, as well as his response to pain.

Margo McCaffery, a nursing expert on pain, describes pain as "whatever the person says it is, and existing whenever the person says it does" (1968, p. 95). In other words, pain is a subjective experience. Unlike a pulse or blood pressure, you cannot measure pain objectively. In addition, your expectations of your patients' pain will be influenced by your own values, ideals, and life experiences. As McCaffery's definition indicates, you will need to put aside your personal beliefs about pain and focus on the *patient's* experience.

Pain can cause sleep loss, irritability, cognitive impairment, functional impairment, and immobility, and thus it can be destructive to the patient and family. Although we usually think of pain in this negative context, pain is also protective, warning us of potential injury to the body. Recall the last time you touched a hot object with your bare hand. Undoubtedly, you quickly pulled your hand away when you felt discomfort. Without the ability to sense pain, you might have been burned. Pain can also prompt us to change our actions: After you have been sitting at the computer for a while, muscle pain may prompt you to get up and stretch or go out for a walk; or the gastrointestinal discomfort we experience after overeating may remind us to eat more moderately in the future.

You will be able to manage pain more effectively if you can recognize the type of pain the patient is experiencing. But remember that patients often experience more than one kind of pain. Pain can be classified by the origin of pain, cause, duration, and quality of pain.

Origin of Pain

The origin of pain refers to the site where pain is felt, and not necessarily the source of pain.

Cutaneous or **superficial pain** arises in the skin or the subcutaneous tissue. If you have ever touched a hot object or received a paper cut, you have experienced superficial pain. Although the injury is superficial, it may cause significant short-term pain.

Visceral pain is caused by the stimulation of deep internal pain receptors. It is most often experienced in the abdominal cavity, cranium, or thorax. Visceral pain is not well localized and can be described as tight, pressure, or crampy pain. The description of the quality and extent of the pain often serves as a strong clue to the cause. Menstrual cramps, labor pain, gastrointestinal infections, bowel disorders, and organ cancers all produce visceral pain.

Deep somatic pain originates in the ligaments, tendons, nerves, blood vessels, and bones. Deep somatic pain is localized and can be described as achy or tender. A fracture or sprain, arthritis, and bone cancer can cause deep somatic pain.

Radiating pain starts at the origin but extends to other locations. For instance, the pain of a severe sore throat may extend to the ears and head. Or the pain of an episode of gastroesophageal reflux ("heartburn") may radiate outward from the sternum to involve the entire upper thorax.

Referred pain occurs in an area that is distant from the original site. For example, the pain from a heart attack may be experienced down the left arm, through the back, or into the jaw. See Figure 31-1 for other examples of referred pain.

Phantom pain is pain that is perceived to originate from an area that has been surgically removed. Patients with amputated limbs may still perceive that the limb exists and experience burning, itching, and deep pain in that area.

Psychogenic pain refers to pain that is believed to arise from the mind. The patient perceives the pain despite the fact that no physical cause can be identified. Psychogenic pain can be just as severe as pain from a physical cause. See the discussion of somatoform pain disorder in Chapter 12, if you would like more information.

Cause of Pain

Physical pain is either nociceptive or neuropathic. These two types of pain differ in the way they affect the patient as well as in how they are treated.

Nociceptive pain is the most common type of pain experienced. It occurs when pain receptors, which are called **nociceptors**, respond to stimuli that are potentially damaging, for example, as a result of noxious thermal, chemical, or mechanical stimuli. Nociceptive pain may occur as a result of trauma, surgery, or inflammation. It is most commonly described as aching. Two types of nociceptive pain are:

- Visceral pain (i.e., pain originating from internal organs)
- Somatic pain (i.e., pain originating from the skin, muscles, bones, or connective tissue)

Neuropathic pain is a complex and often chronic pain that arises when injury to one or more nerves results in repeated transmission of pain signals even in the absence of painful stimuli. The nerve injury may originate from any of a variety of conditions, such as poorly controlled diabetes, a stroke, a tumor, alcoholism, amputation, or a viral infection (e.g., shingles or HIV/AIDS). Some medications, such as chemotherapeutic agents, can trigger nerve injuries that may cause neuropathic pain even after the medication is discontinued. Neuropathic pain is described as burning, numbness, itching, and "pins and needles" prickling pain.

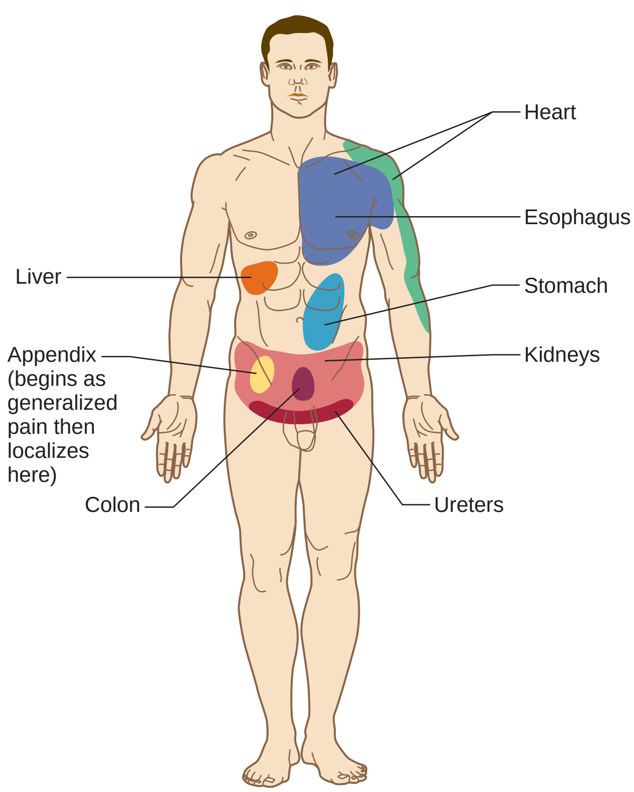


FIGURE 31-1 Most common areas of referred pain.

Duration of Pain

Acute pain has a short duration and is generally rapid in onset. It varies in intensity and may last up to 6 months (American Pain Society, 2006). This type of pain is most frequently associated with injury or surgery. It is protective in that it indicates potential or actual tissue damage. Although acute pain may absorb a patient's physical and emotional energy for a short time, it is helpful for the patient to know that it will generally disappear as the tissues heal.

Chronic pain is pain that has lasted 6 months or longer and often interferes with daily activities. It can be related to a progressive disorder, or it can occur when there is no current tissue injury, as in neuropathic pain. Patients with chronic pain may experience periods of remission and exacerbation. Unlike acute pain, chronic pain is often viewed as insignificant and may lead to withdrawal, depression, anger, frustration, and dependence. Next to incurability, chronic pain is the most feared aspect of contracting cancer or other progressive diseases.

Intractable pain is both chronic and highly resistant to relief. This type of pain is especially frustrating for the patient and care provider. It should be approached with multiple methods of pain relief.

Quality of Pain

The words patients use to describe the quality of their pain help care providers to determine the probable cause and most effective treatment. Patients may describe pain quality with a variety of adjectives, such as *sharp* or *dull, aching, throbbing, stabbing, burning, ripping, searing,* or *tingling.* They may refer to its periodicity as *episodic, intermittent,* or *constant.* Patients also use a variety of terms to convey the intensity of their pain, such as *mild, distracting, moderate, severe,* or *intolerable.*

KnowledgeCheck 31-1

How would you classify the pain that the following patients are experiencing?

- A patient with metastatic cancer
- A patient with back pain that was the result of an automobile injury a year ago
- A patient who had bowel surgery yesterday
- A patient with a fractured leg
- A patient who just had his leg amputated but feels as though the leg is still there
- A patient who just received a paper cut while turning the pages of a book.

ThinkLike a Nurse 31-1

How would you expect a patient with neuropathic pain to appear?

WHAT HAPPENS WHEN SOMEONE HAS PAIN?

Review the story of Eunice Chu Ling in the Meet Your Patient scenario. Eunice had been in an auto accident that caused severe injuries. She has had surgery and requires monitoring and invasive devices, such as a ventilator and IV line. She is awake but cannot speak. However, through the maze of equipment you can see that she is grimacing. Consider these aspects of Eunice's experience as we explore the physiology of pain.

Transduction

Pain-sensitive nociceptors are found in the skin, subcutaneous tissue, joints, walls of the arteries, and most internal organs. The skin has the highest density of nociceptors, and the internal organs the least. Eunice's injuries, surgery, and procedures have stimulated nociceptors throughout her body. In a process called **transduction**, nociceptors become activated by the perception of potentially damaging mechanical, thermal, and chemical stimuli.

Mechanical Stimuli **Mechanical stimuli** are external forces that result in pressure or friction against the body. Eunice's injuries are predominantly of this type. They involve stretching of tissue in joints and body cavities related to bleeding and swelling, and compression of body tissues caused by the force of the accident. Other types of mechanical stimuli are surgical incisions, friction or skin shearing that occurs from sliding down in bed, or pressure from a mechanical device, such as a cast or brace.

Thermal Stimuli **Thermal stimuli** result from exposure to extreme heat or cold. If you've ever touched a hot object and rapidly pulled away or suffered an earache when outdoors on a cold day without a hat, you have experienced pain from thermal stimuli.

Chemical Stimuli **Chemical stimuli** can be internal or external. Lemon juice or any acidic substance on an open area in the skin causes sharp, sudden pain. This is an example of pain from *external* chemical stimuli. In contrast, the chest pain experienced during a myocardial infarction (heart attack) is caused by *internal* chemical stimuli; specifically, the chemical changes that result from tissue ischemia. Another example of a chemical source is ingestion of lead-based paint chipping from a deteriorating residence built before the 1940s. The lead poisoning (also called plumbism) produces neurological damage, headache, and other multisystem effects.

In the Meet Your Patient scenario, the physical cues that Eunice may be in pain include bruising, swelling, surgical incisions, and her tubes and IV. However, you will not always see physical, external cues when tissue injuries are present. This is especially true of injuries caused by internal chemical stimuli. This is one reason you need to believe the patient's report of pain.

Tissue damage prompts the release of substances such as bradykinin, histamine, and prostaglandins, which activate nociceptors in the surrounding tissues. Bradykinin is also a powerful vasodilator that triggers a release of inflammatory chemicals that cause the injured area to become red, swollen, and tender. Inflammation is the most frequent cause of pain.

Transmission

Peripheral nerves carry the pain message to the dorsal horn of the spinal cord in a process known as **transmission** (Fig. 31-2). Pain messages are conducted to the spinal cord along either of two types of fibers:

- **A-delta fibers** are large-diameter myelinated fibers that transmit impulses at 6 to 31 meters per second.

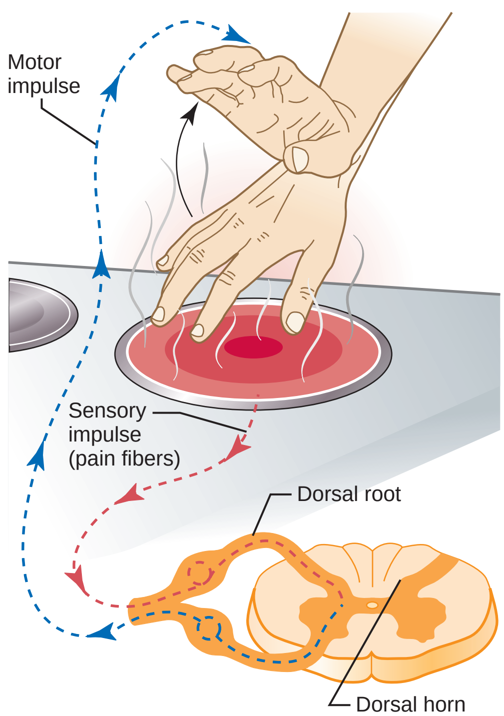

FIGURE 31-2 After nociceptors are activated, pain is transmitted along A-delta fibers or C fibers to the dorsal horn of the spinal cord. From there, the pain message is sent to the brain for perception.

These fibers transmit *fast pain impulses* from acute, focused mechanical and thermal stimuli. For instance, when you bump your knee, the initial sharp pain is carried by A-delta fibers. Pleasurable stimuli to skin receptors, such as from massage, also stimulate A-delta fibers.

- **C fibers** are smaller unmyelinated fibers that transmit *slow pain impulses*, that is, dull, diffuse pain impulses that travel at a slow rate. C fibers conduct pain from mechanical, thermal, and chemical stimuli. If you bump your knee, the lingering ache in the tissue will be carried by C fibers.

At the dorsal horn of the spinal cord, the impulses ascend through via spinothalamic tracts to the brain stem and the thalamus. This process requires chemicals called neurotransmitters (e.g., *substance P*). Most pain impulses are sent to the thalamus of the brain, which acts as an integrating center to direct the impulses to three regions of the brain: (1) the somatosensory cortex perceives and interprets physical sensations; (2) the limbic system is involved in emotional reactions to stimuli; and (3) the frontal cortex is involved in thought and reason. The person now perceives pain.

To see how the pain is transmitted along different nerve routes,

Go to **Animations: Pain Pathway** on Davis*Plus*.

Pain Perception

Perception involves the recognition and definition of pain in the frontal cortex. The point at which the brain recognizes and defines a stimulus as pain is called the **pain threshold**. The number and intensity of stimuli necessary to produce pain, as well as the duration and characteristics of the pain produced, vary from patient to patient. Although the pain threshold usually remains fairly constant for an individual over time, repeated experience with pain can reduce a patient's threshold.

Pain tolerance is the duration or intensity of pain that a person can endure. This varies not only from person to person but also for the same person in different situations. For example, a mother donating a kidney to her child may not report as much postoperative pain as if she had a kidney removed because it was cancerous. Extreme sensitivity to pain is called **hyperalgesia**.

Pain Modulation

A process called **modulation** changes the perception of pain by either facilitating or inhibiting pain signals through the endogenous analgesia system and the gate-control mechanism.

The Endogenous Analgesia System

In the **endogenous analgesia system,** neurons in the brain stem activate descending nerve fibers that conduct impulses back to the spinal cord. These impulses trigger the release of endogenous opioids and other substances to block the continuing pain impulses and provide pain relief. **Endogenous opioids** are naturally occurring analgesic neurotransmitters (enkephalins, dynorphins, and beta endorphins) that inhibit the transmission of pain impulses and the release of substance P. Endogenous opioids bind to opiate receptor sites in the central and peripheral nervous systems at four receptor sites, designated as mu (∝), kappa (∞), delta (∞), and sigma (∞). These sites are also involved in reception when patients take pain medicines. Each of the receptor sites has a different affinity for various medications. Nonpharmacological measures, such as exercise, meditation, visualization, and music therapy, can also prompt the release of endogenous opioids.

The Gate-Control Theory

Pain impulses can also be modulated at the spinal level. The **gate control theory of pain modulation** describes the mechanism of pain sensation, based on the idea that the perception of pain does not occur by direct stimulation of only nociceptors (pain-producing fiber). Instead, pain is perceived by the interplay between two different kinds of fibers—those that produce pain and those that inhibit pain.

As slow-pain impulses travel along C (small) fibers from the periphery to the brain, they encounter a "gate" that either allows or blocks the transmission of pain sensation to the brain. If the source of stimulation is non-painful, the gate would be blocked to feeling pain. Likewise, noxious stimulation keeps the gate open to pain. Imagine that you've just hit your arm against a hard surface. Almost without thinking, you reach down and rub the area. Your massage stimulates skin receptors. These send sensory impulses along fast A-delta (large) fibers, which quickly excite inhibitory neurons at the "gate." These neurons in turn block some of the pain signals being carried along the slower C fibers (Fig. 31-3). Another application of the gate control theory is use of a Sitz bath after childbirth to produce relief from pain at the perineum. The warm water and gentle pressure block the gate to the perception of pain in the brain. The gate control theory is the basis for development and use of the transcutaneous electrical nerve stimulation (TENS) to relieve pain. (See Nonpharmacological Pain Relief Measures later in this chapter.)

Descending impulses from the brain, including impulses related to mood or emotion, are also thought to open or close the gate. For this reason, medications for depression are sometimes used for patients with chronic pain. Nonpharmacological therapies, such as meditation, exercise, relaxation techniques, and laughter, may also compete with C fiber impulses and block the gate. These strategies are discussed later in this chapter.

On a purely physiological basis, pain is simply transduction, transmission, perception, and modulation. However, as we discuss next, our experience of pain involves far more than these four processes.

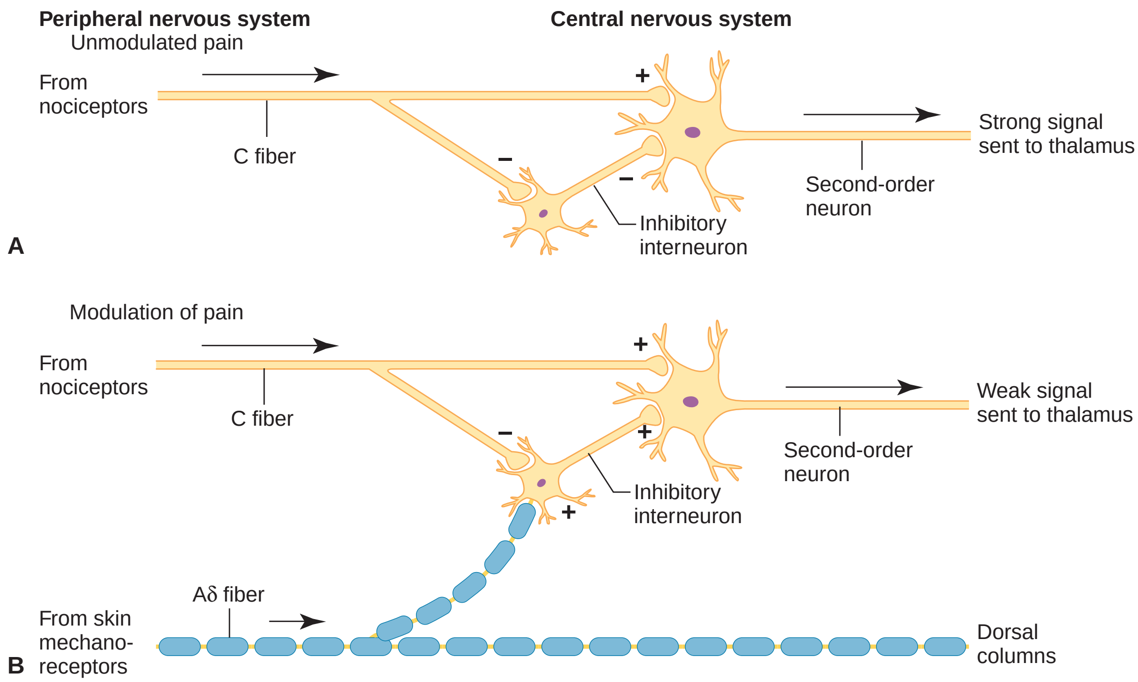

FIGURE 31-3 The gate-control theory of pain modulation. *A*, Normally, C fibers carrying slow-pain signals block inhibitory interneurons and transmit their signals across the synapse unimpeded. *B*, A-delta fibers carrying pleasurable signals (e.g., from touch) excite inhibitory interneurons, which then block the transmission of slow-pain signals (+ equals transmission, – equals no transmission).

KnowledgeCheck 31-2

- What must occur to generate pain?
- What are the four physiological steps involved in the pain process?

ThinkLike a Nurse 31-2

Based on what you have learned about pain modulation, what nursing interventions might help Eunice (Meet Your Patient) be more comfortable?

WHAT FACTORS INFLUENCE PAIN?

Think back to the last time you experienced significant pain. Was it obvious to others that you were in pain? Were you demonstrative? Quiet? Withdrawn? Did you moan or cry out? Now recall Eunice Chu Ling's reaction. What accounts for these different responses to pain?

Pain is universal, yet each person experiences and responds to pain differently. This uniqueness gives you a hint about its nature: Pain is a complex phenomenon that influences and is influenced by emotions, age, sociocultural factors, and communication and cognitive impairments.

Emotions

The most common emotions associated with pain are fear, guilt, anger, helplessness, and loneliness. In Meet Your Patient, imagine how Eunice Chu Ling must be feeling. How might her feelings affect and be affected by her pain?

Fear Some patients (e.g., Eunice) fear that their pain means their illness or injury is life threatening. Others fear their pain will eventually become intolerable. Many fear that if they ask for pain relief, they will be judged as weak or that they will become addicted to pain medications. When such fears remain unresolved, can prolong or increase the patient's pain.

Confusion and Helplessness In addition to fear, Eunice is also probably experiencing confusion and helplessness. Depending on her role in the accident, she may also feel angry or guilty. Fortunately, family members have come to visit, but when they leave and she is by herself, Eunice may experience loneliness or even a sense of abandonment.

Anxiety and Depression As you learned in Chapter 13, anxiety and depression are common in people who are ill or hospitalized. Anxiety is most often associated with acute pain, but the anticipation of pain may also trigger anxiety. Waiting for surgery or a procedure that you know will be painful offers plenty of time to think about the unpleasantness and to become anxious. In contrast, depression is most often linked with chronic pain, especially intractable pain.

Previous Pain Experience Emotional responses to pain are affected by previous pain experiences. Often patients who have had numerous painful experiences are more anxious about the prospect of experiencing pain and are more sensitive to pain. This is especially troublesome for children and adults who require a series of surgeries or painful treatments for their medical conditions. Conversely, patients who have had effective pain relief in the past are usually less anxious and are more confident they will achieve satisfactory pain relief.

From your own pain experiences, you can see that people in pain do not experience one single emotional reaction to the experience. Instead, a flood of feelings may overwhelm them, and these emotions in turn may escalate their pain. Often patients get in a vicious cycle: Illness and pain trigger emotional reactions, and the emotional reactions exacerbate the pain.

Rarely is pain purely physical or emotional. Instead, it is usually a combination of both. Interventions to relieve pain may relieve feelings of fear and helplessness, and interventions addressing these emotions, such as reflective listening and gentle touch, often aid in pain relief.

ThinkLike a Nurse 31-3

Imagine being in a situation similar to that of Eunice Chu Ling. What emotions might you experience?

Developmental Stage

The behavior people exhibit when they have pain is strongly influenced by their stage of development.

Infants and Children.

Newborns have the same sensitivity to pain as older infants and children; preterm infants may have a greater sensitivity (McCaffery & Pasero, 1999). The most common kind of pain that children experience is acute pain resulting from injury, illness, or necessary medical procedures. Infants and small children usually respond to pain by crying loudly. However, in premature and term newborns, the experience of pain does not always evoke detectable behavioral response. Indicators of pain in neonates might be as subtle as skin mottling, grimacing, twitching, crying, poor feeding, increased or decreased activity, averting gaze, temperature fluctuation, elevated blood pressure, and decreased oxygen saturation. As a result, even though an infant has a low pain score based on behavioral assessment tools, he may not be pain free (American Academy of Pediatrics et al., 2001b; Slater, Cantarella, Franck, et al., 2008).

Older Adults

Pain occurs in approximately ½ to ¾ of the geriatric population. Estimates are that as many as 45% to 80% of nursing home residents have significant undertreated pain (Takai, Yamamoto-Mitani, Okamoto, et al., 2010). Some older adults may be unable to report pain because of cognitive impairment. Often their discomfort is evident only in nonverbal cues, such as grimacing, rapid blinking, withdrawal, labored breathing, altered gait, or decreased activity. Some older patients respond to pain in atypical ways, such as mental confusion or collapse (American Geriatrics Society [AGS], Panel on Persistent Pain in Older Persons, 2009; Flaherty, 2007, revised 2012). Undertreated pain often leads to other problems that diminish the quality of life, such as social isolation, depression, sleep disturbances, and mobility-related problems.

Sociocultural Factors

We learn our responses to pain through interaction with family and social support groups. Beliefs about the value of expressing pain or minimizing it are often tied to culture. As you care for clients of various backgrounds, you may notice patterns of behavior. Some patients may gain comfort from crying or moaning when they are in pain, whereas some cultures may value silence and brave endurance of pain. Be careful, however, not to assume that patients will react in the same as others of the same ethnic or cultural group. Each patient is unique. For example, do you respond to pain in exactly the same way as your parents and siblings?

The family and friends of patients in pain also have culturally determined responses to the experience. From the Meet Your Patient scenario, recall how Eunice Chu Ling's family is responding. Although you may think it odd that they are smiling, they may be doing so because they want to make a favorable connection with you, the nurse, because you are responsible for providing care to Eunice. As a nurse, you will be caring for many people in pain and will see a wide variety of responses. Avoid reaching hasty conclusions about the meaning of those responses.

Nurses, too, are affected by their culture. Most nurses respond compassionately to those in pain. However, if you fail to recognize that pain is a unique multidimensional experience, you may misjudge a patient's reaction to injury, surgery, or other discomforts. Disparities exist in the treatment of chronic pain among people of different racial backgrounds. Clinicians should strive to provide culturally competent care and adequate pain control to every patient.

Communication and Cognitive Impairments

One of your greatest challenges as a nurse will be caring for patients in pain who have impaired cognition or communication (e.g., patients who have suffered stroke or dementia, who are intubated, or who have limited command of the local language). Although people with dementia might not appear to be experiencing pain, there is no evidence they have less pain than do other older adults. Cognitively impaired adults are not less sensitive to pain but may rather fail to interpret sensations as painful. Or they might not be able to effectively communicate their pain to others. Although they may not be able to recall their pain, they nonetheless still experience it (Horgas, Yoon, & Grall, 2012; McAuliffe, Brown, & Fetherstonhaugh, 2012). These patients are at risk for underassessment of pain and inadequate pain relief (Baldridge & Andrasik, 2010; Horgas, 2007). You will need to consider their behavioral cues as a form of self-report.

Common nonverbal cues of pain include decreased activity, grimacing, frowning, crying, moaning, and irritability. Less obvious indicators you may see in cognitively impaired patients include the following:

- Facial expressions (e.g., a sad or frightened expression, rapid eye blinking)
- Vocalizations (e.g., noisy breathing, profanity, verbally abusive language)
- Changes in physical activity (e.g., fidgeting, increased pacing or rocking, disruptive behavior)
- Changes in routines (e.g., refusing food, difficulty sleeping)
- Mental status changes (e.g., increased confusion)
- Physiological cues include elevated blood pressure, respiration, and pulse. Be aware, however, that the absence of these cues does not automatically mean that pain is absent.

KnowledgeCheck 31-3

- What are the most common emotional responses to pain?
- What factors influence behavioral responses to pain?

ThinkLike a Nurse 31-4

Eunice Chu Ling is unable to communicate verbally because of her intubation. She is grimacing in pain. After you medicate her for pain, how would you determine whether her pain has been relieved?

HOW DOES THE BODY REACT TO PAIN?

Bodily reactions to pain are influenced by the stage of the pain experience, as well as the intensity, duration, and quality of the pain. Pain triggers a variety of changes in the body. The onset of acute pain activates the sympathetic nervous system. As discussed in Chapter 12, this fight-or-flight (stress) response is protective. It minimizes blood loss, maintains perfusion to vital organs, prevents and fights infections, and promotes healing.

If the pain continues, the body adapts, and the parasympathetic nervous system takes over. However, the pain receptors continue to transmit the pain message so that the person remains aware of the tissue damage. Again, this is largely protective; for example, the pain you feel for several days after you sprain your ankle reminds you to stay off it until it is fully healed.

The severity and duration of the pain significantly affect how the person continues to respond to it. Often the person is able to ignore mild pain, but pain that is severe and unrelieved can consume thoughts and change daily living patterns. Box 31-1 identifies common pain responses.

BOX 31-1 ■ Common Pain Responsese

Physiological (Involuntary) Responses

Sympathetic Responses (Acute Pain)

Dilated blood vessels to the brain, increased alertness

Dilated pupils

Impaired GI motility

Increased heart rate and force of contraction

Increased respiratory rate, shallow breathing

Increased systolic blood pressure

Pallor

Parasympathetic Responses (Deep or Prolonged Pain)

Changeable breathing patterns

Constricted pupils

Decreased pulse rate

Decreased systolic blood pressure, feeling faint, possible syncope

Withdrawal

Behavioral Responses (Voluntary)

Agitation, striking out, fidgeting

Grimacing, frowning, fearful facial expression, grinding teeth

Guarding, bracing, or rubbing the painful area

Moaning, groaning, crying, sighing, crying

Rapid speech (acute pain); slow, monotonous speech (chronic pain)

Withdrawing from painful stimuli, resisting certain movements with care

Eating and sleeping poorly

Reduced energy, reduced interest in others, reduced activity level and mobility

Change in gait

Psychological (Affective) Responses

Anger

Anxiety

Depression

Exhaustion

Fear

Hopelessness

Irritability

Unrelieved Pain

Unrelieved pain can produce harmful effects in various body systems.

Endocrine System Ongoing pain triggers excessive release of hormones, including adrenocorticotropic hormone (ACTH), cortisol, antidiuretic hormone (ADH), growth hormone (GH), catecholamines, and glucagon. Insulin and testosterone levels decrease. These hormone shifts activate carbohydrate, protein, and fat catabolism (breakdown), hyperglycemia, and poor glucose use. The inflammatory process, combined with these endocrine and metabolic changes, can result in weight loss, tachycardia, fever, increased respiratory rate, and even death.

Cardiovascular System Unrelieved pain leads to hypercoagulation and an increase in heart rate, blood pressure, cardiac workload, and oxygen demand. The combination of hypercoagulation and increased cardiac workload may lead to unstable angina (chest pain), intracoronary thrombosis (clot formation in the vessels that supply the heart), and myocardial ischemia and infarction (heart attack).

Musculoskeletal System Unrelieved pain causes impaired muscle function, fatigue, and immobility. Poorly controlled pain can prevent the patient from performing activities of daily living and engaging in physical therapy.

Respiratory System Patients in pain tend to breathe shallowly—to limit thoracic and abdominal movement in an effort to reduce pain. This is called **splinting**. Splinting reduces tidal volume (air exchanged with each breath) and increases inspiratory and expiratory pressures. These changes can lead to pneumonia and atelectasis as well as underventilation (retained carbon dioxide, also called hypercarbia) and respiratory acidosis.

Genitourinary System Unrelieved pain causes release of excessive amounts of catecholamines, aldosterone, ADH, cortisol, angiotensin II, and prostaglandins. These hormones lead to decreased urinary output, urinary retention, fluid overload, hypokalemia, hypertension, and increased cardiac output.

Gastrointestinal (GI) System In response to pain, intestinal secretions and smooth muscle tone increase, and gastric emptying and motility decrease.

KnowledgeCheck 31-4

- What are the effects of untreated pain on each of the body systems?
- How might untreated pain affect the progress of a patient recovering from major illness?

PracticalKnowledge knowing how

As we discussed earlier, a person's *pain threshold* is the point at which that person perceives a stimulus as painful, whereas *pain tolerance* is the amount of pain a person is able to endure. Both differ greatly from person to person. Increases in pain may indicate change in condition or a need for more aggressive pain management. Practical knowledge includes knowing how to assess for and manage patients' pain.

ASSESSMENT

A comprehensive pain assessment includes pain location and quality, intensity, aggravating and alleviating factors, timing and duration, and goals for pain relief. Additionally, you need to ask questions that reveal the patient's functional ability and goals, and psychological/social factors, such as depression or substance abuse (ICSI, 2005, updated 2011). To treat pain effectively, you must first understand the patient's perception of pain. To do this, begin with a pain history. Each agency will have different assessment forms for this history. For a list of questions that are typically asked,

Go to Chapter 31, **Assessment Guidelines and Tools, Focused Assessment: Pain Assessment,** in Volume 2.

You should also make ongoing assessments regularly and, of course, accept the patient's report of pain.

Patient Self-Report This is the most reliable indicator of pain, even for those with mild cognitive impairment (American Association of Critical Care Nurses, 2013; Herr, Bjoro, & Decker, 2006). Self-report is especially important for patients with chronic pain. When pain is ongoing, the autonomic nervous system eventually adapts, so physiological and behavioral signs become less evident (Schneider, 2006–2007).

Patient Satisfaction Patient satisfaction with healthcare can be directly related to how well pain is managed. To ensure patient comfort and satisfaction, teach patients about pain management options and expected outcomes as you assess their responses to pain interventions. This helps involve them in their care and allows for making rapid adjustments to their regimen (Bozimowski, 2012).

Pain, the Fifth Vital Sign

The American Pain Society recommends assessing for pain as the fifth vital sign. This means that you should ask patients to rate their pain intensity whenever you take a full set of vital signs (Berdine, 2002; Molony, Kobayashi, Holleran, et al., 2005; Pasero, 1997). By simply raising the question with each vital signs check, you will prompt your clients to report pain more often. Also, teach nursing assistive personnel (NAP) to ask patients about their pain when taking vital signs and to report their findings to you. Box 31-2 provides the clinical approach to pain assessment recommended by the Agency for Health Care Policy and Research (AHCPR). Perform pain assessments routinely, but not limited to:

- On admission to a healthcare facility
- Before and after each potentially painful procedure or treatment
- When the patient is at rest, as well as when involved in a nursing activity

BOX 31-2 ■ Recommended Clinical Approach to Pain Assessment—Agency for Healthcare Policy and Research

***A**sk* about pain regularly. ***A**ssess* pain systematically.

***B**elieve* the patient and family in their reports of pain and what relieves it.

***C**hoose* pain control options appropriate for the patient, family, and setting.

***D**eliver* interventions in a timely, logical, coordinated fashion.

***E**mpower* patients and their families.

***E**nable* patients to control their course to the greatest extent possible.

- Before you implement a pain management intervention, such as administering an analgesic drug, and 30 minutes after the intervention
- With each check of vital signs, if the pain is an actual or potential problem
- When the patient complains of pain

Assessing Pain in Children

You can assess pain in children through self-report, behavioral observation, or physiological measures. Be sure to consult the parents about the child's stress signals and reaction to pain. With children, use art and play as a way to assess the child's understanding of pain and the pain management plan. Choose age-appropriate toys to engage the child in acting out feelings. Sometimes this indirect method is more effective than directly asking the child. Remember, most children are fearful about injections and may deny pain if they think that describing their pain will lead to an injection. You can also use a pain-rating scale consisting of simple illustrations of faces. For an example,

Go to Chapter 31, **Assessment Guidelines and Tools, Using Pain Scales,** in Volume 2.

Culturally Competent Assessments

Three words—*pain, hurt*, and *ache*—seem to be used across many cultures to describe pain (Pasero & McCaffery, 2011). You might also use descriptions of *burning, itching*, and *cramping* when asking patients about their pain experience. For this reason, many pain assessment tools can be successfully translated into various languages. If you work in an area where there are many non-English-speaking patients, you may benefit from pain assessment tools that have been translated into the languages you are most likely to encounter. To see pain translated into common languages,

Go to Chapter 31, **Tables, Boxes, Figures: ESG Box 31-1, Pain in a Sample of Languages,** on Davis*Plus*.

Difficult-to-Assess Patients

Patients who are under anesthesia or those receiving sedation are difficult to assess for pain. Those with a brain injury may mimic pain-like behavior. Patients with Alzheimer's disease with severe cognitive and expressive deficits are also a challenge for assessing the extent of pain. It may not be possible to elicit a reliable self-report for pain, and their behavioral cues might not be reflective of the pain experience either.

When using a pain scale for cognitively impaired patients, you must allow sufficient time for the patient to respond. There are many pain assessment tools. The Pain Assessment in Advanced Dementia (PAINAD) Scale is a five-item, observational tool, specifically geared to older adults with dementia. The areas for rating include breathing, negative vocalization, facial expression, body language, and consolability. Lower scores indicate less pain. To see this tool,

Go to Chapter 31, **Tables, Boxes, Figures: ESG Table 31-1, Pain Assessment in Advanced Dementia (PAINAD) Scale,** on Davis*Plus*.

You need to judge the intensity and quality of pain based on patient history and current environment. Does the patient have an underlying painful condition? What is the likely source of pain? Are there physical signs that indicate the patient has increased pain with movement, turning, or other motions? Nonverbal signs of pain become important cues for such patients.

Nonverbal Signs of Pain

In addition to the patient's verbal report of pain, you must recognize other responses that may signal pain (see Box 31-1). Pay attention to the patient's physical signs and symptoms. Is the blood pressure or pulse elevated? Does the client appear ashen? These are signs of sympathetic nervous system stimulation. You will see these signs if the pain is acute. If the pain is unresolved or chronic, the blood pressure and pulse may be lower than normal, and the patient may report feeling faint. These are signs of parasympathetic nervous system stimulation.

Key Point: ***However, there can be underlying physiological conditions, medications, or hemodynamic changes that cause changes in vital signs. And, likewise, an absence of vital sign changes doesn't necessarily indicate an absence of pain.***

For guidelines to help you assess for nonverbal signs of pain,

Go to Chapter 31, **Clinical Insight 31-2: Guidelines for Assessing Pain,** in Volume 2.

Quality and Safety Education for Nurses

Assessing and Treating Pain in Cognitively Impaired Patients

Competency: *Patient-Centered Care (Knowledge, Skills, Attitudes)**

Scenario: Mr. Fagin, who has dementia, has been hospitalized for prostate cancer that has metastasized to his pelvis, femur, and ribs. Mr. Fagin seems confused and is loudly singing hymns and banging his hands against his table in rhythm. The RN goes to Mr. Fagin's room, observes him carefully, and speaks with him. When asked if his bones hurt, he nods his head "yes." She also asks Mrs. Fagin about her husband's usual responses to pain. Mrs. Fagin states that her husband has always been very religious and often sings hymns when upset. She also says that he never complained about aches and pains in the past and that she believes he is now having "quite a bit of pain." She says, "I can't stand to see him suffer." The nurse checks the medication administration record (MAR) and obtains the prescribed prn opioid analgesic. While Mrs. Fagin speaks gently to her husband, the nurse administers the opioid analgesic. She documents the medication in the MAR, noting Mr. Fagin's behaviors prior to being medicated. Thirty minutes later the nurse observes Mr. Fagin eating dinner with his wife. His body and facial expression are relaxed, and he has stopped singing. Before leaving, the nurse asks Mr. and Mrs. Fagin whether they would like a visit from the hospital chaplain.

Think about it: A central nursing duty in the patient-centered care competency is alleviating pain and suffering. (1) How is Mr. Fagan's situation is different from that of a patient with normal cognitive function? (2) What knowledge, skills, and attitudes did the nurse apply that demonstrate competency in pain management (and, therefore, in patient-centered care), particularly for the patient with dementia? As you think about it, consider the following:

- Why was it important to ask Mrs. Fagin about her husband's usual behavior?
- Was it appropriate to ask the Fagins whether they wanted a visit from the chaplain?
- How did the nurse show respect for Mr. and Mrs. Fagin's preferences, values, and needs?
- Singing loudly doesn't seem like to be an obvious indication of pain; what other factors let the nurse know Mr. Fagin was in pain?
- How is pain assessment modified for cognitively impaired patients?
- Do you see how the nurse recognized Mr. Fagin and his wife as full partners in care?

For specific Knowledge, Skills, and Attitudes,

Go to the QSEN Web site at **http:www.qsen.org.ksas_prelicensure.php**

Using Pain Scales

To help you assess the intensity of the pain as well as any changes in the pain, you can choose from among a variety of pain scales. Select a pain scale by considering the patient's age, level of education, language skills, eyesight, and developmental level. Keep in mind that when using a simple pain intensity scale, children can communicate the quality of pain before they are developmentally capable of indicating the intensity (O'Rourke, 2004). Once you choose a particular pain scale for a patient, use it consistently to prevent confusion and allow for comparison. To see some pain scales you might use,

Go to Chapter 31, **Assessment Guidelines and Tools, Using Pain Scales,** in Volume 2.

KnowledgeCheck 31-5

- How often should you assess the patient for pain, if pain is a potential problem for the patient?
- What are some of the common pain scales used?

ANALYSIS/NURSING DIAGNOSIS

For nursing diagnoses, NOC outcomes, and NIC interventions associated with Pain,

Go to Chapter 31, **Standardized Language, NANDA-I Diagnoses, NOC Outcomes, and NIC Interventions Associated With Pain,** on Davis*Plus*.

The following NANDA-I labels are commonly used when pain is the focus of the problem:

- *Acute Pain.* Pain with an anticipated or actual duration of <6 months.
- *Chronic Pain.* Pain with an anticipated or actual duration of >6 months.

Notice that NANDA-I uses only duration, not speed of onset or severity, to differentiate between Acute Pain and Chronic Pain.

Pain affects many areas of functioning. Therefore, it is often the etiology of other nursing diagnoses, such as the following:

Ineffective Sexuality Pattern related to pain in joints
Sleep Deprivation related to chronic back pain of more than a year's duration

When writing a pain nursing diagnosis, specify the location of the pain and any etiological or precipitating factors that you are aware of. For example:

Acute Pain (headache) related to changes of position and secondary to increased intracranial pressure.

Also identify any knowledge deficits, fear of addiction, or any other fears or beliefs that may interfere with effective pain management. Focusing on the specific nature of pain enables you to choose the most useful interventions.

PLANNING OUTCOMES

The overall objective when working with a client in pain is to prevent pain whenever possible or, if it is present, to reduce or eliminate pain.

NOC standardized outcomes for pain include these examples: Physical Comfort Status, Pain Control, Pain Level, and Pain: Disruptive Effects.

Individualized goals/outcome statements you might write for a client with pain include the following:

- By day 2 post-op, will require only oral analgesics.
- Within 15 minutes of PCA injection, reports pain is <3 on a 0–10 scale.
- Reports that chronic pain does not prevent her from performing activities of daily living.
- Pain Control: Uses pain relief diary (4: Often demonstrated) (NOC)

Use the goals set in the planning outcomes phase to evaluate the pain relief obtained from nursing and medical interventions.

PLANNING INTERVENTIONS/IMPLEMENTATION

When planning care, remember that each situation is unique. For example, one terminally ill patient may request complete relief of pain even if this leads to heavy sedation. Another may prefer that the pain be decreased to a just manageable level so he can interact with his family or complete any unfinished business. The patient and family must be part of the pain management program. Generally, the most effective and least invasive method of pain control is preferable. Remember to include nonpharmacological interventions.

Although overall care of the patient depends on the cause of the pain, whether pain is acute or chronic, and on the patient's unique situation, there are nursing interventions and activities that address pain, regardless of its cause.

NIC standardized interventions for pain include Analgesic Administration, Sedation Management, Pain Management, Behavior Modification, and several others (see the Standardized Language table on Davis*Plus*).

Individualized nursing activities (including focused assessments) for clients with Acute Pain and Chronic Pain include the following:

- Actively listen to the patient's reports of pain.
- Support the patient in maintaining an active role in treatment by including her as part of the pain management team.
- Provide prescribed analgesics promptly.
- Assess for response to analgesics and nonpharmacological measures, including level of sedation. Make assessments approximately 30 to 60 minutes after the administration of an oral medicine. Injectable medications work more quickly, so adjust the assessment time accordingly.
- Alter the treatment if the pain is not adequately relieved.
- Provide interventions to manage the side effects of medications.
- Reduce anxiety and fear by offering explanations about care and medications, by allowing the patient to be in control of his pain management, and by providing positive encouragement.
- Consult with the healthcare team about complex pain management issues.
- Delegate appropriate pain management strategies to a NAP.

See Box 31-3 for a list of strategies that may be delegated to NAPs.

Nonpharmacological Pain Relief Measures

Integrating complementary therapies into a pain management plan can help ease chronic pain and reduce the need for drug therapy (Bishop, Yardley, & Lewith, 2008; Ernst, 2008; Hart, 2008). According to the 2007 National Health Interview Survey (NHIS), 38% of adults used some form of complementary and alternative medicine (CAM) when confronted with pain or stress (Barnes, Bloom, & Nahin, 2008).

Nonpharmacological measures, such as exercise, meditation, visualization, and music therapy, can prompt the release of endogenous opioids. They offer an alternative for people with mild pain who do not wish to take potent drugs for pain relief. For many patients, they are satisfying and empowering. However, they should be used as an adjunct to pharmacological therapies for patients with moderate to severe pain.

BOX 31-3 ■ Pain Management Tasks That May Be Delegated to Nursing Assistive Personnel

Nursing assistive personnel (NAP) may assist you in caring for patients with pain. However, you may never delegate the responsibility to assess the patient's pain, monitor the patient's response to pain management strategies, or evaluate the pain management plan. The following tasks may be delegated:

- Repositioning, using pillows for support
- Back rub or massage
- Providing darkness and quiet in the room for sleep
- Straightening sheets
- Mouth care
- Soft music of the patient's preference
- Using distraction (talking or setting up a favorite game for the patient)

Cutaneous Stimulation

Cutaneous stimulation (stimulation of the skin) is a method of pain relief based on the gate-control theory of pain. As we discussed earlier, skin stimulation sends impulses along the large sensory fibers, which in turn excite inhibitory interneurons in the spinal cord to "close the gate." This process diminishes the patient's perception of pain. Cutaneous stimulation works best on pain that is localized and not diffuse.

TENS Units A **transcutaneous electrical nerve stimulator (TENS)** is a battery-powered device about the size of a pager that is worn externally. TENS units consist of electrode pads, connecting wire, and the stimulator. The pads are directly applied to the painful area. Once activated, the unit stimulates A-delta sensory fibers. A TENS unit can be worn intermittently or for long periods of time, depending on the patient's pain.

PENS Units **Percutaneous electrical stimulation (PENS)** combines a TENS unit with percutaneously placed (through the skin) needle probes to stimulate peripheral sensory nerves. PENS is effective in short-term management of acute and chronic pain. PENS therapy in some patients promotes physical activity, increases the sense of well-being, reduces the use of nonopioid medication, and improves sleep.

Spinal Cord Stimulator Chronic neurological pain may be treated by a surgically implanted **spinal cord stimulator (SCS)**. The SCS produces a tingly sensation that interferes with the perception of pain.

Acupuncture Application of extremely fine needles to specific sites in the body to relieve pain is called **acupuncture**. It is believed to stimulate the endogenous analgesia system. Acupuncture is well documented to provide relief from low back pain (Lee, Choi, Lee, et al., 2013). It is used to relieve dental pain and has been used extensively after surgery and chemotherapy to treat nausea. Of all the complementary therapeutic approaches, acupuncture enjoys the most credibility in the medical community (Hart, 2008). There have been some reports in which acupuncture has led to lightheadedness, which may be a concern for patients who are at risk for falls.

Acupressure Similar to the ancient art of acupuncture, from which it evolved, **acupressure** stimulates specific sites in the body. However, instead of needles, fingertips provide firm, gentle pressure over the various pressure points. This process may have a calming effect through the release of endorphins. Patients can be readily taught key points to stimulate so that they can self-administer acupressure at any time.

Massage Massage has been shown to be effective in reducing pain (Cassileth, Trevissan, & Jyothirmai, 2007). By providing cutaneous stimulation and relaxing the muscles, **massage** helps to reduce pain. **Effleurage**, or the use of slow, long, guiding strokes, is used for obstetrical patients during labor and as back rubs for postsurgical patients. Massage requires little effort from the patient and may improve sleep. For most patients, superficial massage is soothing and relaxing, both mentally and physically. However, some patients do not like to be touched, and you should always obtain verbal permission for a massage.

Application of Heat and Cold The application of cold causes vasoconstriction and can help prevent swelling and bleeding. Cold can be especially effective in reducing the amount of pain that occurs during procedures. Apply a cold pack to the site before and after a procedure to reduce pain. Heat promotes circulation, which speeds healing. Use caution with these methods, however, because the skin may be injured by extremes of either hot or cold. Also, because the addition of moisture to heat or cold amplifies the intensity of the treatment, take extra precautions when applying moist heat or cold.

To safely use heat and cold:

- Avoid direct contact with the heating or cooling device. Cover the hot or cold pack with a washcloth, towel, or fitted sleeve.
- Apply heat or cold intermittently, for no more than 15 minutes at a time, to avoid tissue injury.
- Check the skin frequently for extreme redness, blistering, cyanosis (blue color), or blanching (white color).
- If any of these occur, discontinue the treatment immediately and notify the provider.

Contralateral Stimulation Why does a patient experiencing pain in the right arm experience some relief when lotion is applied and rubbed into the left arm? The principle involved is called **contralateral stimulation—**stimulating the skin in an area opposite to the painful site. Stimulation may be in the form of scratching, rubbing, or applying heat or cold. This intervention is especially helpful if the affected area is painful to touch, under bandages, or in a cast. It has provided some relief to patients who have phantom pain after an amputation.

Immobilization

Immobilizing a painful body part (e.g., with splints) may offer some relief. It is particularly helpful with arthritic joints. You must remember to remove the splints at regular intervals so that the patient can exercise the area to strengthen the site and prevent further injury. Patients in severe pain have the tendency to immobilize a painful area by limiting its use.

Cognitive–Behavioral Interventions

Cognitive–behavioral therapy attempts to alter patterns of negative thoughts and to encourage more adaptive thoughts, emotions, and actions. It is used to decrease depression and anxiety, both of which play a role in pain. Cognitive therapy helps patients to deal with their pain by fostering a sense of control over their illness and decreasing feelings of helplessness. Be sure to obtain the patient's permission before using these methods, because psychological or spiritual distress may occur if she considers them inconsistent with her belief system. Because they are complementary therapies, several of these interventions are discussed in more detail in Chapter 46. If you wish to read more about them,

Go to Chapter 46, **Holistic Healing,** on Davis*Plus*.

Distraction

Distraction is a method of drawing the patient's attention away from the pain and focusing on something other than the pain. It is based on the belief that the brain can process only so much information at one time. When distraction works, the patient has only a peripheral awareness of pain. You may have responded to this strategy in the past. Have you ever had a headache or muscle pain go away when you became busy with other activities? Although distraction can be used for severe pain, it is most effective for mild to moderate pain and for brief periods of time (e.g., for a short procedure such as an injection or infusion). Some patients experience an increase in pain and may become fatigued and irritable when they are no longer distracted. Distraction is useful with all ages, but it should not be used in place of analgesics.

Distraction can be visual, tactile, intellectual, or auditory. The usefulness of the different methods varies among patients.

- *Visual* tactics, such as watching a football game on TV, serve as effective distraction for some patients.
- *Tactile* distraction such as massage, hugging a favorite toy, holding a loved one, or stroking a pet is effective for still other patients.
- *Intellectual* distraction includes becoming engrossed in a crossword puzzle or playing a challenging game.
- *Auditory* distraction in the form of music therapy has been shown to reduce anxiety during childbirth and appears to improve mood and pain tolerance. Music therapy has also been shown to improve patients' perceived effectiveness of pain. Patients' self-reports show pain is reduced and relaxation is achieved more easily. Physiological measures, such as respirations, heart rate, blood pressure, and muscle tension, indicate a less intense pain experience (American Music Therapy Association, n.d.). Music should not be limited to adults; it can be used for infants and children as well.

Relaxation Techniques

Relaxation techniques reduce pain in a variety of medical conditions, especially in chronic pain. In **sequential muscle relaxation (SMR)**, or progressive relaxation, the person sits comfortably and tenses a group of muscles for 15 seconds and then relaxes the muscle while breathing out. After a brief rest, this sequence is repeated using another set of muscles. Patients often start at the facial muscles and work downward to the feet.

Guided Imagery

Guided imagery uses auditory and imaginary processes to affect emotions and help calm, divert, and relax (Hooten, Timming, Belgrade, et al., 2013). Acute and chronic pain, physical and psychological, may respond to guided imagery; however, it is more effective for chronic pain. Audio media featuring guided imagery can help patients use their imagination to create images of temporary escape that will elicit a sense of well-being (Lewandowski, Good, & Draucker, 2005). For a script for a guided imagery session,

Go to Chapter 12, **Supplemental Materials,** on Davis*Plus*.

Diaphragmatic Breathing

Diaphragmatic breathing is an effective measure to invoke relaxation and improve tissue oxygenation for pain management. The goal is to train patients to intentionally take slow, even breaths using the diaphragm to inhale and exhale at the same rate for five to eight breaths per minute.

Hypnosis

Hypnosis involves the induction of a deeply relaxed state. Once the person is in this state, the hypnotist offers therapeutic suggestions to provide relief of symptoms. For example, the hypnotist may suggest to a patient with arthritis that the pain can be turned down, like the volume of a radio. Special training in hypnotherapy is required.

Therapeutic Touch

Therapeutic touch (TT) was developed by nurses and derived from the ancient practice of laying on of hands. Despite its name, therapeutic touch does not require physical contact. It focuses on the use of the hands to direct energy fields surrounding the body. Although research studies on its effect are not consistent, some patients become relaxed and require less pain medication after a session of therapeutic touch.

Humor

Humor has positive effects on a patient's physical and emotional health. For most people, laughter is positive and indicates mental well-being. Humor may boost the immune system as well. It is especially helpful when used before a painful procedure because it lessens anxiety and serves as a form of distraction. Some institutions have humor carts and even humor rooms containing humorous videos, books, and playful items, such as bubbles, fingerpaints, and puppets. Humor is helpful for both children and adults, but it must always be in good taste and age-appropriate. Involve the patient in choosing the humor material, because what one person considers very funny another person may not.

Expressive Writing

Expressive writing can help reduce chronic pain. Some recommend structured writing sessions in which the patient describes stressful events for a specified period of time over consecutive days. This type of therapy is best when done in conjunction with a knowledgeable practitioner to provide direction and support (Hart, 2008). Others benefit from frequent journaling in an informal way, expressing feelings, fears, or what comes to mind.

ThinkLike a Nurse 31-6

What has been your experience with using nonpharmacological pain relief measures to manage your own pain? How would you incorporate these methods into your nursing practice?

Pharmacological Pain Relief Measures

Analgesics are classified into three groups: nonopioids, opioids, and adjuvants. Many health practitioners use the World Health Organization's (WHO) three-step ladder to assist in the selection and titration of an analgesic (Fig. 31-4). Each step on the ladder represents severity of pain, by which the analgesic selection is determined. Choice of treatment is based on the level of pain the patient is experiencing. Patients in severe pain should start at the third step. Titration is accomplished according to the patient's response. Monitoring should be regular and continuous. If the patient's pain is not controlled, adjust by moving up the pain ladder. To apply the ladder correctly, you need to know the interactions and side effects of all the drugs recommended on each step.

Base decisions about the use of analgesics on a thorough pain assessment using valid and reliable pain assessment tools, as well as knowledge of the drug to be administered (see Assessment). Prior to first dose, verify the patient's drug allergy status.

Dosing Administer analgesics at regular times throughout the day if the patient has pain that lasts throughout the day. First, determine the dosage that relieves pain at the patient's desired level, then observe how long the first dose lasts. Administer the next dose before the last dose wears off. Around-the-clock (ATC) dosing prevents the patient from experiencing severe pain several times a day and is believed to be better than prn (as needed) dosing for pain. Explain to the patient

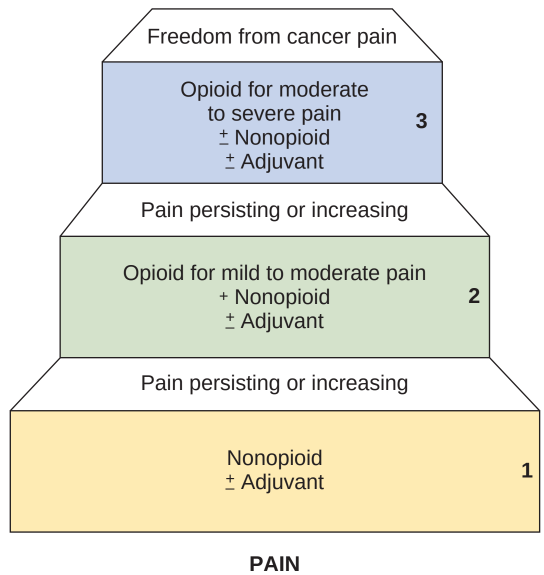

FIGURE 31-4 **The WHO three-step analgesic ladder.** (World Health Organization (WHO). (1990). Cancer pain relief and palliative care: Report of a WHO expert committee. WHO Technical Report series, No. 804. Geneva, Switzerland: Author. Used with permission.)

Toward Evidence-Based Practice

Cole, L. C., & Lobiondo-Wood, G. (2012). Music as an adjuvant therapy in control of pain and symptoms in hospitalized adults: A systematic review. *Pain Management Nursing*. Advance online publication. pii:S1524-9042(12)00144-0. doi:10.1016/j.pmn.2012.08.010.

Seventeen randomized controlled trials were reviewed in a search for the terms *music, music therapy, pain, adults, inpatients*, and *hospitalized* from January 2005 to March 2011. These included surgical, medical, medical-surgical, intensive care, and pregnant patients. These studies supported the use of music as an adjuvant approach to pain management in hospitalized adults.

Topcu, S.Y., & Findik, U.Y., (2012). Effect of relaxation exercises on controlling postoperative pain. *Pain Management Nursing*, 13(1), 11–17.

Sixty patients undergoing upper abdominal surgery were studied. Pain levels were assessed before and after relaxation exercises using the verbal pain scale. Pain levels were reduced after relaxation exercises.

1. For patients using alternative or integrative therapies, such as guided imagery, music, and relaxation to manage pain in various situations, why do you think these techniques might be effective?

2. When teaching alternative or integrative therapies for managing pain, how might you best prepare the setting in order to maximize the effectiveness of the technique?

3. Can you think of reasons patients might resist trying alternative or integrative methods for managing chronic pain? What would you do to encourage patients who seem to oppose the idea of practicing nonpharmacological pain management?

Go to Chapter 31, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

that ATC dosing will keep pain at an acceptable level throughout the day and allow her to function at an optimal level. For optimal pain management, avoid administering small, frequent, ineffective, partial doses within a range; this results in underdosing.

Studies show higher nonsteroidal anti-inflammatory drug doses give longer duration of action rather than greater pain relief in the short term (McQuay, Derry, Eccleston, et al., 2012).

Nonopioid Analgesics

Nonopioid analgesics include a variety of medications that relieve mild to moderate pain. Many also reduce inflammation and fever. Several of these medications, including acetaminophen (Tylenol), aspirin, ibuprofen (Advil, Motrin), and naproxen (Aleve), are available over the counter. All may be used for acute and chronic pain. Most have an onset of action within 1 hour. Box 31-4 features a number of commonly used nonopioid analgesics.

The analgesic properties of acetaminophen and aspirin are often underestimated. Research indicates that 650 mg of aspirin or acetaminophen may relieve as much pain as 50 mg of oral meperidine or 3 to 5 mg of oxycodone, both of which are opioid analgesics. Nevertheless, nonopioid analgesics are often compounded with opioids. This allows for a lower dose of opioid to be administered and reduces the incidence of side effects.

Nonsteroidal Anti-Inflammatory Drugs

The largest group of nonopioid analgesics is made up of nonsteroidal anti-inflammatory drugs (NSAIDs). These include aspirin, ibuprofen, and several others. NSAIDs act primarily in the peripheral tissues by interfering with the production of prostaglandins. Prostaglandins sensitize pain receptors and are involved with inflammation.

One of the most common side effects of NSAIDs is gastric irritation and bleeding. Because of the risk of GI bleeding, the long-term use of nonselective NSAIDs, such as naproxen, oxaprozin, and piroxicam, is generally not recommended in older adults. Additionally, they can lead renal failure, high blood pressure, and heart failure in geriatric patients (American Medical Directors Association [AMDA], 2012).

Taking the medication with food, lowering the dose, or using enteric-coated pills can reduce the incidence of this side effect. Some of the newer NSAIDs are less irritating to the GI so they markedly decrease gastric irritation and bleeding. However, they are expensive and available only by prescription. Combining two nonsteroidal anti-inflammatory drugs (NSAIDs) is not often recommended because it increases the risks of side effects and may not be more effective.

Aspirin is a unique NSAID. In addition to reducing inflammation, fever, and pain, it can inhibit platelet aggregation (clumping), the first step in clot formation. For that reason, NSAIDs should be used with caution in patients with impaired blood clotting, renal disease, and gastrointestinal bleeding or ulcers.

Myocardial infarction, stroke, and thrombophlebitis (a clot in the peripheral veins) are all associated with platelet aggregation. Because of this property, low-dose aspirin (usually 81 mg) is prescribed to decrease risk of these disorders. Regular use of aspirin prolongs clotting time, so teach patients who use aspirin that they will bruise easily and will bleed more if cut. Taking a small daily dose of aspirin to prevent myocardial infarction does not seem to increase the side effects for patients taking other NSAIDs.

Acetaminophen

Unlike most nonopioid analgesics, acetaminophen has very little anti-inflammatory effect. Instead it has analgesic and fever-reducing properties. It has fewer side effects and is probably the safest of the nonopioids. It does not affect platelet function, rarely causes gastrointestinal problems, and can be used in patients who are allergic to aspirin or other NSAIDs. However, even in recommended doses (up to a maximum of 4,000 mg daily), it can cause severe hepatotoxicity (liver toxicity) in patients who take excessive quantities, or who consume alcohol or have liver disease.

BOX 31-4 ■ Commonly Used Nonopioid Analgesics

Chemical Name	Brand Name
Acetaminophen	Tylenol
Acetylsalicylic acid (aspirin)	Excedrin, Bayer, others
Celecoxib	Celebrex
Diclofenac	Voltaren, Cataflam
Etodolac	Lodine
Ibuprofen	Motrin, Advil, others
Indomethacin	Indocin
Ketoprofen	Oruvail
Nabumetone	Relafen
Naproxen	Naprosyn, Aleve, Anaprox

KnowledgeCheck 31-6

- How do NSAIDs induce pain relief?
- What is the main side effect of NSAIDs?
- In which patients are NSAIDs contraindicated?

Adjuvant Analgesics

Adjuvant analgesics reduce the amount of opioid the patient requires. They may be used as a primary therapy for mild pain or in conjunction with opioids for moderate to severe pain. They are especially useful if the patient experiences significant side effects from escalating doses of opioids. Adjuvant analgesics are frequently used in managing neuropathic pain, in which they may be the primary treatment or may be used in conjunction with opioids. Drugs in this category include anticonvulsants, antidepressants, local anesthetics, topical agents, psychostimulants, muscle relaxants, neuroleptics, corticosteroids, and others.

Opioid Analgesics

Opioids are natural and synthetic compounds that relieve pain, although they vary in potency. To some degree, opioids work by finding pain receptor sites to bind with and block the pain impulse. Keep in mind that the process of achieving analgesia is more complex than this. Opiate receptors include mu, delta, kappa, and sigma receptors; however, mu receptors are most effective in relieving pain.

- **Mu agonists** stimulate mu receptors and are used for acute, chronic, and cancer pain. They include codeine, hydrocodone (Vicodin), morphine, hydromorphone (Dilaudid), fentanyl, methadone, and oxycodone. These are excellent medications for **breakthrough pain**—pain that "breaks through" relief provided by long-acting analgesics. Breakthrough analgesia refers to a rescue or extra dose. Drugs used for breakthrough pain should have a rapid onset and short duration. There is no maximum daily dose limit and no "ceiling" to the level of analgesia from mu agonists. You can steadily increase the dose to relieve pain.
- **Agonist-antagonists** are another group of opioids. They stimulate some opioid receptors but block others. Agonist-antagonists are rarely used, but are appropriate for moderate to severe acute pain. This group of drugs includes mixed agonist-antagonists, such as pentazocine (Talwin) and nalbuphine (Nubain), and partial agonists, such as buprenorphine (Buprenex). Agonist-antagonists should not be given to patients taking mu agonists (e.g., morphine) because they may act as antagonists at the mu receptor sites and reduce or reverse the analgesia from the mu agonist.

Opioid Effectiveness

The effectiveness of opioids for pain relief can vary depending on individual differences in metabolism. Some patients metabolize opioids poorly; others very rapidly. Body mass alone is not the sole factor for appropriate opioid dosing (D'Arcy, 2008b; Patanwala, Edwards, Stolz, et al., 2012), even though existing opioid regimens tend to be based on lean body mass.

Chronic pain is relatively resistant to effective long-term, opioid analgesia. Although opioids are shown to be effective for certain types of pain, their usefulness is not appreciable in improving physical function with the activities of daily living. Additionally, chronic use of opioids can invoke other hazards, including overdose, physical dependence, and sedation/cognitive impairment (Hooten, Timming, Belgrade, et al., 2013).

Patient Misconceptions About Opioids

Some people may be concerned about using opioids because they fear respiratory depression, drug tolerance, drug dependence, and addiction. Respiratory depression can be treated with naloxone (Narcan), an opioid antagonist.

- **Tolerance** to opioids can occur, but increasing the dose or changing the route of administration can correct that problem. There is no ceiling on the analgesic effects of opioids. Because of the problem of cross-tolerance, opioid rotation and new opioid compounds are used to produce better pain relief (D'Arcy, 2008b).
- **Physical dependence** leads to withdrawal symptoms when the medication is stopped abruptly; it can be prevented by decreasing the dose slowly over time.
- **Key Point:** ***Psychological dependence,*** *commonly called* ***addiction,*** *occurs in very few patients even after long-term prescribed use of opioids for pain.*

Thus, fear of addiction should not prevent patients from receiving opioids for appropriate pain relief (Pasero, Manworren, & McCaffery, 2008; Patterson, 2008).

Screening for Abuse Potential

Be aware that patients with chronic pain *can* become addicted to or abuse medications. But the addiction is not necessarily *just* because they're taking opioids for pain, but because of their tendencies toward abuse. Considering the prevalence of substance abuse in the general population, assessing the risk for abuse is important for all patients with chronic pain.

Healthcare professionals often fail to recognize substance abuse unless they actively screen for it. Although you may be uncomfortable asking questions about alcohol and illicit drug use, gathering a reliable substance use history is important to provide a foundation for good pain management. This history should include information on the pattern and amount of alcohol intake because patients whose tolerance for alcohol is high may require a higher dose of opioids. Screening should be an integral part of chronic pain management using a validated risk assessment tools, such as the following:

- The **Opioid Risk Tool (ORT).** This is a five-question, yes/no self-report designed to predict a patient's tendency for aberrant behaviors when prescribed opioid analgesia.
- The **Screener and Opioid Assessment for Patients With Pain (SOAPP).** This is a longer, highly reliable tool that may be more appropriate for high-risk populations or when the clinician has time for a thorough assessment.

You can't rely on the normalcy of behavior to indicate opioid abuse. Random drug screening will show opioid use even when aberrant behavior is not evident (Schneider, 2006–2007). To use the Opioid Risk Tool,

Go to Chapter 31, **Tables, Boxes, Figures: ESG Table 31-2, Using the Opioid Risk Tool,** on Davis*Plus*.

Side Effects of Opioids

Most opioids share the same general side effects, but there are some differences among the specific drugs. You should know, or look up, the side effects of the specific opioid you are to administer.

The most common side effects are nausea, vomiting, constipation, and drowsiness. Other side effects of opioids include difficulty with urination, dry mouth, sweating, tachycardia, palpitations, constipation, bradycardia, rashes, urticaria (hives), or pruritus (itching). Some side effects, such as drowsiness and nausea, improve after a few doses. Large doses may lead to respiratory depression and hypotension.

Most patients experience some degree of sedation at the beginning of opioid therapy or when the dose is increased.

Always assess the patient for level of alertness and respiratory status before you administer an opioid. Excessive sedation will precede respiratory depression. Monitor postoperative patients who receive opioids for sedation and respiratory depression every 1 to 2 hours during the first 12 to 24 hours after surgery.

Be aware that some patients may have a **paradoxical reaction** to opioids. That is, their pain may actually increase despite receiving increasing doses of opioids (Hooten, Timming, Belgrade, et al., 2013).

For an example of an agitation sedation rating scale,

Go to Chapter 31, **Assessment Guidelines and Tools, Focused Assessment: Richmond Agitation-Sedation Scale,** in Volume 2.

See Box 31-5 for strategies to prevent common side effects.

KnowledgeCheck 31-7

- What are the most common side effects of opioids?
- Identify at least three things that you should monitor when administering opioids.
- What is the risk of addiction to opioids for patients with acute pain?

Equianalgesia

Equianalgesia refers to the approximately equal analgesia that a variety of opioids will provide. Equianalgesic

BOX 31-5 ■ Preventing and Treating Side Effects From Opioids

Before deciding to add another medication to treat a side effect, consider changing the dose or frequency of the current opioid or changing to another opioid.

Side Effect: Constipation

- Add more fruits, vegetables, and fiber to the diet. Keep in mind, though, this does not help relieve opioid-induced constipation unless the patient's current fiber intake is deficient. Excessive fiber might even put the patient at risk for bowel obstruction due to the opioid-induced decreased peristalsis (refer to Chapter 29, as needed).
- Increase exercise routine. Even walking short distances will help.
- Increase oral fluid intake to eight 8-ounce glasses of water per day.
- If needed, administer stool softeners.
- If the above are not effective, administer a mild laxative.
- If constipation continues, soften stool with glycerin suppository and follow up with a soapsuds enema.

Side Effect: Nausea and Vomiting

- Reduce opioid dose by combining nonopioid or adjuvant drugs.
- Teach patients that nausea will usually subside after several doses.
- Premedicate or medicate consecutively with an antiemetic. Be aware this may increase sedation, depending on the antiemetic chosen.
- Teach relaxation techniques.

Side Effect: Pruritus

- Reduce opioid dose by combining with nonopioid or adjuvant drugs.
- Use cool packs, lotion, or topical anesthetics.
- Administer antihistamines, such as diphenhydramine (Benadryl). Be aware that this may increase sedation.
- Teach the patient that he can generally expect to develop a tolerance to pruritus.
- Use distraction techniques, which frequently work well.

Side Effect: Respiratory Depression

- Assess the patient's respiratory status *before* administering the opioid and frequently afterward.
- Reduce the opioid dose by combining with nonopioid or adjuvant drugs.
- Reduce the opioid dose by 25% when you observe signs of oversedation.
- If the patient is not responsive or is only minimally responsive, stop the opioid and administer an antagonist, such as naloxone (Narcan), diluted and very slowly. After dosing with a narcotic antidote, reassess the patient for respiratory depression. Naloxone is metabolized more quickly than opioids and therefore repeat dosing might be needed.

Side Effect: Drowsiness

- Assess the patient to ensure that the drowsiness is due to opioid administration and not from another cause.
- Teach the patient that drowsiness will generally subside after a few days as she develops tolerance.
- If analgesia is adequate, reduce the opioid by 25%.
- Discontinue all other nonessential CNS depressant medications.
- During the daytime, offer simple stimulants, such as caffeine.
- Offer a lower dose more frequently to decrease peak concentration.
- Consider another opioid or route of administration.

dose calculations provide a starting point when changing from one opioid to another or from one route of administration to another. For example, a parenteral dose of 5 mg of morphine is equivalent to 60 mg of parenteral codeine or 100 mg of oral codeine in terms of the analgesic effect it produces. As another example, 5 mg of parenteral morphine is the equivalent of 15 mg of oral morphine. These doses are approximate and vary according to the number of doses, the variety of opioids the patient has received, and the needs of the patient. To see a table of equianalgesic dosages among opioids,

Go to Chapter 31, **Tables, Boxes, Figures: ESG Table 31-3, Equianalgesic Doses of Commonly Used Opioid Analgesics,** on Davis*Plus.*

Routes of Administration for Opioid Analgesics

Use the safest and least invasive route to relieve pain using opioids.

Oral The oral route is convenient, safe, and generally produces steady analgesic levels. It is the preferred route of administration unless rapid onset of analgesia is desired. Use the oral route to provide relief for mild to severe pain. Oral patient-controlled analgesia (oral PCA) is being used in some hospitals to eliminate the delay between the patient's request for medication and the nurse's administration of it.

Nasal A rich supply of blood in the intranasal area provides the drug easy access to systemic circulation. The mixed agonist–antagonist opioid butorphanol and the mu agonist sufentanil can be administered intranasally. One drawback to this route is that it may cause burning or stinging.

Transdermal The transdermal route delivers a continuous release of drug for up to 72 hours. It is a convenient alternative for a patient who requires constant opioid treatment for pain, however it does not provide immediate relief. Fentanyl (Duragesic) is commonly given as a transdermal patch.

Key Point: ***Use with care on patients who are febrile (increased body temperature increases absorption of the drug). Inform the patient and family about safe storage and proper disposal of transdermal patches. Proper dating and removing patches after the dose is complete can prevent confusion and dosing errors.***

Rectal Suppositories are an excellent alternative to the oral route, especially in infants and young children and when the patient is vomiting, has a gastrointestinal obstruction, or is at risk for aspiration. The rectal route may be contraindicated in patients with neutropenia or thrombocytopenia because of the potential to cause rectal bleeding while inserting the suppository.

Subcutaneous The subcutaneous route may be used for intermittent injections and continuous administration of opioids. Continuous subcutaneous infusion (CSCI) is appropriate for people who cannot tolerate oral opioids or who have dose-limiting side effects from oral administration (e.g., nausea) and who also have limited venous access. Frequently, CSCI of opioids is used for chronic cancer pain and in palliative care. Hydromorphone and morphine are the drugs most commonly used. Absorption and distribution vary based on the placement site chosen. It is better absorbed, is safer, and provides more continuous relief than the intramuscular (IM) route. Small portable medication pumps allow the patient to be mobile. However, some patients find this method painful and time consuming.

Key Point: ***Teach patients and their families how to use the pumps, needles, syringes, and other equipment. Because of the small volume of drug (2 to 3 mL per hour) that can be absorbed, two sites may be needed if higher doses are required.***

Intramuscular (IM) IM injections are painful, the onset of action is slow, and absorption is unreliable. With repeated administration, sterile abscesses and fibrotic tissue can result. The IM route should be avoided in all patients, but especially in children because they often refuse pain medication to avoid having an injection.

Intravenous (IV) The IV route produces immediate pain relief and is desirable for acute or escalating pain. It is most commonly used for short-term therapy and for hospitalized patients who can be monitored. It is, however, also used in the home care setting for patients with cancer and other pain who are unable to tolerate oral opioids. Methods of IV delivery include continuous infusions, bolus, and PCA. Patients on a continuous infusion can deliver a bolus for breakthrough pain or procedures such as wound care. Drawbacks to this route include the need for venous access and the need to maintain a patent line. Patients who previously used oral opioids may find the IV equipment cumbersome but they typically report less pain and fewer side effects than with the oral route.

Intra-articular A pain pump is implanted into a joint during arthroscopic surgery as a measure to control postsurgical pain. A pain pump provides relief to patients by delivering continuous infusion of local anesthetic directly to the surgical site.

Intraspinal and Epidural Analgesics Intraspinal analgesia requires placement of a catheter in the subarachnoid space (for intrathecal analgesia) or the epidural space by an anesthesiologist or a certified registered nurse anesthetist (CRNA). The epidural space is generally preferred because it poses less risk of complications although they can occur, such as dural puncture, infection, hematoma, and nerve damage (see Fig. 31-5). Placement of the catheter, as well as the type and concentration of medication, determines the area affected by the medication. Higher doses are needed for epidural than for intrathecal administration.

The most commonly used opioids for epidural administration are morphine sulfate (Duramorph), fentanyl citrate (Sublimaze), and hydromorphone (Dilaudid). Local

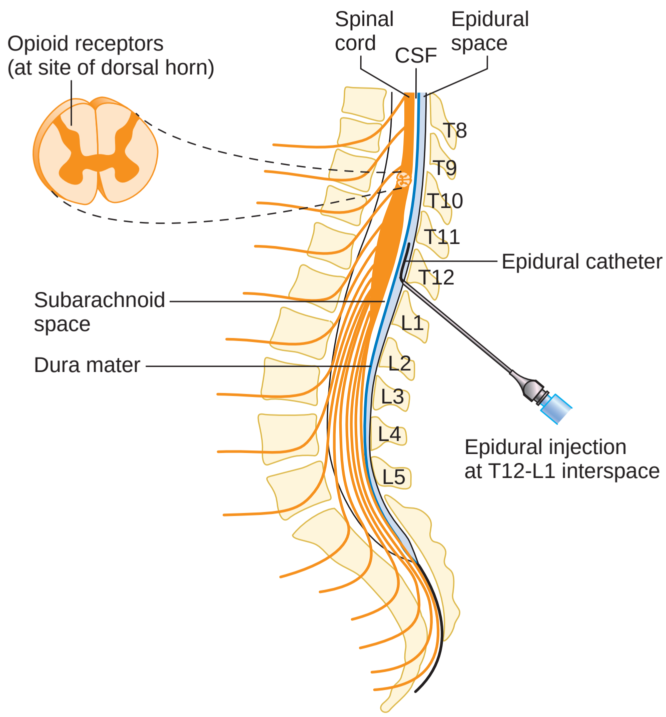

FIGURE 31-5 Placement of an epidural needle and catheter.

anesthetics are frequently combined with the opioids to reduce the total amount of drug necessary to produce analgesia. For nursing care activities associated with caring for a client with an epidural catheter for pain management,

Go to Chapter 31, **Clinical Insight 31-1: Caring for a Patient With an Epidural Catheter,** in Volume 2.

Peripheral Nerve Catheter Pain Management Therapy Infusion of regional anesthesia directly to nerves through a catheter provides pain relief during and for the first few days after certain surgeries (e.g., knee, shoulder, ankle).

Patient-Controlled Analgesia (PCA) PCA pumps are an effective and safe way to deliver opioids by IV, epidural, or subcutaneous routes. They provide excellent pain relief and give the patient a sense of control over the pain. The system consists of a programmable infusion pump, a syringe (or bag), IV tubing, and a button that the patient presses to self-administer a dose. The success of the pump depends on programming a dose that can be administered frequently enough to manage the patient's pain effectively. Rarely, providers order a low continuous rate of infusion (basal rate) that can be supplemented with patient-demand doses.

Most PCA pumps can be programmed with 1- or 4-hour maximum lockout interval to prevent overdosing. If the patient reaches the set limit, the pump will automatically trigger a "lockout" even if the patient keeps pressing the button. You will need to educated patients about this lockout feature, as some might avoid activating the pump in fear of overdosing.

If you are teaching the patient about use of the PCA pump in the postoperative period, make sure he is alert enough to understand the directions and has been given a hearing aid or glasses, if needed, before you offer your explanation. Encourage patients to administer a dose before potentially painful activities, such as walking or physical therapy. PCA pumps are contraindicated in patients who have limited ability to understand direction.

Because of the potential to overdose the patient, only nurses who are trained in PCAs should set up the pump and the program.

As a safeguard, another nurse should do an independent double-check of the setup before patient use.

The accompanying Highlights of Procedures box summarizes the key points involved in use of the PCA. For detailed instruction on use of a PCA pump,

Go to Chapter 31, **Procedure 31-1: Setting Up and Managing a Patient-Controlled Analgesia by Pump,** in Volume 2.

ThinkLike a Nurse 31-7

- What routes of opioid administration have you seen in your clinical rotation?
- What types of pain relief and side effects have you observed?
- What routes of administration would you like to see? Why?

Highlights of Procedure 31-1

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedure in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 31-1: Setting Up and Managing Patient-Controlled Analgesia by Pump

- Determine the patient's baseline vital signs, cognitive status, physical mobility, and pain level.
- Review the physician prescription for PCA, including the demand dose, the lockout interval between each dose, initial bolus (loading) dose, the basal rate (if prescribed), and the 1-hour or 4-hour lockout dose limit.
- Determine whether the patient has an allergy to prescribed medication.
- Verify PCA with two nurses before initiating PCA, after any change in pump settings, change of shift, any transfer in care, and when wasting the remainder of medication.
- Insert the medication cartridge/syringe into the pump, prime the connecting tubing, and lock the pump.
- Set the pump for the demand dose, the lockout interval, loading dose (if prescribed), basal rate (if prescribed), and the 1-hour or 4-hour lockout dose limit.
- Connect the tubing into the patient's maintenance IV line.
- Start the pump.
- Place the button that controls dosing within reach of the patient.
- Change tubing per facility protocol.

Chemical Pain Relief Measures

Nerve blocks and **epidural injection** are types of regional anesthesia. An anesthetic agent is injected into or around the nerve that supplies sensation to a specific part of the body. Most nerve blocks affect a network of nerves called a *plexus.* Nerve blocks may be used for short-term pain relief after surgical procedures or for long-term management of chronic pain.

Local anesthesia is the injection of local anesthetics into body tissues. Short-acting agents, such as lidocaine, and long-acting agents, such as marcaine, may be used. Local anesthetics are injected into subcutaneous tissue for minor surgical procedures. They may also be injected into joints and muscle for pain relief. Pumps are commonly used to administer local anesthetics at surgical sites for postoperative pain relief.

Topical anesthesia involves applying an agent that contains cocaine, lidocaine, or benzocaine directly to the skin, mucous membranes, wounds, or burns. Topical anesthesia is quickly absorbed and provides pain relief for mild to moderate pain. Many topical anesthetic agents are available over the counter. Sunburn relief agents, gel products for tooth and gum pain, and first aid sprays are forms of topical anesthetics.

Radiofrequency Ablation Therapy

Radiofrequency ablation therapy uses electromagnetic waves that travel at the speed of light to target nerves that carry pain impulses. This procedure is used to provide longer term pain relief than that provided by injections of steroids or pain relievers and nerve blocks.

Surgical Interruption of Pain Conduction Pathways

Surgical interruption of pain conduction pathways results in permanent destruction of nerve pathways and is used as a last resort for intractable pain. The various options depend on the type and location of pain.

- **Cordotomy** interrupts pain and temperature sensation below the tract that is severed. This is most frequently done for leg and trunk pain.
- **Rhizotomy** interrupts the anterior or posterior nerve route that is located between the ganglion and the cord. Anterior interruption is generally used to stop spastic movements that accompany paraplegia, and posterior interruption eliminates pain in the area innervated. This procedure may be safely performed at any level along the spine but is most often used for head and neck pain produced by cancer.
- **Neurectomy** is used to eliminate intractable localized pain. The pathways of peripheral or cranial nerves are interrupted to block pain transmission.
- **Sympathectomy** severs the paths to the sympathetic division of the autonomic nervous system. The outcomes of this procedure are improvement in vascular blood supply and the elimination of vasospasm. It is used to treat the pain from vascular disorders, such as Raynaud's disease.

Surgical therapies disrupting pain pathways are not widely used because of advances in oral and transdermal opioid therapies.

KnowledgeCheck 31-8

- Identify three types of chemical pain relief measures.
- What type of patient might be suitable for surgical interruption of a pain pathway?

Misconceptions That Interfere With Pain Management

Key Point: ***Pain is invisible to others but it exists when the patient says it does. It exists even when there are no sure signs of pain or an apparent cause.***

Patients, caregivers, and clinicians sometimes have beliefs about pain or pain management strategies that interfere with the treatment plan. For instance, one older patient may fear that severe pain is a sign of weakness and try to endure it. Others might perceive pain as a part of the normal physical declines that accompany aging instead of an acute situation that requires treatment. An athlete might believe "no pain, no gain," although actually pain can signal a problem. Or a family member may worry that pain medication may make the patient nonfunctional. Others might fear addiction to pain medication even though non-narcotic analgesics are not addictive.

The beliefs of healthcare providers can also interfere with pain management. For example, nurses and other caregivers sometimes doubt the patient's report of pain because:

- Most people don't have pain from that particular illness or procedure.
- There is no obvious, physical cause for the pain.
- They are concerned about drug-seeking behavior and patient addiction.

As you care for patients in pain, remain open to the patient's description of pain, and work with the patient and caregivers to provide pain control. Table 31-1 highlights some of the most common misconceptions about pain.

Managing Pain in Older Patients

Pain, particularly persistent pain, is common among older adults, especially those suffering from degenerative spine conditions, arthritis, nightly leg pain, or pain as a result of cancer. Pain management among older patients is especially complex. Most older adults have at least one chronic condition and take multiple medications. Adding analgesics to a complex medication regimen increases the likelihood of drug interactions. In addition, drug distribution is altered in older patients because of changes in blood

Table 31-1 ➤ Common Misconceptions Among Patients and Caregivers About Pain

FALLACY	TRUTH
The caregiver is more objective than the patient about the amount of pain experienced.	The patient's report is the "gold standard," and the patient is the authority.
You should wait until the pain is severe before taking medication.	You should take pain medication early and on a scheduled basis even if pain is not severe.
There is a significant danger of addiction to pain medications.	Patients in pain rarely become addicted to their pain medications.
Pain is a normal component of aging.	Pain is a symptom that something is wrong and should be treated.
Complaining of pain will label the person as a "bad patient."	The patient should report pain so that it can be treated.
Patients should have severe pain only if they have major surgery.	Even minor surgery and injury can produce severe pain.
Patients will have visible physical or behavioral signs if they are really in pain.	Even when patients are in severe pain, they may not exhibit physical or behavioral signs.

flow to the organs, protein binding, and the difference in body composition. Older adults are at great risk for undertreatment of pain because they and their caregivers may be reluctant to administer analgesics for fear of producing confusion, excessive sedation, drug interactions, and respiratory depression (AGS, Panel on Persistent Pain in Older Persons, 2009).

Another problem for sufficiently treating pain in older adults is that pain is often unrecognized because of dementia, coexisting medical conditions, sensory impairment, or inability to verbally communicate the quality or intensity of pain. Poor pain management can result in falls, poor sleep, delayed healing, reduced activity, prolonged hospitalization, anxiety, and poor quality of life (Horgas, 2007). At the same time, there is a risk of overtreatment due to the higher peak effect and longer duration of pain relief that they experience as a result of changes associated with aging (AGS, Panel on Persistent Pain in Older Persons, 2009; Christo, 2009).

Persistent pain is not a normal part of aging and should not be ignored. For updated recommendations, see the American Geriatrics Society (AGS) Panel on Pharmacological Management of Persistent Pain in Older Persons,

Go to Chapter 31, **Tables, Boxes, Figures: ESG Table 31-4, AGS Panel on Pharmacological Management of Persistent Pain in Older Persons,** on Davis*Plus*.

The AGS guidelines for managing persistent pain in older adults no longer recommend that seniors use over-the-counter (OTC) or prescription NSAIDs, such as aspirin or ibuprofen, before being prescribed an opioid medication. In light of increased cardiovascular risk and gastrointestinal toxicity in this population, the AGS Panel recommends the following:

- Consider opioid therapy for all patients with moderate to severe pain or diminished quality of life due to pain.
- Consider acetaminophen for treatment of persistent pain, particularly musculoskeletal pain, in light of its effectiveness and safety.
- Consult the guidelines about the use of adjuvant therapy for older persons with recurring pain.

ThinkLike a Nurse 31-8

- Which groups of patients are most at risk for inadequate pain management?
- What can you do to assist each group?
- How do past pain experiences affect present pain experience?

Managing Pain in Patients With Substance Abuse or Active Addiction

It is important to differentiate between physical dependence, which is expected and treatable, and addiction. **Addiction** is a state of psychological dependence in which a person uses a drug compulsively and will engage in self-destructive behavior to obtain the drug. Many studies have shown that the properly managed, short-term medical use of opioid analgesic drugs is safe and rarely causes addiction with the exception of those with a personal or family history of drug abuse or mental illness (National Institutes of Health [NIH], National Institute on Drug Abuse, 2001, revised 2011).

Nevertheless, substance abuse is a common problem within our society and is a problem among individuals from all backgrounds. Behaviors that may indicate substance abuse or addiction include the following:

- Repeated requests for injections of an opioid or atypical high dosing when pain should normally be diminishing with recovery from an injury or surgery
- Refusal to try oral medication for pain relief
- "Doctor shopping"—moving from provider to provider in an effort to obtain multiple prescriptions for the drug(s) they abuse
- "Pharmacy shopping"—using multiple pharmacies to dispense controlled substances

If you observe these signs, assess the patient carefully because the signs may also indicate untreated withdrawal or increased pain due to complications. When dealing with clients with active addiction, try to assume a nonjudgmental approach.

Although it is important to recognize opioid addiction, you must be careful not to undertreat pain in patients whom you know or suspect to abuse substances. As a nurse, you will be in a position to help maintain the balance between providing adequate pain relief and protecting against inappropriate drug use.

ThinkLike a Nurse 31-9

You are preparing to give your patient a bath. When you remove his bath equipment from under the bedside table, you find illicit drugs mixed in with the bath equipment. What would you do?

Pain Relief From Placebos

A **placebo** is defined as "any medication or procedure, including surgery, that produces an effect in a patient because of its implicit or explicit intent, not because of its specific physical or chemical properties" (McCaffery & Pasero, 1999, p. 36). Placebos contain inactive substances that do not chemically provide analgesia. Clearly, placebos can relieve pain for some patients. How they do so is not well understood. Theories include operant conditioning, faith, anxiety reduction, and endorphin release. Although use of placebos may be appropriate in clinical trials, they are not suitable for pain management for the following reasons:

- If the patient responds to a placebo, it does not mean that the patient did not have pain. In classic studies done in the 1950s, 36% of patients demonstrated adequate pain relief from a placebo injection the day after abdominal surgery (Evans, 1974). However, there is no way to determine in advance which patients will experience pain relief; therefore, you risk inadequately treating the patient.
- Even in the same patient, placebos may relieve pain at one time and not at another.
- Ethically, the most important reason for not using placebos is that their use involves deceit. If discovered, and it frequently is, the patient's trust in healthcare professionals will be diminished, if not destroyed.

Teaching the Patient and Family About Pain

Patients and caregivers tend to cope more effectively when they are well informed. Because pain can interfere with a patient's learning, be sure to include the patient's family in your teaching. If the patient is discharged from the facility with a prescription for opioids, teach the family how to monitor for excessive sedation and to call the healthcare provider if pain relief is not adequate. You should discuss the following topics with the patient and family:

- The cause of the pain, if it is known
- The normal duration of the pain, if known (e.g., postoperative pain generally decreases every day as tissues heal)
- How to use the selected pain scale; ask for a demonstration of use
- The overall pain management plan
- Information about the analgesic prescribed—dose, interval, and route of administration
- If opioids are prescribed, explanation that the risk of addiction is extremely low
- Nonpharmacological ways to treat pain
- Side effects to observe for
- The need to alter the treatment plan if relief is not achieved
- How to contact the healthcare team regarding side effects, missed doses, change in condition, or ineffective pain management

Documentation

Thoroughly document the pain management plan and the patient's responses. Documentation may be narrative, in either nursing or interdisciplinary notes, or recorded on a pain management flowsheet. Although documentation varies from facility to facility, it typically reflects the entire spectrum of the nursing process:

- The expected outcome for pain management
- The patient's pain level at the present time
- The patient's response to any intervention for pain
- Any adverse reactions that may have resulted from the analgesic
- Planned interventions to improve the pain relief if needed

Typically, pain management flowsheets contain a column for time, pain ratings, and analgesic used, including dose and route, vital signs, and side effects. They are tailored to the patient population, the type of pain being monitored, and the clinical setting. For example, the pain flowsheet for a patient on an IV PCA pump will be more complex than a pain flowsheet for a patient on oral medications at home. Documentation is important because typically pain recall is poor and patients often underestimate their pain after the fact. If pain is not adequately documented, there is no way to prove that it was accurately assessed. For an example of a pain flow sheet,

Go to Chapter 31, **Tables, Boxes, Figures: ESG Figure 31-3, Pain Flow Sheet,** on Davis*Plus*.

EVALUATION

Evaluation is critical to a pain management program. Compare your findings with the expected outcomes to determine whether the pain management strategy is effective. Questions to ask include the following:

- Are the patient's pain scores consistently at or better than the desired level? Are they improving?
- Is the patient's behavior, mobility, range of motion, mood, and affect consistent with pain relief?
- What is the quality of the patient's life, according to the patient's standards?

In addition to evaluating the extent to which the pain was relieved, you need to determine which interventions were or were not effective, as well as any adverse reactions to these interventions. Close examination of the patient's pain relief diary should provide most of the data you need for evaluation. For a sample of a client diary,

Go to Chapter 31, **Assessment Guidelines and Tools, Focused Assessment: Pain Relief Diary,** in Volume 2.

It is important to reassess the patient's pain regularly. An increase in pain may be a sign of inadequate pain management, but it may also be a sign of developing complications. Before implementing a change in the treatment plan, you should determine whether the pain management plan was carried out correctly. If the decision of the healthcare team is to make a change, remember to evaluate again the effect of this change. Do not assume your intervention will provide adequate pain relief.

NURSING PROCESS IN ACTION

Mary Jean Thompson, 30 years old, was admitted to the hospital with severe abdominal pain and underwent an appendectomy yesterday. The surgeon has prescribed hydromorphone (Dilaudid) 2 mg tablet PO q4 hr prn for pain. Ms. Thompson doesn't like the idea of taking pain medication and waits until she rates her pain a 9 or 10 on a scale of 0 to 10 before requesting medication. Even after the medication, her pain never drops below a 7 on a scale of 0 to 10 and she is unwilling to turn or ambulate because of the pain.

When you perform your assessment, she tells you she does not want to be sedated. "I hate that groggy, drugged feeling. I'm willing to have some pain to avoid that." After you discuss the importance of pain management to aid in healing and ability to participate in activities and therapy, Ms. Thompson states that she would like to have a pain score of 3 to 4 today. See the accompanying plan for her pain management.

Pain Management: Nursing Care

Nursing Diagnosis: Acute Pain (surgical incision) related to possible inadequate analgesia (drug and dosing) because of reluctance to take pain medication, as manifested by not requesting medication until her pain is at a score of 9

EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALE
On a scale of 0–10, the patient will verbalize pain relief at a score of 3 or below while in bed and 4 or below while ambulating at all times.	Assess and document the patient's verbal and nonverbal expressions of pain relief with each check of vital signs, with every procedure and ambulation, and when the patient is at rest.	Assessment is necessary to determine the effectiveness of the prescribed medications. Assessment and documentation are legal responsibilities for the nurse as well.
	Discuss with the prescriber the need to modify medication dose or type if pain relief measures are ineffective. Recommend PCA.	Ineffective pain management will cause the patient increased stress and can lead to further complications because the patient will be unwilling to move.
	When you obtain new pain orders for a PCA morphine pump, educate the patient about the pump.	A patient using PCA requires instruction about safe use of the pump.
	Provide nonpharmacological interventions, such as a back rub or other techniques described in this chapter, before rest or sleep, with any exacerbation of pain, and after painful procedures such as ambulation.	Nonpharmacological interventions are synergistic and enhance the relief the opioid gives (Shin & Kolanowski, 2010).
The patient will demonstrate pain relief by participating in ambulation and turning within 24 hours.	Teach the patient to press the self-administered pain medication using the PCA before activities.	Peak blood levels enable the patient to ambulate, cough and deep-breathe, and perform activities of daily living.

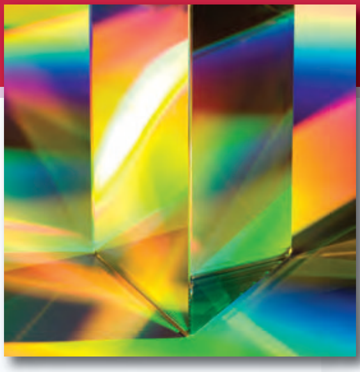
CHAPTER 32



Physical Activity & Mobility

Learning Outcomes

After completing this chapter, you should be able to:

- Discuss the physiology of movement.
- Use proper body mechanics when providing patient care.
- Discuss the concept of fitness.
- Describe the five types of exercise discussed in this chapter.
- Compare the effects of exercise and immobility on the body.
- Describe the physical activity recommended for health promotion, cardiovascular fitness, and maintenance of healthy weight.
- Discuss factors that affect body alignment and activity.
- Identify patients who are at risk for immobility or activity intolerance.
- Develop a plan of care for patients with decreased activity tolerance.
- Implement care related to a patient's mobility problems.

Key Concepts

Physical Activity
Fitness
Mobility

Related Concepts

See the Concept Map on Davis*Plus*.

Example Problem

Hazards of immobility

Meet Your Patients

You are attending a health promotion series at the local hospital in order to fulfill the requirement in your state for continuing nursing education. For the next 4 weeks, the topic is exercise. In the group, you meet the following people:

- Phillip Flanders is a 40-year-old accountant. He works long hours in an office setting doing work that is sedentary and requires concentration. Although he is not physically active, he often feels tired. He does not exercise regularly. Many of his friends have suggested that he begin some kind of exercise program to improve his energy and health. Phillip would like to learn how to get started with an overall fitness program that works with his work and family life. Before getting started, he makes an appointment with his primary care provider for a thorough health evaluation.
- Peter Phan is 28 years old and is a marathon runner and triathlete. On average, he runs 35 miles per week and cycles at least twice per week. Peter has had plantar fasciitis in the past that was painful and caused him to miss exercise. Peter would like to learn what he can do to prevent other injuries.
- Helen Jillian is 72 years old. She has hypertension and high cholesterol levels for which she takes four medications. She is 5 ft 1 in. tall and weighs 290 lb. Recently she began having chest pain when starting a brisk walk. Her physician prescribed nitroglycerin for the chest pain, and after a thorough cardiac evaluation told her to enroll in this class and the CardioFit program at the hospital. She does not understand why she is being asked to do these things because activity seems to trigger her chest pain.

In this chapter, you will find answers to each of these patient questions about activity and exercise. In addition, you will learn more about assisting patients with mobility problems.

Theoretical Knowledge knowing why

Primitive nomadic people were active just meeting their daily needs. Tribes commonly journeyed to hunt for game; women were on foot gathering roots, fruits, and other edible plants. Survival depended on physical activity, such as changing locations to find food or escape a dangerous situation. Later, the shift to an agricultural society reduced the need for most people to hunt and gather food. However, even farming was hard work and people were physically active most of the year.

Today, with modern grocery distribution systems, we expend little to no energy to obtain food. In addition, there are many occupations in which people spend hours at a desk or in front of a computer screen. Many of today's leisure activities, (e.g., watching television, playing video games) are also sedentary. Even though fitness equipment and health clubs are popular, the overall level of fitness in the United States is declining. Nearly half of adolescents do not engage in regular, moderate to vigorous activity. And, more than two-thirds of adults do not achieve the recommended amount of physical activity needed for health and fitness. Regular exercise, one study found, does not reduce the risk of an otherwise sedentary lifestyle (e.g., greater risk of diabetes, cardiovascular disease, obesity, and premature death) (Gray, 2012). To get enough exercise, most people need to make a conscious effort to build exercise and activity into their lives. This chapter will help you to understand why that is important.

ABOUT THE KEY CONCEPTS

Two concepts are widely used to describe human movement: physical activity and fitness. Physical **activity** is bodily movement produced by the contraction of skeletal muscle that increases energy expenditure above a baseline level (U.S. Department of Health and Human Services [USDHHS], 2008). **Exercise** is a subconcept of physical activity. It is planned, structured, and repetitive and purposeful for improving or maintaining physical fitness, physical performance, or health (Caspersen, Powell, & Christenson, 1985). **Fitness** (or physical fitness) is the ability to carry out activities of daily living with vigor and alertness, without undue fatigue, and with enough energy for leisure pursuits and to respond to emergencies (USDHHS, 2008).

As you read this chapter, you will learn how the key concepts of activity, fitness, and mobility are related, and how they relate to subconcepts, such as exercise and body mechanics. Once you have a grasp of these concepts, you should be able to apply them to any patient, regardless of their particular health problem or medical diagnosis.

PHYSIOLOGY OF MOVEMENT

Activity and exercise require body movement (**mobility**). Mobility depends on the successful interaction among the skeleton, the muscles, and the nervous system.

Skeletal System

The skeletal system includes bones, cartilage, ligaments, and tendons. The skeleton forms the framework of the body, protects the internal organs, produces blood cells, and stores mineral salts (e.g., calcium) and fat.

Bones consist of a hard outer shell with a spongy interior (Fig. 32-1). There are 206 bones in the human body. Some bones are long (such as the femur and humerus), some short (phalanges and metacarpals), some flat (sternum and cranial bones), and some are irregularly shaped (vertebrae and tarsal bones). The short, flat, and irregular bones contain red bone marrow that produces red blood cells.

Bones feel strong and tough, so it is easy to forget that they are composed of living tissue that is constantly building and remodeling. **Osteoclasts** are specialized cells that function as housekeepers in the bone by breaking down old or damaged tissue. **Osteoblasts** repair damaged bone and build new bone to keep the skeleton strong. A delicate balance exists between the actions of the osteoblasts and the osteoclasts.

When two bones come close together (**articulate**), a joint is formed. Body movement occurs at the joints. Joints are classified based on the amount of movement they permit:

- **Synarthroses** are immovable joints (e.g., the sutures between the cranial bones). In youth, these joints have some flexibility to allow growth, but they gradually become rigid.

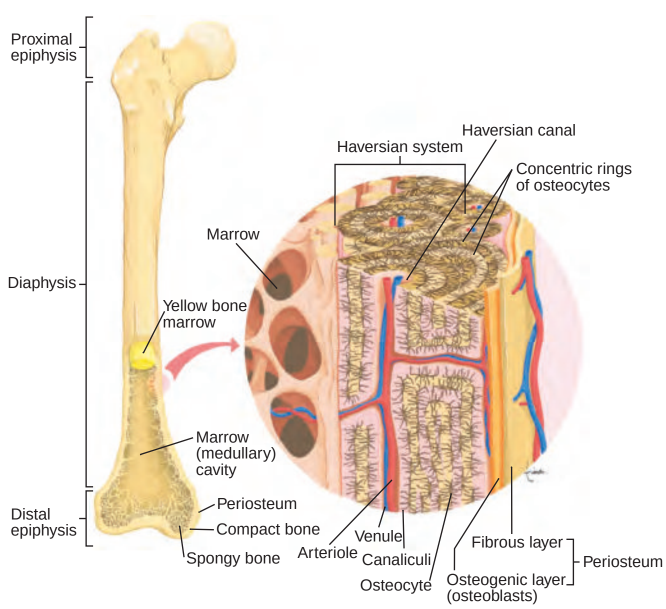


FIGURE 32-1 Bone is complex living tissue.

- **Amphiarthroses** allow for limited movement. Examples are the joints between the vertebrae and pubic bones.
- **Diarthroses,** or **synovial joints**, are freely movable because of the amount of space between the articulating bones. Synovial joints are filled with **synovial fluid**, and the joint surfaces of the articulating bones are covered with smooth **articular cartilage** (connective tissue found in the joints and skeleton). The synovial fluid and articular cartilage prevent friction as the bones move. Table 32-1 identifies the types of movable joints in the body.

Cartilage, ligaments, and tendons serve as the interface between the skeleton and the muscles. Ligaments are fibrous tissues that connect most movable joints. Ligaments are flexible to allow freedom of movement, but strong and tough so they do not yield under force of movement. Tendons are fibrous connective tissues that attach muscles to the bone. Muscles span a joint and attach by tendons to two different bones.

Muscles

Muscles make up 40% to 50% of body weight. When they contract, they cause movement. The type of movement depends on the type of muscle: skeletal, smooth, or cardiac.

- **Skeletal muscle** moves bones and joints.
- **Smooth muscle**, occurring in the digestive tract and other hollow structures, such as the bladder and blood vessels, produces movement of food through the digestive tract, urine through the urinary tract, and blood through the circulatory system.
- **Cardiac muscle** is a unique form of muscle that has the ability to contract spontaneously. It is responsible for the beating of the heart.

Muscles attach to bone at two points: (1) at the ***point of origin***, to the more stationary bone, and (2) at the ***point of insertion***, to the more movable bone. The "belly" (thickest part) of the muscle lies between these two points. When a skeletal muscle contracts, it shortens, thus causing one bone to move at the joint. Muscles work in pairs. For example, the biceps brachii contracts to flex the forearm (bend the elbow joint). When the biceps contracts, the opposing muscle, the triceps brachii, relaxes. Similarly, contraction of the triceps is associated with relaxation of the biceps (Fig. 32-2).

Nervous System

The nervous system controls the movement of the musculoskeletal system. Motor nerves are either autonomic or somatic. The **autonomic nervous system** consists of the sympathetic and parasympathetic nervous systems, which innervate involuntary muscles, such as the heart, blood vessels, and glands. The **somatic nervous system** innervates the voluntary skeletal muscles.

When you make a conscious decision to bend your elbow, the thought originates in the motor area of your cerebral cortex. The upper motor efferent nerves communicate with the lower motor neurons that conduct impulses to the muscles. When the muscle receives sufficient stimuli, it contracts the biceps as the triceps relaxes and moves the elbow. Movement also occurs through reflex mechanisms. Common reflexes include the knee-jerk reflex and corneal reflex. Reflexes are discussed at length in Chapter 22.

A muscle contraction, whether conscious or reflexive, stimulates afferent nerves that convey information to the cerebral cortex and the cerebellum. This information helps control and coordinate movements.

Table 32-1 ➤ Types of Synovial Joints

TYPE	DESCRIPTION	EXAMPLES
Ball-and-socket	A rounded head (ball) fits into a cup-like structure (socket) to allow movement in all planes in addition to rotation.	Shoulder and hip joints
Condyloid	An oval-shaped bone fits into an elliptical cavity to allow movement in two planes at right angles to each other.	Wrist
Gliding	Two flat plane surfaces move past each other.	Intervertebral joints
Hinge	A convex surface fits into a cavity, allowing flexion and extension.	Knee and elbow
Pivot	The joint is formed by a ring-like object that turns on a pivot. Motion is limited to rotation.	The atlas and axis of the first vertebrae and base of the skull
Saddle	One bone surface is concave in one direction and convex in the other. The other surface has the opposite construction so that the bones fit together. Movement is possible in two planes at right angles to each other.	Carpal–metacarpal joint of the thumb

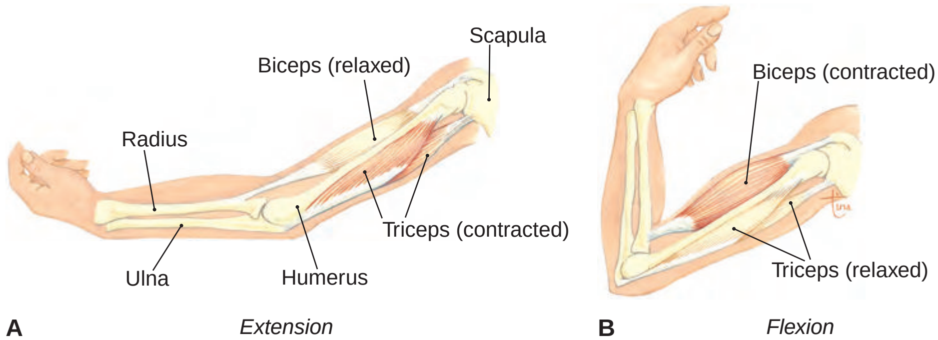

FIGURE 32-2 Antagonistic muscles. *A*, Extension of the forearm. *B*, Flexion of the forearm.

KnowledgeCheck 32-1

- Name three purposes of the skeletal system.
- Define the following movements: abduction, adduction, flexion, extension, circumduction, internal rotation, supination, and pronation.
- Identify three types of muscle.
- How do the muscles and the nerves interact?

BODY MECHANICS

Body mechanics is a term used to describe the way we move our bodies. It includes four components: body alignment, balance, coordination, and joint mobility. You should always use good body mechanics and teach them to patients for back safety and injury prevention. In addition to discussing those components, this chapter also presents some guidelines to use when teaching your patients about safe movement and lifting.

The following are concepts used to describe problems with muscle mass, strength, or mobility.

Body Alignment

Body alignment, or posture, is an important aspect of body mechanics. Proper posture places the spine in a neutral (resting) position. There are four natural curves to the spine (Fig. 32-3). Proper posture maintains these natural curves because it allows movement to occur with less stress and fatigue; the bones are aligned, and the muscles, joints, and ligaments can work at peak efficiency. Good posture contributes to the normal functioning of the nervous system and improves feelings of well-being (see the Self-Care box Tips to Maintain Proper Posture). Most posture problems result from a combination of the following:

Accidents, injuries, and falls
Careless sitting, standing, or sleeping habits
Excessive weight
Foot problems or improper shoes
Negative self-image
Occupational stress
Poor sleep support (mattress)
Poorly designed workspace
Visual difficulties
Weak muscles or muscle imbalance
Skeletal misalignment or malformation (e.g., scoliosis, kyphosis)

Self-Care

Tips to Maintain Proper Posture

- Avoid standing in one position for a lengthy period. If you cannot change positions, elevate one foot on a stool or box, and alternate foot placement frequently.
- Do not lock your knees when standing upright.
- Keep your stomach muscles tight to support your back.
- Do not bend forward at the waist or neck when you are working in a low position.
- When you are seated at your desk, work at a comfortable height.
- Do not wear high-heeled or platform shoes for long periods of time.
- Do not slump when you sit.
- Sit close to your work.
- Use a chair that supports your back in a slightly arched position.
- Sit with your feet flat on the floor and your knees below your hips.
- Sleep on a mattress that is firm but not extremely hard.

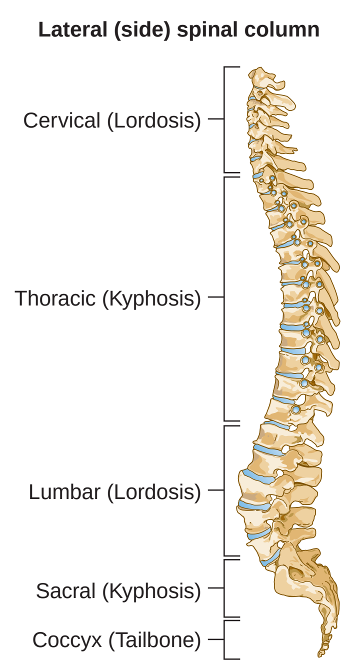

FIGURE 32-3 There are four natural curves to the spine.

Balance

The body achieves balance when it is in alignment. For your body to be balanced, your line of gravity must pass through your center of gravity, and your center of gravity must be close to your base of support. The **line of gravity** is an imaginary vertical line drawn from the top of the head through the center of gravity. The **center of gravity** is the point around which mass is distributed. In the human body, the center of gravity is below the umbilicus at the top of the pelvis. The **base of support** is what holds the body up. The feet provide the base of support.

To avoid injury when moving objects, place your center of gravity closest to your base of support and stand with your head erect, buttocks pulled in, abdominal muscles tight, chest high, shoulders pulled back, and feet wide (Fig. 32-4). Use a wide stance, with feet apart and one foot forward when standing for a long period of time. The broader the base of support, the lower the center of gravity, and the easier it is to maintain balance.

Coordination

Smooth movement requires coordination between the nervous system and the musculoskeletal system. Voluntary movement is initiated in the cerebral cortex. However, the cerebellum coordinates movements. As you may recall, *proprioception*—the awareness of posture, movement, and position sense—is largely controlled by the cerebellum. The basal ganglia, located deep in the cerebrum, assist with coordination of movement. Damage to the motor cortex, cerebellum, or basal ganglia affects coordination of movement. For example, a stroke affecting the motor cortex alters gait and changes posture.

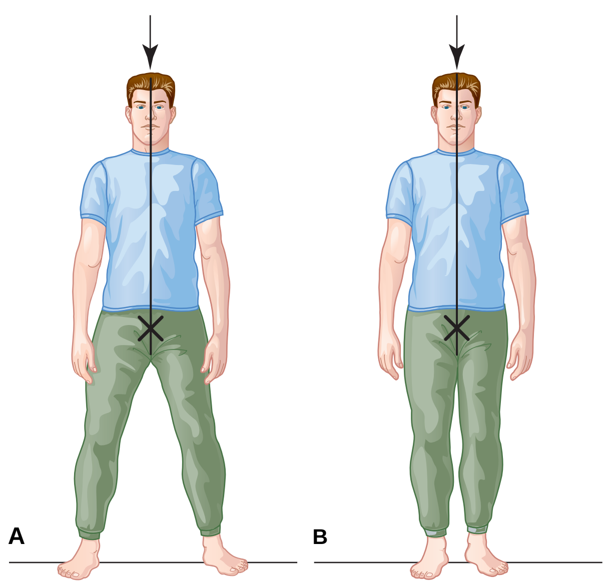

FIGURE 32-4 *A*, With a wide stance, the center of gravity (x) is closer to the base of support. *B*, With a narrow stance, the body is less stable.

Joint Mobility

The key concept **mobility** refers to a person's ability to move within the environment (*Taber's Cyclopedic Medical Dictionary*, 22nd ed.). Joint movement allows us to sit, stand, bend, walk, and perform other activities. **Range of motion (ROM)** is the maximum movement possible at a joint. **Active range of motion** (AROM) is movement of the joint performed by the individual without assistance. The patient independently moves his joints through flexion, extension, abduction, adduction, and circular rotation. AROM involves strength and flexibility; and is part of being physically fit. For that reason, stretching exercises are included in a comprehensive exercise program. **Passive ROM** (PROM) involves moving joints through their ROM when the patient is unable to do so for himself. For other terms describing body movement,

Go to Chapter 32, **Tables, Range of Motion at the Joints,** in Volume 2.

To see animations of joints and range of motion,

Go to **Animations: Range of Motion Animations**, on Davis*Plus*.

Body Mechanics Guidelines

Principles of body mechanics are the rules that allow you to move your body while reducing your risk for injury. Historically, nurses have used body mechanics guidelines as the cornerstone of safe practice for moving and lifting patients. However, because of patient characteristics and condition (e.g., obesity), as well as the patient care environment, you cannot rely on body mechanics alone to prevent injury. Think about it. A patient's weight is not evenly distributed or may be positioned awkwardly. He might be combative or simply a moving target (Howard, 2010; Waters, Nelson, Hughes, et al., 2009). There is no reason to "prove yourself" by transferring without the use of an assistive device (e.g., lift, transfer board, or other staff). The American Nurses Association (ANA) launched the national campaign *Handle With Care* to reduce the risk of back and musculoskeletal injuries among nurses. This campaign emphasizes the use of assistive devices to decrease the risk of injury and recommends virtually no manual lifting (ANA, n.d.). For guidelines to help you assess patients' transfer abilities and use good body mechanics,

Go to Chapter 32, **Clinical Insight 32-1: Applying Principles of Body Mechanics,** in Volume 2.

KnowledgeCheck 32-2

- Identify the four components of body mechanics.
- Give at least five guidelines for good body mechanics.

ThinkLike a Nurse 32-1

While you are attending the health promotion class, Helen Jillian (Meet Your Patients) develops chest pain and must be assisted to a wheelchair for transport to the emergency department.

- Based on what you know about body mechanics, how would you be able to assist Ms. Jillian?
- What additional information do you need to know?

PHYSICAL ACTIVITY AND EXERCISE

Physical activity refers to bodily movement and energy expenditure involving contraction of the skeletal muscles above basal level. Bodily movement can be grouped into two basic categories:

- **Baseline activity** refers to the light-intensity activities of daily living, such as standing, walking slowly, and lifting lightweight objects.
- **Exercise (health-enhancing physical activity)** is more than baseline to produce health-enhancing benefits. People who are physically fit are able to perform activities of daily living with vigor and alertness and with enough energy to enjoy work and leisure activities. (USDHHS, 2008)

Types of Exercise

Health-enhancing physical activity (exercise) may be classified according to the type of muscle contraction it involves and according to whether it uses oxygen for energy.

Isometric exercises involve muscle contraction without motion. They are usually performed against an immovable surface or object, for example, pressing the hand against a wall. The muscles of the arm contract, but the wall does not move. Each position is held for 6 to 8 seconds and repeated 5 to 10 times. Isometric training is effective for developing total strength of a particular muscle or group of muscles. It is often used for rehabilitation because the exact area of muscle weakness can be isolated and strengthening can be administered at the proper joint angle. This kind of training requires no special equipment, and there is little chance of injury. Patients who are bed-bound can use this form of exercise to maintain or regain muscle strength.

Isotonic exercise involves movement of the joint during the muscle contraction. A classic example of an isotonic exercise is weight training with free weights. As the weight is moved throughout the ROM, the muscle shortens and lengthens. Calisthenics, such as chin-ups, push-ups, and sit-ups, all of which use body weight as the resistance force, are also isotonic exercises.

Isokinetic exercise is performed with specialized apparatuses that provide variable resistance to movement. Isokinetic exercise combines the best features of both isometrics and weight training by providing resistance at a constant, preset speed while the muscle moves through the full ROM. Specialized machines available at health and fitness facilities and physical therapy departments are used for this form of exercise.

Aerobic exercise acquires energy from metabolic pathways that use oxygen—the amount of oxygen taken into the body meets or exceeds the amount of oxygen required to perform the activity. Aerobic exercise uses large muscle groups, can be maintained continuously, and is rhythmic in nature. It increases the heart and respiratory rates, thereby providing exercise for the cardiovascular system while simultaneously exercising the skeletal muscles. Jogging, brisk walking, and cycling are common forms of aerobic exercise.

Anaerobic exercise occurs when the amount of oxygen taken into the body does not meet the amount of oxygen required to perform the activity. Therefore, the muscles must obtain energy from metabolic pathways that do not use oxygen. Rapid, intense exercises such as lifting heavy objects and sprinting are examples of anaerobic exercise.

Planning and Evaluating a Fitness Program

A well-rounded fitness program focuses on flexibility, resistance training, and aerobic conditioning. The **mode** of exercise is the type of activity. Aerobic (endurance) and muscle-strengthening (resistance) physical activities both promote better health. Factors when designing or evaluating an exercise program include the following:

Flexibility Training Stretching before exercise helps warm up the muscles and prevents injury during exercise. Stretching after exercise cools the muscles and limits post-exercise stiffness.

As we get older, joints and muscles become stiffer. A regular flexibility program helps maintain mobility as aging occurs.

Resistance Training Movement against resistance increases muscular strength and endurance. Perhaps the most common type of resistance training is weight lifting. When a person is exercising for strength, the goal is to increase the amount of resistance with each exercise (i.e., lift more weight). When a person is exercising for endurance, the goal is to increase the number of repetitions with each exercise (i.e., lift the weight more times).

Aerobic Conditioning Fitness and body composition are improved by aerobic conditioning. Components of aerobic conditioning include intensity, duration, frequency, and mode. Intensity is how hard one is exercising. Box 32-1 describes three common tests used to evaluate exercise intensity.

Amount of Physical Activity **Duration** is the amount of time one is exercising. To achieve and maintain healthy level of fitness, the USDHHS recommends 150 minutes/week or more of moderate-intensity physical activity (e.g., brisk walking) coupled with increasing the activity every day (USDHHS, 2008). The **frequency** of exercise should be 3 to 5 days per week, although the more often and the longer the duration, as tolerated, the better.

Older adults at risk for falls should engage in balance exercises at least 3 days per week. Muscle strengthening should be performed for all major muscles but not on consecutive days. Walking is an excellent form of physical activity for those who can walk safely.

See Box 32-2.

BOX 32-1 ■ Tests for Determining Exercise Intensity

Target Heart Rate Method

In the target heart rate method, the target heart rate (THR) is calculated from an estimate of maximum heart rate. The estimated maximum heart rate is calculated using the following formula:

$$\text{Maximum heart rate} = 220 - \text{age}$$

The THR is calculated as a percentage of the maximum heart rate. Most persons can exercise at 60% to 80% of the maximum heart rate.

For example, consider a 50-year-old woman. Her maximum heart rate is 170 beats/min. To exercise at 75% intensity, her target heart rate is 128 beats/min.

$$\text{Maximum heart rate} = 220 - 50 = 170$$

$$\text{Target heart rate} = 0.75 \times 170 = 128$$

The person's heart rate during exercise should be 128 beats/min, excluding warm-up and cool-down.

Talk Test

The talk test evaluates exercise intensity based on the person's ability to talk while exercising. Short phrases interspersed with breaths or feeling like you can "just respond" is considered an appropriate level of exercise. If you are too short of breath to answer, the level of intensity is too high. An ability to carry on a conversation indicates that you are not exercising hard enough.

Borg Rate of Perceived Exertion Scale®

The Rate of Perceived Exertion (RPE) scale is easy to use. The person who is exercising selects the rating based on how difficult the exercise feels at that time. The exerciser selects one of eight categories that best describes the intensity of activity. RPE ratings range from *No Exertion at All* to *Extremely Hard*. *Extremely Hard* is associated with exercise that corresponds to almost 100% of maximum heart rate. *Somewhat Hard* corresponds with 75% of maximum heart rate; this is the level you should encourage for most individuals.

Sources: Borg, G. (1998). *Borg's perceived exertion and pain scales.* Stockholm, Sweden: Human Kinetics; Foster, C. (2004). "Talk test" measures exercise intensity. *Medicine & Science in Sports & Exercise, 36*(9), 1632–1636.

Many people become discouraged because they don't see immediate results from their efforts. However, subtle changes occur long before the person sees changes in weight or shape. Not only can instructional fitness videos, trainers and group exercise make participation more engaging, but they also help to improve form and safety through demonstration of proper technique. Tips to help develop an exercise program are included in the Self-Care box Teaching Clients How to Set Up a Fitness Program.

Key Point: ***Anyone with a chronic condition or symptoms of a new health issue should be under the care of a healthcare provider.***

BOX 32-2 ■ U.S. Department of Health and Human Services 2008 Physical Activity Guidelines for Americans

Children and Adolescents

- Engage in at least 1 hour of physical activity daily.
- Physical activity should be enjoyable. A variety of activities will improve adherence.
- Most activity should be aerobic, either moderate or vigorous intensity.
- At least 3 days/week, children and teens should participate in vigorous-intensity exercise as well as muscle- and bone-strengthening physical activity.

Adults and Older Adults

- To gain substantial health benefits, get at least 150 minutes per week of moderate-intensity or 75 minutes a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. More frequent exercise (i.e., 300 minutes/week) is even more beneficial.
- Engage in aerobic activity throughout the week in episodes of at least 10 min. Longer periods of time provide additional benefits.
- For additional health benefits, perform moderate or high-intensity muscle and bone-strengthening activities on 2 or more days per week.

Specific to Older Adults

- Older adults unable to perform 150 minutes of moderate-intensity aerobic activity per week should be as physically active as abilities and conditions allow.
- Include exercises that maintain or improve balance, tone, and muscle strength.

Adults, Children, and Adolescents With Disabilities

- Be as physically active as abilities allow with guidance from their healthcare provider.

Healthy Pregnant and Postpartum Women

- Consult with the healthcare provider regarding activity level throughout pregnancy. If the pregnancy or postpartum recovery is uncomplicated, then those who regularly engage in vigorous-intensity aerobic activity or in high amounts of activity can continue with this regimen.
- If not already engaged in vigorous-intensity physical activity, get at least 150 minutes of moderate-intensity aerobic activity per week, preferably spread throughout the week after consulting with healthcare provider.

Source: Adapted from U.S. Department of Health and Human Services (USDHHS). (2008). 2008 physical activity guidelines for Americans. Retrieved from www.health.gov/paguidelines

Benefits of Regular Exercise

Regular physical activity each week, sustained for months and years, can produce long-term health benefits. Strong evidence links regular physical activity with a lower risk for early death, heart disease, stroke, type 2

Self-Care

Teaching Clients How to Set Up a Fitness Program

If you are older than 40, smoke or drink, are sedentary, are overweight, or have a chronic health condition, have a medical evaluation before starting an exercise program.

Getting Started

- Choose a variety of exercises that you enjoy and feel comfortable doing, such as walking, biking, dancing, or a team sport.
- Find allies. Exercising with someone else can make it more fun. If you choose to exercise by yourself, pick a friend with whom you can discuss your exercise progress.
- Vary your routine. You may be less likely to get bored or injured.
- Choose a comfortable time of day.
- Don't get discouraged. It can take weeks or months before you notice some of the changes from exercise.
- Forget "no pain, no gain." Although a little soreness is normal after you first start exercising, pain isn't. Stop if you hurt.
- Make exercise fun. Find fun things to do, such as taking a walk through the park or watching your favorite show while riding a stationary bike.
- Sign a contract committing yourself to exercise.
- Find an accountability partner. A fitness program is not only more enjoyable when shared with someone else but also is more successful with others for whom you are accountable.
- Keep a daily log of your activities.
- Think about joining a health club. The cost gives some people an incentive to exercise regularly.

Exercise Tips

- Warm up your muscles for 5 to 10 minutes before your main session of aerobic exercise.
- Maintain your exercise intensity for 30 to 45 minutes.
- Gradually decrease the intensity of your workout (cool down) and then stretch for 5 to 10 minutes at the end of your workout.
- Accumulate physical activity throughout the day. For example:

  Take the stairs instead of the elevator.

  Go for a walk during your coffee break or lunch.

  Walk all or part of the way to work.

  Park your car at the far end of the parking lot.
- Wear good, shock-absorbing footwear. Shoes that do not support your feet will cause stress on leg bones and the back and, over time, lead to injury.
- Alternate easy and hard exercise days, or alternate modes of exercise (e.g., alternate running, swimming, and biking).
- Take a day off periodically. The body needs a chance to rest and allow bones, joints, and muscles to rest and repair.
- To avoid becoming dehydrated, drink at least 8 ounces of fluid before the exercise, and then pause regularly during the exercise for more. If you are thirsty after the exercise session, drink until you feel satiated. Water is still the best liquid to drink during and after exercise. However, you can't rely on feeling thirsty as a reminder to replace fluid lost through sweating; one of nature's dirty tricks is that exercise suppresses thirst.

diabetes, hypertension, hyperlipidemia, metabolic syndrome, colon and breast cancers, and depression.

For those who have been inactive, walking is a good form of exercise. And for older adults, the risk of injury to joints is lower than other forms of physical activity. Even brisk walking for as little as 30 minutes a day, when done consistently, promotes weight loss and maintenance of normal weight when combined with diet; lowers the risk of disability; and promotes better heart and lung function and muscular fitness. Moderate-intensity walking helps older adults to improve strength, balance, and muscle tone, which helps to prevent falls and to improve overall physical stamina. Otherwise, moderate intensity exercise enhances psychological well-being, reduces depressive symptoms, and improves memory and mental clarity in older adults (Jitramontree, 2010).

Weight-bearing exercise reduces loss of bone density in adults and older adults (USDHHS, 2008). Resistance training does not lead to weight loss; instead, it may increase loss of fat mass and improve muscle tone and strength (Donnelly, Blair, Jakicic, et al., 2009). Exercise is associated with an overall decrease in mortality in men and women of all ages and an overall improvement in quality of life for people in all ethnic groups and across the life span. People with disabilities also benefit from physical activity (USDHHS, 2008). Box 32-3 presents numerous other benefits of regular exercise.

Risks Associated With Exercise

Armed with theoretical knowledge, you should be able to teach your clients realistically about the risks associated with exercise and thereby help them to exercise safely. Risks include cardiac injury, musculoskeletal injury, dehydration, hypoglycemia, and temperature regulation problems. Keep in mind that the benefits of exercise far outweigh the risks. Advise clients to follow the tips in the Self-Care box Teaching Your Patient How to Prevent Back Injury to exercise safely and help prevent injury.

Cardiac Injury Fear of triggering a cardiac event prevents some people from exercising. However, exercise

BOX 32-3 ■ Benefits of Regular Exercise

Cardiovascular System
- Improves pumping action of the heart.
- Decreases heart rate, heart rate variability, and blood pressure.
- Improves circulation by increasing the number of capillaries.
- Improves venous return to the heart.
- Increases blood volume and hematocrit.
- Increases high-density lipoprotein (HDL).
- Decreases low-density lipoprotein (LDL) and total cholesterol.
- Decreases risk of thrombophlebitis.

Respiratory System
- Improves pulmonary circulation.
- Improves gas exchange at the alveolar–capillary membrane, and overal aerobic capacity.
- Dilates bronchioles to increase ventilation.

Musculoskeletal System
- Improves skeletal development in children.
- Increases muscle mass, strength, power, and endurance.
- Improves flexibility.
- Increases coordination.
- Helps maintain joint structure and function; reduces risk of osteoarthritis.
- Improves bone mass and mineral density.
- Improves gait speed, stability, and balance.
- Improves bone mass with aging; reduces risk of osteoporosis.
- Reduces risk of falls and helps older adults maintain an independent lifestyle.

Nervous System
- Speeds nerve impulse transmission.
- Reduces sympathetic response to exercise.
- Improves reaction time.

Endocrine System
- Increases sensitivity to insulin at the receptor sites.
- Increases efficiency of metabolic processes.
- Improves temperature regulation.
- Facilitates weight management.
- Decreases adipose surrounding organs.

Gastrointestinal System
- Improves appetite.
- Improves abdominal muscle tone.
- Decreases risk of colon cancer.

Urinary System
- Increases efficiency of kidney function.

Integumentary System
- Improves skin tone as a result of improved circulation.

Immune System
- Reduces susceptibility to minor viral illnesses.
- Reduces systemic inflammation.

Mental Health
- Boosts energy level.
- Release endorphins, which assist with pain control and stress management.
- Improves self-esteem and body image.
- Provides a nonpharmacological way to relieve symptoms of anxiety and depression.
- Leads to positive outlook and sense of optimism.
- Promotes clearer thinking and improved memory in older adults.
- Enhances feelings of well being and diminishes depressive symptoms.
- Relieves some stress.
- Can be a source of social interaction.

Overall Health
- Burns calories to achieve and maintain healthy body weight.
- Leads to reduced abdominal obesity.
- Improves overall stamina.
- Reduces fatigue.
- Increases sleep time and improves sleep quality.

Source: Adapted from President's Council on Sports, Fitness, and Health. (2010, June). Exercise comes of age: Medicine for older adults. *Research Digest, 10*(3), 1–3. Retrieved from https://www.presidentschallenge.org/informed/digest/docs/june2010digest.pdf

itself is rarely life threatening, especially when compared with the alternative (*not* exercising). Before starting an exercise program or significantly increasing the intensity of normal workouts, seasoned athletes as well as rank beginners should be screened for underlying health problems, such as high blood pressure, thickened heart muscle (cardiac hypertrophy), electrical abnormalities, and blood vessel abnormalities. In people without underlying heart disease, recreational drug use is an important cause of sudden cardiac arrest, whether during exercise or at rest.

Musculoskeletal Injury High-impact exercises, such as running or aerobic dance, may pose a risk for injuries to bones, joints, and muscles. However, you can prevent most such injuries by gradually increasing the activity level or varying activities. Walking is an exercise that most people can do without injury. Injury can also occur from lifting weights. Free weights can cause injury if the

Self-Care

Teaching Your Older Adult Patient About Increasing Physical Activity and Exercise

What Are the Benefits of Physical Activity for an Older Adult?

- Improves and maintains strength so you can stay as independent as possible.
- Maintains balance and prevents falls.
- Gives you more energy to do the things you want to do.
- Helps you to sleep better and feel more rested.
- Perks up your mood and helps reduce depression.
- Prevents or delays some diseases like diabetes, heart disease, and cancer.

What Kind of Physical Activity Should I Do?

- Get at least 30 minutes of *endurance* activity almost every day. Exercise that makes you breathe hard builds strength and staying power.
- Wear a step counter to monitor your level of *endurance* activity. Set goals and monitor your progress. If you are taking 10,000 or more steps per day, you are probably getting an adequate amount of physical activity.
- Incorporate *resistance* into your exercise; use some kind of weight or isometric activity to build strength. Remember that you can do more and are less likely to fall when your muscles are strong.
- Do things to work on your *balance* (e.g., standing on one foot). This can help to prevent falls.
- Daily stretching will help you be more *flexible* and prevent injury.

Who Should Exercise?

Almost anyone can do some type of physical activity, but before starting a new exercise program check with your healthcare provider if you experience:

- Any change in your health in the past 6 months
- Shortness of breath or dizziness
- Chest pain or pressure, or fluttering heart
- Joint pain or swelling
- Unexplained weight loss
- An infection with fever
- Eye problems
- Blood clot
- Hernia
- Recent hip surgery or joint injury

Source: Adapted from the National Institutes of Health, National Institute on Aging. (2011, updated 2013). *Exercise and physical activity: Your everyday guide from the National Institute on Aging*. Retrieved from http://www.nia.nih.gov/HealthInformation/Publications/exercise.htm

Self-Care

Teaching Your Patient How to Prevent Back Injury

- Poor posture is one of the main causes of back pain. Make a conscious effort to maintain good posture at all times.
- Use a firm mattress that provides adequate support.
- Sit with your knees slightly lower than your hips.
- If you must stand for a long period of time, flex your hip and raise one foot on a stool or object 6 to 8 inches off the ground. Periodically switch legs.
- Wear comfortable, low-heeled shoes. Avoid high heels as much as possible.
- Avoid restrictive clothing that inhibits your ability to use good body mechanics.
- Follow principles of body mechanics at all times (e.g., use wide base of support, and do not lift with your back) but keep in mind manual lifting techniques are based on loads that weigh far less than typical patients.
- Manual lifting techniques are based on the assumption that the load is stable and held close to the body.
- Exercise regularly to maintain your optimal weight and strengthen the muscles of your body.
- Include abdominal exercises in your routine. Strong abdominal muscles help support the back.
- Avoid lifting excessive weight.
- Avoid exercises or movements that cause spinal flexion (e.g., toe-touches, sit-ups with knees extended), excessive flexion of the neck (e.g., abdominal crunches with neck curved to chest), or spinal rotation (twisting).

person lifts too much weight or uses poor body mechanics when lifting. Working with a fitness trainer to learn correct form and what are appropriate weights markedly decreases the risk of injury. In addition, exercise machines provide some degree of control and are less likely to cause injury.

Dehydration It is possible to become dehydrated with prolonged exercise, with warm temperatures, or as a result of health problems or medications. During an intense exercise period, the body can lose 2 liters of fluid for every hour of exercise. It is important to drink water before, during, and after the exercise period. Water is still the best choice during and after exercise. Some sports drinks include glucose and electrolytes for replacement and quick energy and can be used for endurance activities or prolonged, intense activity.

Temperature Regulation Problems **Hyperthermia** can occur when the person exercises in a hot climate. Hyperthermia is often accompanied by dehydration. **Heat exhaustion** is a potentially life-threatening event. Signs of heat exhaustion include light-headedness, nausea, headache, fatigue, hyperventilation, loss of concentration, and abdominal cramps. Body temperature rises, but the skin is clammy and cold. In contrast, **hypothermia** can occur when the person does not wear proper clothing or is exposed to cool water for an extended period of time. Hypothermia is characterized by fatigue, confusion, and lack of coordination.

KnowledgeCheck 32-3

- Identify and describe four types of exercise.
- State the components of an exercise program

ThinkLike a Nurse 32-2

- How would you address Helen Jillian's (Meet Your Patients) concerns about the risks associated with engaging in an exercise program?
- Peter Phan (Meet Your Patients) has experienced a number of injuries as a result of his exercise. Based on your knowledge of exercise, what questions would you like to ask Peter about his exercise program?

FACTORS AFFECTING MOBILITY AND ACTIVITY

Recall that physical activity is bodily movement produced by the contraction of skeletal muscles. **Mobility** refers to a person's capacity for bodily movement, or how well the person is able to move about in the environment. Factors influencing activity and mobility include developmental stage, nutrition, lifestyle, attitudes, external factors, diseases, and physical abnormalities. These factors are discussed in the next sections.

Developmental Stage

Neuromuscular development is related to age. A newborn can move his extremities and turn his head from side to side, but he is unable to get from place to place. As the child matures, motor skills and coordination develop. In spite of that, children in the United States are becoming more sedentary, contributing to the continuing rise of obesity among children, adolescents, and adults. The Centers for Disease Control and Prevention (CDC) reports the following:

- More than one-third of adults and almost 18% of youths were obese in 2012. Obesity rates did not differ between men and women. Older adults were more likely to be obese than younger adults (USDHHS, 2012).
- Obesity rates for children have more than doubled, while quadrupling in adolescents in the last three decades. Among children, aged 6 to 11, nearly 18% are obese, compared to 7% in 1980; and now 21% of those ages 12 to 19 are, compared to 5% at that time (Ogden, Carroll, Kit, et al., 2014).
- Only 36% of young adults get regular physical activity in their spare time.
- Only 26% of young adults were doing strength training at least twice per week, which is a minimum recommendation for adults of all ages (CDC, updated 2014).

Healthy People 2020 goals recommend older adults also need to increase physical activity (USDHHS, 2011). The expected physiological changes associated with growing older make it harder to start or maintain an exercise program.

The result is increased risk for chronic health problems. For a discussion of neuromuscular development across the life span and associated nursing considerations as it affects activity and exercise,

Go to Chapter 32, **Tables, Boxes, Figures: ESG Table 32-1, The Influence of Developmental Stage on Activity and Exercise,** on Davis*Plus*.

Nutrition

In the United States, obesity is a major health problem. Centers for Disease Control and Prevention report more than one-third of adults in the United States are obese (Ogden, Carrol, Kit, et al., 2014). Obesity often leads to health problems, which indirectly reduces activity and can in turn contribute to further obesity. For example, joint injuries and osteoarthritis are more prevalent with obesity, which in turn reduces a person's physical activity. Unhealthy eating patterns, such as large portions, consumption of convenience foods, and a diet high in saturated fat and simple carbohydrates, play a major role in the obesity problem. Although the obese person has plenty of calories available to expend on exercise, movement becomes more difficult as body size increases.

In contrast, people with chronic disease may be in negative nitrogen balance—that is, they do not have adequate protein stores available to maintain or repair body tissue. They experience muscle wasting and fatigue, which lead to reduced activity levels.

Lifestyle

Over the last century, manual labor has declined and work environments have become increasingly sedentary. As a result, individuals need to look toward leisure time for exercise and fitness activities. This requires making time for exercise. Personal values about exercise and fitness determine when, or whether, exercise becomes part of a person's routine.

Some people enjoy exercise. Others see it as pure drudgery or as "something I have to do." A person's culture and support system define what exercise the person is likely to accept. For example, swimming requires wearing a bathing suit. People raised in a culture that values modesty may not choose swimming as a form of exercise. Walking, which allows the person to dress in modest clothing, would be a preferred form of exercise.

Stress

How is your stress level? A high stress level can produce fatigue. Although you may view exercise as one more thing you don't have time for, exercise is energizing and can be used to relieve stress. For example, taking a brisk 20-minute walk during a study break may allow you to continue working for several more hours. You can also use this technique when caring for patients. Hospitalized patients and family members often experience a great deal of stress. Helping the patient take a walk to the courtyard, or instructing family members how to handle the wheelchair so they can take a walk around the block, often will help lessen some of the strain.

Environmental Factors

Environmental factors affecting exercise include weather, pollution, neighborhood conditions, finances, and support systems. Weather has a strong influence on activity level. Cold, damp weather encourages people to stay inside, whereas warm, sunny weather makes it fun to go outside and exercise. Encourage patients to choose a variety of activities that they enjoy so they can exercise regardless of the weather. When air quality is poor, suggest indoor activities in order to reduce exposure to allergens and pollutants.

Neighborhood conditions, such as crime or lack of parks, influence attitudes about outside activities. Mall walking is an example of a successful way to incorporate exercise into daily patterns when neighborhood conditions do not encourage activity. Joining a gym or engaging in sports might be practical for some budgets. However, many activities, such as walking or playing basketball or tennis in the community park, are inexpensive.

The support system is perhaps the most influential external factor. Family and friends who are active are likely to promote and support your efforts to exercise. Those who are sedentary may not encourage you to be more active or lose weight.

Diseases and Abnormalities

Diseases and abnormalities in various body systems can negatively influence body alignment, balance, coordination, and joint mobility. In the next sections, we describe some disorders that affect activity and exercise.

Congenital Abnormalities of the Musculoskeletal System

The following are common congenital abnormalities that affect appearance, motor function, and mobility:

- **Syndactylism** is the fusion of two or more fingers or toes. Most cases involving the hands are treated surgically at an early age to limit the effect on fine motor development.
- **Developmental dysplasia of the hip (DDH)** is a congenital abnormality of the development of the femur, acetabulum, or both that shows as hip dislocation.
- **Foot deformities**, such as clubfoot (talipes equinovarus), occur in about 4% of all newborns. Serial casts or surgery may be used to correct the defect and preserve function.
- **Scoliosis** is a lateral curvature of the spine. Scoliosis can result from congenital bone disorders, neuromuscular impairment, or trauma, but approximately two-thirds of cases have no known cause and are termed idiopathic scoliosis. Idiopathic scoliosis is classified as infantile, juvenile, or adolescent depending on the age at onset.

Diseases Related to Bone Formation or Metabolism

Bone formation abnormalities may be congenital, related to dietary deficiencies, or the result of bone disease.

- **Osteogenesis imperfecta (OI)** is a congenital disorder of bone and connective tissue that is characterized by brittle bones that fracture easily. Infants with OI are often born with fractures and continue to fracture with minimal trauma or even spontaneously. Prompt recognition and treatment of fractures helps prevent deformities.
- **Achondroplasia**, or dwarfism, occurs when the bones ossify (harden) prematurely.
- **Paget's disease** is a metabolic bone disease in which increased bone loss results in pain, pathological fractures, and deformities. This disorder usually affects the skull, vertebrae, femur, and pelvis.
- **Vitamin D and calcium** are needed to form and maintain bone. Deficiencies lead to porous bones. In children, prolonged deficiencies can cause the long bones of the legs to become bowed, retard growth, and lead to frequent fractures.

Diseases Affecting Joint Mobility

Diseases of the joints may be degenerative or inflammatory. The most prevalent type of degenerative joint disease is **osteoarthritis (OA)**. OA involves a loss of articular cartilage in the joint, with pain and stiffness as the primary symptoms. Patients may also have decreased ROM and **crepitus**, a creaking or grating sound, with joint motion. Symptoms are aggravated by weight-bearing and joint use and are relieved by resting the affected joints. OA is more common in women, older adults, and people who are overweight.

Rheumatoid arthritis (RA) is a systemic autoimmune disease involving chronic inflammation of the joints and surrounding connective tissue, frequently resulting in difficulty in performing activities of daily living (ADLs). RA causes joint pain, deformity, and loss of function; patients may also experience fever, fatigue, weakness, and weight loss. RA occurs most frequently in the fingers, wrists, elbows, ankles, and knees. It occurs in 1% to 2% of the population, with a greater incidence in women. The illness usually begins in mid-life, but persons in any age group can be affected. Those in the 30- to 50-year-old range are the most frequently affected age group (Swann, 2007). Unlike OA, RA does not improve with rest. Pain is most intense when the person arises from bed. Pain and joint deformities may so severely affect mobility that patients cannot care for themselves.

Ankylosing spondylitis is a chronic inflammatory joint disease characterized by stiffening and fusion of the spine and sacroiliac joints. The inflammation occurs where the ligaments, tendons, and joint capsule insert into the bone. The disease usually develops in young adults, equally in men and women. Signs and symptoms include low back pain and stiffness and decreased ROM of the spine. The convex lumbar curve is lost, and the upper spine curve increases, causing kyphosis (see Chapter 22 for review).

Gout is an inflammatory response to high levels of uric acid. Crystals form in the synovial fluid, and small white nodules, or *tophi*, form in the subcutaneous tissues. Gout produces painful joints and severely limits activity during acute flare-ups.

Problems Affecting Bone Integrity

Osteoporosis is a decrease in total bone density, which occurs when osteoclast activity outpaces that of the osteoblasts. The internal structure of the bone diminishes, and the bone collapses in on itself. Normally bone mass continues to increase up to the third decade of life. After age 30, bone loss begins. Women experience a rapid decline in bone mass at menopause. In men, a gradual loss continues. As bones become porous, they become weak, leading to vertebral collapse or fractures of the long bones of the arms and legs. Fractures may occur spontaneously or with very slight trauma.

Genetics, body frame, menopausal status, chronic disease and lifestyle choices also play a role. The most common risk factors for osteoporotic fracture are advanced age, low bone mineral density, and previous fracture as an adult. Smoking, low calcium and vitamin D intake, excess alcohol use, and sedentary lifestyle also increase the risk (National Institutes of Health, National Institute on Aging, 2012).

The best treatment for osteoporosis is prevention. Teach adolescents and adults to eat a balanced diet high in calcium, fluoride, and other minerals, and to start an exercise program they can continue throughout their lives.

Advise older women that weight-bearing exercise can help decrease the rate of bone loss, and advise them to ask their provider about medications to reduce bone mineral loss (National Osteoporosis Foundation, n.d., a)

The National Osteoporosis Foundation (n. d., b) recommends calcium intake for adults age 50 and older to be 1,200 mg/day and vitamin D 800 to 1,000 IU daily to prevent bone loss. Phosphorus is another important bone mineral. But if there is a disproportionate amount of phosphorus compared to the amount of calcium in the diet, bone loss can occur.

They urge people of all ages, but particularly postmenopausal women, to avoid smoking because tobacco reduces the absorption of calcium in the intestine. In addition, more than two drinks of alcohol per day decreases the matrix of the bone and reduces the body's ability to absorb calcium. Other pharmacological options for postmenopausal women include estrogen, parathyroid hormone, and calcitonin.

Osteomyelitis (infection of the bone) may develop after bone injury or surgery. It can be difficult and expensive to treat and can leave the patient with permanent disability. Bone contains microscopic channels that are impermeable to most of the natural defenses of the body. Once bacteria enter these channels, they multiply rapidly.

Bone tumors may also affect form and function. Tumors in the bone cause considerable pain and severely limit activity.

Trauma

Trauma can affect the entire musculoskeletal system. One of the most significant forms of trauma is a **fracture**, or a break in the bone (see Fig. 32-5). Signs and symptoms of a fracture include tenderness at the site, loss of function, deformity of the area, and swelling of the surrounding tissues. However, x-ray is required for definitive diagnosis. Fractures are classified according to the extent of damage. The type and severity of fracture determine whether casting, traction, or surgical repair is necessary. For a classification and description of several types of fractures,

Go to Chapter 32, **Supplemental Materials: Fractures,** and to **Tables, Boxes, Figures: ESG Figure 32-1, Types of Fractures,** on Davis*Plus*.

FIGURE 32-5 Fracture in hand occurring after traumatic injury.

To learn about caring for a cast in the home, refer to the Home Care box Teaching Care of a Cast at Home.

Sprains and strains are more common than fractures. A **sprain** is a stretch injury of a ligament that causes the ligament to tear. A partial tear can usually heal with rest, but a complete tear often requires surgery to stabilize the joint. A **strain** is an injury to muscle caused by excessive stress on the muscle. Both strains and sprains cause pain at the site of injury, swelling, and loss of function. As you can see, the signs and symptoms are the same as those of a fracture. As a result, x-ray studies are used to distinguish these injuries. Initial treatment of fractures, sprains, and strains include rest, ice, compression, and elevation.

Stretching and tearing injuries to the meniscus (knee cap), lateral knee ligaments, and Achilles tendon are also fairly common. Magnetic resonance imaging (MRI) studies are done to determine the extent of injury. Rest and ice are necessary, but often surgical repair is needed to achieve full healing.

Disorders of the Central Nervous System

Any disorder that affects the motor centers of the brain or the transmission of nerve impulses will affect mobility. Cerebrovascular accident (stroke), head or spinal cord injury, multiple sclerosis (a disorder affecting nerve transmission), and myasthenia gravis (a disease caused by antibodies to the acetylcholine receptors at the neuromuscular junction) are examples. Progressive degenerative disorders of the neurological system also affect mobility and coordination. For example, Parkinson's disease is a progressive degeneration of the basal ganglia. It produces tremor, rigidity, and difficulty coordinating movement.

Diseases of Other Body Systems

Diseases affecting other body systems may affect mobility and activity tolerance, as in the following examples:

- ***Respiratory disorders.*** Any disorder that affects oxygenation limits exercise tolerance. Chronic obstructive

Home Care

Teaching Care of a Cast at Home

- Always keep the cast clean and dry.
- Before bathing, cover the cast with a plastic bag and tape the opening shut or use a commercial cast cover with Velcro straps. Do not place the cast into water unless it is made of water-repellent material. Keep in mind that waterproof casts are not for all types of fractures. They can't be used for recently manipulated fractures or when skin pins are used.
- If the cast gets wet enough that the skin gets wet under the cast, it may break down and infection may occur. Dry it immediately with a blow dryer on the cool setting. Be careful—skin can be burned using the hot setting. If you have any trouble getting the cast dry, the cast may need to be replaced. Call the healthcare provider if the cast doesn't dry properly.
- Sweating under the cast enough to make it damp may cause mold or mildew to develop. Call the healthcare provider if you notice odor coming from the cast.
- Never put anything inside the cast. Do not try to scratch the skin under the cast with any sharp objects, such as a hanger or pencil. This may break the skin under the cast and cause it to become infected. Do not use powders, ointments, or lotions inside the cast.
- Sometimes when swelling goes down, the cast can become loose and rub on the skin. If this is the case, advise your patient to call the primary provider to look at the cast.
- Check the circulation by gently squeezing a finger or toe below the cast. It should blanch (turn lighter) and quickly return to a pink color. The fingers and toes should be warm to the touch, able to move freely, and not tingling or numb.
- Do not trim the cast or break off any rough edges. This may weaken or break the cast. If a fiberglass cast has a rough edge, use a metal file to smooth it or call the healthcare provider.
- A sling may be needed for support if the cast is on the hand, wrist, arm, or elbow. It is helpful to wrap soft sheepskin or padding behind the neck to protect the skin and make it feel more comfortable.
- If the cast is on the foot or leg, do not walk on or put any weight on the injured leg, unless the doctor allows it.
- If the primary provider allows walking on the cast, be sure to wear the cast boot. The boot is to reduce wear and tear on the bottom and has a tread to prevent slipping and falling.
- Crutches may be needed to walk if a cast is on the foot, ankle, or leg. Make sure the crutches are adjusted properly before leaving the hospital or the doctor's office.

pulmonary disease, asthma, and pneumonia are associated with shortness of breath, which becomes worse with increased activity.

- ***Circulatory disorders.*** Impaired arterial circulation limits oxygen delivery to the tissue. As activity increases, skeletal muscle pain develops. Impaired venous circulation causes leg swelling and discomfort, which are relieved by elevating the legs. As a result, patients may become relatively sedentary to relieve the pain and discomfort.
- ***Fatigue.*** Acute illnesses, such as influenza, produce fatigue and limit activity for short periods of time. Disorders that produce long-standing fatigue include anemia, anorexia nervosa, cancer, depression, and grief.
- ***Bedrest*** is part of the treatment for a variety of disorders. For example, a woman with a high-risk pregnancy may be placed on bedrest. You will learn more about bedrest and the effects of immobility in the following section.

KnowledgeCheck 32-4

- In which age groups are you more likely to see health concerns that affect mobility?
- What types of disorders limit activity or mobility?
- What are the signs and symptoms of a fracture?
- What is the difference between a strain and a sprain?

ThinkLike a Nurse 32-3

- Your teenage daughter complains when you ask her to take a calcium supplement and encourage her to exercise. What information should you provide so she understands why these measures are important?
- Phillip Flanders (Meet Your Patients) has never been involved in a regular exercise program. Phil works as an accountant, and most of his friends are work associates. Phil's siblings are overweight and do not exercise. Both of his parents died of heart disease. Many of Phil's friends have suggested that he begin exercising to improve his energy and health. What recommendations can you make to Phil to make it more likely that he will start and continue an exercise routine?

Example Problem: Hazards of Immobility

Most people take their mobility for granted until illness, disease, or trauma affects their ability to move. Even short periods of immobility may be difficult. If you've ever had the flu or an illness that sent you to bed, you know that it can take several days to return to your pre-illness state, especially for older adults and people with

Quality and Safety Education for Nurses

Effects of Teamwork and Collaboration on Outcomes

Chapter Key Concept: *Mobility*

Competency: *Teamwork and Collaboration (Knowledge, Skills, Attitudes); Patient-Centered Care (Knowledge, Skills, Attitudes)**

Situation: Mr. Lee underwent surgery to repair a ruptured quadriceps tendon in his left leg. His discharge instructions did not include information specific to quadriceps tendon repair but provided general guidelines about wound care, signs and symptoms to report, and when to follow up with the physician.

At his 2-week post-op visit, Mr. Lee was making good progress. The surgeon gave him a prescription to start physical therapy, telling him that the therapists at a nearby location knew his protocols. He also told Mr. Lee that he could drive and return to work, but that he should "listen to his body" and rest when he was tired or in pain. Mrs. Lee mentioned that the drive to work was 1 hour each way and wondered if that was too much. After the surgeon left, the nurse removed the staples from the incision and talked to Mr. and Mrs. Lee about potential complications and how to perform wound care.

The next day, Mr. and Mrs. Lee met with Bernadette, a physical therapist at the location the doctor suggested. She scheduled Mr. Lee for therapy on Mondays, Wednesdays, and Thursdays, which fit her schedule. During the first visit Mrs. Lee could hear her husband moaning with pain. On the second visit, Mrs. Lee remarked that the knee was very swollen but the therapist disagreed with her, noting that other patients had much more swelling than Mr. Lee. One week later Mr. Lee went to the surgeon's office afraid that something was wrong. He was experiencing severe pain and a fever of 101°F. The surgeon concluded that the knee was not damaged or infected, but that it was very inflamed. He told Mr. Lee he should not have scheduled back-to-back therapy sessions and that he was "overdoing" it. It took 2 weeks before the pain, swelling, and fever subsided.

Think about it: Patient-centered care, teamwork, and collaboration are considered integral to patient safety and quality care. (1) Were Mr. Lee's outcomes affected by the team's communication pattern? Identify the problems. (2) Did Mr. Lee's care reflect patient-centeredness? While developing your answers, consider the following questions and concepts:

- How would you describe this team's functioning?
- What barriers to team functioning do you think might exist in this scenario?
- What could the office nurse have done to improve collaboration?
- How did teamwork and communication affect safety?
- What system changes would you make to improve communication?
- Did the team value Mrs. Lee's input? How might outcomes have been different if Mrs. Lee had been recognized as a full partner in planning or providing care? Do you think quality, safety, costs, and patient satisfaction were affected?

To learn about specific Knowledge, Skills, and Attitudes,

Go to the QSEN Web site at http://qsen.org/competencies/pre-licensure-ksas/

underlying chronic illness. Severe illness associated with prolonged immobilization causes physiological changes in almost every body system, along with psychological changes. Some changes are reversible, but others are not. These changes are discussed below.

Effect of Immobility on Muscles and Bones

Even a couple of days in bed can leave you feeling tired and weak, because the musculoskeletal system is one of the first systems affected by immobility. Inactivity causes significant wasting of the gastrocnemius, soleus, and leg muscles that control flexion and extension of the hip, knee, and ankle. Confinement to bed leads to 7% to 10% loss of muscle strength (atrophy) per week. Immobility also causes the joints to become stiff. The strongest muscles, usually the flexors, pull the joints in their direction, leading to **contractures**, or joint **ankylosis** (fusion of the joints).

Immobility affects parathyroid function, calcium metabolism, and therefore bone formation. The result of these changes is osteoporosis, calcium depletion in the joints, and **renal calculi** (kidney stones) due to increased excretion of calcium. These changes place the patient at risk for pathological fractures with minimal trauma.

Effects of Immobility on the Lungs

Immobility decreases the strength of all muscles, including those involved in chest wall expansion, which also affects ventilation. When a patient is in bed, the depth of respirations decreases, and secretions pool in the airways. The strength to effectively cough and expectorate secretions diminishes as muscle tone of the abdomen and chest decrease. As a result, pooled secretions block air passages and alveoli, decrease oxygen and carbon dioxide exchange, and often lead to atelectasis (collapse of air sacs), or pneumonia. Even a sedentary lifestyle affects the capacity to increase ventilation in response to exercise (see Chapter 36 if you want more information about ventilation).

Effect of Immobility on the Heart and Vessels

Immobility increases the workload of the heart and promotes venous stasis. When you are active, the skeletal muscles of the legs help pump blood back to the heart. Recall that the veins are thin-walled vessels with valves. Muscle activity propels blood toward the right side of the heart, and the valves prevent backflow of blood. To compensate for immobility, heart rate and stroke volume increase to maintain blood pressure. But with immobility, cardiac reserves are lessened, which means the heart is less able to respond to demands above baseline. Without muscle activity, the force of gravity causes blood to pool in the periphery, which leads to edema. Fluid in the tissue (e.g., heels or sacrum) is more prone to pressure injury.

In addition to venous pooling, immobility leads to compression and injury of the small vessels in the legs and decreased clearance of coagulation factors, causing blood to clot faster. These three changes—stasis, activation of clotting, and vessel injury—make up what is known as **Virchow's triad**, a trilogy of symptoms associated with a greater chance of thrombus formation, such as deep vein thrombosis (DVT).

An immobile person is also more prone to **orthostatic hypotension**. Prolonged bedrest inactivates the baroreceptors involved with constriction and dilation of the blood vessels. As a result, when a person who has been immobilized changes position, he is less able to maintain his blood pressure. The patient complains of feeling dizzy and light-headed and may be unable to support his own weight.

Effects of Immobility on Metabolism

Inactivity increases the level of serum lactic acid and decreases adenosine triphosphate (ATP) concentrations. As ATP concentrations decrease, so do the body's energy reserves. In response, metabolic rate drops, protein and glycogen synthesis decrease, and fat stores increase. Together, these effects cause glucose intolerance and reduced muscle mass. Immobility also triggers the release of epinephrine, norepinephrine, thyroid hormones, adrenocorticotropic hormone (ACTH) from the pituitary gland, and aldosterone from the kidneys. These changes in hormones are the same as occur in the stress response; so, as you can see, immobility can be a stressor in itself.

Effects of Immobility on the Integument

External pressure from lying in one position compresses capillaries in the skin, obstructing skin circulation. Lack of circulation causes tissue ischemia and possible necrosis (death). Nursing interventions include frequent turning and skin care to prevent wounds, known as pressure ulcers, from forming (see Chapter 35 as needed).

Effects of Immobility on the Gastrointestinal System

Immobility slows peristalsis, which leads to constipation, gas, and difficulty evacuating stool from the rectum. In extreme circumstances, a **paralytic ileus** (cessation of peristalsis) may occur. When peristalsis slows, appetite diminishes and food also is digested slowly. The net effect is usually decreased calorie intake and inability to meet the protein demands of the body. Body muscle is broken down as a fuel source, causing further wasting.

Effects of Immobility on the Genitourinary System

Being supine inhibits drainage of urine from the renal pelves and bladder. Urine becomes stagnant, which creates an ideal environment for infection and kidney stone formation. Immobility triggers a rise in calcium levels,

BOX 32-4 ■ Preventing Complications of Bedrest

- Position the patient to allow for lung expansion and prevent atelectasis and pneumonia.
- Provide a healthy diet to prevent loss of muscle mass.
- Prevent orthostatic hypotension by having the patient sit on edge of bed before the first time out of bed.
- Turn the patient every 2 hours to prevent pressure on the skin and minimize edema.

which also contributes to stone formation. Diminished muscle tone leads to a decrease in bladder tone, and many patients have difficulty voiding in a bedpan or urinal.

Psychological Effects of Immobility

Prolonged immobility, whether in the hospital or at home, leads to isolation and mood changes. In the 1960s, the effects of immobility were studied among astronauts. Along with the many physical effects of immobility, these healthy men showed signs of depression, anxiety, hostility, sleep disturbances, and changes in their ability to perform self-care activities. Patients who are in bed for long periods of time can suffer all these problems, as well as disorientation, apathy, and altered body concept. Other notable psychological effects of immobility/bedrest included a diminished ability to concentrate, recall sequential events, problem-solve, and perform self-care.

For tips on preventing complications of bedrest, see Box 32-4.

KnowledgeCheck 32-5

- Identify the effects of immobility on the cardiovascular, musculoskeletal, and integumentary systems.
- Why might immobility be referred to as a stressor?
- What are three effects of immobility on the GI system?
- What changes in mood might be seen with immobility?

PracticalKnowledge knowing how

As you have seen in the preceding sections, immobility can result in serious health consequences. In the remainder of the chapter, we discuss nursing activities to promote activity and exercise and eliminate the hazards of immobility.

ASSESSMENT

Perform an assessment focused on mobility and exercise for any patient who has musculoskeletal concerns, is obese, has limited mobility, or is confined to bed or home. As always, you will validate the nursing history data with physical examination. Box 32-5 defines a variety of terms used to describe problems with muscle mass, strength, or mobility. For a comprehensive focused assessment tool,

Go to Chapter 32, **Assessment Guidelines and Tools, Focused Assessment: Assessing Activity and Exercise,** in Volume 2.

To help you with focused mobility assessments in the home, see the Home Care box Home Assessment for a Patient With Mobility Concerns.

Focused Nursing History

A nursing history focused on activity and exercise addresses usual activity, fitness goals, mobility problems, underlying health problems, lifestyle, and external

Home Care

Home Assessment for a Patient With Mobility Concerns

Assess the Environment

- Are there stairs or other obstacles that the patient must negotiate?
- What aspects of the home environment assist with patient care?
- What aspects of the home environment hinder patient care?
- What is the patient's history of falls or other mobility concerns?
- Would the patient benefit from assistive equipment (e.g., hospital bed, walker)?
- Can the patient negotiate the distance between the bedroom, bathroom, and kitchen?

Assess the Family's or Caregivers' Abilities and Needs

- Who is providing care?
- Is the available care sufficient to meet the patient's needs?
- Are additional support persons available to assist with care?
- Can the caregiver safely move the patient in bed or assist the patient out of bed?
- What are the health concerns or physical limitations of the caregivers?
- What is the backup plan if the family or caregiver can no longer meet the patient's needs?

Assess Resources

- What community resources are available to the patient or caregiver (e.g., Meals on Wheels, physical therapy, Visiting Nurses Association)?
- Are the patient and caregiver willing to use community resources?
- What services are provided by the patient's insurance?
- Can the patient or family afford private services? If so, what services are they interested in?

BOX 32-5 ■ Terms Used to Describe Problems with Muscle Mass, Strength, or Mobility

Atrophy is a decrease in the size of muscle tissue due to lack of use or loss of innervation.

Clonus is spasmodic contraction of opposing muscles resulting in tremorous movement.

Flaccidity is a decrease or absence of muscle tone.

Hemiplegia is paralysis of one side of the body.

Hypertrophy is an increase in the size or bulk of a muscle or organ.

Paraplegia is paralysis of the lower portion of the trunk and both legs.

Paresis is partial or incomplete paralysis.

Paresthesia is numbness, tingling, or burning due to injury of the nerve(s) innervating the affected area.

Quadriplegia is paralysis of all four extremities.

Spasticity is a motor disorder characterized by increased muscle tone, exaggerated tendon jerks, and clonus.

Tremor is involuntary quivering movement of a body part.

factors. When caring for patients with very limited activity, assessing the ability to perform ADLs or instrumental activities of daily living (IADLs) may be more appropriate. Recall that ADLs focus on hygiene, feeding, toileting, and transfer out of bed. In contrast, IADLs focus on tasks that are instrumental in helping a patient maintain independent living status. Assessment tools for ADLs and IADLs were presented in Chapter 3.

Focused Physical Assessment

Important data to include in a physical assessment related to activity and exercise include vital signs, height, weight, body mass index, body alignment, joint function, gait, muscle strength, and activity tolerance. This section summarizes a few of these components.

Before beginning the exam, be fully aware of the patient's mobility status and any restrictions in movement, pain, injury, or otherwise. As you move through the exam, observe for pain, inflammation, and mobility limitations in all areas. For a thorough discussion of physical assessment of the musculoskeletal system, see Chapter 22. For an illustration of joint ROM,

Go to Chapter 32, **Tables, Range of Motion at the Joints,** in Volume 2.

For guidelines when performing ROM exercises,

Go to Chapter 32, **Clinical Insight 32-3: Tips for Performing Passive Range-of-Motion Exercises,** in Volume 2.

The Functional Independence Measure

Also known as the FIM Scale, the functional independence measure is used to assess the severity of patient disability and how much assistance is required for the person to carry out ADLs. The dimensions on the assessment include eating, bathing, grooming, upper body dressing, lower body dressing, shower transfer, toilet transfer, bladder and bowel management, mobility, safe use of stairs, problem-solving, expression, social interaction, cognitive comprehension, and memory. On admission, patients are scored for baseline and then serially until discharge and later in the outpatient or home setting to monitor improvement.

Gait

The way a person moves communicates a great deal about his general state of health, mood, and risk for falls. You might want to assess abnormal gaits in patients with injury, neurological issues, or with the following characteristics:

- **Antalgic gait**—limp to avoid pain when bearing weight on the affected side
- **Propulsive gait**—a stooped, rigid posture, with the head and neck bent forward; movement forward is by small, shuffling steps with involuntary acceleration; also known as festinating gait; common in Parkinson's disease
- **Scissors gait**—legs flexed slightly at the hips and knees with the thighs crossing in a scissors-like movement; common with cerebral palsy, stroke, or spinal tumor
- **Spastic gait**—a stiff, foot-dragging walk caused by one-sided, long-term, muscle contraction; seen with cerebral palsy, head trauma, or brain tumor
- **Steppage gait**—an exaggerated motion of lifting the leg to avoid scraping the toes of a foot with footdrop (foot appears floppy with the toes pointing down); seen with Guillain-Barré syndrome
- **Waddling gait**—a distinctive rolling motion in which the opposite hip drops; seen in patients with muscular dystrophy or developmental dysplasia of the hip; characteristic gait in late pregnancy.

Go to Chapter 22, **Volume 2, Abnormal Atlas: Abnormal Gaits,** on Davis*Plus*.

Activity Tolerance

To promote the benefits of physical activity, people need to pace themselves during exercise, especially those who have been inactive. Health professionals can teach people to rate the perceived level of exertion and monitor target heart rate. Target heart rate requires a pulse check during exercises and staying within 50% to 85% of the maximum heart rate. To figure this out, take 220, subtract the person's age, and then multiply times 0.5 for a target heart rate for low intensity exercise; or multiply times 0.85 for maximum heart rate during high intensity exercise.

For more information about optimal target heart rates during exercise, see Box 32-1 or

Go to the American Heart Association Web site. **Target Heart Rates** are available at http://www.heart.org/HEARTORG/GettingHealthy/PhysicalActivity/Target-Heart-Rates_UCM_434341_Article.jsp

KnowledgeCheck 32-6

- Describe a focused assessment for a patient experiencing mobility concerns.
- Identify the assessment methods (inspection, palpation, percussion, and auscultation) used when performing a physical examination focused on mobility concerns.

ThinkLike a Nurse 32-4

Review the Meet Your Patients scenario. Which, if any, of the class participants requires a physical examination focused on mobility concerns? Explain your reasoning.

ANALYSIS/NURSING DIAGNOSIS

Nursing diagnoses that specifically describe activity and exercise problems include the following:

- *Activity Intolerance* is a state in which a patient has insufficient physical or psychological energy to carry out daily activities.
- *Impaired Physical Mobility* is limitation of independent purposeful movement of the body. Impaired Physical Mobility is a broad, general diagnosis. Use the following, more descriptive diagnoses when the patient has specific deficits: Impaired Bed Mobility, Impaired Walking, Impaired Wheelchair Mobility, and Impaired Transfer Ability.
- *Risk for Disuse Syndrome* exists when a patient's prescribed or unavoidable inactivity creates the risk for deterioration of other body systems.
- *Sedentary Lifestyle* is a habit of life that is characterized by a low physical activity level.

Mobility problems may also be the etiology of other diagnoses. The following are examples:

- Acute Pain r/t musculoskeletal injury.
- Ineffective Health Maintenance r/t prescribed bedrest.
- Risk for Injury r/t unsteady gait.

Keep in mind that Immobility, especially bedrest, can be the etiology of problems in all body systems, as well as psychosocially. For more examples and for further information about mobility diagnoses,

Go to Chapter 32, **Standardized Language, NANDA-I Diagnoses for Activity and Exercise Problems,** on Davis*Plus*.

To see a nursing care plan and care map for the diagnosis Impaired Physical Mobility,

Go to Chapter 32, **Nursing Care Plan, Impaired Physical Mobility and Care Map,** on Davis*Plus*.

PLANNING OUTCOMES/EVALUATION

For *associated NOC standardized outcomes* for mobility diagnoses,

Go to Chapter 32, **Standardized Language, Selected NOC Outcomes for Energy Maintenance and Mobility,** on Davis*Plus*.

Individualized goals/outcome statements depend on the nursing diagnosis used. Because activity and exercise abilities are individualized, goals must consider the patient's current condition, expected condition changes, lifestyle, and values. Examples:

Will independently transfer to the wheelchair by [date].

Will discuss his feelings about his activity restrictions by [date].

PLANNING INTERVENTIONS/IMPLEMENTATION

Because attitudes about fitness and activity vary widely, mobility is often a difficult topic. Some people are devastated by activity limitations caused by disease or treatment. Others are able to accept these changes. For these reasons, it is important for you to convey an attitude of acceptance about the patient's current activity level and provide care that helps the patient achieve his optimal level of function.

For *NIC standardized interventions and activities* for patients with mobility problems,

Go to Chapter 32, **Standardized Language, Selected NIC Interventions for Activity and Exercise Management and Immobility Management,** on Davis*Plus*.

Individualized nursing activities to promote exercise and mobility include promoting exercise, preventing injury from exercise, positioning patients, moving patients in bed, transferring patients out of bed, performing ROM exercises, and assisting with ambulation. The rest of this chapter will explain those interventions.

In addition, when caring for patients with specific diseases and abnormalities, you will need to add the following interventions:

- **For congenital anomalies**—Nursing responsibilities include early detection and referral for additional treatment, and parent counseling.
- **For bone formation abnormalities**—Nursing responsibilities include collaborative treatments, providing comfort, and patient education to promote mobility. Also teach patients to consume a balanced diet that meets the minimum recommendations for vitamins and minerals.
- **For joint mobility problems**—Nursing activities focuse on providing comfort and teaching about medications. If mobility is severely restricted, you will also assist patients with ADLs.
- **For osteomyelitis or bone tumors**—Nursing activities include collaborative treatments, patient education about the treatment plan, and providing comfort.

Promoting Exercise

Nurses are in a perfect role to encourage and educate people of all ages to be active for healthy living. Here are some common steps to help people attain and maintain fitness. Also see the Self-Care box Teaching Clients to Set Up a Fitness Program.

- *Personalize the benefits of regular physical activity*. In other words, find out what motivates your patient. For instance, your patient might want to lose weight and improve his physical appearance. Yet another patient might be interested in improving the quality of sleep or overcoming periods of low energy during the day.
- *Set personal goals for physical activity*. Simple, realistic goals tend to be best. Be sure to define them so they are specific and measurable.
- *Include a variety of activities to keep the patient from feeling bored.*
- *Remind your patient to recognize and appreciate success.*
- *Suggest strategies to achieve the patient's goals*. For instance, you might suggest a fitness program that is fun and entertaining. You can also inform your patient about ways to avoid joint injury or falls.
- *Provide encouragement*. Sometimes just the right approach is a positive, enthusiastic one. You might offer praise for taking steps toward health and fitness. Support from spouse, family members, friends, and coworkers can improve compliance and consistency.
- *Promote physical exercise as an enjoyable activity*.
- *Discuss barriers to regular activity and elicit ways to overcome those obstacles*.

People give various reasons for failing to develop a regular exercise program. See Box 32-6 for suggestions on dealing with such objections.

Preventing Injury From Exercise

As previously discussed, the benefits of exercise outweigh any associated risks. Advise clients to follow the tips in the Self-Care boxes Teaching Clients How to Set Up a Fitness Program and Teaching Your Patient How to Prevent Back Injury. Also re-read the theoretical knowledge in the section Risks Associated With Exercise if you need a review.

Positioning Patients

Healthy people regularly shift position to maintain comfort. However, many patients are unable to move without assistance. They require a change of position at least every 2 hours to prevent skin breakdown, muscle discomfort, damage to superficial nerves and

BOX 32-6 ■ Suggestions for Overcoming Objections to Exercise

Objection	Suggestion
"I hate to exercise."	Pick activities that you enjoy.
"I burn out on exercise."	Plan ahead and build in rest days and varied activities.
"I am self-conscious about going to the gym and don't have the motivation to exercise by myself."	Find a friend to exercise with, or develop a reward system for yourself if you continue to exercise. An exercise "buddy" can help increase motivation and consistency in the weekly routine.
"I am too busy with work or family."	Develop a routine that you can do at lunchtime, or exercise with your family.
"I find exercise boring."	Change your routine frequently.
"I can't afford to join a health club, hire a fitness trainer, or buy expensive equipment."	Just get active doing things you enjoy. Go for a brisk walk, or play with your grandkids. Some of the best core exercises require no equipment at all (e.g., push-ups, planks). You can also use a chair, jump rope, or many things around the house to build into your fitness routine.
"I'm too tired to exercise."	The hardest part is getting started, but after a few minutes or so, you'll feel better and have more energy after you finish.
"Exercise hurts."	Make sure to exercise at your target heart rate, and plan a rest day after every weight-lifting session.
"I don't have time."	Schedule your exercise time. If need be, schedule several short 10- to 15-minute sessions throughout the day, and do more as time allows. It all adds up and will benefit you.
"I have pain about all the time."	Take pain medication an hour or so before starting physical activity. If fatigue is the problem, try to arrange schedule to keep a balance of rest and activity as well as avoid stimulants (e.g., caffeine or nicotine) that might interfere with the quality of sleep.
"I have difficulty getting around sometimes."	Stretch adequately before starting exercise, but not to overstretch joints. Also, you will need to walk on smooth, even surfaces.
"I am diabetic and have trouble with my feet. My vision is not very good, either."	Be sure shoes fit properly and the area is well-lit.
"I'm too old to exercise."	It's never to late to get active, and any physical activity you do is better than none. Exercises that build strength, stamina, flexibilty and balance improve the quality of life and reduce the risk for falls.

blood vessels, and contractures. Immobile people are more prone to pressure injury as a result of reduced circulation, impaired oxygen exchange to the tissues, and edema.

A firm mattress provides support to the patient's body and makes it easier to turn the patient (because he does not sink down into the mattress). Most hospital mattresses are firm. However, when you provide home care, you will find mattresses of various types and conditions. To provide additional support, you can place a piece of plywood under a sagging mattress.

A clean, dry bed also makes it easier to turn the patient and decreases the risk of skin maceration or pressure ulcer formation. Bedding should provide coverage and warmth but not be tucked in so tightly as to restrict movement.

Protecting the Nurse's Back

According to the U.S. Bureau of Labor Statitics (2013), healthcare workers providing direct patient care rank fifth in the number of work-related musculoskeletal injuries. Nurses are at risk for back and shoulder injury as a result of manual moving and repositioning of patients, residents, or clients. Rising obesity rates in the United States, aging of the workforce, and the shortage of nurses impact the physical demands on caregivers (CDC, n.d., updated 2014).

To protect yourself from back injury as you move patients, avoid manual lifting as much as possible. Some lifts and patient care tasks require multiple staff members to accomplish safely, and, because low staffing makes this teamwork difficult, nurses often attempt these tasks alone (Waters, Nelson, Hughes, et al., 2009). Use assistive equipment and devices, as recommended by the ANA (2013), and always make sure you have adequate help. The amount of help you need depends on the size of the patient, the level of assistance the patient can offer, your size and strength, and the equipment or lines attached to the patient.

Other measures to reduce the risk for injury for nurses include the following:

- Avoid slippery or wet surfaces during ambulation or moving patients.
- Remove physical obstructions (e.g., cabinets, toilets) when moving or transferring patients.
- Arrange a clutter-free environment that allows for free movement of equipment and personnel.
- Watch out for uneven floor surfaces or movable rugs.
- Lock wheels of furniture and equipment before moving patients.
- Avoid moving patients through too small a width to the entrance way.

Positioning Devices

Devices used to maintain body alignment, prevent contractures, and promote comfort are briefly discussed in the next sections. Positioning devices are commonly used to help minimize the risk for the example problem, Hazards of Immobility. For guidelines for using common positioning devices, including hip abduction pillows,

Go to Chapter 32, **Clinical Insight 32-2: Using Common Positioning Devices,** in Volume 2.

Adjustable Beds

An adjustable bed, often referred to as a hospital bed, assumes a variety of positions. You can elevate or lower the head of the bed, and elevate the foot of the bed. Often the bed breaks, or "gatches," at the knee to keep the patient from sliding down when the head is elevated. You can also adjust the height of the bed. You should raise the bed to waist height when providing care so that you can use proper body mechanics; place the bed in its lowest position before helping a patient get out of bed or if the patient is at risk for falling.

Several types of specialized beds are used in treating and preventing pressure ulcers. These include alternating, low air loss, immersion (air-fluidized), and oscillating beds. The mattresses may be composed of air, water, or gel. Special beds are discussed further in Chapter 35. A circular bed and Stryker frame are used in the care of patients with severe mobility restrictions. Both can rotate a patient from supine to prone. With the advent of low-pressure specialized beds, these latter two types of beds are now in limited use.

Pillows

Pillows are the most common devices used to assist with positioning, provide support, and elevate body parts. They help position a patient by molding to the body and expanding the weight-bearing area. You will need a variety of sizes to position patients who are unconscious, paralyzed, frail, or who have had surgery. To obtain the right size or type (e.g., abductor pillows), or if pillows are not available, you can use folded blankets or towels. Foam wedge pillows are useful for elevating the upper body when an adjustable bed is not available and for abducting the hips after hip surgery.

Siderails

Most hospital beds are equipped with siderails. The rails may run the full length of each side of the bed or consist of an upper or lower rail on each side.

Siderails are designed to ensure patient safety. They serve as a reminder that the patient should call for assistance before getting out of bed and provide a grip for the patient who is able to reposition himself in bed. Although siderails are designed to protect patients, they can be a source of injury. Patients can get tangled in the railing or fall between the bed and rail, and confused patients may injure themselves trying to climb over the rails.

Siderails may also be considered a form of restraint, so follow your agency's policy for use and be sure to discuss their purpose with patients and family. See Chapter 24 if you need to review restraint use.

Trapeze Bar

A trapeze bar is a triangular-shaped device that is attached to an overhead bed frame (see Clinical Insight

32-2). The patient can use the base of the triangle as a grip bar to move up in bed, turn, and pull up in preparation for getting out of bed or getting on and off the bedpan. Patients can use the trapeze to move about in bed and to exercise their upper extremities. Frail patients may not be able to use a trapeze bar because of the amount of effort it requires.

Footboard

When a person is supine, the toes tend to point downward toward the bed (**footdrop**), and the feet are in plantar flexion. Able-bodied persons usually shift position throughout the night, so the foot and leg muscles are periodically contracted and relaxed. In contrast, the patient who is unable to move independently will experience a shortening of the gastrocnemius muscle and may have difficulty walking again if prolonged plantar flexion occurs. A footboard is a device placed at the end of the bed to prevent footdrop and outward hip rotation, but it does not relieve heel pressure (Fig. 32-6). For the footboard to be effective, the heels must be touching it. Each time you turn the patient, you may need to reposition the footboard to ensure proper position.

Other Positioning Devices

The following are other positioning devices used in the clinical setting:

- ***Trochanter rolls*** are made from tightly rolled towels, bath blankets, or foam pads. They are placed snugly adjacent to the hips and thighs to prevent external rotation of the hips. To learn how to make them,

Go to Chapter 32, **Clinical Insight 32-2: Using Common Positioning Devices,** in Volume 2.

- ***Hand and wrist splints*** may be manufactured or fashioned from rolled washcloths. Often splints are custom made for patients. The purpose of splints is to hold the wrist and hand in natural position and prevent claw-hand deformities.
- ***Hand rolls*** prevent hand contractures. Some are commercially made. Otherwise, you can make a hand roll from a tightly rolled washcloth.
- ***Hip abduction pillows*** prevent internal hip rotation and hip adduction when the patient is in a supine position. These wedge-shaped pieces of spongy material are used after femoral fracture, hip fracture, or surgery. Lateral indentations and straps that wrap around the patient's thighs hold the patient in the correct position.
- ***Boots*** made of spongy rubber with heel cutouts and ankle cushioning prevent footdrop, skin breakdown, and external hip rotation. If any part of the boot is made of a latex product, be sure the patient does not have a latex allergy before applying.
- ***Foot cradles*** are metal or plastic devices that are secured at the foot of the bed to hold bedding up off the toes and feet, allowing for free movement.
- ***High-top sneakers*** may be used to prevent heel drop, but they do not reduce heel pressure. They do help in positioning hips and pelvis to prevent hip rotation.
- ***Sandbags*** are small fabric bags filled with sand. They are used in the same manner as pillows and trochanter rolls; however, they provide firmer support.

FIGURE 32-6 A footboard is placed at the end of the bed to prevent footdrop.

Positioning Techniques

In the next section we briefly describe the various ways to position patients. Table 32-2 illustrates these positions; identifies potential problems associated with them; and offers solutions to prevent the problems. The positions are also described and illustrated in Chapter 22, Table 22-1.

Fowler's Positions

Fowler's position is a semisitting position, in which the head of the bed is elevated 45° to 60°. This position promotes respiratory function by lowering the diaphragm and allowing the greatest chest expansion. It is also an ideal position for some patients with cardiac dysfunction. Common variations include **semi-Fowler's position**, in which the head of the bed is elevated only 30°, and **high-Fowler's position**, in which the head is elevated 90°.

In the **orthopneic position**, the head of the bed is elevated 90° and an overbed table with a pillow on top is positioned in front of the patient (Fig. 32-7). Have the patient lean forward, resting his arms and head on the pillow. This position is helpful for a patient with shortness of breath.

Lateral Positions

The **lateral position** is a side-lying position with the top hip and knee flexed and placed in front of the rest of the body. The lateral position creates pressure on the lower scapula, ilium, and trochanter but relieves pressure from the heels and sacrum. The **lateral recumbent position** is side-lying with legs in a straight line (see

Table 32-2 ➤ Positioning a Bed-Bound Patient

POSITION	POTENTIAL PROBLEM	SOLUTIONS
Fowler's 	Hyperextension of the neck	Use a small pillow under the head and neck.
	Posterior flexion of the lumbar curvature	Use a firm mattress. Position the patient so that the angle of elevation begins at the hip.
	Dislocation of the shoulders	Position a pillow under the forearms to prevent pull on the shoulders.
	Flexion contracture of the wrist and edema of the hands	Support the hands on pillows in alignment with the forearms.
	Flexion contracture of the fingers and abduction of the thumbs	Use hand splints if appropriate, or provide a large roll in the palm of the hand.
	External rotation of the legs	Place sandbags or rolls alongside the trochanters and upper thighs.
	Hyperextension of the knees	Place a small pillow under the lower legs from the ankles to below the knees. Do this for short periods only; avoid pressure on the popliteal area.
	Footdrop	Use a footboard or high-top sneakers to hold the feet in dorsiflexion.
Lateral 	Lateral flexion of the neck	Place a pillow under the head and neck to provide alignment.
	Internal rotation and adduction of the upper shoulder and limited respirations	Place a pillow under the upper arm, and comfortably flex the lower arm.
	Internal rotation and adduction of the femur	Support the upper leg from groin to foot with pillows.
	Twisting of the spine	Align the shoulders with the hips.
	Flexion of the cervical spine	Place a pillow under the head and neck to provide alignment, unless drainage from the mouth is desired.
Prone 	Hyperextension of the lumbar curvature, pressure on the breasts in women or genitals in men, impaired respirations	Place a small pillow under the abdomen.
	Footdrop	Move the patient down in bed so the feet extend over the edge of the mattress, or place a small pillow under the shins so that the toes do not touch the bed.
	Lateral flexion of the neck	Place a pillow under the head and neck to provide alignment, unless drainage from the mouth is desired.

Table 32-2 ➤ Positioning a Bed-Bound Patient—cont'd

POSITION	POTENTIAL PROBLEM	SOLUTIONS
Sims' 	Internal rotation and adduction of the upper shoulder and limited respirations	Place a pillow under the upper arm, and comfortably flex the arm at the elbow.
	Pressure on the shoulder and axilla of the inferior arm	Position the lower arm behind and away from the back.
	Internal rotation and adduction of the femur	Support the upper leg from groin to foot with pillows.
	Twisting of the spine	Align the shoulders with the hips.
	Footdrop	Support the feet in dorsiflexion with sandbags.
	Hyperextension of the neck	Place a pillow under the head and neck to provide alignment.
Supine 	Internal rotation of the shoulders and extension of the elbows	Position the upper arms next to the body. Place pillows under the forearms, and position the wrists in slight pronation.
	Flexion of fingers and abduction of the thumbs	Use hand splints if appropriate, or provide a large roll in the palm of the hand.
	Flexion of the lumbar curvature and hips	Provide a firm mattress, or place a small pillow under the lumbar curvature.
	External rotation of the legs	Place sandbags or rolls alongside the trochanters and upper thighs.
	Hyperextension of the knees	Place a small pillow under the lower legs from the ankles to below the knees.
	Footdrop	Use a footboard or high-top sneakers to hold the feet in dorsiflexion.

Table 22-1). The **oblique position** is an alternative to the lateral position that places less pressure on the trochanter. The patient turns on the side with the top hip and knee flexed; however, the top leg is placed behind the body (Fig. 32-8).

FIGURE 32-7 The orthopneic position is ideal for a patient with shortness of breath.

Prone Position

In the **prone position**, the patient lies on his abdomen with his head turned to one side. This is the only position that allows full extension of the hips and knees. It also allows secretions to drain freely from the mouth and thus is helpful for an unconscious patient. However, this is the most difficult position to move an unconscious or frail patient into, because it requires the greatest amount of manipulation to position the patient appropriately. The prone position creates a significant lordosis (inward curving of the spine in the lower back)

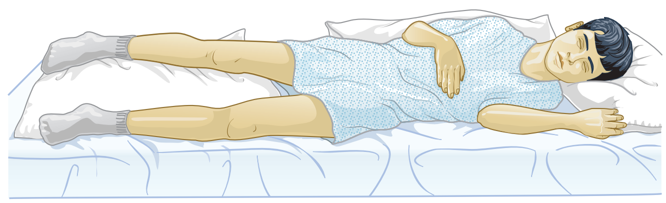

FIGURE 32-8 The oblique position is a modified lateral position that places less pressure on the trochanter.

and rotation of the neck. Therefore, it should not be used for patients with cervical or lumbar spine problems. You should not use the prone position for patients with cardiac or respiratory difficulty because it inhibits chest wall expansion and, therefore, oxygenation. As a rule, you can use this position only for short periods of time.

Sims' Position

Sims' position is a semiprone position. The lower arm is positioned behind the patient, and the upper arm is flexed. The upper leg is more flexed than the lower leg. Sims' position facilitates drainage from the mouth and limits pressure on the trochanter and sacrum. This is an ideal position for administering an enema or a perineal procedure.

Supine Position

In the **supine position**, also known as the **dorsal recumbent position**, the patient lies on his back with head and shoulders elevated on a small pillow. The spine is aligned and the arms and hands comfortably rest at the side.

KnowledgeCheck 32-7

- Describe the following positions: Fowler's, lateral, prone, Sims', and supine.
- What is the advantage of the oblique position versus the lateral position?
- Identify and describe six positioning devices.
- What are three uses for siderails?

ThinkLike a Nurse 32-5

You are providing care for a young man who is recovering from Guillain-Barré syndrome, which produces a reversible paralysis after viral illness. He has been healthy until this present illness. How would you position this patient? Explain your reasoning.

Moving Patients in Bed

To position patients, you must be adept at moving and lifting them in bed. This involves positioning the patient in the length of the bed, as well as turning with as little friction and shearing on the skin as possible. Moving patients in bed is a common intervention to help minimize the risk for the example problem, Hazards of Immobility.

Moving Up in Bed Frail patients tend to slide down in bed because of gravity and their inability to correct their position. Elevating the head of the bed accentuates the slide and places the patient in an awkward position. If the patient is light in weight or able to provide assistance, you will be able to move her independently (see the Highlights of Procedures box for a summary). For complete instructions,

Go to Chapter 32, **Procedure 32-1A: Moving a Patient Up in Bed,** in Volume 2.

Turning in Bed Turn patients at least every 2 hours to protect their skin and prevent other complications of immobility. For efficient use of time, try to time turning to coincide with moving the patient up in bed. Use pillows and other positioning devices to help the patient maintain the new position (see the Highlights of Procedures box for a summary). For a complete description,

Go to Chapter 32, **Procedure 32-1B: Turning a Patient in Bed,** in Volume 2.

Logrolling Logrolling is a special turning technique used when the patient's spine must be kept in straight alignment. You will need at least two nurses for this procedure, more if the patient is large. Logrolling moves the patient's body as a unit. One nurse is positioned at the level of the patient's head. The other staff members are distributed along the length of the patient. All must move the patient in unison (see the Highlights of Procedures box for a summary). For a complete description,

Go to Chapter 32, **Procedure 32-1C: Logrolling a Patient,** in Volume 2.

Friction-Reducing Devices You can use one of a variety of friction-reducing devices when moving a patient in bed. Transfer roller sheets are thin, low-friction fabric sheets that may be placed beneath the drawsheet to facilitate moving the patient in bed (Fig. 32-9). A scoot sheet is also a thin, low-friction fabric sheet that is often positioned under the drawsheet of the patient, but it is attached to a mechanical crank (Fig. 32-10). By turning the crank, a single person can move a patient up in bed. Transfer roller sheets are relatively inexpensive and are widely available on clinical units. If one is not available, you can improvise by placing a large, clean, unused plastic bag under the drawsheet to help you move the

FIGURE 32-9 A transfer roller sheet reduces friction and facilitates movement.

FIGURE 32-10 A scoot sheet allows one or two nurses to easily move a patient up in bed.

patient. The plastic bag reduces drag and facilitates movement. However, unlike the thin fabric of transfer sheets, plastic allows moisture to pool under the patient. Consequently, you should not leave a bag in place under the drawsheet.

Transferring Patients Out of Bed

Stretchers and wheelchairs are used to transport patients between units and to tests or procedures. A stretcher is usually reserved for the patient who is weak, sedated, or has a condition that does not permit transfer by wheelchair. A wheelchair may be used for transport or as part of an activity program. In addition, you may transfer patients to a stationary chair to increase their general activity level (see the Hightlights of Procedures box for a summary). For complete procedural steps,

Go to Chapter 32, **Procedure 32-2A: Transferring a Patient From Bed to Stretcher, Procedure 32-2B: Dangling a Patient at the Side of the Bed,** and **Procedure 32-2C: Transferring a Patient From Bed to Chair,** in Volume 2.

To know what type of assistive device is appropriate for patient safety and to prevent back injury to the nurse,

Go to Chapter 32,**Clinical Insight 32-1, Applying Principles of Body Mechanics,** in Volume 2.

Transfer Board

A **transfer board** is a wood or plastic device designed to assist with moving patients. Using a transfer board reduces your risk of injury and promotes a smooth transfer. Place the board under the patient on the side to which he will be moved. It is best to use a drawsheet to slide the patient across the board (Fig. 32-11). Transfer boards are also used by patients with long-standing mobility problems to increase their independence.

FIGURE 32-11 Transfer boards are used by patients with chronic mobility problems to increase their independence.

Mechanical Lift

A **mechanical lift** is a hydraulic device used to transfer patients. Place a fabric sling under the patient, and attach chains or straps from the sling to the lifting device (Fig. 32-12). A mechanical lift is especially useful when providing care for obese and immobile patients. Lifts are often used in home care because they allow one person to transfer the patient safely. Most lifts position patients in a seated position and thus are ideal for assisting the patient into a chair. Others suspend the patient in a supine position; they may be used to transfer the patient from bed to stretcher or to suspend the patient while the bed is made. Many such lifts include scales that weigh the patient while he is suspended in the sling. Some mechanical lifts are mounted on the ceiling to reduce caregiver back injuries and increase patient safety (see Fig. 32-13).

FIGURE 32-12 A mechanical lift is useful when providing care to patients with impaired mobility.

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 32-1A: Moving a Patient Up in Bed

- Use a friction-reducing device to move the patient if the patient can assist with movement. Use a full body sling if the patient cannot assist.
- Remove the pillow. Have the patient flex her neck, fold her arms across her chest, and place her feet flat on the bed.
- Position a nurse on either side of the patient.
- Use a wide base of support.
- Have the patient, on the count of 3, push off with his heels as you shift your weight forward.

Procedure 32-1B: Turning a Patient in Bed

- Use a friction-reducing device and drawsheet to move the patient. Position at least one nurse on each side of the bed.
- Place the patient's near leg and arm (e.g., the left arm and leg when turning to the right) across his body, and abduct and externally rotate the far shoulder.
- Each nurse places one arm at the level of the patient's shoulders and the other at the level of the patient's hips. Each nurse shifts her weight as both simultaneously roll the patient in the intended direction.

Procedure 32-1C: Logrolling a Patient

- Move the patient as a unit to the opposite side of the bed; raise the siderail on that side.
- Move to the side of the bed that the patient will be turning toward; lower the siderail.
- Each staff member evenly distributes his arms across the patient's length. One nurse is responsible for moving the head and neck as a unit.
- Shift your weight backward as you roll the patient toward you.

Procedure 32-2A: Transferring a Patient From Bed to Stretcher

- Move the patient to the side of the bed where the stretcher will be placed.
- Position the stretcher next to the bed, and lock it in place.
- Keep the destination device (i.e., bed to stretcher or vice versa) situated a little lower than the surface the patient is on.
- Using the drawsheet, roll the patient away from the stretcher.
- Place the transfer board against the patient's back halfway between the bed and stretcher. Position a friction-reducing device over the transfer board. Turn the patient to his back and onto the transfer board with the drawsheet.
- On a count of three, use the drawsheet to slide the patient across the transfer board onto the stretcher.

Procedure 32-2B: Dangling a Patient at the Side of the Bed

- Place the patient in a supine position, and raise the head of the bed to 90°.
- Apply a gait transfer belt, and place the bed in a low position.
- Stand facing the patient with a wide base of support. Place your foot closest to the head of the bed forward of the other foot.
- Position your hands on each side of the gait transfer belt.
- Rock onto your back foot as you move the patient into a sitting position, and pivot to bring the patient's legs over the side of the bed.
- Stay with the patient as he dangles.

Procedure 32-2C: Transferring a Patient From Bed to Chair

- Ask the patient to wear nonskid footwear.
- Place the bed in the low position, and lock the wheels.
- Assist the patient to dangle at the side of the bed (see Procedure 32-2B).
- Brace your feet and knees against the patient. Bend your hips at the knees, and hold on to the transfer belt.
- If two nurses are available to assist with the transfer, one nurse should be on each side of the patient.
- Instruct the patient to place her arms around you between your shoulders and waist. Ask the patient to stand as you move to an upright position by straightening your legs and hips.
- Instruct the patient to pivot and turn with you toward the chair.
- Ask the patient to flex her hips and knees as she lowers herself to the chair. Guide her motion while maintaining a firm hold on her.
- If the chair is a wheelchair, lock the wheels.

Procedure 32-3: Assisting With Ambulation

- Ask the patient to wear nonskid footwear.
- Place the bed in low position, and lock the wheels.
- Assist the patient to dangle at the side of the bed (see Procedure 32-2B).
- If two nurses are available, each nurse should stand facing the patient on opposite sides of the patient.
- Brace your feet and knees against the patient. Bend your hips at the knees, and hold onto the transfer belt. Pay attention to any known weakness.
- Instruct the patient to place her arms around you between your shoulders and waist (the location depends on the height of the patient and the nurses). Ask the patient to stand as you move to an upright position by straightening your legs and hips.
- Allow the patient to steady herself for a moment.
- One nurse: Stand at the patient's side, placing both hands on the transfer belt. If the patient has weakness on one side, position yourself on the weaker side.
- Two nurses: One nurse stands on each of the patient's sides, grasping hold of the transfer belt.
- Slowly guide the patient forward. Observe for signs of fatigue or dizziness.
- If the patient must transport an IV pole, allow the patient to hold onto the pole on the side where you are standing. Assist the patient to advance the pole as you ambulate together.

FIGURE 32-13 A ceiling mounted mechanical lift is used to support patients in the standing position.

Standing assist devices are mechanical lifts that help the patient move from a sitting to a standing position or support a patient in the standing position. A sling is positioned around the back and under the arms of the patient (Fig. 32-14). Specialized chairs and wheelchairs are also available. Each has a mechanical lift in the seat that rises to assist the patient to a standing position. Mechanical lift devices reduce the risk of back and musculoskeletal injury.

Transfer Belt

A **transfer belt** is a heavy belt several inches wide that is used to facilitate transfer or provide a secure mechanism to hold the patient when ambulating. Apply the belt around the patient's abdomen, close to the patient's center of gravity. The belt may have external grip holds, or you may grip the entire belt with your hand (Fig. 32-15).

FIGURE 32-14 A mechanical lift with a sling chair is used to safely transfer an immobile patient into a wheelchair.

The fit should not be overly tight or cause the patient discomfort. You should be able to easily place your hand under the belt. Do not place it over the rib cage, as this could compromise breathing. Do not use a transfer belt around the patient's hip. This could cause unsteadiness and lead to a patient fall. You would not use a transfer belt after abdominal surgery or with other abdominal wound, colostomy, or internal organ contusion or other injury.

KnowledgeCheck 32-8

- What criteria determine whether your patient should be logrolled when he is repositioned?
- How often should you turn and reposition a patient?
- Identify the most appropriate device for the following activities:
  Transferring an obese patient from a bed to a stretcher
  Assisting an immobile patient to a recliner chair
  Helping a weak patient from bed to chair

Performing Range-of-Motion Exercises

Patients with limited mobility are at risk for developing complications of disuse, such as muscle atrophy, joint stiffness, and contractures. To limit the complications of

FIGURE 32-15 A transfer belt is placed close to the patient's center of gravity. It may have external grip holds to facilitate transfer or provide a secure mechanism to hold the patient when ambulating.

immobility, patients recovering from illness, injury, or surgery often perform AROM as a rehabilitation procedure. Additionally, movement with ADLs improves joint mobility, circulation, muscular strength,

Passive range of motion (PROM) is movement of the joints through their range of motion by another person. Both AROM and PROM improve joint mobility, increase circulation to the area exercised, and help maintain function. However, AROM also improves and respiratory and cardiac function. For an explanation of how to perform PROM,

Go to Chapter 32, **Clinical Insight 32-3: Tips for Performing Passive Range-of-Motion Exercises,** in Volume 2.

Continuous passive motion, also called CPM, is a device that repetitively but gently flexes and extends the knee joint. The CPM machine is often used after knee replacement or other knee procedures to allow the joint to improve range of motion, eliminate the problem of stiffness, and prevent the development of adhesions, which can limit motion further.

Assisting With Ambulation

Prolonged bedrest is no longer the standard of care. However, as a nurse, you will provide care to patients whose illnesses and injuries curtail their ability to walk and be active. Assisting patients with ambulation includes physical conditioning to prepare the patient for ambulation, as well as assisting the patient to walk.

Physical Conditioning

Patients who have been confined to bed for more than a week or who have sustained major injury require conditioning before they are able to resume walking. The following conditioning exercises are summarized here; they are explained in detail,

Go to Chapter 32,**Clinical Insight 32-4: Assisting With Physical Conditioning Exercises to Prepare for Ambulation,** in Volume 2.

Quadriceps and Gluteal Drills The quadriceps muscle group and the gluteal muscles are the largest muscles of the body. Patients who are confined to bed can perform isometric exercises to prepare them for walking.

Arm Exercises Patients use the biceps and triceps muscles when getting out of bed and for crutch walking. Exercises to help prepare the patient for ambulation include using a trapeze bar, and doing "push-ups" off the mattress or a chair.

Be mindful of any cardiac or musculoskeletal precautions that restrict arm movement, weight-bearing on the hands and wrists, or other upper body injury. If lymphedema is present in the upper extremities, do not encourage arm exercises or use of the trapeze, unless directed by the primary care provider.

Dangling Use this position to prepare the patient to get up in a chair, to stand, or to ambulate.

Patients who have been confined to bed frequently become light-headed or develop orthostatic hypotension when first getting up. Dangling allows the patient to experience being upright with limited risk of falling.

Some common approaches used for orthostatic problems include antiembolism stockings with compression wraps to prevent pooling of venous blood. Sometimes abdominal binders are used for this purpose as well. Medication is available to control orthostatic hypotension. Patients with spinal cord injury experiencing autonomic dysfunctions need a high-back reclining wheelchair so the back of the chair can be lowered (and someone might even have to lift up their legs for a few minutes) until blood pressure stabilizes. Tilt-table therapies are also used.

Daily Activities Moving around in bed and performing ADLs (e.g., brushing one's hair) exercise many of the muscle groups needed for ambulation. Getting up into a chair accustoms the patient to an upright posture and is an important predictor of success with ambulation.

Assisting the Patient to Walk

Before getting the patient out of bed, assess his readiness to walk. Also obtain the appropriate equipment and assistance. Move floor rugs and loose objects from the path of the patient and caregiver. Be sure the floor is not slippery. When possible, use a transfer belt. Have a chair or additional assistance available on the first few attempts at ambulation.

If the patient becomes faint or begins to fall, do not attempt to hold him up by yourself. Instead, protect the patient as you guide him to a seated or lying position. Create a wide base of support, and project forward the hip closest to the patient. Help the patient slide down your leg as you call for help (Fig. 32-16). Protect the patient's head as his body descends.

The Hightlights of Procedures box summarizes ambulation with one-nurse assist and with two-nurse assist. For the complete procedures,

Go to Chapter 32, **Procedure 32-3A: Assisting With Ambulation (One Nurse),** and **Procedure 32-3B: Assisting with Ambulation (Two Nurses),** in Volume 2.

Assisting Older Adults When assisting older adults to ambulate, find out how much assistance, if any, the patient typically requires and modify support as needed. Consider the following nursing interventions.

- Observe constantly during ambulation for weakness and fatigue. Plan for periods of rest during ambulation, if needed. The older adult might become

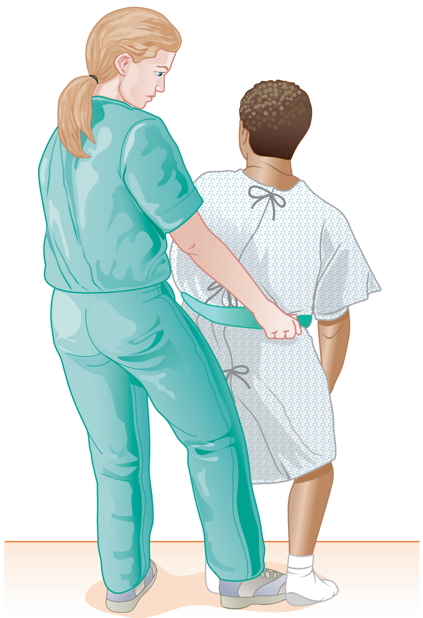

FIGURE 32-16 If the patient begins to fall, the nurse guides the patient gently to the floor or to a chair.

fatigued more quickly and recover more slowly from the physical demands of walking, especially if a heart or lung condition is present.

- Move the patient gradually to a sitting position and allow him to dangle at the bedside before coming to a standing position. Observe for dizziness or light-headedness.
- Assess for falls risk factors. For example, some medications cause dizziness or lethargy; and patients with neurological or cognitive disorders, such as Parkinson's or Alzheimer's disease, have a greater potential for falls. For more information about assessing a patient's risk for a fall see Chapter 24.
- To reduce the risk for falling in the home, recommend family place nonskid strips on stairs or other smooth flooring.
- Assistive devices, such as walkers, canes, and transfer belts, can be useful for older adults or others who require additional support.
- Be cautious when using a transfer belt for the patient with osteoporosis or back pain. Too much pressure from the belt can cause injury or pain.

KnowledgeCheck 32-9

- Identify four principles to be followed when performing PROM.
- Describe activities that can promote a patient's readiness for ambulation.
- What action should you take if a patient begins to fall when ambulating?

Mechanical Aids for Walking

A variety of aids is available to promote stability and independence when walking. Some aids are intended for short-term use; others will be incorporated into the patient's lifestyle. Some patients consider the use of aids a sign of weakness or inconvenience. As a result, they avoid using the aid and increase their risk of falls. However, most people dread loss of independence, so you can promote the use of walking aids by stressing their importance in helping the person maintain independence.

Go to Chapter 32, **Clinical Insight 32-6: Teaching Patients to Use Canes, Walkers, and Crutches,** in Volume 2.

Canes

The following are three basic types of canes used (Fig. 32-17):

- ***Single-ended cane with a half-circle handle.*** This is ideal for the patient who needs minimal support and is able to negotiate stairs.
- ***Single-ended cane with a straight handle.*** This is ideal for the patient with hand weakness who has good balance.
- ***Multiprong canes.*** A multiprong cane usually has three or four prongs, and all types have a straight handle. These canes provide a wide base of support and are useful for patients with balance problems.

Walkers

A walker is a lightweight metal frame device with four legs that provides a wide base of support as a patient ambulates. Various forms of walkers are available. Some models have wheels that allow the walker to be rolled forward; others have a seat that allows the patient to rest periodically (Fig. 32-18). These walkers are best for patients whose mobility problems are related to fatigue or shortness of breath rather than gait instability.

Braces

Braces support joints and muscles that cannot independently support the body's weight. They are most commonly used in the lower extremities. Physical

FIGURE 32-17 Three types of canes.

medicine specialists usually fit the brace. Nursing responsibilities include assisting the patient into and out of the brace and monitoring the condition of the skin under the brace.

Crutches

Crutches are commonly used for rehabilitation of an injured lower extremity. The purpose of using crutches is to limit or eliminate weight-bearing on the leg(s) by forcing the user to rely on strength in the arms and shoulders for support. Two forms of crutches are available.

The *forearm support crutch* is more likely to be used by a patient with permanent limitations. It is usually constructed of lightweight aluminum with a hand hold and a forearm support (Fig. 32-19A).

Axillary crutches are for both short- and long-term use (Fig. 32-19B). Properly fitted axillary crutches support the body weight in the hands and arms, not the axilla. For guidelines on how to measure a patient for an axillary crutch,

Go to Chapter 32, **Clinical Insight 32-5: Sizing Walking Aids,** in Volume 2.

Crutch walking taxes the arms and hands and may cause discomfort to the axillae, arms, and palms where the patient is bearing weight. There are five crutch gaits: two-point gait, three-point gait, four-point gait, swing-to gait, and swing-through gait. Two-point and four-point gait are used for partial weight-bearing, whereas three-point gait is used when weight-bearing must be avoided. Swing-to and swing-through are used when weight-bearing is permitted.

For basic gaits and guidelines for teaching patients to use crutches,

Go to Chapter 32, **Clinical Insight 32-6: Teaching Clients to Use Canes, Walkers, and Crutches,** in Volume 2.

To see animations of crutch gaits,

Go to **Animations: 5 Types of Crutch Gaits,** on Davis*Plus*.

FIGURE 32-18 Walkers. *A*, The basic walker is picked up and advanced as the patient steps ahead. *B*, Some walkers have wheels and seats that allow the patient to rest periodically.

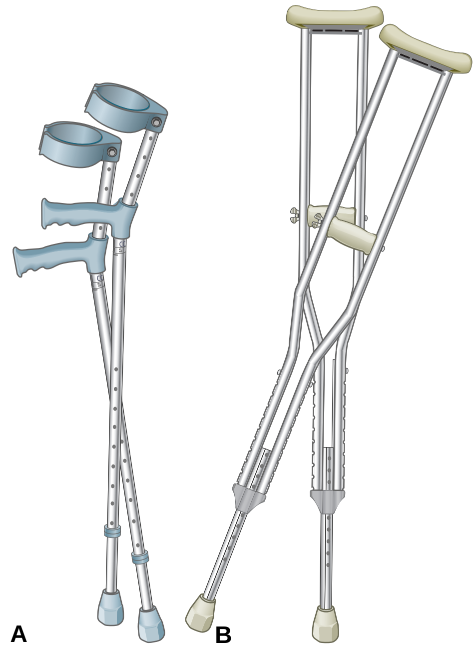

FIGURE 32-19 Crutches. *A*, Forearm support crutches. *B*, Axillary crutches.

KnowledgeCheck 32-10

- What type of cane should a patient with significant balance problems use?
- When are forearm support crutches used?
- Identify five crutch gaits.

ThinkLike a Nurse 32-6

Discuss crutch walking with your peers and family. What instruction would facilitate the best understanding of proper crutch-walking technique?

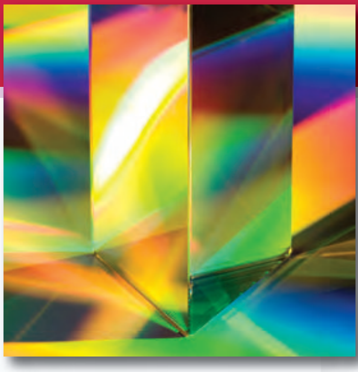
CHAPTER 33



Sexual Health

Learning Outcomes

After completing this chapter, you should be able to:

- Identify the female and male reproductive organs.
- Describe the physical, emotional, social, and spiritual aspects of human sexuality.
- Explain how gender, gender identity, and sexual orientation contribute to expression of sexuality throughout the life cycle.
- Differentiate between typical and atypical forms of sexual expression.
- Explore physical and psychological issues that affect sexuality and sexual functioning.
- Complete a sexual history as part of a comprehensive nursing assessment.
- State nursing diagnoses to describe sexuality problems.
- Explain how sexual health is challenged by high-risk sexual behaviors, sexually transmitted infections (STIs), menstrual problems, infertility, negative intimate relationships, sexual harassment, rape, and disorders of the sexual response cycle.
- Provide nursing interventions that enhance sexual well-being.
- Discuss strategies to increase your personal comfort and confidence in providing holistic nursing care.
- Describe approaches for dealing with inappropriate sexual behavior from patients or in the work environment.

Key Concepts

Sexual dysfunction
Sexual health
Sexuality

Meet Your Patients

- Two days after undergoing a fine-needle aspiration to evaluate a small breast mass, Jocelyn Carter's surgeon informed her that the mass was malignant. He recommended a mastectomy (removal of the breast). Today, she arrives alone at the surgery registration area. You ask how she is feeling, and she tells you that the past week has been a whirlwind of activity. "I had to arrange childcare, cancel a business trip, and organize the house so that I could take a few days off to have the surgery. My husband is working overseas this fall, so he couldn't be here to help me. Honestly, I don't know how I'm feeling. I haven't had time to think about it." A few minutes later, as she waits in the surgery holding area, she begins to cry. You hold her hand and ask whether she would like to talk. She asks you, "Do you think my husband will still want me? I'm afraid he will be turned off when he looks at me."
- Gabriel Thomas comes to the outpatient clinic complaining of a throbbing headache for the past 3 days. He explains that he has tried several over-the-counter (OTC) medicines and has had no relief. You check his blood pressure, and measure the reading at 240/130 mm Hg. When

Meet Your Patients (continued)

you ask whether he has ever been treated for high blood pressure, he replies, "Are you another one of these people trying to get me to take drugs that will ruin my sex life?"

- Frank Thanee, who has heart disease, had a mitral valve replacement 3 days ago. He has been transferred to the cardiology floor for an additional day of hospitalization. His partner, Greg, has spent the past 3 days at the hospital and has just left to check on the apartment and feed their cat. Frank confides that he is worried about his parents' expected visit. "I've never been able to tell them about Greg. They wouldn't be able to understand it, never mind approve. I don't know how to handle this. What do you think I should do?"

Although each of these clients has a different medical diagnosis, all are experiencing a concern related to sexuality. In this chapter, we explore the relationship between health and sexuality, and the nurse's role in promoting sexual health.

Theoretical Knowledge knowing why

When a baby is born, the first question the parents ask is, "Is it a boy or a girl?" In fact, many parents want to know the gender of their baby early in the pregnancy at the first sonogram. Hopes and dreams of future parent–child relationships (e.g., mother–daughter) often begin to form even during the first months of pregnancy. As you will learn, sexuality encompasses much more than gender. It includes how we perceive ourselves, how we relate to others, and how we express ourselves as sexual beings.

ABOUT THE KEY CONCEPTS

Like many people, you may have been socialized to avoid talking openly about sexuality. As a nurse, though, you will find that you must discuss a variety of issues pertaining to sexuality that are vital for clients' optimal wellness. Some of these discussions may include sexual dysfunctions, infections, or behaviors. As you learn about concepts related to sexuality and sexual function, you will be challenged to confront and set aside your own biases to comfortably and competently address your clients' sexual health needs.

SEXUAL AND REPRODUCTIVE ANATOMY AND PHYSIOLOGY

The role of the reproductive system in human life extends far beyond its basic function of producing children. It influences body image, sexual desire, and sense of sexual identity. The first step in exploring human sexuality is to understand the basics of reproductive anatomy and physiology.

Female Reproductive Organs

The female reproductive system consists of a pair of ovaries and fallopian tubes, the uterus, vagina, and external genital tissues (Fig. 33-1). **Ova** (eggs) are produced in the ovaries and travel through the fallopian tubes to the uterus. If fertilization occurs, the embryo embeds in the wall of the uterus for further development.

The **vagina** is a muscular tube that receives sperm during sexual intercourse, allows the exit of menstrual flow if fertilization does not occur, and serves as a birth canal at the end of pregnancy.

The external genitalia and the mons pubis are a source of pleasurable sensations. The **mons pubis** is a pad of fatty tissue over the symphysis pubis. It is covered with coarse hair and contains sensitive nerve endings. The external genitalia, or **vulva**, consist of the clitoris, labia majora, labia minora, Bartholin's glands, urinary meatus, and vaginal introitus. The **clitoris** contains erectile tissue, blood vessels, and nerves. It is extremely sensitive and reacts to pleasurable stimuli. The **labia minora** also engorge and become sensitive during sexual stimulation. External genital organs, such as the clitoris, are protected by the **labia majora**.

The breasts are important to female sexual arousal; in fact, some women can be brought to orgasm solely by caressing the breasts and nipples. The mammary glands, enclosed within the breasts, are also part of the reproductive system. Their function is to produce milk to provide nourishment for an infant after birth.

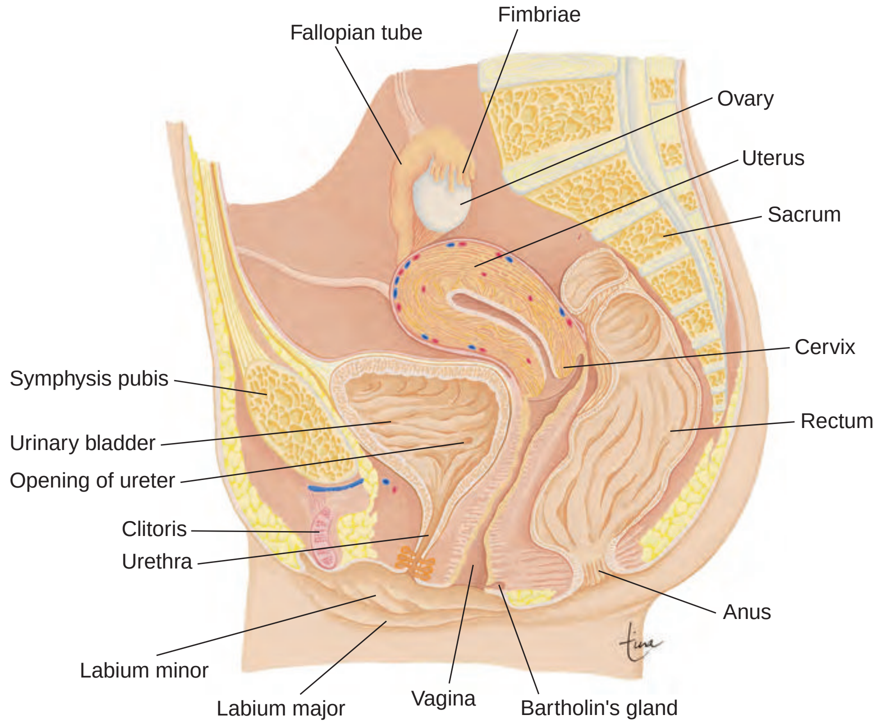

FIGURE 33-1 The female reproductive system.

The Menstrual Cycle

Menstruation begins with puberty and involves hormone changes that prepare the body for pregnancy. The phases of the menstrual cycle are triggered by hormonal changes (Fig. 33-2).

Menstrual Phase Menstruation usually lasts 3 to 7 days, averaging 5 days. During this phase, the uterus sheds the endometrial lining and several ovarian follicles develop. Follicle-stimulating hormone (FSH) from the anterior pituitary gland begins to increase during this phase, leading to a rise in estrogen levels.

Follicular Phase This phase begins on the first day of menstrual bleeding and is associated with growth of ovarian follicles and regrowth of the endometrium of the uterus. This phase ends with **ovulation**, or release of the ovum from the mature follicle, around day 13 or 14 of the menstrual cycle. Luteinizing hormone (LH) levels from the anterior pituitary gland rise, as does the estrogen level.

Ovulatory Phase A surge in LH and FSH occurs, lasting about 16 to 36 hours. The follicle then ruptures and the egg is released for fertilization. Estrogen peaks and progesterone rises, which stimulates growth of the endometrium.

Luteal Phase If fertilization occurs, the endometrium thickens to support an embryo. The pregnancy hormone, called chorionic gonadotropin, is produced. Pregnancy tests are based on detecting levels of this hormone. If fertilization does not occur, progesterone levels drop, and menses begins.

Male Reproductive Organs

The male reproductive system consists of the testes and a series of ducts and glands that transport sperm. Sperm are produced in the testes and transported through the epididymis, ductus deferens, ejaculatory duct, and urethra (Fig. 33-3). Along the path, the reproductive glands (seminal vesicles, prostate, and bulbourethral glands) add secretions that mix with the sperm to produce semen.

The penis functions in the urinary system to transport urine from the bladder to the outside of the body. It also has important functions in the reproductive system. Within the penis are three sections of erectile tissue: the corpus cavernosum and sections of corpus spongiosum above and below the urethra. During sexual arousal these erectile tissues fill with blood, making the penis erect. **Ejaculation** (the expulsion of semen) is brought about by peristalsis of the reproductive ducts and contraction of the prostate and muscles of the pelvic floor. With each ejaculation, approximately 100 million sperm cells are expelled in 2 to 4 mL of semen.

KnowledgeCheck 33-1

- Identify the major structures of the female reproductive system.
- Summarize the phases of the menstrual cycle.
- Identify the major structures of the male reproductive system.

SEXUALITY

What do you think of when you see the term *sexuality*? What images come to mind? The World Health Organization (WHO) notes that "sexuality is experienced and

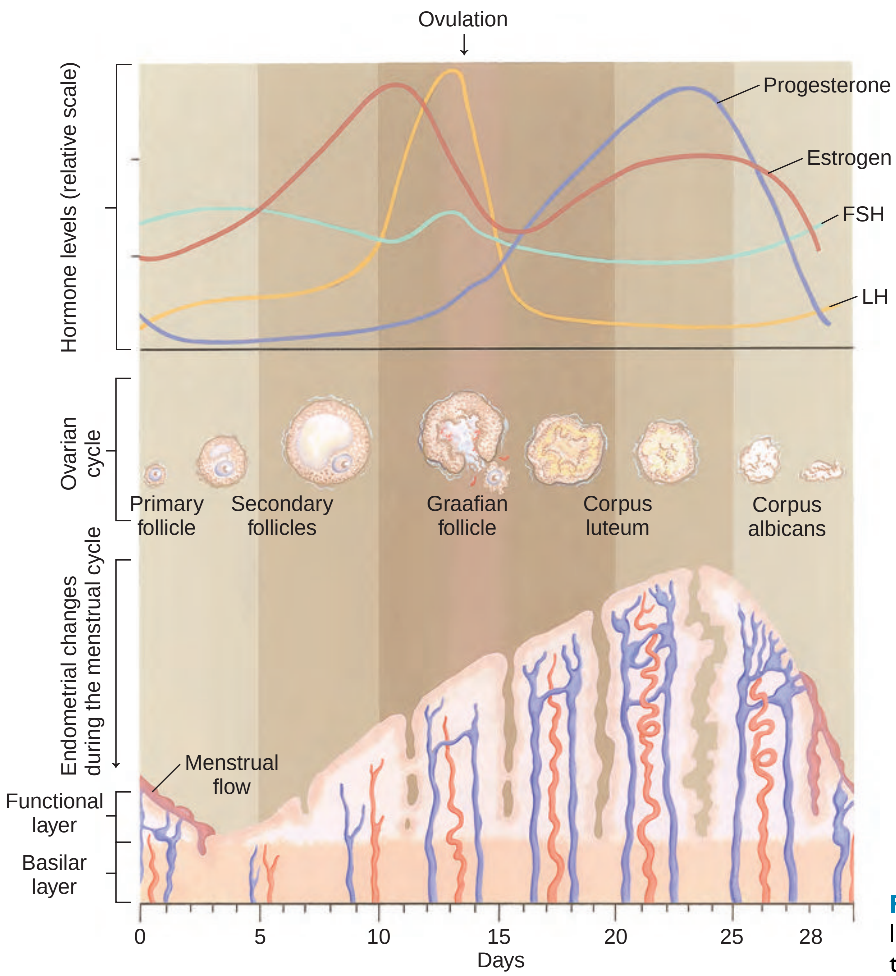

FIGURE 33-2 The menstrual cycle. Hormone levels and endometrial thickness throughout the cycle are shown.

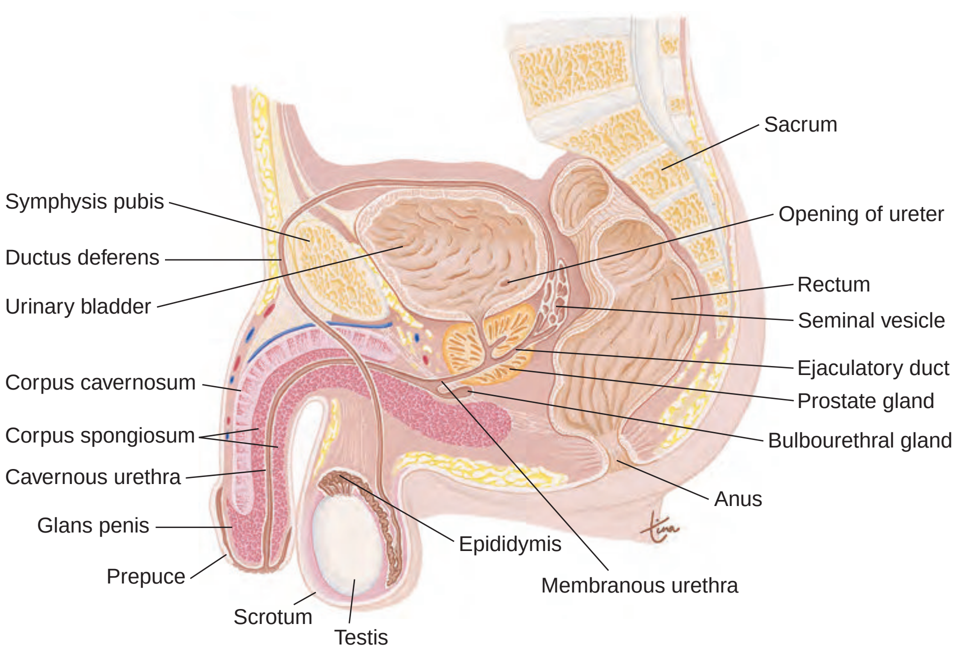

FIGURE 33-3 The male reproductive system.

expressed in thoughts, fantasies, desires, beliefs, attitudes, values, behaviors, practices, roles and relationships." **Sexuality** is recognized as a "central aspect of being human throughout life and encompasses sex, gender identities and roles, sexual orientation, eroticism, pleasure, intimacy and reproduction" (WHO, 2006, updated 2010). **Sexual identity** is a person's perception of his or her gender, gender identity, gender role, and sexual orientation. All of these are also a part of the person's overall self-concept (see Chapter 13 to review self-concept).

What Is Gender?

People often think of *sexuality* as a synonym for *sex*. This is inaccurate. In fact, even the word *sex* has multiple meanings. For example, *sex* is used to describe intimate pleasurable activity (e.g., "We had sex yesterday") or to indicate whether an individual is male or female (e.g., "What sex is your baby?"). In this chapter, we use the term **gender** to indicate biological sex status (male or female) and follow the World Health Organization's definition of sexuality.

Gender is determined at the moment of conception, when an ovum is fertilized by a sperm. The ovum always provides an X chromosome, whereas the sperm may contribute either a second X chromosome, which results in a female offspring, or a Y chromosome, resulting in a male offspring (Fig. 33-4).

Gender Roles

Gender roles are the societal norms for gender-appropriate behavior. During the 1950s, the media portrayed the father in a suit who went off to work to support his family. Mother, in her apron, spent the day cooking, cleaning, and caring for her perfect children and devoted husband. Even then, many Americans did not identify with this stereotype, and today it may seem unreal. But many of these values remain embedded at some level within our contemporary culture (Fulcher & Coyle, 2011).

Historically in Western culture, people expected men to be strong and control their feelings, and women to be gentle and express their feelings. Boys received positive reinforcement for "masculine" behaviors, such as competitiveness, and ridicule or teasing for showing emotions or being passive. In girls, "feminine" behaviors, such as passivity and cooperation were reinforced, whereas assertiveness was often labeled as unacceptable aggression. In the past 50 years, expectations regarding gender roles have changed and expanded. Women now perform jobs formerly thought to be "for men only" (e.g., physician, police officer) and men are active in professions once dominated by females (e.g., teaching, nursing).

Today, many parents encourage some **androgyny** in their children. The word *androgyny* is a combination of the Greek words for male, *andro,* and female, *gyn.* By one of its definitions, *androgyny* refers to a blending of traditional masculine and feminine roles. It means that everyone has some skills, traits, and behaviors that may be classified as "masculine" and some that may be "feminine." Androgyny is a positive trait in that it gives an individual greater adaptability in life situations.

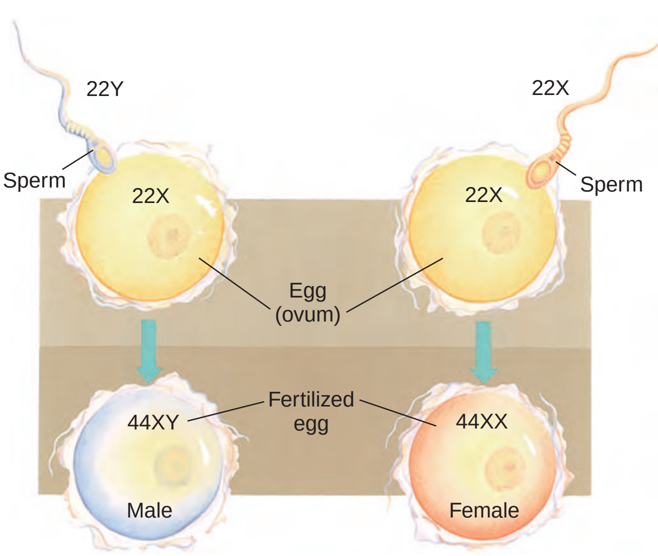

FIGURE 33-4 The woman provides the X chromosome, and the man may contribute either a second X chromosome, which results in a female offspring, or a Y chromosome, resulting in a male offspring.

ThinkLike a Nurse 33-1

- Provide at least three examples of nonconformity to traditional gender role expectations.
- As a parent, how might you encourage androgyny in your children, if you wished to do so?

Gender Identity

Gender identity, one component of sexual identity, is the image we have about ourselves as a man or woman. It is an internal experience: whether we "feel like" a woman or a man. However, when a person forms a gender identity that is not the same as their biological gender, he or she is considered **transgendered** (or "differently gendered"). The *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* replaced the concept of gender identity disorder with gender dysphoria and emphasizes that gender nonconformity is not a mental disorder (American Psychiatric Association [APA], 2013a).

Key Point: ***You should understand the numerous and different terms associated with the concept of "transgender" to provide nonjudgmental and appropriate care (e.g., transsexual, intersexed, transvestite, heterosexual, homosexual, or bisexual) (Dickinson, Cook, Playle, et al., 2012; Walsh, Barnsteiner, De Leon Siantz, et al., 2012).***

- **Transsexuals** are people who identify with the opposite gender from their biology—for example, a person with the physical appearance and reproductive organs of a woman who "feels" and perceives herself to be a man. It is common for transsexuals to express dissatisfaction with their gender at an early age. They may insist that they will grow up to be the opposite gender. Their preference for dress and play is typically those of the other gender.

- **Preoperative transsexuals** are adults who alter their physical appearance through dress, makeup, and/or the use of hormones so that their external appearance corresponds to their gender identity. After extensive counseling and successfully living in the opposite gender role for a period of time, they may decide to undergo surgery to reconstruct their external genitalia and remove the reproductive organs of the biological birth gender. After sex reassignment surgery, the **postoperative transsexual individual** legally changes gender. In an inpatient facility, during the perioperative period, assignment to a single room is more appropriate.
- **Intersexed** people (formerly referred to as **hermaphrodites**) are born with ambiguous sexual organs. For example, the person may have female internal organs (ovaries, a uterus), but enlarged clitoral tissue resembling a penis. Initially, a developing embryo is in an **undifferentiated sexual state—**neither male nor female until about the seventh week of pregnancy when the gonads form into either testes or ovaries. A mutation of any of the genes involved in sexual differentiation or an alteration in hormonal secretion may result in altered genitalia. Parents must decide whether to have the child undergo surgery to make the assigned sex consistent with the physical appearance or to delay assignment and allow the child to choose at a later time.
- A **transvestite** (or **cross-dresser**) is a person (male or female) who occasionally or frequently wears the clothing characteristic of the opposite sex, particularly the under-garments, as a form of sexual expression. The person often carries out this behavior in secret. Cross-dressers may be heterosexual, homosexual, or bisexual (see the next section, What Is Sexual Orientation?).

Do you believe that androgyny is a positive attribute? Explain your thinking.

What Is Sexual Orientation?

Sexual orientation refers to the general tendency of a person to feel sexually attracted to people of a certain gender. Because most people in Western culture are thought to be **heterosexual** (sexually attracted to members of the opposite sex), heterosexuality is the predominant cultural expectation. However, in the mid-20th century, the research of Alfred C. Kinsey indicated that a population's sexual orientation falls on a bell curve, with the majority of people experiencing at least some attraction to people of the same gender (Kinsey 1948, reprinted 1998). Kinsey theorized that society influences people to sublimate homosexual feelings and choose exclusively heterosexual relationships.

Klein, Sepekoff, and Wolf (1985) described sexual orientation as an ongoing dynamic process, with people's gender-based inclinations changing over time. In truth, we do not fully understand what makes up sexual orientation or how it develops. With increasing research on the biological aspects of sexual orientation, more professionals are concluding that people come to "recognize" the object of their sexual desire rather than "choose" or "prefer" it. Therefore, "sexual orientation" is probably a more accurate term than "sexual preference."

Heterosexuality

Heterosexuals are people who are sexually and emotionally attracted to members of the opposite sex. In informal conversation, people may refer to this segment of the population as *straight*. Many major religious traditions reinforce heterosexual behaviors and gender roles. Although some heterosexuals have had same-gender sexual thoughts or limited experiences during childhood, adolescence, or adulthood, they still consider themselves heterosexual and have relationships with people of the opposite gender.

Homosexuality

The focus of sexual attraction for **homosexuals** is a person of the same gender. Homosexuals may be referred to as *gay* men and *lesbian* women. Accurate prevalence statistics are difficult to obtain because most of the studies rely on self-report data. Homosexuality is not an aspect of the dominant culture and is prohibited by some religions. As a result, there has been significant discrimination against homosexuals. It can be difficult for gays and lesbians to share this aspect of their lives with employers, colleagues, family, and friends, as well as with researchers and pollsters. Some homosexuals openly acknowledge to both self and others that they are gay, while others hide their sexual orientation from family, friends, employers, and people in their communities.

Bisexuality

A person who is **bisexual** is sexually and emotionally attracted to both males and females. This group is perhaps least understood and least accepted by both the heterosexual and homosexual communities. They are less likely to be found in long-term monogamous relationships and often experience feelings of isolation. However, some bisexuals maintain stable and satisfying marriages because of their sustained sexual attraction to and amiable relationship with their spouse and the importance they place on parenting. Compatibility within the marriage depends on the partner's acceptance of the bisexual spouse's sexual orientation and sexual relationships outside the marriage, if any.

How Does Sexuality Develop?

We are sexual beings from birth to death. Expression of our sexuality evolves through the life span. If you require additional discussion on sexuality and developmental stages,

Go to Chapters 9 and 10, **Expanded Discussion,** on Davis*Plus*.

Birth Through Preschool

Beginning at birth, parents, caregivers, and others respond to the infant with preconceived thoughts of what that gender role entails. The first 2 years of life can be highly sensual; as infants are nursed, stroked, bathed, and massaged, they develop their first attachment experience through bonding with the parent or caregiver (Fig. 33-5). It is not unusual for children in this age group to touch their genitals and enjoy being nude. This behavior is part of their exploration of their bodies and is a normal part of child development. By age 3, most children recognize gender differences and know the names of body parts. Toddlers are interested in their bodies and curious to see the genitals of others.

FIGURE 33-5 Parent–infant attachment occurs through daily contact and care through activities such as feeding, bathing, and holding.

By age 5, children mimic adults by holding hands or hugging. Adults, who find these actions amusing or endearing, frequently reinforce such behaviors. Young children also may practice getting married, playing house, or playing doctor. It is not unusual for preschool children to masturbate and ask questions about "where babies come from." Parents should give factual answers without offering explanations beyond what the child asks.

School Age Through Puberty

The school-age child strongly identifies with the same-sex parent and has mostly same-sex friends. Through interaction at home, school, and other activities, children gain awareness of gender roles and emerging gender identity.

From age 8 to 12, the child is in transition between childhood and puberty. Secondary sex characteristics become apparent. In females, breast buds form, and pubic hair appears. For a significant number of girls, **menarche** (beginning of menstruation) occurs. Boys become more muscular, the voice deepens, hair in facial and axillae develop, and the genitals begin to increase in size. The first attraction, either heterosexual or homosexual, may occur during this stage, and the child may begin to masturbate more frequently, but privately. For information on the Tanner stages of sexual development in boys and girls,

Go to Chapter 22, **Procedures 22-17** and **22-18,** in Volume 2.

Many school-age children are curious and may ask explicit questions about sexual activity, reproduction, and sex roles. Parents and nurses should answer with facts and follow up with age-appropriate printed material. When children reach age 10 to 12, parents should begin teaching them basic information about approaching body changes, menstruation, sexual intercourse, and reproduction.

Adolescents

Adolescence is a time of heightened sexual interest and activity. There are two reasons for this: (1) the hormonal changes accompanying puberty and (2) the culture's emphasis on sex. Masturbation is common. It is a safe and comforting sexual activity that has neither interpersonal nor disease risks. However, some adolescents may encounter parental, cultural, or religious disapproval of masturbation.

Sexual exploration usually begins with kissing, moves on to fondling, and can lead to genital contact. This progression may occur over a period of years, or there may be an early initiation of oral, vaginal, or anal intercourse. In 2011, 47% of teenagers in U.S. high school students surveyed had engaged in sexual intercourse (Centers for Disease Control and Prevention [CDC], 2012a). However, the birth rate for adolescents and teenagers reached a record low in 2011 (CDC, updated 2013a). The incidence of oral sex is increasing in U.S.

youth. Two-thirds of youths between the ages of 15 and 25 have engaged in oral sex (Copen, Chandra, & Martinez, 2012). Many teens believe that this behavior allows them to maintain their virginity and incorrectly assume that it carries no health risks. Sexuality education in the home and school dispels myths and prepares teens for adult roles. To make informed choices as they move toward adulthood, adolescents need information about body changes, interpersonal relationships, **contraception** (birth control), and preventing **sexually transmitted infections (STIs)**.

To review physical changes of adolescence, see Chapters 9 and 22.

Young Adults

Not so many years ago it was generally assumed that young adults would abstain from sexual intercourse until marriage. The husband and wife would then become sexually active and start a family. Today, the age of first marriage is higher than in previous decades and young adults engage more openly in sexual activity outside of marriage. Many young adults practice **serial monogamy**, in which the partners are mutually faithful but make no lifelong commitment. When the relationship ends, each partner usually enters another monogamous relationship.

During early adulthood, people define their sexual identity and resolve issues related to their sexual orientation and self-concept. As a part of sexual maturity, they develop an intimate relationship in which there is both communication and respect. Many people find a life partner during this period and make long-term plans, which often include parenting. However, some adults continue to struggle with their sexual identity, sexual orientation, or ability to form or commit to intimate relationships.

Young adults often wonder whether their sexual behaviors and responses are normal (e.g., "How often do most people have intercourse?" "Do other women have an orgasm every time they have sex?"). Many still need information about birth control, prevention of STIs, and relationship and communication issues.

Middle Adults

Adults in the middle years experience life changes that may enhance physical and emotional intimacy. For many parents, their children are now young adults who no longer rely on parental support, and they have more privacy and time to spend together. However, new stressors may arise. In times of economic downturn, for example, middle-aged adults are also one of the groups most seriously affected. In addition, this may also be a time when physical changes and chronic diseases emerge that could affect sexual patterns.

Female Transitions Women transition through **menopause** (cessation of menstruation), a process that varies widely. Some are relieved that the prospect of childbearing has ended, while others may mourn the loss of the ability to give birth. Normal physiological changes include decreased vaginal secretions and vaginal wall thinning that result from decreased levels of estrogen and progesterone. These changes may result in painful intercourse and decrease a woman's desire for sexual activity. Some women also experience hot flashes, sleep disturbances, and mood changes.

Male Transitions As a result of the aging process or health conditions (e.g., type 2 diabetes or hypertension), men may experience erectile difficulty. They may perceive this problem as a threat to their masculinity and sexual attractiveness, and their self-image may suffer. Men also experience a decrease in the sex hormone testosterone. Many men remain fertile into old age, although sexual desire and the ability to achieve and maintain erection decrease gradually with aging.

It may be a challenge for you to view middle adults as individuals who engage in and enjoy sexual relations. Patients of this age may remind you of your parents and thus it may be difficult for you to see them as persons who have sexual relationships. Holistic nursing care requires you to assess and formulate strategies to address their sexual concerns.

Aging Adults

Most older adults are sexually active and regard sexuality as an important part of life. Little evidence exists to support the premise that age-related changes result in decreased sexual relationships (Delamater, 2010). A substantial number of men and women engage in vaginal intercourse, oral sex, and masturbation even in their 80s and 90s (Delamater, 2010; Lindau, Schuman, Laumann, et al., 2007; Taylor & Gosney, 2011). You should recognize that older adults have sexual needs (e.g., reassurance from a sexual partner or sexual stimulation) and sexual problems (e.g., lack of closeness).

Sexual problems are more likely to result from failing physical health and medication side effects than from age alone. For example, as noted earlier, men with diabetes are more likely to have difficulty achieving and maintaining an erection. Other obstacles for sexual expression are lack of a partner (especially for women) and lack of privacy (e.g., for those who live with family members or in a long-term care facility) (Bauer, McAuliffe, Nay, et al., 2013).

As a result of age-related changes, postmenopausal women report less sexual stimulation and reduced desire, so they tend to need more foreplay and direct clitoral stimulation for sexual enjoyment. They may have fewer orgasms or orgasms that are weaker in intensity. Nevertheless, some women "rediscover" sexual desire after menopause.

Older women may complain of loss of vaginal lubrication and experience pain during intercourse, caused by vaginal thinning and dryness. You can help your patients by suggesting water-soluble lubricants to counteract vaginal dryness and enhance pleasurable sensations during sexual activity.

Some men report erectile difficulty and need more time and more direct genital stimulation to achieve erection. It may take longer to ejaculate, and the orgasmic contractions may be less intense. When penetration is not possible (e.g., because of male erectile dysfunction), many couples find satisfaction with alternate forms of sexual stimulation and expression.

In the past, many healthcare providers have hesitated to offer sexual counseling out of fear that such intimate discussion might offend their patients. Older adults may also hesitate to discuss their sexual problem with healthcare providers unless encouraged to do so. You should address the topic as you would any other area (e.g., "We have discussed your medical needs and your dietary needs; let's now discuss your sexual needs"). Once you introduce the subject and people feel comfortable, they are usually eager for advice and solutions (American Geriatric Society Foundation, updated 2012).

You can help aging clients to understand that sexual feelings do not necessarily disappear with age, and sexual expression need not stop (Fig. 33-6). For example, sexual expression may include hugging, caressing, oral sex, and mutual manual stimulation. In addition, you may suggest ways to adapt coital positions to accommodate bodily changes, for example, when a partner is obese or has joint immobility.

What Factors Affect Sexuality?

Culture, religion, lifestyle, sexual knowledge, and physical health all influence our attitudes toward sexuality, sexual behaviors, and intimate relationships. This section will help you begin to broaden your understanding of the key concepts of sexuality and sexual health to provide nonjudgmental, holistic care to people who have a wide range of values, lifestyles, and states of well-being.

Culture

Culture influences our ideas about gender role, gender identity, marriage, sexual expression, and social responsibilities. However, it is not unusual for people to be **ethnocentric**—that is, to see their own culture and sexual behaviors as the norm for all. Because the United States is a multicultural country, beliefs and practices related to human sexuality vary widely. Consider the following examples of cultural influences:

- Puritan and Victorian-era legacies have influenced many European Americans, some of whom consider sex to be "not nice," particularly if engaging in certain sexual activities or positions.
- African Americans are influenced by the dominant Anglo-Saxon culture, their African heritage, history in America, and current economic and social situation. Marriage rates for blacks are lower than for other ethnic groups, in part because of economics, an unequal gender ratio (84 males per 100 females), and cultural acceptance of single parenting (Hummer & Hamilton, 2010; Hyde & DeLamater, 2010).
- Many Latinos have strong ties to the Roman Catholic Church and a tradition of rigidly defined gender roles. The norm in Hispanic culture is for the male to be given more freedom as a child, but he is expected to be a virile, responsible provider for his family as an adult. In contrast, the female is typically raised to be more passive and obedient throughout her life.
- Asian Americans and Muslim Americans tend to be the most sexually conservative of the major U.S. cultural groups.

Culture determines what is acceptable and what is not. In some societies, **polygamy** (marriage to more than one partner) may be acceptable. Another culture may permit or prohibit sexual play among children. Many cultures have special rites of passage at puberty, such as the Jewish bar mitzvah for boys and bat mitzvah for girls, or the Native American vision quest.

Generally, you should honor cultural practices unless they are harmful. An example of a harmful practice is female genital mutilation (formerly known as **female circumcision**), which is illegal in most countries but is still performed among certain tribes. In this procedure, the labia majora, labia minora, and clitoris are excised, and/or the vagina is sutured closed (**infibulation**). Infibulation may be done to ensure that the girl remains a virgin, whereas clitoral excision is meant to reduce sexual desire and ensure that the woman remains faithful to her husband. In addition to its psychosocial consequences, the procedure carries a high risk of infection and can cause the development of scar tissue that makes vaginal birth impossible. The U.S. Congress passed a law in 1996 making female genital mutilation for girls younger than 18 a federal offense. The World Health Organization in 1997 and again in 2010, with the support of the United Nations, issued statements to abolish the practice of female genital mutilation (WHO, 2010, updated 2013).

Religion

Religion also has a powerful influence on sexuality. Religious practices restricting premarital sex, birth control, homosexuality, abortion, extramarital relationships, and masturbation are common. Some religions restrict opposite gender healthcare providers and have rules about body coverings and modesty. Even education about the structure and function of the human body is governed by some religions. The "sexual revolution" that began in the 1960s has led to permissive sexual values in the broader Western culture. When these values conflict with a person's traditional religious values, anxiety and sexual dysfunction may result. To review the influence of religion on health, see Chapter 16.

ThinkLike a Nurse 33-4

How have religion and culture influenced your views on sexuality?

Lifestyle

Life experiences encompass our interactions with others and the environment. Family, socioeconomic status, employment factors, and interpersonal relationships shape our lifestyle, although they do not fully determine it. Consider the following examples:

- Having a beloved brother reveal to you that he is gay might alter your perception of homosexuality. Similarly, being raised by a same-sex couple might affect your view of gender roles.
- Growing up in a low-income neighborhood in which prostitution is a visible and accepted part of the environment might influence your views on acceptable sexual behavior.
- Dedication to a high-stress job or family demands might leave you too exhausted to desire sex with your spouse.
- Being in an abusive relationship would affect how you feel about yourself and might cause you to avoid intimacy in the future.

Lessons learned through day-to-day experience create powerful impressions on our views and often modify cultural and religious influences.

Sexual Knowledge

Although sexuality and family life are part of the curriculum in many public schools, you cannot assume that young adults have adequate sexual knowledge. Community values play a large role in determining how sexuality is viewed and taught. Thus, even if a state mandates sex education, a particular school may limit discussion on reproduction, STIs, birth control, intimacy, exploitive relationships, domestic abuse, or rape, believing that these topics are best addressed by the family or church. In addition, many children are home-schooled or taught in private or church-affiliated schools that do not allocate any class time to sex education. Even in schools with a comprehensive curriculum, parents have the right to exclude their child from sex education classes. Do not let your clients' age, level of education, or life experiences lead you to make assumptions about their knowledge of sexuality. For example:

- A married person may not be sexually active.
- A woman with several children may not know what is involved in a pelvic exam or how conception occurs.
- A highly educated person may be uninformed regarding his body structure and function.

It is difficult for most people to admit to a professional that they lack knowledge. Therefore, you must assess each client's knowledge and understanding of sexual terms. At times you may need to use the vernacular or "street" terminology to be understood. You can then introduce medically specific terminology.

KnowledgeCheck 33-5

- What sexual knowledge would you expect an adult male with children to have?
- What sexual knowledge would you expect a nursing student to have?

Health and Illness

Sexuality involves body, mind, and spirit so it is not surprising that health status affects sexuality. For example, healthful nutrition and physical exercise are commonly reported to increase satisfaction in sexual relationships, whereas obesity and inactivity can undermine one's own feelings of attractiveness or one's attraction for one's partner. The importance of sexuality is readily apparent in the clinical setting. For example, the clients in the Meet Your Patients scenarios all expressed concerns related to their sexuality.

Physical Illness

Diseases, injuries, and medical treatments may demand lifestyle changes in multiple areas, including sexual functioning.

- ***Heart disease or respiratory disease*** may cause people to restrict sexual activity because of fatigue, dyspnea, or fear of overstressing the heart.
- ***Diabetes mellitus*** leads to neurological changes that may cause male erectile dysfunction; women may experience vaginal dryness and loss of orgasmic

ability. In addition, vaginal yeast infections are common with diabetes, causing itching and painful intercourse.

- *Cancer* may be accompanied by body image changes, fatigue, treatments that create nausea, and fear of death—all of which may lead to feeling unattractive, with a reduced desire for sexual activity.
- *Spinal cord injury* may make it impossible for the person to feel physical stimulation. Depending on the level of the injury, the person may or may not experience psychogenic or reflexogenic genital arousal. Some men may be able to achieve erection and ejaculation and are fertile; others may have no genital response.

Surgeries

Surgery may alter a person's body image. At the least, surgery leaves a physical scar. At worst, it removes a body part or creates other disfigurement. When the surgery involves body parts important to sexual functioning (e.g., a breast, a testicle), the effect is even more likely to be negative. Some people may avoid sex because of sexual esteem issues (e.g., feeling unattractive, concern about partner's reaction). This may be especially true after a hysterectomy, mastectomy, orchiectomy, prostatectomy, or colostomy (or other ostomy).

- *Hysterectomy* (surgical removal of a uterus) may enhance the sexual experience if it relieves pain and bleeding that were present before surgery. In contrast, some women report difficulty becoming aroused or having less intense orgasm after hysterectomy. These problems may be related to trauma to nerves in the pelvic area, to the absence of uterine contractions during orgasm, or to anxiety because the woman's gender identity is tied to childbearing.
- *Mastectomy* (surgical removal of a breast) can have a significant influence on a woman's self-esteem and negatively impact sexuality. Research found that among sexually active women, body image problems were related to breast reconstruction, fertility, hair loss from chemotherapy, weight gain or loss, and a partner's difficulty understanding one's feelings (Katz, 2011).
- *Prostatectomy* (removal of the prostate gland, usually to treat prostate cancer) may be accompanied by erectile and other sexual dysfunction.
- *Orchiectomy* (removal of the testicle) is usually performed for testicular cancer. Males can experience infertility, which is associated with loss of self-concept, sexual identity, and intimacy (Bradford, 2012).
- A *colostomy* is a surgical procedure that brings a portion of the colon through a surgical opening in the abdomen (see Chapter 29 for review). The patient must usually wear a pouch, in which to expel feces. Ostomy surgery profoundly impacts sexuality. Patients with ostomies often experience body image difficulties; loss of desire for intercourse; fears about leakage, noise from flatulence, and pain; and concern about how their partners will react (Schuler, 2013).

If a person becomes disabled while in a marriage or other committed relationship, the strain can threaten the relationship. In contrast, a person who is single or has a lifelong disability may experience difficulty establishing an intimate relationship because of physical limitations, social isolation, poor self-image, or discrimination. A need for intimacy still exists even when people lose interest in sexual activities. Communication about sexual needs and desires may be difficult for couples, but as a nurse, you can support and facilitate discussions of your patients' concerns. Holistic rehabilitation programs may offer comprehensive services and promote discussions regarding sexuality and relationship issues.

Mental Health Disorders

Psychiatric disorders can lead to interpersonal disruptions and difficulty with sexual expression.

- A depressed person experiences significant loss of interest in activities that previously brought pleasure. Thus it is common for people with depression to avoid engaging in interpersonal activities, including sex.
- Conversely, a person with hypomania or mania may be preoccupied with pleasurable activities and increased sexual activity, as well as verbalization and acting out. Both extremes are disruptive to a relationship.
- For a person with psychosis, interpersonal relationships and sexual patterns are disrupted by lack of contact with reality or frank delusions.

Counseling for the couple is important when symptoms are controlled. During times of acute illness, it is vital that the partner have medical and psychological support.

Medications

Many medications used to treat health problems have unwelcome sexual side effects. Gabriel Thomas (Meet Your Patients) clearly illustrates the concern some clients have about commonly prescribed medications. Table 33-1 lists a number of drugs and their effects on sexual function.

Medications may be prescribed to enhance sexual function, particularly for men experiencing erectile dysfunction (ED), for example, those with diabetes mellitus or who are taking beta-adrenergic blocking agents to treat high blood pressure. Three oral drugs are available for impotence: sildenafil, vardenafil, and tadalafil. These drugs generally work within 1 hour of administration, but have no effect without sexual stimulation. They increase blood flow to the corpus cavernosum of the penis.

Medications used to treat ED should be used with caution in patients with cardiovascular disease because of its vasodilation effects and is contraindicated in patients receiving nitrate drugs. You should conduct a careful medication history and conduct the appropriate patient teaching.

Table 33-1 ➤ Effects of Drugs on Sexual Function

MEDICATION	POSSIBLE EFFECT
Alcohol	In limited quantities, alcohol may enhance desire and function. However, heavy or chronic use may lead to decreased libido, orgasmic dysfunction, and erectile dysfunction.
Anti-anxiety agents	Decreased libido, delayed ejaculation
Anticonvulsants	Decreased libido, prolonged painful erections, difficulty achieving orgasm
Antidepressants	Decreased libido, difficulty achieving orgasm Bupropion (Wellbutrin) and trazodone (Desyrel) are least likely to cause sexual side effects.
Antihistamines	Decreased libido, decreased vaginal lubrication
Antihypertensives	Decreased libido, erectile dysfunction, delayed ejaculation Calcium channel blockers are least likely to cause sexual difficulties.
Chemotherapy	Fatigue, decreased libido
Opioids	Decreased libido, erectile dysfunction
Stimulants (cocaine, methamphetamines)	Initially stimulants cause increased intensity of the sexual encounter; however, with continued use, sexual dysfunction develops.

KnowledgeCheck 33-6

- Identify four factors associated with physical illness that may affect sexuality or sexual functioning.
- What determines our sexual attitudes?

SEXUAL HEALTH

The World Health Organization defines **sexual health** as "a state of physical, emotional, mental, and social well-being related to sexuality; it is not merely the absence of disease, dysfunction, or infirmity. Sexual health requires a positive and respectful approach to sexuality and sexual relationships, as well as the openness and opportunity to have pleasurable and safe sexual experiences, free of coercion, discrimination, and violence. For sexual health to be attained and maintained, the sexual rights of all persons must be respected, protected, and fulfilled" (WHO, 2006, updated 2010). To promote sexual health effectively, you will need theoretical knowledge about sexual responses, modes of sexual expression, and problems affecting sexuality.

ThinkLike a Nurse 33-5

Examine your own beliefs about sexuality. Identify areas of concern you have regarding sexuality. How do you think this will affect your ability to assist patients with sexual health concerns?

What Is the Sexual Response Cycle?

The **sexual response cycle** is the sequence of physiological events that occur when a person becomes sexually aroused. Based on research conducted in the 1950s, Masters and Johnson (1966) identified a four-stage sexual response: excitement, plateau, orgasm, and resolution (Fig. 33-7). Some scholars have suggested that the stage of desire be added to the original Masters and Johnson model. In some people, desire can either precede or follow excitement (Basson, 2001, 2008).

Although it is most intense in the genitals, sexual response is a total body response, involving many physiological changes (e.g., increased heart rate, flushing). The emotional and mental aspects of sexual activity are equally important to the person's satisfaction. The body has many **erogenous zones** (areas that cause sexual arousal when stimulated): the genitals, the skin, lips, ears, breasts, buttocks, and thighs. Box 33-1 shows normal physiological changes in sexual response that occur with aging.

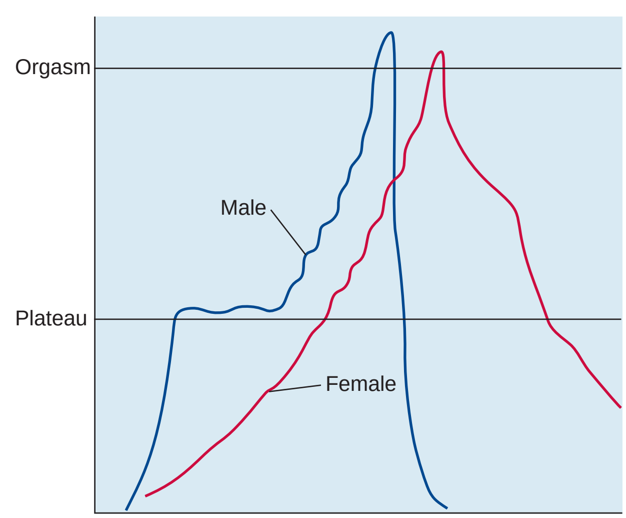

FIGURE 33-7 The sexual response cycle.

BOX 33-1 ■ Normal Physiological Changes in Sexual Response That Occur With Aging

Sexual Response Stage	Changes in Women	Changes in Men
Desire	Decreased libido	Decreased libido
Excitement and plateau	Delayed nipple erection	Delayed nipple erection
	Reduced labial separation and swelling	Delayed and less-firm erection
	Reduced vaginal expansion	Longer excitement stage
	Reduced lubrication	Decreased pre-ejaculatory emissions
	Decreased elevation of the uterus	Reduced muscle tension
	Reduced muscle tension	Reduced lifting of the scrotum and testes
	Reduced vaginal tone (in those who have had multiple vaginal deliveries); results in less stimulation during intercourse	Shorter phase of impending orgasm
		May require more direct stimulation to achieve and maintain an erection
Orgasm	Reduced spread of sexual flush	Shorter ejaculation time
		Fewer ejaculatory contractions
		Reduced volume of ejaculate
Resolution	No cervical dilation	More rapid loss of erection
		Longer refractory period
		Nipple erection lasts longer after orgasm

Desire

Desire is a stage of varying length characterized by an interest in sexual intimacy. Desire occurs in the mind and is communicated either verbally or through body language. This communication may be subtle and easily misread. In different cultures, behaviors meant to communicate desire may vary along gender lines. **Libido** is an individual's typical level of desire. Desire increases in proportion to the level of the sex hormones (e.g., a man with low testosterone is not as interested in sex). For women, desire reaches a peak each month near the time of ovulation, when estrogen levels are high.

In many people, desire is readily aroused by erotic stimuli, such as sights, sounds, and fantasies. However, research indicates that a majority of women and a minority of men do not experience desire until after they have become aroused; in these people, physical excitement prompts the desire for sex (Basson, 2001, 2008).

What is considered "sexual" or "attractive" can vary greatly, because societal, cultural, and personal values influence the range of stimuli that provoke sexual desire. Desire may last only moments or be ongoing for years. Transient sexual thoughts are fleeting moments of desire that might be triggered by exposure to sexually explicit media or erotic thoughts, words, or actions. Love and desire do not have to occur within a sexual relationship; this kind of example of desire can last for years.

Excitement

Excitement is the body's physical response to desire. During excitement the following bodily changes occur: Heart rate, blood pressure, and respiratory rate increase; muscles tense (**myotonia**); nipples become erect; and genital and pelvic blood supply increases (**vasocongestion**). In women, vasocongestion leads to vaginal lubrication, swelling of the breasts, rise of the uterus, and swelling of the labia and clitoris. In men, erection begins as the penis increases in length and diameter. The testes rise closer to the body, and the scrotum thickens.

Excitement may lead to further sexual activity, but this is not inevitable. For both sexes, the person may lose and regain initial physical excitement many times without advancing to the next stage. Excitement may be communicated verbally or through body language.

Plateau

If stimulation continues, the person reaches the **plateau** phase. Plateau is associated with continued increases in pulse, respiratory rate, blood pressure, and muscle tension. Some people flush around the face, neck, and chest in this phase. In women, the areolae become firmer, the clitoris retracts into the clitoral hood, Bartholin's glands lubricate, and the lower vagina swells and narrows. With a male partner, the vagina tightens around the man's penis, increasing his sexual stimulation. In men,

Toward Evidence-Based Practice

The sexual behaviors of older adults and the relationship between quality of life and sexuality in older adults is the subject of ongoing research.

Penhollow, T. M., Young, M., & Denny, G. (2009). Predictors of quality of life, sexual intercourse, and sexual satisfaction in older adults. *American Journal of Health Education, 40*(1), 13–22.

This study attempted to identify aspects of sexuality that have the greatest influence on sexual intercourse, sexual satisfaction, and overall quality of life of residents in a retirement community. Sexual self-confidence was found to be the single most important predictor of sexual intercourse and sexual satisfaction and (for women) quality of life. Cultural (sexual acceptance, sexual priority), psychological (sexual desire, sexual self-confidence, and control), and social factors (satisfaction in relationship and social life) help to explain sexual satisfaction beyond the physical health.

Syme, M., Klonoff, E., Macera, C., et al. (2013). Predicting sexual decline and dissatisfaction among older adults: The role of partnered and individual physical and mental health factors. *Journals of Gerontology Series B: Psychological Sciences and Social Sciences, 68*(3), 323–332.

Researchers measured the concept of sexual unwellness in adults 63 to 68 years of ages. The majority of adults (64.2%) were sexually active at least once a month to once a day or more. Fatigue symptoms, history of diabetes, and poor spousal health were associated with a lack of sexual satisfaction and inability to maintain the sexual relationship. Gender differences revealed that women were more likely to report a lack of sexual satisfaction, which was usually partner related. For males, spousal support and good spousal health decreased the risk of unsatisfactory sexual relations.

Doll, G. (2013). Sexuality in nursing homes: Practice and policy. *Journal of Gerontological Nursing, 39*(7), 30–37.

Administrators or social workers in 91 nursing homes responded to a survey regarding sexual expressions of residents in nursing homes and residential care facilities. Results revealed that residents engaged in sexual talk (85%) (e.g., sexually explicit language, verbal propositioning); demonstrated sexual acts (85%) (e.g., masturbation, fondling, intercourse); formed romantic relationships (66%); and showed implied sexual acts (60%) (e.g., reading pornography). The reactions of the nursing staff varied, from informing the supervisor (68.9%), trying to respectfully help the resident (51.1%), following the facility's policy (41%), ignoring the issue (27.8%) to panic (20%).

1. What trend in the research about sexuality in older adults do you see?

2. In the Penhollow study, what was the single most important factor influencing sexual satisfaction and quality of life, other than physical health? What additional factor was identified in the Syme study? What do you think nurses can do to promote it?

3. Based on these studies, how do you think nurses can affect the quality of sexuality in older adults?

Go to Chapter 33, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

the ridge of the glans penis becomes more prominent, pre-ejaculate (two or three drops of fluid) is emitted, and the testes rise closer to the body. The person may achieve, lose, and regain the plateau phase several times without experiencing orgasm.

Orgasm

Orgasm occurs at the peak of the plateau phase. At the moment of orgasm, the sexual tension that has been building is released. The heart rate, respiratory rate, and blood pressure reach their peak, and there is loss of voluntary muscle tone.

- *In women,* spinal cord reflexes cause powerful rhythmic contractions of the vagina, uterus, anus, and pelvic floor muscles; feelings of warmth spread through the pelvic area. The cervical canal dilates, allowing easy transport of the sperm to the uterus. Orgasm may last for a few seconds or up to nearly a minute.
- *In men,* spinal cord reflexes cause the urethra, anus, and pelvic floor muscles to contract followed by **ejaculation** (the expelling of semen through the urethra). For men, orgasm usually lasts no more than 30 seconds.

The intensity of orgasm varies among individuals and in each individual from one sexual experience to another. Orgasm may involve intense spasm associated with intense focus on the sexual pleasure, or it may be signaled by as little as a sigh or subtle relaxation.

Resolution

Resolution is the period of time following orgasm. The muscles relax, and the body returns to its pre-excitement state. Immediately after orgasm, men experience a **refractory period**, during which they cannot achieve an erection. The duration of this period varies among individuals and increases with age. Women experience no refractory period—they can either enter the resolution stage or return to the excitement or plateau stage immediately following orgasm.

KnowledgeCheck 33-7

Identify the phase of the sexual response cycle described.

- This phase is reached if there is ongoing stimulation. This stage may be achieved, lost, and regained several times without the occurrence of orgasm.
- This stage occurs in the mind and may be communicated between potential sexual partners either verbally or through body language.
- This phase is associated with the release of sexual tension.

ThinkLike a Nurse 33-6

Critique the theory of Masters and Johnson, as represented in the preceding discussion of the sexual response cycle. How would you respond to the statement that the theory does not adequately address variation among individuals and even within an individual's sexual response?

What Are Some Forms of Sexual Expression?

People express their sexuality and gain sexual satisfaction in different ways. Although opinions vary, a range of behaviors is socially acceptable and therefore considered "normal" by most people in our society. These behaviors are discussed in the next few sections.

Developing Intimate Relationships

Developing intimate relationships involves a willingness to take risks and offer trust. Intimacy involves openness, mutual respect, caring, commitment, protection, honesty, and devotion. Although we often think of intimate relationships as sexual, they are not necessarily so. Furthermore, in our society, many sexual relationships occur without intimacy.

Fantasies and Erotic Dreams

Most men and women have sexual fantasies. They may be related to past experiences, dreams, or desires; or stories heard, seen, or read. Sexual fantasies serve to increase self-esteem and sexual arousal and serve as an outlet to explore sexual desires. People in long-term monogamous relationships may fantasize to bring variety and excitement into a routine sexual encounter. Erotic dreams are also common among both men and women. Nocturnal orgasm may or may not occur with the dream.

Masturbation

Masturbation is self-stimulation of the genitals. Although there are many techniques, men typically hold and stroke the shaft of the penis, and women typically stimulate the clitoris manually. Young children touch their genitals as a part of body exploration, but they quickly learn either that touching certain areas is not acceptable or that it should be done in private. Adolescents, particularly males, may masturbate frequently. Adults may masturbate for sexual release when a partner is not available or for variety in a partnered relationship. Sex therapists often recommend masturbation as a means to resolve orgasm difficulties in women and ejaculatory problems in men.

Religious and social taboos discouraging masturbation are common. Some people mistakenly believe that masturbation is harmful, causing acne, warts, blindness, or insanity. More commonly masturbation is considered a "dirty," shameful, or perverted act. For example, former U.S. Surgeon General Joycelyn Elders retired after receiving some criticism for advocating masturbation as a method of safe sex.

Shared Touching

Mutual masturbation, or shared touching, may be an alternative to sexual intercourse. This is particularly appealing to individuals who seek to maintain their virginity, decrease the risk of STIs, or for those who have mobility or other physical problems that make intercourse difficult. Mutual masturbation is recognized as a form of safer sex because body fluids are not likely to be exchanged. This behavior can be satisfying because it allows for a significant level of sexual intimacy and for participants to experience orgasm.

Sexual Intercourse

Sexual intercourse and **coitus** are terms used to describe penile penetration of the vagina. People use a variety of positions for intercourse, depending on preference, mobility, cultural and religious influences, the relationship, and other personal beliefs. For some women, manual stimulation of the clitoris is also necessary to achieve orgasm. Partners typically do not reach orgasm at the same time, despite the romantic preoccupation with this phenomenon.

Unprotected coitus may lead to conception, so the couple should use some method of contraception if they want to avoid pregnancy. Because it involves exchange of body fluids, sexual intercourse may also lead to the transmission of infections. Using a lubricated condom decreases this risk, but it is not a foolproof measure to prevent STIs.

Oral–Genital Stimulation

Both heterosexual and homosexual couples practice oral–genital stimulation (oral sex). Couples in committed relationships may engage in it for sexual variety or as foreplay. Oral sex provides intimacy, without an unplanned pregnancy, and many believe that it does not affect their virginity status. For the latter reasons, oral sex has become prevalent among adolescents. Oral–genital contact may, however, lead to STIs.

Cunnilingus is the oral stimulation of a woman's genitals. **Fellatio** is stimulation of the male genitals by a partner's mouth. Although swallowing semen is not a health issue, it may be a matter of personal preference as to whether the recipient ejaculates in the partner's mouth. Dental dams, plastic wrap, or latex condoms can be used to prevent the transmission of STIs.

Anal Stimulation or Anal Intercourse

Both homosexual and heterosexual couples engage in oral–anal stimulation (called **anilingus**). Objects for sexual stimulation, or the partner's finger, tongue, and mouth, may be used to stimulate the anus. **Anal intercourse** (also termed *sodomy*) is the insertion of the penis into the partner's rectum. When a couple engages in anal intercourse, lubrication is essential to lessen the chance of tiny tears to the rectal mucosa or damage to the anal sphincter. A lubricated condom can be used to lessen the chance of STIs. The condom must be changed before vaginal penetration to avoid the transfer of *Escherichia coli* bacteria from the rectum to the vagina. Couples should follow the same precaution when using objects for sexual pleasure.

Celibacy

Celibacy, or abstinence, is a state in which an individual refrains from sexual activity. Traditionally, a celibate is a person who remains unmarried, often for religious reasons, and sublimates sexual desire through prayer, meditation, and service. There are numerous reasons a person may remain celibate:

- Fear of or lack of desire for intimate relationships
- Childhood sexual trauma
- A developmental or physical disability that limits opportunities for meeting prospective partners, limits privacy, or interferes with the ability to communicate or act on desires
- The desire to focus energies elsewhere because of a low libido.
- The need to regain balance after the loss of a relationship, whether through separation, divorce, or death.

Married couples may also be celibate and have a happy stable relationship. Others might be celibate after the loss of a relationship, whether through separation, divorce, or death, often feeling a considerable void.

Alternative Forms of Sexual Expression

The *DSM-5* (APA, 2013a) describes eight categories of sexual deviation or **paraphilias**: exhibitionism disorder, fetishism disorder, frotteurism disorder, pedophilia disorder, sexual masochism disorder, sexual sadism disorder, transvestic disorder, and voyeurism disorder. Some people may experience guilt, shame, and depression about their paraphilia, while others are distressed only by societal disapproval, restrictions, and possible criminal charges associated with their mode of expression. If you need more information about paraphilias,

Go to Chapter 33, **Supplemental Materials: Alternative Forms of Sexual Expression,** on Davis*Plus*.

Important things you can teach parents and other caregivers to do to reduce children's risk of sexual violence, predators, or other unhealthy exposure are contained in the Self-Care box Teaching Children About Predators.

Self-Care

Teaching Children About Predators

Set the Stage for Open Discussion

- Talk openly and directly with your child about her own development and sexuality. This establishes trust and makes it easier for the child to come to you when she has questions.
- Be open to your child's questions. Acting embarrassed discourages further conversation.
- Assure your child that she won't get in trouble for "tattling" on someone who asks her to keep a secret about sexual or touching encounters.
- Make discussion a natural part of growing up—don't save it "for later."

Know What's Going On

- Be involved in your child's everyday life and ask questions—that is, where he is, who he's with, what he's doing, what his closest friends are doing.
- Know the other adults your child is around. Go to your child's activities and get to know the adults involved.
- Know what he watches on TV, the iPod or iPad, the computer, or media games.
- Locate computers in a central area in the home where you can monitor Internet use.
- Install a parental control to limit access to and monitor Web sites that would expose your child to sexual content or predators.
- Know if sexual predators live near you. Check out the sexual predators registry in your area.
- Establish curfew times and contingency communications if curfew is breached. Teach your child to use a code word that communicates he is in trouble.

Just Say No

- Teach your child about body parts that are private and should not be touched or seen by others—except for medical reasons.
- Teach your child to firmly say no and get away if someone tries to touch or look at her in a way that makes her feel uncomfortable.
- Urge your child to tell you or another trusted adult if someone tries to touch or look at private areas or if the person tries to show the child his or her own private body parts.
- Teach your child never to get in the car with strangers and never go near a stranger's car for any reason.
- Always use a buddy system to prevent the child from being alone.
- Teach your child to yell, "Help! Stranger!" if anyone tries to follow her, walking or in a car.
- Place limits on Internet use.
- Teach children not to disclose personal information in public settings or on the Internet, even social networking sites.

KnowledgeCheck 33-8

- What are aspects of an intimate relationship?
- Identify solitary types of sexual expression and those that may be conducted with a partner.

What Problems Affect Sexuality?

Sexual well-being is a complex mesh of physical, emotional, cognitive, social, and spiritual components. Therefore, it is not surprising that many people experience challenges to their sexual health. Difficulties can arise in loving, healthy and in dysfunctional relationships. Sexual dysfunction may be temporary and situational, or it may be long standing.

Sexually Transmitted Infections

An STI may be caused by bacteria, virus, fungi or parasites. STIs are spread through direct sexual contact with an open wound or with body fluids, such as semen, vaginal secretions, or blood that contains pathogens. Contrary to many myths, STIs are not transmitted by casual touching, coughing, or other indirect means.

STIs are among the most common infectious diseases in the United States today. More than 20 different STIs have been identified and affect millions of men and women each year. **Reportable** (or **notifiable**) **diseases** have a significant effect on public health. When healthcare providers diagnose a reportable disease, mandatory reporting laws require it to be reported to the local public health department or the Centers for Disease Control and Prevention (CDC). Examples include the following:

- *Chlamydia trachomatis.* The most common transmitted infection in the U.S. is also known as the "silent infection" because the infected person may not have symptoms. Chlamydia can cause serious damage to a female's reproductive system if untreated. About 1 in 15 sexually active persons will become infected. In 2011, an estimated 2.8 million cases occurred, although 1.4 million cases were diagnosed and treated (CDC, 2012b, updated 2013).
- *Gonorrhea.* This infectious disease is caused by a bacterium and is a common STI among sexually active teenagers and young adults. An estimated 820,000 new cases occur each year, although in 2011, 321,849 cases were reported to the CDC (2012c, updated 2013).
- *Syphilis.* Although 46,042 new cases were reported in 2011, the actual number of cases is higher. This STI is caused by a bacterium that is transmitted from person to person by direct contact with the syphilis sore, which can occur on the external genitalia, vagina, lips, mouth, anus, and in the rectum. If left untreated, long-term neurological complications and even death may occur (CDC, 2012d, updated 2013).
- *Genital Human Papillomavirus*. Also called HPV, this STI can infect the genital areas, mouth, and throat of males and females. It can also cause genital warts and certain types of cancers (e.g., cervical, genital, oropharyngeal). Many people with HPV do not know they are infected, and in many instances the STI will go away without intervention. There are more than 40 types of HPV and it is possible for a person to get more than one type. The HPV vaccine is recommended to minimize the chance of contracting HPV (CDC, 2013b).

Nearly two-thirds of all STIs occur in people younger than 25 years. Because many STIs have few or no initial symptoms, an infected person can transmit the infection without knowing it. For example, up to 90% of women infected with gonorrhea or chlamydia have no symptoms. To find out whether a patient has an STI, you must obtain a culture, that is, a swab of secretions from the genitals. In a man, the swab is put into the urethral opening. In a woman, the swab is obtained from secretions near the cervix. A culture of the throat or rectum is obtained if the person has had oral or anal sex.

Many STIs can be treated fairly easily with antibiotics; however, if left untreated, they may cause serious problems. In women, the pathogens can travel up through the uterus into the fallopian tubes and cause pelvic inflammatory disease (PID). Untreated PID may cause sterility.

The best ways to prevent STIs are to practice abstinence or to participate only in a committed, mutually monogamous sexual relationship with someone who has never had an STI and is at low risk for one. Risk for an STI increases if a person has unprotected sex or sex with more than one partner. Other risk factors include alcohol and drug use, sharing needles, and noncompliance with the STI treatment regimen.

To read about various STIs, their symptoms, treatment, and effect on sexual functioning, fertility, and childbearing,

Go to Chapter 33, **Tables, Boxes, Figures: ESG Table 33-1, Common Sexually Transmitted Infections (STIs),** on Davis*Plus*.

Dysmenorrhea

Dysmenorrhea is painful menstruation caused by strong uterine contractions that cause ischemia of the uterus. The patient may experience cramping, lower abdominal pain, back and upper thigh pain, headache, vomiting, and diarrhea. Treatments include bedrest, application of heat to the back and abdomen, and analgesics such as aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), for example, ibuprofen or naproxen.

Premenstrual Syndrome

Premenstrual syndrome (PMS) is characterized by physical and emotional changes occurring 3 to 14 days before the onset of the woman's menstrual period. Physical symptoms include headaches, constipation, breast tenderness, and weight gain associated with bloating, abdominal swelling, or swelling of the hands and feet. Some women feel as though they are on an emotional roller coaster, with periods of depression, anxiety, irritability, tension, and an inability to concentrate. Some women have difficulty maintaining social interactions at work or school because of severe emotional symptoms. Client teaching for PMS is discussed later in this chapter.

Women experiencing more severe forms of menstrual cycle dysfunction (**premenstrual dysphoric disorder [PMDD]**) become seriously depressed for a week or more before their periods. In contrast, PMS is shorter, usually milder, and involves more physical symptoms. A woman can suffer from both PMS and PMDD at the same time, or may have one and not the other.

KnowledgeCheck 33-9

- Identify three methods to decrease the transmission of STIs.
- What are physical and emotional symptoms of premenstrual syndrome (PMS)?

Negative Intimate Relationships

Many couples are happy, and their sexual relationship becomes even more satisfying as they mature. However, some intimate relationships are not mutually satisfying, even when they do not involve neglect, or physical or emotional abuse. Couples may be involved in a celibate or loveless union for financial security, social status, for "the sake of the children," or because of cultural or religious restrictions regarding divorce. In reality, many relationships fall in between—sometimes satisfying and other times less so—depending on a wide variety of factors, such as stress, physical and mental illness, hormones, fatigue, distractions, low self-esteem, and financial pressure. The most negative relationships involve *domestic violence* (also called *intimate partner violence*), which may include physical and/or emotional intimidation, assault, and rape.

Although either gender partner may be a victim of domestic violence, most often a man is the perpetrator. The anger, domination, and physical violence of the partner lead to fear, intimidation, and submission in the victim. Often victims come to believe they deserve the abuse and may hesitate to admit the cause of their injuries, even in hospital settings. Many abused women are either emotionally or financially dependent on their partner and believe staying in the relationship is their only option. If you wish to learn more about abuse and violence, see Chapters 9 and 10.

Sexual Harassment

Sexual harassment occurs when a person in power makes unwanted sexual advances that implicitly or explicitly relate to the victim's employment, academic status, or success. "Advances" can take the form of sexual comments or behaviors (such as touching). Because of the power imbalance, the victim may keep silent and suffer physically and psychologically. **Sexual assault** includes contact with or without penetration, sexual touching of intimate parts, and any unwanted sexual activity in situations of intoxication, coercion, or misconception.

PICOT

Sexuality, Dementia, and Competency

Situation: The adult children of a widow with early onset Alzheimer's disease are concerned about their mother's sexual advances directed at another resident at the assisted living facility. Although the residents are, legally, consenting adults, the children are concerned about their mother's judgment and sexual appropriateness.

PICOT Components:

P	Population/client	=	Adults with early onset Alzheimer's disease
I	Intervention/indicator	=	Nonpharmacological behavior modification
C	Comparator/control	=	No sexual relationships
O	Outcome	=	Appropriate, consensual sexual relationships
T	Time	=	Late adulthood

Searchable Question: Do __________ (P) who receive/are exposed to __________ (I) demonstrate __________ (O) as compared to __________ (C) during __________ (T)?

Example of Evidence: All people have needs for intimacy, companionship, and touch. Clients with dementia pose a particularly difficult situation for both family and professionals, who may consider sexual behavior to be inappropriate, based on the elderly client's age, setting, situation, or health issues. The central question for you to answer is whether the client is competent. The family and staff need to carefully and sensitively assess the following areas: Is the client's mental status suited to engaging in a consensual, sexual relationship? Who is initiating sexual contact? Is the client able to consent to sexual intimacy? Is the client aware of emotional and physical potential risks, such as the relationship ending? Is the sexual activity consistent with behavior the client exhibited prior to the onset of the dementia? Although there are no established treatment guidelines, various nonpharmacological plans may help to assure appropriate expression of sexuality.

Practice Change: After obtaining a thorough sexual assessment, the nurse may plan nonpharmacological behavior modification for the client to demonstrate appropriate sexual behaviors and meet the client's intimacy needs.

Joller, P., Gupta, N., Seitz, D. P., et al. (2013). Approach to inappropriate sexual behaviour in people with dementia. *Canadian Family Physician, 59*(3), 255–260.

Sexual harassment may take two forms: (1) In *quid pro quo,* the employer makes the employee feel that she must engage in unwelcome sexual advances to maintain employment. (2) In *hostile environment* situations, the sexual advances are more subtle, but persistent, and create an intimidating environment.

Rape

Although rape is actually a crime of violence rather than of sex, we discuss it here because it often involves the sexual organs and usually has negative effects on the victim's sexuality. **Rape** is nonconsensual vaginal, anal, or oral penetration. It occurs through force, by the threat of bodily harm, or when the victim is incapable of giving consent. All states consider rape, even within a marriage, to be a crime.

Victims of rape range from infants to older adults and may be either gender, although females are more likely to be victims. One in 6 women and 1 in 33 males are victims of attempted or completed rape (National Institute of Justice, 2010). Forced oral assault, multiple assailants, and weapons are more likely involved with male victims. In two-thirds of cases, the victim knows or is related to the assailant, especially when the victim is a young child (National Institute of Justice, 2010; Rennison & Rand, 2008). People with developmental disabilities, especially mental retardation, are at double the risk for sexual assault than the general population.

- **Group (gang) rape** occurs when more than one person sexually assaults a victim. Group rape usually occurs when drugs and alcohol are involved.
- **Statutory rape** is sexual activity between an adult and a person under the "age of consent" (this ranges from 14 to 18 years of age, depending on state regulations). This charge may be filed even when the sex is consensual.
- **Date rape** is rape by an acquaintance when the assault occurs during an agreed-on social encounter or date. Although date rape is not a lesser violation, our society tends to blame the woman when date rape occurs.

Many rapes go unreported. Rape is an assault that involves significant psychological and physical injury; however, the police often become involved because the victim requires medical attention. After a rape or other forms of sexual assault, care may be delayed, particularly for teens, if alcohol or drugs are involved. Other reasons for not reporting rape include fear of the assailant, fear of consequences to the assailant, knowledge of the low conviction rate for rapists, the desire to avoid a trial, shame and embarrassment, past sexual history, self-blame, wanting to "move on," and the wish to deny the event and its possible consequences.

In addition to psychological and physiological trauma, the rape victim is at risk for STIs and pregnancy. Three-quarters or more of sexually assaulted teens experience post-traumatic stress disorder. Referral to a local sexual assault support group is critical. A ***sexual assault nurse examiner (SANE)*** is a registered nurse who has received special training in the immediate care of sexual assault victims. To learn about providing care to sexual assault victims,

Go to Chapter 33, **Clinical Insight 33-1: Providing Care After Sexual Assault,** in Volume 2.

Sexual Response Cycle Disorders

Disorders in various stages of the sexual response cycle may affect desire, arousal, excitement, and orgasm.

Low Libido

Low libido (hypoactive sexual desire) manifests as a significant decrease in or absence of both sexual fantasies and sexual activity. Low libido may affect both men and women. It can be transient or long term. The person may experience low libido only with one particular partner, or the lack of desire can extend to all sexual activity. Persons with low libido may reluctantly engage in sexual encounters or avoid all sexual contact. However, once sexual activity has been initiated, the person is usually able to achieve orgasm.

Factors contributing to hypoactive sexual desire include sexual trauma, a negative attitude toward sex, negative relationships, and biological factors (e.g., hormone deficiencies, perimenopause, side effects of various medications). Low sexual desire, in both men and women, may respond positively to testosterone administration.

Arousal Disorders

In women, arousal disorders manifest as minimal or absent pelvic congestion and vaginal lubrication even though desire may be present.

- **Dyspareunia**, or painful intercourse, further decreases sexual desire. Dyspareunia is often caused by vaginal dryness resulting from hormonal changes, the aging process, tampons, and medications, including antihistamines. A water-based lubricant or saliva helps to resolve vaginal dryness. Other causes of female dyspareunia include vaginal or urinary tract infections, pelvic inflammatory disease, and endometriosis.

  Dyspareunia in men most commonly results from urinary tract infection or **phimosis**, a condition in which the foreskin of the penis is too tight. **Balanitis**, inflammation of the penis, is another cause of dyspareunia in men.
- **Vaginismus** is a rare disorder affecting desire and arousal. It is characterized by intense involuntary contractions of the perineal muscles, which close the vaginal opening and prevent penile penetration. Vaginismus may be associated with psychological disorders (e.g., negative attitudes toward sex, history of sexual abuse or trauma) or physiological disorders (e.g., trauma during childbirth).
- **Erectile dysfunction (ED)**, formerly known as *impotence* is a sexual arousal disorders in men. Men with ED have persistent or recurring inability either to achieve or to maintain an erection sufficient for satisfactory sexual performance. The most common cause of ED is diseases of the blood vessels (e.g., hypertension, high cholesterol, or diabetes). ED may also result from underlying neurological (e.g., spinal cord injury, Parkinson's disease, stroke) or endocrine problems (diabetes). Common psychological problems that contribute to ED include performance anxiety, childhood sexual abuse, relationship

issues, or mental illness. Some medications can also cause ED, such as antihistamines, antidepressants, antipsychotics, and antihypertensives. While testosterone plays a major role in libido (desire), it has only a minor role in erectile function.

Orgasmic Disorders

Orgasmic disorder is a delay in or absence of orgasm after a normal sexual excitement phase. Once a woman has had orgasms, it is uncommon for her to lose that ability unless there has been a sexual trauma, poor sexual communication, a conflicted sexual relationship, a mood disorder, a medical condition, or direct physiological effects from a drug. Orgasmic disorder is more prevalent in younger women who have not had adequate sexual experience to learn how to reach orgasm. It is not unusual for a woman to require manual clitoral stimulation to reach orgasm because not all women can achieve orgasm through intercourse alone.

Men, too, can experience orgasmic disorders. Some cannot achieve orgasm during intercourse, but are able to reach orgasm through masturbation or manual or oral stimulation by their partner.

Premature ejaculation occurs when the male reaches orgasm and ejaculates before, at the time of, or shortly after penetration. The disappointment of both partners may lead to issues with self-esteem, sexual avoidance, and ED. There are sexual techniques as well as medications that can help to delay ejaculation.

Retrograde ejaculation occurs when the semen empties into the bladder instead of being ejaculated through the urethra. Normally this cannot occur because the internal bladder sphincter closes in the orgasmic phase. However, some medications, prostate surgery, and spinal cord injuries may lead to retrograde ejaculation, resulting in sterility.

KnowledgeCheck 33-10

- Identify three forms of sexual victimization.
- In which phases of the sexual response cycle can sexual dysfunction occur?

PracticalKnowledge knowing how

Although you understand the importance of comprehensive client assessment, you may find it difficult to gather information related to sexuality. Students, and some nurses, may be shy, or may be concerned that the client will be embarrassed to talk about sexual topics since these matters are personal and private, and can threaten a person's self-esteem. Including sexuality as a routine part of your nursing assessment reinforces the concept that sexuality is an integral part of life and provides an opportunity for much-needed patient teaching. Many patients will not raise the topic of sexuality, so to meet patient needs, you must include this topic in your assessment.

ASSESSMENT

The extent to which you will assess a client's sexual health status varies. For example, for a woman with a suspected STI, you would perform a comprehensive health assessment and a focused sexual health assessment. Similarly, clients with illnesses that affect their sexual functioning should receive a full assessment. Jocelyn Carter (Meet Your Patients) is an example. Recall that chronic illness can have a profound effect on sexual functioning (e.g., Frank Thanee and Gabriel Thomas in the Meet Your Patients scenario). A focused sexual health assessment is needed in the following situations:

Pregnancy, infertility workup, request for birth control
Menstrual cycle irregularities or problems
Annual health visit
Unusual discharge from or change in genital organs
Urination problems
As part of a comprehensive physical examination
A known sexual problem (e.g., dyspareunia)
Illness or surgeries that may affect sexual function (e.g., arthritis, colostomy)
Medications

Sexual History

Most healthcare facilities use a standard nursing assessment form. Some address sexuality in a comprehensive manner, but most have only a few superficial questions or nothing at all. You will need to be sensitive to your client's verbal and nonverbal cues to identify and explore relevant issues that are not on the form. For topics to include in a sexual history and for suggestions for questions to ask,

Go to Chapter 33, **Assessment Guidelines and Tools, Focused Assessment: Guidelines and Questions for Taking a Sexual History,** in Volume 2.

Tips for Taking a Sexual History When you are asking personal questions, always provide privacy. It is one thing to discuss blood pressure in the presence of family, but quite another to discuss sexual health issues, which may threaten the very core of a relationship. For example, a wife is not likely to discuss domestic violence with her abusing husband at her side, and an 18-year-old man will probably not admit to having sex with another man when his father is present. For other suggestions,

Go to Chapter 33, **Clinical Insight 33-2: Guidelines for Taking a Sexual History,** in Volume 2.

Focused Physical Examination

Sexual health assessment includes a physical examination focused on the reproductive system. For detailed instructions about performing these examinations,

Go to Chapter 22, **Procedure 22-17: Assessing the Male Genitourinary System,** and **Procedure 22-18: Assessing the Female Genitourinary System,** in Volume 2.

If there is reason to suspect that a client has an STI, you should obtain cultures of any discharge or lesions. Other laboratory tests may also be ordered.

KnowledgeCheck 33-11

What techniques can you use to increase comfort and communication during a sexual history assessment?

ThinkLike a Nurse 33-7

Review the three case scenarios in the Meet Your Patients discussion. Consider the following questions for each patient:

- Would you be comfortable caring for and responding to each of these patients?
- What topics, if any, that have been raised by these patients would be difficult for you to handle?
- How would you answer each of the patients' questions?

ANALYSIS/NURSING DIAGNOSIS

NANDA-I has two nursing diagnoses for describing sexual problems. The following discussion should help you differentiate between them.

Ineffective Sexuality Patterns Use this diagnosis when the patient expresses concerns about his sexuality. Examples of such concerns might include conflict about sexual orientation, value conflicts, fear of acquiring an STI, lack of knowledge about how to adapt sexual techniques to altered body function, lack of privacy, not having a partner, or impaired relationship with the partner.

Sexual Dysfunction This diagnosis applies when there is an actual change in sexual function during the phases of desire, excitation, or orgasm that the patient views as unsatisfying, unrewarding, or inadequate. This includes sexual response cycle disorders, such as low libido, arousal disorders, orgasmic disorders, vaginismus, premature ejaculation, and erectile dysfunction. If these defining characteristics for Sexual Dysfunction do not seem to "fit" the patient, then use the more general diagnosis, Ineffective Sexuality Patterns.

There is much overlap between these two NANDA-I diagnoses. The only defining characteristic of Ineffective Sexuality Pattern is that the patient reports difficulties, limitations, or changes in sexual behaviors or activities; Jocelyn Carter (Meet Your Patients), for example, is not actually experiencing problems with sexual satisfaction or performance. She is expressing a broader concern about her sexuality—about her future desirability as a sex partner. Therefore, the better diagnosis for her is Ineffective Sexuality Patterns. The same is true for Gabriel Thomas, who is expressing fear that he may have sexual problems in the future.

Sexual Dysfunction is the more specific diagnosis for physiological problems and for concerns about sexual performance. Thus, it is best to use Sexual Dysfunction when the patient has one or more of the following defining characteristics:

Changes in achieving sexual satisfaction
Change of interest in self or others
Inability to achieve sexual satisfaction
Verbalization of a sexual problem
Actual or perceived limitations imposed by disease or therapy
Changes in ability to achieve perceived sex role
Seeking confirmation of desirability

Etiologies of Sexuality Diagnoses

Several other nursing diagnoses may be the cause of sexuality problems. The following are the more common ones:

- *Activity Intolerance* and *Fatigue* (e.g., from cardiac or respiratory disease) may cause the person to alter her lifestyle, including sexual activity, to conserve energy. Lack of energy may decrease the person's interest in sex, or it may require a change in the mode of sexual expression.
- *Impaired Physical Mobility* (e.g., as occurs with arthritis, spinal cord injuries) may affect a person's ability to interact, meet potential partners, and perform sexually (e.g., assume certain positions, make certain movements).
- *Fear* that sexual activity may be dangerous can inhibit desire and the ability to perform (e.g., after heart surgery). This diagnosis may also apply to the client's partner, who may afraid that sexual activity will hurt the client after surgery, or hurt a pregnant partner or the baby.
- *Chronic Pain* may directly affect interpersonal relationships, interest in sex, or comfort during sexual intimacy. It may cause fatigue, indirectly affecting sexuality.
- *Chronic Low Self-Esteem* may result from chronic health problems and their consequences (e.g., loss of employment, inability to perform parenting roles). Sexual expression may also become a challenge, yet the intimacy and reassurance that accompanies sexual encounters can be vital to self-esteem and a sense of wholeness.
- *Self-Care Deficits.* For clients who need assistance with activities of daily living (ADLs), for example with toileting, family or caretakers often find it difficult to accept and facilitate sexual relationships. When a person with a physical disability lives in a residential facility, lack of opportunity and privacy may interfere with sexual expression (Fig. 33-8).
- *Delayed Development.* Relationship challenges also exist for people who are developmentally disabled. Those with very low cognitive functioning are unable to seek out or understand sexual relationships. Unfortunately, this makes them vulnerable to sexual abuse. Sex education is vital for these individuals to help them understand body structure and function, relationship issues, and ways to avoid exploitation and abuse.

FIGURE 33-8 Adults with physical restrictions or those living within group settings, such as skilled nursing care, can maintain sexual relationships.

Sexuality Problems as Etiologies of Other Diagnoses

Sexuality problems can be the etiology of other nursing diagnoses, for example:

- *Disturbed Body Image* related to change in appearance secondary to orchiectomy (removal of a testicle)
- *Pain (during coitus)* related to inadequate vaginal lubrication secondary to aging
- *Fear* related to sexual abuse by father
- *Rape-Trauma Syndrome* (Note that you do not need an etiology for this nursing diagnosis. It is self-explanatory, as are most syndrome diagnoses.)

ThinkLike a Nurse 33-8

Give a specific example (patient situation) for each of the defining characteristics of Sexual Dysfunction listed in the preceding section.

PLANNING OUTCOMES/EVALUATION

For *NOC standardized outcomes* associated with Ineffective Sexuality Patterns and Sexual Dysfunction,

Go to Chapter 33, **Standardized Language, Examples of NOC Outcomes for Sexuality Problems,** on Davis*Plus*.

Individualized client outcomes and goals, as always, depend on the nursing diagnosis you identify. For Sexual Dysfunction and Ineffective Sexuality Patterns, you might write the following desired outcomes:

- Expresses comfort with sexual orientation.
- Describes plans for resolving values conflicts about extramarital sex (e.g., will talk to his minister).
- Describes techniques for preventing STIs.
- Reports using a condom for all sexual activities involving exchange of body fluids.

The following are examples of outcomes that apply specifically to Sexual Dysfunction:

- Communicates sexual needs and preferences to partner.
- Maintains penile erection through orgasm.
- Describes ways to adapt positions for intercourse to accommodate painful knee joints.

PLANNING INTERVENTIONS/IMPLEMENTATION

For *NIC standardized interventions* and selected nursing activities for sexuality,

Go to Chapter 33, **Standardized Language, Examples of NIC Interventions and Nursing Activities for Sexuality Problems,** on Davis*Plus*.

Specific nursing activities for sexuality problems depend on the etiology of the problem and on the goals selected. Broadly speaking, nursing interventions involve teaching about sexual health and self-care, counseling for altered sexual functioning, and dealing with inappropriate sexual behavior. Those interventions are discussed in the following sections.

You will also find a nursing care plan and care map for Ineffective Sexuality Problems on the following pages.

Teaching About Sexual Health

Before you begin teaching, take the time to get to know your client and find out what she already knows about sexuality. The time you take putting the client at ease is well spent. When you develop rapport and trust, the client will be more likely to speak openly with you about sensitive or embarrassing topics, to retain what you teach, and to feel free to ask questions. Offer to include the partner in the discussion if the client wishes. See Chapter 19 for a review of teaching and learning.

As part of teaching focused on sexuality, you should discuss prevention of STIs with all clients and discuss contraception with clients who are heterosexual or bisexual. Other common topics are presented in the next sections.

Body Function and Reproduction

A person's age, experience, and educational level do not ensure knowledge of sexual functioning. Before you begin any teaching, explore your client's knowledge base by asking open-ended questions such as "What questions do you have about sex?"

Visual aids (e.g., a diagram of reproductive system anatomy) are helpful. For example, for pregnant clients you could use drawings and charts illustrating fetal development. Most agencies provide handouts and brochures so that clients can review information at home.

As part of your general discussion on sexuality and bodily function, you may wish to discuss common myths and misconceptions about sex. Below are several statements about sex that provide a good starting point for discussion. **Key point:** ***The statements are all false.***

- You can't get pregnant the first time you have sex.
- You can't get pregnant if you're using a condom.
- You can tell the size of a man's penis by the size of his feet.
- You always have symptoms if you have an STI.
- People over 70 don't have sex.
- A vaginal orgasm is better than a clitoral orgasm.
- If the relationship is good, the man and woman will achieve simultaneous orgasm.
- It is not healthful to have intercourse during menstruation.
- The only normal position for intercourse is face-to-face. Anything else is deviant or at least "not nice."
- Only "dirty" people have STIs. You will not get an STI if your partner has good hygiene habits.
- If a woman does not have an orgasm, she does not really love her partner. The same is true for a man.

Douching

Teach women that douching is unnecessary and is associated with significant risks. It can wash away the lactobacilli that clean the vagina and protect it from infection. Women who douche are at increased risk for some STIs and for PID (Gollub, Cyrus-Cameron, Armstrong, et al., 2013; Rew, 2009). Furthermore, douching is essentially useless as a method of contraception. Some women douche because they notice an odor. Reassure them that this is normal during certain times of their menstrual cycle. If the odor doesn't disappear after washing, they should see their healthcare provider.

Menstruation

Many women require information about self-care to dispel myths about menstruation. For example, it is not dangerous to engage in sexual activity during menstruation. The bloody fluid is from the uterus, not the vagina, so intercourse will not harm the vagina. Actually, some women and men enjoy sex more during menstruation because the increased vascularity, warmth, and lubrication in the pelvic region increase their pleasurable sensations, and orgasm may relieve women's menstrual cramps. If the flow is very heavy, the woman can place protective padding under her buttocks to protect the bed linens. Some women use a diaphragm to keep the flow from entering the vagina during sexual activity.

To prevent odor, the woman should use good perineal hygiene, bathe or shower every day, and change pads or tampons frequently. Advise women to follow the manufacturer's directions for tampons to reduce the risk for toxic shock syndrome. Deodorized pads and tampons are not very effective and can cause irritation to the vulva and vagina.

For mild cramping occurring before or during menses, aspirin and other NSAIDs, such as ibuprofen or naproxen, are effective and can be taken unless contraindicated for other reasons. These drugs inhibit uterine contractions and have analgesic properties. A warm bath or heating pad may be comforting; lying supine also keeps the abdomen warm.

Premenstrual Syndrome

For women with PMS, you may suggest a variety of nonpharmacological treatments: getting adequate sleep; eating small, frequent meals; reducing dietary intake of sugar, caffeine, alcohol, and salt; taking vitamin and mineral supplements; and exercising. Selective serotonin reuptake-inhibiting drugs (SSRIs) such as fluoxetine (Prozac) and sertraline (Zoloft) are increasingly being used as a front-line therapy for managing symptoms of PMS.

Menopause

Hormone replacement therapy (HRT) (estrogen-only, progestin-only, or combination) remains the most effective treatment to relieve symptoms of menopause, such as itching, dryness, discomfort with intercourse, hot flashes, sleep disturbances, and other symptoms. HRT can either increase or decrease risk of heart disease, depending on when hormone therapy is started; how long women remain on it; and individual differences. HRT can help prevent loss of bone density in menopausal women, which leads to fewer hip fractures among users. Also beneficial is the reduced risk of colorectal cancer.

The risks associated with long-term use in a small number of women include heart disease, blood clots, breast and ovarian cancer, and dementia. Therefore, consumers, healthcare providers, and third-party payors have become more conservative in using HRT or reserving treatment for short-term use. Counsel women to discuss the risks and benefits of HRT with their primary care provider, and inform them that there are some natural remedies and bioidentical therapies that may provide symptom relief (see the related CAM box).

Self-Examination

Breast self-examination and testicular self-examination are vital aspects of sexual health. For more information and for details about these assessments, see Chapters 9, 22, and 42.

Breast Exam Any change in how the breasts normally look and feel should be immediately provided to the healthcare provider. The American Cancer Society (ACS) (2012, updated 2013) recommends that women in their 20s and 30s should have a clinical breast exam at

Complementary & Alternative Modalities (CAM)

CAM for Perimenopausal Symptoms

Help, including hormone therapy, is available for perimenopause symptoms. In addition to finding a primary care provider with whom to discuss their symptoms, you might advise women to try the following:

- Eat a balanced diet, low in fat and rich in calcium.
- Use supplemental vitamins, if necessary.
- Get adequate sleep.
- Exercise daily.
- Avoid tobacco use.
- Limit alcohol and caffeine.
- Drink plenty of water to counteract the drying effect of low estrogen levels.
- Use soy products (e.g., soy milk, tofu, and soy flour), which are rich in phytoestrogens that are converted during digestion to very weak estrogens.
- Try the herbal remedies red clover and black cohosh.
- Use natural progesterone cream, which is made from a yam root. Women usually apply a small amount of the cream for 12 days out of each month.

least every 3 years, be educated on the benefits and limitations of breast self-exam (BSE), and taught how to conduct a BSE. Women should have yearly mammograms to screen for breast cancer after age 40. Although some researchers and professional groups have contrary recommendations (e.g., mammograms every 2 years for women ages 50 to 74), these guidelines represent an extensive review of the health literature and input from an expert advisory group.

Testicular Exam The ACS (2012) advises men to be aware that a lump in the testicle could be a sign of testicular cancer. However, because the benefit of testicular self-exams has not been studied enough to show they reduce the death rate from this cancer, the ACS does not make a recommendation about monthly self-exams. However, after puberty checking for lumps is a good idea, especially if the man had undescended testicle or family history of testicular cancer.

Preventing Sexually Transmitted Infections

STIs are a worldwide health concern, and education is a key component of prevention. The only absolutely safe sex is total avoidance of sexual activity with a partner. However, most adults do not choose abstinence. The next safest sex occurs within a long-term, mutually monogamous relationship. Other safer sex practices involve the consistent, correct use of a condom and limiting the number of sexual partners. For information about the use of male and female condoms,

Go to Chapter 33, **Clinical Insight 33-3: Teaching Your Patient to Use a Condom,** in Volume 2.

Teach your clients the proper use of condoms and encourage them to discuss sexual feelings, activity, and safety with their partners. If people are not comfortable talking about birth control, STIs, and safer sex with a potential partner, they need to consider whether it is wise to begin a sexual relationship. Planned Parenthood advocates the following behaviors for safer sex:

- Be honest about current sexual practices and sexual history, as well as sexual health concerns.
- Avoid the exchange of body fluids, including semen, blood, and vaginal secretions, by correctly and consistently using latex barriers.
- Avoid contact with genital sores or growths.
- Have routine checkups for infection.
- Consult a healthcare provider for diagnosis and treatment of symptoms such as abnormal discharge from the vagina, penis, or rectum; a burning sensation with urination; sores in the genital area; or painful intercourse.
- Accept responsibility for your actions.

Also advise clients to choose a healthcare provider with whom they can comfortably discuss these issues. Freedom to speak frankly and openly about their sexual health concerns is important to their health. Assure them that testing, examination, and treatment for STIs are always confidential.

Contraception

For clients who are heterosexual or bisexual, your sexual health teaching may include methods for preventing unwanted pregnancies. Several fertility control and family planning strategies are available, each with advantages and disadvantages. For information on several fertility control methods,

Go to Chapter 33, **Tables, Fertility Control Methods,** in Volume 2.

Counseling for Sexual Problems

The PLISSIT model was developed as a guideline for counseling for sexual problems (Annon, 1976). Basic nursing education does not prepare you to provide sex therapy. However, the first three PLISSIT steps have been successfully adapted to address sexual knowledge deficits, which you are qualified to treat. The acronym PLISSIT represents the following:

***P**ermission*. Permission means that you communicate an open, accepting attitude so that the client feels free to ask open-ended questions and express concerns and feelings and to engage in sexual behaviors with a consenting partner. For example, you might state, "Many women experience decreased vaginal lubrication after menopause. Tell me how well you have been lubricating."

***L**imited **I**nformation*. Supplying limited information may include teaching about normal sexual functioning, expected changes in sexual functioning, medication side effects, and medical and surgical impacts on sexuality. For example, you might say, "Some women experience decreased vaginal lubrication because of decreased levels of certain hormones."

Specific Suggestions. You might make specific suggestions for self-care, as presented in this chapter. For example, you might say, "Some women have found that using a water-soluble lubricant is helpful."

Intensive Therapy. If these interventions do not relieve the client's concerns, you should refer the client to someone with specialized knowledge of sexual health. For example: "You might consider discussing this with your gynecologist."

Dealing With Inappropriate Sexual Behavior

Nursing involves intimate contact. We see people disrobed, literally touch bodies, and discuss private topics. In most cases, patients recognize this as professional behavior associated with providing healthcare. Occasionally they may respond inappropriately. For example, a client may make sexually suggestive comments, request sexually related care that is not required (e.g., ask you to bathe his genitalia when he can do it adequately himself), disrobe or expose body parts that are not involved in the care delivered, or touch or grab you as you provide care. The following are the most common reasons for sexually inappropriate behaviors:

- Confusion
- Neurological disorders, especially those involving the frontal lobe
- Mental illnesses
- Poor impulse control
- Misinterpretation of nursing care
- Need to have power or control over others, especially when the client feels powerless in other aspects of his life
- Worries about sexual functioning
- Unrealistic view of nursing based on sexual stereotypes

If you believe a client is demonstrating inappropriate sexual behaviors, immediately tell the client that the behavior is inappropriate. Do not express anger, but use clear statements, such as, "I don't like your comments. They are inappropriate and make me feel uncomfortable. Please stop." Next, let the client know what behavior you expect. Be direct with your comments. If the client is exposing himself, let him know what you expect him to wear ("I expect you to keep your pajama bottoms on)." If the client is attempting to touch you, tell him, "Don't touch me." Refocus the client's attention to the care you are delivering ("Hold still now, while I tape your IV"). If you are extremely uncomfortable or the client persists in the comments or actions, leave the room and report the incident to your instructor or the nurse assigned to the client. Your instructor may need to change your assignment. You may also wish to consider discussing the situation with the client while another person is in the room.

Sexual harassment is a unique form of inappropriate sexual behavior (refer to Sexual Harassment in the Theoretical Knowledge section). If you believe you are being sexually harassed, you should confront your harasser and clearly state your concerns. If you feel unable to confront your harasser (e.g., if the harasser is a teacher or supervisor), keep a written record of the events, and report your concerns to the worksite or school official in charge of personnel. By law, all worksites and educational environments must have a written procedure for handling cases of sexual harassment. It will tell you how to file a grievance, what forms you need to use, to whom to report the incident, and details of the procedure for a hearing and resolution. For further information, see Chapter 45.

PUTTING IT ALL TOGETHER

Consider the three patients discussed in the Meet Your Patients scenario. Each situation illustrates how important sexual identity is to the sense of self. Each of the patients is concerned about how their medical problem might affect their sexuality:

- Jocelyn Carter is worried about how surgery will affect her relationship with her husband.
- Gabriel Thomas is concerned that blood pressure medications will impair his sexual abilities.
- Frank Thanee, recovering from open-heart surgery, is focused on explaining his long-term same-sex relationship to his family.

To help patients identify and resolve sexual health concerns, you will need to examine your own beliefs and values. The self-knowledge gained from examining your own views on sexuality will help you to be open to your patients' sexual concerns. The full-spectrum nursing model can help you to find the best approach when dealing with sexual health. Following, we use the three patients from Meet Your Patients to illustrate how this works.

Thinking

Theoretical Knowledge A sound knowledge base enables you to teach and respond sensitively to all your clients. Many myths and taboos surround the subject of sexuality, so it is important that you remain objective and current regarding these topics. You will need theoretical knowledge about sexuality, the effect of health concerns on sexual function and expression, and treatment of sexual health problems. What knowledge do you already have that would enable you to address Gabriel Thomas's concerns? What knowledge do you still need?

Critical Thinking To help Gabriel Thomas, you will need to focus on what he is experiencing and critically examine his concerns in light of what is known about

(text continued on page 877)

Nursing Care Plan

Client Data

Emilio Juarez is a 50-year-old man hospitalized for cardiac monitoring after an acute myocardial infarction (MI, heart attack). He has no history of diabetes or hypertension. Mr. Juarez owns a computer software company and is active in the community (president of the Chamber of Commerce).

After dinner, Mr. Juarez's nurse sits down to teach Emilio and his wife, Luz, about the medications he will be taking. She also begins to talk to them about a cardiac rehabilitation program. Mr. Juarez asks, "What do you mean by 'activity restriction'? Do I have to stop doing all the things I did before?" The nurse asks, "What things are you thinking about?" Mr. Juarez hesitates, then says, "Oh, like working in the yard, going up the stairs, and, you know, personal things." Mrs. Juarez immediately says, "There is no need to talk about that now. The most important thing is for my Emilio to feel better and get home—there is plenty of time for other things later." The nurse tells the Juarezes that many couples are anxious about resuming sexual activity after a heart attack and says, "I'd like to give you some information about that and answer any questions you might have."

Nursing Diagnosis

Ineffective Sexuality Patterns related to lack of knowledge about post-MI sexual activity and reluctance to ask questions, as evidenced by Mrs. Juarez's comment, "There is no need to talk about that now."

NOC Outcomes	Individualized Goals / Expected Outcomes
Sexual Identity (1207) Sexual Functioning (0119) Body Image (1200)	*By discharge, Mr. Juarez will:* 1. Be able to identify two resources he can use to learn more about sexual activity after myocardial infarction. 2. Commit to attending the cardiac rehabilitation classes offered at the hospital. *During and by the end of the cardiac rehabilitation program, Mr. Juarez will:* 1. Identify stressors in his life related to sexual activity. 2. Report a desire to resume sexual activity to pre-MI levels. 3. Resume previous sexual activity. 4. Discuss any problems encountered.

Nursing Care Plan (continued)

NIC Interventions/Activities	Rationale
NIC Interventions Sexual counseling (5248) Body image enhancement (5220) Anxiety reduction (5820)	
Nursing Activities	
1. Initiate discussions about sexual activity after MI, beginning with general, nonthreatening statements.	Clients and significant others are often too embarrassed to ask about sexual matters. The client's perception of his sexuality impacts personal and social behavior outside the bedroom (Steinke, 2002; Svedberg, Johansson, Persson, et al., 2012). Patients should be reassured that after recovery from an MI, sexual activity presents no great risk of another MI ("Sex After Heart Attack," Mayo Clinic, 2013).
2. Allow Mr. Juarez to control the discussion of sexual matters.	The subject of sexual activity should be raised with patients within the context of cardiac rehabilitation (Cooper, Skinner, Nherera, et al., 2007; Paull, Arndt, Petkovski, et al., 2011). This shows respect for the client's privacy and his sexual being. Controlling what issues are discussed and when enhances self-esteem (Steinke, 2000; Paull, Arndt, Petkovski, et al., 2011).
3. Listen carefully to Mr. Juarez's verbal and nonverbal expression of concerns.	Anxiety interferes with patients' return to sexual activity after an acute cardiovascular event (Moser, 2007). Some men may overtly express uninterest in discussing sexual matters; others avoid the topic by joking, avoiding eye contact, or brushing off concerns as not pressing. Men commonly avoid verbalizing feelings in this area because of the personal nature and threats to masculine identity. Although depressive symptoms are more common in women after an MI and contribute to higher rates of rehospitalization, men also show depression (Moser, 2007; Parashar, Rumsfeld, Reid, et al., 2008).
4. Seek consultation from other members of the healthcare team as needed.	When nurses are uncomfortable talking about sexual matters and do not initiate the conversation, the client may think sexual activity is prohibited after MI. It is imperative that healthcare professionals incorporate sexuality into the plan of care to effectively meet the care needs of their clients (Parker & Yau, 2011; Paull, Arndt, Petkovski, et al., 2011).
5. Include Mrs. Juarez in counseling as much as possible, with Mr. Juarez's consent.	Marriage and close interpersonal relationships allow each member to support the other and alleviate negative effects of stress. The client and spouse may have different perceptions of recovery, anticipated needs, sexuality, and other uncertainties that must be addressed to minimize stress (Baird & Eliasziw, 2011).

(continued on next page)

Nursing Care Plan (continued)

NIC Interventions/Activities	Rationale
Nursing Activities	
6. Be clear about exploring Mr. and Mrs. Juarez's specific concerns, and correct any misinformation.	Anxiety about sexual activity after MI often arises from misconceptions. Fewer than 1% of MIs occur during sexual activity ("Sex After Heart Attack," Mayo Clinic, 2013). There is no evidence suggesting that sexual activity poses a risk for sudden death ("Sex After Heart Attack," Harvard Health Letter, 2013). Regular exercise, such as in a cardiac rehab program, reduces the risk of MI from sexual activity (DeBusk, Drory, Goldstein, et al., 2000; Muller, 2000). For some cardiac patients, sexual problems begin before a heart attack. Erectile dysfunction, the consistent inability to sustain an erection, affects more than 50% of men older than 60 and is a recognized symptom of cardiovascular disease. The typical period of maximum risk (which is still very low) is within 4 weeks of the MI (DeBusk, Drory, Goldstein, et al., 2000). Exercise training after acute MI improves cardiovascular efficiency and reduces myocardial oxygen demand during customary activities, including sexual activity (Miner, 2006). Erectogenic drugs, when used correctly, do not increase overall cardiovascular risk in patients after an MI (Cooper, Skinner, Nherera, et al., 2007).
7. Discuss the risks of using drugs for erectile dysfunction together with nitrates.	An unsafe drop in blood pressure can occur when erectile dysfunction medication is taken with nitrates (Cooper, Skinner, Nherera, et al., 2007). Men should be taught to contact their prescribers if they experience an erection lasting more than 4 hours or if a change in vision occurs.

Nursing Care Plan (continued)

Evaluation

After Mrs. Juarez left for the evening, the nurse returned to bring Mr. Juarez a medication. He said, "Thanks for bringing that up and for leaving the booklet. I love my wife, and I was worried. I sure didn't want to have another heart attack. She was embarrassed to let on that it is important to her, but we will be sure to make use of the rehab program." The nurse followed up later by giving the Juarezes a DVD that discusses sexual issues, which they can take home and watch in privacy and comfort when they are ready to do so.

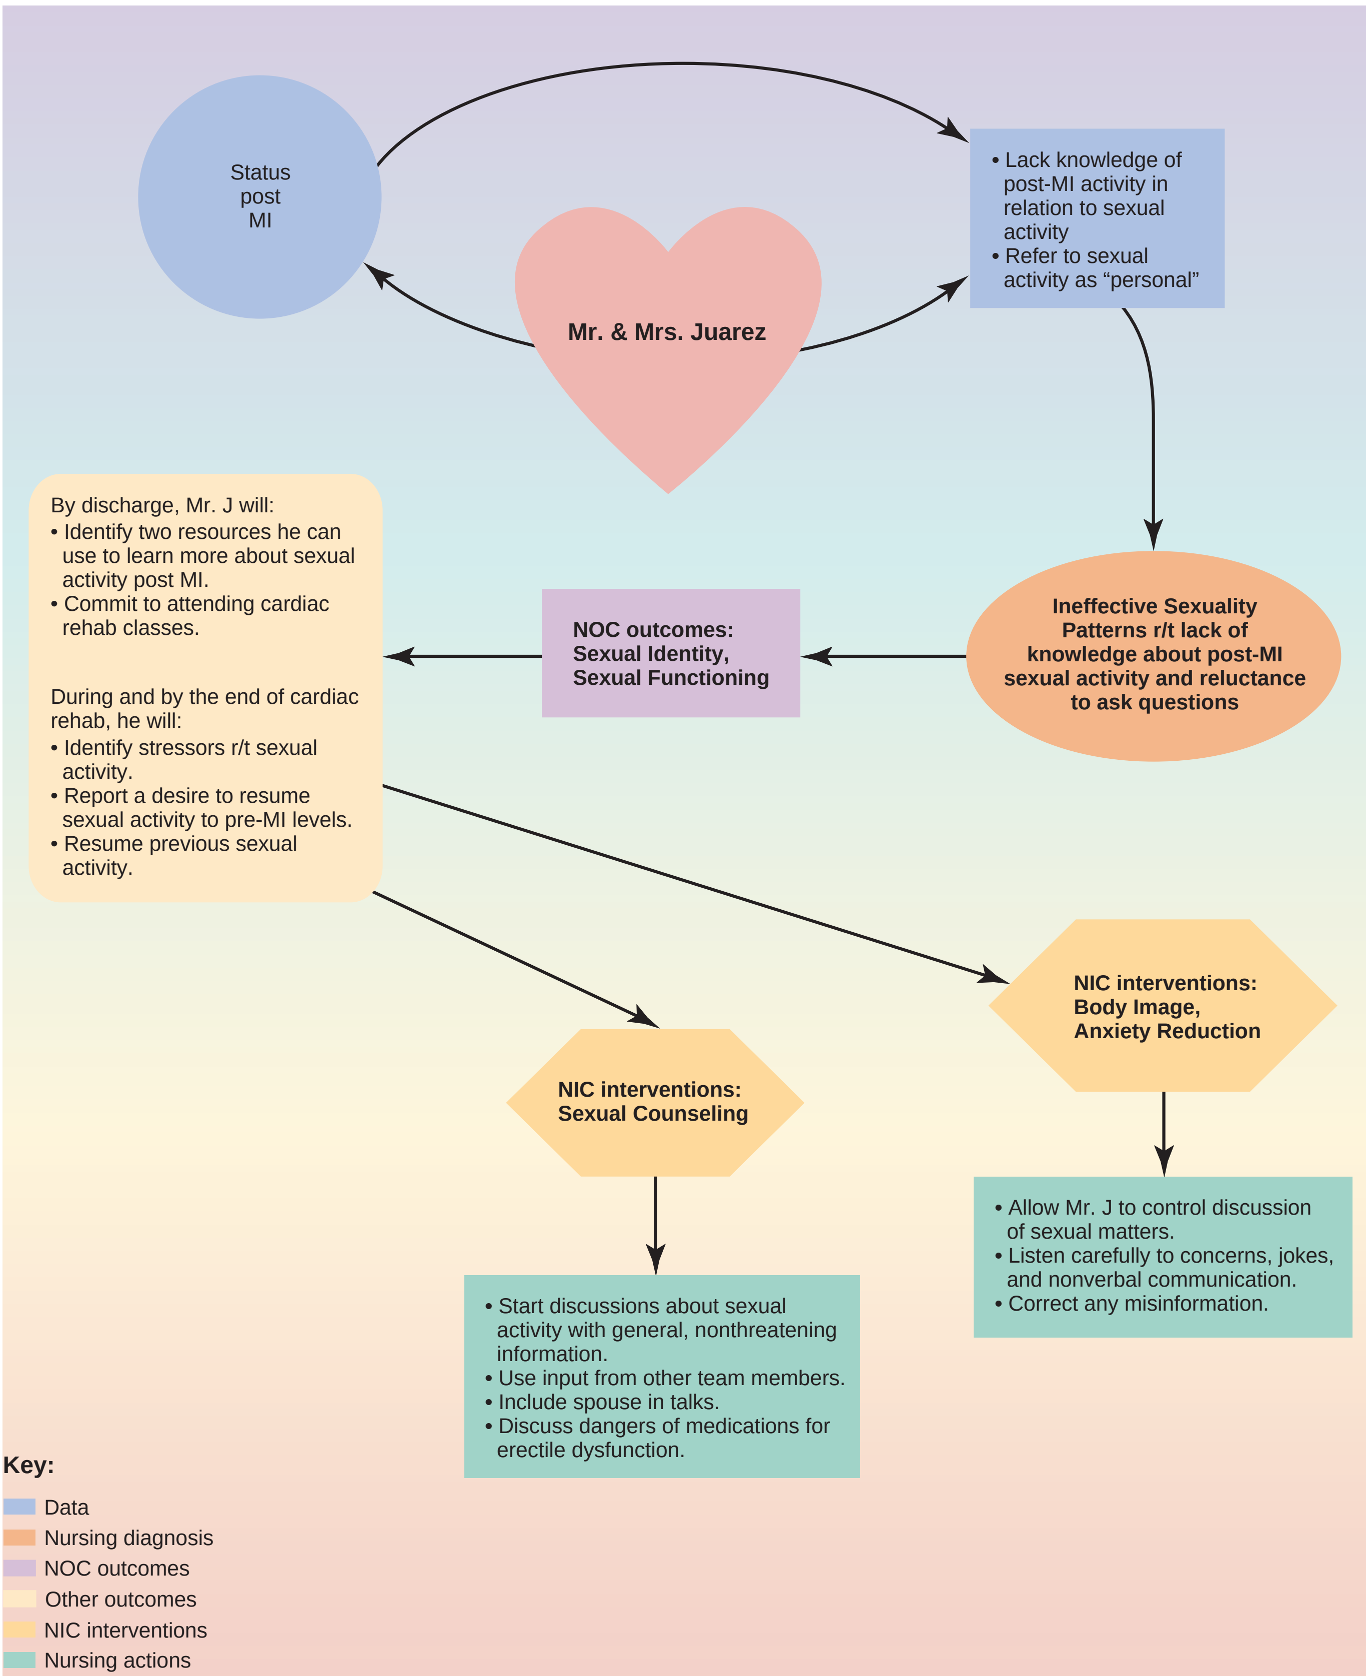
Care Map



Status post MI
Mr. & Mrs. Juarez
• Lack knowledge of post-MI activity in relation to sexual activity
• Refer to sexual activity as "personal"
Ineffective Sexuality Patterns r/t lack of knowledge about post-MI sexual activity and reluctance to ask questions
NOC outcomes: Sexual Identity, Sexual Functioning
By discharge, Mr. J will:
• Identify two resources he can use to learn more about sexual activity post MI.
• Commit to attending cardiac rehab classes.
During and by the end of cardiac rehab, he will:
• Identify stressors r/t sexual activity.
• Report a desire to resume sexual activity to pre-MI levels.
• Resume previous sexual activity.
NIC interventions: Sexual Counseling
NIC interventions: Body Image, Anxiety Reduction
• Start discussions about sexual activity with general, nonthreatening information.
• Use input from other team members.
• Include spouse in talks.
• Discuss dangers of medications for erectile dysfunction.
• Allow Mr. J to control discussion of sexual matters.
• Listen carefully to concerns, jokes, and nonverbal communication.
• Correct any misinformation.
Key:
Data
Nursing diagnosis
NOC outcomes
Other outcomes
NIC interventions
Nursing actions

hypertension and its treatment. You will need to prioritize your concerns about Mr. Thomas, balancing the need to control his blood pressure with his sexual requirements. Help him consider the consequences of various approaches, for example, by discussing alternative forms of sexual expression.

Doing

Practical Knowledge When dealing with sexuality, communication skills are essential practical knowledge. Your verbal and nonverbal skills demonstrate to patients your comfort with sensitive topics. Consider the situation of Jocelyn Carter. Suppose you responded to Jocelyn's question by telling her, "That's the least of your worries." How do you think she would feel? Now consider what might happen if you responded, "You must be worried about your sexual relationship. Tell me a little more about what you're feeling."

Nursing Process To help Mr. Thomas, you will need to assess his knowledge and concerns, clearly identify his problems (elevated blood pressure and Ineffective Sexuality Pattern), and use the nursing process to develop a plan of care that is acceptable to him. When working with patients with sexual health concerns, tailor your approach to each individual's needs, just as you do in all areas of health.

Caring

Self-Knowledge To help patients identify and resolve sexual health concerns, you will need to examine your own beliefs and values. The self-knowledge gained from examining your own views on sexuality will help you to be open to your patients' sexual concerns. What are your beliefs about sex and sexuality? Are you uncomfortable around people whose sexual orientation is different from yours? Imagine how you would feel if Frank Thanee asked you for help with his family relationships.

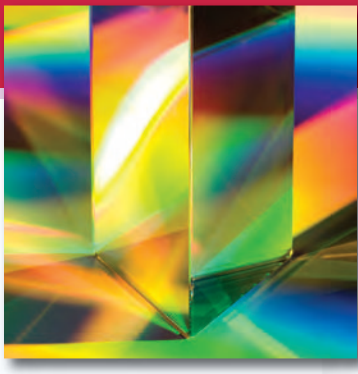
CHAPTER 34



Sleep & Rest

Learning Outcomes

After completing this chapter, you should be able to:

- Explain why rest and sleep are important.
- Describe the functions and physiology of sleep.
- Explain circadian rhythms and how they relate to sleep.
- Identify factors that influence rest and sleep.
- Discuss how sleep impacts physical, mental, and spiritual well-being.
- Describe nursing implications for age-related differences in the sleep cycle.
- Identify at least five common sleep disorders.
- Perform a comprehensive sleep assessment using appropriate interview questions, a sleep diary, and a sleep history.
- Formulate nursing diagnoses that identify sleep problems that may be treated through specific nursing interventions.
- Plan, implement, and evaluate nursing care related to specific nursing diagnoses addressing sleep problems.

Key Concepts

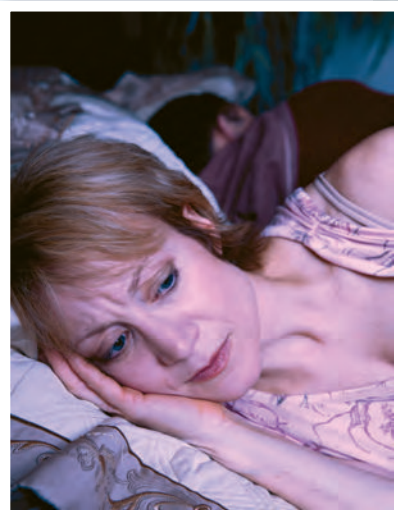
Sleep

Rest

Related Concepts

See the Concept Map at the end of this chapter.

Meet Your Patients



You are a nurse working on a surgical unit. Today you are meeting with Anne for preoperative teaching. She is scheduled for a complete hysterectomy next Monday. She has a secondary diagnosis of fibromyalgia, a chronic disorder characterized by widespread muscle pain and nonrestorative sleep.

Anne is a 49-year-old married woman with three children. She works full-time and manages the family with her husband. She says, "I'm a little nervous about the surgery, but I know I need it. But I haven't been sleeping well because of thinking about it." Anne tells you that she has actually had trouble sleeping for the last 20 years. "I take an Ambien pill, 10 mg, every night to help me sleep. Will I be able to get that in the hospital? I really can't sleep at all without it," explains Anne.

As you continue the interview, Anne explains that she suffered from physical and emotional abuse as a young woman and has had sleep problems ever since. She has been to counseling, but that did not improve her sleep. In addition to her upcoming surgery, she has been coping with the recent death of her father. You realize that sleep-promoting measures will be an important part of her nursing care.

What clues would cause you to suspect that Ann will have difficulty sleeping while in the hospital? What characteristics of the hospital environment might interfere with Anne's sleep? You may not have enough theoretical knowledge and experience to feel confident about your answers to these questions, but use your present knowledge and your life experiences to think about them.

Theoretical Knowledge knowing why

Have you felt tired after waking up from a night's sleep? Have you ever been tired, but not sleepy, and, after relaxing a while, felt your normal energy return? How do you think sleep and rest are different? How are they alike? This chapter will help you to make those distinctions.

ABOUT THE KEY CONCEPTS

In this chapter we will examine the concepts of rest and sleep, along with related concepts (e.g., stages of sleep, sleep disorders).

Rest is a condition in which the body is inactive or engaging in mild activity, after which the person feels refreshed. A person at rest is calm, at ease, relaxed, and free of anxiety and stress (Fig. 34-1). People rest by doing things that they find calming and relaxing.

Sleep is a cyclically occurring state of decreased motor activity and perception (Fig. 34-2). Body functions slow, and metabolism falls by 20% to 30%, so the body conserves energy. Sleep is characterized by altered consciousness: A sleeping person is unaware of the environment and responds selectively to external stimuli. For example, an alarm clock, bright light, or other meaningful stimuli usually awaken a sleeper, but everyday background noises and soft light do not.

Although necessary and beneficial, rest without sleep is inadequate. At rest, the body is disturbed by all exterior stimuli, whereas in sleep it is screened from them by altered consciousness. Thus, sleep restores the body; rest alone cannot do this.

WHY DO WE NEED TO SLEEP?

We spend more time sleeping than in any other single activity: about 8 hours a day, or 2,688 hours a year—nearly one-third of our lives! So why is sleep so important?

FIGURE 34-1 Woman receiving hospice care resting comfortably.

FIGURE 34-2 Boy sleeping in hospital setting.

Before you try to answer, think back to the last time you slept poorly. Remember the mental fogginess, the physical fatigue, the feeling of slight nausea? Poor quality or insufficient length of sleep for even one night can reduce mental performance, and long periods of sleep deprivation can result in stress-related illnesses (e.g., cardiac events) and injuries (e.g., from an automobile accident). The reason is that sleep and rest are essential for physical, mental, and spiritual well-being.

Sleep affects almost every tissue in our bodies. Sleep isn't essential just for the brain; it also affects growth and stress hormones, and even hormones that affect appetite and control body weight. Research also indicates that sleep strengthens the immune system (Cohen, Doyle, Alper, et al., 2009; Ranjbaran, Keefer, Stepanski, et al., 2007) and helps the body to fight infection. Lack of sleep increases the risk heart disease, stroke, infections (National Institutes of Health, 2013), and possibly even cancer (Hakin, Wang, Zhang, et. al., 2014).

Sleep is an important regulator of energy metabolism. Despite the fact that some regions of the brain are more active during sleep than when we are awake, total energy output is reduced during sleep, giving the body time for restoration and repair. Without sleep, the body is less able to tolerate glucose and yet responds with insulin resistance. Sleep restriction is also linked to increased appetite through changes in the appetite control hormones, leptin and ghrelin. Additionally, not enough sleep leads to reduced energy expenditure, all of which can lead to obesity and type 2 diabetes. (Broussard, Ehrmann, van Cauter, et al., 2012).

Sleep may also improve learning and adaptation. It gives the individual a chance to mentally repeat and rehearse facts and situations before they are encountered in wakeful life. Some evidence suggests that sleep and dreaming may facilitate the storage of long-term memory, perhaps by assisting the brain in reorganizing and storing information (National Institutes of Health, 2010, reviewed 2012).

Older adults have an even greater need for sleep to protect against the natural decline in cognitive function that comes with aging (Mander, Tao, Lu, et al., 2013).

Sleep also appears to reduce stress and anxiety, improving our ability to cope and concentrate on activities of daily living. More sleep also reduces the body's sensitivity to pain (Roehrs, Harris, Randall, et al., 2012).

Similarly, nonrestorative sleep contributes to widespread pain, which is common in older adults (McBeth, J., Lacey, R. J., & Wilkie, R., 2014).

Sleep/rest and illness are interrelated (Fig. 34-3). Illness and injury increase the need to sleep and at the same time make it difficult to sleep. In turn, lack of sleep increases the susceptibility to illness by compromising the immune system. People who are ill or injured need more sleep to restore energy needed for tissue repair and healing. However, they often have difficulty resting because of pain and other symptoms of their illness.

For further discussion of sleep theories,

Go to Chapter 34, **Supplemental Materials: Theories of Sleep,** on Davis*Plus*.

KnowledgeCheck 34-1

- Compare and contrast sleep and rest. How are they different? Alike?
- Why is promoting sleep an important nursing intervention?

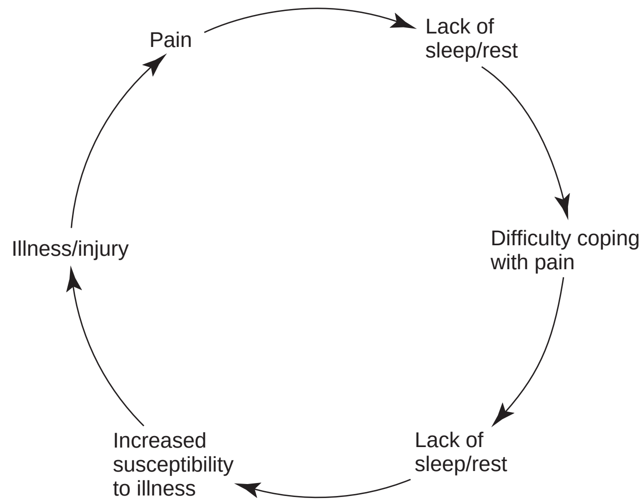


FIGURE 34-3 Relationship between sleep/rest and illness. Lack of sleep and rest increases susceptibility to illness. Likewise, the pain and stress of illness disturb sleep.

ThinkLike a Nurse 34-1

What effect do you think surgery will have on Anne's sleep (Meet Your Patient)? Why?

HOW MUCH SLEEP DO WE NEED?

Key Point: ***Sleep needs vary widely among individuals. Even though the accepted standard has been 8 hours per night for adults, there is really no amount or pattern of sleep that is best suited for all people.***

PICOT

Acupuncture for Neuropathic Pain

Situation: The nurse is caring for a client with peripheral neuropathy secondary to uncontrolled diabetes. The client is showing signs of daytime drowsiness, irritability, and restlessness. He states he has trouble sleeping, but does not want to take medication for pain. He is willing to try alternative therapies.

PICOT Components

P	Population/client	=	Sleep-deprived adults with chronic pain
I	Intervention/indicator	=	Acupuncture
C	Comparator/control	=	No acupuncture
O	Outcome	=	Decreased pain and increased sleep
T	Time	=	(none needed)

Searchable Question: Do __________ (P) who receive/are exposed to __________ (I) demonstrate __________ (O) as compared to __________ (C)?

Example of Evidence: Persistent neuropathic pain can interfere with quality of life and impair sleep. It has been associated with depression, anxiety, and loss of sleep. Acupuncture has been helpful in decreasing neuropathic pain. In one study, 77% of clients reported pain relief after six courses of acupuncture. Therefore, the client with neuropathic pain might use acupuncture to rest more comfortably and minimize the sleep disturbances that were impairing the sleep and rest cycle.

Application to Practice: The client who reports unsatisfactory sleep requires a more in-depth sleep history, including questions about the quality of sleep, sleep hygiene, napping, and bedtime routines. A complete medication and pain history should be obtained. As sleep disturbance may increase a patient's pain, the nurse may decide to explore with the healthcare team the possibility of suggesting acupuncture to a patient who is dealing with chronic pain.

Vinik, A. I., & Casellini, C. M. (2013). Guidelines in the management of diabetic nerve pain: Clinical utility of pregabalin. *Diabetes, Metabolic Syndrome, and Obesity.* 6, 57–78. doi:10.2147/DMSO.S24825

Some people are refreshed after napping for 15 or 20 minutes; others feel groggy after napping; others cannot nap at all. Many people routinely awaken several times a night and do not report being tired, whereas others report fatigue and loss of mental clarity if their sleep is even minimally interrupted. In spite of individual variations, however, different sleep patterns are characteristic of different age groups.

Infants and Children Infants have an overall greater total sleep time than any other age group. Newborns sleep as much as 16 to 18 hours a day, in periods ranging from one to several hours. Sleep time gradually decreases over the next few months, but throughout the first year of life, a minimum of 14 hours of sleep per day is recommended (Centers for Disease Control and Prevention, 2013b). Most infants sleep several hours during one overnight period, with a morning and afternoon nap each day.

The U.S. Centers for Disease Control and Prevention (CDC) (2013a) recommends that toddlers get 12 to 14 hours of sleep; preschoolers, 11 to 13 hours; and adolescents aged 10 to 17, 8.5 to 9.5 hours. There has been concern that U.S. children are getting too little sleep. As a result, children with insufficient sleep experience problems with behavior, coping, and school performance, as well as health risks.

Adults After the first year of life, sleep duration gradually lessens (Table 34-1). In most adults, sleep of 7 to 8 hours is fully restorative; however, there are wide individual variations. In some cultures, total sleep time is divided into an overnight sleep period and a midafternoon nap.

Older Adults

Older adults spend significantly less time sleeping but need more rest than younger adults. Usually older adults rest or nap during the day, go to bed early, and get up early. They take longer to fall asleep, and their arousal periods during sleep are longer and more frequent. Frequent waking is commonly due to physical discomfort, anxiety, and nocturia (Polan & Taylor, 2010). If sleep is interrupted, the person needs to increase the total time in bed in order to get adequate sleep. Otherwise, she may experience fatigue, irritability, and impaired cognition.

Table 34-1 ➤ Average Sleep Requirements

AGE GROUP	HOURS/DAY
Newborns (birth–4 weeks)	16–20
Infants (4 weeks–1 year)	14–16
Toddlers (1–3 years)	12–14
Preschoolers (3–6 years)	11–13
Middle and late childhood (6–12 years)	10–11
Adolescents (12–18 years)	8.5–9.5
Young adults (18–40 years)	7–8
Middle-age adults (40–65 years)	7
Older adults (65 years and older)	5–7

ThinkLike a Nurse 34-2

- How much sleep might Anne (Meet Your Patient) need in a normal night?
- How will a good night of sleep benefit Anne while she is in the hospital?
- If you were preparing for an important test, would it be better to stay up all night studying, or should you try to get a good night of sleep?
- How many hours of sleep do *you* need to feel rested and function well the next day? Compare notes with family members, friends, and classmates. Do they all need the same amount of sleep as you?

PHYSIOLOGY OF SLEEP

Our environment plays a role in the physiology of our sleep, so let's begin with an exploration of circadian rhythms, by which the body maintains synchronicity with nature. **Synchrony** occurs when something happens at the same time or works or develops on the same time scale as something else.

How Do Circadian Rhythms Influence Sleep?

Biorhythms are "biological clocks" that are controlled within the body and synchronized with environmental factors (e.g., gravity, electromagnetic forces, light, and darkness). Biorhythms influence many physical and mental functions. For example, body temperature is typically lowest when the person wakes up in the morning, and female menstruation follows an approximately 28-day cycle, like the lunar cycle on which our calendar months are based.

A **circadian rhythm** is a biorhythm based on the day–night pattern in a 24-hour cycle. The term comes from the Latin words *circa*, meaning "about," and *dies*, meaning "day"—once a day. A person's circadian rhythm is regulated by a cluster of cells in the hypothalamus of the brainstem that respond to changing levels of light. Circadian rhythm affects our overall level of functioning; for example, most people have a higher energy level in the daytime and less energy at night. However, some people are more alert and active in the morning, and others function at a higher level in the afternoon or evening.

Do you feel sleepy at about the same time each night? Do you often awaken before the alarm clock goes off? If so, that's because the timing of sleep and waking is also influenced by your circadian biorhythm. Sleep quality is best when your sleep and wake times are in synchrony with your circadian rhythm. For this reason, people who work evening and night shifts (e.g., healthcare workers, police officers) can suffer significant sleep deprivation until their bodies adjust to the new pattern. Changing time zones can also disrupt sleep–wake cycles and can thus be troublesome for people who travel frequently. Hospitalization can also interfere with a patient's circadian rhythm. Noises, lights, waking the patient for vital signs or medications, altered normal bedtime rituals, absence or presence of family members, homesickness, recent losses, worry, fear of the unknown, and pain may compromise the patient's quality of sleep and the ability to fall and stay asleep (Meltzer, Davis, & Mindell, 2012).

Self-Care

Fatigue and Sleep Deprivation Among Healthcare Workers

Extended work hours and rotating shift work significantly increase fatigue and impair on-the-job performance and safety.

Impact of Fatigue

- Lapses in attention and memory; poor concentration
- Irritability
- Reduced motivation, apathy, and indifference
- Diminished reaction time
- Impaired judgment and decision making
- Altered communication
- More errors, needlestick and sharps injuries, and adverse events to patients

Fight Sleepiness on the Job

- Be honest with yourself about how you tolerate rotating shifts, night shift, and longer shifts (e.g., 12 hours), and schedule accordingly. Plan rest days in between consecutive work days.
- Engage in conversation with others, not just listen and nod.
- Do something that requires physical action periodically, even if it means just geting up and moving around.
- Take frequent breaks (e.g., every 1 to 2 hours) during the night shift, if possible.
- Be smart about your caffeine use; that is, don't take caffeine when you don't need it to stay awake, and avoid caffeine at the end of your shift before sleep.
- Practice good sleep hygiene measures during your off hours. See the Self-Care box Teaching Your Patients About Sleep Hygiene.

ThinkLike a Nurse 34-3

What may upset Anne's circadian rhythm?

How Is Sleep Regulated?

What makes us fall asleep? What happens in the brain during sleep? The mechanisms of sleep are complex and poorly understood, but we know that sleep is controlled by centers in the lower part of the brain that produce sleep by actively inhibiting wakefulness. As just noted, a major factor in regulating sleep is the amount of light received through the eyes. The increasing light of a dawning sky signals the hypothalamus (Fig. 34-4) to induce gradual arousal from sleep. Another collection of nerve cell bodies within the brainstem, called the **reticular formation**, is responsible for maintaining wakefulness. The reticular formation is activated by stimuli from the cerebral cortex. Together, these reticular and cortical neurons are called the **reticular activating system (RAS)**. Neurotransmitters associated with excitatory and inhibitory sleep mechanisms include catecholamines, acetylcholine, serotonin, histamine, and prostaglandins.

An **electroencephalogram (EEG)** is used to record the electrical activity of the neurons in the brain. Electrical impulses are transmitted from the brain through electrodes attached to the scalp. These impulses create five different wave patterns, or *brain waves*. Figure 34-5 shows examples of different types of brain waves during sleep:

- **Alpha waves** are high-frequency, medium-amplitude, irregular waves. These occur in the drowsy stage.
- **Beta waves** are high-frequency, low-amplitude, irregular waves. These occur during periods of wakefulness.

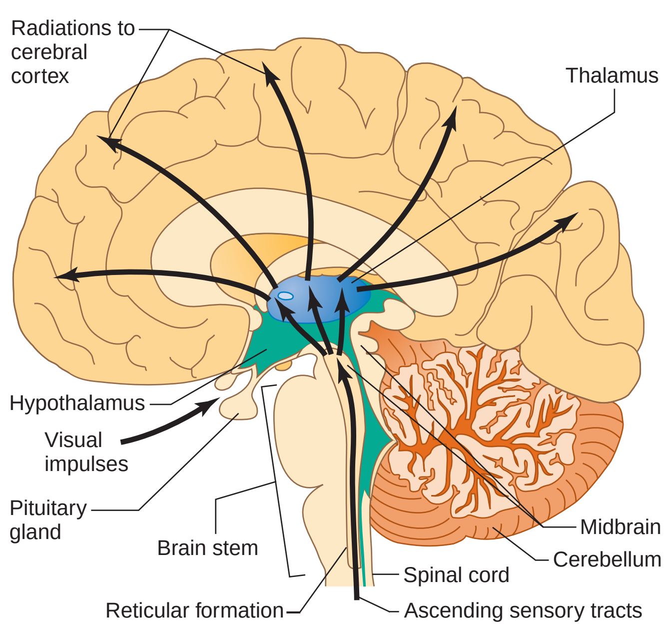

FIGURE 34-4 The reticular activating system works to regulate sleep and wakefulness.

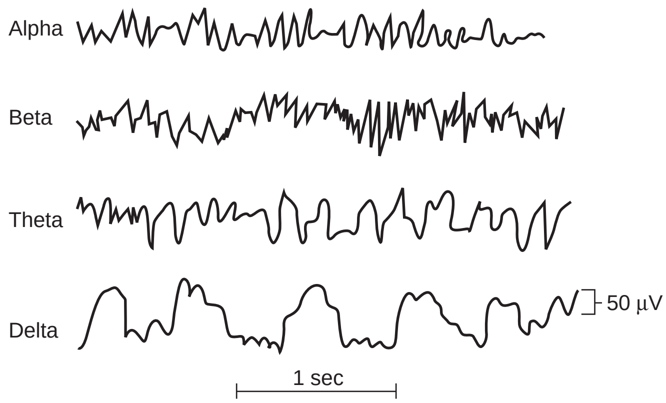

FIGURE 34-5 Four different types of brain waves.

- **Spindles** or **K-complexes** are peaked, irregular waveforms that occur in the earlier phases of NREM sleep.
- **Theta waves** are high-amplitude waves that are common in children but rare in adults. These occur with delta waves when transitioning to a deeper sleep stage.
- **Delta waves** are low-frequency, high-amplitude, regular waves common in deep sleep.

The EEG of a waking person differs greatly from that of a sleeping person. In general, the greater the brain activity is, the more rapid will be the brain waves on the EEG. While the person is awake, brain waves are very rapid, irregular, and low in amplitude, mostly alpha and beta waves. Many neurons are firing at different intervals, at different times, and with different strengths. When a person is relaxed without intense stimulation of the senses, the EEG records mostly alpha activity. During sleep, alpha waves disappear. They are replaced by slower, higher amplitude delta waves.

What Are the Stages of Sleep?

There are two distinct types of sleep, NREM and REM. The body moves back and forth between them during the sleep cycle.

NREM Sleep

NREM (non–rapid eye movement) sleep is generally the restful phase of sleep in which physiological function is slow. NREM sleep is also called slow-wave sleep (SWS) because it is characterized by the presence of delta waves. NREM is divided into three stages, each deeper than the one preceding it. The parasympathetic branch of the autonomic nervous system becomes progressively more dominant during each stage of NREM sleep. During this phase, muscles relax; body temperature lowers; and heart rate, respirations, and blood pressure decrease.

REM Sleep

During **REM** (rapid eye movement) sleep the brain becomes highly active and the brain waves resemble those of a person who is fully awake. Rapid eye movements occur, which can often be detected even though the sleeper's eyelids are closed. More spontaneous awakenings occur during this stage than any other.

REM sleep is essential for mental and emotional restoration. Loss of REM sleep impairs memory and learning. A person who is deprived of REM sleep for several nights will usually experience *REM rebound*; that is, the person will spend a greater amount of time in REM sleep on successive nights, keeping the total amount of REM sleep constant over time.

Sleep Cycles

Cycling between REM and NREM sleep produces restorative rest. The American Association of Sleep Medicine (2007) identifies four stages of sleep (three NREM stages and the REM stage) have been identified, based on brain activity and other physiological characteristics (Table 34-2). The NREM/REM sleep cycle repeats four to six times throughout the night, depending on the total amount of time spent sleeping (Fig. 34-6). Each cycle lasts about 90 to 100 minutes. The first REM period may last only about 20 minutes, but with each cycle, the REM period lengthens until, in the last cycle of a typical 8-hour sleep period, REM may last as long as 60 minutes. The amount of time spent in each sleep stage varies over the life span.

KnowledgeCheck 34-2

- List the stages of sleep.
- Describe the progression of a typical sleep cycle for a young adult.
- Describe the physiological activity characteristic of each stage of sleep.
- What is the stage that must be "made up" if not enough time is spent in it?

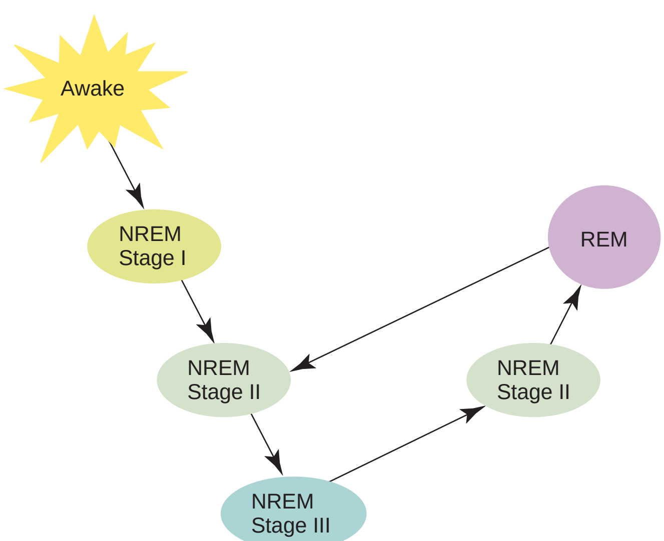

FIGURE 34-6 The normal adult sleep cycle. All but NREM stage I are repeated four or more times a night.

Table 34-2 ➤ Characteristics of Stages of Sleep

STAGE	TYPICAL BRAIN WAVE TYPE	CHARACTERISTICS
W (Wakefulness)	Beta waves with some alpha waves	Ranges from full alertness to the early stages of drowsiness. Reading eye movements Eye blinks with eyes open or closed
NI (NREM)	Alpha waves with occasional low frequency theta waves	Transition between wakefulness and sleep Slow eye movements Light sleep; can be awakened easily Relaxed but aware of surroundings Groggy, heavy lidded Regular, deep breathing; eyelids open and close slowly. Accounts for about 5% of total sleep. Dreams are usually not remembered.
NII (NREM)	Theta waves, K-complexes and sleep spindles	Light sleep Easily roused Temperature, heart rate, and blood pressure decrease slightly. Accounts for about 50% of total sleep.
NIII (NREM)	Delta waves; sawtooth waves	Deep sleep Difficult to rouse; if awakened in this stage, may be confused. Parasympathetic nervous system predominates: temperature, pulse, respirations, and blood pressure slow even more. Skeletal muscles are very relaxed. Snoring may occur. Some dreaming may occur, but dreams are less vivid than those that occur in REM sleep. This sleep stage is especially important for restorative processes such as healing, growth, and tissue renewal. Makes up 20-25% of total sleep time.
REM	5–30 minutes (usually at least 20–30)	Highly active sleep with spontaneous awakenings Less restful than NREM sleep Eyes move rapidly and small muscles twitch. Essential for mental and emotional restoration Metabolism, temperature, pulse, and blood pressure increase. Pulse may be rapid and irregular. Apnea may occur. Gastric secretions increase. Deep-tendon reflexes are depressed. Dreaming occurs. If awakened, person will react normally. Accounts for about 25% of total sleep.

Think Like a Nurse 34-4

- Anne's (Meet Your Patient) physician has prescribed zolpidem (Ambien) for her. Ambien is a sedative/hypnotic (nonbarbiturate) used in the short-term treatment of insomnia. Why do you think the doctor prescribed a sleeping medication even though Anne is physiologically and psychologically dependent on the medication?
- Anne will undoubtedly receive narcotic analgesics after surgery. How do you think they will affect her sleep?

WHAT FACTORS AFFECT SLEEP QUALITY AND DURATION?

People vary not only in the amount of sleep they need, but also in their sleep patterns. **Sleep quality** has both subjective and objective components. It is related to (1) the total amount of sleep, (2) how well the person slept, and (3) whether the person obtained the needed amounts of NREM and REM. Several factors affect the amount and quality of sleep.

Age

Age is an important factor affecting the duration of sleep (see Table 34-1). But sleep *patterns* are also affected by age. For example, newborns and young children experience prolonged REM sleep periods; young adults spend about 25% of their sleep in REM sleep; and older adults typically enter REM sleep quicker and spend more time in this active phase of sleep.

Children and Adolescents

A survey by the National Sleep Foundation found that 2 out of 3 young children experience sleep-related problems a few times a week. The problems included trouble falling asleep, frequent awakenings, nightmares, and heavy snoring (CDC, 2013a, 2013b). Environmental stimuli, such as the sounds and lights of other family members' activities, may make it difficult for a young child to sleep, or the child may have difficulty "winding down" after hectic activities in the late afternoon and early evening hours.

- *Toddlers and preschoolers* may be frightened to go to bed because of imaginary figures or intruders, or they may waken frequently at night because of bad dreams, the need to use the bathroom, illness, heavy snoring, tossing off the bedclothes, or falling out of bed. Some have difficulty self-calming enough to achieve a restful state before falling asleep.
- *School-age children* may suffer significant sleep disturbances because of anxiety or depression. Others might have more temporary sleep difficulty related to isolated situations, stress, excitement, or social concerns, such as anticipating a school event or sports competition.
- *In adolescence,* the growth spurt that occurs increases the need for sleep (Polan & Taylor, 2010), yet only 31% of high school students report getting at least 8 hours of sleep on an average school night (CDC, 2010). At the same time, teenagers may not sleep well because of increased demands at school; staying up late to study, watch television, text or social network; dating or staying out late with friends; or using alcohol or drugs. Some teens consume large amounts of caffeinated colas and other beverages that can delay or disturb sleep.

Young Adults

College students may pull "all-nighters" to cram for exams or experience difficulty falling asleep or staying asleep because of worries about grades or future career choices. Young adults may drive themselves too hard to succeed, prompting late nights at work or sleep loss due to hectic travel schedules or work-related stress. Others might not obtain enough sleep because of social and personal entertainment choices during the night. Others might work evening or night shifts.

Sleep for parents of young children is often interrupted. Breastfeeding mothers typically need to feed their infants one or more times each night until the infant begins solid foods. Parents of toddlers often wake to care for a child who is having a nightmare, is ill, or needs to use the bathroom. The National Sleep Foundation (2008) survey found that some parents lose as many as 200 hours of sleep a year because of their children's poor sleeping patterns.

Middle-Aged and Older Adults

Middle-aged adults may experience sleep difficulties because of the depression, anxiety, and tension that result from the stress and competing demands on time, such as work or career, the need to care for a parent, marital discord, worry about teenaged children, or financial problems. The lack of sleep compounds the problem, leading to reduced ability to cope, and again to lack of sleep. Sleep interruptions are common due to access to technology, such as text messaging and social networking. As a physiological example, menopausal women may be awakened by hormonal fluctuations. Obstructive sleep apnea (OSA) also plays a role in insufficient sleep.

Older adults may suffer sleep disturbances because of nocturia, the side effects of medications, underlying illnesses, depression, discomfort, or pain. In addition, the levels of melatonin, the natural hormone that controls sleep, decline in the latter decades of life.

Lifestyle Factors

Lifestyle factors influencing sleep include work, exercise, nutrition, and use of medications and drugs. As noted earlier, a person who changes work shifts frequently may find it difficult to sleep at the right time or for long enough to feel rested and restored. Moreover, people who cross time zones frequently because of travel may experience difficulty falling asleep, early wakening, or daytime fatigue.

Physical Activity If it occurs at least 2 hours before bedtime, exercise promotes sleep. Fatigue from a normal physically active day is thought to promote a restful night's sleep. However, the more tired a person is, the shorter the first period of REM sleep will be. Additionally, sedentary lifestyle is a factor for sleep disorder.

Diet Foods can either promote or interfere with sleep. A meal high in saturated fat near bedtime may interfere with sleep. Dietary L-tryptophan and adenosine are essential amino acids (meaning the body does not produce its own), found in milk, cheese, and animal products, that may help to induce sleep by converting into serotonin.

Carbohydrates seem to promote relaxation through their effects on brain serotonin levels. In general, satiation induces sleep, whereas many people, especially infants and children, have difficulty falling asleep when they are hungry.

Nicotine and Caffeine Central nervous system stimulants, such as nicotine and caffeine, interfere with sleep. Smokers tend to have more difficulty falling asleep and are more easily roused than nonsmokers. People who stop smoking often experience temporary sleep disturbances during the withdrawal period. Caffeine blocks adenosine and thereby inhibits sleep. However, individuals vary greatly in their sensitivity to caffeine. Some people can consume coffee throughout the day and evening and suffer no loss of sleep, whereas others cannot consume even small amounts of caffeine early in the day without suffering sleep difficulty later.

Alcohol Consumption of alcohol, especially if heavy, may hasten the onset of sleep; however, it disrupts REM and slow wave sleep and may cause spontaneous awakenings with difficulty returning to sleep. In addition, in some people heavy alcohol consumption can prompt vivid dreams during REM sleep. Because alcohol is a diuretic, it can interrupt sleep by inducing nocturia.

Medications Many of the medications people take cause either sleeplessness or excessive grogginess and sedation. Medications to induce sleep (i.e., hypnotics) tend to increase the amount of sleep while decreasing the quality. Zolpidem tartrate (Ambien) promotes normal REM sleep and appears to influence sleep quality less than do other hypnotics. Amphetamines, tranquilizers, and antidepressants reduce the amount of REM sleep; barbiturates, in addition, interfere with NREM sleep. Opioids, such as morphine, suppress REM sleep and cause frequent awakening. Beta blockers are reported to cause sleep disorders and nightmares.

Illness

Illness increases the need for sleep and rest. At the same time, its associated mental and physical distress can cause sleep problems. Fear of the unknown outcome of an illness and role changes associated with hospitalization can cause anxiety. Disease symptoms, such as fever, pain, nausea, and respiratory conditions (e.g., shortness of breath, dyspnea, sinus congestion), can also interfere with sleep. Specific disease conditions altering the quality of sleep include allergies, hyperthyroidism, and Parkinson's disease.

Anxiety increases gastric secretions, intestinal motility, heart rate, and respirations, all of which contribute to a restless night. Anxiety also stimulates the sympathetic nervous system, increasing the level of norepinephrine. This decreases stage III and REM sleep and leads to more awakenings. Depression may be associated either with too much sleep or with difficulty sleeping.

Environmental Factors

Environmental factors can promote or inhibit sleep. Some people need a cool room, whereas others need warmth. Some prefer heavy blankets, and others like to sleep with just a light sheet. Noise can also inhibit sleep, but a person can become habituated to noise over time and be less affected by it. Some people routinely fall asleep to music or while listening to a radio or television. Often loud noises are needed to awaken a person in NREM stages III and REM sleep.

Any change in the usual environmental stimuli can affect sleep. For example, a patient used to falling asleep next to his wife may have trouble sleeping alone in a hospital bed. Equipment noise, the muffled sounds of a busy medical-surgical unit, or the labored breathing or snoring of a roommate also can interfere with the patient's ability to sleep.

When people who are accustomed to sleeping in a dark room are hospitalized, they may have trouble falling asleep because of light outside their window or filtering into the room from the hallway. However, light can be therapeutic for some patients suffering from sleep problems. Exposure to bright light can alter circadian rhythms in some adults.

Light therapy has not been shown to be effective in older adults with dementia living in skilled nursing facilities (Haesler, 2004).

KnowledgeCheck 34-3

- For each of the following patients, propose at least two factors that might affect sleep:
  A newborn in the neonatal intensive care unit
  A preschooler being treated for pneumonia
  An adolescent with cancer
  A breastfeeding mother of a newborn
  An older man who has fractured his hip
- Identify at least three types of environmental stimuli that can disturb sleep.

WHAT ARE SOME COMMON SLEEP DISORDERS?

Sleep disorders are classified by their signs and symptoms. The more common disorders fall into two groups:

- **Dyssomnias**—Sleep disorders characterized by insomnia or excessive sleepiness. They include insomnia, sleep–wake schedule (circadian) disorders, sleep apnea, restless leg syndrome, hypersomnia, and narcolepsy.

- **Parasomnias**—Patterns of waking behavior that appear during sleep (e.g., sleepwalking)

Insomnia

Insomnia as defined by the Diagnostic and Statistical Manual, 5th edition (DSM-5), is the predominant complaint of dissatisfaction with sleep quantity, associated with the inability to fall asleep, remain asleep, or go back to sleep. The sleep disturbance causes significant distress or impairments in social, occupational, academic, behavioral, and other important areas of functioning. True insomnia occurs at least 3 nights per week, and is present for 3 months or longer, even when there is ample opportunity for sleep (American Psychological Association, 2013).

Sleep difficulty may be *transient/short term* (less than a month) or *chronic* (longer than a month). People with sleep difficulty usually report an insufficient quantity and quality of sleep and wake without feeling refreshed, even though they are often observed to sleep more than they perceive that they do.

Insomnia is the most common sleep disorder. Two out of three people say they have trouble sleeping at least once a week (National Sleep Foundation, 2011), but 10 to 20% of the general population meet the DSM-5 diagnostic criteria for insomnia disorder (American Psychological Association, 2013). It is more prevalent in women and in adults older than 60 years; those who suffer from chronic illness (e.g., hypertension, obesity, cancer, thyroid disorders) (Institute of Medicine, 2006; Budhiraja, Roth, Hudgel, et al., 2011); and shift workers (Budhiraja, Roth, Hudgel, et al., 2011).

Daytime consequences of insomnia, which include symptoms of excessive daytime sleepiness, poor concentration, fatigue, lethargy, and irritability. Insomnia can also create an increased risk for depression, anxiety, and possibly cardiovascular disorders (Wilson, Nutt, Alford, et al., 2010). Or it may be the presenting symptom of other primary sleep disorders, such as restless leg syndrome.

Recent evidence suggests a link between abnormal hypothalamic–pituitary–adrenal gland activity and insomnia and mood disorders (Roth, Roehrs, & Pies, 2007). Insomnia may occur as a result of illness, depression, anxiety disorders, acute stress, substance abuse, side effects of medications (e.g., steroids, central adrenergic blockers, bronchodilating agents), or inadequate sleep hygiene (e.g., watching TV in bed, drinking caffeine-containing beverages before bedtime).

Primary care providers can diagnose and manage most cases of insomnia. Once underlying medical or psychiatric conditions have been identified and treated, a combination of behavioral and pharmacological therapy may be effective. The use of medication to induce sleep is controversial because some types can become habit forming, become less effective when taken continuously, and can have serious side effects. However, sedative–hypnotic treatment is justified in short-term insomnia to avoid the negative effects of insomnia on mood and performance. Short-term aggressive treatment may prevent the development of chronic insomnia.

Sleep–Wake Schedule (Circadian) Disorders

Abnormalities in sleep–wake schedules may be caused by rapid time-zone changes (jet lag), shift work, or a change in total sleep time from day to day. Symptoms include decreased vigilance, decreased ability to perform psychomotor tasks, and short sleep episodes *(microsleeps)* that the person is not aware of. People suffering jet lag need several days to adjust their sleep–wake schedule.

Restless Leg Syndrome (RLS)

Restless leg syndrome (RLS) is a disorder of the central nervous system characterized by an uncontrollable movement of the legs while resting or before sleep onset. It tends to run in families. It affects 5% to 15% of Americans (U.S. Deptartment of Health and Human Services, et al., 2005, revised 2011). Children and young adults experience this condition, but it is especially common in older adults, and is sometimes associated with low levels of iron (Ball & Caivano, 2008; Hening, 2007) and use of some antidepressants.

It tends to be familial, more often occurring in women than in men. Symptoms include unpleasant creeping, crawling, itching, or tingling sensations in the legs. Symptoms are relieved only by moving the legs, which prevents the person from relaxing and falling asleep.

If RLS is severe, treatment may include **neuroleptic** agents and medication used to treat Parkinson's disease (Birath & Martin, 2009). People with RLS should avoid stimulants (e.g., caffeine). Other self-care measures include walking, massaging, stretching, heat or cold compresses, medication, vibration, and acupressure. Some people with severe symptoms might require anticonvulsant medication to control the creeping and crawling sensation in the legs (National Sleep Foundation, n.d.).

Sleep Deprivation

Sleep Deprivation is a NANDA-I nursing diagnosis. It is not actually a sleep disorder, but rather a result of prolonged sleep disturbances (e.g., insomnia and parasomnias), resulting from NREM or REM deprivation, or both. According to the CDC (2013b), nearly 30% of adults reported an average of less than 6 hours of sleep per day. Persons experiencing sleep deprivation are likely to feel drowsy during the day or a general feeling of malaise. They have difficulty performing daily tasks, impaired cognitive processing, problem-solving, and decision making; restlessness, perceptual disorders, slowed reaction time, irritability; and somatic (body) complaints (e.g., hand tremors).

Toward Evidence-Based Practice

Broussard, J. L., Ehrmann, D. A., Van Cauter, E., et al. (2012). Impaired insulin signaling in human adipocytes after experimental sleep restriction: A randomized, crossover study. *Annals of Internal Medicine, 157*(8), 549–557.

Sleep may be an important regulator of energy metabolism. The investigators found that in people who were sleep deprived, the body's fat cells' response to insulin reduced by 30%, thereby increasing the risk for insulin resistance, type 2 diabetes, and obesity.

Roehrs, T. A., Harris, E., Randall, S., et al. (2012). Pain sensitivity and recovery from mild chronic sleep loss. *Sleep, 35*(12), 1667–1673.

With a small sample of healthy adults, investigators found that increased sleep time lessens daytime sleepiness and reduces pain sensitivity.

Ong, J. C., Stepanski, E. J., & Gramling, S. E. (2009, February 15). Pain coping strategies for tension-type headache: Possible implications for insomnia. *Journal of Clinical Sleep Medicine, 5*(1), 52–56.

Study participants reported both stress and sleep problems as a trigger of headaches, and going to sleep as a strategy for dealing with pain. Study findings suggest that too much or too little sleep can lead to headaches; people with headaches often take naps to deal with headache pain. Chronic insomnia can occur from napping during the day.

Ruiter, M. (2012, June 11). Top risk of stroke for normal-weight adults: Getting under 6 hours of sleep. Presented at Sleep 2012, the annual meeting of the Associated Professional Sleep Societies. Abstract #0829.

The 3-year study of 5,666 adults ages 45 and older found that stroke risk was four times higher with less than 6 hours of sleep a night versus 7 to 8. Enrollees in the *Reasons for Geographic and Racial Differences in Stroke (REGARDS)* study were of normal weight and at low risk for sleep apnea. They had no history of stroke, no symptoms, and were not at high risk for sleep apnea. Chronic sleep deprivation (<6 hours of sleep per night) is thought to increase the risk of stroke as a result of changes in the autonomic functions of the body, including blood pressure, heart rate, inflammation, and glucose levels.

1. Sleep deprivation produces detrimental effects for many people, even those of normal weight and at low risk for sleep apnea. In what other ways do you think sleep deprivation creates problems for the body?

2. Considering the findings of the REGARDS study, what else would you want to know if your patient has been getting less than 6 hours of sleep per night?

3. On one hand, sleep can be a way for people with headaches to deal with the pain. On the other hand, too much sleep, such as daytime naps, can wreak havoc in getting a good, restful sleep at night. How would you use the Ong study to guide patients who are dealing with the pain of a migraine?

Go to Chapter 34, **Toward Evidence-Based Practice Suggested Responses,** on Davis*Plus*.

Insomnia is a major contributor to injuries caused by motor vehicle accidents and other unintentional fatal injuries (American Academy of Sleep Medicine, 2014).

Functional imaging studies contrasting sleep-deprived and well-rested brains reveal the importance of adequate sleep for memory and learning (Chee & Chuah, 2008; Walker, 2009). If sleep deprivation is severe and prolonged, delusions, paranoia, and other psychotic behavior may occur. Studies of sleep-deprived adults revealed changes in the levels of certain immunoglobulins and other markers of the immune system (Hui, Hua, Diandong, et al., 2007; Ranjbaran, Keefer, & Stepanski, 2007), which means going without sleep can weaken the body's protection against infection.

Illness and hospital care are common causes of sleep deprivation, especially for patients in critical care units (CCUs). In this environment, lights are on most of the time, and equipment noise, frequent treatments, and assessments all combine with the client's fragile physical condition to create sleep deprivation. Likewise, healthcare providers who work long and late hours or rotating day–night shifts experience serious fatigue that can lead to medical error, increased risk of occupational injury, and patient injury or death (The Joint Commission, 2011).

Hypersomnia

Hypersomnia is excessive sleeping, especially in the daytime. People with excessive daytime sleepiness doze, nap, or fall asleep at times and in situations when they need or wish to be awake and alert. The sleep disorders that commonly cause hypersomnia are obstructive sleep apnea and narcolepsy. Hypersomnia may also be caused by disorders of the central nervous system, kidney, or liver or by metabolic disorders (e.g., diabetic acidosis and hypothyroidism). It can also be a symptom of depression.

Sleep Apnea

Sleep apnea is a periodic interruption in breathing during sleep—an absence of air flow through the nose or mouth during sleep. Typically the soft tissue of the pharynx and soft palate collapse and obstruct the airway. Episodes may occur several or a hundred times a night and may last up to 1 minute or longer. During periods of apnea, the oxygen level in the blood drops, and the carbon dioxide level rises, causing the person to wake up. This may result in cardiac dysrhythmias (irregularities) and increases in pulse and blood pressure. Many people with sleep apnea complain of unrefreshed sleep, fatigue and morning headache, and easily falling asleep during sedentary activity; however, some may experience mild sleep apnea without any symptoms (Epstein, Kristo, Strollo, et al., 2009).

OSA is diagnosed clinically by reports of at least five witnessed breathing interruptions or awakenings due to gasping or choking events per hour (Epstein, Kristo, Strollo, et al., 2009). To definitively diagnose sleep apnea, a sleep study consisting of an EEG, monitoring of arterial oxygen saturation, and an electrocardiogram (ECG) is recommended. Treatment depends on the type of apnea involved. Untreated sleep apnea is associated with polycythemia, hypertension, angina, coronary artery disease, right-sided heart failure, stroke, impotence, depression, personality changes, and mood swings. The two main types of sleep apnea (obstructive and central) have different etiologies. **Mixed apnea** is a combination of the two main types.

Obstructive Sleep Apnea Obstructive sleep apnea (OSA) is caused by airway occlusion (usually by the tongue or palate) during sleep, but the person continues to try to breathe. Sleeping partners often report that the person snores, snorts, grunts, or thrashes about during sleep. Airway occlusion may also be due to a collapse of the hypopharynx or from other structural abnormalities (e.g., enlarged tonsils, adenoids, a deviated nasal septum, or thyroid enlargement). Although most often males over age 40, particularly if overweight, are affected by sleep apnea, the condition occurs in females of any age and weight. Treatment of OSA might involve surgery to remove any obstruction within the airway or applying CPAP (continuous positive airway pressure) treatment. This is a device that delivers oxygen using forced air pressure and keeps the airways open when apnea occurs. Patients with OSA should avoid alcohol and smoking and lose excess weight (Epstein, Kristo, Strollo, et al., 2009). Caution patients with sleep apnea about driving if drowsy. They are 5 to 7 times more likely to have a motor vehicle accident than those without apnea (Laugsand, Strand, Vatten, et al., 2014).

Central Sleep Apnea Central sleep apnea (CSA) is a complete suspension of breathing resulting from a dysfunction in central respiratory control. Only about 10% of sleep apnea is central in origin. People with CSA tend to awaken during sleep and, therefore, experience daytime sleepiness.

Snoring

Snoring is a hallmark sign of OSA, but it does not necessarily indicate OSA. Even so, snoring can significantly reduce the quality of sleep for the bed partner. Snoring results when the muscles at the back of the mouth relax during sleep, obstruct the airway, and vibrate with each breath. Obstruction is usually more pronounced when the person sleeps on his back. Many treatments have been invented to open the air passages, such as nose tapes or even surgery. Saline sprays, nose drops, and cortisone sprays are also used—all with mixed success.

Narcolepsy

Narcolepsy is a chronic disorder caused by the brain's inability to regulate sleep–wake cycles normally. The distinction between being asleep and being awake are blurred. At various times, the person with narcolepsy experiences a sudden, uncontrollable urge to sleep lasting from seconds to minutes, even though the person sleeps well at night. The person cannot avoid the sleep episodes but awakens easily.

Narcolepsy is characterized by sleepiness, slurred speech, slackening of the facial muscles, a feeling of impending weakness of the knees, paralysis, and hallucinations. Performance is impaired during these micro-sleep episodes. Sleep episodes can come on suddenly, even while the person is having a conversation. If they occur while the person is driving, working, or operating machinery, they can be dangerous. People with narcolepsy awaken from episodes of unavoidable sleep feeling refreshed (National Institute of Neurological Disorders and Stroke, 2009, updated 2011). Some have other symptoms, such as **cataplexy**, a sudden loss of muscle tone usually triggered by an emotional event (e.g., laughter, surprise, or anger), but most only have hypersomnia.

Narcolepsy affects up to 1 in every 2,000 Americans, males about as often as females (National Institute of Neurological Disorders and Stroke, 2009, updated 2011). It can develop at any age, but symptoms typically first appear during adolescence and early adulthood. Each micro-sleep episode begins in the REM stage instead of progressing through the NREM stages first. People with narcolepsy do not tolerate irregular sleep–wake patterns, such as shift work, and have difficulty staying awake with passive activity, such as watching television. The condition is controlled by central nervous system stimulants, such as methylphenidate (Ritalin), with little evidence of tolerance, dependence, or abuse.

Other individuals might suffer **pseudo-narcolepsy**, which is characterized by involuntary episodes of sleep but are related to acute or chronic sleep deprivation. When the person is well rested, the episodes resolve.

KnowledgeCheck 34-4

- What is the most common dyssomnia?
- What factors in the hospital may contribute to sleep deprivation in patients?
- What are the clinical signs of sleep deprivation?
- Why are sleeping pills not recommended for chronic insomnia?
- Why is snoring significant?

ThinkLike a Nurse 34-5

Compare and contrast insomnia and hypersomnia. How are they different? How are they alike?

Parasomnias

The parasomnias include sleepwalking, sleeptalking, bruxism, night terrors, REM sleep behavior disorders, and nocturnal enuresis.

Sleepwalking Sleepwalking (somnambulism) occurs during stage III of NREM sleep, usually 1 to 2 hours after the person falls asleep. The sleeper leaves the bed and walks about, with little awareness of surroundings. He may perform what appear to be conscious motor activities (e.g., brush his teeth, make coffee), but he does not wake up. The person is not aware of sleepwalking and has no memory of the event on awakening. The event may last 3 to 4 minutes or longer. Children sleepwalk more than adults do. If the child does not outgrow the condition or serious safety risks exist, medication may be given to suppress the deepest stage III sleep. Stress, fatigue, and some drugs can trigger sleepwalking.

Sleeptalking Sleeptalking occurs during NREM sleep, just before the REM stage. It does not usually interfere with the person's rest but may be disturbing to a bed partner.

Bruxism Bruxism grinding and clenching of the teeth, usually occurs during stage II NREM sleep. It can eventually erode tooth enamel and loosen the teeth. The noise can also disturb the bed partner's sleep.

Night Terrors Night terrors are sudden arousals in which the person (often a child) is physically active, often hallucinatory, and expresses a strong emotion such as terror. Children experiencing night terrors typically cry or scream in fear, thrash about, and resist all attempts by their parents or other caregivers to hold or console them. The child appears to be fully awake, but she is not; in fact, children in the midst of night terrors are extremely difficult to awaken. Episodes may last from 10 to 30 minutes. However, the child typically returns to sleep without awakening, and in the morning has no memory of the event. Unlike *nightmares* (unpleasant, frightening dreams), which occur during REM sleep, night terrors occur during stage III (deep NREM) sleep.

REM Sleep Behavior Disorders REM sleep behavior disorders are associated with REM (or dreaming period) sleep, in which the sleeper violently acts out the dream. People have actually injured themselves or others without waking.

Nocturnal Enuresis Nocturnal enuresis (bedwetting) is nighttime incontinence past the stage at which toilet training has been well established (Polan & Taylor, 2010). It has incorrectly been associated with dreaming; however, most incidents occur during NREM sleep, during the first third of the night when the child is difficult to rouse. It may be distressing to the child and family because of the importance society places on continence, the inconvenience of keeping bed linens clean, and the misconception that the child is bedwetting to act out against parents. Because the great majority of children outgrow enuresis, the best strategy is patience (McCance & Huether, 2009). If the problem persists, the child should have a full medical evaluation.

Secondary Sleep Disorders

Secondary sleep disorders occur when a disease causes alterations in sleep stages or in quantity and quality of sleep. The following are the most common causes:

- **Depression.** Depressed people may spend a great deal of time in bed. However, in general, they have difficulty falling asleep, experience less slow-wave (deep) sleep, spend less time in REM sleep, awaken early, and have less total sleep time.
- **Hyperthyroidism or hypothyroidism.** An increase in thyroid secretion causes an increase in stage III sleep; hypothyroidism causes a decrease in those stages. Hyperthyroidism increases metabolic rate, making it difficult for the person to fall asleep.
- **Pain.** Both acute and chronic pain interfere with sleep. Chronic pain affects both the quality and quantity of sleep. It inhibits sleep, increases arousals during sleep, and causes longer waking intervals during the night.
- **Airway passage obstruction or CNS dysfunction.** These conditions were discussed under Sleep Apnea.

Disorders That Are Provoked by Sleep

Sleep-provoked disorders are those that occur when signs and symptoms of the disease appear or become worse during sleep. Diseases affected by sleep include the following (McCance & Huether, 2009):

- **Coronary artery disease**. During REM sleep, dreams may increase heart rate and provoke angina and ECG changes.
- **Asthma**. People with asthma may experience bronchospasm during REM sleep. In adults, asthma attacks frequently occur during the night as the esophageal sphincter relaxes and reflux results. In children, they occur mostly during the final two-thirds of the night, when there is less stage III sleep.
- **Chronic obstructive pulmonary disease (COPD).** Persons with COPD experience lowered oxygen tension and increased carbon dioxide retention during sleep, especially during REM sleep, when neuromuscular control is normally depressed. This can result in pulmonary spasm and transient pulmonary hypertension.
- **Diabetes.** Blood glucose levels vary during sleep. When diabetes is uncontrolled, it may profoundly affect the blood sugar level during sleep, when the person is not alert enough to deal with it. Therefore, patients with uncontrolled diabetes may need to have blood glucose levels monitored during sleep.

- **Gastric and intestinal ulcers.** During REM sleep, people with duodenal ulcers secrete up to 20 times more gastric acid than do people who do not have duodenal ulcers. Peptic ulcers also contribute to increased acid, often producing nocturnal epigastric pain and sleep loss.
- **Epilepsy**. Seizures are sensitive to sleep patterns. Sleep deprivation can trigger seizures, increase their intensity, or cause seizures to last longer. Some forms of epilepsy are especially reactive to sleep cyles or transitions between sleep states (Schachter, Shafer, & Sirven, 2013).

KnowledgeCheck 34-5

- List and define at least three parasomnias.
- Describe ways in which depression can affect sleep.
- List two sleep-provoked disorders, and explain how the sleep stage affects the disease.

PracticalKnowledge knowing how

Because sleep enhances wellness and speeds recovery from illness, promoting sleep is an important independent nursing intervention. In this section, you will learn how to assess for signs of sleep disturbance, as well as specific interventions to facilitate sleep for each client.

ASSESSMENT

It is important to assess usual sleep patterns and rituals for all patients who are being admitted to the hospital or seeking help for a sleep problem. A brief assessment for all patients should include questions about the following:

- Usual sleeping pattern
- Sleeping environment
- Bedtime routines/rituals
- Sleep aids
- Sleep changes or problems

Key Point: ***The nurse would conduct a more in-depth sleep assessment for patients who wake up at least three times a night; those who take more than 30 minutes to fall asleep; and if the difficulty falling or staying asleep has been going on for more than 30 days.***

For a list of additional questions you can use to obtain this information,

Go to Chapter 34, **Assessment Guidelines and Tools, Questions for a Sleep History,** in Volume 2.

If the person reports experiencing satisfactory sleep, that is an adequate assessment, and you merely need to support her usual sleep patterns and rituals. When you suspect a sleep problem, you will perform a more in-depth assessment, such as a detailed sleep history or sleep diary.

A **sleep history** (self-report) includes in-depth questions about the person's usual times for sleep, any preparation, preferences and routines, quality of sleep, napping habits (if any), and whether she wakes early and cannot return to sleep.

A **sleep diary** provides very specific information on your patient's patterns of sleep. This allows you to identify trends in sleep/wakefulness and associate behaviors interfering with sleep. You will usually tell the patient to keep the diary for 14 days; remind him that it is important to be diligent in maintaining it.

For examples of a sleep history and a sleep diary,

Go to Chapter 34, **Assessment Guidelines and Tools, Questions for a Sleep History** and **Sleep Diary,** in Volume 2.

To find the National Sleep Foundation Sleepiness Diary online,

Go to Chapter 34, **Resources for Caregivers and Healthcare Professionals,** on Davis*Plus*.

An **actigraph** is a device worn on the wrist or may be an application on a mobile device that estimates a person's sleep and wake patterns, including time spent in various sleep stages. A **sleep study** is most useful in detecting sleep apnea and other sleep disorders, such as narcolepsy, night terrors, and periodic limb movement disorder. One of the most common sleep studies performed in a sleep lab is **polysomnography**, which records brain wave activity, eye movement, oxygen and carbon dioxide levels, vital signs, and body movements during the sleep phases.

ANALYSIS/NURSING DIAGNOSIS

It is important to determine whether lack of sleep is a problem, is a symptom of a problem, or is contributing to (etiology of) a different problem. For health promotion applications, use the NANDA-I diagnosis Readiness for Enhanced Sleep when a client has no particular sleep problem but wishes to move to a higher level of functioning in the area of sleep.

Sleep as the Problem

When you wish to focus on interventions to promote sleep, use the following NANDA-I labels on the problem side of the nursing diagnosis.

Use *Insomnia* for patients who have a disruption in the amount of quality of sleep to the extent that it impairs functioning.

Use *Sleep Deprivation* as the nursing diagnosis when the patient's amount, consistency, or quality of sleep is decreased over prolonged periods of time. Defining characteristics of Sleep Deprivation are more severe than those for Disturbed Sleep Pattern, so nursing activities may focus as much on relieving symptoms (e.g., confusion, paranoia) as on sleep promotion.

Use *Disturbed Sleep Pattern* as the diagnosis when assessment data points to a time-limited sleep problem due to external factors (e.g., inability to sleep in the unfamiliar hospital environment). The problem should be one that can be treated by nursing therapy. Add modifying words to specify the type of sleep problem, as in the examples. This will help you to focus goals appropriately.

- Disturbed Sleep Pattern (difficulty falling asleep) related to worries about family
- Disturbed Sleep Pattern (difficulty falling and remaining asleep) related to noise of hospital environment and need for scheduled treatments
- Disturbed Sleep Pattern (premature awakening) related to sleeping aid dependence and lack of knowledge of nonpharmacological aids for insomnia
- Disturbed Sleep Pattern (excessive daytime sleeping) related to effects of biological aging and depression
- Disturbed Sleep Pattern (altered sleep–wake patterns) related to frequent rotations of shift and overtime

Carefully describe the etiologies for sleep problems, because they determine your interventions.

ThinkLike a Nurse 34-6

In the following nursing diagnoses, how do you think your interventions would be different for each diagnosis?
Disturbed Sleep Pattern related to:

- Changes in bedtime routines
- Exercising within 2 hours before sleep
- Drinking caffeinated beverages, eating chocolate, and drinking alcohol
- Emotional or physical pain
- Drug dependence or withdrawal
- Physical illness

Sleep Pattern as an Etiology

Disturbed Sleep Pattern and Sleep Deprivation affect many areas of functioning, so they often are the etiology of other nursing diagnoses, as in these examples:

- Risk for Injury or Falls related to sleepwalking (or REM sleep behavior disorder or narcolepsy)
- Fatigue (or Activity Intolerance) related to chronic insufficient quality or quantity of sleep (e.g., secondary to insomnia)
- Ineffective Coping related to decreased cognitive functioning and awareness, secondary to lack of sleep
- Disturbed Thought Processes related to decreased cognitive functioning, secondary to lack of sleep
- Anxiety (or Fear) related to fear of death from sleep apnea

Sleep Pattern as a Symptom

Difficulty sleeping may be one of the symptoms of another problem. For example, a client may have Spiritual Distress related to challenges to belief system *as manifested by nightmares, sleep disturbances, and verbalization of inner conflict about beliefs.* In this instance, you would focus on interventions for Spiritual Distress, assuming that the sleep pattern would improve as the Spiritual Distress is resolved. Other nursing diagnoses that may cause sleep loss include Anxiety, Chronic Sorrow, Death Anxiety, Decisional Conflict, Complicated Grieving, Diarrhea, Impaired Gas Exchange, Nausea, Pain, and Relocation Stress Syndrome.

KnowledgeCheck 34-6

- For a chronic, long-term sleep problem, would you use a diagnosis of Sleep Pattern Disturbance, Sleep Deprivation, or Readiness for Enhanced Sleep?
- Name at least two nursing diagnoses that might have a sleep problem as the etiology.
- Name at least one nursing diagnosis that might have a sleep problem as the defining characteristic.

PLANNING OUTCOMES/EVALUATION

NOC standardized outcomes linked to the NANDA-I sleep labels are as follows:

- For Disturbed Sleep Pattern: Rest, Sleep, and Personal Well-Being
- For Sleep Deprivation: Rest, Sleep, and Symptom Severity
- For Insomnia: Concentration, Endurance, Fatigue Level, Mood Equilibrium, Personal Health Status, Personal Well-Being, Quality of Life, Rest, and Sleep

When sleep disturbances are the etiology of another nursing diagnosis, you will need to use the NOC outcomes associated with that diagnosis. For example:

Nursing diagnosis: Anxiety related to Sleep Deprivation
NOC outcomes for Anxiety: Anxiety Control, Coping

Individualized goals/outcome statements you might use to evaluate the success of interventions to promote sleep include the following:

- Verbalizes feeling rested or feeling less fatigue.
- Falls asleep within 30 minutes; sleeps 6 hours without awakening.
- Maintains a sleep–wake pattern that provides sufficient energy for the day's tasks.
- Demonstrates self-care behaviors that provide a healthy balance between rest and activity.
- Identifies stress-relieving rituals that enable falling asleep more easily.
- Demonstrates decreased signs of sleep deprivation.
- Verbalizes feeling less fatigued and more in control of life activities.

PLANNING INTERVENTIONS/IMPLEMENTATION

NIC standardized interventions for Sleep Deprivation and Sleep Pattern Disturbance include the following: Coping Enhancement, Energy Management, Environmental Management: Comfort, Relaxation Therapy, and Sleep Enhancement. Linkages have not yet been established for Insomnia.

Specific nursing activities for clients with sleep problems are described in the next sections.

For a care plan and care map for Sleep Pattern Disturbance,

Go to Chapter 34, **Care Plan** and **Care Map**, on or Davis*Plus*.

Schedule Nursing Care to Avoid Interrupting Sleep

Use nursing judgment to decide when a procedure must be done and when it is more important for your patient to sleep. Healthcare routines usually allow time for rest periods. In addition, you may consider the following:

- Some patients need to rest after a procedure or after meals.
- If the person looks sleepy, give a prescribed sleeping pill early to avoid waking him later in the evening.
- You can often alter routines; for example, you can allow the patient to sleep as long as he can in the morning and bring his breakfast later. Or if the care provider has prescribed a sleeping pill, give it early in the evening if he seems sleepy.
- Cluster care to avoid unnecessary interruptions in sleep. Unless the patient is critically ill, do not wake him for morning vital signs if he is sleeping.
- Keep the noise level to a minimum. Be aware that activities, conversation, and equipment, even outside the patient's room, can disrupt sleep (Meltzer, Davis, & Mindell, 2012).

For examples of NOC outcomes and NIC interventions for sleep diagnoses,

Go to Chapter 34, **Standardized Language: Selected NOC Outcomes and NIC Interventions for Sleep Diagnosis**, on Davis*Plus*.

Create a Restful Environment

Many people find it difficult to sleep in a strange bed, even a comfortable one. Hospital beds are not noted for their luxury, but you can help make them more comfortable.

- Be sure the bed linens are tight on the bottom and loose on top to allow movement.
- Keep linens clean, dry, and free of irritants. Perspiration on the hospital gown or linens can lead to chill.
- Good body alignment also facilitates relaxation. Use extra pillows, a blanket from home, or any other item that may help the patient rest.
- Keep the room dark and quiet, unless the patient prefers a light.
- As much as possible, control the temperature of the room and provide good ventilation.

Highlights of Procedure 34-1

For steps to follow in *all* procedures, refer to the Universal Steps for All Procedures found on the inside back cover of Volume 2. Go to the full procedures in Volume 2 to practice and learn the procedure steps. Use these procedure highlights later to help you review key points.

Procedure 34-1: Giving a Back Massage

- Warm the lotion.
- Raise the bed to working height.
- Position the patient comfortably on her side or prone.
- Place lotion on your hands.
- Rub down the length and then up the sides of the back.
- Never rub directly over the spine.
- Apply gentle thumb pressure on either side of the spine at the midback, pushing outward for about 2.5 cm (1 in.) along the trapezius muscle.
- Always apply pressure away from the spine, not toward it.
- Go to the spots that felt the tightest or that the patient states are tight. Work in small circles, using gentle thumb pressure.
- Gently shake the scapula.
- Apply horizontal strokes across the scapula, using your thumb.
- Apply pressure in circles using the heels of your hands down both sides of the spine.
- Apply horizontal strokes using the heels of your hands across the latissimus dorsi muscle.
- Gently rub your hands up either side of the spine from the base of the back to the base of the neck, and then down the sides of the back.

Promote Comfort

Pain, itching, and nausea may all be deterrents to rest and sleep in an ill person. Be sure to offer pain medications at their scheduled times, and before the patient's sleep time. Other comfort measures include providing a restful environment (see the preceding intervention) and offering fluids, cool cloths, or a massage or back rub. For detailed instructions for back massage,

Go to Chapter 34, **Procedure 34-1: Giving a Back Massage**, in Volume 2.

Also see the accompanying Highlights of Procedure 34-1 box.

Support Bedtime Rituals and Routines

Most people have some kind of a routine before bed, be it reading, watching TV, drinking warm milk, or praying or meditating, to allow them to prepare for sleep. For children, a favorite doll, blanket, bedtime story, as well as brushing their teeth and hair, may enhance sleepiness. Be sure to include any routines or rituals in the nursing plan of care to ensure continuity. Advise patients who smoke not to smoke after the evening meal.

Offer Appropriate Bedtime Snacks or Beverages

Complex carbohydrates (e.g., bread, cereal) seem to help most people sleep. A small amount of protein (e.g., milk, cheese) with the snack reduces the sugar boost and keeps blood glucose more stable. The dietary amino acid L-tryptophan promotes sleep. Advise the client to avoid alcohol, especially in the evening. Although it may induce sleepiness at first, alcohol interferes with the deep sleep cycle. The client should also avoid taking caffeine-containing foods and beverages (e.g., tea, coffee, energy drinks, chocolate, colas) after the evening meal. Advise the client to drink plenty of fluids during the day but to restrict fluids close to bedtime. Nicotine is a stimulant and should be avoided.

Promote Relaxation

You will base your choice of relaxation strategies on your repertoire of techniques and on patient preference. Relaxation strategies may include a massage, a warm bath, or one of the following:

- *Guided imagery* can be used to help your patient move in his mind to a safe place, where relaxation is possible. You may ask the patient what type of place will soothe him and "guide" him there through visualization. See Chapter 12 if you need to review.
- *Progressive muscle relaxation*, relaxing each muscle independently and progressing from head to toe, may help to promote sleep.
- *Music therapy* has been shown to be effective in promoting relaxation. Some patients respond well and can put away their troubles while listening to music, whereas others may find music irritating. Slow, quiet music or a recording of forest or ocean sounds may be soothing.

You may wish to refer to Chapter 46 for more details about relaxation strategies.

Maintain Patient Safety

A person who sleepwalks needs protection from injury because the risk of falling is great (e.g., stairs). Intravenous infusions, catheters, and nasogastric tubes can produce injury if they are pulled out of the body when the person gets out of bed. Guide sleepwalkers back to bed, and remember that they startle easily, so be gentle and quiet.

Safe Sleep for Infants

Infant suffocation is a common cause of death in infants, and is often associated by infant position and the sleep environment, such as use of blankets, pillows, and infant positioners. The safest position for infants under 3 months of age is supine position (not on the side) on a firm sleep surface, and sharing a room but not a bed. Commercial positioning devices are not recommended to keep infants on their backs unless prescribed (American Academy of Pediatrics Task Force on Sudden Infant Death Syndrome & Moon, 2011; CDC, 2012).

Teach About Sleep Hygiene

Most people with sleep problems manage them at home by creating a restful environment, relaxing, avoiding distractions, and trying various sleep strategies without using sleep-inducing medication. Refer to the Self-Care box (Teaching Your Client About Sleep Hygiene) when teaching clients self-care for sleep.

Administer and Teach About Sleep Medications

When considering sleep medications, it is important for the patient to understand the options, be aware of potential side effects, and know what questions to ask. Some medications are habit forming; others may have unpleasant side effects. When patients first start taking prescription sleep aids, they should use caution during morning activities until they are sure how the drug affects them. Long-term effects of these medications are not known. As a general rule, they are not recommended for long-term use. Some natural or homeopathic aids can lead to rest and sleep.

Prescription Sleep Medications

You should be familiar with the various prescription and nonprescription sleep medications your patients may be taking.

Nonbenzodiazepines These sedative/hypnotics have a short half-life, which means that they are eliminated from the body quickly and do not cause daytime sleepiness. They are also selective, meaning that they target specific receptors that are thought to be associated with sleep rather than depressing the entire central nervous system. Examples are zolpidem tartrate (e.g., Ambien) and zaleplon (e.g., Sonata). The newest type of sedative/hypnotic, although not technically a nonbenzodiazepine, is ramelteon (e.g., Rozerem). It is the first sleep drug not designated as a controlled substance. It works by targeting melatonin receptors.

General side effects of nonbenzodiazepines include drowsiness, dizziness, fatigue, headache, and unpleasant taste. Long-term effects of these medications are not yet known, although an increased risk of fatal overdose has been reported.

Benzodiazepines This class of sedative/hypnotics is the first-line treatment for insomnia, and includes both long-acting and short-acting drugs. Long-acting medications linger in the body and potentially cause daytime drowsiness. Many benzodiazepines were originally

Self-Care

Teaching Your Client About Sleep Hygiene

- Follow a regular routine for bedtime and morning awakenings.
- Go to bed each night at the same time, even on days you are off work.
- If you cannot fall asleep in 30 minutes, get up and do something nonstimulating, but avoid using the computer. The wavelengths of blue light emitted from the screen arouse the brain into a wakeful state. When you feel sleepy, go back to bed.
- Use relaxation methods to promote sleep; read a book, pray, or meditate.
- Avoid going to bed angry; and stay clear of emotional discussions before going to sleep.
- Don't depend on sleeping aids; be aware of the potential dangers of sleeping medications.
- Use your bedroom only for sleep; do not turn your bedroom into the family room.
- Avoid caffeine, alcohol, tobacco products, and heavy meals before going to sleep. Remember that some beverages and foods, such as black tea, chocolate, and cola, contain caffeine. Alcohol interferes with the transition to deeper phases of sleep. Heavy alcohol consumption can contribute to breathing impairment during the night.
- Avoid eating carbohydrates (e.g., crackers, cereal, or bread) before bed; they boost blood glucose levels, so a few hours later, the rapid drop in sugar will wake you.
- Use aromatherapy to relax.
- If you take prescription drugs, ask your prescriber or pharmacist about the side effects.
- Use earplugs to block out noise.
- Walk or exercise in the early evening at least 1 hour before going to sleep; doing so will raise your body temperature and tire your muscles. Even 15 minutes a day of exercise will give your body the activity and oxygen it needs to help you relax more and sleep better.
- Take a warm bath just before going to sleep. This will raise your body temperature and relax you to help you fall asleep more easily.
- Avoid naps during the day, unless you are an older adult who takes short "power naps." Daytime napping can lead to nighttime insomnia.
- Don't try to "catch up" on sleep. Rise at your regular time, even if you went to bed later than usual.
- Try to keep your bedroom as dark as possible. Even an illuminated bedroom clock is a source of light that can be distracting when trying to fall asleep. Either replace the clock or block the light with something.
- Close your eyes and visualize something peaceful when trying to fall asleep. Imaging your favorite, relaxing place where you find comfort or familiarity can relax you and help you get to sleep.
- Try progressive relaxation to fall asleep. Follow recorded instructions directing you in a sequence of relaxing certain muscle groups.

formulated to treat anxiety. Examples are diazepam (e.g., Valium), alprazolam (e.g., Xanax), flurazepam (e.g., Dalmane), lorazepam (e.g., Ativan), and triazolam (e.g., Halcion). The risk for rebound insomnia and dependency and tolerance, especially in older adults, is greater with this class of sleep-inducing drugs. They are potentially dangerous when combined with alcohol and some medications.

Barbiturates These sedative/hypnotics and anticonvulsants are rarely prescribed for insomnia because of the risk of addiction, abuse, and overdose. Examples are amobarbital (e.g., Amytal), pentobarbital (e.g., Nembutal), and secobarbital (e.g., Seconal).

Tricyclic Antidepressants At times, primary care providers prescribe antidepressants to promote sleep. Although none of these medicines is specifically FDA approved for this purpose they have shown clinical benefit for some people with insomnia who also suffer with depression. Examples are amitriptyline (e.g., Elavil), doxepin (e.g., Sinequan), imipramine (e.g., Tofranil), and nortriptyline (e.g., Aventyl, Pamelor).

Older adults are particularly at risk for daytime sleepiness and dizziness.

Nonprescription Sleep Medications

Nonprescription sleep medications usually contain an antihistamine, which may induce drowsiness that lasts into the next day. It is important to check the ingredient label of any over-the-counter (OTC) medication to see whether it contains an antihistamine. Advise clients that OTC sleep medications can interact with other medicines they may be taking, so they should consult their prescriber or pharmacist before using them. An example is diphenhydramine hydrochloride (Benadryl). Other nonprescription sleep aids include the following:

- *Melatonin*. Melatonin is a natural hormone produced by the pineal gland to modulate sleep. Commercial products containing melatonin are widely sold as sleep aids; however, the effectiveness remains controversial. Although approved by the Food and Drug Administration (FDA) and generally safe for short-term use, melatonin is unregulated and varies in strength and purity across manufacturers and may pose a risk for people taking blood thinners, such as warfarin. There also is increased risk of seizure in children with brain disorders.
- *Herbal sleep aids*. Herbal remedies for sleep problems include chamomile tea, valerian root, hops, lavender,

and passionflower. These herbal remedies have not undergone extensive testing for benefits and safety and have not been proved to be effective sleep aids.

KnowledgeCheck 34-7

- What is the classification of zolpidem (Ambien)? Why is it an especially desirable medication for sleep?
- What are two other classes of medications that are sometimes prescribed for sleep?
- Describe three independent nursing interventions to promote sleep.
- Why should people contact their prescriber before taking nonprescription sleep aids?

PUTTING IT ALL TOGETHER

Anne (Meet Your Patient) has arrived back on the surgical unit after her surgery. She has a urinary catheter, oxygen mask, IV line, and morphine by patient controlled analgesia (PCA) for pain control. She is nauseated from the anesthesia and moaning in pain. Her husband, Eric, and their three children are there to greet her, and they are worried. Anne looks dreadful! "With all this equipment, and her moaning, is she going to be okay?" Eric asks. He tells you that Anne didn't sleep at all the night before surgery. "She was nervous and didn't want to take a sleeping pill because we were supposed to be at the hospital by 5:30 a.m.," he explains.

You perform an initial assessment. Anne's vital signs are as follows: BP, 118/74 mm Hg; pulse, 88 beats/min and regular; respirations, 26 breaths/min; and T, 99.48°F. Her lungs are clear, the dressing is dry and intact, and the urinary catheter shows a small amount of light yellow urine draining from the bladder. The oxygen mask is partially off. You check Anne's oxygen saturation. It is 99%. The notes from the operating and recovery rooms indicate that Anne has not received anything for pain in more than 90 minutes. The PCA is connected, but the pump supplies analgesia only when the patient triggers the device. Anne has been groggy and does not understand or remember that she must push the button to obtain pain medication. You trigger a bolus of morphine and show Anne and the family how the PCA works. You realize that she is sedated and may not remember what you have taught her, but Eric assures you that they will be staying for the day and will reinforce your instruction.

Several minutes later Anne is calm. Her respirations have slowed to 20 breaths/min, and she is lightly snoring. Eric sighs in relief. "I guess she'll sleep for a while now," he says. You explain that she will sleep with the pain medication, but it will not be as restful as good-quality sleep. "With the morphine she will wake frequently and not get much REM sleep—that's a type of sleep we all require for health," you explain.

You were able to gather data preoperatively from Anne about her sleep habits and routines. You are also aware that Anne has had chronic sleep problems. In the nursing care plan, you have written the diagnosis Disturbed Sleep Pattern related to pain (secondary to fibromyalgia), dependence on Ambien, anxiety, grief, stresses of surgery, and unfamiliar environment. You tell Eric that you would like him to bring from home Anne's pillow, toothbrush, and face cream because she has indicated that these are all part of her usual bedtime ritual. When Eric volunteers that Anne sometimes listens to music before bedtime, you suggest that he also bring her favorite music.

At dinnertime, Eric and the kids go home and gather Anne's belongings. When they return, she is more alert and comfortable. She tells them she feels exhausted, but not in pain. When you make your rounds, you explain that you would like to keep her usual bedtime routine and that she will be getting Ambien this evening. She is visibly relieved by your comments.

This scenario demonstrates full-spectrum nursing and shows how a nurse can make a difference for patients and their families by recognizing the need for sleep and providing appropriate interventions.

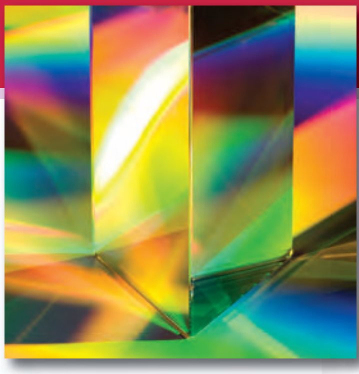
CHAPTER 35



Skin Integrity & Wound Healing

Learning Outcomes

After completing this chapter, you should be able to:

- Discuss the factors that affect skin integrity.
- Identify wounds based on accepted classification schemes.
- Describe the three phases of wound healing.
- Distinguish primary intention healing, secondary intention healing, and tertiary intention healing.
- Describe three types of wound drainage.
- Review the major complications of wound healing.
- Explain the factors involved in the development of pressure ulcers.
- Use the Braden scale to assess risk for pressure ulcers.
- Assess and categorize pressure ulcers based on the pressure ulcer staging system.
- Provide nursing care that limits the risk of pressure ulcer development.
- Differentiate the kinds of chronic wounds.
- Accurately chart assessment of a wound.
- Demonstrate appropriate techniques for irrigating a wound.
- Describe care of a wound with a drain.
- Differentiate the five forms of wound debridement.
- Discuss the different kinds of tissue found in wounds.
- Discuss when and how to use absorbent, alginate, collagen, gauze dressings, transparent films, hydrocolloids, hydrogels, and foam and antimicrobial dressings.
- Describe guidelines to follow when applying heat or cold therapy.
- Demonstrate bandage and binder application.

Key Concepts

Skin integrity
Wound
Wound healing

Example Problem

Pressure ulcers

Meet Your Patient

William Harmon is a 78-year-old man who fell 3 days ago. His fall resulted in a fractured left hip. He was admitted to the hospital and underwent an open reduction and internal fixation (ORIF) of the left hip. Today is his second postoperative day. He is still bed bound and is unable to roll or pull himself up in bed.

Mr. Harmon's weight on admission was 140 lb (63.64 kg). His height is 73 in. His family reports that he has been steadily losing weight. He expresses little interest in eating and says he has been depressed since his wife died last year.

While performing your assessment of Mr. Harmon, you notice that a large dressing covers the left hip incision. You loosen the dressing and see the staples are intact at the incision site and there is a minimal amount of serosanguineous drainage on the bandage. As you turn him in bed, you see a 10 cm by 6 cm reddened area on his coccyx and a 2 cm by 3 cm purple bruise-like area on his left heel. Mr. Harmon now has three wounds, an intentional surgical wound and two pressure ulcers that have resulted from his impaired mobility. How will you care for each of these wounds? What factors contributed to each of the wounds, and how will you promote healing?

Theoretical Knowledge knowing why

The integumentary system consists of the skin, hair, nails, sweat glands, and the subcutaneous tissue below the skin. The skin is the largest organ of the body. The major functions of the skin include protection of the internal organs, unique identification of an individual, thermoregulation, metabolism of nutrients and metabolic waste products, and sensation.

ABOUT THE KEY CONCEPTS

For optimal function, **skin integrity** must be preserved—that is, all layers of the skin must be intact. A **wound** is a disruption in the normal skin integrity. It is easy to see how the concepts of skin integrity and wound are related; they are opposites. You will use your knowledge of both these concepts as you protect your patients' skin and promote the physiological process of **wound healing**.

WHAT FACTORS AFFECT SKIN INTEGRITY?

To understand skin integrity, you need to understand the structure of the skin (Fig. 35-1).

Epidermis The **epidermis** is the outer portion of the skin. The epidermis is made up of four or five layers, of which the most important are the inner and outer layers.

- The **stratum corneum**, the outermost layer, is composed of numerous thicknesses of dead cells. Functioning as a barrier, it restricts water loss and prevents fluids, pathogens, and chemicals from entering the body.
- The **stratum germinativum**, the innermost layer of the epidermis, continually produces new cells, pushing the older cells toward the skin surface. In the dermal layer, the **keratinocytes** are protein-containing cells that give the skin strength and elasticity. Deeper in the epidermis are **melanocytes**, which produce melanin, a pigment that gives skin its color and provides protection from ultraviolet light. **Langerhans cells** are mobile. Their function is to phagocytize (engulf) foreign material and trigger an immune response.

Dermis The **dermis** lies below the epidermis and above the subcutaneous tissue. It is made of irregular fibrous connective tissue that provides strength and elasticity to the skin and is generously supplied with blood vessels. Within the dermis are sweat glands, sebaceous (oil) glands, ceruminous (wax) glands, hair and nail follicles, sensory receptors, elastin, and collagen.

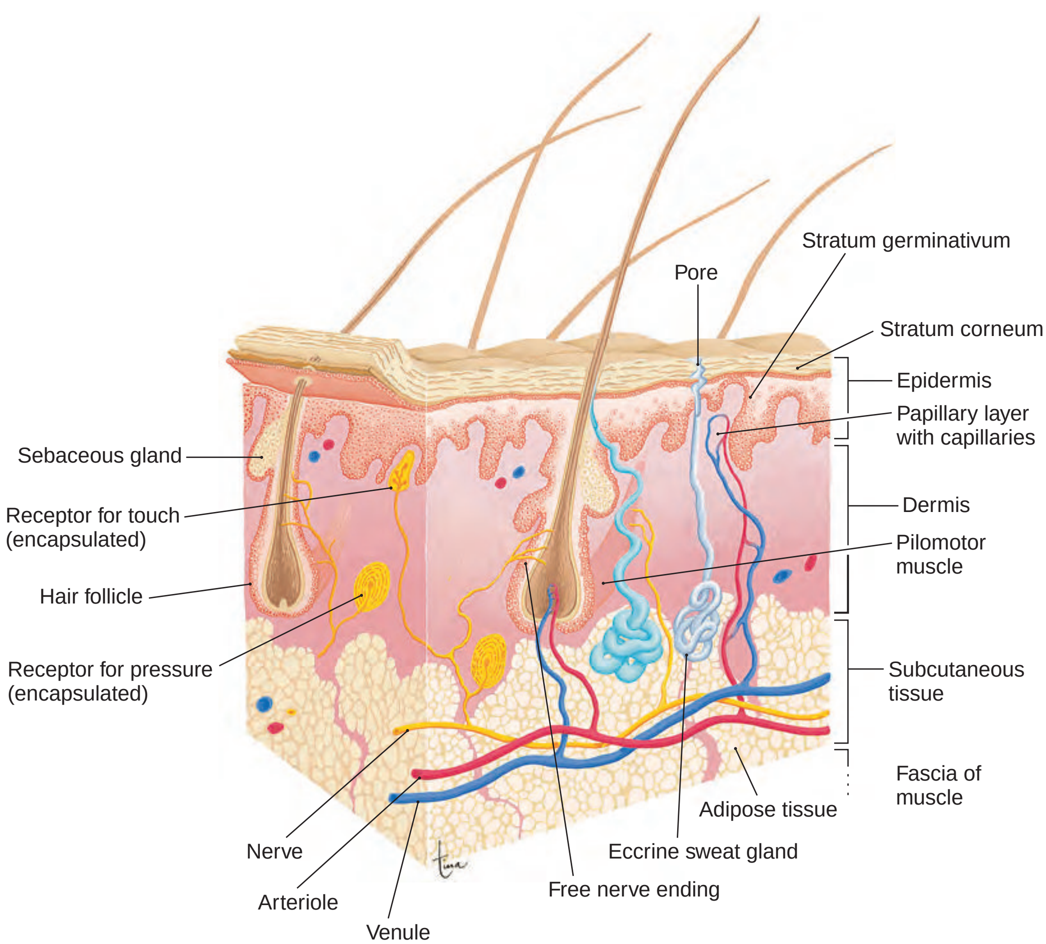

FIGURE 35-1 The structure of the skin.

Subcutaneous Tissue The **subcutaneous layer** is composed primarily of connective and adipose tissue. It provides insulation, protection, and a reserve of calories in the event of severe malnutrition. This layer varies in thickness in different body sites. Sex hormones, genetics, age, and nutrition also influence the distribution of subcutaneous tissue.

For optimal function, all layers of the skin must be intact. Breaks in the skin (e.g., surgical incisions, injuries) increase the risk of infection. In the following sections you will learn about factors that influence the ability to maintain intact skin and heal wounds (e.g., age).

Age-Related Variations

Age affects the condition and structure of the skin. Infants, for example, are born with varying amounts of *vernix caseosa*, a creamy substance that protects their skin. Their skin is thinner and more permeable than that of adults, which predisposes infants to skin breakdown (e.g., diaper rash). The subcutaneous layer (brown fat) and sweat glands are not fully developed, especially for preterm infants. As a result, in the first few weeks of life thermoregulation is inadequate, and the infant must be swaddled to maintain body heat.

The skin of infants and young children feels smooth, but as they are exposed to sun and other environmental elements, skin texture becomes coarser. Sex hormones released during puberty increase sebaceous and sweat gland activity, which leads to perspiration odor and sometimes acne. In women, high estrogen levels may contribute to the softening of connective tissue and cause striae and darkening of the skin, particularly on the face, areolae, nipples, vulva, and umbilicus, particularly in people with dark skin.

As adults age, the activity of the sebaceous and sweat glands diminishes, resulting in drier skin. **Xerosis** (itchy, red, dry, scaly, cracked, or fissured skin) is a problem for up to 85% of older adults and can be a threat to the integrity of their skin. Along with loss of lean body mass, the subcutaneous tissue layer thins, giving the individual a sharp, angular appearance. Excess weight can offset this change of appearance, though. The strong bond between the epidermal and dermal layer decreases as the dermal layer loses elasticity as a result of changes in its collagen fibers. These changes make the skin prone to breakdown and prolong wound-healing time. Regeneration of healthy skin takes at least twice as long in an 80-year-old as in a 30-year-old. In addition, many older adults have chronic diseases that interfere with healing. Diabetes, for instance, predisposes to infection, and liver dysfunction interferes with synthesis of blood-clotting factors.

Impaired Mobility

A healthy person moves and shifts position unconsciously when he senses pressure or discomfort. However, for people who are unable to move independently, the weight of the body on the bed or chair causes an increase in pressure leading to skin breakdown. Impaired mobility is caused by conditions that require complete bedrest or that seriously limit activity (e.g., paralysis, extreme fatigue, high-risk pregnancy, sedation, casts, traction, and altered sensory perception).

KnowledgeCheck 35-1

- Identify the major functions of the skin.
- What is the function of the stratum corneum, the outermost layer of the skin?
- What is the function of the subcutaneous layer?
- What effect does aging have on skin?
- What effect does immobility have on skin?

Nutrition and Hydration

Skin condition reflects overall nutritional status, and at the same time nutritional intake affects the skin. Adequate intake of protein, cholesterol, calories, fluid, vitamin C, and minerals is essential to maintaining skin integrity.

Protein Healthy skin depends on adequate protein levels to maintain the skin, repair minor defects, and preserve intravascular volume. As protein levels decline from excess loss or inadequate intake, minor defects cannot be repaired, fluid leaks from the vascular compartment of dependent areas, and edema (excess fluid in the tissues) develops. Edema decreases skin elasticity and interferes with the diffusion of oxygen to the cells. Therefore, the skin becomes prone to breakdown.

Cholesterol Low cholesterol levels predispose patients to skin breakdown and inhibit wound healing. Patients on low-fat tube feedings may experience deficiencies in cholesterol, fatty acids, and linoleic acid. Together, these fats aid in providing fuel for wound healing and maintain a waterproof barrier in the stratum corneum.

Calorie Intake If calorie intake is inadequate, the body uses proteins for energy (catabolism); they are then unavailable for building and maintenance functions (anabolism) (see Chapter 27 as needed). When undernutrition is prolonged, the person experiences weight loss, loss of subcutaneous tissue, and muscle atrophy. As a result, padding between the skin and the bones decreases, predisposing the skin to pressure ulcers.

Ascorbic Acid, Zinc, and Copper Vitamin C, or ascorbic acid, is involved in the formation and maintenance of collagen, so a deficiency can delay wound healing. Zinc and copper are also involved in collagen formation, and deficiencies of either may impair healing.

Hydration Skin turgor depends on hydration. Poor skin turgor may occur as a result of dehydration, whereas edema may result from overhydration. Both dry, dehydrated, as well as edematous, overhydrated, skin are prone to injury, especially when exposed to pressure, shearing, friction, and moisture. For further discussion on fluid requirements, see Chapter 38.

Diminished Sensation or Cognition

Clients with peripheral vascular disease, spinal cord injury, diabetes, cerebrovascular accident, trauma, or fractures often have diminished tactile sense. They are therefore more prone to skin breakdown. If you've ever touched a hot surface and quickly pulled back your hand, you know the importance of tactile sensation.

Clients with diminished sensation are less able to sense a hot surface and would likely suffer a burn. A cut or wound in an area with limited sensation may go unnoticed and therefore untreated. They are also unable to feel pressure in an affected area. As a result, they may not shift position to relieve pressure over bony prominences or be aware that shoes or clothing are constricting.

PICOT

Pressure Ulcers and the Malnourished Older Adult

Situation: While caring for an emaciated patient after surgery, the nurse notes two new wounds on the patient's bony prominences. Pressure ulcers have developed secondary to the patient's immobility, friction, shear, and postoperative drainage.

PICOT Components:

P Population/patient	=	Malnourished adults
I Intervention/indicator	=	Nutritional supplements
C Comparator/control	=	Diet without supplements
O Outcome	=	Improved (or faster) healing time
T Time	=	

Searchable Question: Do ________ (P) who receive/are exposed to ________ (I) demonstrate ________ (O) as compared to ________ (C) during ________ (T)?

Example of Evidence: Protein intake has been associated with improved wound healing. To prevent pressure wounds, many acute care facilities recommend that patients' diets have increased protein content, as do many long-term care facilities. To examine the effect of nutritional intervention in pressure ulcer care, researchers reviewed six clinical trials using oral nutritional supplementation (ONS) enriched with arginine, vitamin C, and zinc for pressure ulcer care. Results showed pressure ulcer healing and reduced risk of developing pressure ulcers.

Practice Change: The nurse caring for patients at risk for pressure wounds needs to address the patient's nutritional needs, including a diet high in protein.

Schols, J. M., Heyman, H., & Meijer, E. W. (2009). Nutritional support in the treatment and prevention of pressure ulcers: An overview of studies with an arginine enriched oral nutritional supplement. *Journal of Tissue Viability, 18*(3), 72–79.

Clients with impaired cognition (i.e., Alzheimer's disease, dementia, altered level of consciousness) are at higher risk to have skin breakdown because they are not aware of the need to reposition. Cognitive impairment can be subtle and difficult to recognize. Talk to your patient's family or caregiver and review past medical records so that the plan of care can be adjusted.

Impaired Circulation

The vascular system brings oxygen-rich blood to the tissues and removes metabolic waste products. Circulatory impairment interferes with tissue metabolism. *Impaired arterial circulation* restricts activity, produces pain, and leads to muscle atrophy and thin tissue that can lead to ischemia and necrosis. *Impaired venous circulation* results in engorged tissues containing high levels of metabolic waste products that make the tissue susceptible to edema, ulceration, and breakdown. Both forms of circulatory impairment delay wound healing. Circulatory impairment is one of the main causes of chronic wounds.

Medications

Side effects and idiosyncratic reactions to medications can affect skin integrity and wound healing. Any medication that causes pruritus (itching), dermatoses (rashes), photosensitivity, alopecia, or pigmentation changes can result in changes that impair skin integrity or delay healing (Fig. 35-2). The following are examples:

- *Blood pressure medications* decrease the amount of pressure required to occlude blood flow to an area, creating a risk for ischemia.
- *Anti-inflammatory medications,* such as over-the-counter (OTC) nonsteroidal anti-inflammatory drugs (NSAIDs, e.g., ibuprofen) and steroids (e.g., prednisone), inhibit wound healing.
- *Anticoagulants* (e.g., heparin, warfarin [Coumadin]) can lead to extravasation of blood into subcutaneous tissue. As a result, even minimal pressure or injury can cause a hematoma.
- *Chemotherapeutic agents* delay wound healing because of their cellular toxicity.
- *Certain antibiotics, psychotherapeutic drugs,* and *chemotherapy agents* for cancer increase sensitivity to sunlight, increasing the risk for sunburn.
- *Several herbal products*, such as those containing lavender and tea tree oil, cleanse the skin but also have a drying effect.

Moisture on the Skin

Excessive exposure to moisture leads to **maceration** (softening of the skin) and increases the likelihood of skin breakdown. Incontinence and fever are the most common sources of moisture. Bowel incontinence is particularly troublesome because feces contain digestive enzymes and microorganisms that can readily lead

FIGURE 35-2 Skin reaction to medication.

to **excoriation** (denuding) of superficial skin layers. This can lead to **moisture-associated skin damage (MASD)**, **dermatitis** (inflammation of the skin), pressure ulcers, and infection.

Fever

Fever is a risk factor for skin breakdown for two reasons. First, it leads to sweating, which can cause maceration. Second, it increases the metabolic rate, thereby raising the tissue demand for oxygen. An increased demand for oxygen is difficult to meet if there is any circulatory impairment or tissue compression secondary to pressure.

Contamination or Infection

Contamination of a wound refers to the presence of microorganisms in the wound. All chronic wounds are considered contaminated. As bacteria begin to increase in number, a wound is said to be **colonized**, though the microorganisms are causing no harm. Wounds are colonized from the surrounding skin and local skin organisms, the external environment, and internal sources, usually from the mucous membranes of the gastrointestinal system. The acid nature of the skin keeps bacteria attached to the skin (Zulkowski, 2013). A wound becomes **critically colonized** when the bacteria begin to overwhelm the body's defenses. Critical colonization may be detected by subtle signs, such as an increase in drainage, or by more pronounced signs, such as a new foul odor, a change in color of the wound bed, new tunneling of the wound, or absent or friable granulation tissue.

An **infection** implies the microorganisms are causing harm by releasing toxins, invading body tissues, and increasing the metabolic demand of the tissue. Infection of the skin makes it more vulnerable to breakdown and impedes healing of open wounds. If not stopped, bacteria can then gain access to the systemic circulation.

Lifestyle

Some lifestyle habits affect skin integrity:

- *Tanning* exposes the skin to ultraviolet radiation, thereby increasing the risk for skin cancer as well as drying the skin.
- *Hygiene habits* that involve either excessive or insufficient skin hygiene are not healthy for skin integrity. Frequent bathing and use of soap remove skin oils and may lead to drying, which jeopardizes the skin's barrier function. Infrequent cleansing of the skin contributes to excessive oiliness, clogged sebaceous glands, and inadequate removal of microbes on the skin, which can then infect a wound or lesion.
- *Regular exercise* improves circulation, which is necessary for skin integrity and wound healing.
- *A nutritious diet* provides the nutrients needed to maintain skin integrity, as already discussed.
- *Smoking* compromises the oxygen supply to the tissues, making skin more prone to breakdown and delaying wound healing. It also interferes with vitamin C absorption, which is needed for collagen formation.
- *Body piercings and tattoos* present a risk for infection and scarring. Complications, which occur in about 20% of piercings, include local infections, sepsis, endocarditis, hepatitis, and toxic shock syndrome. Intraoral and perioral piercings can result in gingivitis, damage to teeth and gums, and choking. Advise patients to become informed about the procedure and about aftercare and to find reputable piercers.

KnowledgeCheck 35-2

- Identify the factors that affect skin integrity.
- What nutritional components are essential to maintain skin?

ThinkLike a Nurse 35-1

- Review the case of William Harmon (Meet Your Patient). What risks, if any, does Mr. Harmon have for skin breakdown or delayed healing?
- What additional information do you need to know to fully evaluate his risk?
- What risks do you have for impaired skin integrity? What actions can you take to protect your skin?

WOUNDS

Wounds are a disruption in the normal integrity of the skin. Wounds may be intentional, such as a surgical wound, or unintentional, such as a cut or a pressure ulcer.

Types of Wounds

Wounds are classified according to length of time the wound has existed, as well as the condition of the wound (e.g., contamination, severity).

Skin Integrity The simplest wound classification system is based on the integrity of the skin. If there are no breaks in the skin, the wound is described as **closed**. Contusions (bruises) or tissue swelling from fractures are common closed wounds. A wound is considered **open** if there is a break in the skin or mucous membranes. Open wounds include abrasions, lacerations, puncture wounds, and surgical incisions. A compound fracture may also lead to an open wound caused by the projection of bone through the skin. Several open and closed wounds are described in Table 35-1.

Length of Time for Healing The length of time for wound healing varies according to the skin integrity and the factors affecting it, discussed in the previous section. **Acute wounds** are expected to be of short duration. In a healthy person, these wounds heal spontaneously without complications through the three phases of wound healing (inflammation, proliferation, and maturation). Wounds that exceed the expected length of recovery are classified as **chronic wounds**. The natural healing progression has been interrupted or stalled because of infection, continued trauma, ischemia, or edema. Chronic wounds include pressure, arterial, venous, and diabetic ulcers. These wounds are frequently colonized with several types of bacteria, and healing is slow because of the underlying disease process. Unless the type of wound is properly diagnosed and the underlying disease process treated, a chronic wound may linger for months or years (Table 35-2).

Level of Contamination **Clean wounds** are uninfected wounds with minimal inflammation. They may be open or closed and do not involve the gastrointestinal, respiratory, or genitourinary tracts (these systems frequently harbor bacteria). There is very little risk of infection for a clean wound. **Clean-contaminated wounds** are surgical incisions that enter the gastrointestinal, respiratory, or genitourinary tracts. There is an increased risk of infection for these wounds, but there is no obvious infection.

Contaminated wounds include open, traumatic wounds or surgical incisions in which a major break in asepsis occurred. The risk of infection is high for these wounds. Wounds are considered **infected** when bacteria counts in the wound tissues are above 100,000 organisms per gram of tissue. However, the presence of *beta-hemolytic streptococci*, in any number, is considered an infection. Signs of wound infection include erythema and swelling around the wound, fever, foul odor, severe or increasing pain, large amount of drainage, or warmth of the surrounding soft tissue.

Depth of the Wound **Superficial wounds** involve only the epidermal layer of the skin. The injury is usually the result of friction, shearing, or burning. **Partial-thickness wounds** extend through the epidermis but not through the dermis. **Full-thickness wounds** extend into the subcutaneous tissue and beyond. The descriptor **penetrating** is sometimes added to indicate that the wound involves internal organs. Wound depth is a major determinant of healing time: The deeper the wound, the longer the healing time.

KnowledgeCheck 35-3

- Explain the difference between an acute and a chronic wound.
- Describe the wound categorization system based on the level of contamination.
- How does wound depth affect healing?

Table 35-1 ➤ Types of Wounds

TYPE	DESCRIPTION
Abrasion	A scrape of the superficial layers of the skin; usually unintentional but may be performed intentionally for cosmetic purposes to smooth skin surfaces
Abscess	A localized collection of pus resulting from invasion from a pyogenic bacterium or other pathogen; must be opened and drained to heal
Contusion	A closed wound caused by blunt trauma. May be referred to as a bruise or ecchymotic area.
Crushing	A wound caused by force leading to compression or disruption of tissues. Often associated with fracture. Usually there is minimal or no break in the skin.
Incision	An open, intentional wound caused by a sharp instrument
Laceration	The skin or mucous membranes are torn open, resulting in a wound with jagged margins.
Penetrating	An open wound in which the agent causing the wound lodges in body tissue.
Puncture	An open wound caused by a sharp object. Often there is collapse of tissue around the entry point, making this wound prone to infection.
Tunnel	A wound with an entrance and exit site

Table 35-2 ➤ Chronic Wounds

TYPE	ETIOLOGY	CHARACTERISTICS
Pressure Ulcers	Caused by pressure, resulting in tissue ischemia and injury	Appearance depends on the stage or tissue layers involved. Pressure ulcers tend to be located over bony prominences. Can cause serious tissue damage.
Arterial Ulcers	Caused by inadequate circulation of oxygenated blood to the tissue, which leads to tissue ischemia and damage	Ulcer appears "punched out," small and round with smooth borders. The wound base is usually pale with or without necrotic tissue. They tend to occur over the distal part of the leg, especially the ankles, toes, side of the foot, and shin. The surrounding skin appears shiny, thin, and dry and is cool to touch. Often there is loss of hair in the surrounding area. The area has delayed capillary refill time, and patients may complain of pain that worsens with increased activity. Arterial ulcers are most common in lower extremities but can occur anywhere. This type of ulcer can lead to serious injury and even death.
Venous Stasis Ulcers	Caused by incompetent venous valves, deep vein obstruction, or inadequate calf muscle function, resulting in venous pooling, edema, and impaired microcirculation of the skin	Usually located around the inner ankle, or in the lower part of the calf. Surrounding skin is reddened or brown and edematous. Wounds are usually shallow, with irregular wound margins. The wound bed appears "ruddy" or "beefy" red and granular. Drainage may be moderate to heavy depending on amount of edema. Pain usually occurs with leg dependence and dressing changes.

Wound Healing Process

All wounds heal through a physiological process in which epithelial, endothelial, and inflammatory cells, platelets, and fibroblasts migrate into the wound to bring about tissue repair and regeneration. The process is essentially the same regardless of the type of injury or the type of tissues involved.

Types of Healing

Wounds may heal by regeneration or by primary, secondary, or tertiary intention.

Regenerative/Epithelial Healing When a wound affects only the epidermis and dermis, **regenerative/epithelial healing** takes place. No scar forms and the new (regenerated) epithelial and dermal cells form new skin that cannot be distinguished from the intact skin. Partial-thickness wounds heal by regeneration.

Primary Intention Healing When a wound involves minimal or no tissue loss and has edges that are well approximated (closed), **primary (first) intention** healing takes place (Fig. 35-3A). Little scarring is expected. A clean surgical incision heals by this method.

Secondary Intention Healing Healing by **secondary (second) intention** occurs when a wound (1) involves extensive tissue loss, which prevents wound edges from approximating, or (2) should not be closed (e.g., because it is infected). Because the wound is left open, it heals from the inner layer to the surface by filling in with beefy red **granulation tissue** (a form of connective tissue with an abundant blood supply) (Fig. 35-3B). Epithelial tissue may appear in the wound as small pink or pearl-like areas. **Key Point:** ***Do not mistake this as a sign of infection. Wounds that heal by secondary intention heal more slowly, are more prone to infection, and develop more scar tissue. Pressure ulcers (discussed later) and infected wounds are examples.***

Tertiary Intention Healing A wound heals by **tertiary (third) healing**, also called *delayed primary closure*, when two surfaces of granulation tissue are brought together (Fig. 35-3C). This technique may be used when the wound is clean-contaminated or contaminated. Initially the wound is allowed to heal by secondary intention. When there is no evidence of edema, infection, or foreign matter, the wound edges are closed by bringing together the granulating tissue and suturing the surface. Such wounds require strict aseptic technique during all dressing changes because they are prone to infection. Tertiary intention healing creates less scarring than does secondary, but more than primary intention healing.

Phases of Healing

Wound healing occurs in three stages: inflammatory, proliferative, and maturation (Fig. 35-4).

Inflammatory Phase—Cleansing The inflammatory (cleansing) phase lasts from 1 to 5 days and consists of two major processes: hemostasis and inflammation.

- ***Hemostasis.*** At the time of injury, tissue and capillaries are destroyed, causing blood and plasma to leak into the wound. Area vessels constrict to limit blood

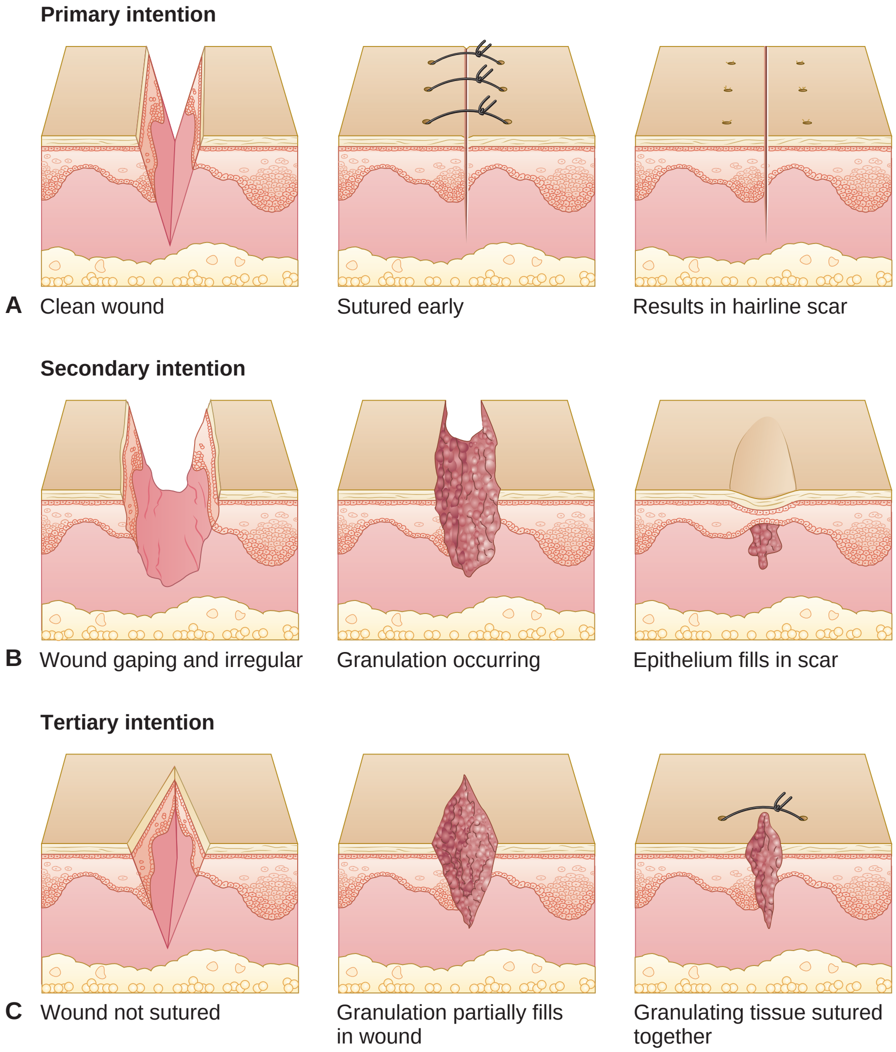

FIGURE 35-3 *A*, In a wound with minimal tissue loss, the edges may be sutured together, resulting in rapid healing and minimal scarring. *B*, A wound that heals by secondary intention heals from the inner layer to the surface. Healing takes longer, and there is scarring. *C*, A wound that heals by tertiary intention is initially healed by secondary intention and later sutured.

loss. Platelets aggregate (clump together) to slow bleeding. At the same time, the clotting mechanism is activated to form a blood clot.

- ***Inflammation.*** The inflammatory reaction is characterized by edema, erythema, pain, temperature elevation, and migration of white blood cells into the wound tissues. Within 24 hours, macrophages begin engulfing bacteria (**phagocytosis**) and clearing debris. Along with plasma proteins and fibrin, they form a scab on the wound surface, which seals the wound and helps prevent microbial invasion.

Proliferative Phase—Granulation The proliferative phase is also called regeneration or healing. It occurs from days 5 to 21. Cells develop to fill the wound defect and resurface the skin. **Fibroblasts** (connective tissue cells) migrate to the wound where they form **collagen**, a protein substance that adds strength to the healing wound. New blood and lymph vessels sprout from the existing capillaries at the edge of the wound. The result is the formation of granulation tissue, a beefy red tissue that bleeds readily and is easily damaged. As the clot or scab is dissolved, epithelial cells begin to grow into the wound from surrounding healthy tissue and seal over the wound (**epithelialization**).

Maturation Phase—Epithelialization The maturation phase (or remodeling) is the final phase of the healing process. It begins in the second or third week and continues even after the wound has closed. Over the next 3 to 6 months, the initial collagen fibers that were laid in the wound bed during the proliferative phase are broken down and remodeled into an organized structure (e.g., scar tissue), increasing the tensile strength of the wound. A wound that has healed by primary intention leaves little scarring. Even so, a scar is only 80% as strong as the original tissue.

KnowledgeCheck 35-4

Identify the type of wound healing (primary, secondary, or tertiary intention):

- A wound that heals from inner layer to the surface
- A wound with approximated edges
- A wound that heals by approximating two surfaces of granulation tissue
- A wound that is sutured and has minimal or no tissue loss

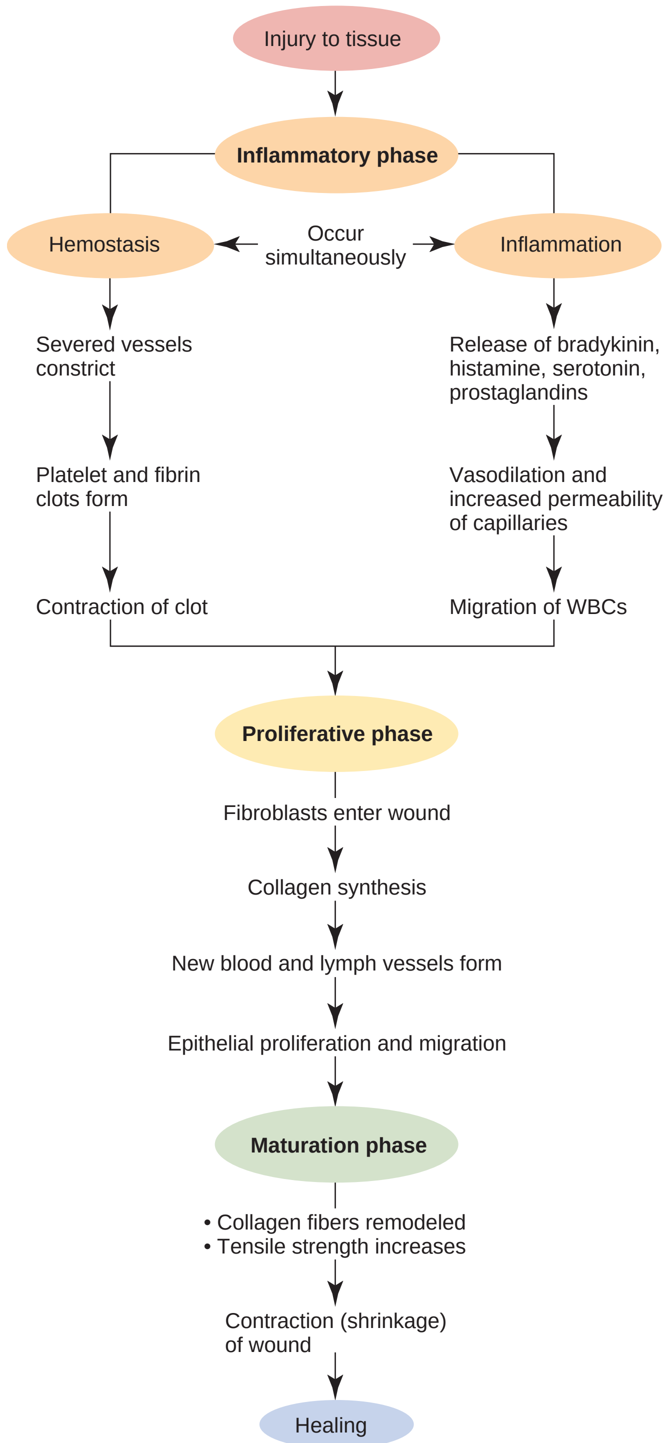

FIGURE 35-4 Stages in the wound healing process.

Wound Closures

Wounds that heal by primary and tertiary intention may be closed in several ways. Adhesive strips, sutures, staples, surgical glue, negative-pressure closure, and compression are the current choices.

Adhesive Strips In the following situations, adhesive strips (e.g., Steri-Strips) are used:

- Closing superficial low-tension wounds, such as skin tears or lacerations
- Closing the skin on a wound that has been closed subcutaneously to aid in healing and reduce scarring
- Giving additional support to a wound after sutures or staples have been removed

Adhesive strips are often kept in place until they begin to separate from the skin on their own. For a summary of how to apply adhesive skin closures, see the Highlights of Procedures box. For complete instructions,

Go to Chapter 35, **Procedure 35-10: Placing Skin Closures,** in Volume 2.

Sutures The traditional wound closures are sutures ("stitches"). Suturing leads to small puncture wounds along the track of the laceration or incision. Several types of suture materials are available.

- *Absorbent sutures* are used deep in the tissues, for example, to close an organ or **anastomose** (connect) tissue. Because they are made of material that will gradually dissolve, there is no need to remove absorbent sutures.
- *Nonabsorbent sutures* are placed in superficial tissues and require removal, usually by the nurse. For a summary of how to remove sutures and staples, see the Highlights of Procedures box. For complete steps,

Go to Chapter 35, **Procedure 35-12: Removing Sutures and Staples,** in Volume 2.

Surgical Staples Made of lightweight titanium, surgical staples provide a fast, easy way to close an incision (Fig. 35-5). They are also associated with a lower risk of infection and tissue reaction than are sutures. The downside of staples is that some wound edges are more difficult to align. The most common sites for wound stapling

FIGURE 35-5 Surgical stables in the scalp.

are arms, legs, abdomen, back, scalp, or bowel. Wounds on the hands, feet, neck, or face should not be stapled.

Surgical Glue This is a relatively new method for wound closure. It is safe for use in clean, low-tension wounds. It is an ideal wound closure method for skin tears.

Advanced Wound Treatments

Collaborative treatments are necessary for wounds that will not heal despite aggressive care. Such treatments include the following:

- **Surgical options**, such as extensive debridement, skin grafts, secondary closure of the wound, and flap techniques (partially detached tissue placed over a wound) are used for complicated wounds.
- **Hyperbaric oxygen therapy (HBOT)** is the administration of 100% oxygen under pressure to a wound site. HBOT increases oxygen concentration in the tissue, stimulates the growth of new blood vessels, and enhances white blood cell (WBC) action.
- **Platelet-derived growth factor** augments the inflammatory phase of wound healing and accelerates collagen formation in the wound.

Types of Wound Drainage

Drainage is the flow of fluids from a wound or cavity. It is often referred to as **exudate** and is fluid that oozes as a result of inflammation. Exudate may take several forms.

- **Serous Exudate.** Clean wounds typically drain serous exudate. It is watery in consistency and contains very little cellular matter. Serous exudate consists of *serum*, the straw-colored fluid that separates out of blood when a clot is formed.
- **Sanguineous Exudate.** You will often see sanguineous exudate with deep wounds or wounds in highly vascular areas. Sanguineous exudate is bloody drainage. It indicates damage to capillaries. Fresh bleeding produces bright red drainage, whereas older, dried blood is a darker, red-brown color.
- **Serosanguineous Drainage.** In new wounds, you will most commonly see serosanguineous drainage, a combination of bloody and serous drainage.
- **Purulent Exudate.** The thick, often malodorous, drainage that is seen in infected wounds is called purulent exudate. It contains pus, a protein-rich fluid filled with WBCs, bacteria, and cellular debris. It is commonly caused by infection from **pyogenic** (pus-forming) bacteria, such as streptococci or staphylococci. Normally, pus is yellow in color, although it may take on a blue-green color if the bacterium *Pseudomonas aeruginosa* is present.
- **Purosanguineous Exudate.** Red-tinged pus is called purosanguineous exudate. It indicates that small vessels in the wound area have ruptured.

Complications of Wound Healing

Recall that wounds heal by moving through the phases of inflammation, proliferation, and maturation. At times, this process is interrupted by complications. The most common complications are hemorrhage, infection, dehiscence, evisceration, and fistulas.

Hemorrhage

Whenever a capillary network is interrupted or a blood vessel is severed, bleeding occurs. **Hemostasis** (cessation of bleeding) usually occurs within minutes of the injury. Hemostasis is delayed, however, when large vessels are injured, a clotting disorder exists, or the client is on anticoagulant therapy. If bleeding begins again after initial hemostasis, something is probably wrong. Possible causes include a slipped suture, erosion of a blood vessel, a dislodged clot, or infection. The risk of hemorrhage is greatest in the first 24 to 48 hours following surgery or injury. Bleeding may be internal or external.

Internal Bleeding Swelling of the affected body part, pain, and changes in vital signs (i.e., decreased blood pressure, elevated pulse) may indicate internal bleeding. By *internal bleeding,* in this chapter, we are referring to a **hematoma**, a red-blue collection of blood under the skin, which forms as a result of bleeding that cannot escape to the surface. A large hematoma causes pressure on surrounding tissues. If the hematoma is located near a major artery or vein, it may impede blood flow.

External Hemorrhage External hemorrhage is relatively easy to recognize. You will see bloody drainage on the dressings and in the wound drainage devices. When there is a brisk hemorrhage, blood often pools underneath the client as the dressings become saturated. To be sure that you are aware of the full extent of the bleeding, remember to look underneath the patient.

Infection

Microorganisms can be introduced to a wound during an injury, during surgery, or after surgery. Suspect infection if a wound fails to heal. Localized swelling, redness, heat, pain, fever (temperatures higher than 38°C [100.4°F]), foul-smelling or purulent drainage, or a change in the color of the drainage may also indicate infection. The symptoms are likely to occur in a contaminated or traumatic wound within 2 to 3 days. In a clean surgical wound, you will usually not see signs and symptoms of an infection until the fourth or fifth postoperative day. Incisions that begin draining within 5 to 7 days of surgery are at risk for dehiscing.

Dehiscence

Rupture (separation) of one or more layers of a wound is called **dehiscence** (Fig. 35-6). Wound dehiscence is most likely to occur in the inflammatory phase of healing, before large amounts of collagen have been deposited in the wound to strengthen it. The most common causes of

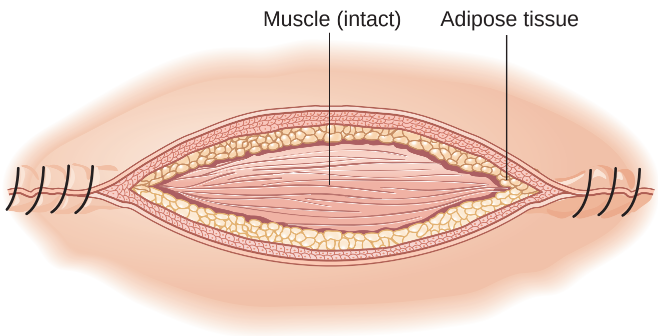

FIGURE 35-6 Dehiscence is separation of one or more layers of a wound. It is most common in the inflammatory phase of healing.

dehiscence are poor nutritional status, inadequate closure of the muscles, wound infection, or increased tension on the suture line (coughing, lifting an object). Obese clients are also more likely to experience dehiscence because fatty tissue does not heal readily and the patient's mass increases the strain on the suture line.

Dehiscence is usually associated with abdominal wounds. Patients often report feeling a "pop" or tear, especially with sudden straining from coughing, vomiting, or changing positions in bed. Usually there is an immediate increase in serosanguineous drainage. Nursing interventions include maintaining bedrest with the head of the bed elevated at 20° and the knees flexed. To prevent *evisceration*, a binder may be applied. The provider should be notified of the dehiscence to examine the wound.

Evisceration

Evisceration is total separation of the layers of a wound with internal viscera protruding through the incision (Fig. 35-7). This rare complication is a surgical emergency. Immediately cover the wound with sterile towels or dressings soaked in sterile saline solution to prevent the organs from drying out and becoming contaminated with environmental bacteria. Have the patient stay in bed with knees bent to minimize strain on the incision. Do not put a binder on the patient. Notify the surgeon and ready the patient for surgery (see Chapter 39 for perioperative care).

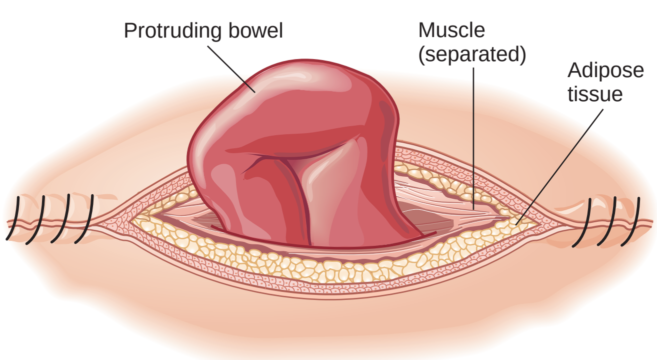

FIGURE 35-7 Evisceration is total separation of the layers of a wound with internal viscera protruding through the incision.

Fistulas

A **fistula** is an abnormal passage connecting two body cavities or a cavity and the skin. Fistulas often result from infection or debris left in the wound. An abscess forms, which breaks down surrounding tissue and creates the abnormal passageway. Chronic drainage from the fistula may lead to skin breakdown and delayed wound healing. The most common sites of fistula formation are the gastrointestinal and genitourinary tracts. Figure 35-8 illustrates a fistula between the rectum and vagina.

KnowledgeCheck 35-5

- Describe four types of wound closures.
- Identify five types of wound complications.
- Describe three signs of internal hemorrhage.
- Differentiate between dehiscence and evisceration.

ThinkLike a Nurse 35-2

Recall the case of Mr. Harmon (Meet Your Patient). What form of wound healing (primary, secondary, or tertiary) is he undergoing? How long would you expect it to take before his wounds heal?

CHRONIC WOUNDS

A chronic wound is one that has not healed within the expected time frame. It has not moved through the repair process in an orderly fashion (inflammation, proliferation, maturation). Wounds that do not heal within 2 to 4 weeks may be considered chronic. Pressure ulcers are a type of chronic wound.

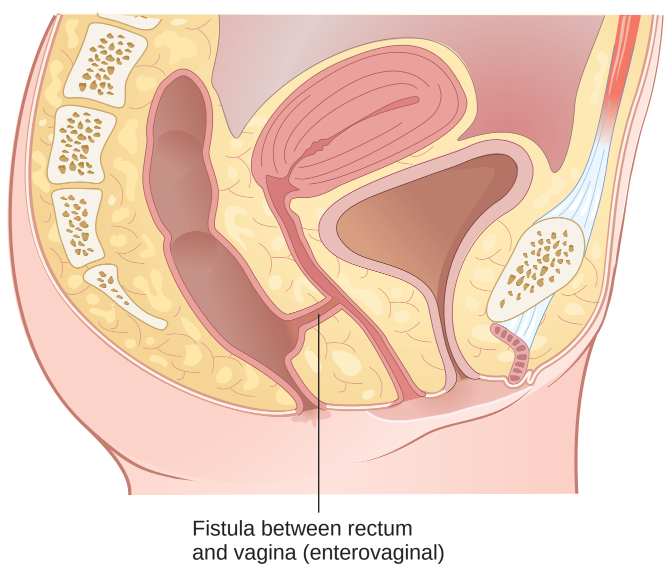

FIGURE 35-8 A fistula is an abnormal passage connecting two body cavities or a cavity and the skin. Fistulas are most common in the gastrointestinal and genitourinary tracts.

Pressure Ulcers

Pressure ulcers (formerly called *decubitus ulcers, pressure sores,* and *bedsores*) are localized areas of injury to the skin, and possibly the underlying tissue, usually over a bony prominence. We discuss them separately because vigilant nursing care can prevent most pressure ulcers; if they do form, nurses play a major role in their treatment. In fact, a higher rate of pressure ulcers may signal overall poor care. Additionally, patients who develop pressure injuries have generally longer hospital lengths of stay, are more likely to be readmitted within 30 days after discharge, and may even be more likely to die during the hospital stay than those without this complication (Lyder, Wang, Metersky, et al., 2012). Unless the pressure injury is present on admission (POA), in most circumstances Medicare will decline payment for treatment for that ulcer.

How Do Pressure Ulcers Develop?

Patients at risk for developing pressure ulcers are those with immobility, friction and shear, moisture, incontinence, poor nutrition, perfusion, age, skin condition, and altered level of consciousness (Stechmiller, Cowan, Whitney, et al., 2008). Pressure ulcers are caused by unrelieved pressure, or pressure in combination with shearing forces. These compromise blood flow to an area, resulting in *ischemia* (inadequate blood supply) in the underlying tissue. Tissue ischemia leads to tissue anoxia (lack of oxygen) and cell death.

Key Point: ***The key variables in ischemia are time and pressure. Small amounts of pressure over an extended period of time or a large amount of pressure for a short period of time results in tissue ischemia. Pressure ulcers can occur in as little time as 2 hours, though they may take as long as 5 days for the full extent of tissue damage to be known.***

When ischemia first occurs, the skin over the area is pale and cool. When you relieve the pressure (e.g., by turning the patient), vasodilation occurs, and extra blood rushes to the area to compensate for the ischemic period. The area flushes bright red (**reactive hyperemia**). If the redness does not disappear quickly, tissue damage has occurred. The redness should last about half as long as the duration of the ischemia. For example, if the tissue was compressed for an hour, reactive hyperemia should not last more than about 30 minutes.

Several other factors predict the likelihood of pressure ulcer formation (Fig. 35-9). Some factors are intrinsic and some are extrinsic.

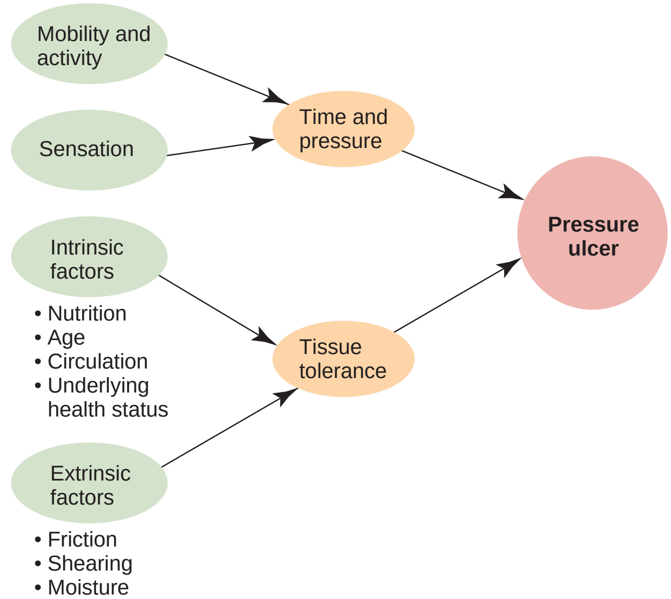

FIGURE 35-9 Several factors contribute to the development of pressure ulcers.

Intrinsic Factors Certain intrinsic (internal) factors alter skin and tissue integrity or oxygen delivery capabilities, decreasing the amount of force required to create a pressure ulcer. Examples include immobility and impaired sensation, as occur with spinal cord injuries, stroke, or coma; poor nutrition; edema; aging; low arteriolar pressure; and fever. Septicemia is one of the most common principal reasons for hospitalization among patients with secondary pressure ulcers (Russo, Steiner, & Spector, 2008). The previous section, "What Factors Affect Skin Integrity?," discussed a variety of intrinsic factors.

Poor nutrition or dehydration can weaken the skin and lead to pressure ulcers. Adequate intake of calories, protein, vitamin C, and zinc is necessary to prevent pressure ulcers and promote healing of injured tissue (Institute for Clinical Systems Improvement [ICSI], 2012).

Extrinsic Factors The following extrinsic (external) factors contribute to the development of pressure ulcers:

- ***Friction*** damages the outer protective epidermal layer, decreasing the amount of pressure needed to develop skin lesions (Black, Baharestani, Cuddigan, et al., 2007).
- ***Shearing*** occurs when the epidermal layer slides over the dermis, causing damage to the vascular bed. It most commonly occurs when the head of the bed is elevated and the patient slides downward, causing shear in the sacral area. When shearing occurs, the amount of pressure needed to occlude circulation is cut in half.
- ***Moisture***, especially in the form of urine, feces, or perspiration, macerates the skin and decreases the amount of pressure required to produce ulceration.
- ***Compression*** can also cause pressure ulcers by reducing blood flow to a body area. This most commonly occurs over bony prominences, but can also occur under casts, splints, endotracheal tubes, and other assistive devices (Black, Cuddigan, Walko, et al., 2010). Skin can be compressed between the bone and the hard surface of a bed or chair. When the patient is supine, these pressure points are the occiput, scapulae, elbows, sacrum, and heels. Figure 35-9A–D illustrates the pressure points in the supine, lateral, prone, and sitting positions.

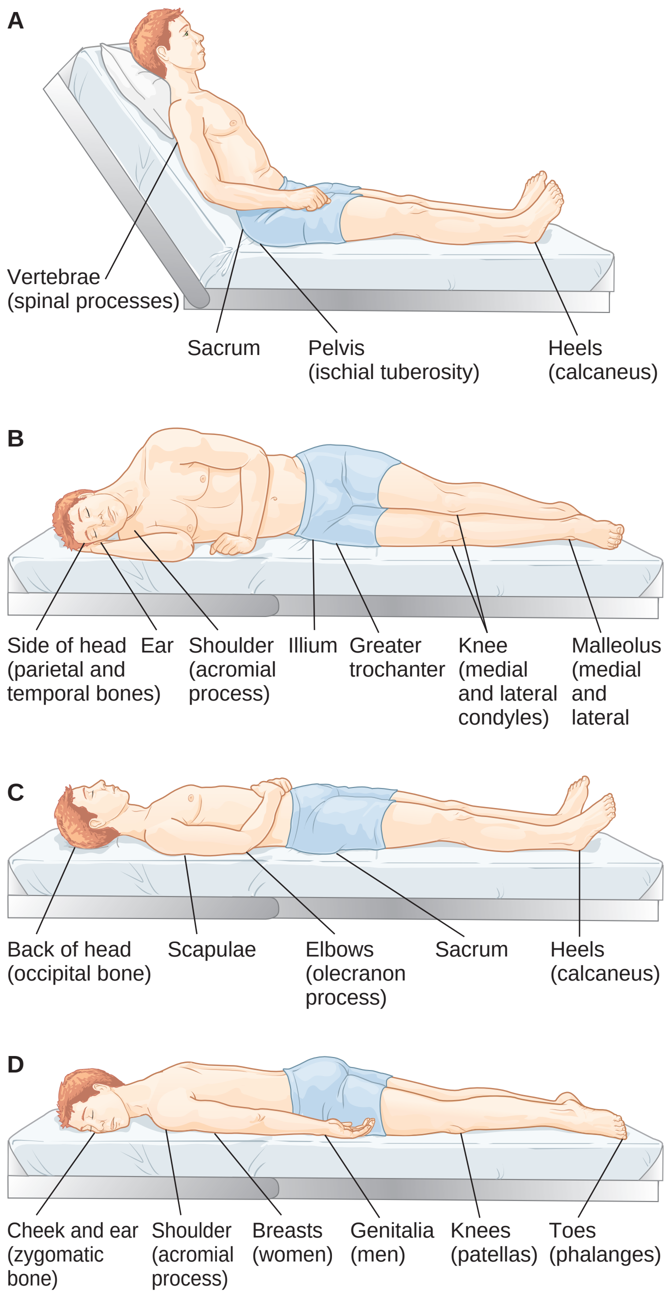

FIGURE 35-10 *A–D*, Most commonly, pressure ulcers develop over the bony prominences. *A*, Sitting. *B*, Lateral. *C*, Supine. *D*, Prone. (Adapted from AHRQ Clinical Practice Guidelines.)

How Are Pressure Ulcers Staged?

Pressure ulcers are classified by the degree of tissue involvement (Table 35-3). The National Pressure Ulcer Advisory Panel (NPUAP) developed a standardized staging system. Only wounds caused by pressure are staged. Other classification systems exist to describe other chronic wounds, such as diabetic foot ulcers and venous stasis ulcers.

Key Point: *Healing ulcers are not "reverse" staged. The healing process cannot cause a stage IV pressure ulcer to become a stage III. Pressure ulcers become progressively shallower by filling in with granulation tissue, but lost muscle, subcutaneous fat, and dermis are not replaced. Therefore, reverse staging does not accurately characterize what is physiologically occurring in the ulcer (NPUAP, n.d.). Instead, pressure ulcers maintain their original staging classification throughout the healing process, but they are described as healing (e.g., "stage IV ulcer: healing" or "stage I ulcer: healing").*

Other Types of Ulcers

This chapter focuses primarily on pressure ulcers. However, not all lower extremity ulcers are related to pressure.

Venous Stasis Ulcers are irregularly shaped lesions caused by venous congestion, often from damage to valves in the veins (e.g., from deep vein thrombosis). They occur usually between the inside ankle and the knee, not necessarily over a bony prominence, and are typically red in color, shiny and taught, and may even feel warm or hot. Fluid drainage can be significant.

Diabetic Foot Ulcers occur when diabetes causes the narrowing of arteries, decreasing oxygenation to the feet that results in delayed healing and tissue necrosis. Because people with diabetes lose protective sensation, they may walk on sores, continuously damaging the tissues. Diabetic foot ulcers, often painless, occur mainly on the plantar surface of the foot, the ball of the foot, or top and bottom of the toes. Patients with diabetic foot ulcers are highly susceptible to wound infection because of the poor sensation, circulation, and immune protection (Woo, Santos, & Gamba, 2013).

Arterial Ulcers occur when there is a non-pressure-related blockage of arterial blood to an area (e.g., by a clot or stenosis of the arterioles), causing ischemia and tissue necrosis. This type of wound usually occurs over the lower leg, ankle, or bony areas of the foot. The wound bed tends to be dry and pale, with little drainage. Arterial ulcers are usually very painful, especially at night.

For more detailed information about these three types of ulcers,

Go to Chapter 35, **Supplemental Materials,** on Davis*Plus*.

KnowledgeCheck 35-6

- What stage pressure ulcer does Mr. Harmon (Meet Your Patient) have?
- What factors have contributed to its development?

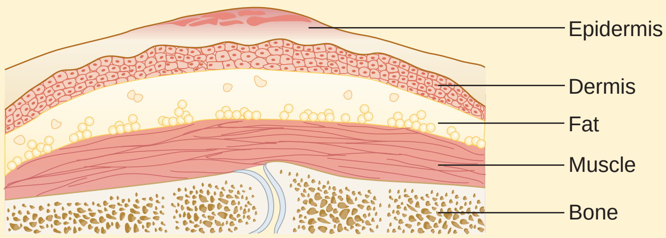
ThinkLike a Nurse 35-3

Based on your knowledge of the factors that have contributed to Mr. Harmon's pressure ulcer development, what actions may lead to healing of the pressure ulcer? *Note:* To answer this question, you do not need to know about wound care (e.g., irrigation) for a pressure ulcer.

Table 35-3 ➤ Staging Pressure Ulcers

<table>
<tr><th>STAGE</th><th>CLINICAL FINDINGS</th><th>DISCUSSION</th></tr>
<tr><td>

Stage I Pressure Ulcer



</td><td>

Localized area of intact skin with nonblanchable redness, usually over a bony prominence.

The area may be painful, firm, soft, or warmer or cooler as compared with adjacent tissue.

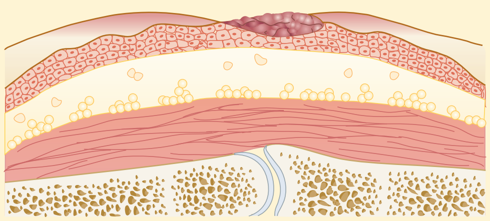
Discoloration will remain for >30 minutes after pressure is relieved.

</td><td>

Dark skin may not have visible blanching; its color may differ from that of the surrounding area. Therefore, stage I may be difficult to detect.

</td></tr>
<tr><td>

Stage II Pressure Ulcer



</td><td>

Involves partial-thickness loss of dermis.

Stage II pressure ulcers are open but shallow and with a red pink wound bed.

There is no slough.

May also be an intact or open/ruptured serum-filled blister; or a shiny or dry shallow ulcer without slough or bruising.

</td><td>

Do not use this stage to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.

Do not mistake moisture-associated skin damage or fungal infections for Stage II pressure ulcer.

Stage II ulcers do not involve sloughing or bruising.

</td></tr>
</table>

Table 35-3 ➤ Staging Pressure Ulcers—cont'd

STAGE	CLINICAL FINDINGS	DISCUSSION
Stage III Pressure Ulcer  	A deep crater characterized by full-thickness skin loss with damage or necrosis of subcutaneous tissue. May extend down to, but not through, underlying fascia. Undermining (deeper-level damage under boggy superficial layers) of adjacent tissue may be present. Bone/tendon is not visible or directly palpable.	Some stage III pressure ulcers can be extremely deep when located in an area with significant adipose layers.
Stage IV Pressure Ulcer  	Involves full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or support structures. Exposed bone/tendon is visible or directly palpable. Slough or eschar may be present. Undermining and sinus tracts (blind tracts underneath the epidermis) are common.	The depth of a stage IV pressure ulcer varies by location. They can be shallow on the bridge of the nose, ear, occiput, and malleolus because these areas do not have subcutaneous tissue. Stage IV ulcers can extend into muscle and supporting structures (e.g., fascia, tendon, or joint capsule). Often require a full year to heal. Even once healed, the site remains at risk for future injury because the scar is not as strong as the original tissue.

Continued

Table 35-3 ➤ Staging Pressure Ulcers—cont'd

STAGE	CLINICAL FINDINGS	DISCUSSION
Suspected Deep Tissue Injury 	An area of skin that is intact but discolored. It might be purplish or deep red, painful, boggy, or have a blister.	Occurs owing to damage of underlying soft tissue from pressure or shear. Findings can be subtle enough that often DTI is not recognized until after severe tissue damage has occurred. May heal or evolve further and become covered by thin eschar, rapidly exposing additional layers of tissue even with optimal treatment. In darker pigmented individuals, discoloration might go undetected.
Unstageable Pressure Ulcer 	Involves full-thickness skin loss. The base of the wound is obscured by *slough* (tan, yellow, gray, green, or brown necrotic tissue) or *eschar* (tan, black, or brown leathery necrotic tissue).	Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. *Stable eschar* is dry, adherent, and intact without erythema or fluctuance. Do not remove stable eschar, as it serves as "the body's natural cover."

Practical Knowledge knowing how

As a nurse, you will care for many patients who have wounds or who are at risk for skin breakdown. In the remainder of the chapter, we will discuss how to maintain skin integrity, prevent pressure ulcers, and treat wounds.

ASSESSMENT

The National Pressure Ulcer Advisory Panel (NPUAP) recommends nurses perform a comprehensive wound assessment while identifying other health problems and their impact on wound healing. Existing wounds require additional assessment. A thorough skin assessment includes a nursing history, physical examination, and diagnostic testing. For a list of competencies for nurses treating pressure ulcers (NPUAP, 2010),

Go to Chapter 35, **Tables, Boxes, Figures: ESG Box 35-1, Competencies for Registered Nurses Treating Pressure Ulcers,** on Davis*Plus*.

Focused Nursing History

To assess wound healing ability and the risk for skin breakdown, you will need to gather data on factors that affect skin integrity (discussed previously): age, mobility, nutrition, hydration, sensation, circulation, medications, moisture, lifestyle, underlying health and disease status, and the presence of microorganisms. Also consider the psychosocial issues related to coping with chronic wounds (Woo, 2011). For instance, you will need to assess with care and compassion how the patient copes with the pain of a chronic wound, handles the loss of control and independence, is adapting to changes in body image, deals with the financial burden of caring for complex wounds, and adjusts to the social isolation that comes with impaired mobility and chronic illness. For history questions to help you assess these factors,

Go to Chapter 35, **Assessment Guidelines and Tools, History Questions for Skin and Wound Assessment,** in Volume 2.

For example, patients with poor circulation, such as those with diabetes, atherosclerosis, or low blood pressure, are at risk for tissue injury. Patients who use tobacco or are anemic have reduced oxygen supply in the blood, predisposing them to pressure ulcers. Those with limited mobility or reduced sensation because of nerve damage, head injury, stroke, spinal cord injury, or diabetes, experience a loss of protective sensations to reposition themselves (ICSI, 2012).

Pressure Ulcer Risk Assessment Measures

Patients may have multiple risk factors for skin problems. A comprehensive risk assessment tool enables you to evaluate the cumulative risk. Among the most commonly used tools are the Braden and Norton scales. To see these scales,

Go to Chapter 35, **Assessment Guidelines and Tools, The Braden Scale for Predicting Pressure Sore Risk,** and **The Norton Scale for Assessing Risk of Pressure Ulcers,** in Volume 2.

The Braden Scale is used to identify persons at risk for developing pressure ulcers. The Braden scale evaluates six major risk factors: sensory perception, moisture, activity, mobility, nutrition, and friction and sheer. The final score reflects the patient's risk; the lower the score, the more likely the patient will develop a pressure ulcer. A score of 18 or less for hospitalized patients indicates risk. Interventions should be based on individual risk factors, as well as the total score. You should use this scale to assess the patient on admission to the facility and again in 48 to 72 hours or per facility policy. Studies have shown the second score to be more predictive, probably related to an increased awareness of the patient's status. The Braden Q is a modified scale used in children.

The Norton Scale assesses risk based on the patient's physical condition, mental state, activity, mobility, and incontinence. A low score indicates a high risk. Some have suggested that the Norton scale should be modified by adding categories for skin appearance, medication, and nutrition.

ThinkLike a Nurse 35-4

Review the Braden scale. Apply this risk assessment scale to Mr. Harmon (Meet Your Patient).

- What additional information, if any, do you need to complete these assessments?
- Calculate a Braden score based on Mr. Harmon's risk factors if he had also been incontinent of urine twice that day.

Focused Physical Examination

Physical assessment of skin integrity focuses on the two following areas:

Inspecting the Skin Inspect all areas of the body routinely. Evaluate the skin for color, integrity, temperature, texture, turgor, mobility, moisture, lesions, and hair distribution. Check pressure points for erythema, tenderness, or edema. Assess all bony prominences of individuals "at risk" for skin breakdown routinely. Include skin under special garments, such as shoes, heel elevators, and antiembolism stockings. Also assess vulnerable pressure points for bed- or chair-bound patients. See Chapter 22 if you need more details on skin assessment.

Assessing Mobility and Activity Level Patients who are have some degree of immobility are at a higher risk for developing pressure ulcers, and should be closely monitored to detect early signs of the formation of pressure-related wounds (Wound, Ostomy and Continence Nurses Society [WOCNS], 2010). See Chapter 32 if you need additional information about activity and mobility.

Assessing Treated Wounds

All wounds require a focused assessment. Assessment frequency depends on the condition of the wound, the work setting, the patient's overall condition and underlying disease process, the type of wound, and the type of treatment used for the wound. If you are providing wound care, you will assess the wound with every treatment. Assessment parameters include the following. Also, for a wound assessment summary,

Go to Chapter 35, **Assessment Guidelines and Tools, Physical Examination: Wound Assessment,** in Volume 2.

Location Describe the wound location in anatomical terms. For example, describe an incision from cardiac surgery as a midsternal incision extending from the manubrium to the xiphoid process. An accurate description of the location is important because:

- *Location influences the rate of healing*. Wounds in highly vascular regions, such as the scalp or hands, heal more rapidly than wounds in less vascular regions, such as the abdomen or a heel.

- *Location affects movement*. Wounds that can be readily stabilized heal more rapidly than those in areas that are affected by the constant stress of movement.
- *Location can give you clues to the wound etiology*. A wound over a bony prominence could be related to pressure, whereas one on the bottom of the foot could be a diabetic foot ulcer.

Type of Wound Is it an acute wound? If the wound is sutured, examine the closure. Are the wound edges approximated (together)? Is there tension on any aspect of the wound? Are the stitches intact? Or is this a chronic wound?

Size Measure the length and width of the wound in centimeters. It is important that nurses use a ruler and measure a wound the same way. The NPUAP recommends using a head-to-toe orientation, the longest length head to toe, and the widest width side to side, perpendicular (90° angle) to length, encompassing the entire wound. Use serial photographs with grids showing the wound's dimensions, especially if the wound has an irregular border, to document the baseline and wound healing (European Pressure Ulcer Advisory Panel [EPUAP] and NPUAP, 2009). To measure wound depth, gently insert a sterile cotton-tip applicator into the deepest part of the wound. Measure the applicator from the tip in the wound bed to the skin level.

Undermining or Tunneling Assess the wound edges for any undermining or tunneling. Pay close attention to any tissue that appears to have a separation either in tissue type or plane, as frequently tunnels may be found. Measure the depth and location of any undermining or tunneling using the face of a clock as a guide. If the top of the wound is 12:00 and the bottom of the wound is 6:00, for example, record "2 cm of undermining is present from 1:00 to 4:00" or "6 cm tunnel exists at the center of the wound tracking in the 3:00 direction."

Periwound Examine the skin surrounding the wound. Skin discoloration may indicate a hematoma or additional injury to the surrounding tissue. Look for maceration, undermining, crepitus, blistering, erythema, and epiboly, slough, and eschar.

Maceration is caused by excessive moisture from pooled drainage on intact skin for periods of time or when a moist dressing is inappropriately applied, left on too long, or overlaps onto healthy skin. The skin may appear as pale and wrinkled or "pruned," and may flake and peel.

Undermining will produce a boggy feel around the wound.

Crepitus is gas trapped under the skin. If you palpate the surrounding skin and feel a crackling sensation, this is crepitus. Crepitus may be due to air leaking from the lung in a chest wound or may indicate the presence of gas-producing bacteria.

Erythema, **swelling**, or other signs of irritation indicate that the surrounding tissue is in jeopardy.

Quality and Safety Education for Nurses

Improving Wound Care With Information Technology

Competency: *Informatics (Knowledge); Quality Improvement (Knowledge); Evidenced-Based Practice (Attitudes)**

Situation: Information technology (IT) can have a significant impact on wound care management—from reducing documentation time to tracking outcomes. Extensive documentation of wound care is required for both clinical and reimbursement reasons. Electronic documentation systems eliminate duplication. They save time by using data entered once and adding it in all the other fields where it is required. This allows for more time to spend in patient care.

In addition to reducing paperwork, wound management software incorporates best practices into care management algorithms, decision supports, and alerts based on the type and stage of each wound. Changes in wound characteristics or new patient information initiates computer prompts that request more information or suggest treatment changes. For example, if the patient begins a new medication that can delay wound healing, a prompt may ask whether another medication may be used instead, or the prompt might suggest more frequent monitoring of wound characteristics.

When you upload photographs and multiple measurements of the patient's wound(s), they become part of the electronic care plan and pop up in chronological order so that you can visualize how the wound is healing. Clinicians can also set reminders for initiating future steps or referrals, eliminating the need to rely on memory and reducing errors.

Think about it: Informatics is the use of information and technology to communicate, manage knowledge, mitigate error, and support decision making. Can you think of how other patient conditions can benefit from specific management software? What might the information technology software look like for patients with high blood pressure or obesity?

- What data would be collected?
- What information might be generated from the data?
- What errors might be prevented?

For specific Knowledge, Skills, and Attitudes,

Go to the QSEN Web site at **http://qsen.org/competencies/pre-licensure-ksas/**

Source: DeGaspari, J. (2013). Not skin deep: Lower costs and better outcomes in wound care. *Healthcare Informatics*. Retrieved from http://www.healthcare-informatics.com/article/not-skin-deep-lower-costs-and-better-outcomes-wound-care

Epiboly is closed or rolled wound edges. Examine wound edges for epithelial tissue and contraction. Epiboly may indicate that epithelial cells have moved down and rolled under the wound edges. Once the cells reach the wound bed, they will stall wound healing.

Slough is usually soft, stringy, and pale yellow or gray.

Eschar, also known as an *unstageable pressure ulcer*, is thick, hard, and black or brown.

Extent and Type of Tissue in Wound Base Assessment of the types of tissue and their amounts can give you an idea of the severity of the wound, treatment options, and/or healing of the wound. Table 35-4 outlines different types of tissue you might see in a wound bed. Viable (living) tissue must be distinguished from nonviable tissue. Many wounds may have different types of tissue at the same time. Describe each type with percentages. For example, "80% of the wound bed contains granulation tissue, and 20% remains necrotic." Granulation tissue is evidence of healing. A pale color or dry texture may indicate a delay in healing. Necrotic tissue of any type will delay wound healing and should be removed. The exception is stable eschar on a heel that is firmly attached to the healthy wound edges without signs of infection.

Drainage Determine whether exudate is present. If so, describe the amount, color, consistency, and odor. Compare changes in the exudate to the patient's previous status.

- *Amount.* Describe the amount as none, light, moderate, or heavy. Drainage amounts vary according to the type of wound (i.e., venous stasis ulcers usually produce more drainage than arterial ulcers).
- *Drains.* If a drain is present, measure the amount of fluid in the collection container.
- *Color.* Describe the color or consistency as serous or clear, serosanguineous, sanguineous, purulent, or seropurulent (composed of serum and pus).
- *Odor.* Describe odor as absent, faint, moderate, or strong. Clean the wound of all exudate or foreign material before assessing for odor because odor characteristics vary depending on the wound moisture, organisms, amount of nonviable tissue, or types of dressings used. Odor may indicate fistula formation or bacterial contamination. For example, if a patient has an abdominal wound that was odorless but begins to smell of bile or feces, you should carefully assess for presence of a fistula.

Wound and Tissue Pain Routinely ask your patients about pain or discomfort related to the wound or wound care (EPUAP and NPUAP, 2009). You will need to develop a pain management plan if the patient is uncomfortable. Always take seriously the patient's complaint of pain, especially if there is a sudden increase. Pain is often an early symptom of infection. In the immunocompromised patient, pain may be the only symptom of infection.

Nutritional Status Screen and assess the nutritional status of each patient admitted with a pressure ulcer; and whenever there is a change in the patient's condition (WOCNS, 2010). A referral to the dietitian for early assessment and intervention may be necessary if nutritional problems are present. Sufficient calories are needed for wound healing. This may involve adding oral supplemental meals, or even enteral or parenteral nutrition (Association for the Advancement of Wound Care, 2005, revised 2010).

Table 35-4 ➤ Types of Tissue in the Wound Bed

TYPE OF TISSUE	DESCRIPTION	NURSING GOAL
Slough	Soft, moist, devitalized (necrotic) tissue; may be white, yellow, tan; may be stringy, loose, or adherent to bed.	Debride the wound.
Eschar	Necrotic tissue; dry, thick, leathery; may be black, brown, or gray depending on moisture level.	Debride the wound.
Granulation Tissue	Pink to red moist tissue; made of new blood vessels, connective tissue, and fibroblasts; surface is granular or pebble-like.	Cleanse, protect. Promote epithelialization.
Clean, Nongranulating	Absence of granulation tissue, but bed is pink, shiny, and smooth.	Cleanse, protect. Promote growth of healthy tissue.
Epithelial	Regenerating epidermis; may appear pink or pearly white as it crosses the wound bed; may begin as a ring around the wound or from epithelial cells lining hair follicles.	Cleanse, protect.

Assessing Untreated Wounds

For an untreated wound, make the same assessments as for a treated wound. Also, make additional assessments that allow you to determine the immediate treatment needed. For example, assess for bleeding. If bleeding is profuse, apply direct pressure to the site. If bleeding continues after you apply pressure for 5 minutes or if blood is spurting from the wound, call the provider immediately. Severe pain, numbness, or loss of movement below the wound also requires immediate, comprehensive evaluation. For a description of focused assessment for an untreated wound,

Go to Chapter 35, **Assessment Guidelines and Tools, Physical Examination: Wound Assessment,** in Volume 2.

Also determine whether the patient needs a tetanus immunization. Tetanus-prone wounds include compound fractures, gunshot wounds, crush injuries, burns, punctures, foreign object injuries, wounds contaminated with soil, and wounds neglected for more than 24 hours. An immunization should be given if:

- The last immunization was 10 years ago or longer (Immunization Action Coalition, U.S. Department of Health and Human Services, Centers for Disease Control and Prevention [CDC], 2012).
- The wound is contaminated with dirt or debris or is a burn, and the most recent tetanus immunization was given more than 5 years ago.
- It is uncertain when the patient last received an immunization.

Evaluating Pressure Ulcer Healing

In addition to the Braden and Norton risk assessments previously described, the Agency for Healthcare Research and Quality (AHRQ) and NPUAP recommend use of the *PUSH tool* to evaluate pressure ulcers (NPUAP, 1998). The tool provides a comprehensive means of reporting the progression of a pressure ulcer. Surface area, exudate, and type of wound tissue are scored and totaled. As the ulcer heals, the total score falls. To see the PUSH tool,

Go to Chapter 35, **Assessment Guidelines and Tools, The PUSH Tool for Evaluation of Pressure Ulcers,** in Volume 2.

Laboratory Data

You should integrate laboratory data with your history and physical assessment findings. The most common laboratory assessments related to skin integrity are protein levels, complete blood count, erythrocyte sedimentation rate, glucose, thyroid and iron levels, coagulation studies, and wound cultures. To learn more about these tests and see the normal ranges,

Go to Chapter 35, **Diagnostic Testing: Tests for Assessing Wounds,** in Volume 2.

Wound cultures may be ordered to determine the types of bacteria present. Local or systemic signs of infection, suddenly elevated glucose levels, pain in a neuropathic extremity, or lack of healing after 2 weeks in a clean wound may indicate the need for a wound culture. Cultures may be obtained by swab, aspiration, or tissue biopsy.

Swabbing The most common and most noninvasive method to obtain a culture is with a swab. Swab specimens have been shown to be acceptably accurate in representing bacteria counts biopsied from a wound (Mutluoglu, Uzun, Turhan, et al., 2012). The WOCNS (2007, revised 2011) recommends using swab cultures as a reasonable alternative to biopsy in the clinical setting. However, other recent studies refute this, claiming deep tissue biopsies are the most accurate way to detect infection (Aggarwal, Higuera, Deimemgian, et al., 2013).

The Highlights of Procedures box summarizes swabbing. For the full procedure,

Go to Chapter 35, **Procedure 35-1: Obtaining a Wound Culture by Swab,** in Volume 2.

Needle Aspiration Specifically trained providers (e.g., physicians, advanced practice nurses) may perform needle aspiration of a wound. This involves insertion of a needle into the tissue to aspirate tissue fluid. Organisms present in the tissue fluid can then be detected. Needle aspiration is an invasive procedure, with the risk of inadvertent needle damage to tissue and underlying structures.

Tissue Biopsy The most accurate method for culturing a chronic wound is *tissue biopsy.* It has long been considered the "gold standard." Tissue is removed from the wound edge by a specially trained provider. However, many facilities do not have the equipment needed to process tissue samples. This is an invasive procedure. It creates a risk of sepsis, causes pain, and disrupts the wound bed, sometimes delaying healing.

KnowledgeCheck 35-7

- What should be included in a wound assessment?
- What is the preferred method of wound culture that may be performed by a registered nurse (RN)?
- Identify three types of laboratory data that may be associated with a delay in wound healing.

What Assessments Can I Delegate?

Initial assessment of a wound, as well as ongoing evaluation of a wound that requires treatment, must be done by the RN. You may delegate to nursing assistive personnel (NAP) inspection of the skin for evidence of skin breakdown. Instruct the NAP to notify you of redness, tissue warmth, or drainage that they observe during their care of the patient. You may also delegate turning and position changes to the NAP. You must provide them with the times for the turning and how they should position the patient at each turn. A turning chart at the bedside is helpful. Turning and movement prevent tissue damage from ischemia, thereby preventing pressure ulcers.

ANALYSIS/NURSING DIAGNOSIS

The following nursing diagnoses are appropriate for patients who are at risk for skin breakdown or for patients who have wounds.

- *Risk for Impaired Skin Integrity* is appropriate for patients who have one or more risk factors for skin breakdown (e.g., immobility, incontinence, extremes of age, impaired circulation, impaired sensation, undernutrition, emaciation). NANDA International (2009) recommends that you use a risk assessment tool (e.g., Norton or Braden scale) to identify these patients.
- *Impaired Skin Integrity* is appropriate for patients who have experienced damage to the epidermis or dermis, for example, patients who have superficial wounds or stage I or II pressure ulcers.
- *Impaired Tissue Integrity* is appropriate for patients with wounds that extend into the subcutaneous tissue, muscle, or bone. Use this diagnosis for patients with deep wounds or stage III or IV pressure ulcers.
- *Risk for Impaired Tissue Integrity* is appropriate for clients with Impaired Skin Integrity who are at risk for delayed healing. For example, Mr. Harmon (Meet Your Patient) has a stage I pressure ulcer but is at risk for further progression of the ulcer because of his age, nutritional state, and the presence of another wound. Note that this is not a NANDA-I diagnosis; however, it is useful in the situation described.

Skin problems and wounds can be the etiology for other nursing diagnoses as well, for example:

- *Risk for Infection* is an appropriate diagnosis if the patient has a traumatic wound or is immunosuppressed, undernourished, or immobile.
- *Pain* is a diagnosis that may be used for patients who are experiencing discomfort from the wound or from the treatments required to heal the wound.
- *Disturbed Body Image* should be used if the patient is experiencing distress about the wound. Consider this diagnosis even if the patient is expected to make a complete recovery. Some patients experience extreme distress about wounds. You will certainly want to consider this diagnosis if the patient experiences an injury that is expected to result in disfigurement.

PLANNING OUTCOMES/EVALUATION

For associated NOC standardized outcomes for skin and tissue integrity diagnoses,

Go to Chapter 35, **Standardized Language, Selected Standardized Outcomes and Interventions for Skin and Wound Diagnoses,** in Volume 2.

Individualized goals/outcome statements should address the need to maintain intact skin or heal the wound. For patients who have a diagnosis of Risk for Impaired Skin Integrity, you might write a goal such as the following:

> Maintains intact skin throughout treatment, as evidenced by good skin turgor with no erythema, edema, or breaks in the skin.

For patients who have a wound (actual Impaired Skin Integrity or Impaired Tissue Integrity), you might write a goal such as the following:
