Mupirocin (Bactroban) and retapamulin (Altabax) are topical antibiotics used to treat impetigo and other minor skin infections due to *Staph aureus* or *Strep pyogenes*. Mupirocin is also approved for nasal decolonization of methicillin-resistant *Staph aureus* (MRSA). Retapamulin is not approved for MRSA nor is it intended to be used inside the nose. Both mupirocin and retapamulin inhibit bacterial growth by disrupting protein synthesis; however, they bind at different sites. Mupirocin is applied three times per day for up to 12 days, and retapamulin is applied two times per day for 5 days. Mupirocin is available as a generic drug, making it less expensive than retapamulin. More severe skin infections require oral antibiotics.

CHAPTER SUMMARY

- Drugs that inhibit protein synthesis may be bacteriocidal or bacteriostatic.
- Gentamicin is the prototype for aminoglycoside agents.
- Gentamicin is used for serious infections caused by gram-negative bacilli.
- Gentamicin use is limited by its potential for adverse effects, especially neurotoxicity, nephrotoxicity, ototoxicity, and neuromuscular blockade which are all Black Box warnings.
- Gentamicin is generally given parenterally but may be given orally to exert a local effect on the GI tract because oral drugs are more poorly absorbed.
- Clindamycin, the lincosamide prototype, is used for infections caused by gram-positive cocci and many gram-negative or gram-positive anaerobes.
- Clindamycin is reserved for treating serious infections that have not responded to less toxic antibiotics.
- Clindamycin therapy is limited by its potential for adverse effects, especially pseudomembranous colitis which is a Black Box warning.
- Macrolides, such as erythromycin, are used to treat an array of infections caused by gram-positive organisms. They are less effective against gram-negative organisms.
- Erythromycin is used for patients with a hypersensitivity to penicillin.
- Erythromycin has a spectrum of activity similar to that of penicillins and cephalosporins.
- Oxazolidinones and streptogramins are the newest classes of antibiotics developed to manage "superbugs" that do not respond to vancomycin.
- The prototype oxazolidinone is linezolid.
- The unique mechanism of action of linezolid may reduce the emergence of resistance.
- Quinupristin/dalfopristin, the prototype streptogramin, is a combination drug that is 16 times more potent than each drug alone.
- The tetracyclines have been used for many types of infections in the past; therefore, resistance to these drugs is now a problem.
- Tetracyclines remain useful in treating infections caused by *Rickettsiae* species, *Mycoplasma pneumoniae,* and *Chlamydia* species. They are also used to treat acne.
- Tigecycline, a glycylcycline antibiotic, is structurally similar to tetracycline but is designed to circumvent key bacterial resistance mechanisms.
- Chloramphenicol is used for serious gram-positive or gram-negative infections that have not responded to less toxic antibiotics.
- Chloramphenicol passes the blood–brain barrier and is useful in treating brain abscesses or meningitis.
- Chloramphenicol therapy is limited by its potential for adverse effects, especially blood dyscrasias which is a Black Box warning.

QUESTIONS FOR STUDY AND REVIEW

1. List disadvantages of tetracycline therapy.
2. Why are aminoglycosides used only in serious infections?
3. What are the most serious adverse effects of chloramphenicol therapy?
4. After a patient receives erythromycin for 10 days for a severe skin infection, the patient develops a vaginal yeast infection. Explain why this infection occurred.
5. A patient who is taking clindamycin at home calls you to report violent, watery, and bloody diarrhea. Explain the probable cause for these symptoms. What advice would you give to this patient?
6. Describe the differences between quinupristin/dalfopristin and linezolid for managing VRE and MRSA.

NEED MORE HELP?

Chapter 40 of the Study Guide to Accompany *Drug Therapy in Nursing,* 4th Edition, contains additional NCLEX-style questions and other learning activities to reinforce your understanding of the concepts presented in this chapter. 41

Drugs That Are Miscellaneous Antibiotics

Learning Objectives

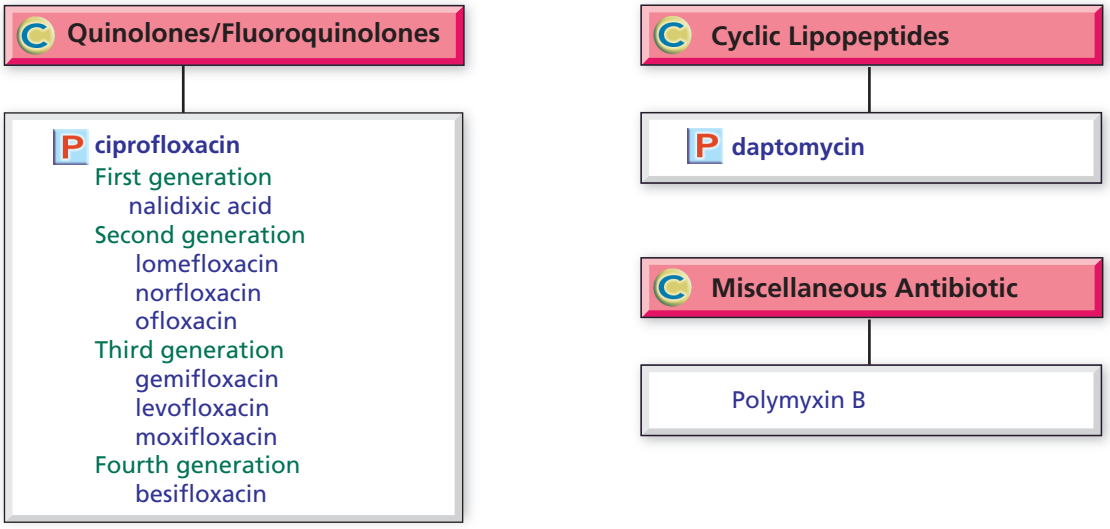
At the completion of this chapter the student will:

1. Identify core drug knowledge pertaining to miscellaneous antibiotic agents.
2. Identify core patient variables pertaining to miscellaneous antibiotic agents.
3. Relate the interaction of core drug knowledge to core patient variables for miscellaneous antibiotic agents.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for miscellaneous antibiotic agents.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for miscellaneous antibiotic agents.
6. Determine key points for patient and family education for miscellaneous antibiotic agents.

Key Terms

arthropathy
cyclic lipopeptides
fluoroquinolones
quinolones

Drugs That Are Miscellaneous Antibiotics



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Miscellaneous antibiotics are those that have a mechanism of action other than disrupting the cell wall or protein synthesis of bacteria. These drugs include the fluoroquinolones, cyclic lipopeptides, rifampin, metronidazole, and polymyxin B. This chapter discusses the fluoroquinolones, with their prototype ciprofloxacin; cyclic lipopeptides, with their prototype daptomycin; and polymyxin B. Rifampin, the prototype for drugs affecting leprosy, is discussed in Chapter 43. Metronidazole is used most frequently to manage protozoan infections and thus is discussed in Chapter 47.

QUINOLONES/ FLUOROQUINOLONES

The **quinolones** have been used to treat infections for the past 40 years. They have undergone substantial advances in their antibiotic activity and have developed into a class of synthetic antibiotics that are effective for aerobic gram-negative and gram-positive infections. Like cephalosporins, quinolones are subdivided into generations. The first-generation drugs are called quinolones, whereas subsequent generations are called **fluoroquinolones** because a fluorine atom has been added to the quinolone structure of these drugs. First-generation quinolones are used only to treat uncomplicated urinary tract infections (UTIs). Second-generation fluoroquinolones have increased gram-negative and systemic activity. Third-generation fluoroquinolones have extended activity against gram-positive pathogens, but they are less active than second-generation drugs against *Pseudomonas* species. Fourth-generation fluoroquinolones have extended activity against *Pseudomonas;* however, at this time they have all been removed from the market. Table 41.1 summarizes selected fluoroquinolones. The prototype drug for the fluoroquinolone class is ciprofloxacin (Cipro).

Nursing Management of the Patient Receiving P Ciprofloxacin

Core Drug Knowledge

Pharmacotherapeutics

Ciprofloxacin is most active against aerobic gram-negative organisms and group D streptococci.

Ciprofloxacin also has been used extensively to treat serious gram-negative infections; however, resistance has developed in strains of *Pseudomonas aeruginosa* and *Serratia marcescens*. Ciprofloxacin is generally active against aerobic gram-positive organisms, but resistance has been noted in *S. aureus* and *Pneumococcus* species. It is not active against anaerobic organisms.

Ciprofloxacin is useful in treating infections in the urinary tract (Box 41.1) and upper and lower respiratory tract; gonorrhea; infections in bone, skin, subcutaneous tissues, and joints; bacterial conjunctivitis; and otitis externa. Ciprofloxacin is also used in the treatment of and prophylaxis against anthrax and for the treatment of typhoid fever.

Pharmacokinetics

Ciprofloxacin is available in oral, parenteral, and topical formulations. Topical formulations include both otic and ophthalmic preparations. Oral preparations are absorbed rapidly from the gastrointestinal (GI) tract and undergo minimal first-pass metabolism. In healthy, fasting adults, 40% to 85% is absorbed, and peak serum concentrations are reached in 0.5 to 2.3 hours. Ciprofloxacin is distributed widely into most tissues because protein binding is low. Penetration into cerebrospinal fluid is minimal when the meninges are not inflamed. Ciprofloxacin is eliminated through renal and nonrenal routes. Renal excretion accounts for 15% to 40% of unchanged drug, whereas fecal excretion accounts for 20% to 40% of the dose. Intravenous (IV) ciprofloxacin has an onset of action within 10 minutes, and peak effects occur within 30 minutes. Topical ciprofloxacin has an onset of 5 minutes.

Pharmacodynamics

Ciprofloxacin, like other antibiotics, has no direct effect on the body but acts on the bacterial cell. Ciprofloxacin is bactericidal. It inhibits deoxyribonucleic acid (DNA) gyrase, an enzyme needed for bacterial DNA replication. Although human cells contain an enzyme that functions in the same manner, this enzyme is not affected by bactericidal concentrations of ciprofloxacin. Both rapid- and slow-growing organisms are inhibited by ciprofloxacin. In addition, ciprofloxacin exhibits a prolonged postantibiotic effect; organisms may not resume growing for 2 to 6 hours after exposure to ciprofloxacin, despite undetectable drug levels. Ciprofloxacin is concentrated within human neutrophils, which may explain its effectiveness in treating mycobacterial infections.

Contraindications and Precautions

Ciprofloxacin is contraindicated in patients who are pregnant or lactating and in patients with a known allergy to any fluoroquinolone. Oral and parenteral ciprofloxacin is contraindicated for children younger than 18 years, with the exception of complicated UTIs and the treatment of anthrax. Topical ciprofloxacin may be used in children without restriction.

Caution should be used in patients with GI disease (especially colitis), diabetes mellitus, renal dysfunction, hepatic dysfunction, and in patients who are dehydrated and those receiving warfarin. Because ciprofloxacin can stimulate the central nervous system (CNS), it should be used with caution in patients with CNS disorders (such as seizures) or cerebrovascular disease (e.g., cerebral arteriosclerosis).

Adverse Effects

Ciprofloxacin is generally well tolerated. The most clinically important adverse reaction is **arthropathy** (joint disease). This often irreversible adverse reaction tends to occur in children under 18 years of age and adults over the age of 60. There is a black box warning for ciprofloxacin related to an increased risk of tendinitis and tendon rupture. This risk

TABLE 41.1 Summary of Selected Miscellaneous Antimicrobials

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Fluoroquinolones			
P ciprofloxacin (Cipro)	Uncomplicated UTI Respiratory, bone, joint infections Severe skin infections Infectious diarrhea Complicated UTI Inhalation anthrax	*Adult:* PO, 250 mg bid × 7–14 d; IV, 200 mg q12 h *Adult:* PO, 500 mg q12 h; IV, 400 mg q12 h *Adult:* PO, 750 mg q12 h *Adult:* PO, 500 mg bid 5–7 d *Child:* Not recommended *Adult:* PO, 500 mg bid 10–21 d; IV, 40 mg q12 h *Child:* IV, 6–10 mg/kg twice daily *Child:* PO, 10–20 mg/kg twice daily *Adult:* IV, 400 mg every 12 h, then switch to PO, 500 mg twice daily, after susceptibility tests returned *Child:* IV, 10 mg/kg every 12 h, then switch to 15 mg/kg twice daily after susceptibility tests returned	*Onset:* PO, varies; IV, 10 min *Duration:* 4–5 h $t_{1/2}$: 3.5–4 h
First Generation			
nalidixic acid (NegGram)	UTI	*Adult and child >12 y:* PO, 1 g qid 1–2 wk; prolonged therapy, 2 g/d *Child 3 mo–12 y:* PO, 55 mg/kg/d in four divided doses; prolonged therapy, 33 mg/k/d	*Onset*: varies *Duration*: unknown $t_{1/2}$: 1–2.5 h
Second Generation			
lomefloxacin (Maxaquin)	Lower respiratory tract infections, uncomplicated UTI Complicated UTI Prophylaxis	*Adult*: PO, 400 mg qd × 10 d *Adult*: PO, 400 mg qd × 14 d *Adult*: PO, 400 mg 2–6 h prior to surgery *Child*: Not recommended	*Onset*: Varies *Duration*: 8–10 h $t_{1/2}$: 8 h
norfloxacin (Noroxin)	Uncomplicated UTI Complicated UTI STD Prostatitis	*Adult*: PO, 400 mg q12h × 7–10 d *Adult*: PO, 400 mg q12h × 10–21 d *Adult*: 800 mg single dose *Adult*: PO, 400 mg q12h for 28 d *Child*: Not recommended	*Onset*: Varies *Duration*: Unknown $t_{1/2}$: 3–4.5 h
ofloxacin (Floxin)	Uncomplicated UTI Complicated UTI, lower respiratory tract infections, skin infections Prostatitis Uncomplicated gonorrhea Cervicitis, urethritis	*Adult*: PO, 200 mg bid for 3 d *Adult*: PO, 200 mg bid for 10 d *Adult*: PO, 300 mg bid for 6 wk *Adult*: PO, 400 mg single dose *Adult*: PO, 300 mg bid for 7 d *Child*: Not recommended	*Onset*: Varies *Duration*: 9 h $t_{1/2}$: 5–10 h
Third Generation			
gemifloxacin (Factive)	Pneumonia Chronic bronchitis	*Adult*: PO, 320 mg qd *Child*: Not recommended	*Onset*: Rapid *Duration*: 24 h $t_{1/2}$: 7 h
levofloxacin (Levaquin)	Pneumonia, skin infections Sinusitis Chronic bronchitis UTI, nephritis	*Adult*: PO/IV, 500 mg qd for 7–14 d *Adult*: PO/IV, 500 mg qd 10–14 d *Adult*: PO/IV, 500 mg qd × 7 d *Adult*: PO/IV, 250 mg qd × 10 d *Child*: Not recommended	*Onset*: Varies *Duration*: 3–5 h $t_{1/2}$: 4–7 h
moxifloxacin (Avelox)	Pneumonia, sinusitis Chronic bronchitis	*Adult*: PO, 400 mg qd × 10 d *Adult*: PO, 400 mg qd × 5 d *Child*: Not recommended	*Onset*: Varies *Duration*: Unknown $t_{1/2}$: 12–13.5 h

(*Continued*)

TABLE 41.1 Summary of Selected Miscellaneous Antimicrobials *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Cyclic Lipopeptide			
P daptomycin (Cubicin)	Serious infections, especially MRSA and VRE	*Adult*: IV, 4 mg/kg once a day for 7–14 d *Child*: Not recommended	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 8 h
C Miscellaneous Antibiotic			
Polymyxin B	Bacterial corneal ulcer Bacterial infection of eye Infection due to Pseudomonas aeruginosa Meningitis	*Adult*: Topical, 1–3 drops every hour; increase interval as response indicates; Ointment, apply every 3–4 h for 7–10 d IV, 15,000 to 25,000 U/kg/d divided every 12 h; maximum 25,000 U/kg/d IM, 25,000 to 30,000 U/kg/d divided every 4 to 6 h *Child >1 y*: IM, 25,000 to 30,000 U/kg/d divided every 4–6 h *Adult*: Intrathecal, 50,000 U once daily for 3 to 4 d, then 50,000 U every other d	*Onset*: IV, rapid; IM, gradual *Duration*: Unknown $t_{1/2}$: 4.3–6 h

is further increased in older patients, usually over age 60; in kidney, heart, and lung transplant recipients; and with patients taking concomitant steroid therapy. Other potential serious adverse effects include pseudomembranous colitis, superinfection, hepatotoxicity, nephrotoxicity, myelosuppression, and peripheral neuropathy.

The most common adverse reactions are GI effects, including nausea and vomiting, diarrhea, and abdominal pain. For the most part, CNS reactions, such as headache and restlessness, occur in only 1% to 2% of patients. Other CNS effects that occur in fewer than 1% of patients include dizziness, vertigo, insomnia, nightmares, hallucinations, confusion, agitation, drowsiness, anxiety, malaise, depression, paresthesias, and increased intracranial pressure. In predisposed patients, seizures may occur.

Cardiovascular adverse effects, such as palpitations, atrial flutter, premature ventricular contractions, syncope, angina, myocardial infarction, cardiac arrest, and cerebral thrombosis, have been reported with ciprofloxacin, but they occur rarely.

Photosensitivity may occur with ciprofloxacin. However, this adverse effect occurs more frequently with other fluoroquinolones. Lastly, ciprofloxacin may induce dysglycemia (either hyperglycemia or hypoglycemia).

Adverse reactions to ophthalmic ciprofloxacin usually are associated with local effects, such as burning or discomfort. Other adverse effects of ophthalmic ciprofloxacin include lid margin crusting, crystals, scales, foreign body sensation, pruritus, conjunctival hyperemia, and a bad taste following administration.

BOX 41.1 FOCUS ON RESEARCH

Ciproflaxin Therapy for UTI

How Long is Long Enough?

Lutters, M., Vogt-Ferrier, N. B. (2008). Antibiotic duration for treating uncomplicated, symptomatic lower urinary tract infections in elderly women. *Cochrane Database of Systematic Reviews*, 16(3):CD001535.

The Study

The purpose of this study was to determine the optimal duration of antibiotic treatment for uncomplicated symptomatic lower UTI in elderly women. The authors researched all randomized controlled trials comparing different treatment durations of oral antibiotics for uncomplicated symptomatic lower UTIs in elderly women. Fifteen studies were evaluated. Three studies compared single dose with short-course treatment (3 to 6 days), six compared single dose with long-course treatment (7 to 14 days) and six compared short- with long-course treatment. There was a significant difference for persistent UTI between single dose and short-course treatment and single versus long-course treatment. Short versus longer treatments showed no significant difference in efficacy. Rate of adverse drug reactions increased significantly with longer treatment durations in one study.

Conclusion

Short-course treatment (3 to 6 days) could be sufficient for treating uncomplicated UTIs in elderly women, although more studies on specific commonly prescribed antibiotics are needed.

Nursing Implications

UTIs are the most common infection for elderly women. Elderly women are more likely to forget to take medication when prolonged treatment is prescribed. They are also more likely to have difficulty affording prescriptions. Short-term therapy appears to be as efficacious as long-term therapy and will be a cost saving for the patient. Nurses should continue to keep abreast of the latest information to appropriately answer questions from their patients.

Drug Interactions

Ciprofloxacin has many potential drug–drug interactions. Most interactions are related to either inhibiting the metabolism of the interacting drug or decreasing the absorption of ciprofloxacin. Many of the precautions for use of ciprofloxacin stem from the potential drug–drug interactions. For example, patients receiving warfarin may obtain subtherapeutic levels for anticoagulation, those receiving sulfonylureas may have hypoglycemia, and those receiving cyclosporin are at risk for nephrotoxicity. Table 41.2 summarizes drug interactions with ciprofloxacin.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a patient history to evaluate for pre-existing GI disease, renal or hepatic dysfunction, CNS disorder, pregnancy, or lactation. Communicate any positive finding to the prescriber. Assess for any known reactions to antibiotics.

Physical examination should include an examination of the skin for any rash or lesions, to provide a baseline for comparison if an allergic reaction is suspected. For the same reason, assess respiratory status, checking breath sounds for wheezing. When ciprofloxacin is proposed for long-term use, additional assessments should be done. For patients with pre-existing renal or hepatic disease obtain baseline blood tests to document current functioning. Patients with pre-existing anemias should have a complete blood count (CBC). Patients with pre-existing cardiac disorders should have an electrocardiogram.

Life Span and Gender

Assess the patient for pregnancy and lactation. Because ciprofloxacin crosses the placenta and enters breast milk, pregnant

TABLE 41.2 Agents That Interact with P Ciprofloxacin

Interactants	Effect and Significance	Nursing Management
Antacids	Concurrent administration of antacids and ciprofloxacin may decrease the absorption of ciprofloxacin.	Administer antacids 6 h before or 2 h after ciprofloxacin.
cyclosporine	Ciprofloxacin may decrease cyclosporine metabolism, resulting in increased risk for adverse effects and toxicity.	Monitor for nephrotoxicity. Contact the prescriber if symptoms occur.
didanosine	The magnesium and aluminum cations in the buffers of didanosine decrease GI absorption of ciprofloxacin.	Administer ciprofloxacin 2 h before or 6 h after didanosine.
Food	Food interferes with the absorption of ciprofloxacin.	Administer on an empty stomach. Lengthen interval between milk and ciprofloxacin as much as possible.
Hydantoins	The mechanism of action is unclear, but ciprofloxacin may reduce serum phenytoin concentrations. This may result in seizure activity.	Monitor serum phenytoin levels. Discuss adjustment of dose with the prescriber.
methadone	Ciprofloxacin may decrease methadone metabolism, resulting in increased risk for adverse effects and toxicity.	Monitor for CNS depression and hypotension. Ensure patient safety.
procainamide	Ciprofloxacin may decrease procainamide metabolism, resulting in increased risk for adverse effects and toxicity.	Monitor for QT interval prolongation. Contact prescriber immediately if symptoms occur.
Salts iron zinc	GI absorption of ciprofloxacin may be decreased by the formation of iron–ciprofloxacin complex.	Avoid coadministration.
sucralfate	GI absorption of ciprofloxacin may be decreased by sucralfate.	Administer sucralfate 6 h after ciprofloxacin.
Sulfonylureas	Severe and persistent hypoglycemia may occur.	Increase frequency of blood glucose monitoring. Monitor for signs of hypoglycemia.
Theophyllines	Ciprofloxacin inhibits the hepatic metabolism of theophyllines. This may result in theophylline toxicity.	Monitor for theophylline levels. Observe for signs of toxicity. Discuss adjustment of dose with the prescriber.
tizanidine	Ciprofloxacin may decrease tizanidine metabolism, resulting in increased risk for adverse effects and toxicity.	Monitor for dizziness and hypotension. Contact prescriber if symptoms occur.
warfarin	Ciprofloxacin may decrease warfarin metabolism, resulting in increased risk for adverse effects and toxicity.	Monitor PT and INR. Monitor for signs of bleeding. Contact prescriber immediately if symptoms occur. Discuss adjustment of dose with the prescriber.

or breast-feeding women should not take ciprofloxacin. As with other fluoroquinolones, the patient's age should be noted before administering ciprofloxacin. Fluoroquinolone antibiotics have caused arthropathies, such as cartilage deterioration, when administered to immature animals. Although similar consequences of therapy have not been demonstrated in humans, ciprofloxacin should not be used in patients younger than 18 years except for the treatment of complicated urinary tract infections or anthrax. However, ciprofloxacin ophthalmic solution is approved for use in children. Elderly patients should be monitored carefully for renal or hepatic dysfunction and receive reduced dosages of ciprofloxacin as needed. Older patients taking warfarin should be monitored closely. Studies have shown they have an increased risk for upper GI bleeding while on ciprofloxacin therapy.

Lifestyle, Diet, and Habits

It is important to assess the patient's typical food, caffeine, and over-the-counter drug use. Caution the patient that food or caffeine may interrupt the action of ciprofloxacin. Remind patients with frequent dyspepsia that antacids can decrease the absorption of ciprofloxacin and that some vitamins also can decrease the absorption of ciprofloxacin. The safest advice would be to take any vitamin therapy at least 2 hours before or after administration of ciprofloxacin.

Environment

Ciprofloxacin is administered in a variety of environments. In acute care settings, administer parenteral ciprofloxacin over 60 minutes through a large vein to minimize discomfort and reduce the risk of venous irritation.

In the home, the patient should take ciprofloxacin every 12 hours on an empty stomach. Advise patients using the ophthalmic or otic solutions not to contaminate the tip of the dispenser by contact with the eye, ear, fingertips, or other surface.

Nursing Diagnoses and Outcomes

- Diarrhea related to adverse drug effects
  Desired outcome: *The patient will avoid dehydration, maintain fluid intake, and contact the prescriber if diarrhea persists.*
- Imbalanced Nutrition: More or Less than Body Requirements, related to GI effects, alteration in taste, and superinfections
  Desired outcome: *The patient will maintain body weight and contact the prescriber if persistent adverse effects alter nutritional status.*
- Risk for Injury related to drug-induced dizziness, confusion, and other CNS effects
  Desired outcome: *The patient will remain free of injury and contact the prescriber about persistent CNS disturbances.*
- Risk for Impaired Tissue Integrity related to drug-induced photosensitivity
  Desired outcome: *The patient will take measures to protect his or her skin from prolonged sun exposure*

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that the patient receives the full course of ciprofloxacin as prescribed, around the clock, to increase effectiveness. Coordinate the administration of drugs to decrease potential drug–drug interactions.

Review culture and sensitivity reports to confirm that the causative bacteria are sensitive to ciprofloxacin.

Minimizing Adverse Effects

Institute safety measures to protect the patient if CNS effects occur. For patients with adverse GI effects, provide small, frequent meals as tolerated.

Frequent mouth care and sucking on ice chips may relieve stomatitis and sore mouth.

Providing Patient and Family Education

- One of the most important features of patient and family education is teaching patients that ciprofloxacin is one drug in a class of drugs. Advise patients who have had any type of allergic reaction to a fluoroquinolone never to take any other drug with a name that ends with "oxacin."
- Advise patients who are pregnant or breast-feeding not to take ciprofloxacin.
- It is important to explain that ciprofloxacin is prescribed for a particular infection. Tell patients that ciprofloxacin should not be used to self-medicate or treat any other infection or any other person, especially not a child.
- Instruct patients to call the prescriber if their symptoms do not improve within 3 days.
- It is important to instruct patients to complete the full course of drug therapy, even when they feel better.
- Advise patients to take ciprofloxacin every 12 hours. A forgotten dose can be taken as soon as it is remembered, but not if it is almost time for the next dose.
- Teach patients symptoms of an allergic reaction to ciprofloxacin (i.e., rash, welts, itching, or shortness of breath) and instruct patients to stop taking the drug at once and notify the prescriber if these symptoms occur.
- Advise patients who experience GI upset to eat small, frequent meals and to increase their fluid intake, particularly if they have diarrhea. For patients with a sore mouth or throat, sucking on ice chips may provide relief.
- Caution patients about possible photosensitivity and encourage them to avoid sunlight or ultraviolet light, to wear appropriate clothing, and to apply a sunscreen with a sun protection factor of at least 15 if exposure is unavoidable.
- Advise patients of signs and symptoms of a superinfection, such as discoloration of the tongue, fatigue, easy bruising, or vaginal discharge. In addition, tell patients that ciprofloxacin may cause CNS disturbances or cardiovascular symptoms, and that patients should contact the prescriber immediately if these adverse reactions occur.
- Tell patients to report any tendon pain to the prescriber immediately because of the potential for tendon rupture as an adverse effect of ciprofloxacin therapy.

CRITICAL THINKING SCENARIO

HOW DID THAT HAPPEN?

Keri H., age 25 years, comes to your clinic after a weekend of skiing in the mountains with a complaint of chest pain, cough, and shortness of breath. She is diagnosed with pneumonia and is started on ciprofloxacin, 400 mg bid. Four days after starting the medication, Keri calls the clinic and asks, "Can I come back and get seen again? My chest pain and cough are gone but I am limping and my left heel hurts. I guess I must have done something while I was skiing, but I don't remember hurting myself." How would you respond to Keri? Can you correlate this scenario with why ciprofloxacin is contraindicated during pregnancy?

- Inform women who use oral contraceptives to use a backup method of contraception during ciprofloxacin therapy because their birth control pills may be less effective while they are taking ciprofloxacin.

Ongoing Assessment and Evaluation

Antibiotic therapy can result in superinfection with nonsusceptible organisms. Due to the possibility for overgrowth of candidal organisms with ciprofloxacin therapy, monitor patients closely during treatment. In addition, patients who develop diarrhea while taking—or soon after taking—ciprofloxacin should be considered for differential diagnosis of antibiotic-associated pseudomembranous colitis.

Drugs Closely Related to P Ciprofloxacin

First-Generation Quinolone

Nalidixic acid (NegGram) is an oral quinolone agent that is indicated for use in UTIs because it concentrates in the urine and achieves only low concentrations in serum, making it ineffective for infections outside the urinary tract. Nalidixic acid is not commonly used because fluoroquinolones are more efficacious.

MEMORY CHIP

P Ciprofloxacin

- Used for infections caused by aerobic gram-negative organisms
- Major contraindications: hypersensitivity, children younger than 18 years, pregnancy, or breast-feeding
- Most common adverse effects: GI
- Most serious adverse effect: arthropathy (in children younger than 18 years)
- Maximizing therapeutic effects: Complete the full course of antibiotic therapy.
- Minimizing adverse effects: Provide small, frequent meals for GI distress.
- Most important patient education: Importance of completion of therapy and, for women, use of a backup method of contraception
- **Black box warning: increased risk of tendinitis and tendon rupture.**

Second-Generation Fluoroquinolones

Second-generation fluoroquinolones include lomefloxacin, norfloxacin, and ofloxacin. Contraindications, adverse effects, and drug interactions for lomefloxacin and norfloxacin are the same as those listed for ciprofloxacin.

Lomefloxacin (Maxaquin) is used to treat lower respiratory tract infections, such as bronchitis, and UTIs. It also may be given as a preoperative prophylaxis to patients undergoing transurethral procedures or transrectal prostate biopsy. Lomefloxacin is a once-a-day oral preparation. The drug may induce serious photosensitivity reactions and should be discontinued at the first sign of rash, redness, or burning sensation on the skin.

Norfloxacin (Noroxin) is used to treat UTIs, prostatitis, and urethral or endocervical gonorrhea. It is an oral agent very similar to ciprofloxacin, with the same antimicrobial spectrum.

Ofloxacin (Floxin), which is available in oral and topical formulations, is very similar to ciprofloxacin in antimicrobial spectrum, pharmacotherapeutics, and adverse effects. However, ofloxacin is considered to be less efficacious. Drug interactions also are similar to those of ciprofloxacin, except that ofloxacin does not affect theophylline levels.

Third-Generation Fluoroquinolones

The third-generation fluoroquinolones include gatifloxacin, gemifloxacin, levofloxacin, and moxifloxacin.

Gatifloxacin (Tequin) has been removed from the market because of its ability to induce serious cases of diabetes and other potentially fatal blood sugar abnormalities. It is still available for ophthalmologic application as the drug Zymar.

Gemifloxacin (Factive) is used to manage acute exacerbations of chronic bronchitis caused by susceptible organisms such as *Streptococcus pneumoniae, Haemophilus influenzae, Haemophilus parainfluenzae,* and *Moraxella catarrhalis*. It is also used to manage community-acquired pneumonia caused by these bacteria or by *Mycoplasma pneumoniae, Chlamydia pneumoniae,* or *Klebsiella pneumoniae*. It is a once-a-day oral drug that is well tolerated. Common adverse effects include rash, photosensitivity, and elevations in liver enzymes.

Levofloxacin (Levaquin) may be more active than other fluoroquinolones against pneumococci and certain "atypical" respiratory pathogens. It is indicated for acute maxillary sinusitis, acute bacterial exacerbation of chronic bronchitis, community-acquired pneumonia, uncomplicated skin and skin-structure infections, complicated UTIs, acute pyelonephritis, cystitis, and prostatitis; sexually transmitted diseases such as urethral and cervical gonorrhea, nongonococcal urethritis, and cervicitis; and mixed infections of the urethra and cervix. It is administered orally or parenterally. Oral preparations require once-a-day dosing.

Important precautions related to levofloxacin involve giving the drug to patients with CNS disorders that predispose them

to seizure activity and kidney failure. Severe renal impairment requires dosage reduction. Levofloxacin is associated with QT prolongation and can cause photosensitization, but incidence of these adverse effects is relatively low. Interaction studies have shown that levofloxacin, unlike other fluoroquinolones, causes few or no problems with drugs such as theophylline, warfarin, digoxin, and cyclosporine. However, levofloxacin is more likely than ciprofloxacin to cause dysglycemia.

Moxifloxacin (Avelox) is indicated for treating acute exacerbations of chronic bronchitis, acute sinusitis, and pneumonia. It is especially efficacious in eradicating pathogens that cause exacerbations of chronic bronchitis. An important consideration for moxifloxacin is that to date, because it is a new drug, no organisms have been shown to be resistant to it. Moxifloxacin is being investigated currently for use in managing tuberculosis. Moxifloxacin is administered orally once a day for 5 to 10 days.

Like levofloxacin, moxifloxacin is reportedly associated with substantial prolongation of the QT segment. It should be avoided in patients who have conditions or are taking medications known to prolong the QT interval and in patients with a predisposition to arrhythmias.

Fourth Generation

Fourth generation besifloxacin (Besivance), an opthalmic fluoroquinolone for bacterial conjunctivitis, may be considered a 4th generation fluoroquinolone, although it has similar characteristics to 2nd generation fluoroquinolones as well. Historically, opthalmic fluoroquinolones were first used systemically then became approved for opthalmologic uses. Besifloxacin is the first fluoroquinolone to be initially used in opthalmology.

CYCLIC LIPOPEPTIDES

Daptomycin (Cubicin) is the only drug in a new class of antibiotics called **cyclic lipopeptides.** This class of antibiotics has a substantially different mechanism of action than other antibiotic drugs. Another benefit of daptomycin is its ability to retain potency against antibiotic-resistant gram-positive bacteria. Table 41.3 presents an overview of daptomycin.

Nursing Management of the Patient Receiving P Daptomycin

Core Drug Knowledge

Pharmacotherapeutics

Daptomycin is FDA approved for treatment of bacteremia due to *S. aureus* (including MRSA and right-sided endocarditis) and complicated skin and skin structure infections caused by a wide variety of gram-positive bacteria. Daptomycin may also be used in the treatment of vancomycin-resistant enterococcal (VRE) bacteremia.

Pharmacokinetics

Daptomycin is a once-daily IV medication. It reaches maximum serum concentration within 1 hour. 78% of daptomycin is excreted as unchanged drug by the kidneys. For that reason, a patient with severe renal impairment should receive a lower dose of medication.

Pharmacodynamics

Daptomycin is a bacteriocidal antibiotic that has a unique mechanism of action. It works by binding to the bacterial membrane and interfering with the integrity of the cell wall. This disruption causes a rapid depolarization of the membrane potential that leads to inhibition of protein, DNA, and RNA synthesis and, eventually, bacterial cell death. Daptomycin also has a postantibiotic effect that lasts approximately 6 hours.

At this time, no mechanism of resistance to daptomycin has been identified, there are no known transferable elements (plasmids) that confer resistance, and cross-resistance has not been reported.

Contraindications and Precautions

The only contraindication to the use of daptomycin is hypersensitivity. Precautions include pre-existing GI disorders, myopathy, and peripheral neuropathy. It should be used cautiously in elderly people and in patients with pre-existing renal dysfunction. Whether daptomycin enters breast milk is unclear; therefore, it should be given cautiously to women who breast-feed.

Like other antibiotics, daptomycin may alter the normal flora of the GI tract. Patients with pre-existing GI disorders have a higher risk of developing pseudomembranous colitis. Daptomycin has also been associated with inducing muscle weakness and pain. For that reason, patients with pre-existing myopathy and peripheral neuropathy should be monitored closely during daptomycin therapy.

Adverse Effects

Daptomycin is generally well tolerated. The most common adverse effects are constipation, diarrhea, nausea and vomiting, and injection site reactions. In the CNS, daptomycin may induce headache, insomnia, or dizziness. Cardiovascular adverse effects include hypotension or hypertension and unspecified chest pain. Hematopoietic

TABLE 41.3 Overview of Daptomycin

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
daptomycin (Cubicin)	Complicated skin and skin structure Bacteremia	*Adult:* IV, 4 mg/kg once a day for 7–14 d *Adult IV:* 6 mg/kg once a day for 2–6 wk *Child:* Not recommended	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 8 h

effects such as anemia, eosinophilia, leukocytosis, and thrombocytopenia may occur.

Metabolic and nutritional adverse reactions such as electrolyte disturbance, hyperglycemia, hypoglycemia, hypokalemia, hypomagnesemia, and increased serum bicarbonate have been reported. Elevations of creatine kinase (CK), hepatic enzymes, alkaline phosphatase, and INR may also occur.

In addition, daptomycin may induce problems with the musculoskeletal system, including arthralgia, back pain, limb pain, muscle cramps, muscle weakness, myalgia, and osteomyelitis. Cases of rhabdomyolysis also have been reported

Drug Interactions

Daptomycin may interact with other drugs that have the ability to cause myopathy, such as HMG-CoA reductase inhibitors. Another theoretical drug–drug interaction is warfarin because daptomycin may elevate INR.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for contraindications or precautions to the use of daptomycin. Be especially vigilant for a history of renal insufficiency or current medications that may induce myopathy, such as HMG-CoA reductase inhibitors. Review the culture and sensitivity report to ensure that daptomycin is recommended for the invading organism. Review the CBC, renal function tests, liver function tests, comprehensive metabolic panel, and a baseline CK. Alterations in these laboratory values should be discussed with the prescriber before starting therapy.

Life Span and Gender

Daptomycin is in FDA pregnancy category B. Caution the patient to avoid breast-feeding while taking daptomycin, because it is unclear whether the drug enters breast milk. Dosing for the elderly should be adjusted if the patient has renal insufficiency. Daptomycin is not approved for use in children.

Environment

Daptomycin is used for serious infections that have not responded to other types of medications; thus, the patient will be admitted to an acute care hospital. In rare circumstances, daptomycin may be administered in the home environment by a home health nurse.

Nursing Diagnoses and Outcomes

- Acute Pain related to myopathy
  Desired outcome: *The patient will contact the health care provider should pain or tingling in the extremities occur.*
- Imbalanced Nutrition: Less than Body Requirements, related to drug-induced GI effects, such as nausea, vomiting, diarrhea, or dyspepsia
  Desired outcome: *The patient will maintain consistent body weight and consult prescriber about persistent adverse effects that affect nutritional status.*
- Diarrhea related to drug therapy
  Desired outcome: *The patient will avoid dehydration, maintain fluid intake, and contact prescriber about persistent diarrhea.*
- Risk for Infection related to overgrowth of nonsusceptible organisms
  Desired outcome: *The patient will report signs of superinfection to the prescriber.*
- Fatigue related to metabolic and hematopoietic alterations
  Desired outcome: *The patient will immediately report signs of fatigue to the health care provider.*

Planning and Intervention

Maximizing Therapeutic Effects

Review the culture and sensitivity report to ensure that daptomycin is an appropriate drug. Before administration, visually inspect daptomycin for particulate matter and discoloration. Administer daptomycin with 0.9% sodium chloride or lactated Ringer's solution because daptomycin is not compatible with dextrose-containing solutions. Check your hospital's policy prior to administration. Daptomycin may be infused over 30 minutes without any other IV substances, additives, or other medications. Recent studies have shown that daptomycin also may be given IVP over 2 minutes without altering its pharmacokinetics or increasing its adverse effects. Before and after daptomycin infusion, flush the primary line with a compatible solution.

Minimizing Adverse Effects

Evaluate the IV site before administering daptomycin. Teach the patient the importance of reporting diarrhea, muscle pain or tingling, dark-colored urine, and fatigue immediately because these signs and symptoms signal potentially severe adverse effects.

Providing Patient and Family Education

- Explain the potential adverse effects and need for periodic blood monitoring.
- Teach patients the importance of reporting diarrhea, muscle pain or tingling, dark-colored urine, and fatigue to the prescriber immediately.
- Advise patients to stop taking HMG-CoA reductase inhibitors until advised to resume the medication by the prescriber.

Ongoing Assessment and Evaluation

Evaluate for resolution of the presenting infection. Question the patient frequently concerning the onset of musculoskeletal pain or tingling, and arrange for a weekly CK to be drawn. Notify the provider if the patient has symptoms of myopathy and the CK is five times the upper limit of normal. If the CK elevates to 10 times the normal limit, it is necessary to discontinue the drug even if the patient is asymptomatic.

MEMORY CHIP

P Daptomycin

- Used for serious aerobic gram-positive complicated skin and skin structure infections caused by *Enterococcus faecalis, Staphylococcus aureus, methicillin-resistant S. aureus, Streptococcus agalactiae, Streptococcus dysgalactiae, and Streptococcus pyogenes.*
- Major contraindication: hypersensitivity
- Most common adverse effects: nausea, vomiting, diarrhea, dyspepsia
- Most serious adverse effect: myopathy
- **Life span alert: Elderly patients may need a reduced dose of daptomycin because of renal insufficiency.**
- Maximizing therapeutic effects: Obtain culture and sensitivity report before administration.
- Minimizing adverse effects: Administer over 30 minutes. Monitor weekly CK.
- Most important patient education: Notify prescriber if diarrhea, muscle pain, or tingling occurs.

By the end of daptomycin therapy, the initial infection should be resolved. Any adverse effects should be resolved or at least should be addressed. The patient should have normal laboratory values or be receiving appropriate electrolyte or hematopoietic replacement.

MISCELLANEOUS ANTIBIOTIC: POLYMYXIN B

Polymyxin B is an older antibiotic that is completely different from the fluoroquinolones and cyclic lipopeptides. Its spectrum of activity is limited to gram-negative bacteria, with the exception of *Proteus* and *Neisseria* species. Polymyxin B binds to phospholipids in the cell membranes of gram-negative bacteria. This binding increases the permeability of the cell membrane, which results in loss of metabolites essential to bacterial existence.

Polymyxin B is administered commonly as either a topical, ophthalmic, or otic drug. It rarely is used systemically, because of its potential for causing nephrotoxicity or neurotoxicity. It frequently is used in combination with other drugs such as trimethoprim B (Polytrim) or bacitracin and neomycin (Neosporin). It also is used in combination with neomycin alone as a urinary tract irrigant.

CHAPTER SUMMARY

- Quinolone antibiotics inhibit an enzyme needed for bacterial DNA replication.
- Quinolone antibiotics, like cephalosporin antibiotics, are categorized into generations.
- First-generation quinolones are used only to treat uncomplicated UTIs.
- The second, third, and fourth generations of quinolone drugs are called fluoroquinolone antibiotics.
- All fluoroquinolones have systemic activity.
- Third-generation fluoroquinolones have extended activity against gram-positive pathogens but are less active than second-generation drugs against *Pseudomonas* species.
- Ciprofloxacin is the prototype fluoroquinolone.
- Fluoroquinolones should not be used during pregnancy, while breast-feeding, or in children because of their potential to cause arthropathies in children.
- Daptomycin, a cyclic lipopeptide, is the only member of this new class of antibiotics.
- To decrease the possibility of antibiotic resistance development, daptomycin should be reserved for infections that do not respond to other antibiotics.
- Polymyxin B is another type of miscellaneous antibiotic.

QUESTIONS FOR STUDY AND REVIEW

1. Describe the spectrum of activity of the four generations of quinolone antibiotics.
2. How do fluoroquinolone drugs, such as ciprofloxacin, inhibit bacteria?
3. In addition to hypersensitivity, which other contraindications are associated with ciprofloxacin use?
4. Why is it important that patients take ciprofloxacin on an empty stomach?
5. What are the characteristics of daptomycin that are different from other antibiotics? Why is one of its characteristics so important?
6. Why is polymyxin B rarely used in its parenteral form?

Drugs Treating Urinary Tract Infections

Learning Objectives

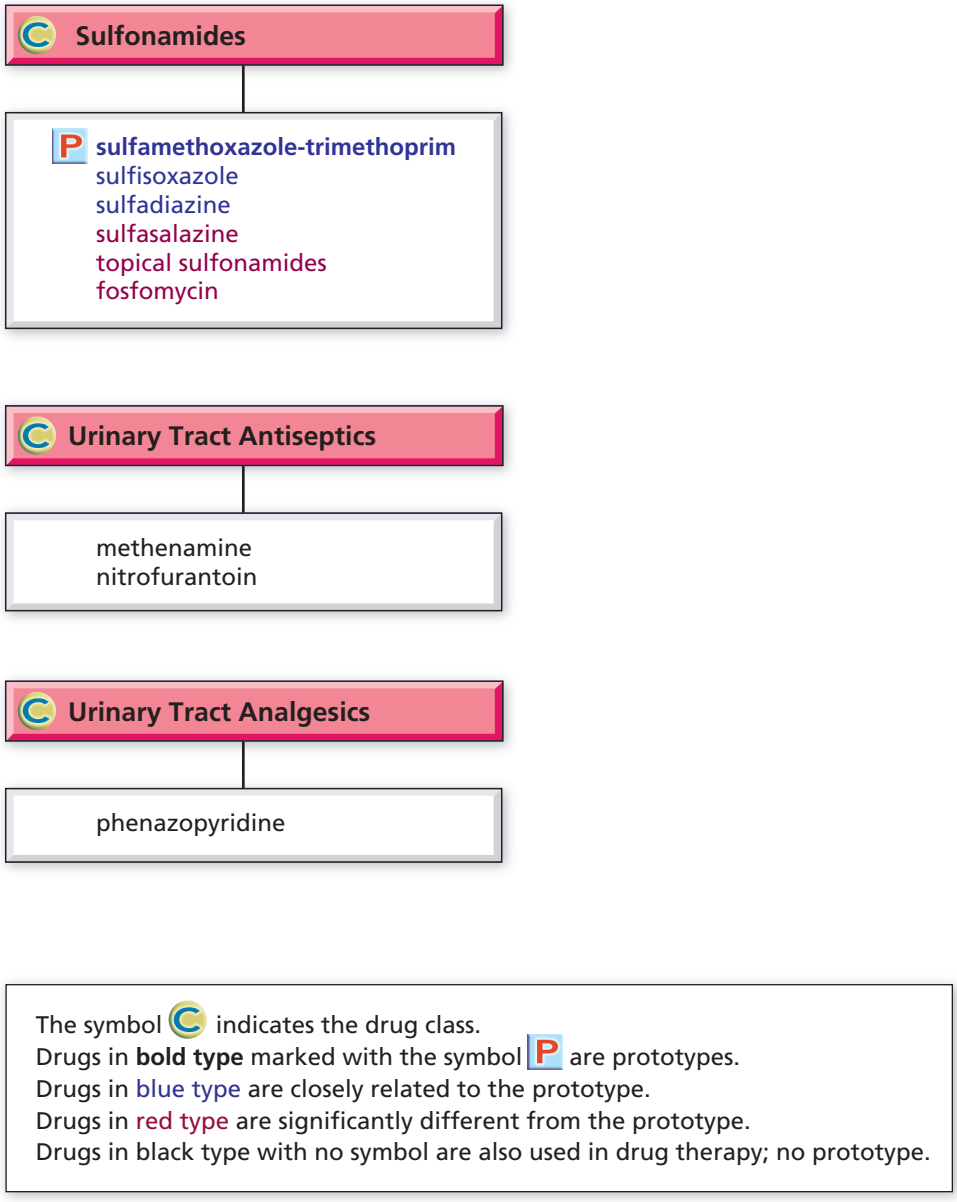
At the completion of this chapter the student will:

1. Describe the primary therapeutic uses for sulfonamides, urinary tract antiseptics, and urinary tract analgesics.
2. Identify core drug knowledge about drugs that are used for treating urinary tract infections.
3. Identify core patient variables relevant to drugs that are used for treating urinary tract infections.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that are used for treating urinary tract infections.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that are used for treating urinary tract infections.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that are used for treating urinary tract infections.
7. Determine key points for patient and family education for drugs that are used for treating urinary tract infections.

Key Terms

crystalluria
cystitis
prostatitis
pyelonephritis
recurrent infection
reinfection
relapse
sulfonamides
urethritis

Drugs Treating Urinary Tract Infections



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

A urinary tract infection (UTI) is a clinical condition caused by microorganisms infecting structures within the urinary system. It is the most common cause of infection in the United States, affecting more than 7 million people yearly. Females are more likely than males to have UTIs because of their short urethras and the potential for contamination of the vaginal vestibule with fecal flora. Men have protection from UTIs because of the length of their urethras and the antibacterial properties of prostatic fluid. However, after 50 years of age, men become more prone to UTIs because of prostatic hypertrophy, which can obstruct the urethra. Several disorders can be classified as UTIs. These conditions include cystitis, acute urethral syndrome, prostatitis, and acute pyelonephritis.

This chapter discusses drugs used to manage UTIs. They include several classes of antibiotics, especially sulfonamide antibiotics, urinary tract antiseptics, and urinary tract analgesics. The prototypical sulfonamide is sulfamethoxazole-trimethoprim (SMZ-TMP) (Bactrim, Septra).

PHYSIOLOGY

Normally, several host defenses protect a person from UTI. The urinary bladder is lined with a mucin layer that acts as a barrier against bacterial invasion. This layer also secretes protective substances that eventually become part of the mucin layer. Elderly and postmenopausal women produce less mucin and therefore are at a higher risk for UTI.

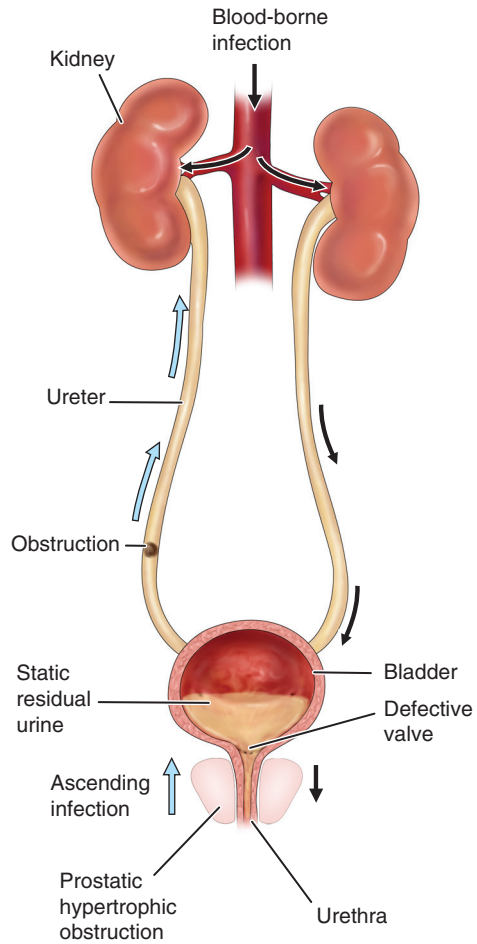
Another host defense is the washout phenomenon. The ureters assist the movement of urine out of the renal pelvis to the bladder by peristaltic movement. During micturition, bacteria are washed out of the ureters and bladder. Interruption of outflow, such as urethrovesicular reflux (in which urine from the urethra backs up into the bladder) or vesicoureteral reflux (in which urine from the bladder backs up into the ureters) can increase the risk of UTI by introducing bacteria into the renal system. Obstructed outflow results in stasis of urine, which under static conditions acts as a medium for microbial growth. Functional obstructions, such as neurogenic bladder, constipation, or infrequent voiding, can also increase the risk of UTIs.

Immune mechanisms provide another host defense. These mechanisms include immunoglobulin A, which provides an antibacterial defense, and phagocytic blood cells, which remove bacteria from the urinary tract. Alterations in the immune system increase the risk of UTIs.

PATHOPHYSIOLOGY

Urinary tract infections are generally classified as complicated or uncomplicated. An uncomplicated UTI is a bacterial infection, whereas a complicated UTI, also caused by bacteria, is associated with some anatomical or structural abnormality. UTIs are also divided into upper and lower UTIs. Upper UTIs are commonly associated with symptoms such as fever, nausea and vomiting, and flank or back pain. Lower UTIs are associated with symptoms such as dysuria (painful urination), hematuria (blood in urine), urgency, and frequency. It is important to use these distinctions only as general guidelines because studies have indicated that a patient may have an upper UTI while exhibiting only lower tract symptoms (Figure 42.1).

UTIs can be acute, **recurrent,** or chronic. Acute UTI is also known as the "initial infection." Recurrent UTIs are those caused by **relapse** or **reinfection.** A relapse is caused by the same organism that caused the initial infection and usually occurs within 2 weeks of the initial infection. A reinfection is caused by a new organism. Chronic UTIs are those that need prophylactic pharmacotherapy because of the frequency of infection.



• FIGURE 42.1 Urinary tract infections (UTIs) result from various causes: blood-borne infections that cycle through the renal system; ascending infection from external or other sources; stagnant urine (urinary stasis) caused by immobility or obstructions, which allows microorganisms to colonize; defective valves that may allow infected urine to flow backward; and other problems.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria is diagnosed when the patient has no symptoms but the urinalysis shows significant numbers of bacteria. The condition is usually harmless but can increase the risk for symptomatic UTI. Asymptomatic bacteriuria is common during pregnancy. It is important to identify in pregnant women because it increases the risk for pyelonephritis during the second and third trimesters. Additionally, untreated UTI is associated with an increased risk for miscarriage.

Cystitis

Cystitis is an infection of the lower urinary tract caused by introduction of a pathogen into the bladder. This infection results in redness, inflammation, irritation, and edema of the bladder mucosa, with multiple submucosal hemorrhages and sometimes pus. Symptoms may include urgency, frequency, incontinence, dysuria, hematuria, burning or a feeling of warmth on urination, bladder cramps or spasms, perineal itching, suprapubic discomfort, mild backache, or a low-grade fever. Nosocomial bladder infections, which are infections acquired in the hospital, are frequently caused by instrumentation and urinary catheterization. They are more difficult to treat because the bacteria that cause them are often resistant to drug treatment and patients are often in poor health. More commonly, bladder infections occur in the community. Factors that increase the risk of community-acquired UTIs include pregnancy, diaphragm with spermicide use, sexual intercourse, and delayed postcoital micturition. Complications include chronic cystitis, acute pyelonephritis, or urosepsis, especially in the elderly (Box 42.1).

Urethritis

Urethritis is a term that is generally associated with a syndrome of sexually transmitted infections (STIs) and is most commonly divided into nongonococcal urethritis (NGU) and gonococcal urethritis. NGU is characterized by redness, irritation, and edema of the urethral mucosa. Common pathogens causing NGU include *Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Mycoplasma genitalium,* or *Trichomonas vaginalis*. In women, urethritis may also be associated with irritation by chemicals in feminine deodorants, suppositories, bubble baths, and spermicidal gels. In postmenopausal women, NGU is commonly caused by tissue changes related to low estrogen levels. Gonococcal urethritis has symptoms similar to NGU with the addition of a discharge that may be yellow, green, brown, or tinged with blood, and production is unrelated to sexual activity. Many patients, including approximately 25% of those with NGU, are asymptomatic and present only after partner screening.

Complications of urethritis include chronic urethritis, cystitis, periurethral abscess, urethral stricture or fistula, pyelonephritis, and in men, prostatitis or epididymitis.

In cases of either type of urethritis, the nurse explains the importance of partner notification. If the partner is not simultaneously treated, the infection will recur in the patient.

Prostatitis

Prostatitis is usually associated with urethritis or cystitis. Organisms can infect the prostate gland through the bloodstream or by ascending from the urethra. Symptoms include fever, chills, dysuria, urethral discharge, and a boggy, tender prostate. Diagnosis may be made by massaging the prostate, which results in a urethral discharge of prostatic secretions full of white blood cells. Complications include chronic prostatitis, epididymitis, and pyelonephritis.

Acute Pyelonephritis

Acute pyelonephritis is an infection of the kidneys and renal pelvis. Infection can occur by way of the bloodstream or ascending organisms from the bladder. Approximately 80% of cases of pyelonephritis are caused by a uropathogenic strain of *Escherichia coli* that has specific fimbriae that attach to the epithelial cells of the kidney. When microorganisms invade the kidney, an inflammatory process is initiated, resulting in local edema. As the edema subsides with treatment, fibrosis and scar tissue develop. This scarring may lead to impaired tubular reabsorption and diminished renal function.

Predisposing factors are UTI, urinary tract instrumentation, catheterization, pregnancy, vesicoureteral reflux, and neurogenic bladder. Symptoms include acute onset of chills and fever, flank pain, hematuria, general malaise or fatigue, headache, and costovertebral angle tenderness. Complications of pyelonephritis include chronic pyelonephritis, scarring of the kidneys, and permanent kidney damage.

DIAGNOSIS OF UTI

Diagnosis of UTI is frequently based on the patient's subjective description of symptoms and a positive urine dipstick test. The dipstick test is recommended for nonpregnant women at low risk for recurrent infection and without symptoms suggesting other problems, such as vaginitis. The dipstick is placed in a fresh specimen of urine and examined for a positive reaction to nitrates, leukocytes, and blood. This test is difficult to read if the patient has been taking an over-the-counter urinary analgesic because it will discolor the urine bright orange.

A urinalysis (UA) is required for women who are pregnant or over the age of 55, men with urinary symptoms, and patients with recurrent symptoms. A successful UA requires a midstream or clean-catch urine specimen. When obtaining urine for a UA from a catheterized patient, the urine must be withdrawn from the proximal port on the catheter tubing and not from the urine collection bag.

When the specimen is obtained from a noncatheterized patient, the nurse instructs the patient to:

- Wash his/her hands thoroughly before starting the procedure
- Cleanse the penis or vulva and surrounding area three times, using a new sponge each time, with a front to back motion.
- Urinate into the toilet, then place the sterile container to capture the mid portion of the stream
- Complete urination into the toilet after the specimen is obtained
- Secure the container lid without touching the inside of the container

A urine culture and sensitivity test are usually performed on the clean-catch urine specimen to identify the organism for appropriate antimicrobial therapy (see Chapter 38).

SULFONAMIDES

Sulfonamides have been the mainstay of treatment for UTIs for many years. Unfortunately, the incidence of sulfonamide-resistant bacteria has steadily increased. Sulfonamides have similar structures, functions, and therapeutic indications. These drugs are categorized as short acting, intermediate acting, topical, and long acting, although the long-acting sulfonamides are not available for use in the United States because of their ability to cause Stevens-Johnson syndrome. Sulfamethoxazole (SMZ) is an intermediate-acting sulfonamide that is only available in the United States in combination with the drug trimethoprim (TMP). The prototype sulfonamide, SMZ-TMP, is a combination of these two drugs. Table 42.1 provides a summary of sulfonamides and other selected drugs that are used to treat UTIs.

Nursing Management of the Patient Receiving P Sulfamethoxazole-Trimethoprim

Core Drug Knowledge

Pharmacotherapeutics

SMZ-TMP (Cotrimoxazole, Bactrim DS, Septra DS) has a broad range of therapeutic uses. It is indicated for uncomplicated UTIs and systemic infections caused by susceptible organisms. SMZ-TMP is frequently used for respiratory infections caused by *Haemophilus influenzae* or *Streptococcus pneumoniae*. It is an alternative treatment for *Legionella pneumophila* pneumonia. Gastrointestinal (GI) infections treated with SMZ-TMP include shigellosis and salmonella infection. SMZ-TMP concentrates in prostate and vaginal fluids and thus is an effective treatment for infections at these sites. SMZ-TMP is also effective treatment for sexually transmitted diseases, such as acute gonococcal urethritis and oropharyngeal gonorrhea. In some circumstances, SMZ-TMP may be used for skin and skin structure community-acquired MRSA.

For patients with HIV, SMZ-TMP is used for prophylaxis and treatment of *Pneumocystis jiroveci* pneumonia (formerly known as *P. carinii*) and toxoplasma encephalitis.

Pharmacokinetics

SMZ-TMP is completely absorbed following oral administration. It is metabolized in the liver to inactive by-products and excreted primarily in the urine. Peak plasma levels generally occur within 4 hours. After intravenous (IV) administration of SMZ-TMP, peak plasma levels occur in approximately 1 hour; the half-life is age dependent. SMZ-TMP is well distributed throughout the body, crosses the blood–brain barrier and the placenta, and is excreted in breast milk.

Pharmacodynamics

SMZ-TMP inhibits microorganisms by interfering with the synthesis of tetrahydrofolic acid (THF). Reduced availability of THF inhibits thymidine synthesis and subsequently DNA synthesis. SMZ, which is structurally similar to para-aminobenzoic acid (PABA), displaces PABA and blocks the synthesis of dihydrofolic acid, which is an interim step in the production of tetrahydrofolic acid.TMP binds to bacterial dihydrofolate reductase (in preference to human dihydrofolate reductase), also preventing the formation of THF. Although TMP and SMX are weak bactericidal agents when given alone, the combination is highly bactericidal. The presence of necrotic tissue, pus, or serum interferes with the action of SMZ-TMP because these materials contain PABA.

Contraindications and Precautions

SMZ-TMP is contraindicated in patients with hypersensitivity to sulfonamides, deficiency of glucose-6-phosphate dehydrogenase (G6PD) or other folate deficiency disorders, porphyria (porphobilinogen in urine), and urinary obstruction. Patients with G6PD deficiency may develop dose-related hemolytic anemia. SMZ-TMP is used cautiously in patients with hepatic or renal failure. Patients with hypersensitivity to thiazide diuretics or sulfonylureas may have cross-sensitivity to sulfonamides because of the related sulfa structures of these drugs.

Use in pregnant women at term, in children younger than 2 months (except for treating congenital toxoplasmosis), and in mothers nursing infants younger than 2 months is also contraindicated because sulfonamides may promote kernicterus (staining of certain areas of the brain by bilirubin) in the newborn by displacing bilirubin from plasma proteins.

Adverse Effects

SMZ-TMP is well tolerated in routine use. However, in patients with HIV, the adverse effect rate is 25% to 50%, with many of the reactions being severe. Although nausea, vomiting, and diarrhea occur most frequently with SMZ-TMP, there are three classic potential adverse reactions to this drug: hematologic effects (such as anemia), allergic reactions, and crystalluria.

Hematologic effects are related to the direct action of SMZ-TMP on bone marrow. SMZ-TMP can induce megaloblastic anemia in patients with folate deficiency. Other blood

TABLE 42.1 Summary of Selected Drugs to Treat Urinary Tract Infections

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Sulfonamides			
P sulfamethoxazole-trimethoprim (SMZ-TMP; Bactrim) single strength (SS): 80 mg TMP/400 mg SMZ; double strength (DS): 160 mg TMP/800 mg SMZ; pediatric suspension: 40 mg TMP/200 mg SMZ per tsp (5 mL)	UTIs, otitis media, acute bronchitis, skin or soft tissue infections	*Adult:* 1 DS or 2 SS or 4 tsp suspension q 12 h for 10–14 d *Alternate:* 6 tablets at one time *Child >2 mo:* Up to 10 kg: 1 tsp; 11–20 kg: 2 tsp or 1 SS tab; 21–30 kg: 3 tsp or 1.5 SS tab; 31–40 kg: 4 tsp or 2 SS tab or 1 DS tab for 10–14 d	*Onset:* Varies *Duration:* 6–12 h $t_{1/2}$: 8–12 h
	Diarrhea or shigella	Same dose as above but stop after 5 days	
	PCP	*Adult and child:* 15–20 mg/kg TMP and 75–100 mg/kg SMZ in 24 h in divided doses every 6 h for 14–21 d	
	PCP prophylaxis	*Adult:* 1 DS every day *Child:* 150 mg/m^2/d TMP with 750 mg/m^2/d SMZ in equally divided doses 2 ×/d on 3 consecutive days per week	
sulfadiazine	Chancroid, trachoma, inclusion conjunctivitis, nocardiosis	*Adult*: PO, initially 2–4 g, followed by 2–4 g, divided into 3–6 doses, every 24 h *Child >2 mo*: PO, initially 1/2 the 24-h dose of 150 mg/kg or 4 g/m^2, divided into 4–6 doses, every 24 h, with a maximum of 6 g every 24 h.	*Onset*: Varies *Duration*: Unknown $t_{1/2}$: Unknown
Sulfisoxazole/erythromycin (Eryzole, Pediazole)	Otitis media	*Adult*: PO, 400 mg erythromycin/1,200 mg sulfisoxazole (10 mL) every 6 h *Child >2 mo*: PO, 50 mg/kg/d (erythromycin component) and 150 mg/kg/d (sulfisoxazole component) in 3 or 4 divided doses for 10 d	*Onset*: Varies *Duration*: Unknown $t_{1/2}$: 4.5–7.8 h
sulfasalazine (Azulfidine)	Ulcerative colitis	*Adult*: PO 3–4 g/d in evenly divided doses not exceeding 8-hour intervals; maintenance, 2 g/d in divided doses not exceeding 8-h intervals; *Child >6 y*: PO, 40–60 mg/kg/d divided in 3–6 doses; maintenance 30 mg/kg/d divided in 4 doses up to a maximum of 2 g/d	*Onset*: 1 h *Duration*: 6–12 h $t_{1/2}$: 5–10 h
	Rheumatoid arthritis	*Adult PO*: 0.5–1 g/d once daily or in divided doses twice daily; maintenance, 1 g twice daily up to a maximum of 3 g/d *Child >6 y*: PO, 30–50 mg/kg/d in 2 evenly divided doses up to a maximum of 2 g/d	
	Crohn's disease	*Adult*: PO, 3–6 g/d in divided doses	
fosfomycin (Monurol)	UTIs	*Adult*: PO, 3 g, one time only *Child <18 y*: not recommended	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 5.7 h
Urinary Tract Antiseptics			
methenamine (Hiprex, Urex)	UTIs	*Adult*: PO, 1 g >qid *Child 6–12 y*: PO, 500 mg qid; <6 y: PO, 50 mg/kg in 3 divided doses	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 3–6 h
nitrofurantoin (Furadantin, Macrodantin, Macrobid)	UTIs	*Adult*: 50–100 mg qid 10–14 d; suppressive history: 50–100 mg PO hs *Child >1 mo*: 5–7 mg/kg/d in 4 divided doses; suppressive history: 1 mg/kg/d	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 20–60 min
Urinary Tract Analgesic			
phenazopyridine (Pyridium)	UTIs	*Adult*: PO, 200 mg tid after meals *Child 6–12 y*: 12 mg/kg/d in three divided doses	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: Unknown

dyscrasias, such as hemolytic anemia, agranulocytosis, leukopenia, thrombocytopenia, and aplastic anemia, may occur. Patients at high risk for folate deficiency are elderly adults, patients with long-term alcoholism, patients with malabsorption disorders, and patients with malnutrition.

Allergic reactions are common. SMZ-TMP is associated with several cutaneous reactions, including urticaria, maculopapular rashes, pruritus, contact dermatitis, and erythema nodosum. More severe reactions, such as Stevens-Johnson syndrome and exfoliative dermatitis, have been reported. Photosensitivity reactions may also occur and can continue for months after discontinuing the drug. Immunocompromised patients have a higher risk for photosensitive cutaneous eruptions. The mechanism for this increase in cutaneous eruptions is not clear.

Although the newer sulfonamides are much more soluble than older formulations, sulfonamides in general have poor solubility in water. If the urine volume and pH value drop, these drugs may crystallize in the renal tubules. This condition, called **crystalluria,** results in severe renal damage. To avoid crystalluria, patients should be instructed to maintain hydration by drinking at least 1.5 L of water every day.

Other potential adverse reactions may involve the central nervous system (CNS). Effects such as drowsiness, dizziness, and ataxia may occur. Additionally, depression and psychosis have been reported, although these effects are rare.

Drug Interactions

Certain sulfonamides are highly bound to serum proteins. When given in combination with other drugs that are also protein bound, sulfonamides may displace those drugs from their binding sites and enhance their action. This interaction occurs most frequently with drugs such as oral hypoglycemics, phenytoin, oral anticoagulants, and the antineoplastic drug methotrexate. The action of sulfonamides may be diminished when administered with local anesthetics, such as procaine, that are derived from PABA. Table 42.2 lists drugs that interact with SMZ-TMP.

Foods that can acidify the urine (such as cranberry juice) should be avoided. When the urine pH falls, the sulfonamides may precipitate and cause crystalluria.

Assessment of Relevant Core Patient Variables

Health Status

Carefully assess for potential hypersensitivity to sulfonamides and other contraindications for drug therapy. Cross-sensitivity may also occur with chemically related drugs, such as the thiazide or loop diuretics and the oral sulfonylureas. SMZ-TMP should not be administered to patients with hepatic or renal dysfunction, porphyria, blood dyscrasias, or G6PD deficiency. Closely monitor patients with folate deficiency or with increased risk for folate deficiency.

When therapy is anticipated to last more than 2 weeks, complete blood counts (CBCs) should be performed to establish a baseline value before starting therapy.

Life Span and Gender

Evaluate the patient's pregnancy or breast-feeding status. To avoid inducing kernicterus, do not administer SMZ-TMP and the other sulfonamides to pregnant or lactating women. Do not give these drugs to infants younger than 2 months. Monitor elderly patients taking warfarin closely. Studies have indicated they have an increased risk for upper GI bleeding when on SMZ-TMP therapy.

TABLE 42.2 Agents That Interact With P Sulfamethoxazole-Trimethoprim (SMZ-TMP)

Interactants	Effect and Significance	Nursing Management
Anticoagulants	Sulfonamides inhibit the hepatic metabolism of oral anticoagulants, resulting in an increased risk for hemorrhage.	Monitor PT and INR closely. Monitor for signs of bleeding. Consult with prescriber about adjusting dose as needed.
cyclosporine	Although the mechanism is unknown, sulfonamides may increase the risk of nephrotoxicity associated with cyclosporine.	Monitor cyclosporine levels. Monitor serum creatinine frequently. Monitor I/O. Avoid coadministration if possible.
dofetilide	TMP inhibits the renal cation transport system responsible for dofetilide elimination.	Avoid coadministration if possible. Monitor for cardiac arrhythmias.
Hydantoins	Sulfonamides inhibit the hepatic metabolism of hydantoins, resulting in an increased risk for toxicity.	Monitor hydantoin levels. Monitor for speech, cognitive, or motor changes. Consult with prescriber about adjusting dose as needed.
methotrexate	Sulfonamides may displace methotrexate from protein binding sites and decrease renal clearance of drug. This results in an increased risk for methotrexate-induced bone marrow suppression.	Monitor closely for signs of hematologic toxicity. Monitor CBC. Consult with prescriber about adjusting dose as needed.
Oral Hypoglycemics	Trimethoprim may inhibit the metabolism of oral hypoglycemics, resulting in hypoglycemia.	Monitor blood glucose frequently. Monitor for signs of hypoglycemia.

Lifestyle, Diet, and Habits

Ask the patient about dietary intake of foods and fluids that acidify the urine, because many drugs are affected by urine's pH, and acidic urine increases the risk for crystalluria. Determine whether the patient has a condition that contraindicates an increased fluid intake, because increasing fluids decreases the potential for crystalluria. Assess the patient for alcohol use or abuse. Advise the patient to refrain from alcohol while taking SMZ-TMP, because it may cause a disulfiram-like reaction.

Environment

Evaluate the amount of time the patient spends outdoors because photosensitivity may occur. The patient should avoid direct sunlight; if going outdoors is unavoidable, encourage the patient to wear sunscreen with a minimum skin protective factor of 15 and appropriate clothing.

Nursing Diagnoses and Outcomes

- Pain related to altered comfort level (nausea, vomiting, diarrhea, dizziness, or headache) from adverse effects of SMZ-TMP

  Desired outcome: *The patient will develop strategies to cope with pain and take the drug as directed for the full course of therapy.*
- Risk for Injury related to drug-induced hypersensitivity reactions, liver or kidney dysfunction, or blood dyscrasias

  Desired outcome: *By the end of therapy, the patient will be free from avoidable drug therapy–related injuries and infection.*
- Risk for Impaired Tissue Integrity related to drug-induced photosensitivity

  Desired outcome: *The patient will take measures to protect his or her skin from prolonged sun exposure.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer SMZ-TMP 1 hour before or 2 hours after a meal with a full glass of water to enhance the absorption of the drug. Patients who experience adverse GI effects may take the drug with food.

Minimizing Adverse Effects

Administer SMZ-TMP with a full glass of water. Unless contraindicated, the patient's fluid intake should increase by 1.5 L/day. Increasing fluid intake decreases the potential for crystalluria and decreases the ability of bacteria to multiply because the urine is diluted. Encourage the patient to take precautions before exposure to the sun. When administering SMZ-TMP by the IV route, infuse the drug slowly, over 60 to 90 minutes. After completing the infusion, flush all lines to remove any residual SMZ-TMP.

Providing Patient and Family Education

- Teach patients the optimal way to take SMZ-TMP, advising them to take it 1 hour before or 2 hours after a meal. However, if the patients become nauseated, vomit, or cannot eat, the drug may be taken with meals to minimize discomfort.
- Teach interventions to decrease the risk for adverse effects. Patients should avoid foods that may acidify the urine and drink at least 1.5 L of water a day. They should also wear sunscreen and protective clothing when outside. These interventions decrease the risk of crystalluria and photosensitivity reactions, respectively.
- Explain the potential adverse effects of SMZ-TMP and advise patients to contact the prescriber immediately if a skin rash, fever, sore throat, blood in the urine, easy bruising, or nose bleeds develop.
- Advise patients to refrain from alcohol while taking SMZ-TMP.

Ongoing Assessment and Evaluation

Monitor patients for signs of hematologic dysfunction, such as sore throat, fever, bruising, or bleeding. Also, carefully monitor fluid intake and output of hospitalized patients. Optimally, patients should maintain an output of 1,500 mL daily. Monitor urine pH as well. Urine pH below 5.5 may potentiate crystalluria. Patients with acidic urine may need sodium bicarbonate to neutralize the urine. With prolonged therapy, monitor hematologic function and kidney function. Perform periodic urine testing to check for crystals. For patients receiving parenteral SMZ-TMP, monitor the IV site for signs of phlebitis.

Drug Closely Related to P Sulfamethoxazole-Trimethoprim

Of the short-acting sulfonamides, sulfisoxazole (Eryzole, Pediazole) is the most frequently used. Sulfisoxazole is highly water soluble, which minimizes the risk for crystalluria. It is also approved for management of otitis media.

Sulfadiazine, another oral short-acting sulfonamide, is a Food and Drug Administration (FDA)-indicated treatment and prophylaxis for AIDS and toxoplasmosis, as well as meningitis. A non-FDA indication for sulfadiazine is rheumatic fever. The drug is also used as adjunctive therapy in the management of malaria and toxoplasmosis encephalitis. Sulfadiazine is less soluble than sulfamethoxazole; thus, there is an increased risk of crystalluria.

CRITICAL THINKING SCENARIO

TEACHING STRATEGIES FOR SULFAMETHOXAZOLE-TRIMETHOPRIM (SMZ-TMP) THERAPY

Melissa Hawthorne, a 25-year-old graduate student, comes to the campus health clinic with a complaint of dysuria and urinary frequency and urgency. She is diagnosed with a UTI and given a prescription for SMZ-TMP.

1. Prepare some instructions related to drug therapy for Melissa, explaining the rationale for the instructions.
2. How would you vary the instructions if Melissa were 78 years of age or had a history of chronic heart failure?

MEMORY CHIP

Sulfamethoxazole-Trimethoprim (SMZ-TMP)

- Used for UTI, prophylaxis and treatment of *Pneumocystis jiroveci* pneumonia, and infection by *Legionella, Shigella,* or *Salmonella* species; *Haemophilus influenzae;* or *Streptococcus pneumoniae*
- Major contraindications: hypersensitivity, deficiencies in G6PD or other folates, porphyria, urinary obstruction, term pregnancy just ready to deliver, and age less than 2 months old
- Most common adverse effects: nausea, vomiting, diarrhea
- Most serious adverse effects: hematopoietic effects, crystalluria, Stevens-Johnson syndrome
- **Life span alert: to avoid inducing kernicterus, this drug should not be given to pregnant or breast-feeding women or to infants younger than 2 months old.**
- Maximizing therapeutic effects: Administer 1 hour before or 2 hours after a meal.
- Minimizing adverse effects: Increase fluids by 1.5 L/d to avoid crystalluria.
- Most important patient education: Teach the patient strategies to avoid disulfiram-like reactions, photosensitivity, and crystalluria.

Drugs Significantly Different From P Sulfamethoxazole-Trimethoprim

Other Sulfonamides

Sulfasalazine

Sulfasalazine (Azulfidine), another short-acting sulfonamide, is given as an enteric-coated tablet for treating ulcerative colitis. Within the colon, sulfasalazine splits into its components aminosalicylic acid and sulfapyridine, which are the active antimicrobial metabolites. Its action begins in the bowel lumen instead of systemically. Its potential adverse effects and adverse reactions are similar to those of other sulfonamides.

Topical Sulfonamides

Mafenide (Sulfamylon) and silver sulfadiazine (Silvadene, SSD, Thermazene) are used topically to prevent bacterial or fungal infection in burn patients. Both drugs may be used in children who are at least 2 months of age. When applied, mafenide may cause pain or a burning feeling, whereas silver sulfadiazine does not. When topically applied, both drugs are absorbed in amounts that cause systemic effects.

It is important to use topical sulfonamides appropriately. Before applying them, cleanse the wound completely and remove dead or burned skin and other debris. Take care to remove all of the left-over medication when cleansing the wound. Wear sterile gloves to apply a thin layer (about 1/16 inch) to the wound. After application, leave the wound covered or uncovered, as ordered by the health care provider.

Drugs That Belong to Other Antibiotic Classes

Several other classes of antibiotics can also be used to manage UTIs.

Aminoglycoside drugs such as gentamicin, tobramycin, and amikacin are used for infections that originated in the urinary tract but have become systemic. This kind of infection is known as urosepsis. These drugs are all administered intravenously.

Cephalosporins may be given orally or parenterally. Oral drugs include cephalexin, cephradine, and cefadroxil. Ceftazidime and ceftriaxone may be given orally or parenterally. Although these drugs are effective, they offer no clear advantage over less expensive drugs.

The fluoroquinolones ciprofloxacin, norfloxacin, and ofloxacin are very effective for managing UTIs. Fluoroquinolones have a broad spectrum of activity that affects most microbes that cause UTIs. Many prescribers use these drugs as first-line agents, despite their expense, because of the increasing resistance to SMZ-TMP. Other prescribers use these drugs after treatment failure with SMZ-TMP.

The penicillin drugs ampicillin, amoxicillin, and amoxicillin-clavulanate may also be administered. Ampicillin may be given orally or parenterally. Other parenteral penicillin drugs include ticarcillin, mezlocillin, and piperacillin. Penicillins are useful against most microbes that cause UTI; however, some penicillin resistance has been reported among *Escherichia coli* isolates.

Tetracycline drugs are most useful in managing UTIs caused by *Chlamydia* species, but incidence of resistance is high among other causative microbes.Both tetracycline and doxycycline are effective against sensitive organisms.

BOX 42.1 FOCUS ON RESEARCH

UTI in Women

Juthani-Mehta, M., Quagliarello, V., Perrelli, E., et al. (2009). Clinical features to identify urinary tract infection in nursing home residents: a cohort study. *Journal of the American Geriatrics Society,* 57(6):963–970.

The Study

The objective of the study was to identify clinical features associated with bacteriuria plus pyuria in non-catheterized nursing home residents with clinically suspected urinary tract infection (UTI).

The researchers developed a prospective, observational cohort study utilizing 5 nursing homes in New Haven, Connecticut between the years 2005 to 2007. The study had 228 participants with 399 episodes of clinically suspected UTI with a urinalysis and urine culture performed; 36.8% of participants were found to have bacteriuria plus pyuria. The clinical features associated with bacteriuria plus pyuria were dysuria, change in character of urine, and change in mental status.

Conclusions

Dysuria, change in character of urine, and change in mental status were significantly associated with the combined outcome of bacteriuria plus pyuria. Absence of these clinical features identified residents at low risk of having bacteriuria plus pyuria, whereas presence of dysuria plus one or both of the other clinical features identified residents at high risk of having bacteriuria plus pyuria.

Nursing Implications

Elderly patients are more likely to be admitted to an acute care facility. They also have physical changes related to aging that increase the risk for UTI. The nurse should frequently assess elderly patients for dysuria, change in character of urine, and change in mental status because these symptoms are highly associated with UTI. Early identification of infection decreases the risk for complications of UTI such as urosepsis.

Fosfomycin

Fosfomycin (Monurol) is classified as a miscellaneous antibiotic. It works by inhibiting an enzyme, pyruvoyl transferase, which is critical in the synthesis of bacterial cell walls. Fosfomycin is active against most urinary tract pathogens and has a prolonged post-antibiotic effect of 3.4 to 4.7 hours. The drug is distributed to the kidneys, bladder wall, prostate, and seminal vesicles. Fosfomycin has been shown to cross the placenta; however, whether it enters breast milk is unknown. It is not metabolized, and excretion occurs through both urine and feces.

Fosfomycin is administered orally for acute UTI as a one-time dose, without regard to meals. Advise the patient to place the entire contents of a sachet containing the equivalent of 3 g of fosfomycin into 3 to 4 oz (1/2 cup) of water, then stir to dissolve it. It is best not to use hot water. The patient should take the medication immediately after dissolving the powder.

Fosfomycin is in FDA pregnancy category B. It is not recommended for children younger than 12 years.

The most frequent adverse effects with fosfomycin therapy are asthenia, diarrhea, dizziness, dyspepsia, headache, nausea and vomiting, rash, and vaginitis. Although rare, serious adverse effects such as angioedema, aplastic anemia, asthma exacerbation, cholestatic jaundice, hepatic necrosis, and toxic megacolon have been reported.

URINARY TRACT ANTISEPTICS

Urinary tract antiseptics are drugs that work by local action because high serum levels are not achievable. Because of their local action, few systemic effects occur. No true prototype exists; thus, each drug is discussed separately here.

Methenamine

Methenamine (Hiprex, Urex) is indicated for suppressing or eliminating bacteriuria (bacteria in urine) associated with chronic cystitis and other chronic UTIs. It is effective against both gram-positive and gram-negative organisms. In fact, the only resistance to methenamine comes from organisms such as *Proteus vulgaris* and *Pseudomonas aeruginosa,* which raise urine pH.

In acidic urine, methenamine is hydrolyzed to ammonia and formaldehyde in the bladder. Because methenamine must be hydrolyzed into its components to be effective, it does not work for upper UTIs because the time through the upper urinary tract is insufficient for this action to occur. Additionally, patients with indwelling catheters have a constant outflow of urine, again negating the time needed for hydrolysis occur. Therefore, methenamine is not useful in patients with upper UTIs and indwelling catheters.

Methenamine is contraindicated in patients with hepatic dysfunction because ammonia is also a product of its hydrolysis. Patients with hepatic dysfunction cannot eliminate ammonia, and the high ammonia levels that result can adversely affect the CNS. Methenamine should not be given concurrently with sulfonamides because the combination forms an insoluble precipitate in acidic urine.

Adverse reactions are minimal. The most common are nausea, vomiting, and anorexia. Methenamine may also cause bladder irritation, dysuria, hematuria, and crystalluria when administered as long-term prophylaxis.

Nitrofurantoin

Nitrofurantoin (Furadantin, Macrodantin, Macrobid) is another synthetic urinary tract antiseptic. It works by interfering with several bacterial enzyme systems, which may explain the lack of bacterial resistance to it. Although nitrofurantoin has a broad spectrum of activity, it is not an effective systemic drug because it is rapidly excreted by the kidneys and thus does not achieve high blood levels. It is highly effective against gram-negative and gram-positive organisms in the urinary system because high concentrations are found in urine. Resistant microbes include *Enterobacter, Klebsiella, Proteus,* and *Pseudomonas* species.

Nitrofurantoin is available in two pill formulations: microcrystalline nitrofurantoin (Furadantin) and macrocrystalline nitrofurantoin (Macrodantin, Macrobid). Although both types of nitrofurantoin have equal therapeutic efficacy, macrocrystalline nitrofurantoin is absorbed more slowly and induces less GI distress.

Nitrofurantoin is contraindicated in patients with renal impairment, in infants younger than 1 month because of the possibility of hemolytic anemia, and in pregnant women at term. As previously mentioned, nitrofurantoin achieves high concentrations in urine but low concentrations in blood. In the presence of kidney dysfunction, its concentration in urine decreases and concentration in blood increases. This effect decreases the efficacy of treatment and increases the risk of toxic adverse effects. Nitrofurantoin should be used with caution in the elderly (because of their decreased renal function) and in patients with G6PD deficiency, anemia, vitamin B deficiency, diabetes mellitus, or electrolyte abnormalities. It is a pregnancy category B drug.

The most common adverse reactions are anorexia, nausea, and vomiting. Other adverse reactions include abdominal pain, diarrhea, parotitis, and pancreatitis. Hepatic reactions, including hepatitis, have occurred. Nitrofurantoin may induce an asthma attack in patients with a history of asthma. As with other urinary tract antiseptics, nitrofurantoin may cause hematopoietic effects, especially in patients with folate deficiency.

Nitrofurantoin has potentially serious adverse reactions. Peripheral neuropathy is one of the most serious toxic effects; however, it is reversible if detected early. Permanent damage may result if the drug is not discontinued. Peripheral neuropathy may be enhanced in debilitating diseases, such as diabetes mellitus, anemia, and vitamin B deficiency.

Nitrofurantoin is also associated with acute and chronic pulmonary reactions. Acute reactions are manifested by sudden onset of fever, cough, chills, myalgias, and dyspnea. As with other drugs, the effects are reversible if the drug is discontinued. Subacute pulmonary reactions develop over time with many of the same symptoms; however, diffuse interstitial pulmonary fibrosis may be irreversible. Subacute pulmonary reactions occur most frequently in patients on therapy longer than 6 months.

URINARY TRACT ANALGESIC

Phenazopyridine (Pyridium) is used frequently for UTIs but does not itself have any antibacterial activity. It is excreted in the urine, where it exerts a topical analgesic effect. It is indicated for the symptomatic relief of pain, burning, frequency, and urgency caused by the irritation that infection produces in the urinary tract mucosa. The precise mechanism of action is not known. Phenazopyridine is contraindicated for patients with known hypersensitivity or renal insufficiency. Adverse reactions include headache, rash, pruritus, and GI disturbances. Phenazopyridine is an azo dye, which colors the patient's urine orange or red. It is important to inform the patient to expect this change in urine color.

Phenazopyridine is available as an over-the-counter (OTC) medication (AZO Urinary Pain Relief). It is important to teach patients that they must contact their provider for urinary pain even if the pain is relieved by the OTC product because an untreated UTI may become a more serious problem such as pyelonephritis. Chronic use of phenazopyridine may cause a cumulative toxicity, resulting in hemolytic anemia, thrombocytopenia, acute renal failure, hepatitis, and skin pigmentation.

CHAPTER SUMMARY

- A urinary tract infection (UTI) is caused by microorganisms infecting any structure within the urinary system.
- UTI is the most frequent type of infection in the United States.
- Sulfamethoxazole-trimethoprim (SMZ-TMP) is the prototype sulfonamide, which is the drug class most commonly used to treat UTI.
- Many other drug classes may be used to treat UTI. These include aminoglycosides, cephalosporins, fluoroquinolones, penicillins, tetracyclines, and fosfomycin.
- Urinary tract antiseptics work directly in the urinary tract and have minimal systemic activity. These drugs include methenamine, nitrofurantoin, nalidixic acid, and cinoxacin.
- Phenazopyridine has no antimicrobial effects. It is used as a urinary analgesic in combination with antimicrobial drugs.

QUESTIONS FOR STUDY AND REVIEW

1. In addition to UTI, which other diseases or disorders are treated with SMZ-TMP?
2. Why are sulfonamides ineffective against organisms that do not synthesize their own folate?
3. What is the difference between antibiotics used to manage UTI and urinary tract antiseptics?
4. What is the purpose of prescribing phenazopyridine (Pyridium) for a UTI, if it has no antibacterial activity?
5. What are the key points in the proper application of a topical sulfonamide cream?

Drugs Treating Mycobacterial Infections

Learning Objectives

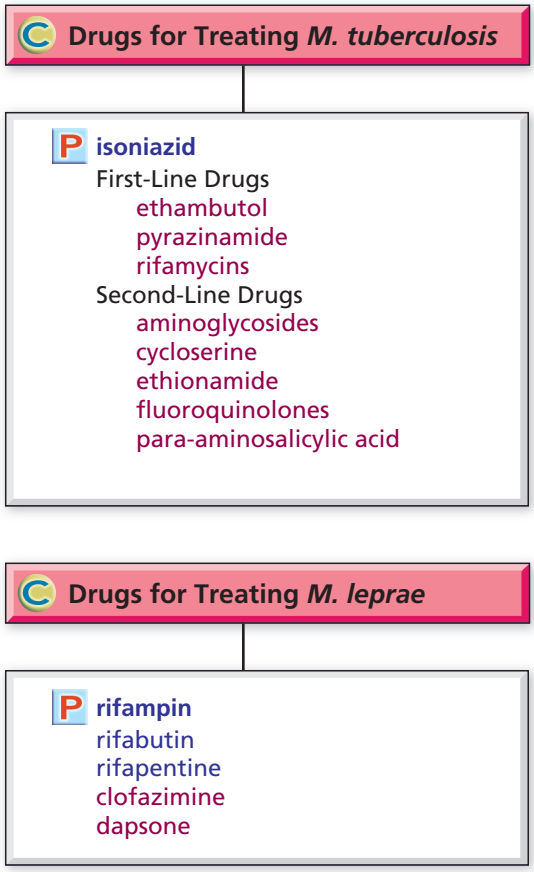
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that are used for treating mycobacterial infections.
2. Identify core patient variables relevant to drugs that are used for treating mycobacterial infections.
3. Relate the interaction of core drug knowledge to core patient variables for drugs that are used for treating mycobacterial infections.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that are used for treating mycobacterial infections.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that are used for treating mycobacterial infections.
6. Determine key points for patient and family education for drugs that are used for treating mycobacterial infections.

Key Terms

chemoprophylaxis
leprosy
Hansen disease
MDR TB
Mycobacteria
XDR TB

Drugs Treating Mycobacterial Infections



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

This chapter discusses pharmacologic management of mycobacterial infections. **Mycobacteria** are slow-growing microbes that require prolonged treatment, generally with multiple medications. Many of the antimycobacterial drugs may be used for more than one type of infection. Table 43.1 presents a summary of antimycobacterial drugs.

Although many *Mycobacterium* species exist, this chapter focuses on three species: *M. tuberculosis, M. leprae,* and *M. avium*. The prototype drug for treating *M. tuberculosis* infection is isoniazid (INH), and the prototype for treating *M. leprae* infection is rifampin. The drugs of choice for *M. avium* are clarithromycin and azithromycin; both of these macrolide drugs are discussed in Chapter 40.

PATHOPHYSIOLOGY

Tuberculosis

Tuberculosis (TB) is a mycobacterial infection that is found most frequently in the lungs; however, it may invade any organ of the body. The two types of TB are *Mycobacterium tuberculosis hominis* (human) and *Mycobacterium tuberculosis bovis* (bovine). Human TB is an airborne disease spread by tiny, invisible particles called droplet nuclei. Bovine TB is spread through the gastrointestinal (GI) system after drinking milk from infected cows. In the United States, bovine TB is very rare because dairy herds are strictly monitored, and pasteurization of milk is widespread. Symptoms of active TB include night sweats, cough, low-grade fever, fatigue, weight loss, and anorexia.

TABLE 43.1 Summary of Selected Antimycobacterial Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P isoniazid (Nydrazid; Laniazid)	TB in conjunction with other drug therapy, prophylaxis of TB	*Adult:* PO, active TB, 5 mg/kg/d up to 300 mg in single dose; prophylaxis, 300 mg/d in single dose *Child:* PO, active TB, 10–20 mg/kg/d; prophylaxis, 10 mg/kg/d in single dose	*Onset:* Varies *Duration:* 24 h $t_{1/2}$: 1–4 h
clofazimine (Lamprene)	Leprosy	*Adult:* 50 mg qd self-administered and 300 mg q mo *Child:* 1 mg/kg/d	*Onset:* 1 h *Duration:* Unknown $t_{1/2}$: Terminal 8 d, tissue 70 d
cycloserine (Seromycin Pulvules)	Tuberculosis	*Adult:* PO, 250 mg every 12 h × 2 wk, then 250 mg every 6–8 h *Child:* PO, 10–20 mg/kg/d every 12 h	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 10 h
dapsone (Avlosulfon)	Leprosy	*Adult:* PO, 100 mg qd *Child:* 1–2 mg/kg/d	*Onset:* 2 h *Duration:* Unknown $t_{1/2}$: 30 h
ethambutol (Myambutol; *Canadian:* Etibi)	TB in conjunction with other drug therapy, prophylaxis of TB	*Adult:* PO, mg/kg/d as single oral dose; retreatment, 25 mg/kg/d, reduced after 60 d to 15 mg/kg/d once daily *Child:* Not recommended for children younger than 13 y	*Onset:* Rapid *Duration:* 20–24 h $t_{1/2}$: 3.3 h
ethionamide (Trecator)	Tuberculosis	*Adult:* PO, 15–20 mg/kg/d in 2–3 divided doses *Child:* PO, 10–20 mg/kg/d in 2–3 divided doses	*Onset:* Rapid *Duration:* 9.5 h $t_{1/2}$: 2–3 h
para-aminosalicylic acid (PAS, Paser)	Tuberculosis Crohn's disease	*Adult:* PO, 4 g 3 × d *Child:* PO, 275–420 mg/kg/d in 4 divided doses *Adult:* PO, 500 mg 3 × d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 26.4 min
pyrazinamide	TB in conjunction with other drug therapy, prophylaxis of TB	*Adult:* PO, 15–30 mg/d once daily *Child:* Same	*Onset:* Rapid *Duration:* 9.5 h $t_{1/2}$: 9–10 h
rifabutin (Mycobutin)	TB, leprosy, MAC	*Adult:* 300 mg PO qd, may be given 150 mg bid to decrease GI distress *Child:* Not approved	*Onset:* 1 h *Duration:* Unknown $t_{1/2}$: 16–69 h
rifapentine (Priftin)	TB	*Adult and child >12 y:* 600 mg 2 × wk for 2 mo, then 1 × wk for 4 mo *Child:* Not recommended	*Onset:* 5–6 h *Duration:* Unknown $t_{1/2}$: 13 h

Human TB can become a devastating disease, although the bacteria themselves are not particularly virulent. The damage to the human host is a result of a hypersensitivity response evoked by the bacteria. Untreated TB may result in death, whereas inadequately treated TB may result in multidrug-resistant TB.

TB may be latent or active. Latent tuberculosis infection (LTBI) occurs when the patient has been infected with *M. tuberculosis*, but does not have active disease and is not infectious. Approximately 10% of patients with LTBI will develop active TB later in life. The diagnosis is made by administering a purified protein derivative (PPD) test, the screening test for TB. The PPD test involves a solution that is placed intradermally on the forearm of the patient. After 48 to 72 hours, the injection site is evaluated for induration. More than 10 mm of induration at the site of injection (or 5 mm of induration for an immunocompromised patient) is a positive reaction. Another method for diagnosing LTBI is Interferon Gamma Release Assays (IGRA) testing, sometimes referred to as ELISPOT. There are two available tests: the QuantiFERON-T Gold (QFT-G) and TB SPOT.TB. The IGRA test are more sensitive than the PPD and the results are obtainable in 24 hours. Another advantage of IGRA testing is that they are unlikely to produce false positives because of Bacillus Calmette-Guérin (BCG) vaccination, or because of the boosting effect from serial PPD testing that is done with heath care workers and other people at high risk of exposure. The BCG vaccine is not used in the United States because of its variable efficacy, however, it is used extensively in countries throughout the world (Box 43.1).

People with latent TB may benefit from chemoprophylaxis. Chemoprophylaxis greatly decreases the potential for LTBI to progress to active disease. The CDC has identified certain groups that have an increased risk for the development of active disease (Box 43.2)

Active TB results from activation of previously healed primary lesions. Activation may occur as the body's defenses decline as the patient ages or acquires other diseases that weaken the immune system. Active TB is diagnosed by chest radiography, sputum smear microscopy, and then sputum culture and drug susceptibility testing. Patients with active or reactivated TB require multidrug therapy (MDT) for 6 to 24 months. Therapy is based on the susceptibility of the infecting organism and the immunocompetence of the patient. Immunocompromised patients need a longer duration of therapy because their ability to fight infections is reduced.

Treatment of active TB is done by Direct Observed Treatment (DOTS), Short Course (Box 43.3); inadequate drug therapy due to patient nonadherence is the most common cause of multidrug-resistant TB. Multi-drug resistant tuberculosis (**MDR-TB**) is defined as TB that is resistant at least to isoniazid (INH) and rifampin, the two most powerful first-line anti-TB drugs. Extensively drug resistant TB (**XDR TB**) is defined TB that is resistant to isoniazid and rifampin and to any fluoroquinolone and at least one of three injectable second-line drugs (amikacin, kanamycin, or capreomycin). These types of TB infection require extremely close supervision throughout treatment.

BOX 43.1 FOCUS ON RESEARCH

Vaccine on the Horizon?

Sander, C. R., Pathan, A. A., Beveridge, N. E., et al. (2009). Safety and immunogenicity of a new tuberculosis vaccine, MVA85A, in Mycobacterium tuberculosis-infected individuals, *American Journal of Respiratory and Critical Care Medicine*, 179(8):724–733.

The Study

The purpose of the study is to evaluate the safety and immunogenicity of a leading new TB vaccine, recombinant Modified Vaccinia Ankara expressing Antigen 85A (MVA85A) in individuals with latent TB infection (LTBI). The researchers completed a phase I clinical study with patients recruited from TB clinics in Oxford and London, England. Patients were assessed clinically and had blood samples drawn for immunological analysis over a 52-week period after vaccination with MVA85A. Thoracic computed tomography scans were performed at baseline and at 10 weeks after vaccination. The study determined that MVA85A is safe and highly immunogenic in individuals with LTBI. Further trials in TB-endemic areas are needed.

Nursing Implications

The United States does not currently utilize a vaccine for TB prophylaxis, but many countries throughout the world use the Bacillus Calmette-Guérin vaccine (BCG). BCG has a variable efficacy and does not provide life-long immunity. Because multi-drug resistant TB has become a global concern, the need for a more efficacious vaccine has become even more important. The nurse must consistently update his/her knowledge regarding infectious diseases such as TB and potential new treatment options for our patients.

Box 43.2 CDC RECOMMENDATIONS FOR TREATMENT OF LTBI

Chemoprophylaxis is considered for patients with a positive PPD greater than 10 mm if they are:

- Recent arrivals (less than 5 years) from high-prevalence countries
- Injectable drug users
- Residents and employees of high-risk settings (e.g., correctional institutions, nursing homes, homeless shelters, hospitals)
- Mycobacteriology laboratory personnel
- Persons with clinical conditions that make them high risk (e.g., diabetes, chronic malnutrition, ESRD, pre-existing lung disease)
- Children less than 4 years of age or children or adolescents exposed to adults in high-risk categories

Chemoprophylaxis is considered for patients with a positive PPD greater than 5 mm if they are:

- HIV infected persons
- Recent contacts of a TB case
- Patients with fibrotic lung changes consistent with old TB
- Patients with organ transplants
- Patients who are immunocompromised (e.g., prolonged corticosteroid therapy, taking TNF-Alpha antagonists)

Box 43.3 THE FIVE ELEMENTS OF THE DOTS STRATEGY FOR THE TREATMENT OF TUBERCULOSIS

- Political commitment with increased and sustained financing
- Case detection through quality-assured bacteriology
- Standardized treatment, with supervision and patient support
- An effective drug supply and management system
- Monitoring and evaluation system, with impact measurement

Leprosy

Leprosy was first described in 1873 by G. A. Hansen; thus, its alternate name is **Hansen disease.** It is a chronic infectious disease caused by *M. leprae,* an acid-fast, rod-shaped bacillus. The disease affects mainly the skin, the peripheral nerves, the mucosa of the upper respiratory tract, and the eyes.

The two classifications of leprosy are paucibacillary leprosy (PB) and multibacillary leprosy (MB). They can be classified on the basis of skin-smear results or clinical manifestations. In the classification based on skin smears, patients who have negative smears at all sites are grouped as having PB, whereas those who have positive smears at any site are grouped as having MB. However, in practice, most prescribers use clinical criteria for classifying the disease and deciding the appropriate treatment regimen for individual patients because skin-smear services are not always available or dependable. The clinical system of classification uses the number of skin lesions and nerves involved as the basis for grouping leprosy. Patients with fewer than five lesions are diagnosed with PB leprosy, and patients with six or more lesions are diagnosed with MB leprosy.

The correct classification is important because the treatment regimens differ between the two types of leprosy. Like TB, leprosy must be treated with a multidrug regimen for 6 to 12 months. For MB leprosy, rifampin, clofazimine, and dapsone are used, and for PB leprosy, rifampin and dapsone are used. For patients with single-skin lesion PB leprosy, ofloxacin and minocycline are used in combination with rifampin.

Mycobacterium Avium Complex

Mycobacterium avium complex (MAC) is the term used to describe an opportunistic infection caused by two similar types of bacteria named *M. avium* and *M. avium-intracellulare*. Because these bacteria are so similar, they are referred to together as a "complex." However, *M. avium* is the predominant infective organism seen in most MAC infections in people with AIDS.

M. avium and *M. intracellulare* are very common. They are found in water, soil, dust, and food, and almost everyone has them in their body. A healthy immune system controls MAC, but immunocompromised people can develop a MAC infection. MAC can be localized or disseminated (sometimes called DMAC). It often occurs in the lungs, intestines, bone marrow, liver, and spleen. Symptoms of MAC include high fevers, chills, diarrhea, weight loss, stomachaches, fatigue, and anemia. When MAC disseminates, it can cause blood infections, hepatitis, pneumonia, and other serious problems.

MAC bacteria can mutate and develop resistance to pharmacotherapy. As with other mycobacterial infections, a combination of antibacterial drugs is used to manage MAC. Immunocompromised patients are started on MAC prophylaxis when their T-cell count drops below 50. Once an immunocompromised patient develops a MAC infection, treatment must continue for life to avoid recurrence. The drugs of choice for MAC prophylaxis and treatment are azithromycin and clarithromycin. These drugs are discussed in Chapter 40. Additional drugs that may be used against MAC include rifampin, rifabutin, and clofazimine, which are described in this chapter in the section on drugs for *M. leprae* infection.

C DRUGS FOR TREATING *MYCOBACTERIUM TUBERCULOSIS* INFECTION

Antitubercular drugs are divided into two major categories: first- and second-line drugs. First-line drugs are those that are effective for treatment and have manageable toxicities. First-line drugs include isoniazid, rifampin, rifapentine, rifabutin, ethambutol, and pyrazinamide. Because TB can easily become drug resistant, combination therapy with three to four drugs is common

Isoniazid is referred to as INH, an abbreviation related to its clinical structure. Isoniazid is included in all therapeutic regimens, except in those for INH-resistant TB. For that reason, INH is the prototype for antitubercular drugs. Table 43.1 presents a summary of drugs used to treat TB.

Nursing Management of the Patient Receiving P Isoniazid

Core Drug Knowledge

Pharmacotherapeutics

INH is an antibacterial drug used to treat or prevent TB and other susceptible mycobacterial infections. *Mycobacterium* organisms generally considered susceptible to INH therapy include *M. avium, M. bovis, M. intracellulare, M. kansasii, M. szulgai,* and *M. xenopi*.

Pharmacokinetics

INH is administered orally and intramuscularly. It is absorbed rapidly from the GI tract, with peak serum levels attained within 12 hours. It is distributed into all body tissues and fluids and crosses the blood–brain barrier to achieve therapeutic levels in the cerebrospinal fluid (CSF). It also crosses the placenta and is distributed into breast milk. INH is metabolized in the liver to inactive metabolites. About 75% of the drug and its metabolites are excreted in the urine, and the rest is excreted in the feces, saliva, and sputum.

Pharmacodynamics

INH is bactericidal or bacteriostatic, depending on the drug concentration within an infected site and the susceptibility of the organism. It works by disrupting the synthesis of the bacterial cell wall. Some patients have experienced adverse effects after ingesting tyramine-containing foods. This interaction suggests that INH may inhibit plasma monoamine oxidase, although this action has not been documented. INH has no direct effect on the body.

Contraindications and Precautions

INH is contraindicated in patients with acute hepatic disease and in patients with a history of INH-induced hepatic disease. INH should be used with caution in patients with chronic hepatic disease, alcoholism, or severe renal impairment because these conditions can prolong elimination of the drug, increasing the likelihood of adverse reactions.

INH should also be given with caution to patients with diabetes mellitus, malnutrition, or alcoholism because its effects (antagonism or increased excretion) on pyridoxine (vitamin B_6) can cause peripheral neuropathy in these patients. Pyridoxine generally is given concurrently with INH to decrease the risk for this adverse effect.

Data conflict about INH use during pregnancy; it is classified as a U.S. Food and Drug Administration (FDA) pregnancy category C drug. Because INH is given as part of a multidrug regimen to combat TB, studies have not been able to elicit the exact risk that INH poses to the fetus. INH appears to be safe for use during lactation.

Adverse Effects

The major adverse effect of INH therapy is hepatotoxicity, which is a Black Box warning. Hepatitis, elevated hepatic enzyme levels (aspartate transaminase, alanine transaminase), bilirubinemia, and jaundice may also occur.

Another frequent adverse effect is peripheral neuropathy. This effect may present with paresthesias in the hands and feet. As previously mentioned, malnourished patients and those with diabetes and alcoholism have a higher risk for this adverse effect. Encephalopathy, convulsions, memory impairment, toxic psychosis, and optic neuritis have been reported, but these events are rare.

INH may induce endocrine changes, such as pellagra, hyperglycemia, metabolic acidosis, and gynecomastia. Because it alters vitamin D metabolism, INH may cause hypocalcemia and hypophosphatemia.

Infrequently, INH may also cause adverse effects in the GI, hematologic, and integumentary systems. GI effects include diarrhea, abdominal pain, nausea, and vomiting.

Hematologic effects are agranulocytosis, hemolysis with anemia, sideroblastic anemia, aplastic anemia, pancytopenia, and thrombocytopenia. Integumentary effects include maculopapular rash, acneiform rash, or exfoliative dermatitis. Injection site reaction can be seen with intramuscular (IM) administration of INH. Rarely, INH may cause interstitial nephritis or central nervous system (CNS) toxicity, resulting in seizures.

Drug Interactions

Isoniazid interacts with a variety of drugs, including antiseizure drugs (carbamazepine and the hydantoins), alcohol, aluminum-based antacids, benzodiazepines, disulfiram, enflurane, ketoconazole, meperidine, warfarin, and rifampin. Table 43.2 lists drugs that interact with INH.

Because INH has some monoamine oxidase inhibitor activity, interactions may occur with tyramine-containing foods. INH may also interact with foods containing histamine.

Assessment of Relevant Core Patient Variables

Health Status

Prophylaxis with INH is given for 9 months, whereas treatment for active TB may last up to 24 months. Assess for pre-existing hepatic disease or disorders such as drug or alcohol abuse, which would predispose the patient to hepatic toxic effects. Coordinate baseline liver function tests (LFTs) and schedule serial LFTs throughout therapy. Some prescribers believe all patients should have these baseline tests, whereas others believe only those patients with an increased risk should be tested.

Evaluate the patient for other pre-existing disorders, such as diabetes mellitus or anemias,. Patients with diabetes should have a baseline A_{1C} evaluation because INH may cause hyperglycemia. This test indicates the general glucose control for the patient over the preceding 3 months. Patients with pre-existing anemias should have a baseline complete blood count (CBC) because they are at risk for hematologic disorders.

Life Span and Gender

INH is classified as FDA pregnancy category C. Therefore, evaluate the patient's pregnancy or breast-feeding status. Although no studies have demonstrated potential fetal risk, INH use in pregnant women should be restricted to active TB therapy. Pregnant women who need INH prophylaxis should begin therapy after delivery because the risk that TB will become active increases after childbirth. Assess infants of nursing mothers for signs of peripheral neuritis and hepatitis.

Determine the patient's age before therapy begins. Patients 35 years or older are three times more likely to develop drug-induced hepatitis than those younger than 35 years. INH prophylaxis for patients older than 35 years should be restricted to patients who are immunocompromised or whose PPD results indicate recent seroconversion. Monitor these patients closely with serial LFTs for signs of hepatotoxicity. There is also an increased risk for hepatitis in females, especially black and Hispanic women.

Lifestyle, Diet, and Habits

Ask the patient about diet and alcohol consumption. INH has some monoamine oxidase inhibitor (MAOI) activity

TABLE 43.2 Agents That Interact with P Isoniazid

Interactants	Effect and Significance	Nursing Management
alcohol	Isoniazid and alcohol may induce hepatotoxicity.	Advise the patient to limit ingestion of alcohol throughout therapy. Monitor for signs of hepatitis.
carbamazepine	Isoniazid is suspected to inhibit carbamazepine metabolism, resulting in carbamazepine toxicity. Carbamazepine may increase isoniazid degradation to hepatotoxic metabolites, resulting in an increased risk for hepatotoxicity.	Monitor carbamazepine serum concentrations. Monitor liver function test results.
chlorzoxazone	INH may inhibit the metabolism of chlorzoxazone, resulting in an increased risk for adverse effects.	Monitor for an ataxic gait. Monitor for dizziness or drowsiness Maintain a safe environment.
disulfiram	The combination of disulfiram and isoniazid may induce excess dopaminergic activity.	Monitor patient for acute behavioral and coordination changes. Refer to health care provider immediately if any occur.
enflurane	Fast acetylation of isoniazid produces high concentrations of hydrazine, facilitating defluoridation of enflurane. This may result in high-output renal failure.	Monitor renal function, especially in fast acetylators.
Hydantoins	Isoniazid inhibits the metabolism of hydantoins, resulting in increased serum hydantoin concentrations and increased risk for toxicity.	Monitor serum hydantoin levels frequently. Monitor for signs of hydantoin toxicity.
meperidine	These drugs in combination may induce hypotension or CNS depression. The mechanism of action is unknown.	Use combination cautiously. Monitor blood pressure. Monitor for CNS depression. Maintain a safe environment.
rifampin	Hepatotoxicity may occur more frequently when combined.	Monitor liver function test results.
warfarin	The anticoagulant activity is increased when given concurrently with isoniazid. This results in an increased risk for hemorrhage.	Monitor PT and INR frequently. Monitor for bruising or bleeding

and some providers believe patients should refrain from a tyramine-rich diet. Foods that contain tyramine include cheese and dairy products, beef or chicken liver, beer and ale, red wine, avocados, bananas, figs, raisins, caffeine, and chocolates. Other providers believe that INH is a very weak MAO inhibitor that rarely causes symptoms. Monitor the patient and advise the provider if flushing, sweating, diarrhea, elevated BP, or other unusual symptoms occur.

Patients should also refrain from foods containing histamine. Foods in this category include tuna, brine, or yeast extract. The patient may experience headache, palpitations, sweating, hypotension, flushing, diarrhea, or itching.

Daily consumption of alcohol increases the risk of INH-induced hepatitis and can increase the clearance of INH.

Environment

INH therapy is routinely conducted in the home. Because of its long duration (up to 24 months), adherence is an issue. With the patient, explore factors in the home environment that may affect adherence. Additionally, stress that he or she needs to have periodic follow-up examinations and laboratory testing to monitor for severe and potentially fatal adverse reactions.

Culture and Inherited Traits

INH is metabolized in the body by a process called acetylation. In some people, this process occurs more rapidly than it does in others. Fast acetylators are at higher risk for hepatic toxicity from INH therapy, whereas slow acetylators are at higher risk for high serum levels and more frequent adverse effects. Because the determination of fast acetylators or slow acetylators is genetically controlled, it is important to be aware of the patient's ethnic background. Eskimos, Asians, and about 50% of African Americans or European Americans from North America are fast acetylators. The remainder of African Americans and European Americans, Scandinavians, and people of Arab or Jewish heritage are slow acetylators.

Nursing Diagnoses and Outcomes

- Altered Protection related to drug-induced hepatitis
  Desired outcome: *The patient will call the prescriber immediately if signs or symptoms of hepatitis occur.*
- Risk for Infection related to drug-induced blood dyscrasias
  Desired outcome: *The patient will monitor for signs of infection and contact the prescriber if any occur.*
- Risk for Peripheral Neurovascular Dysfunction related to drug-induced neuropathy
  Desired outcome: *The patient will take pyridoxine throughout INH therapy to decrease potential for peripheral neuropathy.*
- Risk for Trauma related to adverse CNS effects
  Desired outcome: *The patient will encounter no injury related to CNS effects brought on by using INH.*
- Impaired Skin Integrity related to drug-induced acne
  Desired outcome: *The patient will practice careful skin care to prevent breakdown from acne resulting from drug effects.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer INH to the patient with an empty stomach 1 hour before or 2 hours after meals to increase absorption. For patients with GI distress, INH may be given with meals. To avoid possible drug interactions, do not administer antacids less than 1 hour before or 2 hours after administering INH.

Minimizing Adverse Effects

The early identification of symptoms of potential adverse effects is the best way to minimize complications of INH therapy. Advise patients to report any of the prodromal symptoms of hepatitis, including anorexia, malaise, fatigue, jaundice, or nausea. Also advise patients to report burning or pain in the extremities, numbness or tingling, or symptoms of anemia. The drug should be discontinued if clinical symptoms of hepatitis occur.

Most prescribers discontinue the drug if LFT results indicate elevations ranging from three to five times higher than the upper limit of normal values.

Providing Patient and Family Education

- Advise patients to take the drug on an empty stomach every day and emphasize the importance of taking the drug as prescribed. Patients who stop and start INH therapy repeatedly are at risk for developing drug- resistant TB. Although it is important to take the drug as prescribed, it is more important not to double the dosage if a drug dose is forgotten.
- Explain diet and alcohol restrictions to limit the risk of adverse reactions. A written list of foods that contain tyramine or histamine is most helpful to patients.
- Teach patients the signs of hepatotoxicity such as anorexia, malaise, fatigue, jaundice, or nausea. Explain the importance of notifying the prescriber if any of these symptoms occur.
- Teach patients the signs of peripheral neuropathy such as burning or pain in the extremities, numbness, or tingling. Advise them to contact the prescriber if any of these symptoms occur.
- Explain the importance of follow-up visits, including laboratory testing and eye examinations.

Ongoing Assessment and Evaluation

Ongoing assessment is extremely important in INH therapy. Monitor for signs of adverse effects, especially hepatitis. Question the patient about symptoms such as yellow skin or eyes, anorexia, nausea, vomiting, fatigue, malaise, or weakness. Also, ask about rash, itching, or darkened urine. It is also important to question the patient regarding symmetric numbness or tingling in the extremities. Optimally, results of the patient's serial blood tests will be available for evaluation during the visit.

INH should be discontinued if signs or symptoms of hepatic damage become evident. Discontinuing INH should be considered if LFT values exceed three to five times the upper limit of normal ranges.

At each visit, review diet and alcohol recommendations. Also, review the signs and symptoms of hepatitis and peripheral neuropathy and remind the patient to call the prescriber if any symptoms occur. It may be preferable to arrange for the next follow-up appointment rather than wait for the patient to call.

CRITICAL THINKING SCENARIO

EXPOSURE TO THE TUBERCULOSIS (TB) MYCOBACTERIUM

David Haversham, age 32 years, works as a correctional officer in the local jail. Following policy, David goes to the clinic for his yearly TB test. His test result last year was negative, and David does not recall having been exposed to TB. Two days later, you call David to tell him that his purified protein derivative (PPD) measured 12 mm and to arrange for him to have a chest x-ray (CXR). David calls the clinic today and learns that his CXR is normal and then asks, "So, what does all this mean?"

1. How would you answer David's question?
2. What therapy, if any, would you anticipate for this patient?
3. Would this therapy change if the patient were 40 years of age?
4. What questions would you ask the patient before initiating therapy?
5. Develop a patient teaching plan for the patient.
6. How would this scenario change if David were HIV-positive?

MEMORY CHIP

P Isoniazid

- Used for prophylaxis and management of tuberculosis and for other susceptible mycobacterial infections
- Important contraindications: acute hepatic diseases
- Most common adverse effects: peripheral neuropathy, elevated liver enzyme levels
- Most serious adverse effects: hepatotoxicity, optic neuritis
- **Life span alert: patients over the age of 35 years have an increased risk for isoniazid-induced hepatic dysfunction**
- Maximizing therapeutic effects: Administer on an empty stomach, unless GI distress occurs.
- Minimizing adverse effects: Promptly identify signs and symptoms of potential adverse effects, especially hepatitis.
- Most important patient education: Teach patients about the role of adherence in avoiding drug resistance.
- **Black box warning: hepatotoxicity**

Drugs Significantly Different From P Isoniazid

First-Line Drugs

Ethambutol

Ethambutol (Myambutol) appears to be more effective and less toxic than other antitubercular drugs. It works by inhibiting the synthesis of certain metabolites, with subsequent impairment of cell metabolism leading to cell death. Ethambutol is effective against INH and rifampin-resistant bacilli.

Ethambutol is administered orally, partially metabolized in the liver, and excreted primarily in urine, with approximately 25% excreted unchanged in feces. A widely distributed drug, it reaches high concentrations in the kidneys, lungs, and saliva. It penetrates inflamed meninges to reach therapeutic levels in the CSF. Although ethambutol crosses the placenta and is distributed into breast milk, no adverse effects on the fetus or nursing infant have been reported. It is not recommended for use in children under the age of 13.

One of the main adverse effects of ethambutol is optic neuritis. Patients with pre-existing ocular disease should have a baseline ophthalmologic examination and be closely monitored for changes in visual acuity and color discrimination. The drug should not be used in children whose visual acuity cannot be adequately assessed. Other serious adverse effects include hepatotoxicity, peripheral neuropathy, and blood dyscrasias. Ethambutol may also cause hyperuricemia; therefore, patients with a history of gout should be closely monitored for exacerbations.

Pyrazinamide

Like ethambutol, pyrazinamide (PZA) appears to be more effective and less toxic than other antitubercular drugs. It is indicated only for use in treating *M. tuberculosis*. The exact mechanism of action of PZA is not known; however, it exhibits bacteriocidal action. Studies indicate that PZA is most effective in the induction phase of treatment.

PZA is administered orally, metabolized into active metabolites, and excreted in the urine, primarily by way of glomerular filtration. It is widely distributed and penetrates inflamed meninges. Whether PZA crosses the placenta is unknown, but the drug does enter breast milk.

PZA should be given cautiously to patients who are pregnant and those with alcoholism, gout, or hepatic disease. The most severe adverse effect is hepatotoxicity. In rare instances, liver atrophy and fatalities have occurred. Common adverse effects include arthralgias, GI disturbances, and photosensitivity. Nongouty arthritis may occur because PZA inhibits urate excretion, resulting in hyperuricemia. Rarely, hematopoietic effects, such as thrombocytopenia and sideroblastic anemia, may occur.

Patients receiving PZA should have baseline laboratory tests completed before initiating treatment and periodically throughout therapy. These tests include a CBC, liver and renal function tests, and uric acid level.

Rifamycins

The rifamycins rifampin, rifapentine, and rifabutin are also first-line drugs used to manage TB. Rifampin is the drug of choice for managing leprosy and thus will be discussed as the prototype for that disease.

Second-Line Drugs

Aminoglycoside Antibiotics

Amikacin (Amikin), capreomycin sulfate (Capastat), kanamycin (Kantrex), and streptomycin are aminoglycoside antibiotics that are effective against *M. tuberculosis*. They are all given by the parenteral route. As with other aminoglycoside antibiotics, adverse effects include damage to the eighth cranial nerve, resulting in hearing loss or balance disturbances and nephrotoxicity. For detailed information regarding aminoglycoside antibiotics, see Chapter 40.

Cycloserine

Cycloserine (Seromycin), a bacteriostatic drug, works by inhibiting cell wall synthesis. It is always given in conjunction with another antitubercular drug. Cycloserine is contraindicated in patients with epilepsy, depression, anxiety, psychosis, severe renal insufficiency, and alcohol abuse. Major adverse effects include seizures, confusion, dizziness, headache, and somnolence.

Ethionamide

Ethionamide (Trecator) is structurally similar to INH but less effective. It is always given in conjunction with another antitubercular drug. Ethionamide is used infrequently in the management of TB because of its severe affects on the GI system. In addition to the GI adverse effects, ethionamide may induce hepatotoxicity, orthostatic hypotension, hypoglycemia, and impotence. Because of its structural similarity to INH, INH-resistant TB also may be resistant to ethionamide.

Fluoroquinolones

The fluoroquinolones are used for multidrug-resistant TB, although they are not FDA approved for this indication. Moxifloxacin (Avelox) has the most *in vitro* activity against tuberculosis, followed by levofloxacin (Levaquin), ofloxacin (Floxin), and ciprofloxacin (Cipro). For detailed information regarding the fluoroquinolones, see Chapter 41.

Aminosalicylic Acid

Aminosalicylic acid (Paser), also known as para-aminosalicylic acid (PAS), is similar to sulfonamides. It works by inhibiting the synthesis of folic acid. Aminosalicylic acid is usually used for TB in children, in place of ethambutol. In addition, aminosalicylic acid is used for the maintenance of Crohn's disease. Aminosalicylic acid may induce GI adverse effects such as nausea, vomiting, and diarrhea. Rarely, hepatotoxicity may occur.

Check the packet for granules that appear swollen or have lost their tan color and have turned dark brown or purple. Do not use if these changes have occurred. To administer, sprinkle granules on applesauce or yogurt or suspend in tomato, orange, grapefruit, grape, cranberry, or apple juice or in punch that contains fruit juice.

C DRUGS FOR TREATING *MYCOBACTERIUM LEPRAE* INFECTION

MDT, the standard approach for other mycobacterial infections, is also recommended for treating leprosy. Rifampin is the drug of choice for both types of leprosy (see Pathophysiology), except in cases of rifampin resistance. For that reason, rifampin is the prototype drug for treating leprosy. Table 43.3 presents a summary of selected rifamycins.

Nursing Management of the Patient Receiving P Rifampin

Core Drug Knowledge

Pharmacotherapeutics

Rifampin is one of the first-line drugs used in treating TB, although it should never be used as a single drug, because resistance develops rapidly. Its only other FDA-approved use is meningococcal infectious disease. Rifampin frequently is used as an off-label drug. It is a primary drug for leprosy, although it is always a part of MDT for this purpose. In addition, it is used in the treatment of other mycobacterial infections, MAC infection, staphylococcal infections (including MRSA), bacterial meningitis, osteomyelitis, infective endocarditis, and as prophylaxis against *Neisseria meningitidis* and *H. influenzae*.

Pharmacokinetics

Rifampin may be administered orally or parenterally. It is well absorbed from the GI tract, except in the presence of food, which decreases both the rate and extent of absorption. Rifampin is widely distributed into most body tissues and fluids including CSF, and concentrates intracellularly (up to five times that of extracellular concentrations), primarily in leukocytes. Rifampin is metabolized in the liver to an active metabolite and undergoes enterohepatic circulation with substantial reabsorption. It is excreted primarily through biliary elimination in feces.

Pharmacodynamics

Rifampin works by blocking initiation of RNA transcription by inhibiting bacterial DNA-dependent RNA polymerase. It is bactericidal or bacteriostatic, depending on the concentration reached within an infected site and the

TABLE 43.3 Summary of Selected Rifamycins

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P rifampin (Rifadin)	TB in conjunction with other drug therapy, prophylaxis of TB Leprosy *Mycobacterium avium* complex (MAC)	*Adult:* PO or IV, 600 mg in single daily dose until improvement occurs; direct observed treatment (DOTS) 10 mg/kg 2 × wk *Child:* 10–20 mg/k not to exceed 600 mg qd *Adult:* PO or IV 600 mg 1 × mo for 6–24 mo *Child:* Not recommended *Adult:* 600 mg PO or IV in combination with other antimycobacterials *Child:* 10–20 mg/kg PO or IV in combination with other antimycobacterials	*Onset:* PO, varies; IV, rapid *Duration:* 6 h $t_{1/2}$: 3–5.1 h
rifabutin (Mycobutin)	TB, leprosy, MAC	*Adult:* 300 mg PO qd, may be given 150 mg bid to decrease GI distress *Child:* Not approved	*Onset:* 1 h *Duration:* Unknown $t_{1/2}$: 16–69 h
rifapentine (Priftin)	TB	*Adult and child >12 y:* 600 mg 2 × wk for 2 mo, then 1 × wk for 4 mo *Child:* Not recommended	*Onset:* 5–6 h *Duration:* Unknown $t_{1/2}$: 13 h

susceptibility of the organism. It does not bind to RNA polymerase in human cells; thus, RNA synthesis in the host is not affected.

Contraindications and Precautions

Rifampin should not be administered to patients with known rifamycin hypersensitivity, including rifabutin, because cross-sensitivity between agents is possible. Parenteral rifampin contains sulfite sodium formaldehyde sulfoxylate. Therefore, parenteral rifampin is contraindicated in patients with sulfite hypersensitivity because it has been associated with serious or potentially fatal anaphylactoid reactions, although the incidence of such reactions is low. Rifampin is also contraindicated for use in patients taking nonnucleoside reverse transcriptase inhibitors (NNRTIs).

Because of its potential adverse effects on the liver, rifampin is used cautiously in patients with a history of hepatic dysfunction and in patients known to have alcoholism. It is also used cautiously with patients taking other medications known to be hepatotoxic.

Adverse Effects

Rifampin may cause adverse effects similar to those of INH, especially hepatic injury. Additionally, rifampin can discolor bodily fluids, such as urine, saliva, tears, and sputum. Wearers of soft contact lenses should be cautioned that the lenses may be permanently discolored.

Although rifampin is generally well tolerated, it may cause GI disturbances such as nausea and vomiting, anorexia, flatulence, cramps, and diarrhea. Other common adverse effects include headache, drowsiness, fatigue, dizziness, and rash. Rarely, rifampin may induce pseudomembranous colitis or thrombocytopenia or other blood dyscrasias, and acute renal failure.

Drug Interactions

Rifampin is a potent inducer of the cytochrome P-450 hepatic enzyme system and its subsets. Induction may result in reduced plasma concentrations of other drugs metabolized by the P-450 enzyme system. When these drugs are given concurrently with rifampin, their dosage may need to be increased. In some cases, the drugs are contraindicated for concurrent use. Table 43.4 lists drugs that interact with rifampin.

Assessment of Relevant Core Patient Variables

Health Status

Assess for diseases or disorders that contraindicate the use of rifampin or require strict monitoring during therapy, especially those that increase the risk of hepatotoxicity. Assess for any medications that may interact with rifampin or other drugs known to be hepatotoxic. Communicate any positive findings to the prescriber before starting therapy.

Pay special attention to patients with a diagnosis of HIV infection or AIDS. Many drugs used to treat these disorders are contraindicated for use with rifampin. Additionally, patients with HIV infection or AIDS need TB therapy for a longer duration than other patients do, increasing the problem of drug resistance.

Arrange for baseline laboratory tests before administering rifampin. These tests include a CBC and hepatic and renal studies.

Life Span and Gender

Rifampin is an FDA pregnancy category C drug; therefore, it is important to evaluate the patient's pregnancy status. The drug may be used in children younger than 1 month. Rifampin may increase the metabolism of oral contraceptives, placing the patient at risk for pregnancy. Advise women taking oral contraceptives to use another form of birth control while taking rifampin.

Lifestyle, Diet, and Habits

Assess for alcohol consumption and explain the increased risk for hepatotoxicity when alcohol consumption is combined with rifampin therapy. Because rifampin can discolor body fluids red-orange, suggest that soft contact lens wearers change to a different type of contacts or regular glasses throughout therapy. Dietary changes are not needed.

Environment

Rifampin can be given in any environment. Oral rifampin is most frequently used in the home environment; intravenous (IV) rifampin is most frequently administered in an acute care hospital. Be aware of the environment in which the drug will be administered and explore with the patient any factors in the home setting that may affect adherence to drug therapy.

Nursing Diagnoses and Outcomes

- Risk for Injury related to hepatic injury
  Desired outcome: *The patient will remain free of injury and contact the prescriber if signs such as yellow skin, itching, or fatigue occur.*
- Imbalanced Nutrition: Less than Body Requirements, related to potential nausea, vomiting, anorexia, and diarrhea
  Desired outcome: *The patient will have balanced nutrition throughout therapy.*
- Ineffective Protection related to blood dyscrasias
  Desired outcome: *The patient will remain without injury throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer IV rifampin by slow infusion over 2 hours. Oral rifampin should be given 1 hour before or 2 hours after a meal to avoid decreasing absorption. Promote adherence to oral rifampin therapy by explaining the importance of taking the medication daily.

Minimizing Adverse Effects

Evaluate the patient for contraindications to its use and avoid administering rifampin to a patient with signs of

TABLE 43.4 Agents That Interact with P Rifampin

Interactants	Effect and Significance	Nursing Management
Drugs affected by induction: • anticoagulants • beta blockers • oral contraceptives • corticosteroids • cyclosporine • digitoxin • disopyramide • doxycycline • estrogens/progestins • haloperidol • HMG Co-A reductase inhibitors • hydantoins • nifedipine • ondansetron • oral antidiabetic agents • quinine derivatives • tacrolimus tamoxifen • theophyllines • tricyclic antidepressants • zolpidem	Increased hepatic microsomal enzyme metabolism (induction) by rifampin results in decreased action of interactant drugs.	Monitor for efficacy of interactant drugs. Discuss adjustment of interactant drug dosages with provider.
azole antifungal agents	Rifampin may induce the metabolism of azole antifungal drugs resulting in decreased action of azole antifungal drugs. Additionally, azole antifungal drugs interfere with the absorption of rifampin resulting in decreased serum rifampin levels.	Monitor for efficacy of azole antifungal drugs. Monitor for efficacy of rifampin. Consult with prescriber about adjusting drug dosages as needed.
benzodiazepines	The oxidative metabolism of benzodiazepines may be increased resulting in decreased pharmacologic effects.	Monitor for efficacy of benzodiazepine drugs. Consult with prescriber about adjusting benzodiazepine drug dosages as needed.
buspirone, verapamil	Rifampin induces first-pass metabolism of these drugs resulting in decreased plasma concentration.	Monitor for efficacy of interactants. Consult with prescriber about adjusting dosages of interactants as needed.
isoniazid	Rifampin may cause an alteration in the metabolism of isoniazid. Hepatotoxicity may occur at a rate higher than with either agent alone.	Monitor for signs of hepatotoxicity. Monitor liver function studies. Discontinue as needed.
macrolide antibiotics	The metabolism of rifampin may be inhibited while the metabolism of macrolide antibiotics may be increased, resulting in decreased antimicrobial effects and increased GI adverse effects.	Monitor for efficacy of macrolide antibiotics. Monitor for adverse GI effects of macrolide antibiotics. Consult with prescriber about using azithromycin or dirithromycin as alternative drugs because they do not undergo metabolism.
NNRTI	Rifampin may increase the metabolism of NNRTI drugs, resulting in a decreased efficacy of both drugs.	Monitor NNRTI drug levels. Discuss increasing rifampin dose with provider.
Opioids	Rifampin stimulates the metabolism of opioid analgesics, resulting in decreased efficacy.	Monitor the patient's clinical response to opioids. Monitor for signs of withdrawal. Discuss an alternative analgesic with the provider.
Protease inhibitors (PIs)	Rifampin may reduce PI plasma levels, decreasing their effect. PI drugs may increase rifampin levels, resulting in an increased risk for toxicity.	Discuss alternative drug therapy with the provider. If ordered, observe for efficacy of PI drugs and toxicity from rifampin.

hepatotoxicity. Assess patients taking other hepatotoxic drugs such as INH and PZA carefully, because the risk of hepatotoxicity is increased.

Providing Patient and Family Education

- Explain the potential effect of rifampin on the liver. Advise patients to contact the prescriber immediately if they experience anorexia, nausea, fatigue, malaise, jaundice, cola-colored urine, or pale stools. Also, explain that many drugs increase the risk for hepatic damage and that the patients should contact the prescriber before taking any new drugs, even those prescribed by another provider. In addition, explain that alcohol consumption may also increase the risk of hepatic damage.
- Advise patients with soft contact lenses to consult their ophthalmologist for an alternate form of contacts or glasses. Assure patients that the discoloration of body fluids is not harmful.
- Advise women using oral contraceptives to use another method of birth control while taking rifampin.
- Because adherence is always difficult when rifampin must be taken for a prolonged time, explain the importance of taking the medication consistently, even though patients will not feel different.
- Explain the importance of consistent follow-up visits to ensure that the microbes are eradicated and to monitor for adverse effects.

Ongoing Assessment and Evaluation

Ask patients whether they have experienced any symptoms suggestive of hepatic dysfunction. Periodic testing of hematopoietic, renal, and hepatic function should also be arranged.

By the end of therapy, the microbes should be eradicated, and the patient should be free from any adverse effects from rifampin therapy.

MEMORY CHIP

P Rifampin

- Used to manage acute TB and leprosy; also used to manage other mycobacterial infections
- Important contraindication: hypersensitivity
- Most common adverse effects: discoloration of body fluids, GI disturbances
- Most serious adverse effect: hepatotoxicity
- Maximizing therapeutic effects: Administer on an empty stomach.
- Minimizing adverse effects: Evaluate the patient for potential drug–drug interactions.
- Most important patient education: Teach patients the role of adherence in preventing resistance and the importance of contacting the prescriber if any signs of hepatic dysfunction occur.

Drugs Closely Related to P Rifampin

Two drugs, rifabutin and rifapentine, are similar to rifampin. Contraindications, precautions, adverse effects, and drug interactions for both of these drugs are the same as those for rifampin.

Rifabutin

Rifabutin (Mycobutin) is a derivative of rifamycin. It is used for prophylaxis or treatment of TB and MAC. *M. leprae* is also considered to be susceptible to rifabutin, but leprosy is not a labeled indication. Rifabutin appears to be a less potent hepatic enzyme inducer than rifampin, although similar drug–drug interactions may still occur. Rifabutin does not interfere with the metabolism of INH.

The most serious adverse effects of rifabutin are uveitis and blood dyscrasias. Like rifampin, rifabutin may cause discoloration of body fluids. Rifabutin is contraindicated for concurrent use with NNRTIs, hard-gel formulation saquinavir, or ritonavir. It can be given cautiously with other antiretroviral agents, but the dosage of those agents may need to be increased.

Rifapentine

Rifapentine (Priftin) is very similar to rifampin. Although many mycobacteria are considered susceptible to rifapentine, its only approved use is in managing TB. The major difference between rifapentine and rifampin is rifapentine's extended half-life, which allows for twice-a-week dosing.

Drugs Significantly Different From P Rifampin

Clofazimine

Clofazimine (Lamprene) is used as an antimycobacterial and anti-inflammatory agent, although access to this drug is restricted in the United States. It is bacteriocidal against *M. tuberculosis* and *M. leprae;* however, its action against *M. leprae* is very slow. It is bacteriostatic against *M. avium-intracellulare*. Clofazimine works by binding to mycobacterial DNA, thus inhibiting reproduction and growth. As an anti-inflammatory agent, it inhibits neutrophil motility and enhances the phagocytic activity of the polymorphonuclear cells and macrophages.

Clofazimine is insoluble in water and is incompletely absorbed from the GI tract. The extent of absorption varies with the person and with the form of the drug administered. Clofazimine concentrates and can crystallize in mesenteric lymph nodes, adipose tissue, adrenals, liver, lungs, gall-bladder, bile, and spleen. It crosses the placenta and enters breast milk. Clofazimine is excreted unchanged in feces.

The only contraindication to clofazimine therapy is hypersensitivity. Precautions include pre-existing GI disease and hepatic dysfunction. Common GI adverse effects to clofazimine include anorexia, diarrhea, nausea and vomiting, and colicky or burning abdominal pain. GI toxicity can include

hepatitis (with elevated hepatic enzyme levels) or jaundice. Rare but serious adverse effects include splenic infarction, GI obstruction or ileus, and GI bleeding. Clofazimine can cause dark, black, or tarry stools that may be misinterpreted as GI hemorrhage.

In addition, clofazimine can cause long-lasting discoloration of the skin. In Caucasians, the skin may be bronze or dark tan. This effect may last months after clofazimine is discontinued. Like rifampin, clofazimine may discolor body fluids.

Dapsone

Dapsone (Avlosulfon) is a synthetic sulfone that is chemically similar to sulfonamides. It is used as an antimicrobial agent for leprosy, for *Pneumocystis carinii* pneumonia (PCP), and for the prophylaxis of malaria. It is also used as an immunosuppressive agent for systemic lupus erythematosus and as a dermatologic agent in a variety of integumentary disorders. In managing leprosy, dapsone is used in combination with other drugs such as rifampin and clofazimine. In the past, dapsone was the mainstay of therapy for leprosy. Now, resistance to dapsone monotherapy is common among *M. leprae*.

Dapsone works by inhibiting folic acid synthesis in susceptible organisms. Although the mechanism of dapsone in integumentary disorders is unknown, it has been suggested that it may act as an immunomodulator. Dapsone is orally administered and almost completely absorbed from the GI tract. It is widely distributed throughout the body, crosses the placenta, and enters into breast milk. Dapsone is metabolized in the liver. Approximately 20% of the drug is excreted unchanged in the urine, whereas 70% to 85% is excreted as metabolites. A small amount can be detected in the feces.

Hypersensitivity is the only contraindication to the use of dapsone. Caution is used in patients with sulfonamide hypersensitivity, but no direct cross-sensitivity occurs. Dapsone is also used with caution in cases of severe anemia, glucose-6-phosphate dehydrogenase (G6PD) deficiency, or methemoglobin reductase deficiency, because hemolytic anemia can occur.

Other serious effects that may be induced by dapsone include aplastic anemia, agranulocytosis, methemoglobinemia, acute tubular necrosis, and hepatotoxicity. More common adverse effects include fever, myalgias, headache, chills, fatigue, malaise, rash, and urticaria.

Probenecid may reduce renal excretion of dapsone, resulting in an increased risk of toxicity and adverse effects. Patients receiving other hemolytic agents, such as folic acid antagonists, should be closely monitored because concurrent use increases the potential for hematopoietic adverse effects.

Miscellaneous Drugs

Other drugs used to manage leprosy include ofloxacin, a fluoroquinolone antibiotic, and minocycline, a tetracycline antibiotic. These drug classes are discussed in Chapters 41 and 40, respectively.

CHAPTER SUMMARY

- The most common mycobacteria are *M. tuberculosis, M. leprae, M. avium,* and *M. intracellulare*.
- Isoniazid, or INH, the prototype for antitubercular drugs, is used for both prophylaxis and treatment of acute active tuberculosis (TB).
- Other first-line drugs for TB include rifampin, ethambutol, pyrazinamide, and streptomycin.
- Rifampin is the prototype drug for managing leprosy (Hansen disease).
- Other medications useful for leprosy include rifabutin, rifapentine, dapsone, clofazimine, ofloxacin, and minocycline.
- *M. avium* and *M. intracellulare* are the causative agents of *Mycobacterium avium* complex (MAC), a condition that frequently affects immunocompromised patients.
- Azithromycin and clarithromycin are the drugs of choice for MAC prophylaxis and treatment.
- Additional drugs used in managing MAC include rifampin, rifabutin, and clofazimine.

QUESTIONS FOR STUDY AND REVIEW

1. What type of patient has the highest risk for developing chemically induced hepatitis from isoniazid, or INH, therapy?
2. What is the difference between chemoprophylaxis and active tuberculosis (TB) therapy?
3. Why does multidrug-resistant TB occur?
4. What are the obstacles to successful drug therapy with rifampin?
5. Why is adherence an issue when treating mycobacterial infections?

Drugs Treating Fungal Infections

Learning Objectives

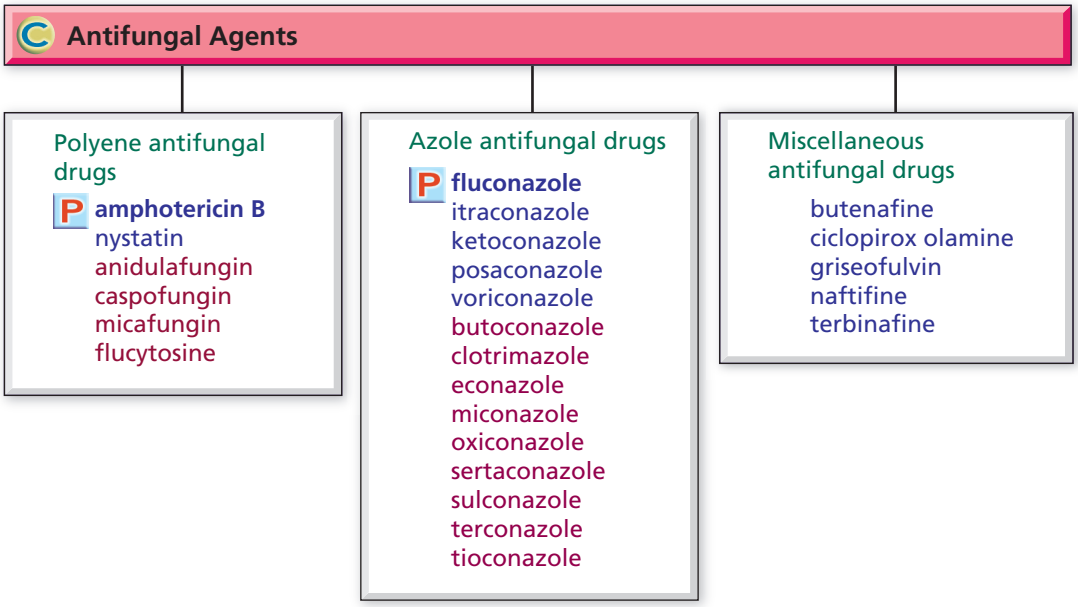
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs used to treat fungal infections.
2. Identify core patient variables relevant to drugs used to treat fungal infections.
3. Relate the interaction of core drug knowledge to core patient variables for drugs used to treat fungal infections.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs used to treat fungal infections.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs used to treat fungal infections.
6. Determine key points for patient and family education for drugs used to treat fungal infections.

Key Terms

Candida
cryptococcosis
dermatophytes
dimorphic fungi
tinea

Drugs Treating Fungal Infections



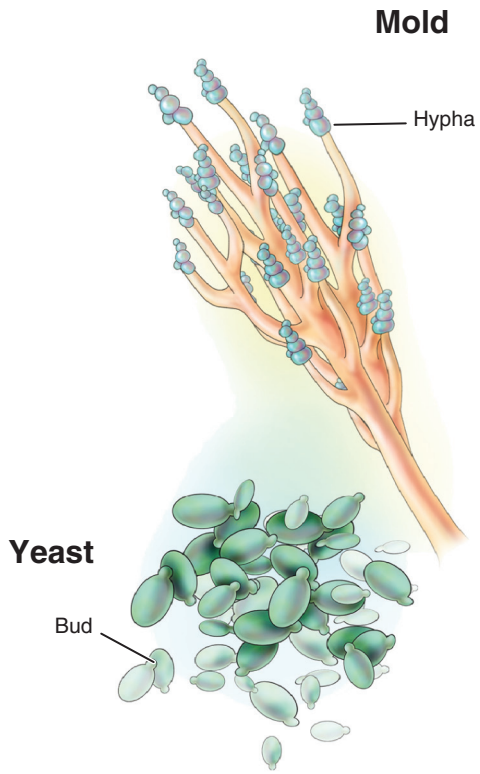
The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Fungal infections can be life threatening in immunocompromised patients. Fungal infections can be divided into two categories: systemic infections and superficial mycoses. Systemic infections, such as aspergillosis, cryptococcosis, blastomycosis, and histoplasmosis, can present serious medical problems. Superficial mycoses can be dermatophytic (skin related) or mucous membrane related; the most common such infections are tinea and candidiasis.

This chapter discusses two classes of antifungal drugs: polyenes (prototype, amphotericin B) and azoles (prototype, fluconazole), used to treat systemic infections. In addition, this chapter describes an additional group of drugs, the topical antimycotics, which are used to treat superficial mycoses. This arbitrary division is made to assist the student in focusing on each specific group of disorders caused by these different microbes.

PHYSIOLOGY OF FUNGAL GROWTH

Fungi can be separated into two groups—yeasts and molds (Figure 44.1). The yeasts are single-celled organisms that are approximately the size of a red blood cell. These organisms reproduce by a budding process. After the buds separate from the parent cell, they mature into identical daughter cells. Molds produce long, hollow, branching filaments called hyphae. The term **dimorphic fungi** describes a limited number of fungi that are capable of growing as yeasts at one temperature and as molds at another. Reproduction for most fungi may be sexual or asexual.



• FIGURE 44.1 Fungus family.

Fungi can produce disease in humans only if they can grow at the temperature of the infected body site. Fungi that cannot grow at core body temperature are called **dermatophytes.** Infections caused by these fungi are contained at the cutaneous level of the body. They are called superficial mycoses, as opposed to systemic mycoses, which are serious, deep-tissue fungal infections caused by organisms capable of growth at core body temperature.

Normally, the body has yeast colonies on the skin, mucous membranes, and gastrointestinal (GI) tract. Intact immune mechanisms and competition for nutrients, provided by the body's normal bacterial flora, ordinarily keep colonizing fungi in check. Alteration of either of these components by disease states or antibiotic therapy can upset the balance, permitting fungal overgrowth and opportunistic infections.

PATHOPHYSIOLOGY OF SELECTED OPPORTUNISTIC FUNGAL INFECTIONS

Aspergillosis

Aspergillus is a fungus commonly found in soil, water, and decaying vegetation. It has been cultured from unfiltered air, ventilation systems, contaminated dust dislodged during hospital renovation and construction, horizontal surfaces, food, and ornamental plants. It has been recognized increasingly as a cause of severe illness and mortality in highly immunocompromised patients, such as those undergoing chemotherapy, those with acquired immunodeficiency syndrome (AIDS), or those with bone marrow or vital organ transplants.

Infection with *Aspergillus* that is airborne may be acquired by inhaling the fungal spores. In severely immunocompromised patients, primary aspergillus pneumonia results from local lung tissue invasion. Colonization of the lower respiratory tract by *Aspergillus* in patients with pre-existing lung disease, such as chronic obstructive lung disease, cystic fibrosis, or inactive tuberculosis, can predispose patients to invasive pulmonary or disseminated infection. After pulmonary invasion, the fungus may disseminate through the bloodstream to involve multiple organs. The most reliable technique for diagnosis is a lung biopsy, although the fungus may be cultured from sputum or from specimens acquired by bronchoalveolar lavage.

Candidiasis

Candida is a yeast-like fungus that is almost always present as part of the normal population of organisms in the mouth, skin, intestinal tract, and vagina. The immune system and other organisms in the mucous membranes normally prevent it from growing in colonies. However, in immunocompromised patients, deterioration of the immune system can lead to candidal colonization; most outbreaks occur when the $CD4^+$ T-cell count falls below 400 mm^3.

Human immunodeficiency virus (HIV)–infected infants and children are particularly prone to serious and extensive candidal infections. Other factors that can promote growth

of *Candida* species in healthy individuals include use of broad-spectrum antibiotics (which alter the natural population of organisms in the mouth and vagina); use of topical and systemic corticosteroids; diabetes; ill-fitting dentures; drugs or conditions that alter saliva flow; radiation therapy; cancer; chemotherapy; nutritional deficiency in iron, folate, vitamin B_{12}, or zinc; oral contraceptives with a high estrogen content; pregnancy; poor oral or dental hygiene; smoking; stress; depression; and use of antihistamines.

Cryptococcosis

Cryptococcosis, which usually manifests as cryptococcal meningitis, is the most serious of the fungal infections in immunocompromised patients. Cryptococcosis rarely occurs when the $CD4^+$ T-cell count is over 100 mm^3 and is most likely when the count drops below 50 mm^3. It is caused by a yeast-like organism, *Cryptococcus neoformans*. This fungus is widespread in the environment, especially in soil containing bird droppings. Exposure occurs when contaminated sources become airborne and are inhaled.

In people with intact immune systems, the fungus may form inactive fungal nodules in the lungs, which may be visible on x-ray films and can later produce active infection when the immune response decreases. As cryptococcosis progresses, from either the original infection or a later reactivation, it can take three forms (more than one of which may be present):

- Central nervous system (CNS) infection
- Pulmonary infection
- Disseminated infection

Meningitis, inflammation of the membranes surrounding the spinal cord or brain, is the most common manifestation of cryptococcal infection.

Mucormycosis

Mucormycosis, also known as zygomycosis, is a fungal infection of the sinuses, brain, or lungs caused by fungi such as *Mucor* or *Rhizopus*. These common fungi are found in soil and decaying vegetation. The spores are inhaled into the body through the mouth and nose. In the immunocompetent person, the spores are destroyed by phagocytosis. In the immunocompromised patient, the spores attach to the nasal or oral mucosa. The spores can then spread into the nasal cavity and maxillary sinuses. The spores can also invade the blood vessels, causing systemic spread, or a local inflammatory or thrombotic effect on the vessels.

Common syndromes associated with mucormycosis include rhinocerebral infection, pulmonary infection, or mucormycosis of the GI tract, skin, or kidneys. Symptoms associated with rhinocerebral infection include orbital and facial pain, headache, visual changes, acute sinusitis, fever, proptosis (protrusion of eye orbit), and erythema (redness) of skin overlying sinuses. Necrotic tissue may be seen on the nasal turbinates, septum, and palate. Symptoms of pulmonary involvement include cough, hemoptysis, and shortness of breath. Patients with GI involvement may have abdominal pain or vomiting.

Without treatment, mucormycosis has a mortality rate of 30% to 70%. Unlike other fungal diseases, mucormycosis requires surgical débridement of necrotic tissues in addition to pharmacotherapy to resolve the infection.

PATHOPHYSIOLOGY OF SELECTED NONOPPORTUNISTIC FUNGAL INFECTIONS

Blastomycosis

Blastomycosis is a chronic infection characterized by granulomatous and suppurative lesions. It is caused by inhaling the dimorphic fungus *Blastomyces dermatitidis*. Blastomycosis is endemic in eastern parts of the United States, but it also is seen throughout Canada and Central America.

Two basic forms of blastomycosis are recognized: pulmonary and chronic cutaneous. Most infections originate in the lungs and then disseminate to any organ, but usually to the skin and bones. In chronic cutaneous blastomycosis, the initial skin lesion presents as one or more subcutaneous nodules that eventually ulcerate. They are most common on exposed skin, such as that of the face, hands, wrist, and lower leg. Diagnosis is usually made by direct culture, agents that contain potassium hydroxide, special stains, and measurement of complement-fixing antibodies to various antigens.

Coccidioidomycosis

Coccidioidomycosis (valley fever) is primarily a disease of the lungs, which is common in the southwestern United States and northwestern Mexico. It is caused by the fungus *Coccidioides immitis,* which grows in soil. The fungal spores become airborne when the soil is disturbed by wind, construction, farming, and other activities. Within the lung, the spore changes into a larger, multicellular structure called a spherule. The spherule grows and bursts, releasing endospores, which develop into other spherules. Person-to-person transmission does not occur.

Most cases of coccidioidomycosis are mild. It is thought that more than 60% of infected people either have no symptoms or experience flu-like symptoms and never seek medical attention. Among patients who seek medical care, the most common symptoms are fatigue, cough, chest pain, fever, rash, headache, and joint aches. Some people develop erythema nodosum, which produces painful red bumps that gradually turn brown.

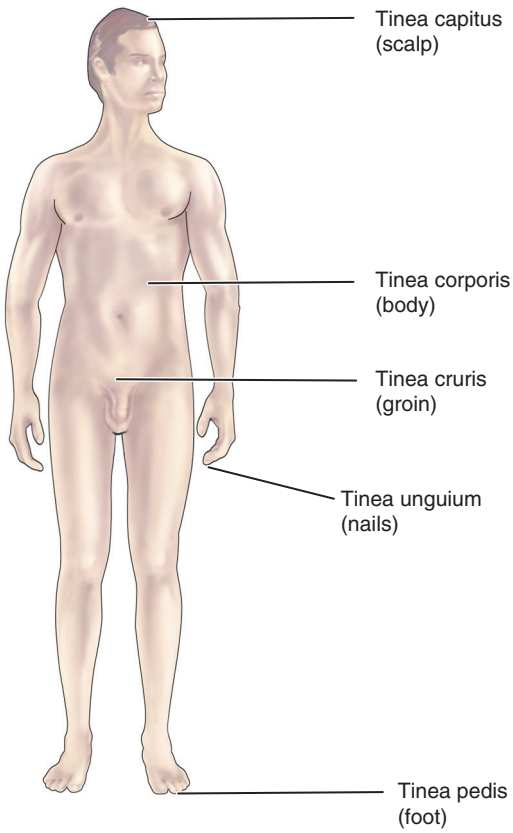
Disseminated disease occurs in less than 0.5% of patients. In patients with disseminated disease, spores may be found in lymph nodes and meningeal, spleen, liver, kidney, and adrenal tissues. Meningitis is the most common cause of death. Patients at risk for disseminated disease are immunocompromised and include patients who have undergone organ transplantation and those with lymphoma, HIV infection, adrenal corticosteroid therapy, or diabetes. Disseminated disease also occurs more frequently in men, in African Americans and Filipinos, and in pregnant women during the third trimester.

Dermatophytic Infections (Tinea, Ringworm)

Dermatophytic infections are commonly called **tinea** or ringworm. It is not a worm infection as the name suggests; rather, it is a fungal infection caused by mold-like fungi called dermatophytes. Tinea lives on the dead tissues on the skin and any structures that grow from the skin (such as hair or nails).

Tinea can affect most skin sites, depending on the specific fungal type. The descriptive terms used in Figure 44.2 refer to the location of the infection and not to the specific type of fungus involved. A slightly different type of tinea infection is known as tinea versicolor. This chronic, noninflammatory infection is characterized only by patchy, hypopigmented discoloration of the skin (Figure 44.3).

The classic features of tinea are itching, redness on the skin, and a circular patchy lesion that spreads along its borders and clears at the center. In time, it may appear as a ring or a series of rings around a clear center, hence its common name, ringworm. These particular characteristics may not always be seen in every infected person; lack of certain signs or symptoms or the presence of additional signs or symptoms depends on which site is infected and how advanced the disease is. On the palms of the hands or soles of the feet, redness may be the only sign. Sometimes there are deep-seated blisters on the soles of the feet that, with time, dry and end up as brown crusts. There may be thick, white scales between the toes. Nails can turn thick and white and eventually crumble if untreated. On the scalp, there may be hair loss as the hairs break off at their shafts.



• FIGURE 44.2 Types of tinea infections.

• FIGURE 44.3 Tinea versicolor.

Histoplasmosis

Histoplasmosis is a fungal infection that affects the lungs or other organs by dissemination. The disease is acquired by inhaling fungal spores. Outbreaks may occur in groups who have been exposed to bird or bat droppings or recently disturbed contaminated soil found in chicken coops or caves. Person-to-person spread of histoplasmosis does not occur. Although anyone can get histoplasmosis, it more often infects immunocompromised patients. Infection usually results in increased resistance to further infection, although the immunity is not complete. Symptoms vary from mild to severe, ranging from flu-like illness to serious lung infection.

There are four clinical forms of histoplasmosis. The most common is acute pulmonary histoplasmosis. Patients with this form of the infection experience a flu-like cough, chest pains, dyspnea, fever, weight loss, and hemoptysis. The symptoms may resolve spontaneously. In children, primary histoplasmosis can lead to disseminated infection. Therefore, children who have HIV and histoplasmosis should receive suppressive therapy for life. The second form of histoplasmosis is chronic pulmonary histoplasmosis, which may develop after acute infection; this form resembles pulmonary tuberculosis. The third form is termed acute disseminated histoplasmosis. Patients with this form may develop hepatosplenomegaly, fever, and prostration. This type of histoplasmosis is usually fatal. The last form of histoplasmosis is termed chronic disseminated histoplasmosis, which may present a diagnostic problem because of the extremely varied presentation. Like the acute form, it also may be fatal.

ANTIFUNGAL AGENTS

Antifungal drugs are generally grouped according to their pharmacotherapeutics into those used to manage systemic infections and those used to manage superficial infections, although some of the antifungal drugs may be used for both.

• Polyene Antifungal Agents

Polyene antimicrobials include amphotericin B and nystatin. These drugs have high affinity for fungal infections and

are therefore useful for treating systemic fungal infections. Unfortunately, the polyene antifungal drugs also have the ability to induce severe adverse effects. Amphotericin B (Fungizone) is the prototype polyene antifungal drug. Table 44.1 presents a summary of selected antifungal agents.

Nursing Management of the Patient Receiving P Amphotericin B

Core Drug Knowledge

Pharmacotherapeutics

Amphotericin B is an antifungal agent used to treat progressive and potentially fatal systemic fungal or protozoal infections. It has a wide spectrum of activity against many fungi, including *Aspergillus, Blastomyces, Candida, Coccidioides, Cryptococcus*, and *Histoplasma*. Certain protozoan infections also are sensitive to amphotericin B, including *Leishmania,* and *Naegleria*.

Intravenous (IV) amphotericin B is available as its conventional formula (amphotericin B deoxycholate [Fungizone]) and three lipid- formulations: amphotericin B lipid complex (Abelcet), amphotericin B cholesteryl sulfate (Amphotec), and liposomal amphotericin B (AmBisome). All of the formulations are used for serious or life-threatening fungal infections. The lipid formulas induce less adverse effects than the conventional formula, especially nephrotoxicity.

TABLE 44.1 Summary of Selected C Antifungal Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P amphotericin B deoxycholate (Fungizone) amphotericin B lipid complex (Abelcet), amphotericin B cholesteryl sulfate (Amphotec), liposomal amphotericin B (AmBisome)	Progressive and potentially fatal systemic fungal or protozoal infections	Fungizone *Adult IV*: 0.1 – 1.5 mg/kg/d Abelcet *Adult IV*: 5 mg/kg/d Amphotec *Adult IV*: 3-4 mg/kg/d AmBisome *Adult IV*: 3-5 mg/kg/d	*Onset:* 20–30 min *Duration:* 20–24 h $t_{1/2}$: 24 h initially and then 15 d; Abelcet, 173.4 h
anidulafungin (Eraxis)	Candidemia or disseminated candidiasis Esophageal candidiasis	*Adult*: IV, 200 mg on first day, then 100 mg once daily	*Onset*: rapid *Duration*: 6 d $t_{1/2}$: 40–50 h
caspofungin (Cancidas)	Invasive aspergillosis Esophageal or oropharyngeal candidiasis	*Adult*: IV, 70 mg on first day then 50 mg/d *Adolescent and child*: Safety not established	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: Triphasic: alpha phase, short; beta phase, 9–11 h; terminal phase, 40–50 h
flucytosine (Ancobon)	Serious infections caused by susceptible strains of *Candida, Cryptococcus*	*Adult*: PO, 50–150 mg/kg/d q6h	*Onset*: Varies *Duration*: 10–12 h $t_{1/2}$: 2–5 h
micafungin (Mycamine)	Candidemia Esophageal candidiasis Prophylaxis of *Candida* infection in hematopoietic stem cell transplantation	*Adult*: IV, 100 mg daily *Adult*: IV, 150 mg daily *Adult*: IV, 50 mg daily *Adolescent and child*: Safety not established	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: 10–15 h
nystatin (Mycostatin)	Candidiasis—oropharyngeal, cutaneous, mucocutaneous, vulvovaginal, intestinal	*Adult*: PO, 500,000–1,000,000 U tid, continued for at least 48 h after clinical cure; PO suspension, 400,000–600,000 U qid (½ dose in each side of mouth; retain the drug as long as possible before swallowing); troche, dissolve 1–2 tablets in mouth 4–5× daily up to 14 daily; vaginal preparation, 1 tablet (100,000 U) intra-vaginally daily for 2 wk; topical, apply to affected area 2–3× daily until healing is complete *Child*: Oral suspension (infants), 200,000 U qid (100,000 in each side of mouth); oral suspension (premature and low-birth-weight infants), 100,000 U qid	Not generally absorbed systemically

Pharmacokinetics

Amphotericin B is no longer available in the United States as an oral preparation. Distribution of IV amphotericin B is limited; it crosses the placenta and may pass into breast milk. Lower concentrations are achieved in aqueous humor and pleural, pericardial, peritoneal, and synovial fluids. Because cerebrospinal fluid (CSF) concentrations are approximately 3% of those in serum, amphotericin B must be given intrathecally to achieve fungistatic concentrations within the CSF.

The metabolism of amphotericin B is unknown. It is presumed that the drug enters the tissues of the body and is released slowly over time. After therapy is discontinued, amphotericin B can be detected for up to 4 weeks in blood and 4 to 8 weeks in urine. The initial half-life is approximately 24 hours, followed by a second elimination phase with a half-life of about 15 days.

Pharmacodynamics

Amphotericin B works by binding to sterols in fungal cell membranes. This binding appears to form pores or channels and results in increased cell permeability, cell leakage, and death. Because human cells also contain sterols, damage to the host's cells also may occur. At low concentrations, amphotericin B is fungistatic; higher concentrations may induce fungicidal activity.

Contraindications and Precautions

Hypersensitivity is the only contraindication for all four of the formulations. Amphotericin B can cause anemia, hypokalemia, and hypomagnesemia. The drug should be administered cautiously to patients with any of these conditions because parenteral therapy with amphotericin B can cause substantial renal electrolyte loss. For patients with pre-existing renal impairment, the patient should be monitored for signs of nephrotoxicity. Amphotericin B is assigned to pregnancy category B and should be used with caution during pregnancy and lactation. Of course, for life-threatening infections, amphotericin B can be given despite the contraindications.

Adverse Effects

Amphotericin B has an extensive adverse effects profile. In fact, some clinicians refer to it as "amphoterrible." Nephrotoxicity occurs in 5% to 80% of patients receiving IV amphotericin B. Nephrotoxicity is manifested in many forms, including renal insufficiency, azotemia, hyposthenuria, renal tubular acidosis, and frank renal failure.

Administration of IV amphotericin B may induce infusion- related reactions, such as headache, chills, fever, rigors, hypotension, bronchospasm, and nausea and vomiting. Administration over more than 4 hours may decrease the severity of these symptoms. Infusion reactions are also less severe when a lipid-based formulation of amphotericin B is administered.

Electrolyte abnormalities, including hypokalemia, hypomagnesemia, hypochloremia, and hypocalcemia, also may occur with amphotericin B therapy. Patients with pre-existing cardiac problems may have exacerbations of their disorders when electrolyte abnormalities occur.

A normocytic, normochromic anemia occurs in most patients receiving amphotericin B. This reaction is believed to be caused by a suppressive effect on erythropoietin production and bone marrow. Transfusions are not usually necessary, and the anemia resolves when therapy is discontinued. Leukopenia and thrombocytopenia also may occur.

Less common adverse effects from amphotericin B consist of ventricular fibrillation, hypertension, cardiac arrest (primarily in situations when infusion is too rapid), hypersensitivity, peripheral neuropathy, and seizures.

Intrathecal amphotericin B can cause blurred vision and, in some cases, difficulty in urination. Polyneuropathy or paresthesias can occur in some patients, resulting in numbness, tingling, pain, or weakness.

Drug Interactions

Amphotericin B should not be coadministered with drugs known to be nephrotoxic or hemotoxic, such as antineoplastic agents, cyclosporine, tacrolimus, or aminoglycosides. It should not be used with drugs that may be affected by electrolyte imbalances, such as corticosteroids, digitalis glycosides, and thiazide diuretics. Other drugs that interact with amphotericin B include neuromuscular blocking agents, imidazoles, and flucytosine. Table 44.2 lists agents that interact with amphotericin B.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a patient history to evaluate for pre-existing renal dysfunction, cardiac disease, electrolyte imbalance, or anemia. Also, assess for use of diuretics or for any concurrent drugs known to be nephrotoxic. Communicate any positive findings to the prescriber.

Perform a complete physical examination, especially assessing the renal system. For patients with pre-existing cardiac disease, a baseline electrocardiogram (ECG) should be performed. Baseline laboratory values should include complete blood count (CBC), complete metabolic profile, and renal function tests.

Life Span and Gender

Assess for pregnancy and lactation. Amphotericin B may be given during pregnancy. However, because of the potential adverse effects, it should be given only when absolutely needed. It should not be given to breast-feeding women because of its potential effects on the infant.

It is important to note the patient's age before administering amphotericin B. Safety of amphotericin B has not been demonstrated in children and older adults. Closely monitor patients when giving them this drug. Elderly patients are more likely to have decreased renal function, which may increase the risk of nephrotoxicity.

TABLE 44.2 Agents That Interact with P Amphotericin B

Interactants	Effect and Significance	Nursing Management
antineoplastic agents	Coadministration of antineoplastic agents and amphotericin B increases the risks for renal toxicity, bronchospasm, and hypotension.	Monitor for adverse effects. Monitor BUN and creatinine levels. Discuss adjustment of dosage with prescriber as needed.
corticosteroids	Concurrent use may cause potential hypokalemia.	Do not coadminister unless needed for control of adverse reactions.
cyclosporine	The nephrotoxic effects of cyclosporine are increased with the addition of amphotericin B. The mechanism of action is unknown.	Monitor BUN/creatinine. Monitor intake and output. Contact the provider immediately if signs of nephrotoxicity occur.
hemotoxic agents	Concurrent use increases the risk for anemia, neutropenia, and thrombocytopenia.	Monitor drug levels closely. Monitor CBC. Monitor for signs of blood dyscrasias. Discuss adjustment of dosage with prescriber as needed.
nephrotoxic agents	Concurrent use increases the risk for nephrotoxicity.	Monitor drug levels closely. Monitor BUN and creatinine levels. Monitor intake and output. Discuss adjustment of dosage with prescriber as needed.
zidovudine	Coadministration increases the risk of myelosuppression and nephrotoxicity.	Monitor BUN and creatinine levels. Monitor CBC. Discuss adjustment of dosage with prescriber as needed.

Lifestyle, Diet, and Habits

Assessing fluid intake in patients on amphotericin B therapy is important. Make sure that patients on amphotericin B therapy are kept well hydrated. This practice may minimize the potential for nephrotoxicity.

Environment

Amphotericin B should be administered in an acute care environment, although therapy with amphotericin B may last for months. Be familiar with administration of IV amphotericin B. Do not reconstitute the drug with a bacteriostatic agent in the solution because doing so may lead to precipitation.

Nursing Diagnoses and Outcomes

- Risk for Injury related to infusion reaction or to electrolyte imbalance imposed by drug therapy
  Desired outcome: *The patient will remain free from injury during drug administration or respond without injury to electrolyte replacement therapy.*
- Ineffective Protection related to drug-induced leukopenia and thrombocytopenia
  Desired outcome: *The patient will remain free from opportunistic infections resulting from leukopenia and thrombocytopenia.*
- Excess Fluid Volume related to renal dysfunction resulting from drug therapy
  Desired outcome: *The patient will have an appropriate ratio of fluid intake to output.*
- Acute Pain related to infusion reaction
  Desired outcome: *The patient will have a decrease in pain after administration of analgesic drug, such as meperidine (Demerol).*
- Ineffective Breathing Patterns due to drug-induced bronchospasm
  Desired outcome: *The patient will maintain adequate oxygenation.*
- Ineffective Cardiopulmonary Tissue Perfusion related to cardiac arrest or arrhythmias resulting from drug therapy
  Desired outcome: *The patient will remain adequately perfused.*
- Disturbed Sensory Perception: Visual, due to drug-related blurred vision
  Desired outcome: *The patient will regain adequate vision after therapy concludes.*
- Risk for Injury related to drug effects of numbness, tingling, or weakness
  Desired outcome: *The patient will remain injury free throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Patients may desire to stop amphotericin B therapy if they have infusion reactions. Prepare the patient for the possibility of this reaction. Also, provide comfort measures, such as

extra blankets, diversion therapy, or warm fluids, to offset the discomfort of this reaction. To reduce the potential for infusion reactions, flucytosine may be prescribed concurrently to decrease the dosage of amphotericin B. Because there is a positive drug–drug interaction between these two, the therapeutic effect remains constant.

Minimizing Adverse Effects

Administer test dose as ordered by provider. Be prepared for the possibility of an infusion reaction which may begin 15 minutes to 3 hours after the initiation of the infusion. Administer preordered drugs, such as diphenhydramine and acetaminophen, before starting therapy to minimize an infusion reaction. Be prepared to administer dantrolene or meperidine if rigors occur. In some cases, steroids may be required. Coordinate the administration of amphotericin B with possible blood transfusions. Infusion-related reactions can be more severe if administration occurs shortly after platelet or granulocyte transfusions.

Administer amphotericin B in a central line, if possible, and make sure that the IV administration set has an in-line filter. Place the solution on an infusion pump and deliver the drug over 2 to 4 hours. If using peripheral veins, rotate the infusion site to decrease the potential of phlebitis. Infuse at the appropriate rate for the specific type of amphotericin B being administered:

- Fungizone: over 6 hours
- Abelcet: 2.5 mg/kg/h
- Amphotec: 1 mg/kg/h over at least 2 hours
- AmBisome: over more than 2 hours

Monitor the patient carefully for signs of nephrotoxicity. In addition to accurately recording fluid input and output, monitor renal function tests and notify the prescriber immediately if the creatinine is higher than 3.5 mg/dL. Be sure the patient remains well hydrated. Administering 1 liter of saline on the day of infusion (sodium loading) decreases the potential for nephrotoxicity.

Coordinate the care of the patient when multiple prescribers are writing orders for the patient. To prevent orders for other nephrotoxic drugs, all prescribers must know that amphotericin B is being administered.

Providing Patient and Family Education

- Describe and explain the possibility of an infusion reaction and the importance of notifying staff immediately if symptoms occur.
- Explain possible adverse effects of amphotericin B and the need for serial blood tests. Because the adverse effects of amphotericin B can induce severe complications, it is important to explain the necessity of reporting any change from baseline that may occur.
- Another important area to discuss with patients and family is the importance of an accurate fluid intake and output record. It is necessary to enlist the assistance of patients and their families to document fluid intake and output as needed.
- Instruct patients to immediately report to the prescriber any symptoms of altered protection against infection, such as easy bruising, sore throat, or fatigue. In addition, tell patients to report CNS symptoms such as numbness, tingling, or weakness.

Ongoing Assessment and Evaluation

During the first dose of amphotericin B, take vital signs every 15 minutes. At this time, evaluate the patient for possible infusion reactions. Should a severe reaction occur, stop the infusion, call for another nurse to stay with the patient, and contact the prescriber immediately. Also, monitor the IV site during administration for signs of phlebitis, because amphotericin B is very irritating to tissues. Assess the infusion solution frequently and discontinue if a precipitate forms.

Throughout therapy, coordinate the collection of samples for laboratory tests, including a CBC, complete metabolic panel, and renal function tests. Renal function testing should be performed every 3 to 4 days. Weigh the patient daily and evaluate fluid intake and output every shift.

It is important to monitor patients with pre-existing cardiac disease for exacerbation of their symptoms. Fluid overload and electrolyte imbalances place these patients at high risk for a cardiac event.

Monitor for adverse effects that may place the patient at increased risk of injury. For patients with sensory-perceptual disturbances or numbness, tingling, and weakness, ensure that the patient understands the need for assistance to and from the bed. Keep the bed in the low position and the side rails up at all times.

MEMORY CHIP

P Amphotericin B

- Used for severe systemic fungal or protozoal infections
- Major contraindication: hypersensitivity
- Most common adverse effects: infusion reactions, electrolyte abnormalities, and anemia
- Most serious adverse effect: nephrotoxicity
- Maximizing therapeutic effects: Prepare the patient for the possibility of an infusion reaction so that the patient does not cease therapy.
- Minimizing adverse effects: Do not administer with other nephrotoxic drugs to minimize the potential for nephrotoxicity.
- Most important patient education: Discuss the potential for an infusion reaction and the need to monitor the hematopoietic and renal systems closely.
- **Black box warning: Amphotericin B deoxycholate should only be used for life-threatening systemic fungal infections.**
- **Patient safety alert: There are four formulations of amphotericin B. Use caution to administer the correct formula at the correct infusion rate.**

Use strict aseptic technique for patients receiving amphotericin B. Most patients have anemia related to the therapy, which increases the risk of infection.

By the end of therapy, the fungal infection should be resolved. In addition, all adverse effects should be identified and appropriate intervention should be started.

Drugs Closely Related to P Amphotericin B

Nystatin (Mycostatin) is an antifungal antibiotic that is nearly identical to amphotericin B in structure. It is available in topical, vaginal, and oral formulations. This agent is not used for systemic fungal infections, because it is poorly absorbed from the GI tract and has high potential for toxicity. Nystatin is used to treat oropharyngeal, cutaneous, mucocutaneous, and vulvovaginal candidiasis.

Adverse effects from nystatin are uncommon. Oral doses can cause mild and transient nausea and vomiting, diarrhea, and abdominal pain. Topical and vaginal forms may produce skin irritation, rash, or urticaria.

The oral suspension of nystatin is called a "swish and swallow" drug. Advise the patient to swish the solution throughout the mouth and then swallow or spit out the drug as directed by the prescriber. When nystatin troches are prescribed, advise the patient to allow them to dissolve completely in the mouth and not to chew or swallow the intact troche. The troche may take up to 30 minutes to dissolve.

Drugs Significantly Different From P Amphotericin B

Echinocandins

Echinocandins are a new class of drugs that have a different mechanism of action than amphotericin B. Echinocandins work by inhibiting the synthesis of a major fungal cell wall component, β-(1,3)-D-glucan, which is not present in human cell walls. Because of their unique mechanism of action, cross-resistance with other antifungal classes of drugs is unlikely.

Anidulafungin

Anidulafungin (Eraxis), an IV antifungal agent, is an echinocandin. It is indicated for candidemia, candida infection of the esophagus, and disseminated candidiasis such as intra-abdominal infection or peritonitis. Anidulafungin undergoes slow chemical degradation at physiologic temperature and pH and is excreted mostly in feces.

The only contraindication to anidulafungin use is hypersensitivity. It is given cautiously to patients with hepatic dysfunction or during pregnancy. Common adverse effects include hypokalemia, headache, nausea, and diarrhea. Less frequent but serious adverse effects include deep vein thrombosis, liver dysfunction, ECG changes, and seizures. Anidulafungin may also induce histamine-mediated symptoms such as rash, urticaria, flushing, pruritus, dyspnea, and hypotension. Limiting the rate of infusion to 1.1 mg/minute decreases the frequency of these adverse effects. There are no significant drug–drug interactions with anidulafungin. It is a pregnancy category C and believed to be excreted in breast milk, so it should not be given to women who are breast-feeding. Anidulafungin has not been approved for use in children.

Caspofungin

Caspofungin (Cancidas) has the same indications as anidulafungin. In addition, it is given for invasive aspergillosis and empiricallyfor febrile neutropenia.

Caspofungin has more precautions than anidulafungin. It is given cautiously to patients with liver impairment, myelosuppression, and renal insufficiency. Hypersensitivity reactions, including anaphylaxis, have occurred but are rare. Common adverse effects associated with the use of caspofungin include abdominal pain, diarrhea, elevated temperature, AST/ALT and alkaline phosphatase, and decreased potassium.

Several drug–drug interactions may occur with caspofungin. When it is given concurrently with P-450 inducers, serum caspofungin levels are substantially decreased. These drugs include carbamazepine, dexamethasone, efavirenz, phenytoin, fosphenytoin, nevirapine, and rifampin. When caspofungin is given concurrently with cyclosporine, caspofungin levels increase, thus increasing the risk of hepatotoxicity. When it is given concurrently with tacrolimus, serum tacrolimus levels are substantially decreased. Caspofungin has the same pregnancy and lactation precautions as anidulafungin and is not recommended for use in children.

Micafungin

Micafungin (Mycamine) is approved for use in the management of esophageal candidiasis, treatment of candidemia, acute disseminated candidiasis, and other candidal infections such as peritonitis and abscesses, and as prophylaxis for patients receiving a bone marrow transplant. It is given cautiously to patients with hepatic and renal dysfunction and in patients with prior hypersensitivity to the other echinocandins, anidulafungin and caspofungin. Common adverse effects include phlebitis at the infusion site, GI effects such as abdominal pain, diarrhea, nausea or vomiting, headache, fever, and abnormal liver function tests. Serious adverse effects include hemolytic anemia/hemoglobinuria, new onset or worsening hepatic failure, elevated BUN, serum creatinine, renal dysfunction, and/or acute renal failure. As with anidulafungin, a histamine-related reaction may occur. Rarely, life-threatening anaphylaxis has occurred.

Micafungin needs to be light-protected during infusion. To decrease the potential of a histamine reaction, the drug should be infused over 1 hour. Micafungin has the same pregnancy and lactation precautions as anidulafungin and caspofungin and is not recommended for use in children.

Flucytosine

Flucytosine (Ancobon) is an oral pyrimidine analog. It is approved for the treatment of meningitis or pulmonary infections caused by *Candida*. In addition, it is approved for septicemia, endocarditis, urinary tract infections, and pulmonary

infections caused by cryptococcus. Frequently, flucytosine is given with amphotericin B to avoid resistance.

Flucytosine acts as an antimetabolite, interfering with pyrimidine metabolism and eventually disrupting both RNA and DNA synthesis. It is not metabolized; more than 90% is excreted by glomerular filtration as unchanged drug. Therefore, it is used cautiously in patients with pre-existing renal impairment. It also is used with caution in patients with pre-existing depression of bone marrow function, recent radiation therapy or cytotoxic drug therapy, dental disease, or a history of a hematologic disease, because these patients are most susceptible to flucytosine's myelosuppressive effects. In patients with hepatic disease, flucytosine can cause hepatitis or jaundice. There is a black box warning to avoid use as monotherapy because resistance develops rapidly.

Flucytosine can induce serious adverse effects. It carries a black box warning to closely monitor hematologic, renal, and hepatic status throughout therapy. All patients must be monitored weekly, especially those who are concurrently taking other drugs also known to cause these toxicities. Flucytosine is toxic to rapidly proliferating tissues, such as the bone marrow and the lining of the GI tract. Therefore, common hematologic adverse effects include anemia, leukopenia, and thrombocytopenia. GI adverse effects include abdominal pain, diarrhea, nausea, vomiting, and anorexia. Other adverse effects caused by flucytosine include hepatic dysfunction, photosensitivity, and CNS effects, such as dizziness, headache, and lightheadedness. Flucytosine is assigned to pregnancy category C and is contraindicated for use during pregnancy and breastfeeding. It is not approved for use in children.

• Azole Antifungal Drugs

The azole antifungal drugs can be classified into two subgroups: imidazoles and triazoles. These two groups differ slightly in their chemical structures but have similar clinical applications. Azole antifungal drugs can be used for both superficial mycoses and more serious systemic mycoses. Fluconazole (Diflucan) is the prototype azole antifungal drug. Table 44.3 presents a summary of azole antifungal agents and Table 44.4 lists topical azole agents.

Nursing Management of the Patient Receiving P Fluconazole

Core Drug Knowledge

Pharmacotherapeutics

Fluconazole is a triazole antifungal agent with a wide spectrum of activity. It is used for esophageal or oropharyngeal candidiasis, candida vaginitis, candiduria, disseminated candidiasis, and cryptococcal meningitis. It is also used prophylactically against fungal infections in patients receiving bone marrow transplants, in immunocompromised patients with a $CD4^+$ T-cell count less than 200 mm^3, and against coccidioidomycosis, cryptococcosis, and histoplasmosis in patients with $CD4^+$ T-cell counts below 50 mm^3.

Pharmacokinetics

Fluconazole is administered orally and intravenously. The pharmacokinetics of both oral and IV fluconazole are similar. GI absorption is rapid and almost complete. Oral bioavailability is more than 90% in fasting adults, and peak serum concentrations are attained within 1 to 2 hours after oral administration.

Fluconazole is distributed widely into body tissues and fluids. Saliva, sputum, nail, blister, and vaginal secretion concentrations are approximately equal to plasma concentrations. High concentrations also can be achieved in the cornea, aqueous humor, and vitreous body following IV administration. Fluconazole distributes well into the CSF and achieves CSF concentrations that are 60% to 80% of plasma concentrations, regardless of the degree of meningeal inflammation. Fluconazole crosses the placenta and enters breast milk. Elimination is mainly renal; about 60% to 80% of a dose is excreted in the urine unchanged and 11% as metabolites. Small amounts of fluconazole are excreted in the feces. Elimination of the drug can be impaired in elderly patients.

Pharmacodynamics

Fluconazole works directly by altering the fungal cell membrane. Fluconazole inhibits synthesis of ergosterol, a cytochrome P-450 enzyme that is an essential component of the fungal membrane. Inhibition of ergosterol synthesis results in increased cellular permeability, causing leakage of cellular contents. Other proposed antifungal effects of fluconazole include inhibition of endogenous respiration, interaction with membrane phospholipids, and inhibition of the transformation of yeasts to molds. It has no direct effects on the body.

Contraindications and Precautions

There are no absolute contraindications to fluconazole use. It should be used with caution during pregnancy and in patients with pre-existing hepatic and renal dysfunction.

Adverse Effects

Triazoles, such as fluconazole, are generally well tolerated. Gastrointestinal symptoms are most frequently reported, including nausea, abdominal pain, vomiting, and diarrhea. Mild elevations in levels of alanine transaminase, aspartate transaminase, alkaline phosphatase, and bilirubin may occur. These abnormalities usually return to pretreatment levels after therapy is completed. Rarely, hepatotoxicity has been reported.

Other symptoms that have occurred during fluconazole therapy include alopecia and exfoliative skin disorders, such as Stevens-Johnson syndrome. These conditions occur most frequently in HIV-infected patients and in patients with a concurrent malignancy who are taking multiple drugs. A direct causative relationship has not been determined. Rarely, fluconazole therapy may induce hypokalemia, eosinophilia, and thrombocytopenia.

TABLE 44.3 Summary of Selected Azole Antifungal Agents

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P fluconazole (Diflucan)	oropharyngeal,	*Adult:* PO/IV, 200 mg on first day, followed by 100-200 mg/d for 7–14 d *Child:* PO/IV, 6 mg/kg on the day 1, followed by 3 mg/kg once daily	*Onset:* PO, slow; IV, immediate *Duration:* 2–4 days $t_{1/2}$: 30 hours
	Esophageal candidiasis	*Adult PO/IV:* 400 mg loading dose, then 200–400 mg daily for 14–21 d *Child PO/IV:* 6 mg/kg on the day 1, followed by 3 mg/kg once daily	
	Vaginal candidiasis Candidal urinary tract infections	*Adult PO:* 150 mg one time only *Adult PO: 200 mg daily for 14 d*	
	cryptococcal meningitis	*Adult:* PO/IV, 400 mg daily as consolidation dose; then 200 mg daily as maintenance dose *Child:* PO/IV, 12 mg/kg on first day, followed by 6 mg/kg once daily;	
	Histoplasmosis; blastomycosis; coccidioidomycosis Candidemia/invasive candidiasis	*Adult PO:* 400–800 mg daily *Adult PO/IV*: 800 mg loading dose followed by 400 mg daily *Child PO/IV*: 6–12 mg/kg/d	
itraconazole (Sporanox)	Oropharyngeal or esophageal candidiasis	*Adult solution:* 200 mg daily	*Onset:* rapid *Duration:* end of infusion $t_{1/2}$: 20–40 h
	Histoplasmosis/blastomycosis Coccidioidomycosis	*Adult PO/IV:* 200–400 mg daily *Adult PO/IV:* 400 to 600 mg in two divided doses	
	Allergic bronchopulmonary aspergillosis	*Adult PO/IV:* 200 mg twice daily	
	Onychomycosis	*Adult PO:* 200 mg daily (toenails) for 12 weeks 200 mg 2x day for 1 week (fingernails) *Child:* safety not established	
ketoconazole (Nizoral)	Systemic fungal infections	*Adult*: PO, 200 mg daily, up to 400 mg/d; treat from 3 wk to 6 mo, depending on infecting organism and site *Child*: PO, >2 y, 3.3–6.6 mg/kg/d as a single dose; <2 y, safety and efficacy not established	*Onset*: PO, varies; topical, slow, not appreciably systemically absorbed *Duration*: Unknown $t_{1/2}$: 8 h
	Dermatophytosis, tinea corporis, tinea cruris, tinea versicolor	*Adult*: Topical, apply daily to affected area; may be treated twice daily; continue treatment for at least 2 wk *Child*: Topical, >2 y, same as adult; <2 y, safety and efficacy not established	
posaconazole (Noxafil)	Prophylaxis for aspergillosis Oropharyngeal candidiasis	*Adult:* PO, 200–300 mg 3×/d *Adult PO:* 100 mg 2x first day, then 100 mg daily for 13 days	*Onset:* 1–2 h *Duration:* Unknown $t_{1/2}$: 35 h
voriconazole (Vfend)	Invasive aspergillosis	*Adult and child >12 y*: IV, 6 mg/kg every 12 h day 1 followed by 3–4 mg/kg 2×/d *Adult and child >12 y*: PO, 400 mg every 12 h day 1 followed by 200 mg 2×/d	*Onset*: 1 h *Duration*: 96 h $t_{1/2}$: 24 h
	Systemic candida infections	*Adult and child >12 y*: IV, 6 mg/kg q12h as an infusion leading dose on first day, followed by 3 mg/kg as an infusion q12h *Adult and child ≥12 y (≥40 kg)*: PO, 200 mg 2×/d for 14 d and for at least 7 d following resolution of symptoms *Adult and child ≥12 y (<40 kg)*: PO, 100 mg 2×/d for 14 d and for at least 7 d following resolution of symptoms *Child <12 y*: Safety and efficacy have not been established	

TABLE 44.4 Summary of Selected Topical Azole Antifungal Agents

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
butoconazole (Gynazole-1, Femstat-3)	Vaginal candidiasis	**Vaginal dosage (vaginal cream):** Apply 1 applicatorful of 2% cream at bedtime for 3 consecutive d (6 d if pregnant)	Not systemically absorbed
clotrimazole (Mycelex, Gyne-Lotrimin)	Tinea infections Candidal infections: skin and mouth	**Topical:** *Adult and child >2 y*: Apply to affected skin and surrounding areas twice daily, morning and evening **Oral (troche) dosage:** *Adult and child >3 y*: Dissolve a 10-mg troche slowly and completely in the mouth 5×/d for 14 d **Vaginal dosage (vaginal cream):** Apply 1 applicatorful of 1% cream once daily at bedtime for 7–14 d **Vaginal dosage (tablets):** 100-mg tablet at bedtime for 7 d; or one 200-mg tablet at bedtime for 3 d; or 500-mg tablet as a single dose at bedtime	Not systemically absorbed
econazole	Tinea infections Candidal infections: skin and mouth	**Topical dosage (1% cream or lotion):** *Adult, adolescent, and child*: Apply to the affected area(s) and the immediately surrounding area(s) 1–2×/d	Not systemically absorbed
miconazole (Oravig)	Oropharyngeal candidiasis	*Adults and children >16 y*: 50 mg buccal tablet against the upper gum above the incisor tooth once daily in the morning for 14 days	
oxiconazole (Oxistat)	Tinea infections	**Topical dosage (1% cream or lotion):** *Adult, adolescent, and child*: Apply to the affected area(s) and the immediately surrounding area(s) 1–2×/d	Not systemically absorbed
sertaconazole (Ertaczo)	Tinea infections	**Topical application (cream):** *Adult, adolescent, and child >12 y*: Apply a thin layer of the 2% cream to the cleansed, dry, infected area twice daily for 4 wk	Not systemically absorbed
sulconazole (Exelderm)	Tinea infections	**Topical dosage (cream and solution):** *Adult*: Apply 1% preparation topically to the cleansed, dry, affected area(s) once or twice daily, morning and evening, for 3 wk	Not systemically absorbed
terconazole (Terazol)	Vaginal candidiasis	**Intravaginal dosage (Terazol 7 cream):** *Adult and adolescent*: Insert 1 applicatorful intravaginally once daily at bedtime for 7 consecutive d **Intravaginal dosage (Terazol 3 cream):** *Adult and adolescent*: Insert 1 applicatorful once daily at bedtime for 3 consecutive d **Intravaginal dosage (Terazol 3 vaginal suppositories):** *Adult and adolescent*: Insert one 80-mg suppository intravaginally once daily at bedtime for 3 consecutive d	Not systemically absorbed
tioconazole (Vagistat-1)	Vaginal candidiasis	**Intravaginal dosage (cream):** *Adult and adolescent*: 1 applicatorful before bedtime as a single dose	Not systemically absorbed

Drug Interactions

Many drug–drug interactions are possible with fluconazole because it inhibits drugs metabolized by the CYP3A4 enzyme system. Several drugs no longer available in the United States—astemizole, cisapride, and terfenadine—can induce fatal arrhythmias when given concurrently with fluconazole. Table 44.5 lists drugs that interact with fluconazole.

TABLE 44.5 Agents That Interact with P Fluconazole

Interactants	Effect and Significance	Nursing Management
antiarrhythmics agents	Fluconazole may decrease the metabolism of the antiarrhythmics such as dofetilide and quinidine.	Monitor antiarrhythmic drug levels. Monitor for arrhythmias.
antidiabetic agents	Fluconazole inhibits the metabolism of oral antidiabetic agents, resulting in an increased pharmacologic effect.	Monitor blood glucose. Monitor for edema.
antipsychotic agents	Fluconazole may decrease the metabolism of the antipsychotics such as haloperidol, quetiapine, and risperidone.	Monitor for CNS depression. Ensure a safe environment.
benzodiazepines	Metabolism of certain benzodiazepines and first-pass effect of benzodiazepines may be decreased.	Monitor for CNS depression. Ensure a safe environment. Discuss adjustment of benzodiazepine dosage with prescriber as needed.
calcium channel blockers	Fluconazole inhibits the metabolism of calcium channel blockers, resulting in an increased pharmacologic effect.	Monitor blood pressure carefully. Advise patient to change positions slowly. Monitor for constipation.
carbamazepine	Fluconazole inhibits the metabolism of carbamazepine.	Monitor carbamazepine levels. Monitor hepatic status.
Corticosteroids	Fluconazole inhibits the metabolism of corticosteroids.	Monitor for corticosteroids adverse effects and toxicity.
cyclosporine	Fluconazole may inhibit cyclosporine hepatic metabolism.	Monitor cyclosporine levels. Monitor serum BUN/creatinine levels. Monitor intake and output. Discuss adjustment of cyclosporine dosage with prescriber as needed.
Fentanyl	Fluconazole inhibits the metabolism of fentanyl.	Monitor for CNS depression. Monitor for respiratory depression.
HMG CoA reductase inhibitors	Fluconazole may decrease the metabolism of the statins.	Monitor for myalgias. Monitor for signs of rhabdomyolysis.
hydantoins	Fluconazole may decrease the metabolism of hydantoins, such as phenytoin.	Monitor hydantoin levels. Monitor patient for sign of toxicity. Monitor the patient's ability to walk, talk, and think. Discuss adjustment of hydantoin dosage with prescriber as needed.
oral contraceptives	Concurrent use with oral contraceptives containing ethinyl estradiol/levonorgestrel may decrease serum concentration of the oral contraceptives.	Advise women taking ethinyl estradiol or levonorgestrel BCP to use another method of contraception.
NSAIDS	Fluconazole inhibits the metabolism of NSAIDS.	Monitor for GI distress. Monitor for GI bleeding. Monitor for renal and hepatic insufficiency.
protease inhibitors	Fluconazole inhibits the metabolism of protease inhibitors.	Monitor protease inhibitor levels. Monitor blood glucose levels. Monitor CBC. Monitor for signs of pancreatitis.
proton pump inhibitors/ H_2 blockers/antacids	PPI/H_2 blockers decrease the absorption of fluconazole.	Monitor for efficacy. If not contraindicated, administer fluconazole with acidic beverage such as Coca-Cola or Pepsi.
rifamycins	Rifamycins may induce the metabolism of fluconazole. This may decrease plasma concentration of fluconazole and decrease antifungal activity.	Monitor for therapeutic efficacy of fluconazole. Discuss adjustment of fluconazole dosage with prescriber as needed.

(*Continued*)

TABLE 44.5 Agents That Interact with P Fluconazole *(continued)*

Interactants	Effect and Significance	Nursing Management
risperidone	Fluconazole inhibits the metabolism of risperidone.	Monitor for risperidone toxicity. Monitor CBC.
tacrolimus	Fluconazole inhibits the metabolism of tacrolimus.	Monitor I/O carefully. Monitor renal function tests. Monitor tacrolimus levels.
tolterodine	Fluconazole inhibits the metabolism of tolterodine.	Monitor for urine retention. Monitor for excessive anticholinergic effects.
tricyclic antidepressants	Fluconazole may inhibit the metabolism of TCA drugs.	Monitor the patient's clinical response to tricyclic agents (TCAs). Monitor cardiac status. Discuss adjustment of TCA dosage with prescriber as needed.
warfarin	Fluconazole may decrease the metabolism of anticoagulants such as warfarin.	Monitor PT and INR at least every 2 d. Monitor patient for signs of bleeding. Discuss adjustment of anticoagulant dosage with prescriber as needed.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a patient history to evaluate for pre-existing renal or hepatic dysfunction, pregnancy, or breast-feeding. It is important to communicate any positive findings to the prescriber. Also, assess for any known reactions to azole antifungal agents.

Perform a complete physical examination, documenting signs and symptoms of the fungal infection. For patients with pre-existing anemia, renal, or hepatic disease or patients expected to be on long-term therapy, obtain samples for baseline CBC, renal, and hepatic function tests to determine baseline organ function.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding. In animal studies, fluconazole has been teratogenic when used in higher doses. Similar teratogenic malformations have been reported in women taking more than 400 mg/d over an extended period of time. Although fluconazole is assigned to pregnancy category C, many providers believe it should be used during pregnancy only if the potential benefit to the mother outweighs the potential risk to the fetus. It achieves high concentrations in breast milk.

Note the patient's age before administering fluconazole. Although a dosage schedule has been established for children, the safety of fluconazole has not been demonstrated in children younger than 13 years. However, drug therapy has been successful, and complications have not occurred in neonates treated with IV fluconazole in emergency treatment situations. With these concerns in mind, closely monitor children throughout therapy. Elderly patients are more likely than others to have decreased renal and hepatic function, which may increase the risk for toxicities.

Lifestyle, Diet, and Habits

Assess whether fluconazole is causing gastric distress in the patient. Fluconazole absorption and bioavailability are not affected by food or changes in gastric pH. Encourage patients who experience GI distress to take the drug with food.

Ask questions to uncover information about alcohol ingestion and other substance use (such as drugs and tobacco). Fluconazole may elevate hepatic enzymes. Caution the patient to refrain from alcohol ingestion throughout therapy because it increases the risk of hepatotoxicity. As with other drugs used as prophylaxis against opportunistic diseases in immunocompromised patients, discuss potential substance abuse (other drugs, alcohol, tobacco) with the patient. Explain how a healthy lifestyle decreases the risk of opportunistic diseases.

Determine which type of over-the-counter (OTC) pain reliever the patient generally uses. Advise the patient to use aspirin instead of acetaminophen for relief of minor discomforts because acetaminophen has the potential to damage the liver or kidneys.

Environment

Fluconazole is administered orally and intravenously. The oral preparation is used in the home environment, often as long-term prophylaxis for fungal infections in immunocompromised patients. Be sure to explain the importance of follow-up visits to assess the efficacy of therapy and to evaluate the patient for possible adverse effects.

IV therapy is usually reserved for patients unable to tolerate or take fluconazole orally and is administered in the hospital

setting. Before administration, visually inspect the solution for particulate matter and discoloration. Do not administer unless the solution is clear. Fluconazole should be administered with an infusion pump at a rate not to exceed 200 mg/h.

Nursing Diagnoses and Outcomes

- Acute Pain related to fluconazole-induced headache
  Desired outcome: *The patient will self-administer aspirin to relieve headache.*
- Ineffective Protection related to adverse effects of blood dyscrasias and Stevens-Johnson syndrome
  Desired outcome: *The patient will report signs and symptoms of these adverse reactions immediately to the prescriber.*
- Disturbed Body Image from drug-related alopecia
  Desired outcome: *The patient will verbalize concerns of changes in body image to the prescriber and develop coping strategies.*
- Imbalanced Nutrition: Less than Body Requirements, related to adverse effects of nausea, vomiting, and abdominal pain
  Desired outcome: *The patient will remain within acceptable weight parameters throughout therapy.*
- Risk for Injury related to elevated hepatic enzymes and hypokalemia resulting from drug therapy
  Desired outcome: *The patient will remain injury free throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer fluconazole in evenly divided intervals throughout the day.

Minimizing Adverse Effects

Carefully screen patients for pre-existing disorders, which may increase the risk for adverse reactions. In the hospitalized patient, contact the prescriber if any drugs known to interact or increase the risk for adverse effects are added to the drug profile. Administer an antiemetic or antidiarrheal agent, if prescribed, for adverse GI effects.

Providing Patient and Family Education

- Advise patients that they should not take fluconazole if they have ever had a reaction to any drug whose name includes the ending "azole."
- Advise patients to notify the prescriber if they are pregnant or breast-feeding.
- Explain that fluconazole is prescribed for a particular infection and should not be used to self-medicate or treat any other infection.
- Unless such use is specified by a physician, caution that this drug should not be used in children younger than 13 years.
- Teach patients about the need to complete the full course of drug therapy, even if the infection resolves. Instruct patients to take forgotten doses as soon as they remember, but not if it is time for the next dose.
- Remind patients of the importance of remaining well hydrated while taking this drug.
- Explain potential adverse effects of fluconazole and potential remedies for these discomforts. Advise patients to contact the prescriber immediately if they experience unusual bruising or bleeding, skin rash (including inside the mouth), redness, blistering, peeling, or loosening of the skin. This advice is especially important for patients taking fluconazole as prophylaxis for opportunistic diseases.
- Discuss the possibility of hepatic injury. Advise patients to contact the prescriber if they experience dark urine, pale stool, jaundice, anorexia, nausea or vomiting, and persistent fatigue.
- Explain that fluconazole may decrease the effectiveness of oral contraceptives and suggest that patients use an alternative form of contraception while taking fluconazole.
- Advise patients taking sulfonylureas to monitor their blood glucose levels frequently and to notify the prescriber in the event of frequent episodes of hypoglycemia.
- Suggest that patients taking anticoagulants have blood tests performed frequently to detect altered prothrombin times. Patients should contact the prescriber if they experience easy bruising or bleeding.
- Advise patients of signs and symptoms of secondary bacterial infections that may occur with superficial mycoses. Recommend that patients contact the prescriber if the affected skin becomes red and hot or exudes pus.
- Assure patients with alopecia that the condition is temporary.

Ongoing Assessment and Evaluation

Monitor the effectiveness of therapy. When treating superficial mycoses, be sure to document new lesions and assess for possible secondary bacterial infections. In the hospital setting, monitor for hepatic or renal dysfunction. It is important to monitor fluid intake and output carefully; enlist the patient and family to document intake and output not observed by nurses.

Throughout therapy, arrange for serial blood testing to evaluate renal, hepatic, and hematopoietic function. For

CRITICAL THINKING SCENARIO

FLUCONAZOLE AND CHRONIC CANDIDIASIS

Janice Wind is a 40-year-old woman infected with HIV. She has been diagnosed with esophageal candidiasis, for which fluconazole therapy has been prescribed. This is her third episode of esophageal candidiasis for which she will receive prolonged therapy. Assume you are Ms. Wind's nurse.

1. Identify the assessments and evaluations you would find valuable before initiating therapy.
2. Propose or construct a patient-teaching plan. Which features would you include?
3. Develop some questions about the effects of therapy to explore with Ms. Wind when she returns to the clinic in 6 weeks for a follow-up evaluation.

MEMORY CHIP

P Fluconazole

- Used to treat candidiasis and prophylaxis for fungal diseases in immunocompromised patients
- Most common adverse effects: nausea, vomiting, diarrhea, abdominal pain, headache, and dizziness
- Most serious adverse effect: Stevens-Johnson syndrome
- Maximizing therapeutic effects: Administer adjunct medications for nausea and diarrhea.
- Minimizing adverse effects: Do not give with any drugs that increase the potential for adverse effects.
- Most important patient education: Watch for signs and symptoms of adverse effects and call the prescriber immediately if any occur.

suspected electrolyte imbalance, reviewing complete metabolic panel test results is important.

Monitor the patient for GI distress, headache, dizziness, exfoliative skin disorders, and hepatic dysfunction. It is important to ensure the safety of the patient experiencing CNS effects by keeping the bed in the low position and the side rails up at all times. To avoid injury, be sure that the patient understands the need to ask for ambulatory assistance if he or she experiences dizziness. By the end of therapy, the patient should be without symptoms of fungal infection. In addition, adverse reactions should be controlled.

Drugs Closely Related to P Fluconazole

Itraconazole, posaconazole, and voriconazole are similar to fluconazole because they are also triazole antifungal agents. Ketoconazole is also closely related to fluconazole, but is an imidazole antifungal agent.

Itraconazole

Itraconazole (Sporanox) is an oral or IV triazole antifungal drug that is related closely to fluconazole. Itraconazole offers a broader spectrum of activity than fluconazole, including endemic fungi, *Sporothrix schenckii*, and *Aspergillus* species. The drug is used as an alternative to IV amphotericin B for the treatment of blastomycosis, histoplasmosis, paracoccidioidomycosis, and sporotrichosis. Absorption of oral itraconazole capsules may be increased when given concurrently with a meal, cola beverage, or cranberry juice because it requires an acidic gastric pH for solubilization. Conversely, drugs such as proton pump inhibitors, histamine-2 receptor blockers, and antacids interfere with its absorption. The oral solution of itraconazole is unaffected by gastric pH and administered on an empty stomach for optimal absorption. Adverse effects are the same as other triazole antifungal agents. In addition, itraconazole may have two serious adverse effects: an aldosterone-like effect, manifested by hypertension, hypokalemia, and peripheral edema and hepatotoxicity. Because of these potential adverse effects, itraconazole should be reserved for use in serious fungal infections, especially in patients with pre-existing cardiac or hepatic disorders. Pregnancy and lactation precautions are the same as fluconazole.

Like fluconazole, itraconazole inhibits drugs metabolized by the CYP3A4 enzyme system but actually has more drug–drug interactions than fluconazole. Coadministration with dofetilide, oral midazolam, pimozide, quinidine, lovastatin, simvastatin, or triazolam is contraindicated. Serious cardiovascular events, including QT prolongation, torsades de pointes, ventricular tachycardia, cardiac arrest, and/or sudden death, have occurred in patients using pimozide or quinidine concomitantly with itraconazole. Patients taking itraconazole should be monitored for hepatotoxicity, neuropathy, and heart failure.

For patients with aspergillosis, histoplasmosis, or blastomycosis, arrange for periodic serum drug level monitoring.

Posaconazole

Posaconazole (Noxafil) is a new triazole antifungal agent approved for use as a prophylactic agent for fungal infections in stem cell transplant recipients and in patients who are neutropenic with either acute leukemia or myelodysplastic syndrome. It is also approved for oral but not systemic candidiasis. It is an oral solution that should be taken with a meal or nutritional supplement. Posaconazole has a chemical structure different than fluconazole and voriconazole; thus, it may inhibit mutated fungal strains resistant to these drugs. Liver and renal function tests should be coordinated at the start of and during the course of therapy. It is necessary to inform the prescriber immediately if serum potassium, magnesium, and calcium levels are elevated, because they must be corrected prior to initiation of therapy. The patient should shake the solution well prior to pouring it and should rinse the supplied spoon after each dose. Adverse effects are similar to other drugs in the triazole class.

Voriconazole

Voriconazole (Vfend) is another triazole antifungal agent that is structurally related to fluconazole. It is used for esophageal candidiasis, primary treatment of invasive aspergillosis, and salvage therapy for infections caused by *Scedosporium* species or *Fusarium* species in patients refractory to or intolerant of other antifungal therapy. Voriconazole can be administered by the oral or intravenous route. Give oral voriconazole on an empty stomach.

Voriconazole is given cautiously to patients with pre-existing hepatic or renal dysfunction, especially when using the intravenous formulation. It is also given cautiously to patients with pre-existing ocular disorders because of the potential for adverse effects to vision.

In addition to the usual adverse effects with triazole antifungal agents, voriconazole is associated with two distinct adverse reactions: transient vision changes and rash. Patients experience visual disturbances that involve enhanced brightness, blurred vision, photophobia, or color vision

changes. Visual hallucinations may indicate voriconazole neurotoxicity. Neurotoxicity may also induce confusion, agitation, myoclonic movements, and auditory hallucinations A photosensitive rash may occur that is not prevented by use of sunscreens. Advise the patient to limit sun exposure throughout therapy. Rarely, severe rash such as Stevens-Johnson syndrome or toxic epidermal necrolysis have occurred. Patients with severe systemic illness have an increased risk for QT prolongation, torsade de pointes, cardiac arrest, and sudden death. Drug–drug interactions are similar to those with fluconazole. Voriconazole is a pregnancy category D drug. Teratogenicity, embryotoxicity, reduced fetal weight, and multiple skeletal abnormalities were noted in animal trials. It is not approved for use in children.

Ketoconazole

Ketoconazole (Nizoral) is available as an oral formulation and as a cream, gel, foam, and shampoo for topical use. Imidazole antifungal agents, such as ketoconazole, have largely been replaced by the triazoles because of superior pharmacokinetics, improved safety profiles, and higher efficacy for the treatment of systemic mycoses. It is effective against most systemic mycoses. In addition to its antifungal activity, ketoconazole possesses actions that may make it useful in other types of conditions. For example, ketoconazole has been used successfully for treating advanced prostate cancer. When used in high doses, ketoconazole can inhibit sterol synthesis in humans, including the synthesis of aldosterone, cortisol, and testosterone.

When ketoconazole is given orally, its bioavailability is affected by the pH of the stomach. Like itraconazole, absorption of oral ketoconazole may be increased when given concurrently with a meal, cola beverage, or cranberry juice because it requires an acidic gastric pH for solubilization. It should not be given concurrently with agents that increase gastric pH, such as food, antacids, histamine-2 blockers, and proton pump inhibitors. Adverse effects are similar to those with fluconazole. Like other azole antifungal agents, ketoconazole interacts with many drugs metabolized by the CYP3A4 enzyme system. Pregnancy and lactation precautions are the same as for fluconazole.

Drugs Significantly Different From P Fluconazole

Butoconazole

Butoconazole (Femstat-3, Gynezole-1) is a topical imidazole antifungal agent that is effective in treating vulvovaginal candidiasis. As other azole antifungals, it exerts its antifungal activity by altering cellular membranes, resulting in increased membrane permeability and growth inhibition.

The only contraindication to the use of butoconazole is hypersensitivity. Butoconazole should be used cautiously in patients with other azole hypersensitivities because cross-sensitivity may occur. Adverse effects associated with the use of butoconazole include vaginal irritation, burning, pruritus, stinging, vaginal pain or soreness, and vaginal discharge.

Women using butoconazole should be advised to refrain from sexual intercourse until 72 hours after therapy is completed because butoconazole contains mineral oil, which may weaken contraceptive devices, including condoms, diaphragms, and cervical caps. Butoconazole is available as an OTC medication. It is a pregnancy category C drug.

Clotrimazole

Clotrimazole (Mycelex, Gyne-Lotrimin) is another imidazole antifungal drug. It is not orally absorbed and is too toxic for IV administration. It is marketed in various forms, including vaginal suppositories and cream, topical lotion and cream, and oral solution and lozenges. It is active against a wide variety of fungi, yeast, and dermatophytes; certain gram-positive bacteria; and superficial fungal infections. These infections include dermatophytosis, vaginal and oral candidiasis, and tinea infections. The ability of clotrimazole's formulations to reach subcutaneous tissues is poor. Therefore, clotrimazole is not indicated for treating subcutaneous mycoses.

Clotrimazole is available as a prescription and an OTC medication. Contraindications are similar to those of butoconazole. Adverse effects include skin blistering, skin irritation, burning, pruritus, and stinging. It is a pregnancy category C drug.

Econazole

Econazole is a topical imidazole antifungal agent used primarily to treat cutaneous candidiasis and tinea infections, including tinea versicolor. Its spectrum of activity is similar to that of clotrimazole, miconazole, or tioconazole. Econazole is not approved for ophthalmic administration or vaginal administration. Contraindications and adverse effects are similar to those of butoconazole. It is a pregnancy category C drug and may be used in children older than 3 months of age.

Miconazole

Miconazole (Monistat, M-Zole, Monistat-derm, Vusion) is a topical imidazole-type antifungal agent. It is also available as a buccal tablet (Oravig). Miconazole is different than other azoles because it has two mechanisms of action. Like other azoles, it inhibits ergosterol synthesis, and it also inhibits peroxidases, which results in the accumulation of peroxide within the cell, resulting in cell death. It is most commonly used topically and intravaginally and is available as an OTC preparation. Prescriptions are required for Monistat-derm (a 2% cream) and Vusion, a topical ointment with zinc oxide and petrolatum for diaper rash caused by candidiasis.

Oxiconazole

Oxiconazole (Oxistat) is a topical imidazole antifungal agent used to manage tinea pedis, tinea corporis, and tinea cruris. It is available as both a cream and a lotion and is administered once daily. Oxiconazole is not approved for ophthalmic

administration or vaginal administration. Contraindications and adverse effects are similar to those of butoconazole. It is a pregnancy category B drug and may be used in children.

Sertaconazole

Sertaconazole (Ertaczo) is an imidazole-type antifungal used for treating tinea pedis in immunocompetent patients. Sertaconazole is administered as a topical cream. Systemic absorption does not occur. Antifungal hypersensitivity is the only contraindication to it use. Skin irritation may occur when sertaconazole is used with other creams or lotions at the same site. Adverse effects include application site reaction, burning, and tenderness. It is a pregnancy category C drug and is generally considered safe to use while breast-feeding.

Sulconazole

Sulconazole (Exelderm) is a topical imidazole antifungal agent used in managing tinea pedis, tinea corporis, and tinea cruris. It has greater efficacy than clotrimazole and miconazole. Like oxiconazole, it is administered only once per day. It is not approved for ophthalmic or vaginal administration. Its contraindications and adverse effects are similar to those for oxiconazole. Topical sulconazole is classified as a pregnancy risk category C drug. It is not approved for use in children.

Terconazole

Terconazole (Terazol) is a triazole antifungal agent that is structurally related to imidazole antifungal drugs. It is available for intravaginal use only. Terconazole is as effective as clotrimazole or miconazole in managing vulvovaginal candidiasis. Contraindications and adverse effects are similar to those of butoconazole.

Tioconazole

Tioconazole (Vagistat-1) is an imidazole antifungal agent available for intravaginal use. It is the only topical antifungal agent approved in the United States as a single-dose treatment for vulvovaginal candidiasis. It is now available as an OTC medication. Contraindications and adverse effects are similar to those of butoconazole.

• Miscellaneous Antifungal Drugs

A summary of miscellaneous antifungal agents is presented in Table 44.6.

Butenafine

Butenafine (Mentax) is an allylamine topical antifungal drug indicated for treating tinea pedis, tinea corporis, and tinea cruris. It currently is under investigation for treatment of onychomycosis. Butenafine is similar to tolnaftate (discussed later in this chapter); however, it also is effective against *Candida* species, whereas tolnaftate is not. No important drug inter-actions or adverse effects have been identified at this time.

Ciclopirox Olamine

Ciclopirox olamine (Loprox) is a miscellaneous broad-spectrum antifungal drug used to treat infections caused by dermatophytes or *Candida* species. It is used primarily for tinea pedis, tinea cruris, tinea corporis, and tinea versicolor. It works by blocking transport of amino acids into the fungal cell, thus altering the cell membrane to allow leakage of intracellular material. Ciclopirox olamine also is manufactured as a nail lacquer (Penlac) for the topical treatment

TABLE 44.6 Summary of Miscellaneous Antifungal Agents

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
butenafine (Mentax)	Tinea pedis, tinea corporis, tinea cruris	*Adult*: Topical, apply to affected area once daily for 4 wk	Not generally absorbed systemically
ciclopirox olamine (Loprox)	Tinea pedis, tinea cruris, tinea corporis, tinea versicolor	*Adult*: Topical, apply to affected area as directed twice daily	Not generally absorbed systemically
griseofulvin (Grifulvin V, Gris-Peg)	Superficial dermatophyte infections (ringworm)–tinea corporis, tinea barbae, tinea capitis, tinea ungulum; tinea pedis and tinea cruris only when unresponsive to topical therapy	*Adult*: PO, 250–500 mg bid for 2 wk, up to 18 mo	*Onset*: 4 h *Duration*: 2 d $t_{1/2}$: 9–24 h
naftifine (Naftin)	Tinea pedis, tinea cruris, tinea corporis	*Adult*: Topical, massage into area bid; do not use longer than 4 wk	Not generally absorbed systemically
terbinafine (Lamisil)	Onychomycosis	*Adult*: PO, 250 mg/d; topical, apply to areabid up to 4 wk *Child*: ≤20 kg, PO, 62.5 mg/d *Child*: 20–40 kg, PO, 125 mg/d	*Onset*: 24 h *Duration*: 90 d $t_{1/2}$: 100 h

of mild to moderate onychomycosis of the fingernails and toenails without lunula involvement in immunocompetent patients.

Ciclopirox olamine is absorbed deeper into the dermal layers than other topical drugs. However, little is absorbed systemically. No important drug–drug interactions are known. Potential adverse effects include irritation, pruritus at the application site, redness, pain, burning, and worsening of clinical signs or symptoms.

Griseofulvin

Griseofulvin (Grifulvin-V, Gris-Peg) is a miscellaneous antifungal drug used in treating superficial dermatophytic infections, such as ringworm and tinea. It is available in a microsize or ultramicrosize formulation. These different formulations are meant to increase the bioavailability of, and to decrease the GI intolerance to, the drug.

Griseofulvin works by disrupting the mitotic spindle structure of the fungal cell, thereby stopping cell division. It also may cause defective DNA that is unable to replicate. It is very effective for superficial mycoses because it is deposited in keratin precursor cells, creating an unfavorable environment for fungal infection. Infected skin, cells, and hair are then replaced slowly by tissue that is not infected by the dermatophyte. Griseofulvin therapy lasts until the infected area has completely regrown. This therapy may take 6 to 12 months in treating tinea unguium.

Griseofulvin is contraindicated during pregnancy and breast-feeding. It should be given with caution to patients with hepatic dysfunction, porphyria, or systemic lupus erythematosus because the drug may exacerbate these conditions.

Griseofulvin has a moderate adverse effect profile. Common adverse effects include nausea, vomiting, flatulence, and epigastric distress. CNS effects may include headache, fatigue, dizziness, insomnia, confusion, psychotic symptoms, and paresthesias of the hands and feet. Integumentary adverse effects may include maculopapular rash, urticaria, and photosensitivity. In addition, hepatitis, elevated hepatic enzymes, granulocytopenia, and leukopenia have occurred after high-dose or long-term therapy.

Griseofulvin interacts with several drugs. Most importantly, it interacts with oral contraceptives by decreasing their effectiveness. Therefore, advise women taking birth control pills to use another method of contraception during griseofulvin therapy. Griseofulvin also may decrease the effectiveness of warfarin.

It is necessary to closely monitor prothrombin time if griseofulvin is either added to or discontinued from warfarin therapy. Barbiturates can decrease the antifungal activity of griseofulvin. Finally, griseofulvin may increase the adverse effects of alcohol when taken concurrently.

Naftifine

Naftifine (Naftin) is a topical allylamine antifungal drug. It is used primarily for tinea pedis, tinea cruris, and tinea corporis. Naftifine is believed to interfere with sterol biosynthesis, but by a different mechanism than azoles. No important drug interactions occur with naftifine. Adverse effects include burning, stinging, dryness, erythema, pruritus, local irritation, and rash.

Terbinafine

Terbinafine (Lamisil) is another allylamine antifungal drug administered either orally or topically. Its topical formulation is now available OTC. Terbinafine is pharmacologically similar to naftifine. Oral terbinafine is highly effective for treating onychomycosis because of its fungicidal activity and ability to concentrate within the nail. In fact, it has been found to be superior to griseofulvin and itraconazole for treating onychomycosis.

Oral terbinafine should be given with caution to patients with hepatic and renal insufficiency and during breast-feeding. The most common adverse effects are GI, followed by elevated hepatic enzyme levels, urticaria, pruritus, and occasionally a distorted sense of taste (dysgeusia). Rare but serious adverse effects include symptomatic idiosyncratic hepatobiliary dysfunction (including cholestatic hepatitis), serious skin reactions, severe neutropenia, and allergic reactions (including anaphylaxis). Some formulations of terbinafine are now available as OTC preparations.

CHAPTER SUMMARY

- Antifungal drugs can be arbitrarily divided into those used to manage systemic infections and those used to manage superficial infections.
- The two types of fungi are yeasts and molds.
- Systemic fungal diseases are categorized by those that are opportunistic and those that occur in every population.
- Amphotericin B is the prototype polyene antifungal and is the drug of choice for most systemic fungal infections.
- Amphotericin B induces severe adverse effects, including infusion reactions.
- Fluconazole is the prototype azole antifungal drug used for both systemic and superficial mycoses.
- Superficial fungal infections are treated with both oral and topical formulations of drugs.

QUESTIONS FOR STUDY AND REVIEW

1. List the potential adverse effects of amphotericin B.
2. What important adverse effects are associated with fluconazole therapy?
3. Which of the azole antifungal agents may be used in managing systemic fungal infections?
4. What follow-up should be performed for a patient taking griseofulvin?
5. Why are there so many adverse effects related to drug–drug interactions with azole drugs?

NEED MORE HELP?

Chapter 44 of the Study Guide to Accompany *Drug Therapy in Nursing,* 4th Edition, contains NCLEX-style questions and other learning activities to reinforce your understanding of the concepts presented in this chapter. For additional information or to purchase the study guide, visit thePoint.

Drugs Treating Viral Infections

Learning Objectives

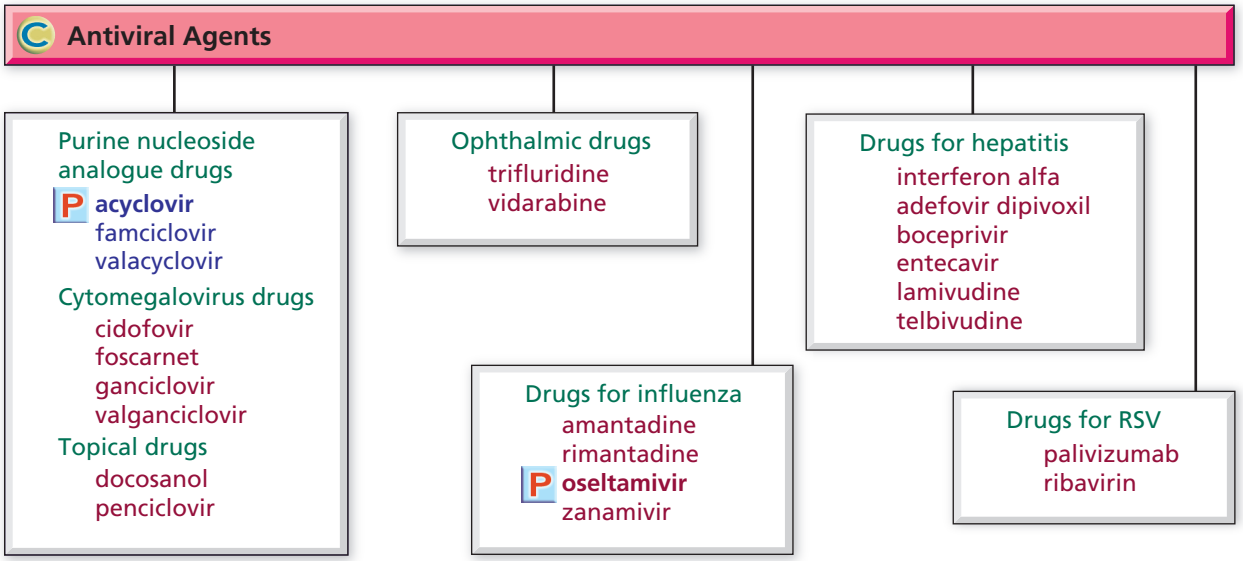
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs used to treat viral infections.
2. Identify core patient variables relevant to drugs used to treat viral infections.
3. Relate the interaction of core drug knowledge to core patient variables for drugs used to treat viral infections.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs used to treat viral infections.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs used to treat viral infections.
6. Determine key points for patient and family education for drugs used to treat viral infections.

Key Terms

cytomegalovirus
herpes simplex virus
herpes zoster
phosphorylation
respiratory syncytial virus

Drugs Treating Viral Infections



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Viral diseases affect people throughout the life span. In healthy people, these diseases may be considered an annoyance; in immunocompromised people, these diseases can be deadly. Viruses are responsible for many infectious disorders, ranging from the common cold to life-threatening meningitis. In contrast to the number of drugs that have been developed to treat bacterial disease, few antiviral drugs have been developed. Because viruses have no metabolic enzymes of their own, they can replicate only within a living host cell by using the metabolic processes of the host. Therefore, most drugs used to eliminate a virus may do substantial harm to the host. However, a few antiviral drugs have been developed that can target the invading virus yet leave the host intact. These drugs have a narrow spectrum of activity, and each drug has specific clinical applications.

This chapter discusses the purine nucleoside analogue drugs; the prototype is acyclovir. Drugs used to manage influenza are represented by oseltamivir, and drugs used in the management of hepatitis B and C are represented by interferon alfa.

PHYSIOLOGY OF VIRAL REPRODUCTION

The reproduction of viruses in humans requires five steps—adsorption, penetration, uncoating, replication, and transcription (the change of ribonucleic acid [RNA] to deoxy- ribonucleic acid [DNA]), all of which precede viral assembly and release. During the adsorption step, the virus attaches itself to receptor sites on the host cell surface. Once attached, the virus releases enzymes that enable the virus to penetrate the cell. After the virus enters the cell, the protein coat of the virus dissolves and releases viral genetic material. The virus then synthesizes new messenger RNA and, using host ribosomes, synthesizes viral proteins. The viral nucleic acids and proteins are assembled into mature viruses that are then released by budding off from infected cells or by lysis of the infected cell (Figure 45.1).

PATHOPHYSIOLOGY OF SELECTED VIRAL INFECTIONS

Cytomegalovirus

Cytomegalovirus (CMV) is a type of herpesvirus. CMV infection is extremely prevalent—approximately 80% of the population demonstrates evidence of infection. In most individuals, infection is asymptomatic. However, in some individuals, such as those with acquired immunodeficiency syndrome (AIDS) and bone marrow transplant recipients, CMV infection is associated with severe and usually fatal disease. CMV infection during pregnancy can be hazardous to the fetus, possibly leading to stillbirth, brain damage, and other birth defects or to neonatal illness.

Although CMV most frequently causes retinitis, it also can cause infection in the lungs, throat, brain, kidneys, gallbladder, liver, and colon. In immunocompromised patients, CMV prophylaxis is started when the $CD4^+$ T-cell count measures less than 50 mm^3.

Hepatitis

There are five types of hepatitis: hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis D (HDV), and hepatitis E (HEV). In North America, the most prevalent types are HAV, HBC, and HCV. Symptoms of hepatitis include jaundice, fatigue, abdominal pain, nausea, and anorexia. Some patients may have dark urine or light-colored stool.

HAV infection is an acute viral syndrome spread by the oral–fecal route. It does not have the ability to become a chronic disease. Hepatitis A vaccine is the preferred method of prevention.

HBV infection is spread when blood or body fluid from an infected person enters the body of a person who is not immune. Infection may occur through having sex with an infected person, through needlesticks or sharps exposures, from an infected mother to the neonate during birth, or by sharing drugs or needles. HBV may present as a mild illness, lasting a few weeks (acute), to a serious long-term (chronic) illness that can lead to liver disease or liver cancer. Like hepatitis A, hepatitis B vaccine is the preferred method of prevention.

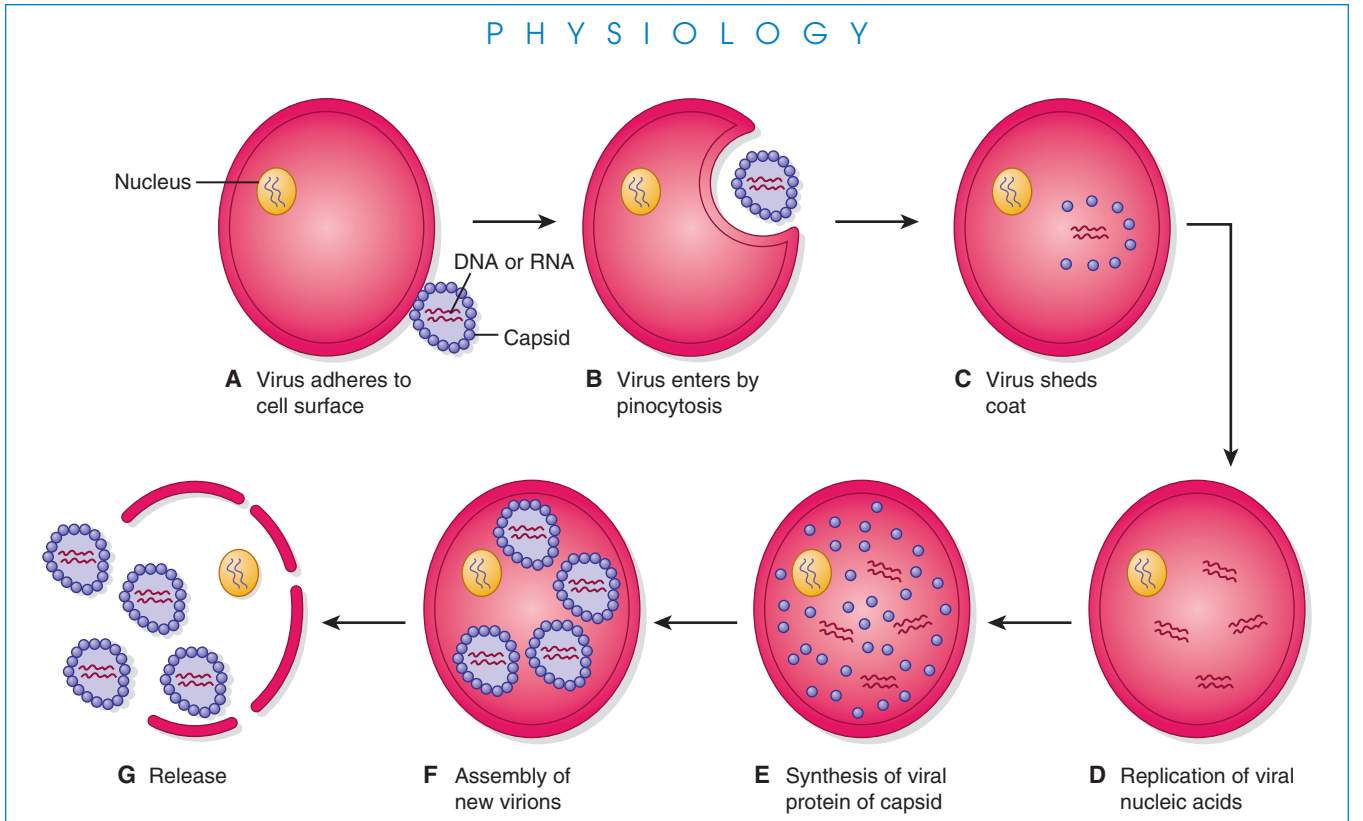
HCV is spread in the same manner as HBV. There are multiple genotypes and subtypes of HCV, a circumstance which makes treatment difficult. An estimated 4 to 5 million people in the United States have chronic HCV. HCV occurs most frequently in people who use intravenous (IV) illegal drugs. There is no preventive vaccine.

Herpes Simplex

Herpes simplex virus (HSV) has two types—type 1 (HSV-1) and type 2 (HSV-2). Both types cause similar infections. HSV-1 is associated generally with herpes labialis (cold sores or fever blisters), signs of which occur on or near the lips. HSV-2 may cause herpes labialis or herpes genitalis (genital lesions). Infection with either virus is characterized by the formation of painful vesicles, which rupture and form a crust when fluid from active lesions contacts parts of the body that have a break in the skin. In between outbreaks, the virus remains in a latent stage in sensory nerve ganglions. Recurrence may be triggered by other infections, sun exposure, or stress. Outbreaks are preceded by a burning or tingling sensation along the nerve and at the site of infection.

Herpes Zoster

Herpes zoster is an acute unilateral and segmental inflammation of the dorsal root ganglia caused by reactivation of the varicella-zoster virus (VZV), which also causes chickenpox. This infection usually occurs in adults and produces localized vesicular skin lesions, confined to a dermatome, and severe neuralgic pain in peripheral areas innervated by the nerves arising in the inflamed root ganglia.



• FIGURE 45.1 Viral replication. Viruses replicate in a series of steps: adsorption, penetration, uncoating, replication and transcription, and assembly and release (APURA). By adsorption (**A**), the virus adheres to receptors on the host cell surface. Then by pinocytosis promoted by enzyme activity, the virus penetrates (**B**) the cell wall. Once inside the cell, the virus uncoats (**C**), shedding its protein cover and allowing the genetic material (RNA) to be replicated (**D**) and changed to DNA. Next, new viral proteins are synthesized (**E**) and assembled (**F**) into new viruses, which are then released (**G**). Antiviral drugs interfere with the various stages of replication to limit or stop the viral disease process. (Adapted with permission from Swonger, A. K., & Matejski, M. P. [1991]. *Nursing pharmacology* [2nd ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Onset of herpes zoster is characterized by fever and malaise. Within 2 to 4 days, severe deep pain, pruritus, and paresthesia or hyperesthesia develop, usually on the trunk and occasionally on the arms and legs. The pain may be continuous or intermittent and usually lasts from 1 to 4 weeks. Up to 2 weeks after the first symptoms, small, red, nodular skin lesions erupt on the painful areas.

After the initial outbreak, the virus retreats back to the dorsal root ganglia, but outbreaks may recur. Postherpetic neuralgia is a common and potentially debilitating complication of herpes zoster that is difficult to manage, especially in elderly patients.

Influenza

Of the many types of influenza virus, influenza A and influenza B are the only types that can be affected by current antiviral agents. Influenza A and B have similar characteristics; however, infection with influenza A is more common and more severe. The virus attacks both the upper and lower respiratory tracts. It is transmitted directly by respiratory droplet or indirectly by contact with a contaminated object. Influenza virus is difficult to combat because it undergoes constant antigenic changes, which limit vaccine development and the ability of individuals to develop long-term immunity.

Influenza has a sudden, acute onset with fever and chills, marked malaise, headache, general muscle aching, sore throat, unproductive cough, and nasal congestion. It may be self-limiting or may progress to pneumonia. Elderly patients, patients with chronic diseases, and immunocompromised patients should be immunized yearly.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a major cause of respiratory illness in all age groups. In adults, infection with RSV tends to cause mild cold symptoms; in school-aged children, it can cause a cold and bronchial cough; and in infants and toddlers, it can cause bronchiolitis (inflammation of the smaller airways of the lungs) or pneumonia. Reinfection throughout life is common.

The highest rates of RSV illness occur in infants 2 to 6 months of age, with a peak at 2 to 3 months. RSV infection is often carried home by a school-aged child and passed to a younger one, especially an infant.

RSV infection is especially dangerous in infants younger than 1 year and in children with asthma, other lung disorders, or heart disease. It is a major cause of hospitalization among children during the winter months. The symptoms of bronchiolitis include a hacking cough and wheezing on exhalation. In addition, children typically have fever and a cloudy nasal drainage; infants often are irritable, and oral intake decreases, sometimes to the point of dehydration.

C ANTIVIRAL AGENTS

• Purine Nucleoside Analogue Drugs

The largest group of antiviral drugs is the purine nucleoside analogue drugs, initially developed as antitumor drugs but used as antiviral drugs for more than 30 years. They have relatively selective toxicity to viruses because viral DNA polymerases are more sensitive than human polymerases to inhibition by these drugs. The prototype purine nucleoside analogue antiviral drug is acyclovir (Zovirax). Table 45.1 presents a summary of purine nucleoside analogue drugs

Nursing Management of the Patient Receiving P Acyclovir

Core Drug Knowledge

Pharmacotherapeutics

Acyclovir is an oral, parenteral, and topical antiviral agent. Its antiviral spectrum is limited to the herpesviruses, including HSV, herpes zoster virus, Epstein-Barr virus, and CMV. Acyclovir is not active against human immunodeficiency virus (HIV). Acyclovir is used to treat herpes simplex (including encephalitis), herpes genitalis, recurrent herpes labialis, herpes zoster, and varicella.

Pharmacokinetics

After topical application, percutaneous absorption is minimal, and no drug is detected in the blood or urine. After oral administration, acyclovir is absorbed poorly from the gastrointestinal (GI) tract, with a bioavailability of approximately 20%. Peak serum concentrations occur in about 1.5 to 2 hours. Acyclovir distributes extensively, with the highest concentrations in the kidneys, liver, and intestines. Cerebrospinal fluid (CSF) concentrations are about 50% of plasma concentrations. Acyclovir crosses the placenta and enters breast milk. Acyclovir is metabolized minimally. Approximately 70% is eliminated by the kidneys unchanged. Half-life in patients with normal renal function is about 2.5 hours. In patients with impaired renal function, the half-life may extend to 20 hours.

Pharmacodynamics

To be active, acyclovir must undergo **phosphorylation,** a process by which a phosphate combines with an organic compound. In an infected cell, acyclovir is converted by the viral enzyme thymidine kinase. Fully active acyclovir triphosphate competes for a position in the DNA chain of the herpesvirus. Once incorporated, it terminates DNA synthesis. Uninfected cells show only minimal phosphorylation of acyclovir; thus, only a small amount of uptake into these cells occurs. Acyclovir is effective only against actively replicating viruses; it does not cure the latent herpesvirus. Acyclovir has only indirect effects on the body.

Contraindications and Precautions

Acyclovir should be used with caution in patients with ganciclovir or valganciclovir hypersensitivity because acyclovir has a similar chemical structure. It also should be given with caution to women who are pregnant or breast-feeding.

IV acyclovir should be used with caution in patients with renal disease and pre-existing neurologic disorders, especially seizures. Systemic acyclovir is excreted primarily by glomerular filtration and tubular secretion. Therefore, renal toxicity may occur in patients with renal disease. Patients with pre-existing neurologic disorders have an increased risk of developing tremors and myoclonus.

Adverse Effects

Acyclovir is well tolerated. Common adverse effects of acyclovir include light-headedness, anorexia, nausea, vomiting, abdominal pain, and headache. More serious adverse effects include confusion, tremors, hallucinations, seizures, or coma. IV acyclovir may be nephrotoxic. Acyclovir nephrotoxicity appears to result from crystallization of the drug in the nephron, which can lead to renal tubular obstruction.

Drug Interactions

Acyclovir may interact with valproic acid, hydantoins, theophyllines, and probenecid. The risk of nephrotoxicity increases when acyclovir is given concurrently with other drugs known to cause nephrotoxicity. Table 45.2 lists drugs that interact with acyclovir.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a patient history to evaluate for pre-existing renal dysfunction, dehydration, pregnancy, or breast-feeding. Also, assess for concurrent use of any drugs known to be nephrotoxic. Communicate any positive finding to the prescriber. Physical examination should include a dermatologic inspection to verify that the patient has active lesions and does not have a secondary bacterial infection (acyclovir does not affect bacterial pathogens). Immunocompromised patients and patients with pre-existing renal dysfunction should have baseline renal function tests documented. For patients with pre-existing neurologic disorders, complete a baseline neurologic assessment.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding. Acyclovir is a pregnancy category B and should be used with caution during pregnancy. Breast milk concentrations

TABLE 45.1 Summary of Selected Purine Nucleoside Analogue Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P acyclovir (Zovirax)	Herpes simplex Herpes genitalis Herpes zoster	*Adult:* IV, 5–10 mg/kg infused over 1 h, q8 h (15 mg/kg/d) for 7 d; PO (initial genital herpes), 200 mg q4h while awake (1,000 mg/d) for 10 d; PO (chronic suppressive therapy), 400 mg bid for up to 12 mo; topical, apply sufficient quantity to cover all lesions six times per day for 7 d; 1.25 cm (1/2 in) ribbon of ointment covers 2.5 cm^2 (4 in^2) surface area q3h *Child:* IV (>12 y), adult dosage; IV (<12 y), 250–500 mg/m^2 infused over 1 h, q8 h (750 mg/m^2/d); PO, safety not established	*Onset:* IV, immediate; PO, varies *Duration:* IV, 8 h; PO, unknown $t_{1/2}$: 2.5–5 h
cidofovir (Vistide)	CMV retinitis in AIDS patients	*Adult:* IV, 5 mg/kg IV infused over 1 h once/wk for 2 consecutive wk during induction (5 mg/kg once every 2 wk for maintenance); probenecid must be administered PO with each dose, 2 g PO 3 h before cidofovir and 1 g at 2 h and 8 h after infusion *Child:* Safety and efficacy not established for children younger than 12 y	*Onset:* Rapid *Duration:* 24 h $t_{1/2}$: 1 h
famciclovir (Famvir)	Acute herpes zoster	*Adult:* PO, 500 mg q8 h for 7 d *Child:* Safety and efficacy not established	*Onset:* Varies *Duration:* 24 h $t_{1/2}$: 2 h
ganciclovir (DHPG, Cytovene)	Recurrent genital herpes CMV infections (retinitis, colitis, esophagitis) in immunocompromised patients Prevention of CMV infection in transplant patients	*Adult:* PO, 125 mg bid for 5 d *Adult:* IV, 5 mg/kg given at a constant rate over 1 h, q12 h for 14–21 d (maintenance: 5 mg/kg given over 1 h once daily, 7 d/wk or 6 mg/kg/d 5 d/wk; PO, 1,000 mg tid with food or 500 mg six times daily q3 h with food while awake) *Child:* Safety and efficacy not established *Adult:* IV, 5 mg/kg over 1 h q12 h for 7–14 d, then 5 mg/kg/d once daily for 7 d or 6 mg/kg/d once daily for 5 d	*Onset:* IV, slow; PO, slow *Duration:* Unknown $t_{1/2}$: 2–4 h; PO, 4.8 h
penciclovir (Denavir)	Herpes labialis	*Adult:* Topical, apply thin layer to affected area q2h while awake. Therapy continues for 4 d	Not generally absorbed systemically
valacyclovir (Valtrex)	Initial or recurrent genital herpes Herpes zoster	*Adult:* PO, 500 mg bid for 5 d *Child:* Safety and efficacy not established *Adult:* PO, 1 g tid for 7 d, most effective if started within 48 h of onset of symptoms	*Onset:* Rapid *Duration:* 3 h $t_{1/2}$: 2.5–3.3 h
valganciclovir (Valcyte)	CMV retinitis Maintenance	*Adult:* PO, 900 mg 2 ×/d × 21 d 900 mg/d	*Onset:* Rapid *Duration:* 12–24 h $t_{1/2}$: 4.8 h
docosanol (Abreva)	HSV	*Adult and child:* Apply cream 5 times/d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown
foscarnet (Foscarvir)	CMV retinitis in patients with AIDS Acyclovir-resistant HSV infections in immunocompromised patients	*Adult:* IV induction, 60 mg/kg q8h for 2–3 wk; maintenance, 90–120 mg/kg *Adult:* IV, 40 mg/kg q8–12 h for 2–3 wk or until healed	*Onset:* Immediate *Duration:* Unknown $t_{1/2}$: 1.4–3 h

of acyclovir are greater than serum concentrations; therefore, it should be given cautiously to nursing mothers.

Note the patient's age before administering acyclovir. Although acyclovir is not contraindicated for use in elderly patients, these patients should be monitored closely for the onset of nephrotoxicity because renal function diminishes with age.

Lifestyle, Diet, and Habits

Advise patients with genital herpes that acyclovir is not a cure and that they are able to transmit the virus to another person, even when asymptomatic. To avoid transmitting the disease, patients should routinely use a condom. Instruct patients to refrain from sexual contact when genital lesions are active. Be aware of patients' economic status. Oral

TABLE 45.2 Agents That Interact with P Acyclovir

Interactants	Effect and Significance	Nursing Management
probenecid	Probenecid inhibits the renal tubular secretion of acyclovir, resulting in increased acyclovir serum concentration and potential for adverse effects of acyclovir.	Monitor I/O. Monitor BUN and creatinine levels. Discuss dosage adjustment with prescriber.
hydantoins	Serum phenytoin concentrations may be decreased, resulting in an increased risk for seizure activity.	Monitor the patient for seizure activity. Ensure patient safety. Discuss dosage adjustment with prescriber.
theophyllines	Acyclovir may inhibit the metabolism of theophyllines, resulting in an increased risk for adverse effects to theophylline.	Monitor theophylline levels closely. Monitor for adverse effects such as tachycardia, nausea, vomiting, diarrhea, seizures, restlessness, irritability, and headache. Discuss dosage adjustment with prescriber.
valproic acid	Serum valproic acid concentrations may be decreased, resulting in an increased risk for seizure activity.	Monitor the patient for seizure activity. Ensure patient safety. Discuss dosage adjustment with prescriber.

acyclovir is expensive. It is one of the drugs approved for reimbursement in many statewide AIDS programs. Patients may qualify for medical assistance from county, state, or federal funds or receive their drugs from local health departments. Refer patients with financial problems to the hospital or clinic's social service department.

Environment

Acyclovir is most frequently given in the outpatient community setting. Caution patients to take acyclovir only when active lesions are present to avoid inducing acyclovir-resistant virus. However, some immunocompromised patients with frequent or severe outbreaks may be placed on a prophylactic regimen. Acyclovir should be protected from light and moisture in the home environment.

Administer IV acyclovir in acute care settings to patients with a severe outbreak. Use reconstituted acyclovir within 12 hours. Administer the infusion over 60 minutes.

Nursing Diagnoses and Outcomes

- Disturbed Thought Processes related to drug-induced confusion, hallucinations, or seizures
  Desired outcome: *The patient will be free of thought aberrations related to drug therapy.*
- Acute Pain related to drug-induced headache
  Desired outcome: *Drug-related pain will subside after administration of acetaminophen.*
- Imbalanced Nutrition: Less than Body Requirements, related to acyclovir-related anorexia, nausea and vomiting, or abdominal pain
  Desired outcome: *The patient will remain within an acceptable weight range.*
- Excess Fluid Volume related to adverse effects of drug therapy, such as nephrotoxicity
  Desired outcome: *The patient will have an adequate fluid intake and output profile.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer acyclovir tablets or capsules with a full glass of water, with or without food. Administering the drug at regular intervals is important.

Minimizing Adverse Effects

Oral acyclovir is well tolerated. However, for patients who report GI complaints, administer the drug with food. Advise the patient to drink at least eight 8-oz glasses of water a day.

To minimize potential nephrotoxicity, ensure that the patient is well hydrated. Administer IV acyclovir over 60 minutes. It is best to use an infusion pump to ensure that administration is timed correctly. Monitor the patient's urine output for 2 hours after the infusion and notify the prescriber if urine output is less than 500 mL/g of acyclovir administered.

Providing Patient and Family Education

- One of the most important points to stress with patients is that they should not take this drug if they have ever had a reaction to any drug with a name that ends in "vir."
- Advise patients to notify the prescriber if they are pregnant or breast-feeding.
- Explain that acyclovir is prescribed for a particular infection and should not be used to self-medicate or to treat any other infection.
- Emphasize that acyclovir does not prevent the transmission of infection to another person and does not cure the infection.
- Instruct patients to complete the full course of drug therapy, even if the lesions resolve. If patients are taking 200-mg tablets, advise them to take the drug five times a day. For patients who have difficulty taking pills, the drug may be taken in 400-mg doses three times a day. However, consult with the prescriber to be sure the alternate method is acceptable.

- It is important to advise patients to keep the drug away from light and moisture, and to instruct them to take forgotten doses as soon as they remember, but not if it is time for the next dose.
- Inform patients of the importance of remaining well hydrated while taking this drug.
- Teach patients to recognize the symptoms of an allergic reaction to acyclovir. Patients should stop taking the drug and contact their prescriber if a rash, welts, itching, or shortness of breath occurs.
- Explain the potential adverse effects of acyclovir and the potential remedies for these discomforts. If patients experience central nervous system (CNS) effects, such as confusion, tremors, hallucinations, or coma, or have signs of nephrotoxicity, such as weight gain or decreased urinary output, the prescriber should be contacted immediately.
- Because autoinoculation is possible with herpetic lesions, it is important to teach patients to wear a glove or finger cot when applying topical acyclovir. Explain the importance of washing the hands after each application, even when barriers are used. The drug should be applied to cover the lesions every 3 hours, six times a day for 7 days.
- Advise patients to contact the prescriber if the lesions turn red, become hot, or exude purulent material, all of which are indications of a secondary bacterial infection.
- Instruct patients to self-administer acetaminophen if headache occurs. For persistent pain, unrelieved by acetaminophen, patients should contact the prescriber.
- Instruct patients to consume frequent small meals if GI distress occurs. If weight loss persists, patients should contact the prescriber.

Ongoing Assessment and Evaluation

Monitor for the effectiveness of therapy, making sure to document new lesions and assess for possible secondary bacterial infections. Also, monitor for adverse effects, such as lethargy, tremors, headache, change in mental status, and GI complaints.

For immunocompromised and elderly patients, monitoring renal function to detect early nephrotoxicity is important. Patients on long-term therapy should have periodic renal function tests. Hospitalized patients receiving IV acyclovir also should be monitored closely for developing nephrotoxicity. Measure and monitor fluid intake and output to ensure adequate hydration. Also, monitor for the development of phlebitis when administering IV acyclovir. By the completion of therapy, herpetic lesions and any adverse effects should be resolved.

Drugs Closely Related to P Acyclovir

Famciclovir

Famciclovir (Famvir) is an alternative to acyclovir in treating acute herpes zoster and recurrent episodes of genital herpes. In patients with chronic HBV infection, famciclovir has decreased HBV, DNA, and aminotransferase activity. Famciclovir's spectrum of activity is similar to that of acyclovir, but its duration of action is longer. Recent studies have shown that 1-day famciclovir therapy is as efficacious as 3-day valacyclovir therapy when treating recurrent genital herpes. Despite famciclovir's advantages of better bioavailability and longer duration of action, acyclovir possesses a higher affinity for thymidine kinase, the enzyme that promotes metabolism.

The adverse effects and drug interactions of famciclovir are the same as those seen with acyclovir. Famciclovir is classified as an FDA pregnancy category B drug; however, it should be used in pregnancy only if the benefit clearly outweighs the potential risk.

Valacyclovir

Valacyclovir (Valtrex) was developed to improve acyclovir's oral bioavailability. Improved bioavailability means that less

CRITICAL THINKING SCENARIO

ACYCLOVIR AND HERPES SIMPLEX VIRUS

Your patient Sara Thompson is HIV antibody positive and has a history of type 1 diabetes and steroid-dependent asthma. Current drugs include Combivir (150/300 mg bid), Kaletra (200/50 mg bid), Lantus (30 units daily), metformin (500 mg twice daily), and prednisone (20 mg daily). Ms. Thompson experienced severe headache, nausea, drowsiness, and confusion and was admitted to the hospital with a diagnosis of altered level of consciousness. After multiple laboratory tests, she is diagnosed with herpetic encephalitis, and the provider prescribes acyclovir (10 mg/kg every 8 hours).

1. What factors do you think contributed to this diagnosis?
2. What additional information do you need?
3. Would you administer this medication?
4. What body systems do you need to monitor closely in this patient?
5. What discharge instructions do you anticipate providing?

MEMORY CHIP

P Acyclovir

- Used for the management of herpes simplex virus, herpes zoster virus, Epstein-Barr virus, and cytomegalovirus
- Major contraindication: hypersensitivity or cross-sensitivity to ganciclovir
- Most common adverse effects: nausea, vomiting, anorexia, light-headedness, abdominal pain, and headache
- Most serious adverse effects: seizures and renal dysfunction
- Maximizing therapeutic effects: Administer the drug at regular intervals.
- Minimizing adverse effects: Ensure hydration to avoid nephrotoxicity.
- Most important patient education: Acyclovir treats the symptoms of the disease; it does not cure the disease or prevent its transmission to another person.

frequent dosing is required for valacyclovir than for acyclovir. Valacyclovir is the drug of choice in treating genital herpes, either as a first episode or as a recurrent episode. It also is the drug of choice in treating herpes zoster. Compared with acyclovir, it demonstrates earlier pain reduction or cessation of pain in treating herpes zoster.

The adverse effects and drug interactions of valacyclovir are similar to those of acyclovir. In immunocompromised patients, valacyclovir also may induce thrombotic thrombocytopenic purpura and hemolytic uremia syndrome. For that reason, it is not indicated for use in immunocompromised patients. It is used with caution in patients with renal dysfunction because accumulation of valacyclovir may induce acute renal failure or neuropsychiatric adverse effects, especially in the elderly. Post-marketing reports indicate the potential for psychosis with manic presentation in young, healthy patients without a psychiatric history. To prevent crystalluria, teach the patient to remain well hydrated to maintain a high urine volume and avoid dehydration. Valacyclovir is in FDA pregnancy category B.

Drugs Significantly Different From Acyclovir

Drugs Used for Cytomegalovirus Infections

Cidofovir

Cidofovir (Vistide) is an IV drug indicated for treating CMV retinitis in patients with AIDS. Cidofovir gel has been effective for topical treatment of acyclovir-resistant mucocutaneous HSV infections in AIDS patients. Cidofovir may also be used in patients with ganciclovir resistance. Its major advantage is its long half-life, which allows for a once-weekly infusion.

Cidofovir use is limited by its serious potential toxic effects. Major adverse effects with cidofovir therapy include renal impairment, granulocytopenia, metabolic acidosis, uveitis, and ocular hypotony. To minimize possible nephrotoxicity, IV normal saline solution and oral probenecid must be used before and after each cidofovir dose. Renal function tests should be completed before each dose of cidofovir. Neutrophil counts also should be monitored throughout therapy. Cidofovir therapy is contraindicated in patients who are taking other nephrotoxic agents. Cidofovir is classified as an FDA pregnancy category C drug and should be used in pregnancy only if the benefit clearly outweighs the potential risk.

Foscarnet

Foscarnet (Foscavir) is an IV antiviral agent that is structurally unrelated to other antiviral agents. Foscarnet currently is indicated for treating CMV retinitis in patients with AIDS. It is also being investigated for treating CMV disease, herpes simplex, and varicella zoster infection in HIV-positive patients. Its mechanism of action is similar to that of acyclovir and ganciclovir, yet it does not require phosphorylation before becoming activated.

Foscarnet therapy should be given with caution to patients with anemia, dehydration, renal impairment, and electrolyte imbalances. Patients who have cardiac disease, are receiving other drugs that influence serum electrolytes, or have a pre-existing seizure disorder or other neurologic disease require close monitoring during treatment. Foscarnet is assigned to pregnancy category C and should therefore be used with caution during pregnancy.

Foscarnet has an extensive and serious adverse reaction profile. Anemia, granulocytopenia, or leukopenia develop in as many as 33% of patients on foscarnet therapy. Electrolyte imbalances, such as hypocalcemia, hypophosphatemia or hyperphosphatemia, hypomagnesemia, and hypokalemia also may occur. GI disturbances, such as anorexia, abdominal pain, nausea, and vomiting, occur in up to 30% of patients. Considerable renal impairment, resulting in azotemia or necrosis, develop in as many as 33% of patients. Patients with renal impairment also are at high risk for seizures. Other CNS effects include headache, peripheral neuropathy, and anxiety.

Foscarnet should be given with caution in combination with other drugs known to be nephrotoxic, such as acyclovir, aminoglycosides, amphotericin B, cisplatin, cyclosporine, gold compounds, lithium, nonsteroidal anti-inflammatory drugs, penicillamine, pentamidine, rifampin, and vancomycin. In combination with ciprofloxacin, foscarnet increases the risk of seizures, whereas the combination of foscarnet and zidovudine increases the risk of anemia.

Ganciclovir

Ganciclovir (Cytovene) is an antiviral agent used to treat CMV infections, especially retinitis, colitis, and esophagitis, in immunocompromised patients. It is the drug of choice to prevent CMV infection in immunocompromised patients, such as patients with HIV or transplant recipients. Its spectrum of activity also includes HSV-1 and HSV-2, herpesvirus type 6, Epstein-Barr virus, varicella zoster virus, and HBV.

Like acyclovir, ganciclovir works by terminating DNA synthesis. It is administered intravenously, orally, and by intravitreal implantation. After implantation, intravitreal ganciclovir is released at a steady rate over 5 to 8 months. After oral administration, ganciclovir is absorbed poorly from the GI tract. Bioavailability is increased when ganciclovir is administered with a high-fat meal. Following IV administration, distribution into body tissues and fluids, including the eyes, is extensive. Ganciclovir crosses the placenta and the blood–brain barrier.

Ganciclovir is not indicated for use in neonates and children and should not be taken during pregnancy and lactation. It must be used with caution in patients with depressed bone marrow function, dehydration, neutropenia, hematologic disease, thrombocytopenia, renal disease or impairment, or recent radiation therapy. Cross-sensitivity is also possible with acyclovir.

Ganciclovir can cause substantial hematologic toxicity. Granulocytopenia, neutropenia, and thrombocytopenia have all occurred during ganciclovir therapy. Like acyclovir, ganciclovir is potentially nephrotoxic. Slight-to-moderate increases in serum creatinine and azotemia have occurred. Elevated liver function test results also may occur during therapy with ganciclovir; such changes are generally reversible. Serial laboratory tests required during therapy include complete blood count (CBC), platelet counts, and renal and liver function tests.

Advise the prescriber immediately if the platelet count is less than 25,000 mm^3 or the neutrophil count is less than 500 mm^3.

Adverse effects, which occur most commonly with IV administration of ganciclovir, include diaphoresis, pruritus, pneumonia, chills, sepsis, and phlebitis. Adverse effects seen with intravitreal administration of ganciclovir may induce bacterial endophthalmitis, retinal detachment, vitreous hemorrhage, cataracts, corneal opacification, hyphema, floaters, ocular pain, posterior chamber inflammation, macular abnormalities, spikes of increased intraocular pressure, optic disc or nerve changes, and uveitis.

Ganciclovir is in FDA pregnancy category C. Based on animal studies, ganciclovir should be considered a potential teratogen in humans, with the potential to cause birth defects. It also suppresses spermatogenesis.

Valganciclovir

Valganciclovir (Valcyte) is an ester of ganciclovir. This oral drug is rapidly metabolized into its active form, ganciclovir. Pharmacotherapeutics for valganciclovir include treatment of active CMV retinitis in patients with AIDS, maintenance therapy for CMV retinitis, secondary prophylaxis in patients with inactive CMV retinitis, and prophylaxis against CMV infections in solid organ transplant patients. Oral valganciclovir has the same efficacy as IV ganciclovir for the management of active CMV retinitis. The drug is also approved for prophylaxis against CMV following heart, kidney, or kidney-pancreas transplantation.

Adverse effects and contraindications for valganciclovir are similar to those for ganciclovir. Serial laboratory tests required during therapy include CBC, renal function tests, and liver function tests.

Valganciclovir is classified in FDA pregnancy risk category C. In animal studies, ganciclovir was found to be mutagenic and teratogenic. Therefore, as a prodrug to ganciclovir, valganciclovir should be considered a potential teratogen in humans, with the potential to cause birth defects.

Topical Drugs

Docosanol

Docosanol (Abreva) is an over-the-counter (OTC) topical cream for recurrent oral-facial herpes simplex episodes. Docosanol works by inhibiting fusion between the plasma membrane and the HSV envelope, thereby preventing viral entry into cells and subsequent viral replication. Other antivirals, such as acyclovir, work by inhibiting viral DNA replication and carry a risk for mutating the virus. Because docosanol does not act directly on the virus, it is unlikely it will produce drug-resistant mutants of HSV. Docosanol has minimal adverse effects; headache is the most common. Successful therapy occurs when the drug is applied at the earliest sign of infection.

Penciclovir

Penciclovir (Denavir) is a topical antiviral agent used to treat herpes labialis. Penciclovir is the active metabolite of famciclovir. It works by inhibiting viral DNA. Penciclovir is applied every 2 waking hours.

Adverse effects associated with penciclovir use include headache, oral and pharyngeal edema, application site reactions, erythematous rash, pain, paresthesias, pruritus, skin discoloration, and urticaria.

Ophthalmic Drugs

Trifluridine

Trifluridine (Viroptic) is an ophthalmic solution used in primary keratoconjunctivitis and recurrent epithelial keratitis caused by HSV-1 and HSV-2. One drop of 1% solution should be instilled into the affected eye every 2 hours during waking hours, up to a maximum daily dose of nine drops. This therapeutic regimen should continue until the corneal ulcer has completely re-epithelialized. At this point, it is important to treat for an additional 7 days with one drop every 4 hours during waking hours, up to a maximum daily dosage of five drops.

No important interactions between trifluridine and other drugs have been reported. Adverse effects include mild transient burning or stinging on instillation, palpebral edema, epithelial keratopathy, irritation, keratitis sicca, hyperemia, and increased intraocular pressure.

Drugs Used for Influenza

While influenza is a debilitating virus, it generally subsides without pharmacotherapy. However, in certain populations, it can be a serious illness, possibly resulting in death. Oseltamivir (Tamiflu) is the prototype anti-influenza drug. Table 45.3 summarizes drugs used for influenza.

Oseltamivir

Pharmacotherapeutics

Oseltamivir phosphate (Tamiflu) is a neuraminidase inhibitor used to manage infection with influenza A or B virus. It is the drug of choice for H5N1 (avian or bird) influenza and the novel H1N1 (swine) influenza (Box 45.1). Since the H1N1 virus became pandemic in 2009, isolates of this virus have become oseltamivir-resistant in many countries. It is also used as prophylaxis against influenza A and B.

Pharmacokinetics

Oseltamivir phosphate is available as an oral capsule or as powder for reconstitution. It is a prodrug that is metabolized into oseltamivir carboxylate, which is the active drug. It is excreted 99% unchanged by the kidneys.

Pharmacodynamics

Influenza A and B viruses contain the viral enzyme neuraminidase on their surfaces, which facilitates the release of newly formed virus particles from infected cells. This mechanism enables infection of adjacent cells. Neuraminidase inhibitors, such as oseltamivir, appear to inhibit the release of viruses from infected cells, thus reducing spread to adjacent cells and limiting tissue damage and the duration of symptoms. The effectiveness of the drug depends on how early the treatment is initiated.

Contraindications and Precautions

Hypersensitivity is the only contraindication to the use of oseltamivir. Precautions include pregnancy, breastfeeding, asthma, CAL, and patients with renal insufficiency.

BOX 45.1 COMMUNITY BASED CONCERNS

Is it a bird, a plane, or a pig?

H5N1 influenza A virus (aka avian or bird flu) had been reported to be the next pandemic threat to the world. Who knew that a pig would take its place? A pandemic event requires three characteristics: it is a new strain of disease that most people do not have a natural immunity to resist, it has the ability to cause human illness, and it is transmissible from human to human.

On June 6, 2009 the World Health Organization (WHO) declared the novel H1N1 influenza A virus (aka swine flu) to be a pandemic event. As of July 27, 2009 there were 134,503 confirmed cases throughout the world with 816 deaths. The novel H1N1 virus was initially called the "swine flu" because laboratory testing showed that many of the genes were very similar to influenza viruses that normally occur in pigs in North America. However, further study has shown that this new virus is very different from the virus that occurs in North American pigs.

The novel H1N1 virus generally presents with symptoms of seasonal influenza: fever, cough, sore throat, malaise, nasal congestion, myalgias, chills, fatigue, and headache. Like seasonal influenza, H1N1 may also cause CNS symptoms including seizure activity. In addition, many patients also experienced vomiting and diarrhea which do not normally occur with seasonal influenza. The largest number of novel H1N1 flu confirmed cases have occurred in people between the ages of 5 and 24 years old. With seasonal influenza, over 90% of deaths and about 60% of hospitalization occur in people older than 65. At this time, there are few cases and no deaths reported in people older than 64 years old.

Not all patients with novel H1N1 virus require pharmacotherapy. Those with mild symptoms need acetaminophen, rest, and fluids. Patients who require hospitalization are treated with oseltamivir or zanamivir, optimally within 48 hours of the onset of symptoms. Pregnant women should receive pharmacotherapy. Influenza causes more severe disease and an increased rate of mortality during pregnancy. Use of acetaminophen is important when fever is present, because hyperthermia during the first trimester has been associated with birth defects and fever during labor is a risk factor for neonatal seizures, encephalopathy, cerebral palsy, and neonatal death. Both oseltamivir and zanamivir are pregnancy category C.

Nursing Implications

H1N1 influenza A is a potentially life-threatening illness, especially in the very young, immunocompromised patients, and those with chronic illness. The media has reported extensively on this pandemic event. Nurses have a special relationship with patients that allow the patient to express his/her fears and seek information from a person they trust. Continue to update yourself on the facts of the H1N1 influenza A virus. Rely on information from medical sources, rather than media sources. Advise your patients to take the same precautions as they would for any type of influenza: stay away from people known to be ill, especially children; wash hands frequently; use bacteriostatic hand gels; and get plenty of rest and fluids. Advise patients with a mild influenza-like illness to self-isolate at home for a minimum of 24 hours after the cessation of symptoms. Encourage patients with more severe symptoms to seek medical attention quickly.

Adverse Effects

The most common adverse effects of oseltamivir are nausea and vomiting, bronchitis, insomnia, and vertigo. In 2006, post-marketing reports indicated a risk for abnormal behavior with subsequent injury, especially in children. It is unclear if oseltamivir is the etiology because influenza itself may cause neurologic and behavioral symptoms such as hallucinations, delirium, and abnormal behavior.

Drug Interactions

There are no known significant drug-drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for influenza symptoms as the patient may not know the difference between influenza and the common cold (Box 45.2).

Life Span and Gender

For women, determine the potential for pregnancy and lactation. Oseltamivir is an FDA pregnancy category C drug. It is unclear whether it passes into breast milk. Weigh children to ensure an accurate dose of medication.

Lifestyle, Diet, and Habits

Assess for a history of fructose intolerance. Oseltamivir suspension contains 2 g of sorbitol per 75 mg dose. It may be taken with or without food.

Environment

Oseltamivir is most frequently given in the community environment. Occasionally, the patient may be severely ill and require hospitalization.

Nursing Diagnoses and Outcomes

- Disturbed Thought Processes related to drug-induced confusion, hallucinations, or seizures
  Desired outcome: *The patient will be free of thought aberrations related to drug therapy*
- Risk for Injury related to abnormal behaviors
  Desired outcome: *The patient will remain free from injury*
- Imbalanced Nutrition: Less than Body Requirements, related to anorexia, nausea and vomiting, or abdominal pain
  Desired outcome: *The patient will remain within an acceptable weight range.*

Planning and Intervention

Maximizing Therapeutic Effects

Question the patient regarding the duration of symptoms. Oseltamivir works best when begun within 48 hours of the onset of symptoms. To prepare the solution, add 23 mL of water to the bottle containing the powder and shake well for 15 seconds. Administer the solution directly in the mouth–do not mix with any liquid. Cleanse the dispenser under running water and allow to air dry. Store the unused solution in the refrigerator. Shake the solution prior to each dose. Store the oseltamivir capsules at room temperature.

Minimizing Adverse Effects

Nausea and vomiting can be reduced by administration with milk, a snack, or a meal.

TABLE 45.3 Summary of Selected Anti-Influenza Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
amantadine (Symmetrel; *Canadian:* Gen-Amantadine)	Influenza A	*Adults <65 y and adolescents:* PO, 200 mg/d daily and continue for 24–48 h after resolution of signs/symptoms *Elderly:* PO, 100 mg/d and continue for 24–48 h after resolution of signs/symptoms *Children:* PO, 10 y and >40 kg: 100 mg 2×/d; 10 y and <40 kg: 5 mg/kg/d PO in two divided doses, not to exceed 200 mg/d; <10 y: 5 mg/kg/d (up to 150 mg/d) in 2 divided doses	*Onset:* 2 h *Duration:* 12 h $t_{1/2}$: 15–24 h
rimantadine (Flumadine)	Influenza A	*Adults and adolescents >14 y:* PO, 100 mg 2×/d for 24–48 h after resolution of signs/symptoms *Elderly:* PO, 100 mg qd for 24–48 h after resolution of signs/symptoms *Children:* PO, 10–13 y and >40 kg: 200 mg qd; 10–13 y and <40 kg: 5 mg/kg/d or 200 mg qd, whichever is less; 1–9 y: 5 mg/kg/d or 150 mg qd, whichever is less	*Onset:* Slow *Duration:* Unknown $t_{1/2}$: 25.4 h
P Oseltamivir (Tamiflu)	Influenza A and B prophylaxis	*Adults and adolescents ≥13 y:* PO, 75 mg 2×/d for 5 d *Children 1–12y:* PO, 2×/d for 5 d >40 kg: 75 mg (6.2 mL) 24–40 kg: 60 mg (5 mL) 16–23 kg: 45 mg (3.8 mL) <15 kg: 30 mg (2.5 mL) 2×/d for 5 d *Infants <1 y:* Not indicated *Adult and Child:* PO Dose as above, once daily for 10 d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 6–10 h
zanamivir (Relenza)	Influenza A and B Influenza prophylaxis during outbreak or exposure	*Adults and children >7 y:* PO, 2 inhalations 2×/d for 5 d *Children <7 y:* Safety and efficacy have not been established *Adults and children >7 y:* PO, 2 inhalations (10 mg) daily *Children ≤7 y:* Safety and efficacy have not been established	*Onset:* 1 h *Duration:* 24 h $t_{1/2}$: 2.5–5.1 h

Providing Patient and Family Education

- Instruct the patient on the correct way to prepare, administer, and store the solution.
- Teach the patient the importance of using the dispenser that accompanies the product to assure an accurate dose of the solution.
- Encourage the patient to take the medication for the full course of therapy as prescribed (5 days for acute illness; 10 days for prophylaxis).
- Instruct families to monitor children closely throughout therapy and contact the provider immediately should any unusual behavior occur.
- Instruct the patient to contact the provider for severe nausea and diarrhea or worsening of symptoms.
- Teach the patient oseltamivir is not a substitute for yearly influenza vaccine.

Ongoing Assessment and Evaluation

Monitor for abnormal behavior; notify the provider immediately if it occurs. Monitor for elevated temperature, nausea, vomiting, and diarrhea. Assess for resolution of the symptoms.

Drugs Closely Related to Oseltamivir

Zanamivir

Zanamivir (Relenza) is the second neuraminidase inhibitor. Its mechanism of action is the same as that of oseltamivir. Zanamivir is an orally inhaled agent that is approved for use in adults and in children older than 7 years of age. Like oseltamivir, the effectiveness of zanamivir is directly related to the promptness with which treatment is initiated.

Box 45.2 SYMPTOMS AT A GLANCE

Signs and Symptoms	Flu	Cold
Onset	Sudden	Gradual
Fever	Common, lasting 3–4 days	Rare
Cough	Dry, can become severe	Hacking, mild
Headache	Prominent	Rare
Muscle/joint aches, pain	Usual, often severe	Slight
Fatigue and weakness	Can last up to 2 weeks	Very mild
Extreme exhaustion	Early and prominent	Never
Chest discomfort	Common	Mild/Moderate
Stuffy nose	Sometimes	Common
Sneezing	Sometimes	Usually
Sore throat	Sometimes	Common

Roche patient information handout

Zanamivir is supplied on a Rotadisk containing four blisters of a powder mixture. The Rotadisk is loaded into a Diskhaler, the blister is punctured, and the patient inhales through the mouthpiece. The actual amount of drug delivered to the respiratory tract depends on the ability of the patient to inhale adequately. Approximately 10% of zanamivir is absorbed systemically. It is excreted renally as unchanged drug.

Adverse effects with zanamivir include headache, dizziness, nausea, diarrhea, and respiratory effects such as sinusitis, bronchitis, cough, nasal symptoms, and infections. Because zanamivir is administered by oral inhalation, it is more likely to cause local adverse effects, such as bronchospasm, than systemic reactions. For this reason, zanamivir is given cautiously to patients with underlying respiratory disorders, especially asthma. Instruct the patient to have a fast-acting inhaled bronchodilator, such as albuterol, available when administering zanamivir. It is an FDA pregnancy category B drug.

Like oseltamivir, zanamivir should not be substituted for yearly influenza vaccine in high-risk populations. The considerations for LAIV apply to zanamivir as well.

Drugs Significantly Different From Oseltamivir

Amantadine

Amantadine (Symmetrel) is a synthetic antiviral agent used for the prophylactic or symptomatic treatment of influenza A virus infection, especially in high-risk patients. It is not recommended for use in the United States because of substantial resistance. It also is used to relieve the symptoms of Parkinson disease. It is not effective for the novel H1N1virus.

As an antiviral, amantadine appears to block the uncoating of the virus particle and subsequent release of viral nucleic acid into the host cell. Amantadine also may interfere with penetration of the cell wall by adsorbed virus. In treating Parkinson disease, amantadine appears to potentiate CNS dopaminergic responses. It may release dopamine and norepinephrine from storage sites and inhibit the reuptake of dopamine and norepinephrine.

Amantadine is administered orally and is well absorbed from the GI tract. It crosses the blood–brain barrier and the placenta; distributes into tears, saliva, and nasal secretions; and is excreted into breast milk. About 90% of amantadine is excreted in the urine by way of glomerular filtration and tubular secretion.

Amantadine should be given with caution to patients with chronic heart failure, peripheral edema, seizure disorders, eczema, and history of psychosis. These conditions may be exacerbated by amantadine therapy. Patients with renal impairment, elderly patients, and pregnant women also should be given amantadine with caution because these conditions increase the risk of adverse effects. Abrupt withdrawal of amantadine should be avoided in patients with Parkinson disease because it may precipitate symptoms of increased rigidity, confusion, urinary retention, or bulbar palsy.

Amantadine has many potential adverse effects. In the GI system, amantadine may cause nausea and vomiting, diarrhea, constipation, anorexia, and xerostomia. CNS effects include dizziness, anxiety, impaired coordination, insomnia, and nervousness. Other CNS effects that occur less commonly are headache, irritability, nightmares, depression, ataxia, confusion, somnolence and drowsiness, agitation, fatigue, and hallucinations. Patients with a history of psychosis may experience an exacerbation of symptoms, including abnormal thinking, weakness, amnesia, slurred speech, and hyperkinesia. In rare cases, amantadine has been associated with more serious effects, including increased frequency of seizures, suicidal ideation, and neuroleptic malignant syndrome. Adverse cardiovascular effects include orthostatic hypotension and peripheral edema. Livedo reticularis, a persistent purplish network-patterned discoloration of the skin, is a common adverse reaction among patients taking amantadine for Parkinson disease. This reaction is believed to be caused by abnormal capillary permeability associated with peripheral vasoconstriction, which results in decreased skin temperature and peripheral blood flow. Amantadine also may cause adverse reactions in the eyes. Diffuse, white, subendothelial corneal opacification may occur. Other ophthalmic adverse reactions include corneal edema, light sensitivity, and optic nerve palsy.

Amantadine should not be used with CNS stimulants, alcohol (ethanol), opiate agonists, hydrochlorothiazide, or triamterene. Nervousness, irritability, insomnia, seizures, or cardiac arrhythmias may occur if amantadine is taken concurrently with CNS stimulants. Ethanol use with amantadine may increase CNS effects, such as dizziness, confusion, light-headedness, fainting, or orthostatic hypotension. Use of opiate agonists may increase the incidence of adverse effects. Hydrochlorothiazide or triamterene, used in conjunction with amantadine, can reduce renal clearance of amantadine, with subsequent increase in plasma amantadine concentrations and possible toxicity.

Rimantadine

Rimantadine (Flumadine) is an oral antiviral agent. It is indicated for prophylaxis and treatment of influenza A virus infection in adults and for prophylaxis only in children. Like amantadine, it is not recommended for use in the United States.

Rimantadine is related chemically and structurally to amantadine, but it does not produce the CNS effects seen with amantadine and does not have therapeutic value in treating Parkinson disease.

Rimantadine is contraindicated for use in infants and neonates. It should be used cautiously in elderly patients and in patients with hepatic or renal dysfunction because delayed metabolism or excretion of rimantadine may increase the risk for toxic effects.

Rimantadine has a much better adverse effects profile than amantadine. The most common adverse effects reported are nausea, vomiting, insomnia, dizziness, anorexia, xerostomia, abdominal pain, headache, asthenia, nervousness, and fatigue.

Clearance of rimantadine is reduced by concurrent administration of cimetidine. Decreased serum concentration may occur if rimantadine is coadministered with acetaminophen or aspirin.

Drugs Used for Hepatitis

Tables 45.4 and 45.5 summarize information about drugs used to treat hepatitis.

Interferons

The interferons are a family of glycoproteins that affect many types of viral illness. They are administered parenterally, either subcutaneously or intramuscularly. Although pharmacologically similar, each is used for specific viral illnesses. The three main classes of interferons are interferon alfa, interferon beta, and interferon gamma. Interferon alfa and interferon beta are used in the management of hepatitis, whereas interferon gamma is used for other types of viral illness. The interferons are presented in depth in Chapter 54.

TABLE 45.4 Summary of Selected Drugs for Hepatitis

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
interferon alfa-2a (Roferon-A)	See Table 45.5.	*Adult:* IM/SC, 3 million international units 3×/wk for 12 mo	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 3.7–8.5 h
interferon alfa-2b (Intron-A)	See Table 45.5.	*Adult:* IM/SC, 5 million international units/d or 10 million international units 3×/wk for 16 wk 3 million international units 3×/wk for up to 18–24 mo if a positive response	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 2–3 h
peginterferon alfa-2a (Pegasys)	See Table 45.5.	*Adult:* SC, 180 mcg once weekly for 24 wk 180 mcg once weekly for 48 wk	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 70–90 h
peginterferon alfa-2b (PEG-Intron)	See Table 45.5.	*Adult:* SC, 1 mcg/kg/wk	*Onset:* Rapid *Duration:* 42–72 h $t_{1/2}$: 4.6 h
interferon alfa-n3 (Alferon)	See Table 45.5.	*Adult:* IM/SC, 3–6 million international units 3×/wk	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown
interferon alfacon-1 (Infergen)	See Table 45.5.	*Adult:* SC, 9 mcg 3×/wk for 24 wk. At least 48 h should elapse between doses.	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown
interferon alfa-2b (SC) and ribavirin (PO) (Rebetron)	See Table 45.5.	*Adults >75 kg:* Ribavirin, PO, 600 mg 2×/d in combination with interferon alfa-2b, 3 million international units SC 3×/wk *Adults, adolescents, and children >61 kg:* Ribavirin, PO, 400 mg in the morning and 600 mg in the evening every day, in combination with interferon alfa-2b, 3 million international units SC 3×/wk *Adults, adolescents, and children 50–61 kg:* Ribavirin, PO, 400 mg 2×/d, in combination with interferon alfa-2b, 3 million international units/m^2 SC 3×/wk *Adolescents and children 37–49 kg:* Ribavirin, PO 200 mg in the morning and 400 mg in the evening every day, in combination with interferon alfa-2b, 3 million international units/m^2 SC 3×/wk *Adolescents and children 25–36 kg:* Ribavirin, PO 200 mg 2×/d, in combination with interferon alfa-2b, 3 million international units/m^2 SC 3×/wk	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 3.7–8.5 h
adefovir (Hepsera)	See Table 45.5.	*Adult:* PO, 10 mg 1×/d	*Onset:* Unknown *Duration:* 24 h $t_{1/2}$: 7.5 h
boceprivir (Victrelis)	Hepatitis C	*Adult PO:* 800 mg 3× day	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 12–15 h
entecavir (Baraclude)	Chronic hepatitis B	*Adult:* PO, 0.5–1 mg every day	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 128–149 h
lamivudine (Epivir-HBV)	Chronic hepatitis B	*Adult:* PO 100 mg daily *Child >2y:* PO 3 mg/kg daily	*Onset:* Rapid *Duration:* 12 h $t_{1/2}$: 5–7 h

TABLE 45.5 Drugs for Managing Hepatitis

Name	Hepatitis B	Hepatitis C
interferon alfa-2a (Roferon-A)		X
interferon alfa-2b (Intron-A)	X	X
peginterferon alfa-2a (Pegasys)	X	X
peginterferon alfa-2b (PEG-Intron)		X
interferon alfacon-1 (Infergen)		X
interferon alfa-2a and ribavirin (Rebetron)		X
adefovir (Hepsera)	X	
entecavir (Baraclude)	X	
lamivudine (Epivir HBV)	X	
tenofovir		
telbivudine	X	

Interferon Alfa

Interferon alfa is an immunomodulator. The name interferon alfa actually refers to several compounds that differ slightly in their amino acid sequence and duration of action. Conventional interferons include:

- Interferon alfa-2a (Roferon-A)
- Interferon alfa-2b (Intron-A)
- Interferon alfacon-1 (Infergen)
- Interferon alfa-n3 (Alferon)

Long-acting interferons include:

- Peginterferon alfa-2a (Pegasys)
- Peginterferon alfa-2b (PEG-Intron)

Interferon alfa is approved for treating hairy cell leukemia, AIDS-related Kaposi sarcoma, condylomata acuminatum, chronic HBV, and chronic HCV It also has been used investigationally for treating renal cell carcinoma, bladder carcinoma, chronic myelogenous leukemia, and lymphomas. Peginterferon combined with oral ribavirin is the treatment of choice for HCV. Ribavirin is discussed later in this chapter.

Other Drugs for Hepatitis

Lamivudine, adefovir, entecavir, tenofovir, and telbivudine are also used in the management of hepatitis B. They are nucleoside or nucleotide analogues (Table 45.4).

Adefovir Dipivoxil

Adefovir dipivoxil (Hepsera) is a nucleoside reverse transcriptase inhibitor (NRTI) used in managing chronic HBV infection. Although it was initially introduced as an antiretroviral drug, it led to a high incidence of nephrotoxicity at the dose needed to affect the HIV virus. Adefovir replaces a nucleotide in the HBV virus, resulting in DNA chain termination.

Common adverse effects of adefovir include GI complaints such as abdominal pain, diarrhea, dyspepsia, flatulence, and nausea, as well as headache or rash. Although the prevalence of nephrotoxicity is much lower with the current recommended dosage of adefovir, it may still occur. The risk of nephrotoxicity is highest in patients with pre-existing renal impairment, and they require a reduction in dose. The drug should also be given cautiously to patients with liver dysfunction. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, may occur with the use of nucleoside analogues alone or in combination with other antiretrovirals. Acute hepatitis may occur in patients who stop taking drugs, including adefovir, for HBV. Serial liver function tests should be performed for several months after ceasing therapy, to monitor for hepatitis.

Caution is necessary when adefovir is given to patients who are taking other drugs that increase the risk of renal or hepatic toxicity and lactic acidosis. Adefovir is an FDA pregnancy category C drug. It is not known whether adefovir passes into breast milk. It is not indicated for use in adolescents or children.

HIV testing should be offered to all patients prior to initiation of adefovir therapy. HIV drug resistance may occur in patients with chronic HBV infection and unrecognized or untreated HIV infection. The patient should be taught the signs of hepatic injury and advised to contact the prescriber immediately if any occur.

Boceprevir

Boceprevir (Victrelis) is a HCV protease inhibitor used in combination with peginterferon and ribavirin, to treat hepatitis C genotype 1. It is a direct acting antiviral drug against the hepatitis C virus. It is contraindicated during pregnancy because of its teratogentic effects. It is given cautiously to patients who also receive drugs that utilize the CYP3A4/5 pathway. Common adverse effects include fatigue, nausea, headache and dysgeusia. Serious adverse effects include birth defects and fetal death, anemia, and neutropenia. Both men and women receiving boceprivir must use 2 forms of birth control during therapy and avoid pregnancy for 6 months following completion of therapy. Women must have monthly pregnancy tests.

Entecavir

Entecavir (Baraclude) is an NRTI similar to adefovir. It is also approved for use in the management of chronic HBV infection. Entecavir works by competing with the substrate deoxyguanosine triphosphate, resulting in inhibition of all three activities of the HBV polymerase: base priming, reverse transcription of the negative strand from messenger RNA, and synthesis of HBV DNA. The drug is available as an oral solution or a tablet.

Common adverse effects of entecavir include nausea, dizziness, headache, and fatigue. Serious adverse effects are similar to those of adefovir. Dosage adjustments are required for patients with pre-existing renal impairment. As with adefovir, severe exacerbations of HBV may occur in patients who discontinue entecavir therapy. Entecavir is a pregnancy category C drug. Teratogenic effects have been seen in animal studies, but human studies have not been performed. Entecavir is not indicated for use in children under the age of 16 years.

Patient education for entecavir is the same as for adefovir. In addition, patients should be advised to take entecavir

2 hours before or after a meal. For patients taking the oral solution, the importance of using the measuring spoon that comes with the product and not diluting the solution with water or any other liquid should be explained.

Lamivudine

Lamivudine (Epivir-HBV) is another NRTI. Epivir-HBV tablets and oral solution contain a lower dose of the same active ingredient (lamivudine) as Epivir tablets and oral solution used to treat HIV infection. If treatment with Epivir-HBV is prescribed for chronic HBV for a patient with unrecognized or untreated HIV infection, rapid emergence of HIV resistance is likely because of the subtherapeutic dose and inappropriate monotherapy.

Common adverse effects of lamivudine include anorexia, nausea, vomiting, headache, and fatigue. Serious adverse effects are similar to those of adefovir and entecavir. The risk of lactic acidosis and severe hepatomegaly with steatosis is higher in women and obese patients who take lamivudine. Lamivudine is also an FDA pregnancy category C drug but may be given to children as young as 2 years.

Telbivudine

Telbivudine (Tyzeka) is another thymidine nucleoside analogue. It works by competitive inhibition of viral DNA polymerase (reverse transcriptase), resulting in DNA chain termination. Unlike the aforementioned NRTI drugs, telbivudine is not approved for the management of HIV infection. Its only approved use is the management of chronic hepatitis B. Telbivudine is used cautiously in patients who have pre-existing myopathy or are taking drugs that might cause myopathy, because of the potential increased risk for myopathy with the drug. Common adverse effects include headache, malaise, fatigue, upper respiratory infection, and abdominal pain. Telbivudine carries a Black Box warning regarding the potential for inducing lactic acidosis and severe hepatomegaly with steatosis and the potential for acute exacerbation of hepatitis B when discontinued. Telbivudine is a pregnancy category B drug. It is not approved for use in children.

Drugs Used for Respiratory Syncytial Virus

Most children with RSV bronchiolitis will not require hospitalization and can be treated successfully at home with albuterol, either as a nebulizer or MDI with spacer (see Chapter 35). For those who are more acutely ill and require hospitalization, one of the following drugs may be used.

Palivizumab

Palivizumab (Synagis) is a humanized monoclonal antibody to RSV prepared by using recombinant DNA technology. As a "humanized" monoclonal antibody, the drug tends to have little immunogenicity.

Palivizumab is administered to high risk children as an intramuscular (IM) injection that is given monthly during the RSV season, which is generally the beginning of fall to the end of spring. It may also be used for acute infection in hospitalized children. In rare circumstances, palivizumab has induced hypersensitivity reactions, including anaphylaxis. Infants who experience any type of hypersensitivity reaction should not receive additional injections. Because palivizumab is given as an IM injection, it is given cautiously to infants with a history of thrombocytopenia or any coagulation disorder.

Common adverse effects include upper respiratory tract infection, otitis media, rhinitis, rash, cough, gastroenteritis, and wheezing. Rarely, infants may experience fever, diarrhea, or vomiting. Palivizumab does not have a risk of pulmonary edema because it is not given by infusion.

Palivizumab powder should be reconstituted with sterile water according to the dose of medication to be delivered. The vial is rolled between the hands but not shaken, and the solution is then allowed to sit for 20 minutes before the injection is administered.

Ribavirin

Ribavirin is a synthetic nucleoside antiviral drug. It is used as a primary agent to treat RSV infections. Intravenous ribavirin is available from the United States Centers for Disease Control and Prevention to treat hantavirus infection and Lassa fever. Oral ribavirin (Rebetol) is approved for treating chronic hepatitis C infection in combination with interferon alfa-2b (PEG-Intron) or interferon alfa-2b (Rebetron). The exact mechanism of antiviral activity of ribavirin is unclear; however, it is thought to increase the mutation rate of RNA viruses, leading to "error catastrophe."

Inhaled ribavirin (Virazole) should be administered using the SPAG-2 aerosol generator. Clinicians should make sure they are thoroughly familiar with the use of this device before administering ribavirin. Solutions placed in the SPAG-2 reservoir should be discarded every 24 hours and before adding newly reconstituted solutions. Reconstituted solutions may be stored at room temperature for 24 hours.

Ribavirin is one of the few antiviral drugs that is indicated for use in children. However, it is contraindicated for use in children who require ventilatory support, because it may precipitate in the respiratory equipment.

Ribavirin is teratogenic and embryotoxic in animals; therefore, it is contraindicated for use in adults because of its potential for producing testicular lesions and teratogenic effects. It is considered a pregnancy category X drug. Pregnant health care workers should not administer aerosolized ribavirin because it can disperse into the immediate bedside area. Additionally, ribavirin should not be given concurrently with zidovudine because it blocks the action of zidovudine.

CHAPTER SUMMARY

- Viral and fungal diseases range from annoying disorders to life-threatening infections.
- Antiviral drugs can be arbitrarily divided into purine nucleoside analogue drugs, ophthalmic antiviral drugs, topical antiviral drugs, drugs used for influenza, drugs used for hepatitis, and drugs for RSV.

- Few effective antiviral drugs exist because eradicating the virus also may severely damage the host.
- Acyclovir is the prototype purine nucleoside analogue drug used to treat viral infections.
- Oseltamivir is the prototype drug for influenza.
- Drugs used for influenza do not replace influenza vaccine.
- Drugs used for hepatitis include interferons nucleoside reverse transcriptase inhibitors and HCV protease inhibitors.
- Drugs used for RSV are divided into those that prevent RSV and those that treat RSV.

QUESTIONS FOR STUDY AND REVIEW

1. Why are there so few effective antiviral drugs?
2. How does acyclovir work to fight herpes infections?
3. Acyclovir should be given cautiously to patients with which types of diseases or disorders?
4. What type of antiviral agents are useful in managing hepatitis?
5. Why should all patients receiving nucleoside reverse transcriptase inhibitors for chronic HBV infection be offered HIV testing prior to treatment?
6. What are pharmacotherapeutic differences between amantadine (or rimantadine) and oseltamivir (or zanamivir)?
7. What special instructions should be given to immunosuppressed patients regarding oseltamivir and zanamivir?
8. Why is ribavirin not generally used in adults?
9. What are pharmacotherapeutic differences between ribavirin and palivizumab and RSV-IG?

Drugs Treating HIV Infection and AIDS

Learning Objectives

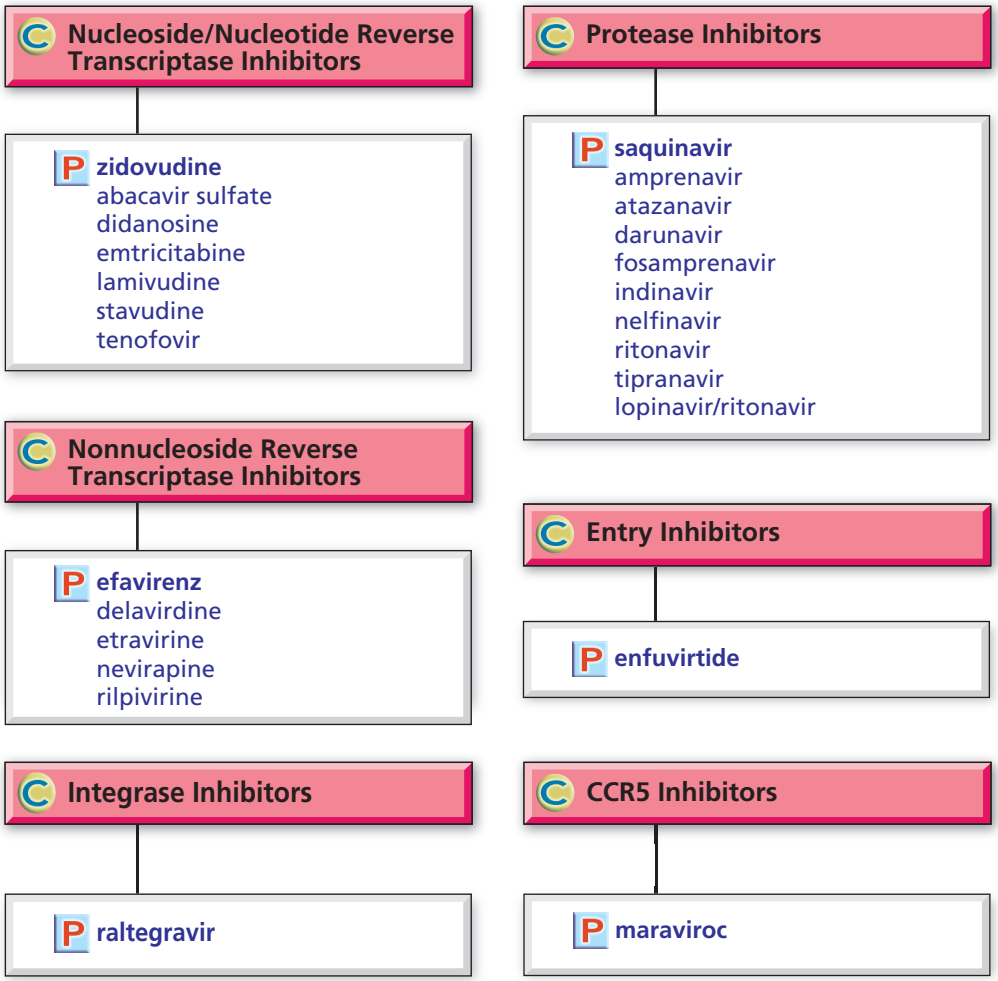
At the completion of this chapter the student will:

1. Describe the parameters that govern the choice of antiretroviral agents.
2. Identify core drug knowledge about drugs that are used in treating human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS).
3. Identify core patient variables relevant to drugs that are used in treating HIV infection and AIDS.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that are used in treating HIV infection and AIDS.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that are used in treating HIV infection and AIDS.
6. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that are used in treating HIV infection and AIDS.
7. Determine key points for patient and family education for drugs that are used in treating HIV infection and AIDS.

Key Terms

CD4 cell count
Chemokine receptor antagonist (CCR5 Inhibitors)
enzyme immunoassay
enzyme-linked immunosorbent assay
fusion inhibitors
highly active antiretroviral therapy (HAART)
integrase inhibitors
HIV RNA count
nonnucleoside reverse transcriptase inhibitors (NNRTIs)
nucleoside reverse transcriptase inhibitors (NRTIs)
protease inhibitor (PI)
rapid HIV testing
resistance testing (genotype, phenotype)
salvage therapy
viral load
Western blot

Drugs Treating HIV Infection and AIDS



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Human immunodeficiency virus (HIV) is a virus that disables the human immune system and makes the infected person susceptible to common opportunistic infections. The virus is generally classified as HIV-1 and HIV-2 and has many subtypes. HIV-1 is the most common strain in the United States, whereas HIV-2 is common in Africa. Both strains are transmitted from person to person through sexual contact, by blood, such as workplace exposure arising out of "needle stick" injury, or through illicit intravenous drug use using an HIV contaminated needle. HIV can also be transmitted perinatally during pregnancy, labor, delivery and also while breastfeeding. Patients infected with HIV have the HIV disease. The syndrome called acquired immunodeficiency syndrome (AIDS) is the late stage of HIV infection, when immunodeficiency has become profound and the patient becomes defenseless against common opportunistic infection compromising his or her health, well being and may ultimately result into death. The Centers for Disease Control and Prevention (CDC) define AIDS as HIV infection plus a CD4 cell count less than 200/mm^3 or an opportunistic (AIDS-defining) illness such as an infection with tuberculosis or Pneumocystis jiroveci pneumonia (PCP), previously known as Pneumocystis carinii pneumonia (Box 46.1).

Pharmacotherapy for HIV infection and AIDS has changed dramatically since AIDS was first identified in 1982, and it continues to evolve. Recommended pharmacotherapy for HIV infection and AIDS is highly individualized. Treatment for HIV includes multi-drug therapy called **highly active antiretroviral therapy** (HAART). This "cocktail" of drugs aims to disrupt the HIV replication at multiple stages of its proliferation. The goal of therapy is to suppress virema, delay drug resistance mutation, and preserve CD4 counts.. Initially, HAART required a high pill burden with a complex administration schedule that ultimately affected the patient's adherence to the therapy. Now, with combination pills, therapy can be accomplished with one pill once or twice a day.

Because of the staggering impact of HIV infection and AIDS-related illnesses, the Food and Drug Administration (FDA) has "fast-tracked" new drugs and new drug classes. Currently, there are 27 antiretroviral drugs, in 6 drug classes, with 6 fixed dose combination medications (2 or 3 antiretrovirals formulated in one pill) promoting easier adherence to therapy. The irony of this rapid drug development is their availability in our pharmacological arsenal but the uncertainty of when to start therapy. Currently the U.S. Department of Health and Human Services (US DHHS) and the International AIDS Society endorse initiation HAART at CD4 counts between 200 and 350 cells/mm for asymptomatic patients.

Nurses and other health care professionals are encouraged to keep abreast of rapid changes in pharmacotherapeutics for HIV infection by reviewing the most current information presented in nursing and medical journals as well as on-line resources.

This chapter presents the drug classes currently used to treat HIV infection and AIDS, which include:

- Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs; prototype, zidovudine)
- Protease inhibitors (PIs; prototype, saquinavir)
- Nonnucleoside reverse transcriptase inhibitors (NNRTIs; prototype, efavirenz)
- Fusion inhibitors (prototype, enfuvirtide)
- Chemokine coreceptor antagonist (CCR5 Inhibitor; prototype, maraviroc)
- Integrase inhibitor (prototype, raltegravir)

In addition to explaining how each of these drug classes works to affect HIV infection and AIDS, this chapter addresses the core drug knowledge, core patient variables, nursing management, potential nursing diagnoses, and patient education related to the administration of antiretroviral agents. This chapter also reviews current treatment recommendations for common opportunistic diseases associated with HIV infection and AIDS and post exposure prophylaxis for accidental occupational exposure.

Box 46.1 DEFINING HIV INFECTION

Lab Criteria

1. Repeatedly reactive ELISA
2. Positive Western Blot or immunofluorescence assay or
3. Positive result or detectable quantity
   a. HIV nucleic acid detection test
   b. HIV p24 antigen test, including neutralization assay
   c. HIV isolation

Case Classification

	AIDS-Defining Illness	CD4+ Lymphocyte Count	CD4+ Lymphocyte % of total Lymphocytes
Stage 1	Absent	≥ 500 cells/mcL	≥29
Stage 2	Absent	200–499 cells/mcL	14–28
Stage 3	Positive	< 200 cells/mcL	< 14

PHYSIOLOGY

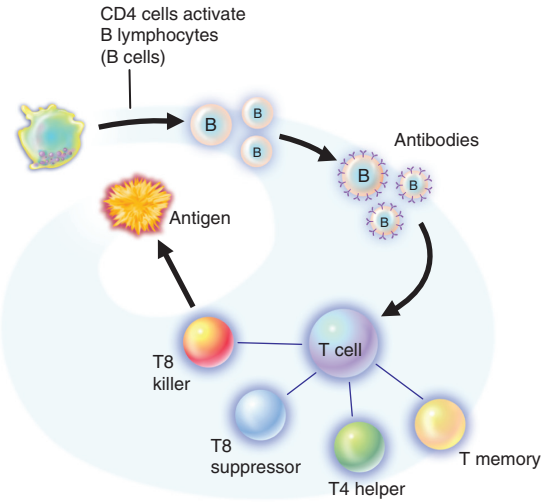
CD4 Cell Function

CD4 cells (previously called CD4+ T cells) are necessary for normal immune function. The CD4 cell recognizes foreign antigens and infected cells and helps activate the antibody-producing B lymphocytes. CD4 cells also induce cell-mediated immunity, in which cytotoxic CD8+ T cells and natural killer cells directly destroy foreign antigens. Phagocytic monocytes and macrophages also are influenced by CD4 cells. Figure 46.1 illustrates normal CD4 T-cell function. Chapter 54 presents a more thorough review of immune system physiology.

Human Immunodeficiency Virus

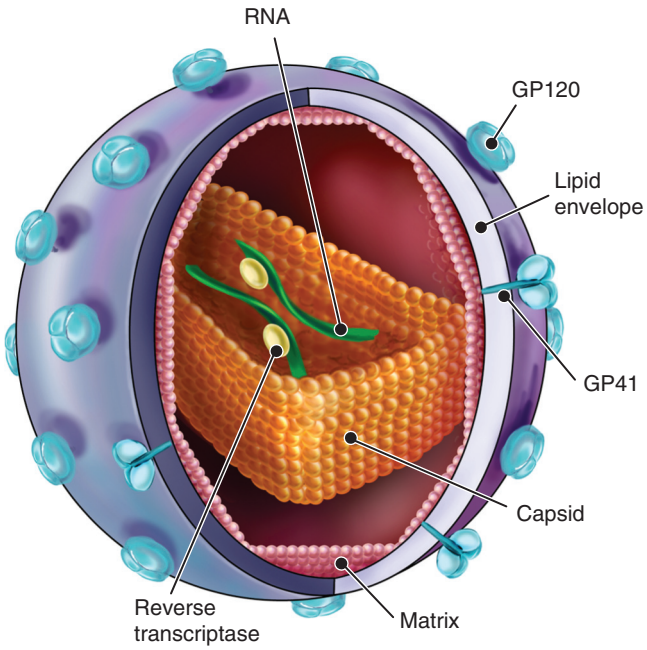
HIV is like all other viruses in structure. Its ribonucleic acid (RNA) is surrounded by core proteins, which are surrounded by a protein shell called a capsid. The capsid, in turn, is surrounded by a lipid bilayer envelope. The envelope contains glycoproteins that are used to attach to host cells. The two glycoprotein subunits, gp41 and gp120, are attached to each other and embedded in the lipid bilayer (Figure 46.2).

PHYSIOLOGY



• FIGURE 46.1 CD4 cells recognize antigens in the body and respond by activating the antibody-producing B lymphocytes. The B lymphocytes, in turn, stimulate the T cells to increase their numbers in order to perform their various functions. T4 helper cells release lymphokines, which enhance macrophage and monocyte activity; T8 killer cells directly attack and destroy the antigen; T8 suppressor cells help to stop the immune response when appropriate; and T memory cells are stored for future use against returning antigens.

HIV is called a retrovirus. The difference between a virus and a retrovirus is in the genetic material. Like all viruses, HIV is an obligate parasite; it cannot replicate unless it is inside a living cell. Retroviruses have positive-sense single-stranded RNA and thus must transcribe their RNA into deoxyribonucleic acid (DNA) to replicate. This process is completed by an enzyme called reverse transcriptase.



• FIGURE 46.2 Structure of HIV.

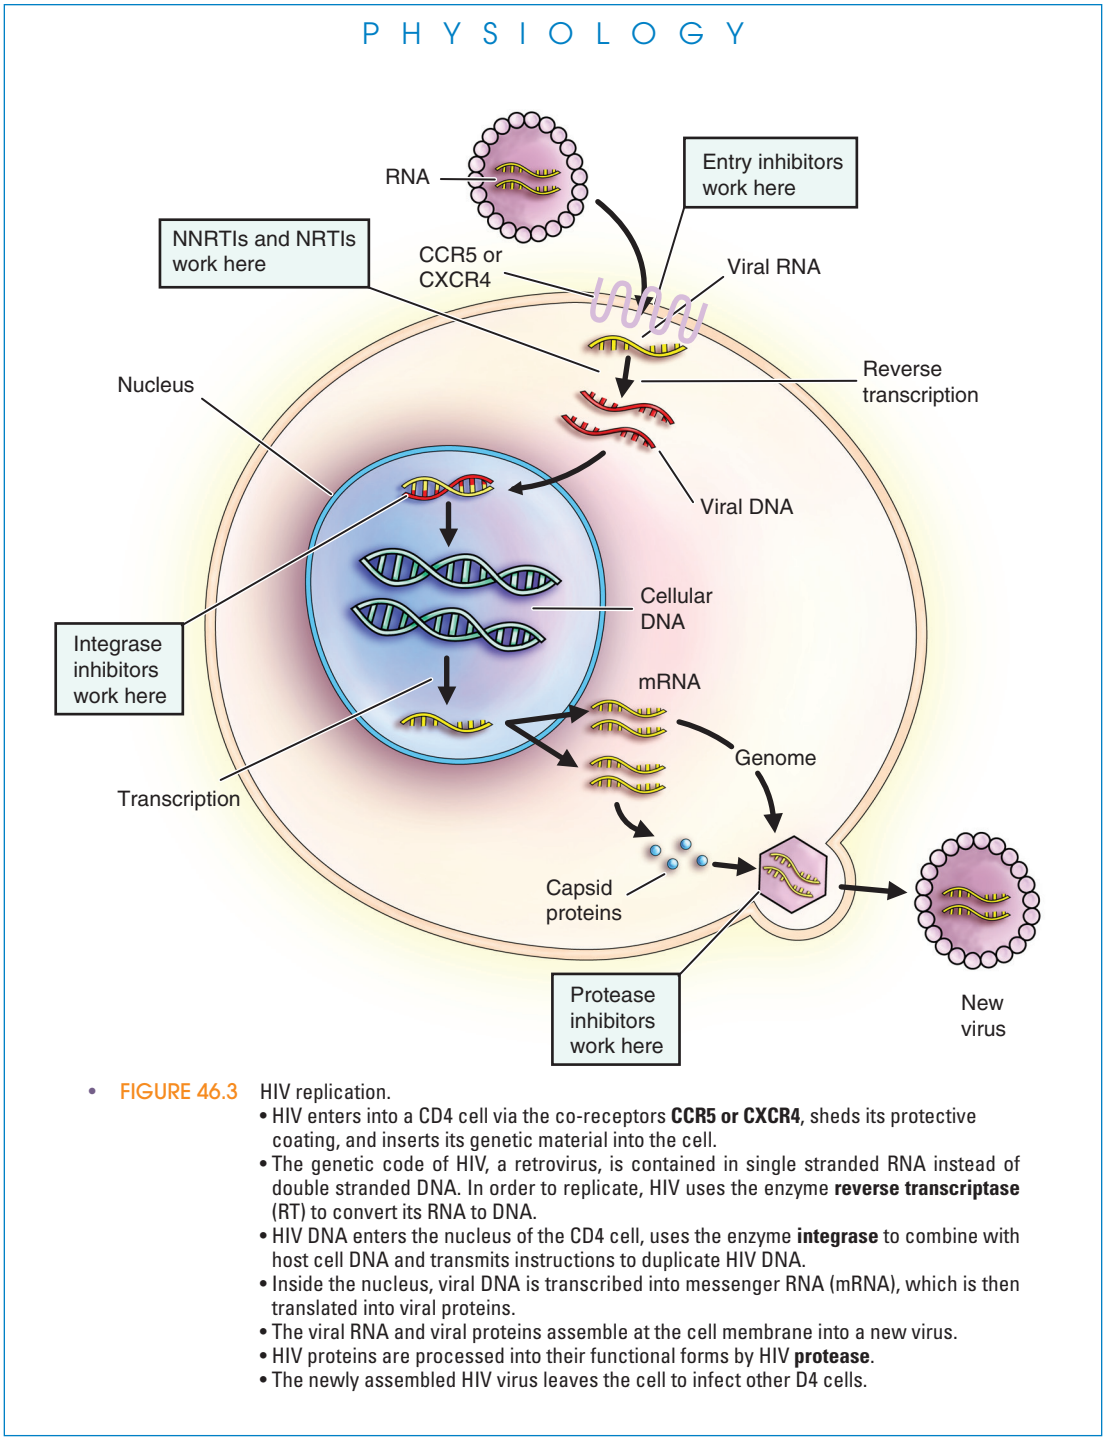
PATHOPHYSIOLOGY

HIV infection begins when gp120, a surface protein on the HIV viral envelope, binds to cells that have a CD4 protein receptor site. These cells include CD4 cells, monocytes, macrophages, and certain nerve cells. Once the virus is bound to the cell, the viral envelope and the plasma membrane fuse, and the genetic material from HIV enters the cell. In the cell, viral RNA is transcribed into a single strand of viral DNA with the assistance of reverse transcriptase, an enzyme made by HIV. This DNA strand replicates itself, becoming double-stranded viral DNA. At this point, viral DNA can enter the cell's nucleus and, using an enzyme called integrase, splice itself into the host cell's genome, thus becoming a permanent part of the cell's genetic structure.

This action results in two major problems. First, because all genetic material is replicated during cellular division, all daughter cells from the infected host cell also will be infected. Second, because the host cell's genome now contains viral DNA, the cell's genetic codes can direct the cell to make HIV. Production of new virus then occurs by translation and transcription of the code from the integrated DNA into viral RNA. Some of this RNA is messenger RNA that codes for HIV proteins. This complex process results in long strands of HIV RNA, which must be cut into viable lengths. Late in replication, when the newly formed virus separates from the host cell, these HIV proteins are cleaved into small proteins by the enzyme protease. Some of these proteins become part of the HIV core, and some become part of the viral protein shell. HIV protease thus is critical for viral infectivity and replication. It has been shown that HIV **provirus** (the virus before it exits the cell) manufactured without protease is noninfectious. Figure 46.3 represents HIV replication.

HIV has an affinity for CD4 cells. The virus destroys these important cells, responsible for normal immune function, which effectively strips the person of protection against common organisms.

Originally, researchers believed that after initial infection, HIV viral replication remained dormant until stimulated by an unknown event. Now we know that viral replication is never dormant as HIV replicates continuously from the time of infection although the *symptoms* of HIV disease may remain undetectable for many years. At the initial stage of infection, the **viral load** (the amount of virus in the body) is exceptionally high and quantifiable through a serological marker, the HIV RNA that measures the amount of virus in the blood. There are two reasons for this high initial viral load. First, because HIV is a new virus entering the host, the immune system is not yet sensitized to the foreign antigen, and the immune response is suboptimal. Second, because the immune system has not yet been affected by the virus, there are many CD4 cells to invade and infect.



• FIGURE 46.3 HIV replication.
- HIV enters into a CD4 cell via the co-receptors **CCR5 or CXCR4**, sheds its protective coating, and inserts its genetic material into the cell.
- The genetic code of HIV, a retrovirus, is contained in single stranded RNA instead of double stranded DNA. In order to replicate, HIV uses the enzyme **reverse transcriptase** (RT) to convert its RNA to DNA.
- HIV DNA enters the nucleus of the CD4 cell, uses the enzyme **integrase** to combine with host cell DNA and transmits instructions to duplicate HIV DNA.
- Inside the nucleus, viral DNA is transcribed into messenger RNA (mRNA), which is then translated into viral proteins.
- The viral RNA and viral proteins assemble at the cell membrane into a new virus.
- HIV proteins are processed into their functional forms by HIV **protease**.
- The newly assembled HIV virus leaves the cell to infect other D4 cells.

During this initial stage, the patient may experience an acute retroviral syndrome that includes fever, pharyngitis, rash, myalgia or arthralgia, diarrhea, and headache. Although these symptoms are common in HIV infection, they may be dismissed initially by the patient as "the flu." After the immune system responds to the viral invasion, the viral load decreases, and the patient may remain asymptomatic for many years. There are patients who harbor the virus but remain asymptomatic while maintaining a healthy number of CD4 over a long period of time. They are called "slow progressors." On the other hand, there those called "rapid progressors" who, in a relatively short period of time, experiences a rapid downturn progression of their disease and a dramatic decline in their CD4 values.

HIV is present in the body fluids, for instance blood, urine, saliva, of infected patients. There are several methods of transmission: sharing of HIV contaminated syringe used intravenously, or "muscling," or "skin popping" of illicit drugs; through blood transfusions; accidental needle sticks injuries at the work place, and sexual contact with an infected

sexual partner. HIV also can be transmitted though breast milk of an infected person; therefore, women with HIV are taught to avoid breast-feeding to limit the potential transmission of the virus to the infant. There is also mucotaneous exposure, such as a splash with a contaminated HIV body fluids, or penetration through an abraded skin, however this type of exposure rarely causes seroconversion.

HIV infection eventually induces symptoms in every body system. In addition to those already mentioned, common symptoms associated with HIV infection include lymphadenopathy, nausea and vomiting, hepatosplenomegaly, thrush (candidiasis of the oral tissues), and weight loss. Neurologic symptoms, such as meningoencephalitis or aseptic meningitis, peripheral neuropathy, radiculopathy, facial palsy, Guillain-Barré syndrome, brachial neuritis, cognitive impairment, or psychosis, affect up to 40% of patients.

DIAGNOSIS OF HIV INFECTION

Diagnosis of HIV infection is initially made by a screening test followed by a confirmatory assay. Screening tests are highly sensitive, whereas confirmatory assays are highly specific. The combination use of these two types of tests produces results that are highly accurate. In 2006, the CDC recommended universal, routine HIV screening for all adults in health care settings ages 13–64. This recommendation now makes HIV screening a routine test that no longer requires counseling or consent and effectively passed the responsibility of testing to the health care provider (Box 46.2). In addition, the CDC advises that pregnant women take the following steps:

- Include an HIV test in the routine panel of prenatal screening tests
- Consent to HIV testing in prenatal care
- May have an option to decline HIV testing
- Have a second HIV test in the third trimester (for women known to be at risk for HIV, in jurisdictions with elevated HIV incidence, or in health care facilities with high HIV prevalence).

Box 46.2 RECOMMENDATIONS FOR HIV SCREENING

- Routine, voluntary HIV screening for all persons 13–64 years of age in health care settings, not based on risk
- Repeat HIV screening of persons with known risk at least annually
- "Opt-out" HIV screening with the opportunity to ask questions and the option to decline
- Inclusion of consent for HIV testing with general consent for care (separate signed informed consent not necessary)
- No requirement for prevention counseling in conjunction with HIV screening in health care settings
- Availability of HIV testing in all health care settings, including inpatient services, emergency departments, urgent care clinics, sexually transmitted disease clinics, tuberculosis clinics, public health clinics, community clinics, substance abuse treatment centers, correctional health facilities, and primary care settings
- Communication of test results in same manner as other diagnostic/screening tests
- Provision of clinical HIV care or reliable referral to qualified providers

Adapted from Centers for Disease Control and Prevention. (2006). Revised recommendations for HIV testing of adults, adolescents, and pregnant women in healthcare settings. Retrieved from *http://www.phppo.cdc.gov/hiv/topics/testing/resources/factsheets/pdf/healthcare.pdf.*

Initially, the **enzyme immunoassay** (EIA) or **enzyme-linked immunosorbent assay** (ELISA) was the only test available. The EIA test poses some problems. It requires that the patient return to the provider to obtain the results of the test, and many patients have the test but never return to obtain the results. The EIA detects antibodies produced in response to infection and is based on the light absorbance of antigen–antibody complexes. If the patient tests positive with the EIA test, a confirmatory **Western Blot** (WB) assay test is administered. The Western Blot assay detects certain protein from the sample tissue and confirms an infection in the presence of HIV specific protein band in the tissue sample.

Now, several tests are approved by the FDA. In addition to EIA, the following tests are available:

- ***Rapid HIV testing.*** These screening tests produce a result within 30 minutes. Rapid testing is a valuable tool during an accidental workplace HIV exposure where a test can be conducted fairly quickly without compromising the time element crucial with post exposure prophylaxis. As with other screening tests, any positive result requires a confirmatory assay to ensure accuracy. There are several rapid HIV tests available:
  - OraQuick Advance Rapid HIV-1/2 may be used with whole blood (fingerstick or venipuncture), serum, or plasma. In addition, it may use oral fluid. Contrary to popular belief, it is not a saliva test but instead uses a small pad to draw fluids that are derived from blood from within the mouth and gums.
  - Reveal G-2 Rapid HIV-1 requires serum or plasma.
  - Uni-Gold Recombigen HIV test may be used with whole blood (fingerstick or venipuncture), serum, or plasma.
- *P24 antigen test*. This test is useful for patient with typical clinical features and negative or indeterminate HIV serologic test, that is the patient has negative HIV AB test. For these patients who are probably in the very early stage of infection, p24 is produced in high amount while the body is still in the process of producing the HIV antibody that normally will only be evident in 2–3 weeks after the infection.
- *Polymerase chain reaction (PCR)*. This specialized blood test looks for HIV *genetic information* rather than HIV antibodies. This test can detect the virus, rather than the viral antibody, even in a person who has been only recently infected. This test is labor intensive and thus very expensive. DNA PCR test is crucial on new born babies who may have the maternal antibodies acquired perinatally, but not necessarily the disease, thus making the HIV antibody test inaccurate.

LABORATORY TESTS

Initial laboratory testing of patients with symptoms consistent with HIV include:

- HIV antibody testing
- Complete blood count (CBC)
- Complete metabolic panel
- Urinalysis
- Rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) testing for syphilis
- Tuberculosis (TB) skin test (unless contraindicated)
- Hepatitis A, B, and C serologies
- Fasting blood glucose and serum lipids
- *Toxoplasma gondii* immunoglobulin G (IgG)
- Papanicolaou smear and pregnancy test in women
- HIV RNA count
- CD4 cell count
- Chest X-ray for positive TST or pulmonary symptoms
- Gonorrhea, Chlamydia to identify high-risk sexual activities

The CD4 cell count and the plasma HIV RNA (viral load) assays are the essential parameters in the decision to initiate, monitor, and change antiretroviral therapies (Box 46.3).

CD4 Cell Count

CD4 cell counts are an indication of the current immunologic status of the patient. In the healthy patient, the CD4 cell count ranges from 800/mm^3 to 1,200/mm^3. In addition, the CD4 cell count is the most important consideration for initiating antiretroviral therapy and initiation and or discontinuation of chemoprophylaxis for opportunistic diseases. CD4 is the strongest predictor of disease progression and survival. As HIV infection progresses, the CD4 cell count generally decreases. The CD4 cell count is performed prior to initiation of HAART and then every 3 to 6 months thereafter to assess an optimal or sub-optimal response to therapy. When HAART is initiated, an increase in the CD4 cell count is ideally expected along with a stable clinical and virological response. Ideally, an accelerated improvement in the CD4 count is seen in the first months of therapy and levels off to a steady state as the treatment progress.

Box 46.3 INDICATIONS FOR INITIATING ANTIRETROVIRAL THERAPY FOR THE PATIENT WITH CHRONIC HIV-1 INFECTION

Panel of Experts Recommendation:

- Antiretroviral therapy should be initiated on patients with AIDS defining illness or a CD4 of less than 350/mm3.
- Antiretroviral therapy should be initiated with the following patients regardless of CD4 count
  - Pregnant patients regardless of CD4
  - Patients with HIV associated nephropathy
  - Patients co-infected with HBV when treatment is indicated.
- Patients' scenario and co-morbidity conditions may be considered for initiation of antiretroviral for patients with CD4 greater than 350.
- The panel also recommends discussion of requirement for long term adherence and identification of barriers to adherence prior to initiation of therapy.

Adapted from the U.S. Department of Health and Human Services (2008) Guidelines for the Use of Antiretroviral Agents in HIV Infected Adolescent and Adults. Retrieved from: http://www.aidsinfo.nih.gov/Guidelines/GuidelineDetail.aspx?GuidelineID=7

Viral Load (HIV RNA) Count

The **HIV RNA counts** are reported as copies per milliliter (mL). Viral load of HIV RNA indicates the risk for disease progression and the most important indicator of treatment response. Three tests are currently approved for use in the United States to measure viral load:

- HIV-1 reverse transcriptase PCR assay (Amplicor HIV-1 Monitor v1.5)
- Signal amplification nucleic acid probe assay (Versant HIV-1 RNA 3.0)
- Nucleic acid amplification test for HIV RNA (NucliSens HIV-1 QT)

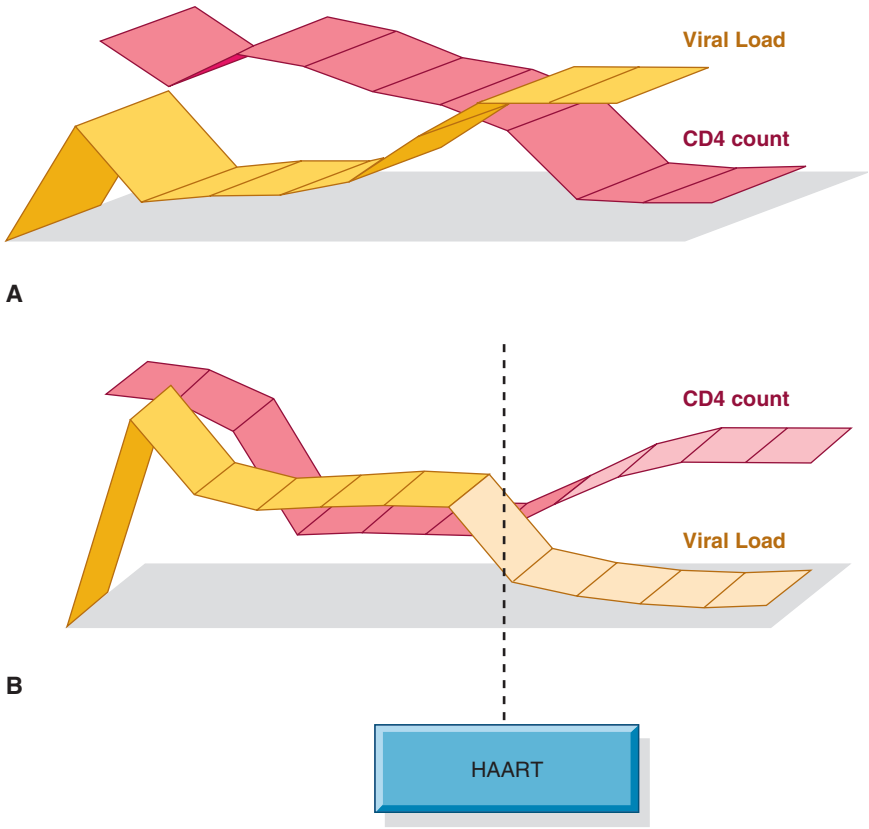
These tests all measure the concentration of virions in blood plasma, although HIV replication occurs in other tissues as well. When the patient is receiving HAART, the virologic response in plasma corresponds with the decay of HIV-1 viral load in tissues; thus, there is currently no clinical indication for viral load testing of tissues other than blood plasma. Because these tests use different technologies, it is essential to know which type of test was used in order to interpret the results accurately.

The viral load is performed at the time of diagnosis and generally every 3 to 4 months thereafter in the asymptomatic HIV-positive patient not receiving HAART. The viral load is measured immediately before starting HAART and ideally again 2 to 8 weeks later. When the therapy proves effective, the viral load is monitored generally every 3 to 4 months to evaluate the continuing efficacy of therapy. Viral load is also measured in conjunction with any clinical event (i.e., opportunistic infection) or significant decrease of the CD4 cell count. The goal is to bring the viral load to undetectable levels (i.e., less than 50 copies/mL) within the shortest time possible and sustained it at the undetectable level overtime

When assessing the need to change antiretroviral therapy, viral load counts, CD4 cell counts and resistance testing should be evaluated at the same time. The goal of antiretroviral therapy is to increase the CD4 cell count overtime and a sustained decrease in the viral load burden for the longest time possible (Figure 46.4).

Resistance Assays

The biology of HIV infection is characterized by a high rate of replication and as a result, introduction of random mutation at each round of the replication process may occur. Drug-resistant HIV may occur due to ineffective drugs and or lack of adherence to medication regimen. The latest recommendation for resistance testing was developed in November 2008 (Box 46.4).



• FIGURE 46.4 (**A**) Natural progression of HIV infection. (**B**) Progression of HIV infection with highly active antiretroviral therapy (HAART). (Adapted with permission from slides designed by Dr. Gita Gupta.)

There are two types of resistance assays: genotypic and phenotypic. **Genotypic testing** evaluates the genetic makeup of a patient's virus and detects the presence of drug resistance mutations that exist in relevant genes. This information is then compared with data that document past trends in HIV treatment failure from a list of significant associated mutations maintained and updated by the International AIDS Society. If the genetic mutations in a patient's virus match genetic mutations that are presumed to be responsible for resistance to a certain drug, then his or her virus is presumed to be resistant to that drug. The test can be done rapidly and test result available in 1 to 2 weeks.

Phenotypic testing, on the other hand, is considered a direct way of measuring drug resistance. It places a sample of a patient's HIV in contact with antiretroviral drugs and observes how the virus reacts. Phenotypic testing is also considered quantitative because it can demonstrate how much of a drug is necessary to stop HIV from replicating. Phenotypic test is more expensive, takes 2 to 3 weeks to get the result, and interpretation is more complicated.

The end result of both types of genotypic and phenotypic testing is the identification of a drug or group of drugs that should not be used for a particular patient. Genotypic testing is more rapid and less costly than phenotypic testing; therefore, it is used more frequently.

Box 46.4 DRUG RESISTANCE TESTING

- HIV resistance testing is recommended for persons with HIV infection when they enter into care regardless of whether therapy will be initiated immediately. If therapy is deferred, repeat testing at the time of antiretroviral therapy initiation should be considered.
- A genotypic assay is generally preferred for antiretroviral-naïve persons.
- HIV drug resistance testing should be performed to assist in the selection of active drugs when changing antiretroviral regimens in cases of virologic failure and HIV RNA levels greater than 1,000 copies/mL. In persons with greater than 500 but less than 1,000 copies/mL, testing may be unsuccessful but should still be considered.
- Drugs resistance testing should also be performed when managing suboptimal viral load reduction.
- Drugs resistance testing in the setting virologic failure should be performed while the patient is taking his/her antiretroviral drugs, or immediately (within 4 weeks) of discontinuation of therapy.

Genotypic resistance testing is recommended for all pregnant women prior to initiation of therapy and for those entering pregnancy with detectable HIV RNA levels while on therapy.

PRINCIPLES OF DRUG THERAPY FOR HIV INFECTION

As researchers learn more about HIV and new drugs and drug classes are developed, the principles of drug therapy continues to evolve. The current goals of therapy include:

- reduce HIV-related morbidity and prolong survival
- improve quality of life
- restore and preserve immunologic function

• maximally and durably suppress viral load, and
• prevent vertical HIV transmission

Tools for achieving these goals include maximizing adherence to the antiretroviral regimens, sequencing drugs rationally, preserving future treatment options, and using drug-resistance testing (U.S. Department of Health and Human Services, 2009).

Box 46.5 PRINCIPLES OF DRUG THERAPY FOR HIV INFECTION

When patients or patient groups ask about drug therapy for HIV, explain the following points:

- Ongoing HIV replication leads to immune system damage and progression to AIDS.*
- Plasma HIV RNA levels indicate the magnitude of HIV replication and its associated rate of CD4 T-cell destruction; CD4 T-cell counts indicate the extent of HIV-induced immune damage already suffered. Regular periodic measurements of plasma HIV RNA levels and CD4 T-cell counts are necessary to determine the risk for disease progression in an HIV-infected individual and to determine when to initiate or modify antiretroviral treatment regimens.
- Because rates of disease progression differ among individuals, treatment decisions should be individualized by level of risk indicated by plasma HIV RNA levels and CD4 T-cell counts.
- Using potent combination antiretroviral therapy to suppress HIV replication below the limits of detection of sensitive plasma HIV RNA assays narrows the potential for selection of antiretroviral-resistant HIV variants, which is the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression. Therefore, maximum achievable suppression of HIV replication should be the goal of therapy.
- The most effective means of accomplishing durable suppression of HIV replication is to simultaneously initiate combinations of effective anti-HIV drugs with which the patient has not been treated previously and that are not cross-resistant with antiretroviral agents with which the patient has been treated previously.
- Each antiretroviral drug used in combination-therapy regimens should always be used strictly according to optimal schedules and dosages.
- The available effective antiretroviral drugs are limited in number and mechanism of action, and cross-resistance between specific drugs has been documented. Therefore, any change in antiretroviral therapy increases future therapeutic constraints.
- Women should receive optimal antiretroviral therapy, regardless of pregnancy status.
- The same principles of antiretroviral therapy apply to both HIV-infected children and adults, although the treatment of HIV-positive children involves unique pharmacologic, virologic, and immunologic considerations.
- People with acute primary HIV infection should be treated with combination antiretroviral therapy to suppress virus replication to levels below the limit of detection of sensitive plasma HIV RNA assays.
- HIV-positive people, even those with viral loads below detectable limits, are infectious and should be counseled to avoid sexual and drug-use behaviors that are associated with transmission of HIV and other infectious pathogens.

*Long-term survival free from clinically important immune dysfunction has improved substantially since HAART was introduced.

Nurses play a pivotal role in maximizing adherence to the antiretroviral regimens. As patient advocates and educators, they must be able to discuss and inform the patient about the potential benefits and risks of HAART In addition, nurses are also responsible for educating patients about self-administration of antiretroviral therapy. It is important to teach patients how the drug works, when to take the drug, such as with or without food, what the potential adverse effects of the drug are, which signs and symptoms to report, and ways to decrease the risk of developing resistance to the HAART regimen. Box 46.5 presents basic principles of drug therapy for HIV infection.

C NUCLEOSIDE/NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS

The **nucleoside reverse transcriptase inhibitors (NRTIs)** are the first class of drugs approved by the FDA to treat HIV infection and AIDS. Although more potent newer drugs and newer drug classes have emerged, nucleoside analogues continue to be crucial drugs in the pharmacologic management of HIV infection and AIDS.

NRTIs are chemically similar to human nucleosides or nucleotides, which are considered the "building blocks" of DNA. To be effective, all of the NRTIs must convert to their active forms. These drugs inhibit reverse transcriptase, an enzyme critical to HIV replication (see Figure 46.3).

Zidovudine was first synthesized as an antineoplastic drug in the 1960s. In 1987, it was found to inhibit the in vitro infectivity of HIV-1 and that same year was approved as the first antiretroviral of its class. Zidovudine (AZT, ZDV, Retrovir) is the prototype NRTI. Table 46.1 presents a summary of drugs in this class.

Nursing Management of the Patient Receiving P Zidovudine

Core Drug Knowledge

Pharmacotherapeutics

Zidovudine is active against the Epstein-Barr virus and hepatitis B virus (HBV) and exerts some antibacterial activity against Enterobacteriaceae, but its main indication is for treating HIV infection in adults and children and preventing transmission of HIV to the fetus in pregnant, HIV-positive women. The parameters for starting antiretroviral therapy are controversial, complex, and constantly changing. However, the persisting theory is that symptomatic patients should begin therapy regardless of laboratory values. The recommendation for initiating treatment in asymptomatic patients is a CD4 cell count between 200–350 cell/mm, or those with HIV nephropathy, or patients with active HBV with the intent to treat the HBV.

Pharmacokinetics

Zidovudine, or AZT, is administered orally or parenterally. Following oral administration, zidovudine is absorbed rapidly from the gastrointestinal (GI) tract. The rate and extent of drug absorption may be decreased by fatty meals. The half-life of zidovudine is about 1 hour

TABLE 46.1 Summary of Selected Nucleoside/Nucleotide Reverse Transcriptase Inhibitors

Drug (Trade) Name	Route and Dosage Range	Pharmacokinetics	Special Considerations
P zidovudine (AZT, ZDV, Retrovir)	*Adult and adolescent:* PO, 300 mg 2×/d PO 200 mg 3×/d *Adult and adolescent:* IV, 1 mg/kg 5–6×/d around the clock *Child and infant ≥90 d:* PO, 160 mg/m^2 q8h;maximum 200 mg Q8 hrs (syrup, capsules, or tablets) *Infant <90 d and neonate:* PO, 2 mg/kg q6h *Child and infant ≥90 d:* IV, 120 mg/m^2 q6h *Infant <90 d and neonate:* IV, 1.5 mg/kg q6h	*Onset:* Rapid *Duration:* 4 h $t_{1/2}$: 1.1 h	No food restrictions Assess for renal insufficiency. Advise provider if positive findings.
abacavir sulfate (ABC, Ziagen)	*Adult and adolescent >16 y*: PO, 300 mg 2×/d or 600 mg once daily *Infant and child 3 mo–16 y*: PO, 8 mg/kg 2×/d	*Onset*: 0.7 h *Duration*: Unknown $t_{1/2}$: 1.5 h	No food restrictions. Monitor closely for rash.
didanosine (ddI, Videx)	*Adult >60 kg*: PO, two 100-mg tablets 2×/d or two 200-mg tablets once daily or one 200-mg tablet 2×/d; 250 mg 2×/d (solution) *Adult and adolescent <60 kg*: PO, 125 mg 2×/d or one 250-mg tablet daily; 167 mg 2×/d (solution) *Child and infant ≥8 mo*: PO, 90–150 mg/m2 q12h *Neonates <2 wk*: PO, 50 mg/m2 PO q12h	*Onset*: Rapid *Duration*: 12 h $t_{1/2}$: 1.6 h	Administer on an empty stomach at least 30 min before or 2 h after a meal.
didanosine (ddI EC, Videx EC)	*Patients >60 kg*: 400 mg once daily *Patients <60 kg*: 250 mg once daily		Take on an empty stomach. Must be swallowed whole.
emtricitabine (FTC, Emtriva)	*Adult*: PO, 200 mg daily *Adolescent, child, and infant*: Safe and effective use has not been established.	*Onset*: Rapid *Duration*: 24 h $t_{1/2}$: 10 h	No food restrictions
lamivudine (3TC, Epivir)	*Adult and adolescent >16 y and >50 kg*: PO, 300 mg daily or 150 mg 2×/d *Adult and adolescent 12–16 y and <50 kg*: PO, 2 mg/kg 2×/d *Infant >3 mo and child*: PO, 4 mg/kg 2×/d	*Onset*: Rapid *Duration*: 12 h $t_{1/2}$: 3–6 h	No food restrictions
stavudine (d4T, Zerit, Zerit XR)	*Adult and adolescent >60 kg*: PO, 40 mg 2×/d *Adult and adolescent <60 kg*: PO, 30 mg 2×/d Extended-release capsules *Adult and adolescent >60 kg*: PO, 100 mg daily *Adult and adolescent < 60 kg*: PO, 75 mg daily Child: Safe and effective dosage has not been established	*Onset*: Rapid *Duration*: 12 h $t_{1/2}$: 1 h	No food restrictions
tenofovir disoproxil fumarate (PMPA, TDF, Viread)	*Adult*: PO, 300 mg daily *Adolescent, child, and infant*: Safe and effective dosage has not been established.	*Onset*: Rapid *Duration*: 24 h $t_{1/2}$: 17 h	No food restrictions Administer 1 h before or 2 h after Videx
Combination Drugs			
abacavir sulfate/lamivudine (ABC, 3TC, Epzicom)	*Adult*: PO, one tablet (600 mg ABC/300 mg 3TC) daily	See individual drugs	No food restrictions
tenofovir/emtricitabine (Truvada)	Adult: PO, 1 tablet (200 mg tenofovir/300 mg emtricitabine) daily *Adolescent, child, and infant*: Safe and effective dosage has not been established.	See individual drugs	No food restrictions
tenofovir/emtricitabine/efavirenz (Atripla)	*Adults*: PO, 1 tablet (600 mg efavirenz/200 mg emtricitabine/300 mg tenofovir) 1×/d *Adolescent, child, and infant*: Safe and effective dosage has not been established.	See individual drugs	Administer on empty stomach, preferably at bedtime
zidovudine/lamivudine (Combivir)	*Adult and child >12 y*: PO, 1 tablet (150 mg lamivudine/300 mg zidovudine) 2×/d	See individual drugs	No food restrictions
zidovudine/lamivudine/abacavir (Trizivir)	*Adult and adolescent >40 kg*: PO, 1 tablet 2×/d *Child*: Not intended for use in pediatric patients or adolescents weighing <40 kg	See individual drugs	No food restrictions

in patients with normal renal function and increases to 1.4 to 2.9 hours in patients with renal dysfunction. Hepatic dysfunction also causes a moderate prolongation of zidovudine half-life.

Zidovudine crosses the blood–brain barrier and the placenta. It is converted into zidovudine triphosphate, its active form, by intracellular conversion and its inactive metabolite by the liver. Both active drug and inactive metabolite are excreted by glomerular filtration and tubular secretion. It is now available in fixed dose combination in one pill, with lamivudine or abacavir.

Pharmacodynamics

Zidovudine inhibits the synthesis of DNA by reverse transcriptase (the viral enzyme that copies viral RNA into DNA). Zidovudine bears a structural resemblance to thymidine, a natural nucleoside. Reverse transcriptase fails to distinguish zidovudine from its natural counterpart, and the enzyme attempts to use the drug to synthesize viral DNA. When zidovudine is incorporated into a strand of DNA, the addition of further nucleotides is blocked, and the full-length viral DNA chain is prematurely terminated.

Contraindications and Precautions

Absolute contraindications to the use of zidovudine include hypersensitivity, breast-feeding, and existing lactic acidosis. Patients with pre-existing hepatic dysfunction, obesity, and prolonged nucleoside analogue therapy have a higher risk of developing lactic acidosis due to the association of NRTIs to liver mitochondrial toxicity. Zidovudine should be given with caution to patients with pre-existing depression of bone marrow function, folate deficiency, or vitamin B_{12} deficiency. Patients with these disorders are at increased risk for severe hematologic toxicity. It is also given with caution to patients who have recently received cytotoxic drugs or radiation therapy because zidovudine may induce myelosuppression. Because of the risk for myelosuppression, patients with dental disease are also given zidovudine with caution.

Zidovudine should be used with caution in patients with hepatic or renal disease. The drug is metabolized in the liver to an inactive metabolite. In patients with impaired hepatic function, zidovudine can accumulate. Both zidovudine and its inactive metabolite are excreted in the urine. Zidovudine can accumulate in patients with renal impairment, causing an increased risk for toxicity.

Adverse Effects

Zidovudine may cause the serious adverse effects associated with all NRTIs, which are listed in Table 46.2. GI symptoms include nausea and vomiting, diarrhea, abdominal pain, dyspepsia, and anorexia. Esophageal ulceration also has occurred. Several central nervous system (CNS) effects have been reported, including headache, seizures, somnolence, paresthesias, agitation, restlessness, and insomnia. Other adverse effects that have been described include nail discoloration, rash, and an alteration in taste.

TABLE 46.2 Potential Life-Threatening and Serious Adverse Effects of Antiretroviral Drug Classes

Class	Effects
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)	Bone marrow suppression Fatigue Hepatic steatosis Hepatotoxicity Lactic acidosis with hepatic steatosis Muscle pain and wasting Pancreatitis Peripheral neuritis
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)	Hepatotoxicity Skin rash Stevens-Johnson syndrome Toxic epidermal necrosis
Protease inhibitors (PIs)	Cardiovascular effects Fat maldistribution GI intolerance Elevated liver enzymes/hepatotoxicity Hyperlipidemia Hyperglycemia Osteonecrosis Uncontrolled bleeding in hemophiliacs
Entry inhibitors	Injection site reactions Pneumonia Hypersensitivity reaction
Chemokine co-receptor antagonist	Cough Pyrexia URI Rash Musculoskeletal symptoms Abdominal pain
Integrase inhibitors	Nausea Diarrhea headache Muscle enzyme elevation

In addition, zidovudine has several Black Box warnings:

- Hematologic toxicities, including granulocytopenia and severe anemia, may occur due to its bone marrow toxicity. Signs of granulocytopenia, such as predisposition to a recurring infection, can develop in 6 to 8 weeks, and signs of anemia, such as fatigue, can develop in 2 to 4 weeks. Discontinuing the drug usually resolves the granulocytopenia and anemia. Although zidovudine actually can produce an increased platelet count, drug-induced thrombocytopenia can occur as well. Initial increases in platelet count usually occur within 1 to

2 weeks of initiation of therapy and can continue for 4 to 7 weeks.

- Prolonged zidovudine use has been associated with symptomatic myopathy. Because myopathy also may be a component of HIV infection, it may be overlooked as an adverse effect. Discontinuation of the drug may lead to some improvement, but rapid worsening can occur when it is readministered. Cardiomyopathy also has been reported.
- Lactic acidosis and severe hepatomegaly with steatosis, including fatalities, may occur with the NRTIs alone or in combination with other medications, HAART included. Although the actual incidence of these adverse effects is low, mortality is extremely high. Patients may complain of fatigue, nausea, vomiting, abdominal pain, weight loss, or dyspnea. Evaluation shows lactic acidosis with elevated levels of creatine phosphokinase (CPK), alanine aminotransferase (ALT), lactate dehydrogenase, or all three; abdominal computed tomography scans and liver biopsy often show steatosis. The initial clinical manifestations of lactic acidosis are variable and may include nonspecific GI symptoms without dramatic elevation of hepatic enzymes and, in some cases, dyspnea. All NRTIs have been implicated, although these effects occur most frequently with stavudine, didanosine, lamivudine, and emtricitabine.

Drug Interactions

The most important drug interaction with zidovudine is with ganciclovir, a medication use to treat cytomegalovirus retinitis, a late opportunistic infection seen with HIV infection, which may induce life-threatening hematologic toxicity. Other drugs that interact with zidovudine include acetaminophen, interferon beta-1b, probenecid, rifampin, trimethoprim, and valproic acid.

Table 46.3 presents a list of drugs that interact specifically with zidovudine. Additionally, Table 46.4 presents drugs with overlapping toxicities, including zidovudine.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for hypersensitivity to zidovudine and for early pregnancy. Also assess the patient for pre-existing hepatic or renal dysfunction. Review the patient's current pharmacotherapies for drugs that are potentially myelosuppressive, nephrotoxic, or directly toxic to red blood cells. Any positive findings should be communicated to the prescriber.

Before starting therapy, perform a complete physical examination. Documenting this baseline status is important because drug therapy may be discontinued or modified

TABLE 46.3 Agents That Interact with P Zidovudine

Interactants	Effect and Significance	Nursing Management
acetaminophen	Enhanced nonhepatic or renal clearance of zidovudine (ZDV) may occur. This may result in subtherapeutic levels of ZDV.	Limit frequency of acetaminophen administration. Discuss dosage adjustment with health care provider.
atovaquone	Atovaquone inhibits metabolism of zidovudine, resulting in increased zidovudine serum concentration.	Monitor for zidovudine adverse effects or toxicity. Monitor CBC.
food	Rate and extent of ZDV absorption may be decreased by fatty meals.	Administer ZDV at least 1 h before meals.
ganciclovir	Although mechanism of action is unclear, ganciclovir in combination with ZDV may induce life-threatening hematologic toxicity.	Verify order with health care provider prior to administration.
interferon beta-1b	Interferon beta may inhibit the glucuronidation of ZDV. This may increase ZDV serum concentrations and induce toxic effects.	Monitor ZDV serum concentration levels. Discuss dosage adjustment of ZDV with health care provider.
methadone	Concurrent use may increase zidovudine serum concentration.	Monitor for zidovudine adverse effects or toxicity. Monitor CBC.
probenecid	Probenecid appears to inhibit ZDV glucuronidation. This may increase ZDV serum concentration levels and induce toxic effects.	Monitor for systemic symptoms, such as malaise, myalgia, and fever. Discuss dosage adjustment of ZDV with health care provider.
rifampin/rifabutin	Rifampin may increase hepatic metabolism of ZDV, resulting in decreased serum concentration.	Discuss dosage adjustment of ZDV with health care provider.
trimethoprim	Pharmacologic effects of ZDV may be increased in patients with impaired hepatic function who receive trimethoprim.	Monitor ZDV serum concentration. Discuss dosage adjustment of ZDV with health care provider.
valproic acid	First-pass glucuronide metabolism of ZDV may be decreased.	Discuss dosage adjustment of ZDV with health care provider when starting, changing, or stopping valproic acid.

TABLE 46.4 HIV-Related Drugs with Overlapping Toxicities

Bone Marrow Suppression	Peripheral Neuropathy	Pancreatitis	Nephrotoxicity	Hepatotoxicity	Rash	Diarrhea	Ocular Effects
amphotericin B	didanosine	cotrimoxazole	acyclovir	azithromycin	abacavir	atovaquone	cidofovir
cidofovir	isoniazid	didanosine	adefovir	clarithromycin	amprenavir	clindamycin	didanosine
cotrimoxazole	linezolid	lamivudine (children)	aminoglycosides	delavirdine	atazanavir	darunavir	ethambutol
cytotoxic chemotherapy drugs	stavudine	pentamidine	amphotericin B	efavirenz	atovaquone	fosamprenavir	linezolid
dapsone	zalcitabine	ritonavir	cidofovir	fluconazole	cotrimoxazole	lopinavir/ritonavir	rifabutin
flucytosine		stavudine	foscarnet	isoniazid	dapsone	nelfinavir	voriconazole
ganciclovir		zalcitabine	indinavir	itraconazole	darunavir	ritonavir	
hydroxyurea			pentamidine	ketoconazole	delavirdine	tipranavir	
interferon-alfa			tenofovir	nevirapine	efavirenz		
linezolid				NRTIs	fosamprenavir

zidovudine							

based on changes from baseline. Laboratory tests may include a CBC, chemistry profile, liver and renal function tests, CD4 cell count, drug resistance testing and plasma HIV RNA measurement.

Life Span and Gender

Assess the patient for pregnancy and breast-feeding. Women who are taking zidovudine and become pregnant should remain on the drug. However, if the patient is not taking zidovudine at the time of conception, it is given antenatally after 14 weeks' gestation and throughout the rest of pregnancy, intravenously during the intrapartum period, and to the newborn for the first 6 weeks of life. In women who have not received antiretroviral therapy during pregnancy, intravenous (IV) zidovudine during labor can reduce the risk of transmitting HIV to the neonate. Box 46.6 describes general considerations for the management of HIV during pregnancy.

The risk of lactic acidosis is increased in women taking zidovudine, and they should be monitored closely for signs and symptoms. Presumptive symptoms of pregnancy can mimic early symptoms of lactic acidosis (nausea, vomiting, fatigue, and anorexia); thus, the patient should be scheduled for periodic serum electrolyte monitoring and liver function tests, especially during the last trimester of pregnancy.

To prevent adverse effects of zidovudine in the neonate, zidovudine should not be given during lactation. In addition, HIV-positive women are advised not to breast-feed in order to avoid potential postnatal transmission to an infant who may not be infected.

Children younger than 15 months should have HIV infection confirmed by PCR test. HIV antibody test findings in infants may reflect maternal antibodies, not the infant's own antibodies.

Lifestyle, Diet, and Habits

It is important to assess the patient's understanding of HIV transmission and to explain that despite drug therapy, the patient can still transmit HIV to others. In addition, assess the adherence issue. Even when zidovudine is taken exactly as directed, resistance may develop. However, resistance develops much more quickly when serum concentrations are suboptimal, which can be caused by imperfect adherence: either missing doses during the day or using the drug intermittently.

Assess the patient's typical dietary habits. Although zidovudine is taken without regard to meals, avoidance of fatty foods is important because these foods decrease the drug's absorption. Outline a high-carbohydrate, moderate-protein, low-fat diet.

It is also important to investigate whether the patient has a problem or a potential problem with substance abuse. HIV infection is highly prevalent among IV drug abusers. Once the diagnosis of HIV infection is made, some patients may see no reason to change their behavior because it is already "too late." The advent of HAART significantly altered the prognoses of HIV from debilitating and ultimately fatal to a disease to a chronic condition that can be managed with judicious care. Explain the toll drug abuse takes on the body and the need for the patient to establish a healthy lifestyle.

Gently question the patient's sexual lifestyle. Explain that unsafe sex may result in transmission of HIV to others, re-infection with another strain, or co-infection with other sexually transmitted and or blood borne diseases.

Box 46.6 HIV MANAGEMENT DURING PREGNANCY

The goal of antiretroviral therapy during pregnancy is to preserve the health of both mother and child.

Clinical Situation	Recommendation Woman	Recommendation Infant
HIV-infected woman who is receiving HAART and becomes pregnant	• Continue current HAART regimen if successfully suppressing viremia, except avoid use of EFV or other potentially teratogenic drugs in the first trimester and drugs with known adverse potential for mother. • HIV antiretroviral drug resistance testing is recommended if the woman has detectable viremia on therapy. • In general, if woman requires treatment, antiretroviral drugs should not be stopped during the 1st trimester. • Continue HAART regimen during intrapartum period (ZDV given as continuous infusion during labor while other antiretroviral agents are continued orally and postpartum. • Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains greater than 1,000 copies/mL near the time of delivery.	• ZDV for 6 weeks started within 6 to 12 hours after birth
HIV-infected pregnant woman who is antiretroviral naïve and has indications for antiretroviral therapy.	• HIV antiretroviral drug resistance testing is recommended prior to the initiation of therapy and if suboptimal viral suppression after initiation of HAART. • Initiate HAART regimen. • For women who require immediate initiation of therapy for their own health, treatment should be initiated as soon as possible, including in the 1st trimester. • Continue HAART regimen during intrapartum period (ZDV given as continuous infusion during labor while other antiretroviral agents are continued orally and postpartum. • Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains greater than 1,000 copies/mL near the time of delivery	• ZDV for 6 weeks started within 6 to 12 hours after birth

HIV-infected pregnant woman who is antiretroviral naïve and does NOT require treatment for her own health.	• HIV antiretroviral drug resistance testing is recommended prior to the initiation of therapy and if suboptimal viral suppression after initiation of HAART.
	• HAART is recommended for prophylaxis of perinatal transmission in women who do not require treatment for their own health.
	  • Consider delaying HAART initiation until after 1st trimester is completed.
	  • Avoid use of EFV or other potentially teratogenic drugs in the 1st trimester and drugs with known adverse potential for mother.
	  • Use of ZDV is recommended as a component of antiretroviral regimen when feasible
	• Use of DDV prophylaxis alone is controversial but may be considered for those women with plasma HIV RNA levels less than 1,000 copies/mL on no therapy.
	• Continue HAART regimen during intrapartum period (ZDV given as continuous infusion during labor while other antiretroviral agents are continued orally and postpartum.
	• Evaluate need for continued therapy postpartum; discontinue HAART unless has indications for continued therapy.
	• Schedule cesarean delivery at 38 weeks gestation if plasma HIV RNA remains greater than 1,000 copies/mL near the time of delivery
		• ZDV for 6 weeks started within 6 to 12 hours after birth

HIV-infected pregnant woman who has not received antiretroviral therapy during pregnancy	• ZDV: continuous infusion during labor OR • ZDV given as a continuous infusion during labor, plus single dose NVP at onset of labor. Consideration should be given to adding 3Tc during labor and maternal ZDV/3TC for 7 days postpartum, which may reduce development of NVP resistance OR • ZDV: continuous infusion during labor	• ZDV: for 6 weeks started within 6 to 12 hours after birth • Single dose NVP plus ZDV for 6 weeks. OR • ZDV in combination with additional drugs in the infant. Consultation with a pediatric HIV specialist is recommended.

Adapted from Public Health Service Taskforce. (2009). Recommendations for use of antiretroviral drugs in pregnant HIV-1 infected women for maternal health and interventions to reduce perinatal HIV-1 transmission in the United States. Retrieved from *http://aidsinfo.nih.gov/ContentFiles/PerinatalGL.pdf*

Be aware of the patient's economic status. Many patients do not have insurance or other resources to obtain this drug. Patients may qualify for medical assistance through county, state, or federal funds, pharmaceutical drug programs, or local health departments through the AIDS Drug Assistance Program (ADAP). Refer patients with financial problems to the hospital or clinic social worker.

Environment

Zidovudine is administered most frequently in an outpatient setting. Because HIV infection is treated routinely with complicated polytherapy, assess the patient's ability to understand complex instructions. Be explicit—in both spoken and written language—concerning the instructions for taking which drug at what time of day.

IV zidovudine, which can be given in any setting, is stable for 24 hours at room temperature and for 48 hours when refrigerated. The drug should be infused over 1 hour. Before infusion, examine the solution for particulate matter and discoloration. If either is present, the solution should not be administered. All preparations of zidovudine should be protected from light once prepared as well as during infusion.

Nursing Diagnoses and Outcomes

- Acute Pain related to headache from drug effects
  Desired outcome: *The patient will self medicate with over the counter remedies such as nonsteroidal anti-inflammatory drugs (NSAIDS), and or practice non-pharmacological pain relief to alleviate the headache.*
- Ineffective Protection related to anemia and granulocytopenia
  Desired outcome: *The patient will remain free of opportunistic diseases related to blood dyscrasias.*
- Imbalanced Nutrition: Less than Body Requirements, related to GI distress
  Desired outcome: *The patient will self medicate with over the counter remedies to control transient GI symptoms and will contact the provider for persistent GI complaints*
- Disturbed Sleep Pattern: Insomnia related to CNS adverse effects
  Desired outcome: *The patient will obtain adequate sleep throughout drug therapy.*
- Disturbed Thought Processes related to adverse CNS effects
  Desired outcome: *The patient will remain oriented and able to communicate effectively with others.*
- Diarrhea related to adverse drug effects
  Desired outcome: *The patient will avoid dehydration and contact the prescriber if diarrhea persists.*
- Risk for Injury related to adverse drug effects
  Desired outcome: *The patient will remain injury free throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer zidovudine 1 hour before meals. Also, make sure the patient receives 600 mg/d in divided doses—200-mg tablets three times daily or 300-mg tablets twice daily. Make sure the patient is on a low-fat diet.

Minimizing Adverse Effects

Intramuscular injections should be cautiously administered to patients receiving zidovudine; they may cause bleeding, bruising, or hematomas because of thrombocytopenia secondary to zidovudine-induced depression of bone marrow function.

Providing Patient and Family Education

- Emphasize that zidovudine does not cure HIV. Encourage the patient to take precautions to avoid exposing others to blood and body fluids and the use of latex condoms during sex.
- Explain the importance of adhering to the therapeutic regimen. The instructions should be clear and preferably in writing and at the patient's reading comprehension level.
- Explain the importance of periodic blood monitoring to ensure the efficacy of therapy and early recognition of adverse effects associated with AZT.
- It is important to advise patients about potential adverse effects, especially the Black Box warnings. Stress the importance of contacting the prescriber if signs of anemia or depressed bone marrow function appear, such as bleeding, easy bruising, or fatigue. Also explain that adverse effects, such as GI distress or headache, may resolve spontaneously after 3 to 4 weeks of therapy. Headaches can be treated with NSAIDs. Persistent problems should be reported to the prescriber.
- Instruct patients to advise the prescriber if any other drugs are ordered by another prescriber. Explain that many drugs may alter the way zidovudine works, and other drugs may increase the risk of adverse effects from zidovudine therapy.
- Advise patients to postpone any dental work if myelosuppression is suspected.
- Instruct patients with sleep disturbance to attempt relaxation techniques or warm baths to facilitate sleep.
- Explain the importance of contacting the prescriber if patients have difficulty thinking or experience memory problems.

Ongoing Assessment and Evaluation

Perform a physical examination at each visit with the patient who is taking zidovudine. Laboratory data should be obtained ideally every 2 to 4 weeks. Once HIV RNA levels are undetectable and the CD4 count is stable and the patient is clinically stable, follow-up visits should ideally occur every other month.

Monitor for signs and symptoms of adverse effects of lactic acidosis, anemia, depressed bone marrow function, or nephrotoxicity. Also monitor for signs of myelosuppression or myalgias. Symptoms of myalgia include proximal muscle weakness and elevations of creatinine kinase values.

MEMORY CHIP

P Zidovudine

- Used for management of HIV and AIDS
- Major contraindications: hypersensitivity, first 14 weeks of pregnancy
- Most common adverse effects: nausea, headache, rash, fever, and abdominal pain
- Most serious adverse effects: anemia, granulocytopenia, and thrombocytopenia; suppression of bone marrow function; lactic acidosis; and hepatomegaly with steatosis
- Maximizing therapeutic effects: Administer 1 hour before meals.
- Minimizing adverse effects: Avoid IM injections because of thrombocytopenia.
- Most important patient education: signs and symptoms of anemia and importance of notifying the prescriber immediately
- **Black box warning: Neutropenia and severe anemia, myopathy with prolonged use, and potential for lactic acidosis and hepatomegaly.**

Monitor for the need to change pharmacotherapy such as intolerance to the regimen, or unwanted results of serological markers, such as a declining CD4 count and or an elevation in the HIV viral load. Remember that blood analysis may be necessary to determine whether changes in therapy are needed because of sub-optimal therapy or, because the patient may remain asymptomatic with the medications associated toxicity such as with mild anemia associated with bone marrow suppression or upward fluctuation of liver enzymes above the upper limits of normal with hepatotoxicity.

The patient should have a stable CD4 count and a declining or undetectable HIV RNA count throughout therapy. The patient should be free of opportunistic infections and signs of anemia or depressed bone marrow function and other known toxic effects of the therapy.

Drugs Closely Related to P Zidovudine

Abacavir Sulfate

Abacavir sulfate (ABC, Ziagen) is an analogue of guanine. Like zidovudine, it must be converted to its active form, carbovir triphosphate, to be effective. It may be substantially more potent than some other reverse transcriptase inhibitors. Abacavir is available in tablet and suspension forms. It has excellent bioavailability and widespread distribution, including the cerebrospinal fluid (CSF). Abacavir plus Lamivudine (Epzicom) is a combination of an NNRTI and an NRTI in one pill and given once a day. Trizivir is co-formulation of three antiretrovirals that include abacavir and zidovudine, and lamivudine that is given twice a day. This formulation combines two NRTIs and one NRTI. Several Black Box warnings are associated with abacavir:

- Serious and sometimes fatal hypersensitivity reactions may occur. This multiorgan clinical syndrome is characterized by two or more groups of the following signs and symptoms: (1) fever; (2) rash; (3) GI symptoms such as nausea, vomiting, diarrhea, or abdominal pain; (4) constitutional symptoms such as generalized malaise, fatigue, or achiness; and (5) respiratory symptoms such as dyspnea, cough, or pharyngitis.
- Hypersensitivity may occur. Monitor the patient for a rash. Most antiretroviral drugs may cause a rash, but the rash caused by abacavir may signal hypersensitivity to the drug.
- The drug should be discontinued as soon as hypersensitivity reaction is suspected
- Any product containing abacavir should be permanently discontinued if hypersensitivity cannot be ruled out, even when other diagnoses are possible. More severe symptoms, which may include life-threatening hypotension and death, can occur within hours of restarting abacavir.
- Lactic acidosis may occur, as with zidovudine.

Check for the completion of HLA-B5701 testing. Inform the provider if the test is positive because abacavir is contraindicated in those patients. Document abacavir as an allergy in the patient's chart if the HLA-B5701 test is positive.

Instruct the patient to refrain from drinking alcohol. Alcohol increases the plasma levels of abacavir by about 40%, which increases the risk of adverse effects. Abacavir can be taken with or without food. It is a pregnancy category C drug. Recommendations during pregnancy are similar to those for zidovudine.

Didanosine

Didanosine (ddI, Videx, Videx EC) was approved in 1991 as a first-line drug for treating HIV infection. The pharmacokinetics of didanosine are similar to those of zidovudine. However, its active metabolite, dideoxyadenosine triphosphate, has a much longer half-life, which allows twice-daily dosing. Like other NRTIs, it is renally excreted, so patients with renal insufficiency should receive a reduced dose.

Didanosine is available in two formulations. In its buffered versions, didanosine decreases gastric pH, thus affecting the absorption of other drugs, such as the fluoroquinolones, dapsone, indinavir, and azole antifungals. This buffering agent also complicates the timing of administration for other antiretroviral drugs and may cause diarrhea. Didanosine can be taken at the same time as other NRTIs, nevirapine, and efavirenz. However, delavirdine and indinavir should be taken at least 1 hour before didanosine, whereas lopinavir/ritonavir and atazanavir should be taken 2 hours before or 1 hour after didanosine. As an enteric-coated capsule, didanosine is taken on an empty stomach (1 hour before or 2 hours after a meal) because it is inactivated by the stomach acid.

The adverse effect profile of didanosine includes GI problems similar to those seen with zidovudine as well as peripheral neuropathy. Didanosine has two Black Box warnings: Fatal and nonfatal pancreatitis can occur. Prior episodes of pancreatitis, active alcohol abuse, or coadministration of other drugs that may cause pancreatitis further increases the risk of pancreatitis. Didanosine should be discontinued at the first signs or symptoms of pancreatitis, such as anorexia, nausea, vomiting, and abdominal pain.

Lactic acidosis can occur, especially among pregnant women who receive a combination of didanosine and stavudine with other antiretroviral combinations..

Didanosine should not be given with drugs that have overlapping toxicities (see Table 46.4). Didanosine should not be given concurrently with tenofovir because this combination may increase the risk of adverse effect. Didanosine is a pregnancy category B drug.

Emtricitabine

Emtricitabine (FTC, Emtriva) is a derivative of lamivudine that must be converted into emtricitabine triphosphate to be active. It is available in combination with tenofovir and efavirenz (Atripla) and in a two–drug, one-pill combination with tenofovir (Truvada). Like lamivudine, emtricitabine is also active against HBV. However, it is not FDA-approved for this use, and there is a Black Box warning that the safety and efficacy of emtricitabine has not been established for the treatment of HBV. Additional Black Box warnings include:

- Lactic acidosis may occur with hepatomegaly and severe steatosis, especially among women.
- Severe acute exacerbations of HBV may occur when emtricitabine is discontinued. Hepatic function should be monitored closely with both clinical and laboratory follow-up for several months after discontinuation of tenofovir in HIV/HBV-coinfected patients.
- Anti-HBV therapy may be needed. Initiation of anti-HBV therapy may be indicated after discontinuation of emtricitabine.

The most common adverse effects associated with emtricitabine are headache, diarrhea, nausea, and rash. Hyperpigmentation on the palms, soles, or both has been observed in nonwhite patients. Because emtricitabine is so similar to lamivudine, patients with HIV that is resistant to lamivudine are unlikely to benefit from emtricitabine treatment. Emtricitabine is approved for patients older than 18 years. The benefit of emtricitabine is its once-daily dosing with or without food. Because it is renally excreted, patients with renal insufficiency should receive a reduced dose. Emtricitabine is not known to interact with CYP450 metabolism and may have limited drug to drug interaction. Emtricitabine is a pregnancy category B drug. Recommendations during pregnancy are similar to those for zidovudine.

Lamivudine

Lamivudine (3TC, Epivir) is an analogue of cytidine, a natural nucleoside, and it must be converted to its active form, lamivudine triphosphate, to be effective. It is available as an individual drug or in the combination products Combivir, with AZT, Epzicom with abacavir, and Trizivir with AZT and abacavir. Lamivudine is approved for use in patients 3 months of age and older. This drug should always be used in conjunction with other antiretroviral agents and should not be used alone to manage HIV infection. In addition to its indication for HIV infection, lamivudine is used as the drug Epivir-HBV in low dose in managing hepatitis B.

Black Box warnings for lamivudine include:

- Like the other NRTIs, lactic acidosis can occur.
- The Epivir-HBV formulation and dosage may not be sufficient to treat HIV infection. Patients with HIV infection should receive only appropriate preparations in proper dosages.
- Severe acute exacerbations of HBV have been reported in HBV/HIV-coinfected patients on discontinuation of lamivudine-containing products. Hepatic function should be monitored for several months after discontinuation.
- Anti-HBV treatment may be needed. Initiation of anti-HBV therapy may be appropriate.

The most common adverse effect of lamivudine is nausea. Also, pancreatitis has been observed with pediatric administration of lamivudine. The drug is renally excreted; therefore, patients with substantial renal impairment should be given reduced doses. Because food decreases the rate but not the extent of oral absorption, lamivudine may be administered with or without food. Lamivudine is a pregnancy category C drug. Recommendations during pregnancy are similar to those for zidovudine. Additionally, lamivudine may be used in combination with zidovudine in women who did not receive zidovudine therapy throughout their pregnancy.

Stavudine

Stavudine (d4T, Zerit) is another analogue of thymidine that is converted to its active form, stavudine triphosphate. Absorption and serum concentrations are not affected by meals, and its half-life enables twice-daily dosing. Stavudine is excreted by the kidneys; therefore, a reduced dose should be considered for patients with decreased renal function.

Stavudine is generally well tolerated. A major clinical adverse effect is peripheral neuropathy and as such should not prescribed with other medications with overlapping and additive toxicities, such as didanosine, INH, or Rifampin. The drug should be discontinued in patients with symptoms of neuropathy, such as tingling, burning, pain, or numbness in the distal extremities. It should not be combined with zidovudine or any combination product containing zidovudine. Stavudine is also known to cause lipoatrophy, clinically manifesting as loss of buccal fat and or thinning of the extremities. Finally, Stavudine is associated with higher rate of lactic acidosis, lipodystrophy, and disorders of lipid metabolism among all the NRTIs and for these reasons is not recommended as part of the initial treatment of HIV. Stavudine is a pregnancy category C drug. It is important to remember that pregnant women taking stavudine in combination with didanosine and other antiretroviral agents have an increased risk of developing lactic acidosis. Black Box warnings for stavudine are the same as for didanosine.

Tenofovir

Tenofovir disoproxil fumarate (TDF, Viread) is the only nucleotide analogue reverse transcriptase inhibitor that is approved by the FDA. In 2008 Tenofovir was approved by the FDA in the treatment of HBV. Nucleotide analogues

differ from nucleoside analogues because they are chemically preactivated and therefore require less processing in the body for them to become active. Tenofovir is a once-daily medication that is taken without regard to meals. Adverse effects include asthenia, headache, diarrhea, nausea, vomiting, and flatulence. Tenofovir is also renally excreted; thus, a dosage adjustment is necessary in patients with renal insufficiency. Serious cases of acute renal failure have been observed with patients on Tenofovir. Monitor renal function, urinalysis and electrolytes. Black Box warnings are the same as for emtricitabine.

C NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIS)

The **nonnucleoside reverse transcriptase inhibitors (NNRTIs)** comprise the second class of drugs used to treat HIV infection. NNRTIs affect only HIV-1; they do not inhibit reverse transcriptase in HIV-2. Although NNRTIs still affect reverse transcriptase, they have a different mechanism of action than NRTIs. Unlike NRTIs, NNRTIs are not incorporated into viral DNA. Instead, they inhibit a specific site on the reverse transcriptase that is required to carry out the process of DNA synthesis; this results in the inability to convert viral RNA into DNA. The NNRTIs are less toxic because they are not structurally similar to natural nucleosides or nucleotides; thus, they have less of an effect on the body's natural enzymes. The prototype NNRTI is efavirenz (Sustiva). Table 46.5 presents a summary of NNRTIs.

Nursing Management of the Patient Receiving P Efavirenz

Core Drug Knowledge

Pharmacotherapeutics

Efavirenz is indicated for use in treating HIV-1 infection in combination with other antiretroviral drugs. It is the preferred component of an NNRTI based HAART for the initial treatment of HIV, except during pregnancy, or high risk for pregnancy due to its high teratogenic potential. Atripla is co-formulation of tenofovir, emtricitabine, and efavirenz rolled into one drug and is the HAART preferred option for the initial treatment of HIV infection. It is a formulation of 2 NRTIs combined with one NRRTI with the tremendous advantage of once a day dosing. Resistant virus emerges rapidly when efavirenz is administered as monotherapy or in combination with other NNRTIs.

Pharmacokinetics

Efavirenz is absorbed readily after oral administration. A high-fat meal significantly increases the bioavailability of efavirenz as well as the potential for adverse effects. Peak plasma concentrations occur within 3 to 5 hours. Efavirenz is approximately 99% protein bound. It is distributed widely in the body, crosses the blood–brain barrier and placenta, and enters breast milk. Efavirenz is metabolized by the P-450 system and excreted in urine and feces.

Pharmacodynamics

Efavirenz inhibits HIV reverse transcriptase. It binds directly to the active site on reverse transcriptase, resulting in the inability to change viral RNA into DNA.

TABLE 46.5 Summary of Selected C Nonnucleoside Reverse Transcriptase Inhibitors

Drug (Trade) Name	Route and Dosage Range	Pharmacokinetics	Special Considerations
P efavirenz (EFV, Sustiva)	*Adult and adolescent >40 kg:* PO, 600 mg daily *Child 32.5–40 kg:* PO, 400 mg daily *Child 25–32.5 kg:* PO, 350 mg daily *Child 20–25 kg:* PO, 300 mg daily *Child 15–20 kg:* PO, 250 mg daily *Child 10–15 kg:* PO, 200 mg daily	*Onset:* Rapid *Duration:* 24 h $t_{1/2}$: 40–55 h	Take on an empty stomach, preferably at bedtime. Administer at least 1 h apart from Videx or antacids. Assess for pregnancy: potentially teratogenic. Monitor for potential interactions with other antiretroviral medications.
delavirdine mesylate (DLV, Rescriptor)	*Adult and adolescent*: PO, 400 mg 3×/d	*Onset*: Rapid *Duration*: 8 h $t_{1/2}$: 5.8 h	No food restrictions Administer at least 1 h apart from Videx or antacids.
nevirapine (NVP, Viramune)	*Adult and adolescent*: PO, 200 mg daily for 14 d, then 200 mg 2×/d *Child >8 y*: PO, 4 mg/kg daily for 14 d, then 4 mg/kg 2×/d; max: 200 mg daily *Child and infant >2 mo–8 y*: PO, 7 mg/kg daily for 14 d, then 7 mg/kg 2×/d; max: 200 mg daily	*Onset*: Rapid *Duration*: 12 h $t_{1/2}$: 25–30 h	No food restrictions
rilpivirine (Edurant)	*Adult PO*: 5 mg daily *Child*: not recommended	*Onset*: 3–4 h *Duration*: unknown $t_{1/2}$: 34–55 h	Administer with meals. Avoid administration with protein drinks

Contraindications and Precautions

Efavirenz is contraindicated for patients with hypersensitivity to any of its components. It is also contraindicated for patients taking the benzodiazepines midazolam or triazolam, ergot derivatives, or voriconazole.

Efavirenz is used cautiously in patients with concomitant use of alcohol or psychoactive drugs because they increase the risk of CNS adverse effects. Patients with a history of psychiatric disorders also have an increased risk of psychiatric adverse effects and therefore this medication should be cautiously used with them. Efavirenz is metabolized by the liver; thus, patients with hepatic impairment are more likely to have increased serum concentrations of efavirenz. The drug should be used with caution in patients with a history of hepatitis B or C; they have an increased risk of hepatotoxicity. Efavirenz is also used with caution in patients with elevated cholesterol or triglycerides because it can cause these lipid disorders.

Efavirenz is a pregnancy category D drug and is contraindicated during pregnancy.

Adverse Effects

More than 50% of patients who take efavirenz have CNS adverse effects such as dizziness, impaired concentration, insomnia, abnormal dreams, and hallucinations which is described as "spacey," "high," or "confused." Therefore, it is best to administer the medication at night to negate these CNS side effects. Also, the patient should be forewarned about cautious driving or not driving at all during the first week of taking the medication and until the body is acclimated to its side effects. These symptoms start within the first 2 days of therapy and generally abate between weeks 1 and 4. Rash is another common adverse effect. The severity of the rash can be mild to severe. Most rashes present as maculopapular skin eruptions or pruritic erythema. Rarely, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur and maybe severe and life threatening.

Other adverse drug effects include hyperlipidemia, lipodystrophy (defective fat metabolism leading to abnormal body fat distribution), GI distress, and hepatotoxicity. In rare circumstances, efavirenz may induce seizures and psychiatric disorders such as severe depression, suicidal ideation, aggressive behavior, and paranoid or manic reactions. Psychiatric adverse effects occur more frequently in patients with a prior history of psychiatric disorders.

Drug Interactions

Efavirenz interacts with drugs that are metabolized by P-450 CYP3A4. It induces the metabolism of many drugs, such as voriconazole, resulting in a reduction of their serum concentration level. Although efavirenz decreases the serum concentration of voriconazole, it in turn increases the serum concentration of efavirenz, resulting in decreased efficacy of voriconazole and increased risk of adverse effects caused by efavirenz. Conversely, efavirenz inhibits the metabolism of drugs such as benzodiazepines and ergot derivatives, leading to dangerously elevated serum concentrations of these drugs. Efavirenz may decrease the effectiveness of oral contraceptives. Table 46.6 presents these drug–drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for hypersensitivity to efavirenz and for pregnancy or lactation. Also, assess the patient for preexisting hepatic dysfunction or lipid abnormalities. Review the patient's current drug therapy for other drugs that may react with efavirenz, or those with overlapping toxicities. Communicate positive findings to the prescriber.

Before the initiation of therapy, perform a complete physical examination. It is important to document this baseline status because drug therapy may be discontinued or modified based on changes from baseline. Laboratory tests should include CBC, complete metabolic profile, lipid panel, liver function tests, CD4 cell count, and plasma HIV RNA measurements.

Life Span and Gender

Assess the patient for pregnancy. Efavirenz is a pregnancy category D drug and considered teratogenic during all trimesters. Women of childbearing age should use birth control methods other than hormonal contraceptives because efavirenz decreases the effectiveness of birth control pills. Almost 40% of children develop a rash. Monitor children closely and report any rash to the health care provider.

Lifestyle, Diet, and Habits

As with other anti-HIV drugs, resistance to efavirenz is more likely when the drug is taken inconsistently. Therefore, assess the patient's understanding of the importance of taking the drug as directed. Also, the patient who abuses drugs or alcohol is more likely to experience CNS or psychiatric adverse effects. Advise the patient to refrain from their use. Assess for use of herbal remedies such as St. John's wort. Instruct the patient to refrain from its use because it decreases the serum concentration of efavirenz. Assess for the use of garlic; it may also decrease the serum concentration of efavirenz.

Assess the patient's financial status because efavirenz is expensive. Refer those without insurance to social services. These patients may qualify for medical assistance through county, state, or federal funds or receive their drugs from local health departments.

Environment

Efavirenz is administered most frequently in an outpatient setting, always as polytherapy. Therefore, assess the patient's ability to understand complex instructions. It is important that the instructions be explicit—both spoken and written—concerning which drug to take at which time of day.

Nursing Diagnoses and Outcomes

- Risk for Injury related to CNS adverse effects
  Desired outcome: *The patient will remain free from injury and contact the health care provider if symptoms should occur*

TABLE 46.6 Agents That Interact with P Efavirenz

Interactants	Effect and Significance	Nursing Management
benzodiazepines	Efavirenz inhibits metabolism of benzodiazepines, resulting in potential toxicity.	Monitor for sedation. Monitor for incoordination. Monitor vital signs, especially respiratory rate.
cyclosporine	Efavirenz may decrease serum concentration of cyclosporine.	Monitor for signs of transplant organ rejection. Discuss dosage adjustment of cyclosporine with health care provider.
ergot derivatives	Efavirenz interferes with hepatic metabolism of ergot derivatives, resulting in potential ergotism.	Monitor for peripheral vasospasm. Monitor for extremity ischemia.
lipid-lowering drugs	Efavirenz may increase serum concentration of these drugs, resulting in increased risk of adverse effects or toxicity.	Monitor for rhabdomyolysis and myopathies.
methadone	Efavirenz may decrease serum concentration of methadone	Monitor for signs of opiate withdrawal.
oral contraceptives	Efavirenz increases hepatic metabolism of estrogenic and progestational components of oral contraceptives	Assess for pregnancy. Instruct patient to use another form of birth control.
protease inhibitors	Efavirenz may decrease serum concentration of protease inhibitors.	Monitor T-cell count. Monitor viral load. Monitor for opportunistic diseases. Discuss dosage adjustment of protease inhibitor with health care provider.
rifamycins	Rifamycins increase metabolism of efavirenz, resulting in decreased serum concentration.	Same as for protease inhibitors
St. John's wort	St. John's wort may decrease serum concentration of efavirenz.	Same as for protease inhibitors
thiazolidinediones	Thiazolidinediones may decrease serum concentration of efavirenz.	Same as for protease inhibitors
voriconazole	Coadministration decreases efficacy of voriconazole as well as increases serum concentration of efavirenz.	These drugs should not be coadministered. Verify order with health care provider.

- Disturbed Thought Processes related to CNS adverse effects
  Desired outcome: *The patient will remain oriented and able to communicate effectively with others.*
- Ineffective Protection related to drug-related rash
  Desired outcome: *The patient will report any rash to the prescriber.*
- Imbalanced Nutrition: Less than Body Requirements, related to GI distress
  Desired outcome: *The patient will maintain adequate weight and nutrition and notify the health care provider about persistent GI symptoms.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer efavirenz once a day, preferably at bedtime. For missed doses, it is important that the patient take the drug as soon as remembered unless it is time for the next dose. Efavirenz must be given concurrently with other antiretroviral medications.

Minimizing Adverse Effects

Administer efavirenz on an empty stomach. Food, especially high-fat food, increases the bioavailability of efavirenz, resulting in an increased risk of developing adverse effects. Also, administering efavirenz at bedtime decreases the severity of CNS adverse effects. Coordinate serial laboratory testing for liver function. Liver function tests should be evaluated prior to initiation of therapy and periodically thereafter. Periodic lipid studies are also important.

Providing Patient and Family Education

- Emphasize that efavirenz does not cure HIV. Encourage the patient to take precautions to avoid exposing others to blood and body fluids and the use of latex condoms during sex.
- Explain the importance of adherence to drug therapy. Make sure the instructions are clear and in writing.
- Explain the importance of periodic blood monitoring to ensure the efficacy of therapy and assessment of potential adverse effects.
- Explain the potential CNS adverse effects. Encourage patients to continue the efavirenz because these symptoms generally abate. Instruct patients to refrain from activities that require concentration if they are experiencing these adverse effects.

- Advise patients experiencing depression, anxiety, or behavior changes and those feeling paranoid or manic to contact the health care provider immediately.
- Inform patients that one of the most common adverse reactions to efavirenz is rash. Instruct patients to contact the health care provider if the skin becomes ulcerated or denuded.
- Instruct patients to monitor for signs of hepatic dysfunction, such as fatigue, jaundice, and nausea or vomiting. Advise them to contact the health care provider immediately if signs of hepatic dysfunction occur.
- Instruct patients to advise their prescriber if any other drugs are ordered by another prescriber. It is important to explain that many drugs may alter the way efavirenz works and that other drugs may increase the risk of adverse effects from efavirenz therapy.
- Instruct patients with GI distress to eat small, frequent meals. For persistent symptoms and weight loss, patients should contact the prescriber.
- Explain to women of childbearing age the importance of using contraceptive measures other than hormonal contraceptives. Instruct female patients to contact the health care provider immediately if they become pregnant while taking efavirenz.
- Caution patients that they may experience changes in their physical appearance. Lipodystrophy may cause increased fat in the upper back, neck, breast, and trunk and loss of fat from the legs, arms, and face.

Ongoing Assessment and Evaluation

Coordinate periodic examinations and blood monitoring in patients receiving efavirenz to assess for potential progression of HIV disease, treatment failure, the emergence of resistance, or development of adverse effects. CD4 cell counts and HIV RNA should be assessed every 3 months. The patient should have a stable CD4 cell count and a declining or undetectable HIV RNA count throughout therapy. Monitor for the need to change pharmacotherapy.

Monitor for CNS adverse effects. Remind the patient to refrain from activities that require mental alertness if he or she experiences these adverse effects. Check for lipid abnormalities. Monitor for a diffuse, maculopapular, or erythematous rash. Refer the patient to his or her health care provider immediately if the rash is accompanied by aching joints or muscles; redness, blistering, peeling, or loosening of skin; unusual tiredness or weakness; or fever; these are symptoms of Stevens-Johnson syndrome. Monitor for signs of liver dysfunction. Coordinate periodic liver function tests.

Drugs Closely Related to P Efavirenz

Delavirdine

Delavirdine mesylate (DLV, Rescriptor) was approved by the FDA in 1997. It is indicated for combined use with NRTIs. Unlike efavirenz and nevirapine, delavirdine is a potent inhibitor of CYP3A4. As a result, concurrent administration of other CYP3A4 drugs may increase their serum drug concentrations, resulting in an increased risk for adverse effects and potential drug toxicity. Delavirdine may inhibit the metabolism of several medications that may result in a clinically important elevation of their plasma concentration. These drugs include amphetamines; anticoagulants (warfarin); anti-infectives (clarithromycin, dapsone, rifabutin, and saquinavir); sedative hypnotics (alprazolam, midazolam, triazolam); cardiovascular agents (nifedipine, quinidine); ergot alkaloids and derivatives; HMG-CoA reductase inhibitors (atorvastatin, cerivastatin, fluvastatin); immunosuppressive agents (dexamethasone, cyclosporine, sirolimus, tacrolimus); methadone; and sildenafil. Drugs known to decrease the

CRITICAL THINKING SCENARIO

Ms. M. Williams is a 24-year-old female diagnosed of HIV about 5 years ago. She has been a transient, moved to several states and cities but has since settled down and now is at the Clinic for a second visit. Her CD4 was 250/mm^3, her viral load is 75,000 copies/mL. The remainders of her laboratory values are within the normal limits. After her consultation with her doctor, she asked if she can talk to you since she has several questions about Atripla, the medication that the provider prescribed. She is puzzled since she has to take only one pill a day when many of her friends who are also infected takes several pills daily. She also said that she heard something about pregnancy but missed a great portion of what the provider said because she got distracted. Also, she asked if she could take it during the day and confided, but did not tell her doctors, that she wants to skip a dose or two to give her body a chance to "rest."

1. What patient education will you provide Ms. Williams about Atripla, its drug classes, their mechanism of action?
2. What patient teaching will you provide her about pregnancy? About taking the medications during the day and its implication? Why will you recommend that she takes the medications during her time of sleep?
3. What will tell Ms. Williams about taking a medication holiday? What are its potential implications?

MEMORY CHIP

P Efavirenz

- Used for the management of HIV infection and AIDS
- Major contraindication: hypersensitivity and taking midazolam or triazolam, ergot derivatives, or voriconazole
- Most common adverse effects: dizziness, impaired concentration, insomnia, abnormal dreams, hallucinations, and rash
- Most serious adverse effects: Stevens-Johnson syndrome, hepatotoxicity, and psychiatric disorders
- Maximizing therapeutic effects: Administer with other antiretroviral agents—never as monotherapy.
- Minimizing adverse effects: Administer at bedtime to decrease CNS adverse effects.
- Most important patient education: Explain the importance of laboratory follow-up to monitor for hepatotoxicity and lipid abnormalities.

bioavailability of delavirdine include antacids, proton pump inhibitors, histamine-2 blockers, anticonvulsants such as carbamazepine, phenobarbital, or phenytoin, and St. John's Wort. Drugs know to significantly increase the plasma concentration of delavirdine include clarithromycin, fluoxetine, ketoconazole, and rifabutin or rifampin.

Adverse reactions associated with delavirdine include rash, which may spontaneously resolve, increased liver enzyme levels, and headache. Delavirdine is a pregnancy category C drug; however, it is not recommended for use during pregnancy.

Nevirapine

Nevirapine (Viramune), the first NNRTI on the market, is also indicated for the treatment of HIV-1. Like efavirenz, resistance emerges rapidly when nevirapine is administered as monotherapy or in combination with other NNRTIs. The drug is lipophilic, which means that it can easily pass through the blood–brain barrier so its concentration in the CSF is greater than that of the other NNRTIs. Unfortunately, that same lipophilic property allows nevirapine to pass through the placental barrier as well as enter breast milk. Although it is a pregnancy category C drug, it is contraindicated during pregnancy.

Nevirapine has several Black Box warnings:

- Severe, life threatening and in some cases fatal hepatotoxicity, particularly in the first 18 weeks, has been reported in patients treated with nevirapine. In some cases, patients presented with non-specific prodromal signs or symptoms of hepatitis and progressed to hepatitis. These events are often associated with rash.
- Female gender and patients with higher CD4 counts at initiation of therapy place patients at increased risk.
- Women with CD4 counts greater than 250 cells/mm^3, including pregnant women receiving nevirapine in combination with other antiretrovirals for the treatment of HIV infection, are at the greatest risk.
- Hepatotoxicity associated with the use of this agent can occur in both genders, all CD4 counts, and at any time during treatment.
- Patients with signs or symptoms or hepatitis, or increased transaminases combined with rash or other systemic symptoms, must discontinue the drug and seek medical evaluation immediately.
- Severe, life-threatening skin reactions (sometimes fatal) have occurred during therapy.
- Cases include Stevens-Johnson syndrome, Toxic Epidermal Necrolysis (TEN), and hypersensitivity reactions characterized by rash, constitutional findings, and organ dysfunction.
- Patients developing signs or symptoms of severe skin reactions or hypersensitivity must discontinue product and seek medical attention immediately.
- Transaminase levels should be checked immediately for all patients who develop a rash within the first 18 weeks of treatment. The 14-day lead-in period with nevirapine 200 mg daily dosing has been observed to decrease the incidence of rash and must be followed.
- Patients must be monitored intensively during the first 18 weeks to detect signs and symptoms of life-threatening skin/hepatic reactions.
- Extra vigilance is warranted during the first 6 weeks of therapy, which is the period of greatest risk of these events.
- Do not start nevirapine following severe hepatic, skin, or hypersensitivity reactions.
- In some cases, hepatic injury has progressed despite discontinuation of treatment.

Like efavirenz, nevirapine may cause rash. Instructions for patients with a rash are the same as for efavirenz recipients. Unlike efavirenz, nevirapine does not generally cause CNS or psychiatric symptoms. Other common adverse effects of nevirapine therapy include fever, headache, nausea, and vomiting.

Nevirapine and efavirenz have similar drug interactions. Other than the requirement of dose escalation during the first 2 weeks of treatment, patient management for nevirapine is the same as that for efavirenz.

Etravirine (Intelence, TMC-125)

Etravirine received accelerated approval by the FDA in January 2008. It is approved for treatment-experienced adults with HIV resistance to other HAART medications, including other NNRTIs. It has not been approved for use in treatment naïve **(never taken HIV therapy)** patients because of insufficient data due to its accelerated approval. Like other NNRTIs, it is not approved for monotherapy.

While there are no contraindications to its use, etravirine is used cautiously in patients receiving many other medications because it is a substrate of cytochrome CYP 450 enzyme system, as well as inducer of CYP3A4, and inhibitor of CYP2CO and CYP2C19 resulting in many potentially serious drug-drug interactions. These drugs include other HAART medications (especially Kaletra), antibiotics, antifungals, heart medications, antiseizure medications, cholesterol lowering medications, erectile dysfunction medications, and herbal medications such as St. John Wart. It is a pregnancy category B; it is not known whether it passes into breast milk.

Rash, nausea, diarrhea, are predictable side effects of NNRTIs, including etravirine. Other possible side effects include vomiting, abdominal pain, tiredness, tingling or pain in hands or feet, numbness, headache and high blood pressure. Laboratory abnormalities include increased serum cholesterol, triglycerides, and transaminitis especially in patients with hepatitis B or C co-infection.

Administer etravirine after a meal, not on an empty stomach. It must be swallowed whole. If your patient is unable to swallow, dissolve the tablet in a glass of water.

Rilpivirine (Edurant)

Rilpivirine is the newest FDA-approved antiretroviral drug. It is used in combination with other antiretroviral drugs for the treatment of HIV-1 infection in adults who are treatment naïve. Like delavirdine, rilpivirine is primarily metabolized by cytochrome P-450 CYP3A and has similar drug-drug interactions that result in either an significant increase or

decrease in its plasma concentration. The most common adverse drug reactions to rilpivirine include depression, insomnia, headache and rash. Rilpivirine is Pregnancy Category B because animal reproduction studies have not shown a risk to the animal fetus but adequate and well-controlled trials in pregnant women have not been conducted. Therefore, rilpivirine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

C PROTEASE INHIBITORS

Protease inhibitors (PIs) are the third major class of drugs used in treating HIV infection and AIDS. Their arrival has changed the opinion of experts as to the ultimate fatality of HIV and AIDS. The PIs represent the most potent anti-HIV drugs. However, their potency and activity vary widely among individual patients.

As with the other classes of antiretrovirals, PIs should not be used as monotherapy. Cross-resistance may occur within the PI class; however, it does not extend to NRTIs or NNRTIs. All of the PIs have the potential to cause serious adverse effects such as hyperlipidemia, lipodystrophy and lipoatrophy (Box 46.7), hyperglycemia, osteopenia or osteoporosis, hepatic dysfunction, and increased bleeding in patients with hemophilia. Saquinavir (Invirase), the first FDA-approved PI, is the prototype PI. Table 46.7 presents a summary of protease inhibitors.

Nursing Management of the Patient Receiving P Saquinavir

Core Drug Knowledge

Pharmacotherapeutics

Saquinavir mesylate is an agent for treating HIV infection in adults. It is approved for use in combination with two reverse transcriptase inhibitors. Combination therapy enables reduced dosage and helps to limit the incidence of adverse events. Saquinavir demonstrates activity against both HIV-1 and HIV-2 and is effective in acutely and chronically infected cells.

Pharmacokinetics

Saquinavir is only about 4% bioavailable after dosing, because of a combination of poor absorption and extensive first-pass metabolism. It is always combined with ritonavir because ritonavir significantly inhibits saquinavir's metabolism, resulting in an increased serum concentration of saquinavir. This is called synergistic boosting.

Metabolism occurs in the liver and is affected by the P-450 enzyme system; the isozyme CYP3A4 is responsible for about 90% of the initial biotransformation of saquinavir. The metabolites of saquinavir have not been identified and appear to play little part in antiviral activity. The serum half-life of saquinavir is 1 to 2 hours. Renal elimination of saquinavir is negligible; only 1% is excreted in urine, whereas 88% is excreted in feces.

Pharmacodynamics

Saquinavir is a competitive inhibitor of HIV protease, an enzyme required for HIV replication. During the later stages of the HIV growth cycle, integrated DNA is translated into polyproteins to become mature budding viral particles. Protease is responsible for packaging these polyproteins into mature virions. Virions produced without protease are immature, rendering the virus noninfectious. PIs also inhibit replication of HIV in the macrophages, which are major reservoirs of HIV.

Contraindications and Precautions

Saquinavir is contraindicated for patients with hypersensitivity to any of its components. The drug is not approved for use in infants, children, or adolescents younger than 16 years.

Saquinavir should be used with caution in patients with pre-existing hepatic dysfunction because the drug is largely metabolized by the liver. It should also be used cautiously

BOX 46.7 FOCUS ON RESEARCH

Lessening Lipoatrophy

Mest, D. R., & Humble, G. (2006). Safety and efficacy of poly-L-lactic acid injections in persons with HIV-associated lipoatrophy: The U.S. experience. *Dermatologic Surgery,* 32(11):1336–1345.

The Study

The researchers evaluated the quantifiable improvement in HIV-infected patients with facial wasting (lipoatrophy) after serial injections of poly-L-lactic acid (PLLA) as well as the long-term safety and durability of the material. Patients underwent up to six treatment sessions with injectable PLLA, and after completion of the treatment, they were followed for 12 months. Quantifiable improvement was evaluated by measuring the increase in total cutaneous thickness, using skin calipers. In addition, before-and-after photographs were taken, and patient-satisfaction questionnaires were completed throughout the study period.

Results showed a mean increase in skin thickness of 65.1% compared with baseline values. This correction was maintained throughout the 12-month follow-up period (68.8% at 6 months and 73% at 12 months). Patient satisfaction was 4.5/5 at the end of treatment and increased to 4.8/5 at 12 months. No serious adverse events were reported. The researchers concluded that PLLA is a safe and well-tolerated treatment option for HIV-associated lipoatrophy.

Nursing Implications

Advise patients of the safety and efficacy of the PLLA treatment. Be sensitive to the changes in appearance that HIV-infected patients who receive HAART may experience. Keep abreast of new treatments to boost the self-esteem of these patients. Advise the patient that PLLA injections may induce the appearance of small bumps under the skin in the treated area. Generally, these bumps are not visible, and they may be noticed only when pressing on the treated area. Advise the patient that other injection-related events at the site of injection, such as bleeding, tenderness, discomfort, redness, bruising, or swelling, may occur.

TABLE 46.7 Summary of Selected C Protease Inhibitors

Drug (Trade) Name	Route and Dosage Range	Pharmacokinetics	Special Considerations
P saquinavir mesylate (SQV, Invirase)	*Adult and adolescent:* PO, five 200-mg hard gel capsules PLUS 100 mg ritonavir 2×/d	*Onset:* Rapid *Duration:* 8 h $t_{1/2}$: 1–2 h	Administer within 2 h of a meal. Must be dosed with ritonavir.
amprenavir (APV, Agenerase)	*Adult and adolescent >13 y weighing >50 kg*: PO, 1,200 mg 2×/d *Adolescent and child 4–16 y weighing <50 kg*: PO, 20 mg/kg 2×/d or 15 mg/kg 3×/d Oral Solution *Adult and adolescent >13 y weighing >50 kg*: PO, 1,400 mg (93.3 mL) 2×/d *Child 4–16 y*: PO, 22.5 mg/kg 2×/d or 17 mg/kg 3×/d *Child <4 y*: Safe and effective dosage has not been established.	*Onset*: Rapid *Duration*: 8–12 h $t_{1/2}$: 7.1–10.6 h	No food restrictions, except high-fat meals Advise patient to avoid supplemental vitamin E.
atazanavir sulfate (ATV, Reyataz)	*Adult*: PO, Treatment-naive: Two 200-mg capsules once daily Treatment-experienced: Two 150-mg capsules PLUS one 100-mg ritonavir capsule once daily *Child*: Safe and effective dosage has not been established.	*Onset*: Rapid *Duration*: 24 h $t_{1/2}$: 7 h	Administer with food. Administer 2 h before or 1 h after Videx.
darunavir (Prezista)	*Adult*: PO, two 300-mg tablets PLUS one 100-mg ritonavir capsule 2 ×/d *Child*: Safe and effective dosage has not been established.	*Onset*: Slow *Duration*: Unknown $t_{1/2}$: 15 h	Administer with food.
fosamprenavir calcium (FPV, Lexiva)	*Adult*: PO, Treatment-naive patients without ritonavir: Two 700-mg tablets 2×/d Treatment-naive patients with ritonavir: Two 700-mg once daily with ritonavir 200 mg once daily Protease inhibitor–experienced patients: One 700-mg tablet with ritonavir 100 mg 2×/d *Child*: Safe and effective dosage has not been established.	*Onset*: Rapid *Duration*: 12–24 h $t_{1/2}$: 7.7 h	No food restrictions
indinavir sulfate (IDV, Crixivan)	*Adult and adolescent*: PO, two 400-mg capsules 3×/d *Child*: PO, 350–500 mg/m^2 q8h has been used; available data inadequate for optimal dosing in pediatric population	*Onset*: Rapid *Duration*: 8 h $t_{1/2}$: 1.5–2 h	Administer 1 h before or 2 h after a meal. May be taken with a light snack Advise the patient to drink at least 1.5 L of water daily. Administer 1 h apart from Videx.
nelfinavir mesylate (NFV, Viracept)	*Adult and adolescent*: PO, 750 mg 3×/d or 1,250 mg 2×/d *Child 2–13 y*: PO, 20–30 mg/kg (max: 750 mg/dose) 3×/d	*Onset*: Rapid *Duration*: 8 h $t_{1/2}$: 3.5–5 h	Administer with food.
ritonavir (RTV, Norvir)	*Adult and adolescent >16 y*: PO, six 100-mg tablets 2×/d *Adolescent and child 2–16 y*: PO, 400 mg/m^2, not to exceed 600 mg, 2×/d	*Onset*: Rapid *Duration*: 12 h $t_{1/2}$: 3–5 h	Mostly used for boosting other drugs Administer with food. Administer 2½ h before or after didanosine. Refrigeration recommended for the capsules
tipranavir (Aptivus)	*Adult*: PO, two 250-mg capsules PLUS two 100-mg ritonavir capsules 2×/d	*Onset*: slow *Duration*: Unknown $t_{1/2}$: 4.8–6 h	Administer with food.
Combination Drugs			
lopinavir/ritonavir (Kaletra)	*Adult and adolescent >45 kg*: PO, 533 mg lopinavir/133 mg ritonavir (4 capsules or 6.5 mL) 2×/d *Adult and adolescent >40 kg*: PO, 400 mg lopinavir/100 mg ritonavir (3 capsules or 5 mL) 2×/d	*Onset*: Rapid *Duration*: 12 h $t_{1/2}$: 5–6 h	No food restrictions Must be swallowed whole

in patients with elevated triglyceride or cholesterol levels because fat redistribution and hyperlipidemia are adverse effects associated with the use of PIs. Saquinavir is also used with caution in patients with diabetes because it causes hyperglycemia. Some patients with hemophilia type A or B have experienced bleeding episodes during saquinavir therapy. Although a direct causal relation has not been established, these patients should be monitored closely.

Saquinavir is a pregnancy category B drug.

Adverse Effects

The most common adverse effects of saquinavir are nausea, diarrhea, stomach discomfort, insomnia, and headache. As previously mentioned, the drug may induce hyperglycemia, resulting in loss of glycemic control in patients with diabetes. Prediabetic patients may need to start antidiabetic medications. Saquinavir is also associated with increased bone loss. Use of calcium and vitamin D supplements reduces the occurrence of osteopenia and osteoporosis.

HIV-positive patients with hemophilia (type A or B) may be at increased risk for bleeding. Episodes of spontaneous skin hematomas and hemarthrosis, in some cases requiring additional doses of factor VIII, have been reported.

As a class, PIs also have been associated with an unusual adverse reaction involving the deposition of fatty-like tissue at the base of the posterior neck ("buffalo hump") and the abdominal area ("protease paunch"). The syndrome is associated with peripheral lipodystrophy, central adiposity, female breast enlargement, hyperlipidemia, and insulin resistance. Although the long-term consequences of fat redistribution are unknown, substantial increases in triglycerides or cholesterol are of concern because of the possible association with cardiovascular events and pancreatitis.

Like other antiretroviral drugs, saquinavir may cause hepatotoxicity. The risk of this condition is highest in patients with pre-existing liver dysfunction and those with a history of hepatitis B or C.

Drug Interactions

Like nevirapine, saquinavir interacts with drugs that are metabolized by P-450 CYP3A4. Saquinavir inhibits the metabolism of many drugs, resulting in elevated serum levels of these drugs, and it can be inhibited by other drugs, resulting in elevated saquinavir levels. Conversely, saquinavir induces the metabolism of some drugs, and its metabolism is induced by several drugs. Table 46.8 presents these complex drug–drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for hypersensitivity to saquinavir. Also, assess for pre-existing hepatic dysfunction, diabetes mellitus, hyperlipidemia, or hemophilia. Patients receiving rifampin or rifabutin for TB should delay the use of saquinavir until rifampin or rifabutin has been deleted from the treatment regimen. Review the patient's current drug therapy for other drugs that may interact with saquinavir or have overlapping toxicities. Communicate positive findings to the prescriber.

Before therapy begins, perform a complete physical examination. Document the patient's baseline status because drug therapy may be discontinued or modified based on changes from baseline. Laboratory tests should include CBC, complete metabolic profile, liver function tests, lipid profile, CD4 cell count, and plasma HIV RNA measurement. Some health care providers may also request a bone density evaluation.

Life Span and Gender

Assess the patient for pregnancy or lactation. In female patients receiving HAART when they conceive, therapy should be continued throughout the pregnancy. If a patient is not receiving therapy when the conception occurs, the patient may consider delaying HAART until after 10 to 14 weeks of gestation. It is unknown whether saquinavir is excreted into breast milk. However, HIV-positive women are advised not to breast-feed, to avoid potential postnatal transmission to an infant who may not be infected.

Note the patient's age before administering saquinavir. Saquinavir has not been studied in patients younger than 16 years or older than 65 years.

Lifestyle, Diet, and Habits

Assess the patient's ability and willingness to adhere to drug therapy. Adherence to the saquinavir drug regimen is crucial. Viral load may increase dramatically when saquinavir is not taken as directed, and as with other anti-HIV drugs, resistance is more likely when drugs are taken inconsistently. The development of viral resistance to this PI may eliminate other drugs in this class from the therapeutic strategy for the patient, because cross-resistance to other PIs does occur. Vigorously discourage nonadherence and drug holidays.

Assess dietary habits. Because of the potential for hyperlipidemia, limit high-fat and high-cholesterol foods. Assess alcohol consumption because of the increased risk of hepatic injury. Advise the patient to refrain from taking saquinavir with grapefruit or pomegranate juice because they inhibit the metabolism of saquinavir. Assess the use of garlic because it may lower saquinavir levels.

As with other antiretroviral agents, discuss potential substance abuse with the patient. Explain how a healthy lifestyle complements pharmacotherapy of HIV infection.

Assess the patient's financial status. Refer patients with financial problems to the hospital or clinic social worker. Patients may qualify for medical assistance through county, state, or federal funds or receive their drugs from local health departments.

Environment

Saquinavir is administered most frequently in an outpatient setting. HIV infection is treated routinely with complicated polytherapy. Therefore, assess the patient's ability to understand complex instructions. It is important that the instructions be explicit—both spoken and written—concerning

TABLE 46.8 Agents That Interact with P Saquinavir

Interactants	Effect and Significance	Nursing Management
amiodarone	Saquinavir may inhibit metabolism of amiodarone.	Monitor for QT prolongation. Monitor for arrhythmias.
azole antifungal agents	Azole antifungal agents may inhibit metabolism of saquinavir.	Monitor for saquinavir toxicity.
benzodiazepines	Saquinavir may inhibit metabolism of benzodiazepines.	Monitor for sedation. Ensure safety. Monitor vital signs, especially respiratory rate.
carbamazepine	Coadministration of these drugs may increase serum concentration level of carbamazepine and decrease serum concentration level of saquinavir.	Monitor CBC. Monitor for rash, seizures, and hepatotoxicity. Monitor T-cell count and viral load. Monitor for opportunistic infections.
cimetidine	Saquinavir may inhibit first-pass metabolism of saquinavir.	Monitor for adverse effects or toxicity of saquinavir.
clarithromycin	Coadministration of these drugs may increase serum concentration of saquinavir and decrease serum concentration of clarithromycin.	Monitor for increased adverse effect or toxicity of saquinavir. Monitor for treatment failure of clarithromycin.
cyclosporine	Coadministration of these drugs may increase serum concentration levels of both cyclosporine and saquinavir.	Monitor for adverse effects of both drugs.
diltiazem	Saquinavir may inhibit metabolism of diltiazem.	Monitor for arrhythmias, bradycardia, hypotension, and CHF.
ergot derivatives	Saquinavir may inhibit metabolism of ergot derivatives.	Verify order with health care provider because coadministration is contraindicated.
felodipine	Saquinavir may inhibit metabolism of felodipine.	Monitor for edema. Monitor for orthostatic hypotension.
fentanyl	Saquinavir may inhibit metabolism of fentanyl.	Monitor for sedation. Ensure safety. Monitor vital signs, especially respiratory rate.
HMG-CoA reductase inhibitors	Saquinavir may inhibit metabolism of HMG-CoA reductase inhibitors.	Monitor for rhabdomyolysis. Monitor for myalgias.
levothyroxine	Saquinavir may inhibit metabolism of levothyroxine.	Monitor for signs of hyperthyroidism.
methadone	Saquinavir may inhibit metabolism of methadone.	Monitor for pain relief. Monitor for opiate withdrawal.
ranolazine	Saquinavir may inhibit metabolism of ranolazine.	Verify order with health care provider because coadministration is contraindicated.
pimozide	Saquinavir may inhibit metabolism of pimozide.	Verify order with health care provider because coadministration is contraindicated. Monitor for life-threatening arrhythmias.
rifamycins	Coadministration of these drugs may increase serum concentration level of rifamycins and decrease serum concentration level of saquinavir.	Monitor for adverse effects and toxicity of rifamycins. Monitor for decreased efficacy of saquinavir.
risperidone	Saquinavir may inhibit metabolism of risperidone.	Monitor for decreased LOC, lethargy, ataxia.
sildenafil	Saquinavir may inhibit metabolism of sildenafil.	Monitor for severe hypotension. Monitor for cardiac arrhythmias. Ensure safety.

(*Continued*)

TABLE 46.8 Agents That Interact with P Saquinavir *(continued)*

Interactants	Effect and Significance	Nursing Management
tacrolimus	Saquinavir may inhibit metabolism of tacrolimus.	Monitor renal function. Monitor tacrolimus levels. Discuss dosage adjustment with health care provider.
trazodone	Saquinavir may inhibit metabolism of trazodone.	Monitor for nausea, dizziness, hypotension.
St. John's wort	St. John's wort induces metabolism of saquinavir, resulting in decreased efficacy.	Monitor for opportunistic infections. Advise patient to refrain from use of St. John's wort.
warfarin	Saquinavir may inhibit metabolism of warfarin.	Monitor PT and INR. Monitor for signs of bleeding or bruising.

which drug to take at which time of the day. Saquinavir tablets and capsules should be stored at room temperature.

Nursing Diagnoses and Outcomes

- Acute Pain related to headache from adverse drug effect
  Desired outcome: *The patient will self-medicate with analgesics such as acetaminophen.*
- Imbalanced Nutrition: Less than Body Requirements, related to GI distress
  Desired outcome: *The patient will maintain body weight and report any persistent symptoms affecting nutritional status to the prescriber.*
- Disturbed Thought Processes related to adverse CNS effects
  Desired outcome: *The patient will remain oriented and able to communicate effectively with others.*
- Diarrhea related to adverse GI effects
  Desired outcome: *The patient will avoid dehydration and report persistent diarrhea to the prescriber.*
- Risk for injury related to hepatotoxicity.
  Desired outcome: *The patient will recognize the symptoms of hepatotoxicity and contact the health care provider immediately.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer saquinavir tablets or capsules within 2 hours after eating a full meal. Administer ritonavir with each dose of saquinavir.

Minimizing Adverse Effects

Give small, frequent meals if GI distress is problematic. Administer acetaminophen for complaints of headache. Encourage a regular exercise program to offset fat redistribution. Encourage a low-fat, low-cholesterol diet.

Providing Patient and Family Education

- Emphasize that saquinavir does not cure HIV. Encourage the patient to take precautions to avoid exposing others to blood and body fluids and the use of latex condoms during sex.
- Explain the importance of adherence to drug therapy. As previously mentioned, it is important to make sure that the instructions are clear and in writing.
- Explain the importance of periodic clinical and blood monitoring to ensure the efficacy of therapy and to monitor for possible adverse effects.
- Advise patients about potential adverse effects. Also, explain that adverse effects, such as GI distress or headache, may spontaneously resolve after 3 to 4 weeks of therapy. Tell patients that persistent problems should be reported to the prescriber.
- Teach patients the signs and symptoms of diabetes. Question patients about polyuria, polydipsia, and polyphagia at each visit. Monitor patients' weight. Advise patients with diabetes to monitor blood glucose frequently.
- Teach patients the signs of hepatotoxicity. Advise patients to contact the health care provider if symptoms such as yellowing of the skin or eyes, nausea, abdominal pain or discomfort, unusual bleeding/bruising, or severe fatigue occur.
- Teach patients with hemophilia to monitor for bleeding, especially in joints.
- Instruct patients to advise the prescriber if any other drugs are ordered by another prescriber. Explain that many drugs may alter the way saquinavir works and that other drugs may increase the risk of adverse effects from saquinavir therapy.
- Instruct patients to use over-the-counter antidiarrheal agents if diarrhea occurs. If diarrhea is persistent, patients should contact the prescriber.
- Instruct patients to develop good eating habits and an exercise plan that decreases the risks associated with fat redeposition. Teach patients about foods that are rich in calcium and vitamin D and low in fat and cholesterol.

Ongoing Assessment and Evaluation

Patients who take saquinavir should have periodic examinations and blood monitoring, which are important to assess for potential progression of the disease, treatment failure, or the emergence of drug resistance or an adverse reaction to the therapy. CD4 cell counts and HIV RNA load should be assessed every 3 months. The patient should have a stable CD4 count and a declining or undetectable HIV RNA load. In addition, the patient should have a stable lipid

MEMORY CHIP

P Saquinavir

- Used for the management of HIV infection and AIDS
- Major contraindications: hypersensitivity, age less than 16 years
- Most common adverse effects: diarrhea, abdominal discomfort, and nausea and vomiting
- Most serious adverse effects: cardiovascular events and pancreatitis resulting from fat redistribution
- Maximizing therapeutic effects: Administer within 2 hours of a high-fat, high-calorie meal.
- Minimizing adverse effects: small, frequent meals to decrease GI distress
- Most important patient education: Refrain from taking any medication that is not prescribed by the health care provider treating the patient for HIV infection.

panel. Monitor for the need to change pharmacotherapy. The patient should be free of opportunistic infections and adverse effects associated with saquinavir.

Monitor patients with hemophilia for signs of bleeding and for clinical signs, particularly those evident in laboratory test results, if necessary. It also is important to monitor patients for hepatic dysfunction. For patients with pre-existing hepatic disorders, monitor liver function test results.

Evaluate the patient for fat redistribution and hypertriglyceridemia or hypercholesterolemia. If these adverse effects occur, check for cardiovascular events and pancreatitis. Potential interventions include dietary modifications or discontinuation of PIs.

Obtain periodic hemoglobin A1C tests in patients with diabetes, and monitor other patients for signs of diabetes. Coordinate periodic bone density testing.

Drugs Closely Related to P Saquinavir

Atazanavir (Reyataz)

Atazanavir is a new PI for treating HIV infection. As a new drug, it has similarities to and differences from other PIs. Like other PIs, it should be used in combination with other antiretroviral drugs.

Atazanavir differs from other PIs in three ways: it is the first drug in its class to be given once daily and this low pill burden may strongly and positively affect compliance; it does not appear to have a substantial adverse effect on lipoprotein concentrations such as low density lipoprotein, triglycerides, total cholesterol, and may positively affect patients with high cardiovascular risk and or problems with lipodystrophy; and it has a unique chemical structure that alters its resistance profile. If the patient's virus is resistant to other PIs, the virus may also be resistant to atazanavir. However, when resistance develops initially to atazanavir, the resistance may or may not be conferred to other PIs.

Atazanavir should be taken orally with a low-calorie, low-fat snack or meal to enhance absorption. Atazanavir requires an acidic gastric pH for dissolution. Proton pump inhibitors, H2 antagonists, or antacids may impair its absorption. Do not administer those drugs within 2 hours of atazanavir. Monitor for efficacy of atazanavir when the patient is receiving any drug that alters gastric pH.

The most common adverse effects of atazanavir are rash, nausea, diarrhea, vomiting, headache, and abdominal pain. It may also increase bilirubin levels, resulting in jaundice. An elevation of indirect bilirubin signals a medication associated abnormality and is inconsequential; on the other hand, an elevation of direct bilirubin infers a liver injury.

Atazanavir has been associated with prolonging the PR interval, resulting in asymptomatic first-degree heart block. It should be used with caution in patients with pre-existing rhythm disturbances and in patients receiving other medications that cause PR-interval prolongation such as atenolol or diltiazem.

Drug–drug interactions of atazanavir are similar to those of saquinavir. Specific drug classes that should be avoided without the approval of the prescriber include PIs, antimigraine medications, antidysrhythmics, and antipsychotics

Atazanavir is not approved for children younger than 16 years. It is a pregnancy category B drug, and recommendations for its use during pregnancy are the same as those for saquinavir.

Darunavir

Darunavir (Prezista) is a PI approved for use in treatment-experienced patients such as those with HIV-1 infection that has been resistant to more than one PI. The risks and benefits of darunavir have not been studied in treatment-naive or pediatric patients. Because darunavir is used in patients who have already experienced resistance to other PIs, genotypic or phenotypic studies are recommended prior to use. Like saquinavir, darunavir must be administered with ritonavir and food. Administration with food increases the bioavailability by approximately 30%.

Darunavir contains a sulfonamide moiety and cannot be used in patients with a sulfa allergy. It is contraindicated in patients taking ergot derivative, pimozide, and the benzodiazepines midazolam and triazolam because of potentially fatal drug–drug interactions. Darunavir should not be taken by patients who take antiepileptics, rifampin, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, or St. John's wort, although the interactions are not potentially fatal. The most common adverse effects are diarrhea or constipation, abdominal pain, and vomiting. Other drug–drug interactions, precautions, and adverse effects are similar to those with saquinavir. Darunavir is a pregnancy category B drug.

Fosamprenavir

Fosamprenavir (Lexiva) is a prodrug of amprenavir, the active metabolite. Fosamprenavir is metabolized by P-450 3A4 isoenzyme and as such may alter the concentrations of other drugs metabolized by this pathway, including rifapentine or rifampin, oral contraceptives, ergot derivates, astemizole, bepridil, simvastatin or lovastatin, pimozide, and midazolam or triazolam. Review the mediation administration record

(MAR) for these drugs and notify the primary provider immediately if other providers order any of these medications. Fosamprenavir should be used with caution in patients with sulfonamide allergy. Since fosamprenavir is metabolized by the liver, monitor patients with hepatic impairment closely. Common adverse effects include rash, appetite loss, headaches, malaise, diarrhea, nausea, and vomiting. Additional adverse effects include numbness/tingling around the mouth (perioral paresthesias). Very often, these adverse effects improve within a few months/weeks of starting fosamprenavir. Fosamprenavir may increase triglycerides. Assess cholesterol, and triglyceride levels prior to initiation of therapy and periodically throughout therapy.

Fosamprenavir is taken twice a day in combination with ritonavir by patients who have previous experience with PIs. It may be taken once daily by PI-naive patients. Fosamprenavir may be taken with or without food. Fosamprenavir is not approved for children younger than 18 years. It is a pregnancy category C drug; recommendations for it use during pregnancy are the same as those for saquinavir.

Indinavir

Indinavir (Crixivan) is another oral PI indicated for treating HIV infection. When indinavir is the only PI in the HAART cocktail, it is given three times a day. It can be given twice a day if given with other PI drugs. It should be taken on an empty stomach for best absorption.

Indinavir may induce serious adverse effects such as kidney stones, elevated liver enzymes, and worsening of preexisting thrombocytopenia. To decrease the potential for kidney stones, instruct the patient to drink at least 1 to 2 L of water a day especially during hot days or episodes of diarrhea. Patients with pre-existing hepatic dysfunction or thrombocytopenia should be monitored closely, and appropriate laboratory testing should be scheduled regularly.

Self-limiting common adverse effects include nausea, headache, fatigue, abdominal pain, vomiting, rash, and dry skin. Other potential adverse effects include paronychia, severely dry skin, or cracked lips.

Drug–drug interactions are similar to those for saquinavir. Drugs to be avoided include rifamycins, benzodiazepines, ergotamines, and drugs for erectile dysfunction. Additionally, instruct the patient to avoid St. John's wort, garlic, and high doses of vitamin C.

Indinavir is not approved for children. It is a pregnancy category C drug; recommendations for its use during pregnancy are the same as those for saquinavir.

Nelfinavir

Nelfinavir (Viracept) is another oral PI. One benefit of Viracept is that resistance that develops to nelfinavir does not always confer resistance to other PIs. Nelfinavir is taken twice daily with a large snack or meal.

The major adverse effect of nelfinavir is diarrhea, which may be controlled with loperamide or other antidiarrheals. Other interventions for nelfinavir-induced diarrhea include twice-daily calcium tablets, probiotics such as yogurt, and soluble fiber supplements. Nelfinavir also is associated with elevations in ALT, aspartate aminotransferase, and CPK levels.

Drug interactions are similar to those with saquinavir.

Nelfinavir is approved for use in children. It is a pregnancy category B drug, and recommendations for its use during pregnancy are the same as those for saquinavir.

Ritonavir

Ritonavir (RTV, Norvir) is an oral PI used to treat HIV infection. It is available as a capsule or oral suspension. It is formulated with lopinavir as Kaletra as fixed combination medication. Low-dose ritonavir is frequently prescribed in combination with another PI to "boost" the anti-HIV effect of the other PI. Ritonavir is the only PI approved for this "boosting" effect. At a full dose, and lone PI, ritonavir is not recommended because of its persistent and long-term adverse effects.

Taking ritonavir within 2 hours of a meal increases its absorption and decreases nausea. Patient management for this PI is similar to that for saquinavir.

Adverse effects are most likely to occur at the beginning of therapy and affect women more frequently than they affect men. They include headache, nausea, vomiting, diarrhea, and tingling or numbness around the mouth. Ritonavir may induce kidney failure in patients with pre-existing renal dysfunction or patients taking nephrotoxic drugs. A Black Box warning concerns coadministration of ritonavir with certain nonsedating antihistamines, sedative hypnotics, antidysrhythmics, and ergot derivatives; serious or life-threatening drug-drug interactions may occur because of its inhibition of P-450 CYP3A and CYP2D6 as well as inducer of other hepatic enzymes.

Ritonavir is available as an oral solution; however, it has a very bitter taste. It may be combined with chocolate milk or Ensure to mask its taste, as long as it is given within 1 hour of mixing. Ritonavir solution is kept at room temperature, but the oral capsules should be kept refrigerated.

Ritonavir is approved for use in children older than 2 years. It is a pregnancy category B drug.

Tipranavir

Tipranavir (Aptivus) is another PI indicated for use in treatment-experienced patients or with patients with HIV-1 infections that are resistant to multiple PIs. All current PIs are theoretically less able to adapt their shape to inhibit protease with minor structural changes, which is the hallmark of mutations. Aptivus is structurally different and as such is more amenable to alterations in these binding site. This flexibility at the binding site is the reason it is thought to be effective against multiple PI resistant viruses. It is not recommended on treatment naïve patients because of insufficient data.

Genotypic or phenotypic testing is recommended prior to treatment. Like darunavir, it is administered with ritonavir and food to increase its efficacy. Patient management for tipranavir is similar to that for saquinavir.

Tipranavir contains a sulfonamide moiety and cannot be used in patients with a sulfa allergy. It is contraindicated

for patients with moderate to severe hepatic insufficiency as well as for patients who take amiodarone, flecainide, propafenone, quinidine, ergot derivatives, pimozide, midazolam, and triazolam because of the risk of life-threatening drug–drug interactions. Tipranavir decreases platelet aggregation. It is given cautiously to patients who are at risk for bleeding from trauma, surgery, or other medical conditions, or those taking drugs known to decrease platelet aggregation such as antiplatelets or anticoagulants The most common adverse effects involve the GI system and include nausea, vomiting, and diarrhea. Also, tipranavir may elevate cholesterol and triglycerides. Assess baseline lipid parameters prior to administration and intermittently throughout therapy.

Tipranavir has two Black Box warnings related to the drug's association with the following:

- Intracranial hemorrhage (fatal and nonfatal) when given in combination with ritonavir
- Clinical hepatitis and hepatic decompensation, including some fatalities, when given in combination with ritonavir. Extra vigilance is warranted in patients with chronic hepatitis B or C coinfection, because these patients have an increased risk of hepatotoxicity.

Other drug–drug interactions, precautions, and adverse effects are similar to those for saquinavir. Tipranavir is a pregnancy category C drug. It should be used during pregnancy only if the benefits outweigh the risks of therapy.

Lopinavir/Ritonavir

Lopinavir/ritonavir (Kaletra) is a relatively new PI for adults and children 6 months and older. It is available in tablet and oral liquid formulations. The tablet may be taken with or without food.

One of the most important attributes of this drug combination is its potency. Because of the addition of ritonavir, lopinavir reaches high serum levels.

Lopinavir/ritonavir is contraindicated in patients who have hypersensitivity to either component and in patients with polyoxyethylated castor oil hypersensitivity. The medication should be given cautiously to patients with pre-existing hepatic disease because it is associated with the development of hepatic dysfunction. The most common adverse effects reported are diarrhea, shortness of breath, nausea, abdominal pain, headache, and vomiting.

Lopinavir/ritonavir can cause multiple drug–drug interactions, which are similar to those of saquinavir. Because ritonavir suppresses a liver enzyme used to break down dozens of drugs, it may boost the blood levels of street drugs such as Ecstasy (3,4-methylenedioxymethamphetamine [MDMA]) or heroin.

The DHHS 2008 Guideline recommends lopinavir/ritonavir as a preferred option of a PI based initial HAART.

It is a pregnancy category C drug, and recommendations for its use during pregnancy are the same as those for saquinavir. The once a day lopinavir/ritonavir combination is not recommended during pregnancy because of lower drug exposure during pregnancy and may need increase dose in third trimester of pregnancy.

INTEGRASE INHIBITORS

The integrase inhibitor raltegravir (Isentress) is the prototype for the newest class HAART therapy approved for the management of HIV disease. The enzyme integrase is a key component that allows the converted HIV viral DNA to enter the host cell DNA to begin producing genetic material for new viruses and raltegravir is the first of its kind to block or inhibit this very crucial step. Table 46.9 presents an overview of raltegravir.

Nursing Management of the Patient Receiving P Raltegravir

Core Drug Knowledge

Pharmacotherapeutics

Raltegravir is approved for use as part of combination HAART for patients with HIV strains that are resistant to multiple antiretroviral regimens and experiencing ongoing viral replication while receiving HAART. In July, 2009, raltegravir received approval for use in treatment naïve adult patients.

Pharmacokinetics

Raltegravir has a half life of approximately 9 hours. It is primarily metabolized in the liver and excreted out of the body by way of feces and urine. It does not require a dose adjustment for gender, renal impairment, or mild to moderate liver impairment.

Pharmacodynamics

Raltegravir is a HIV virus integrase strand transfer inhibitor. By blocking the integrase enzyme the reverse transcribed HIV DNA cannot enter into to the host CD4 cell chromosomes. When this integration does not take place the replication process is disrupted, thus the viral life cycle is not completed and viral replication is terminated

Contraindications and Precautions

There are no known contraindications for raltegravir. It is used cautiously in patients receiving other medications that can cause muscle problems, such as lipid-lowering agents, due to the increased risk for myopathy and rhabdomyolysis.

TABLE 46.9 Overview of P Raltegravir

Drug	Route and Dosage Range	Pharmacokinetics	Special Considerations
P raltegravir (RAL, Isentress)	*Adult* PO: 400 mg 2×/d	*Onset*: rapid *Duration*: unknown *T ½*: 9 h	No food restrictions Do not administer as monotherapy

Adverse Effects

Common adverse effects include diarrhea, nausea, abdominal distension and pain, flatulence, headache, and fatigue. Serious adverse effects include Stevens-Johnson syndrome, depression, and suicidal tendencies. Rarely, elevated liver enzyme levels and pancreatic amylase have occurred. Also, abnormal elevation in muscle enzymes has been observed. Raltegravir is a pregnancy class C.

Drug Interactions

Raltegravir interacts with many of the HAART medications with either an increase or decrease in serum raltegravir levels. However, only tipranavir requires a dose adjustment. In addition, there are substantial interactions with rifampin and proton pump inhibitors. Table 46.10 presents these interactions.

Assessment of Relevant Core Patient Variables

Health Status

Raltegravir initially received approval for treatment experience patients. It is also now approved as an earlier treatment option for treatment naïve patients.

Life Span and Gender

Assess the patient for pregnancy and breast feeding. Raltegravir is a Class C drug and there are no well controlled clinical studies conducted among pregnant patients. As such, raltegravir should only be used if the potential benefits of the medication outweigh the potential risk to the fetus. Clinical studies of raltegravir have not included sufficient numbers of patients aged 65 and over to see how they respond to therapy compared to the younger subjects. Monitor the elderly carefully due to decreased renal, liver, cardiac output, and concomitant disease and other drug therapy found among the older patients.

Lifestyle, Diet, and Habits

Raltegravir can be given with or without food. Like other antiretroviral drugs, instruct the patient that it does not prevent or cure HIV and AIDS. Explain the importance of practicing safe sex with latex condom barriers and abstention from a risky lifestyle.

Environment

Assess the patient for apprehensiveness regarding introduction of a new class of drugs such as raltegravir. The lack of familiarity and paucity of post approval information related to a new drug and new class of drugs maybe disconcerting and intimidating for the patient. Similarly, adverse effects of the medication gathered through the clinical trial phase of the drug may bring apprehensiveness on the part of the patient. A discussion of the benefit-risk of the medication is important.

Nursing Diagnoses and Outcomes

- Nursing Diagnosis: Imbalanced Nutrition: Less than Body Requirements, related to GI distress
  Desired Outcome:
  The patient will self medicate with over the counter remedies to control transient GI symptoms and will contact the provider for persistent GI complaints.
- Nursing Diagnosis: Acute Pain related to headache from drug effects
  Desired Outcome:
  The patient will self medicate with over-the-counter remedies such as nonsteroidal anti-inflammatory drugs (NSAIDS), and or practice non-pharmacological pain relief to alleviate the headache.

Planning and Intervention

Maximizing Therapeutic Effects

Administer raltegravir with or without food. Offer small frequent meals for patients with GI distress. Ensure that raltegravir is administered twice daily. Ensure raltegravir is not used as monotherapy.

Minimizing Adverse Effects

Monitor patients receiving other drugs that are strong inducers of uridine diphosphate glucuronosyltransferase, such as rifampin, for treatment failure.

Providing Patient and Family Education

- Emphasize that zidovudine does not cure HIV. Encourage the patient to take precautions to avoid exposing others to blood and body fluids and the use of latex condoms during sex.
- Instruct patient when a missed dose occur to take it as soon as he/she remembers it, and if not remembered it until the next dose, to skip the dose and take it at the next scheduled dose.
- Explain the importance of consistent use of raltegravir to avoid potential resistance to the drug.

TABLE 46.10 Agents that Interact with P Raltegravir

Interactants	Effect and Significance	Nursing Management
Proton Pump Inhibitors (PPI)	PPI drugs decrease the metabolism of raltegravir resulting in an increased serum concentration and increased risk for raltegravir toxicity.	Monitor for raltegravir toxicity.
Rifampin	Rifampin increases the metabolism of raltegravir resulting in subtherapeutic serum concentration.	Verify order with provider: generally not given together. Monitor for efficacy of raltegravir.

MEMORY CHIP

P Raltegrvir

- Used for the management of HIV infection and AIDS
- Major contraindication: none
- Most common adverse effects: GI distress, headache, fatigue
- Most serious adverse effect: Depression, suicide ideation
- Maximizing therapeutic effect: Offer small frequent meals if GI distress present
- Minimizing adverse effects: Monitor for drug–drug interactions
- Most important patient education: Advise women of childbearing age to contact provider immediately should pregnancy occur

- Instruct the patient to use OTC medications for common adverse effects such as headache or diarrhea and small, frequent meals for GI complaints. Encourage the patient to advise the provider if these symptoms are severe and persistent.
- Instruct women of child-bearing age to advise the provider immediately should she become pregnant.

Ongoing Assessment and Evaluation

Coordinate periodic examinations and blood monitoring in patients receiving raltegravir to assess for potential progression of HIV disease, treatment failure, the emergence of resistance, or development of adverse effects. CD4 cell counts and HIV RNA should be assessed every 3 months. Monitor for the need to change pharmacotherapy. Monitor for opportunistic diseases such as *Pneumocystis jiroveci*, mycobacterium avium complex, or varicella zoster. The patient should have a stable CD4 cell count and a declining or undetectable HIV RNA count throughout therapy.

C ENTRY INHIBITORS

Entry inhibitors are also known as **fusion inhibitors.** Before enfuvirtide's approval, anti-HIV drugs affected the virus inside the infected cell. This class of drugs inhibits HIV from binding to, fusing with, and entering the human cell by binding with a region of HIV envelope glycoprotein gp41 and preventing the viral fusing with the target cell membrane. The prototype fusion inhibitor is enfuvirtide (Fuzeon). Table 46.11 presents a summary of selected entry inhibitors.

Nursing Management of the Patient Receiving P Enfuvirtide

Core Drug Knowledge

Pharmacotherapeutics

Enfuvirtide is approved for managing HIV infection in patients who have experienced treatment failure with drugs from each existing class of antiretrovirals or who have proved unable to tolerate previous antiretroviral regimens. It is not recommended for initial treatment protocols. Enfuvirtide is expensive ($20,000 a year), hard to manufacture, and the complexity of its administration will likely reserve it as part of **salvage therapy** (a treatment for people who are nonresponsive to or cannot tolerate other available therapies).

Pharmacokinetics

Enfuvirtide is a subcutaneous injection that must be reconstituted prior to administration. It can be injected into the arms, upper thigh, or abdomen and reaches plasma concentration within 8 hours. Enfuvirtide is not excreted; it is catabolized by tissue recycling of amino acids.

Pharmacodynamics

Enfuvirtide binds to the gp41 protein on the surface of HIV. This protein is considered to be the "key" used by HIV to bind onto and enter cells. By blocking gp41, enfuvirtide blocks the HIV from entering the cell. Unfortunately, resistance to enfuvirtide has emerged. Resistance to enfuvirtide does not induce resistance to NRTIs, NNRTIs, or PIs. Conversely, resistance to NRTIs, NNRTIs, or PIs does not induce resistance to enfuvirtide.

Contraindications and Precautions

Enfuvirtide should not be used in patients with hypersensitivity to any of its components, including mannitol. Enfuvirtide is associated with the development of bacterial

TABLE 46.11 Summary of Selected Entry Inhibitors

Drug	Route and Dosage Range	Pharmacokinetics	Special Considerations
P enfuvirtide (ENF, Fuzeon, T-20)	*Adult and Child > 16y* SQ: 90 mg 2×/d *Child 6–16 y* SQ: 2 mg/kg 2×/d maximum dose 90 mg 2×/d Child < 6 y: not approved	*Onset*: slow *Duration*: unknown $t_{1/2}$: 3.2–4.4 h	Assess for lung disease and pregnancy. Advise provider if positive. Rotate sites regularly. Use reconstituted drug within 24 h.
maraviroc (Selzentry)	*Adult PO*: 150–600 mg 2x/d *Child*: not approved	*Onset*: slow *Duration*: unknown $t_{1/2}$: 14–18 h	No food restrictions Monitor for rash, eosinophilia, and elevated IgE levels and hepatotoxicity Monitor for reactivation of previous opportunistic infections

pneumonia; thus, it should be used with caution in patients with risk factors that predispose them to infection. Such risk factors include pre-existing pulmonary dysfunction, smoking, or use of IV drugs; patients with low CD4 or high viral load counts are also predisposed to infection.

Enfuvirtide is a pregnancy category B drug.

Adverse Effects

The major adverse effect of enfuvirtide is injection-site reaction but they are normally mild and do not require discontinuation of the therapy. This reaction occurs in 95% of the patients using enfuvirtide. Reactions include itchy rash and red, swollen, puffy, or hardened skin. Patients using the thigh for injection are more likely than others to have cysts or nodules form.

In addition to injection site reactions, enfuvirtide may induce anorexia, nausea, weight loss, fatigue, anxiety, headache, insomnia, peripheral neuropathy, and infections such as sinusitis, herpes simplex, influenza, and conjunctivitis. Patients receiving enfuvirtide are more likely than others to acquire bacterial pneumonia and lymphadenopathy, although a direct correlation with the drug has not yet been established.

Drug Interactions

Drug–drug interactions have not yet been identified. Patients may take rifamycins safely with enfuvirtide.

Assessment of Relevant Core Patient Variables

Health Status

Review the patient's HIV history and treatment plan carefully. Evaluate the patient's potential for adherence with self-administration of a subcutaneous medication and for the ability to follow aseptic guidelines. Assess the patient's dexterity and vision. Filling the syringe and looking for viable injection sites requires coordinated hand and eye effort.

Life Span and Gender

Assess the patient for pregnancy or lactation; as previously stated, enfuvirtide is a pregnancy category B drug. In female patients receiving HAART when they conceive, therapy should be continued throughout the pregnancy. If a patient is not receiving therapy when the conception occurs, the patient may consider delaying HAART until after 10 to 12 weeks of gestation. It is unknown whether enfuvirtide is excreted into breast milk. However, HIV-positive women are advised not to breast-feed, to avoid potential postnatal transmission to an infant who may not be infected.

Note the patient's age before administering enfuvirtide because this drug is not approved for patients younger than 6 years.

Lifestyle, Diet, and Habits

Teach the patient to avoid risk factors that predispose them to infection. Such factors include smoking and IV drug use. Instruct the patient to eat a healthy diet to optimize immune system function.

Be aware of the patient's economic status. The cost of enfuvirtide is prohibitive. In fact, it is so expensive that not all insurers have added enfuvirtide to their formularies. Also, complex manufacturing of the drug may not insure a steady uninterrupted supply.

Environment

Enfuvirtide is most frequently self-administered by the patient at home. Enfuvirtide powder is stored at room temperature. Once the drug is reconstituted, it should remain in the vial, not the syringe, and should be refrigerated. Advise the patient to remove the refrigerated solution and allow it to return to room temperature before administration.

Nursing Diagnoses and Outcomes

- Pain related to injection site reactions and headache
  Desired outcome: *The patient will self-medicate with analgesics such as acetaminophen.*
- Risk for Infection related to drug adverse effect
  Desired outcome: *The patient will recognize symptoms associated with infections such as pneumonia, sinusitis, herpes simplex, influenza, and conjunctivitis and will contact the prescriber immediately for appropriate intervention.*
- Imbalanced Nutrition: Less than Body Requirements, related to anorexia and nausea
  Desired outcome: *The patient will maintain optimal body weight and nutrition throughout therapy.*
- Risk for Injury related to insomnia and peripheral neuropathy
  Desired outcome: *The patient will remain injury free throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Reconstitute the enfuvirtide with sterile water, and then allow the solution to sit until the powder dissolves completely, which may be as much as 45 minutes. When two doses of medication are prepared from the vial, the second dose should be refrigerated in the vial, not in a syringe. After adding the dilutent, tap the vial for several seconds and then roll between hands to allow for full absorption.

Administer subcutaneous enfuvirtide at 12-hour intervals. Rotate the site of administration to optimize absorption. Avoid injecting into the umbilicus, moles, scars, bruises, or areas that could be irritated by a belt or waistband, or areas experiencing an injection-site reaction.

Minimizing Adverse Effects

Use aseptic technique when reconstituting or administering enfuvirtide. Monitor the patient for early signs of infection in areas of skin where an injection site reaction occurs. Also, monitor for signs of systemic infections, such as sinusitis or pneumonia.

Providing Patient and Family Education

- Emphasize that enfuvirtide does not cure HIV. Encourage the patient to take precautions to avoid exposing others

to blood and body fluids and the use of latex condoms during sex.
- Emphasize the importance of aseptic technique when reconstituting and administering enfuvirtide.
- Teach patients and families how to use the enfuvirtide convenience pack correctly. Be sure to explain the different types of syringes (the 3-mL syringe is used to reconstitute the powder, and the 1-mL syringe is used to administer the solution).
- Explain how to inject air into the vial in order to withdraw the solution.
- Teach patients to read the barrel of the syringe (to measure 1.1 mL of solution for administration) accurately.
- Teach patients the correct areas of the body for subcutaneous injection of enfuvirtide (upper arms, upper thigh, and abdomen).
- Teach patients to avoid injecting into the umbilicus, moles, scars, bruises, or areas that could be irritated by a belt or waistband, or areas of skin where an injection site reaction has occurred.
- Explain the potential for injection-site reactions and the need to rotate the injection site to ensure appropriate drug absorption.
- Teach patients healthy lifestyle choices to decrease the potential for infections, especially the need to avoid recreational drugs and tobacco products.
- Teach patients the signs of infection and advise them to contact the prescriber if such signs occur.

Ongoing Assessment and Evaluation

Assess the patient taking enfuvirtide for signs of infectious disorders such as pneumonia, sinusitis, herpes simplex, influenza, and conjunctivitis. Assess for anorexia, nausea, weight loss, fatigue, anxiety, headache, insomnia, and peripheral neuropathy.

Monitor for the need to change pharmacotherapy. It is important to remember that changes in therapy may have to be based on blood analysis because the patient may remain asymptomatic.

MEMORY CHIP

P Enfuvirtide

- Used for the management of HIV infection and AIDS
- Major contraindication: hypersensitivity
- Most common adverse effects: injection-site reactions
- Most serious adverse effect: bacterial pneumonia
- Maximizing therapeutic effect: Rotate injection sites to increase absorption.
- Minimizing adverse effects: Use aseptic technique to administer subcutaneous injection.
- Most important patient education: Teach to reconstitute and administer subcutaneous injections.

The patient should have a stable CD4 count and a declining or undetectable HIV RNA load throughout therapy. The patient should be free of opportunistic infections.

Drugs Significantly Different Than Enfuvirtide

CCR5 Inhibitors

Maraviroc (Selzentry) is a new type of oral entry inhibitor approved by the FDA in 2008. In HIV replication, a protein on the virus (gp120) attaches to a primary receptor which in turn allows binding to a co-receptor, resulting in viral entry into the cell. Only two co-receptor variants, known as CCR5 and CXCR4, are used by all HIV strains. Most viruses predominantly use the CCR5 co-receptor, especially in treatment-naive patients. Maraviroc blocks the CCR5 co-receptor. Once it does this, HIV cannot successfully bind with the surface of CD4 cells, thus preventing the virus from infecting healthy cells. Maraviroc exclusively targets CCR5 co-receptor. It does not work on CCR4 receptors, or dual CCR4/CCR5 tropism. It is hypothesized that blocking the CCR5 co-receptor might stimulate a conversion to HIV that uses the alternative CXCR4 co-receptor. In addition to causing resistance to maraviroc, this may be linked to more rapid disease progression. Ideally, assays should be able to detect coreceptor tropism before maraviroc is used. However, current test are not yet available. Maraviroc is a substrate of CYP3A and P-glycoprotein (Pgp). The recommended dose is 300 mg twice daily; however, the dose must be adjusted for patients receiving other CYP3A inducers or inhibitors. Patients receiving CYP3A inhibitors (PIs, delavirdine, ketoconazole, itraconazole, and clarithromycin) require a lower dose. Patients receiving CYP3A inducers (efavirenz, rifampin, carbamazepine, phenobarbital, and phenytoin) require a higher dose because the faster clearance will result in subtherapeutic levels of maraviroc.

Common adverse effects include cough, pyrexia, upper respiratory infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness. There is a black box warning regarding the risk for hepatoxicity, which may be preceded by symptoms of a systemic allergic reaction such as rash, eosinophilia, and elevated IgE levels. Contact the provider immediately if any of these symptoms occur.

Cardiovascular events, such as acute myocardial ischemia or infarction, have been observed in patients receiving maraviroc, although its connection to this adverse effect has not been identified. Maraviroc may induce postural hypotension, especially in patients receiving antihypertensive medications.

Finally, since maraviroc interferes with CCR5 co-receptors found in immune cells, the patient may experience some form of unintended infection, or reactivation of an infection such as PCP, mycobacterium, or cytomegalovirus infection.

Maraviroc is a pregnancy category B drug.

POSTEXPOSURE PROPHYLAXIS

Postexposure prophylaxis (PEP) may be either occupational (as for health care providers) or nonoccupational. Although the incidence of workplace needle stick exposure has decreased due to education, needle disposal, and engineering changes, the exposure risk is still a significant concern. For the purposes of this text, only occupational PEP will be discussed.

PEP decreases, but does not eliminate, the risk of seroconversion (the development of HIV) after a single exposure. Exposure is defined as a needle stick or cut with a sharp object or contact of mucous membranes or nonintact skin with blood, tissue, or other potentially infectious body fluids (Box 46.8). In terms of rate of exposure, nurses top the list, followed by physicians, phlebotomists, and non laboratory technicians. The risk of seroconversion is low and is estimated to 3 out of 100 without prophylaxis. It is estimated that the risk of seroconversion is reduced by 80% when PEP is administered in a timely fasion. The risk of seroconversion increases with exposure to a larger quantity of blood from the HIV-infected patient (source patient). For example, a needle stick with a needle visibly contaminated with the patient's blood or an exposure after a procedure that involved a needle being placed directly in a vein or artery would increase the risk of seroconversion. The depth of the needle penetration, the placement of the needle, vein or artery in the contact person, and a high viral load are considered high-risk injury. Low-risk injuries, on the other hand, are those that are superficial in depth and the source person has a low viral load. This high versus low risk injury has implications affecting how the exposure is addressed.

PEP is recommended when the source patient is HIV positive. PEP is generally offered to the health care provider if the HIV status of the source is unknown. Ideally, PEP should start within 1 to 2 hours after exposure and no more than 72 hours later. It is thought that PEP effectiveness is lessened if given 24 to 36 hours post-exposure. PEP is continued for 4 weeks, unless the source patient is found to be HIV negative. Approximately one-third of health care providers who start PEP do not complete the regimen because adverse effects to the drugs are significant. For example, efavirenz has the major disadvantage of CNS toxicity which may be is acceptable to someone who requires lifetime treatment, but may be problematic to a health care professional who needs to continue to function at a high cognitive level even though it is a relatively short therapy of at least 4 weeks. It is important to remember that not every health care provider's exposure requires PEP.

There are many variables to consider prior to the initiation of PEP, and the guidelines are complex and well beyond the scope of this text. Currently, the simplified recommendations for occupational PEP are one of the following:

- Basic regimen:
- zidovudine + lamivudine, available as Combivir, *or*
- zidovudine + emtricitabine, *or*
- tenofovir + lamivudine, *or*
- tenofovir + emtricitabine (Truvada)
- Expanded regimen:
- basic regimen + lopinavir/ritonavir (Kaletra)

Remember, these regimens are the simplified version of PEP. There are many alternative regimens, based on specific variables. Laboratory follow-up is essential. Testing for HIV antibodies should be done at 6 weeks, 12 weeks, and 6 months after exposure.

For further information about PEP the information is available online: http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5011a1.htm#tab4. Also, the National Clinician Post Exposure Prophylaxis Hotline telephone number is 888 448 4911 and it has a web site: http://www.ucdf.edu/hivcntr.

Box 46.8 BODY FLUIDS THAT CAN TRANSMIT HIV INFECTION

Potentially Infectious Fluids
blood
cerebrospinal fluid
synovial fluid
pleural fluid
peritoneal fluid
pericardial fluid
amniotic fluid

Noninfectious Fluids (unless they are visibly bloody)
feces
nasal secretions
saliva
sputum
sweat
tears
urine
vomitus

PROPHYLAXIS FOR OPPORTUNISTIC INFECTIONS

The advent of HAART has led to dramatic decline of opportunistic infections because of the improved health of the patient as well as the rise of his or her CD4. However, a patient with HIV infection still has an increased risk for a multitude of opportunistic infections. These opportunistic infections are a significant contributor of mortality and mortality among patients afflicted with HIV.

Many of these diseases must be treated on an individual basis, and routine prophylaxis is not recommended. However, for several diseases there are recommendations for prophylaxis to avoid initial infection (outlined in Table 46.12). In addition to these opportunistic infections, immunocompromised patients are more vulnerable than immunocompetent patients to certain conditions of the mouth (Box 46.9).

TABLE 46.12 Prophylaxis to Prevent First Episode of Opportunistic Disease

Infection	Indication	First Choice	Alternative
Pneumocystis jiroveci pneumonia	CD4 count <200/mm^3 or oropharyngeal candidiasis	Sulfamethoxazole-trimethoprim (SMZ-TMP), 1 DS tablet daily	SMZ-TMP 1 DS tablet 3×/week dapsone, 50 mg bid or 100 mg daily **or** dapsone, 50 mg daily, plus pyrimethamine, 50 mg weekly, and leucovorin, 25 mg, weekly **or** dapsone, 200 mg, plus pyrimethamine, 75 mg, plus leucovorin, 25 mg, weekly **or** aerosolized pentamidine, 300 mg, monthly **or** atovaquone, 1,500 mg daily **or** atovaquone 1,500 mg daily plus pyrimethamine 25 mg and leucovorin 10 mg daily
Mycobacterium tuberculosis	Tuberculin skin test (TST) reaction >5 mm **or** contact with person with active tuberculosis, regardless of TST result	Isoniazid, 300 mg, plus pyridoxine, 50 mg daily for 9 mo **or** isoniazid, 900 mg, plus pyridoxine, 100 mg 2×/wk for 9 mo	Rifampin, 600 mg daily **or** Rifabutin (dose adjusted based on concomitant HAART)
Toxoplasma gondii	Immunoglobin G antibody to *Toxoplasma* and CD4 count of <100/mm^3	SMZ-TMP, 1 double strength daily	SMZ-TMP, 1 single strength daily **or** dapsone, 50 mg daily, plus pyrimethamine, 50 mg, and leucovorin, 25 mg, weekly **or** dapsone, 200 mg, plus pyrimethamine, 75 mg, and leucovorin, 25 mg, weekly **or** atovaquone, 1,500 mg, with or without pyrimethamine, 25 mg, plus leucovorin, 10 mg, daily
Disseminated Mycobacterium avium complex	CD4 count <50/cell/ mL Must rule out active infection	Azithromycin, 1,200 mg weekly **or** clarithromycin, 500 mg twice daily **or** Azithromycin 600 mg 2×/wk	Rifabutin, 300 mg daily
Streptococcus pneumoniae infection	CD4 count <200 cells/mL and no receipt of pneumococcal vaccine in past 5 years	23-valent PPV 0.5mL IM every 5 y	None
Influenza A and B	All HIV positive patients	Inactivated influenza vaccine annually	None
Histoplasma Capsulatum infection	CD4 count <150 cells/mL and occupational exposure or living in area of hyperendemic histoplasmosis	Itraconazole 200 mg daily	None
Coccidiomycosis	CD4 count <250 cells/mL and positive IgM or IgG test in a patient from a disease endemic area	Fluconazole 200 mg daily Itraconazole 200 mg 2×/d	None
Varicella-zoster virus (VZV)	Substantial exposure to chickenpox or shingles for patients who have no history of either condition or, if available, negative antibody to VZV	Varivax, 2 doses 3 mo apart	Vaccinate all household contacts

Adapted from Guidelines for preventing opportunistic infections among HIV-infected persons. (2009). *Morbidity and Mortality Weekly Report, Apr 10;58(RR-4):1-207;*

Box 46.9 ORAL HEALTH CARE FOR IMMUNOCOMPROMISED PATIENTS

Both immunocompetent and immunocompromised patients may have oral health problems. A few conditions are seen only in immunocompromised patients. Conditions that are seen in both populations may cause more problems in immunocompromised patients than in others. These conditions include:

- Dental caries
- Dry mouth
- Periodontal disease
- Human papillomavirus (HPV)
- Oral candidiasis (thrush)
- Aphthous stomatitis (canker sores)
- Herpes simplex virus
- Hairy leukoplakia
- Opportunistic tumors

Teach the HIV-positive patient the importance of having dental examinations twice yearly. Other suggestions may include:

- Regularly brushing and flossing the teeth and gums
- Using artificial saliva products
- Sucking on sugar-free citrus candies
- Engaging in safe oral-sex practices
- Seeking treatment for aphthous ulcers rather than allowing them to self-heal
- Not smoking
- Limiting alcohol use

Pneumocystis Jiroveci Pneumonia

Pneumocystic jiroveci pneumonia (PCP) is a type of pneumonia that affects immunosuppressed patients. In the past, PCP was responsible for serious illness and death among patients with HIV and AIDS. Since the use of HAART began, morbidity and mortality related to PCP have dramatically decreased. Patients should start prophylactic therapy for PCP when their CD4 cell counts are less than 200/cells/μL or when they have a history of oropharyngeal candidiasis. If the CD4 cell count increases to at least 200/ cells/μL, prophylaxis may be discontinued.

The drug treatment of choice is sulfamethoxazole-trimethoprim (SMZ-TMP). Patients who experience non–life-threatening adverse drug effects should continue SMZ-TMP therapy if clinically feasible. If SMZ-TMP cannot be tolerated, alternative prophylactic regimens include dapsone, dapsone plus pyrimethamine, aerosolized pentamidine, or atovaquone. Unfortunately, these alternatives are not as effective as SMZ-TMP. For additional information on SMZ-TMP, see Chapter 42. Pentamidine is discussed in Chapter 47.

Tuberculosis

Patients with a diagnosis of HIV infection should have a baseline tuberculin skin test (TST). Depending on the progression of infection at the time of diagnosis, the TST results may be a false negative whereby the immunocompromised patient is unable to mount an immune response to the test. Clinical evaluation for the potential of TB is needed to determine whether anergy testing should be done at this time.

All HIV-positive patients who have positive TST results (induration exceeding 5 mm) should undergo chest radiography. For patients with positive TST findings and normal chest x-ray findings, prophylaxis with INH and pyridoxine maybe initiated and continued for 9 months, or 6 months, or 12 months, given daily or twice a week depending on institutional policy. Alternative therapies include rifampin or rifabutin daily for 4 months.

Any HIV-positive patients who are in close contact with people who have active TB should be started on prophylaxis therapy with isoniazid regardless of their TST results. Infants of HIV-positive mothers should have a TST between 9 and 12 months. These children should be retested every 2 to 3 years. Additional information on isoniazid can be found in Chapter 43.

Toxoplasma gondii

Patients infected with HIV should be tested for IgG antibody to *Toxoplasma* soon after the diagnosis of HIV infection to detect latent infection with *T. gondii*. Patients harboring toxoplasmosis are at risk for cerebral abscesses and severe morbidity and mortality. The vast majority of patients are positive.

Prophylaxis should be initiated for patients with IgG antibody to *Toxoplasma* and a CD4 cell count of less than 100 cells/μL. The drug of choice is SMZ-TMP. If the patient is unable to tolerate SMZ-TMP, he or she may receive alternative prophylaxis, including dapsone plus pyrimethamine plus leucovorin weekly, or atovaquone with or without pyrimethamine plus leucovorin daily.

Counsel patients to avoid raw or undercooked meat, particularly undercooked pork, lamb, and venison. It also is important to caution patients to wash their hands after touching raw meat, after gardening, and after changing a cat's litter box. Patients with cats should be advised to change the litter box daily.

Disseminated *Mycobacterium avium* Complex

Prophylaxis for disseminated *Mycobacterium avium* complex (MAC) should be initiated when the patient's CD4 cell count falls below 50 cells/μL. The drugs of choice are azithromycin once or twice weekly or clarithromycin twice-daily. Clarithromycin, however, has several drug interactions, including with PIs. In addition to MAC protection, these drugs also offer protection against respiratory bacterial infections.

For patients who cannot tolerate azithromycin or clarithromycin, rifabutin is the alternative drug. It is important to remember that rifabutin interacts with almost all anti-HIV agents; therefore, it should be administered cautiously. Additional information on azithromycin and clarithromycin is located in Chapter 40.

Streptococcus pneumoniae

Streptococcus pneumoniae is very common in the community, and there is no effective way to limit exposure to these bacteria. For patients with a CD4 cell count of at least 200 cells/μL, pneumococcal vaccine should be administered. For patients with a CD4 cell count of less than 200 cells/μL, pneumococcal vaccine may be administered, but the humoral response is likely to be diminished.

Influenza Virus

Every HIV-positive patient should receive annual influenza virus prophylaxis. The preferred drug is inactivated trivalent influenza virus vaccine, one dose annually.

Histoplasma capsulatum

Histoplasma capsulatum is the organism that causes the most common fungal respiratory infections in the world. Most infections are mild; however, approximately 10% of these infections cause serious complications, including inflammation of the pericardium and fibrosis of major blood vessels (see Chapter 44). Prophylaxis is recommended for patients who live in an endemic geographic area and have a CD4 count less than 150 cells/μL. Itraconazole is the drug of choice.

Varicella-Zoster Virus

Prophylaxis against varicella-zoster virus (VZV) is recommended for patients who have no antibodies to VZV and for patients who have been substantially exposed to either chickenpox or shingles. Patients should receive Varivax, 2 doses given 3 months apart. In patients experiencing an active VZV outbreak, treatment centers on antiviral drugs such as acyclovir, valacyclovir, or famciclovir. Information on these drugs is located in Chapter 45.

Hepatitis B

HIV-positive patients should be tested for antibodies to HBV. If the patient tests negative, the hepatitis B vaccine should be administered. This vaccine is administered in three doses, with the second dose given 1 month after the initial dose and the last dose given 6 months after the initial dose.

Hepatitis A

HIV-positive patients should be tested for antibodies to hepatitis A virus. If the patient is negative or has chronic hepatitis C, the hepatitis A vaccine should be administered. This vaccine is administered in two doses.

Cytomegalovirus

Cytomegalovirus (CMV) is found universally throughout all geographic locations and socioeconomic groups and infects between 50% and 85% of adults in the United States by 40 years of age. In the general population, the infection may go unnoticed; however, in the immunocompromised population, CMV may cause infection in many organs of the body, especially in the retina of the eye (see Chapter 45). Patients who are CMV antibody positive and have a CD4 cell count of less than 50 cells/μL should receive ganciclovir, 1 g three times daily.

CHAPTER SUMMARY

- HIV infection and AIDS are chronic diseases affecting the immune system.
- HIV infection is diagnosed by positive results on EIA, ELISA, WB, rapid HIV, oral HIV, or PCR tests.
- HIV infection is monitored by CD4 cell count and HIV RNA load.
- Genotypic and phenotypic resistance assays are available to assess patterns of resistance to HAART.
- Pharmacotherapy should be considered for all symptomatic patients. For asymptomatic patients, drug therapy should be considered when the CD4 cell count is less than 200 cells/μL or any CD4 count if opportunistic infection is present.
- Resistance develops to all classes of anti-HIV agents, especially when the therapeutic regimen is not followed.
- Absorption of individual anti-HIV agents is enhanced by administration either with food or on an empty stomach (while fasting).
- All anti-HIV drugs may produce adverse effects that decrease the patient's quality of life.
- Most anti-HIV drugs have numerous drug–drug interactions that may increase or decrease their effectiveness. Many antiretroviral drugs have Black Box warnings.
- Anti-HIV agents include NRTIs, PIs, NNRTIs, integrase inhibitors, entry inhibitors, and CCR5 inhibitors.
- Antiretroviral therapy may be given throughout pregnancy or during the intrapartum and postpartum periods.
- Not all occupational exposures to HIV require PEP. However, PEP is recommended when the source patient is HIV positive.
- Opportunistic diseases develop as HIV infection progresses. Many opportunistic diseases have recommended prophylactic regimens.

QUESTIONS FOR STUDY AND REVIEW

1. How is HIV infection diagnosed?
2. Why do patients with HIV infection have an increased risk for opportunistic diseases?
3. What information is gained from CD4 cell counts and viral load counts?
4. What is the rationale for highly active antiretroviral therapy (HAART)?
5. Which adverse effects of zidovudine (AZT, ZDV) therapy may indicate a need to stop therapy?
6. Before initiation of zidovudine therapy, what laboratory tests should be completed?
7. What assessments and interventions apply to lifestyle, diet, and habits for the patient taking zidovudine?
8. How do PIs inhibit HIV replication?

9. How do NNRTIs differ in action from NRTIs?
10. How does the action of the entry inhibitors affect the ability of HIV to replicate?
11. Why is opportunistic disease prophylaxis necessary?
12. What is the mechanism of action for raltegravir?

Drugs Treating Parasitic Infections

Learning Objectives

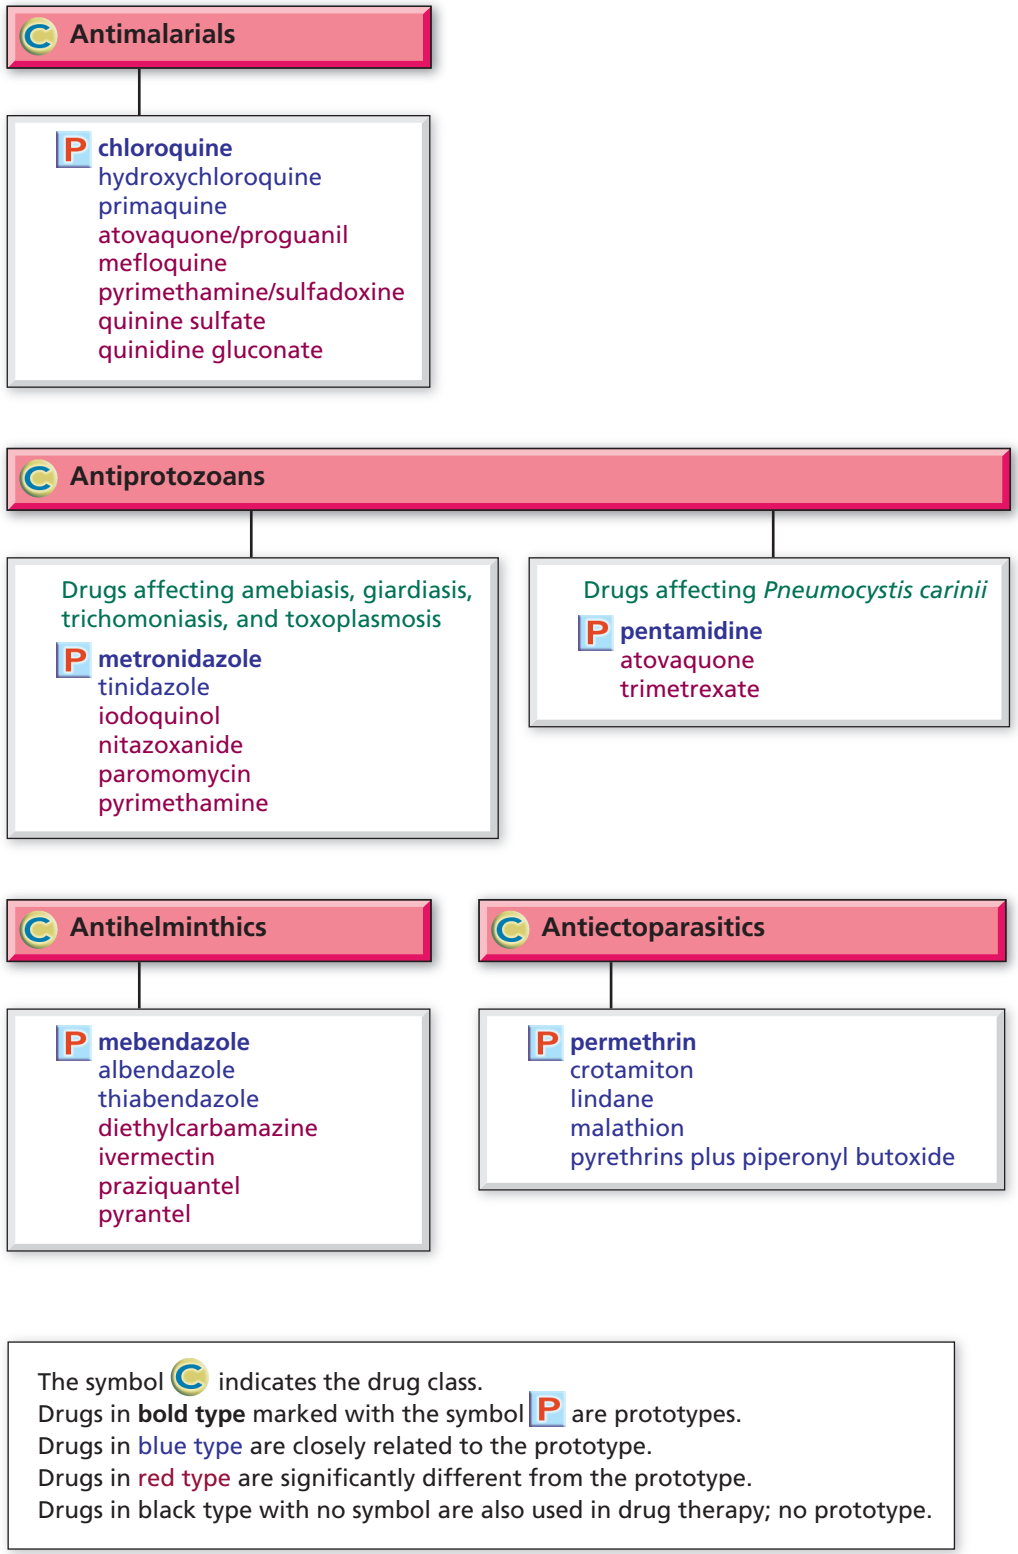
At the completion of this chapter the student will:

1. Describe the guidelines that govern the choice of antiparasitic drugs.
2. Identify core drug knowledge about drugs used to treat parasitic infections.
3. Identify core patient variables relevant to drugs used to treat parasitic infections.
4. Relate the interaction of core drug knowledge and core patient variables to drugs used to treat parasitic infections.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs used to treat parasitic infections.
6. Describe nursing interventions to maximize therapeutic actions and minimize adverse effects for drugs used to treat parasitic infections.
7. Determine key points for patient and family education for drugs used to treat parasitic infections.
8. Explain the hygiene measures needed to prevent parasitic reinfection.

Key Terms

amebiasis
arthropods
cestodes
ectoparasites
giardiasis
helminths
malaria
nematodes
parasite
Pneumocystis jiroveci **pneumonia**
pneumonia
protozoa
toxoplasmosis
trematodes
trichomoniasis

Drugs Treating Parasitic Infections



A **parasite** is an organism that must live on other organisms to survive. The parasitic diseases are commonly grouped according to the type of organism that causes them: helminths, arthropods, or unicellular organisms, such as **protozoa.** Protozoan infections include malaria, amebiasis, giardiasis, *Pneumocystis carinii* pneumonia, toxoplasmosis, and trichomoniasis. **Helminths** (worms) are grouped into three categories: **nematodes** (roundworms), **trematodes** (flukes), and **cestodes** (tapeworms). **Ectoparasites** are vectors of disease, such as ticks, mosquitoes, and biting flies, and other parasites that infect external body surfaces. **Arthropods** include mites (scabies), chiggers, lice (pediculosis), and fleas.

Pharmacologic intervention for parasitic infections must be specific not only to the type of parasite but also to the appropriate stage of its life cycle. Some parasites have simple life cycles, and some have extremely complex life cycles. Thus, many parasitic diseases are treated with a combination of drugs to eradicate all stages of the parasite.

This chapter discusses the appropriate drug or drugs used to eradicate the most common parasitic diseases. Antiparasitic drugs are divided into four drug families: antimalarials, antiprotozoan drugs, anthelminthic drugs, and antiectoparasitic drugs. The antiprotozoan drugs used in treating *Pneumocystis carinii* pneumonia (PCP), a common complication of AIDS, are discussed separately within the antiprotozoan drug class section.

Prototypes presented in the chapter (and their target diseases) include chloroquine (malaria), metronidazole (protozoal infections), pentamidine isethionate (PCP), mebendazole (helminthic infections), permethrin (scabies), and malathion (pediculosis). In addition to explaining how these drugs work, this chapter discusses nursing management related to evaluating the patient's condition, administering antiparasitic drugs, monitoring the patient's response, and teaching the patient and family about antiparasitic therapy.

PATHOPHYSIOLOGY

Malaria

Malaria is caused by protozoan parasites of the genus *Plasmodium*. Four species of *Plasmodium* produce disease in humans—*P. falciparum, P. vivax, P. ovale,* and *P. malariae. P. falciparum* is the most widespread and dangerous of the four. Because *P. falciparum* can destroy up to 60% of circulating red blood cells (RBCs) and induce serious adverse complications such as toxic encephalopathy, it is fatal in about 1% of all cases. That 1% accounts for more than 95% of all malaria-caused deaths worldwide.

The complex life cycle of *Plasmodium* species begins when a female *Anopheles* mosquito bites a human whose blood contains the sexual forms of the malaria parasite (gametocytes). Within the now-infected mosquito, the gametocyte completes a maturation process and becomes a sporozoite that is stored in the salivary glands of the mosquito. When the mosquito next feeds, it inoculates another human host with the sporozoites.

Once the sporozoites are in the human host, the asexual portion of the life cycle begins. The first stage of asexual development, the exoerythrocytic phase, occurs in the liver. During this phase, the form of the *Plasmodium* is called a tissue schizont. At the end of the phase, the *Plasmodium,* now in a form called a merozoite, is released from the liver into the bloodstream.

The second stage of asexual development, the erythrocytic phase, begins when the merozoites are released into the bloodstream. The merozoites invade the erythrocytes and develop into erythrocytic schizonts. They, in turn, develop more merozoites within the red blood cells. At the end of this phase, the RBCs rupture, releasing the merozoites and pyrogenic substances into the bloodstream, where the merozoites invade new RBCs. The release of merozoites into the bloodstream initiates malarial symptoms of fever, shivering, joint pain, and headache. With *P. vivax* and *P. ovale,* merozoites may reinvade the liver tissue and develop a dormant hepatic stage (hypnozoite), which is responsible for subsequent relapses.

The cycle of invasion, multiplication, and RBC rupture is repeated many times. After a few cycles, some of the asexual parasites develop into sexual forms (gametocytes), which remain in the bloodstream. When a mosquito bites a human with gametocytes in the blood, the cycle begins again (Figure 47.1). Because of its complex life cycle, malaria is frequently treated with combination drug therapy.

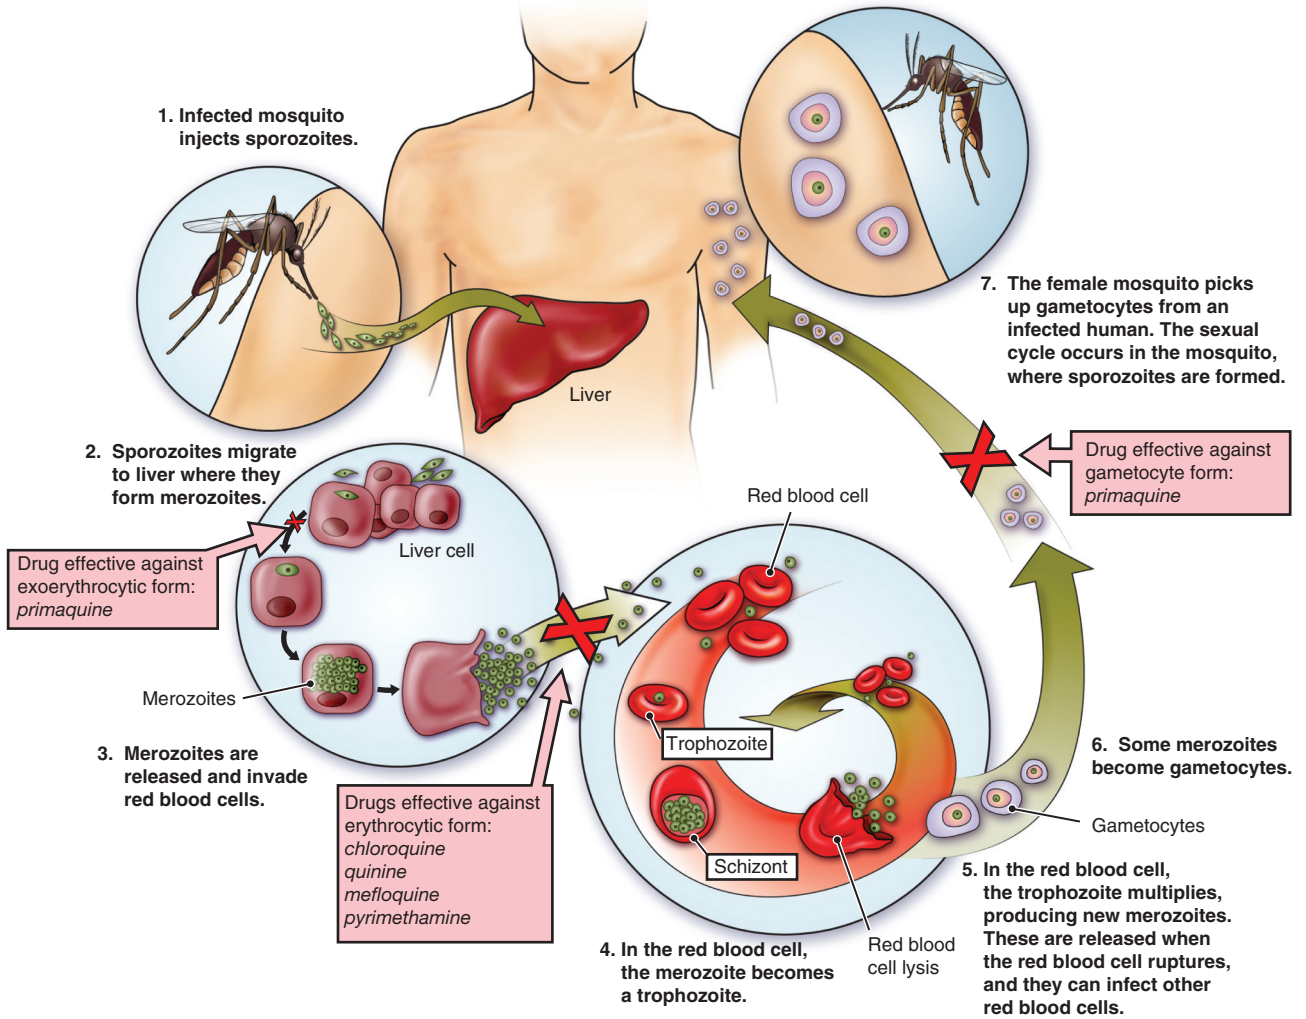
Parasitic Diseases

Amebiasis

Amebiasis is most frequently caused by the microorganism *Entamoeba histolytica,* which is passed from host to host by ingestion of fecally contaminated food or water. It also is transmitted by vectors such as flies. Amebic disease is present worldwide, but it is most common in those tropical areas where crowded living conditions and poor sanitation exist. Africa, Latin America, Southeast Asia, and India have substantial health problems associated with this disease. In the United States, amebiasis is more common among homosexual men than it is in other populations.

Ingested in its cyst form, the microorganism has thick walls that are resistant to stomach acids. In the intestine, the cysts change into a sexually active organism called a trophozoite. The trophozoite produces active amebiasis. The active disease organisms may remain in the intestine (intestinal amebiasis), or the trophozoites may penetrate the intestinal wall and produce abscesses in other tissues and organs (extraintestinal amebiasis). Symptoms may be mild or severe. Mild symptoms include mucoid diarrhea, flatulence, fatigue, weight loss, and colicky abdominal pain. Severe disease may be marked with frequent foul-smelling stools tinged with mucus and blood, fever to 105°F, tenesmus (painful but unsuccessful straining to defecate), generalized abdominal tenderness, and vomiting.

PHYSIOLOGY



• FIGURE 47.1 Life cycle of the malarial parasite and the sites of action of antimalarial drugs. (Adapted from Howland, R. J., Mycek, M. J., Harvey, R. A., & Champe, P. C. [2006]. Lippincott's illustrated reviews: Pharmacology [3rd ed., p. 417]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Cryptosporidiosis

Cryptosporidiosis ("crypto") is a diarrheal disease caused by *Cryptosporidium parvum*. It is found in soil, food, water, or surfaces that have been contaminated with infected human or animal feces. Transmission is fecal–oral, and cryptosporidiosis may be acquired by several mechanisms: swallowing recreational water (from swimming pools, hot tubs, jacuzzis, fountains, lakes, rivers, springs, ponds, or streams) contaminated with sewage or feces from humans or animals; eating uncooked contaminated foods, including raw vegetables and fruits; or swallowing *C. parvum* picked up from surfaces (such as bathroom fixtures, changing tables, diaper pails, or toys) contaminated with feces from an infected person. Symptoms include nausea, vomiting, diarrhea, dehydration, weight loss, stomach cramps or pain, and fever. In immunocompetent persons, symptoms last for 1 to 2 weeks. Immunocompromised patients may experience more severe symptoms, sometimes leading to life-threatening illness.

Giardiasis

Giardiasis is a common disease caused by a flagellated protozoan, *Giardia lamblia*. It is transmitted by fecal contamination. Hikers who drink unfiltered water or travelers to foreign countries where the water supply is impure are most susceptible. Animal reservoirs for the parasites include beavers and dogs.

Giardiasis is more prevalent in children than in adults, possibly because many individuals seem to have a lasting immunity after infection. The disease is common in children's

day-care centers, especially those in which diapering is done. This disease also afflicts many homosexual men, both HIV-positive and HIV-negative individuals, presumably as a result of sexual transmission.

The disease affects only the intestinal system, resulting in acute or chronic diarrhea and possibly malabsorption syndrome. The acute phase may last days to weeks; however, the chronic phase may last years. Symptoms include diarrheal, soft, or steatorrheal stools with mucus but without blood. Abdominal cramps, vomiting, flatulence, and weight loss also may occur.

Trichomoniasis

Trichomoniasis is an infection of the vagina caused by the parasite *Trichomonas vaginalis*. Both sexual partners are generally infected, although both may not be symptomatic. Symptoms of trichomoniasis include a thin, yellow, frothy, and malodorous discharge. The vagina may be inflamed, and the woman may also have a "strawberry" cervix, which is very friable and bleeds easily.

Toxoplasmosis

Toxoplasmosis is caused by a parasite found in a variety of animals, especially cats and birds. Infection results from ingesting oocysts from cat feces, ingesting cysts in raw or undercooked meat, congenital transmission, or transmission during blood transfusion.

In adults, the disease is usually mild with symptoms such as fever, malaise, headache, lymphadenopathy, and sore throat. However, toxoplasmosis is very dangerous to immunocompromised patients. The infection may affect the lungs, heart, and liver, but usually it affects the brain. Patients may succumb to meningoencephalitis.

Congenital toxoplasmosis may result in damage to the eyes (retinochoroiditis) and brain (encephalitis) of the fetus or other congenital anomalies.

Pneumocystis jiroveci Pneumonia

An opportunistic lung infection, ***Pneumocystis jiroveci* pneumonia** (PCP), formerly known as *Pneumocystis carinii* pneumonia, is caused by a phylogenetic fungal species. This particular species is not found in nonhuman hosts. Most people have been exposed to *Pneumocystis jiroveci* because it is in our environment; however, a healthy immune system keeps the fungus from causing illness within the host. In patients with depressed immunity, *Pneumocystis jiroveci* pneumonia causes serious illness.

Patients with the highest risk for the development of PCP include those with a T-cell count below 200; those with oral thrush or unexplained fevers lasting more than 2 weeks, regardless of T-cell count; and those who have previously been infected with PCP.

The symptoms of PCP develop slowly. They include weakness, fever, chest tightness, shortness of breath, dry cough, and weight loss. As the disease progresses, patients have symptoms similar to those of adult respiratory distress syndrome. Historically, PCP has had an exceptionally high mortality rate. Fortunately, with current prophylaxis and treatment options, death occurs in about 10% of cases of PCP.

Helminthic Infections

Intestinal Nematode Infections

The common intestinal nematodes are the giant roundworm, pinworm, threadworm, whipworm, and pork roundworm.

Ascariasis (Giant Roundworm)

Ascariasis is endemic in areas known for poor hygiene or sanitation and those where human feces are used as fertilizer. Ascariasis is transmitted by ingesting fecally contaminated foods or drinks. Once ingested, the worm eggs migrate to the small bowel, where they hatch, releasing larvae. The motile larvae migrate from the small bowel to the heart and lungs, to the esophagus, and back to the small bowel. They can survive up to 5 years and reach a length of 30 cm. Symptoms include low-grade fever, nonproductive cough, blood-tinged sputum, wheezing, dyspnea, and substernal pain.

Enterobiasis (Pinworm)

Enterobius vermicularis is the most common helminthic infection in the United States. Children are infected more frequently than adults. Transmission occurs by contact with eggs in food, water, or bed linens. Adult worms inhabit the cecum and adjacent bowel areas. Female worms migrate through the anus to the perianal skin and deposit large numbers of eggs, especially at night. In a few hours, infection can be transmitted to others or remain in the host. The most common symptoms are rectal itching and vulvar itching.

Strongyloidiasis (Threadworm)

Strongyloidiasis results from infection with *Strongyloides stercoralis*. The infection is potentially serious in adults because the worm can multiply within the host. In its filariform larvae cycle, the parasites penetrate the skin from soil, enter the bloodstream, and travel to the lungs. From the lungs, they escape the alveoli and ascend the bronchial tree to the glottis, where they are swallowed and propelled to the small intestine to mature into adult threadworms. The mature worm embeds itself in the mucosa, where eggs are laid and hatched. The larvae disseminate into the lungs and most other tissues, causing local inflammation and granulomas. Symptoms include skin reactions, such as inflammation, petechiae, and urticaria, and intestinal reactions, such as diarrhea, abdominal pain, and flatulence. Pulmonary symptoms include dry cough, throat irritation, dyspnea, wheezing, and hemoptysis. Hyperinfection syndrome caused by intense dissemination of larvae to the lungs and other tissues can result in complications, such as pleural effusion, pericarditis, and myocarditis. Additional problems include perforation of the colon and peritonitis, gram-negative septicemia, and shock leading to death.

Trichuriasis (Whipworm)

Trichuriasis infection is acquired by ingesting egg-contaminated soil on hands or food. Human-to-human transmission is not possible. Worms attach to the mucosa of the large intestine by means of their anterior whip-like end. Symptoms include abdominal cramps, tenesmus, diarrhea, flatulence, nausea, vomiting, and weight loss.

Trichinosis (Pork Roundworm)

Trichinella spiralis is the parasite that causes trichinosis. The infection is transmitted by ingesting encysted larvae in inadequately cooked meat, especially pork. Gastric juices liberate the encysted larvae, which migrate to the intestines, where they mature, mate, and produce eggs that hatch into new larvae. These larvae are distributed through the body and enter skeletal muscle tissues, producing an inflammatory response. Eventually, the larvae become re-encysted and remain within the tissues. Symptoms include diarrhea, cramps, and malaise. As the infection progresses, patients may experience muscle pain, tenderness, fever, periorbital and facial edema, and conjunctivitis.

Blood and Tissue Nematode Infections

Filarial infections are among the more serious and debilitating helminthiases associated with blood and tissue nematodes. There are two forms of filarial infections. The first form is caused by two microbes, *Wuchereria bancrofti* and *Brugia malayi*. Both microbes are transmitted by mosquitoes.

Bancroftian filariasis also is known as elephantiasis because the helminths migrate to the lymphatic system, causing lymphadenopathy and resultant edema of the extremities. Brugian filariasis also affects the lymphatic system. In this infection, microfilariae are produced and circulated in the bloodstream.

The second type of filariasis also is known as onchocerciasis or river blindness. The adult helminths reside in subcutaneous nodules and migrate to the eye, causing ocular lesions and eventual loss of vision.

Cestode Infections

Cestodes cause taeniasis infections. Tapeworm infections are transmitted in contaminated raw or improperly cooked fish (*Diphyllobothrium latum*), beef (*Taenia saginata*), and pork (*Taenia solium*). The adult tapeworm consists of a head (scolex) that attaches to the intestinal wall and segments called proglottids. The proglottids contain tapeworm eggs and are expelled in feces. Beef and fish tapeworms do not cause serious illness. Pork tapeworms, however, produce larvae that enter the bloodstream and invade other body tissues. Symptoms include nausea, vomiting, diarrhea, fatigue, hunger, and dizziness.

Trematode Infections

Trematodes cause schistosomiasis, which is a leading cause of morbidity and mortality from parasitic diseases. The vector of schistosomiasis is a specific snail; humans acquire this parasite by drinking or contacting contaminated water. There are three major types of schistosomes. Each migrates to a specific part of the human host and produces clinical symptoms specific to each type.

Ectoparasitic Infections

Common ectoparasitic infections include scabies and pediculosis (lice).

Scabies

Scabies is a skin inflammation caused by a mite, *Sarcoptes scabiei*. The mite is barely visible with the naked eye and is transmitted by contact with an infected individual or infested bedding. Characteristic lesions consist of generalized excoriations with small pruritic vesicles, pustules, and burrows. The infestations occur on the sides of the fingers and the palms, wrists, and elbows and around the axillae. The head and neck are usually spared in adults. Diagnosis is made by identifying the parasite or its ova or feces microscopically. Treatment includes all family members and close contacts, which helps prevent reinfestation.

Pediculosis

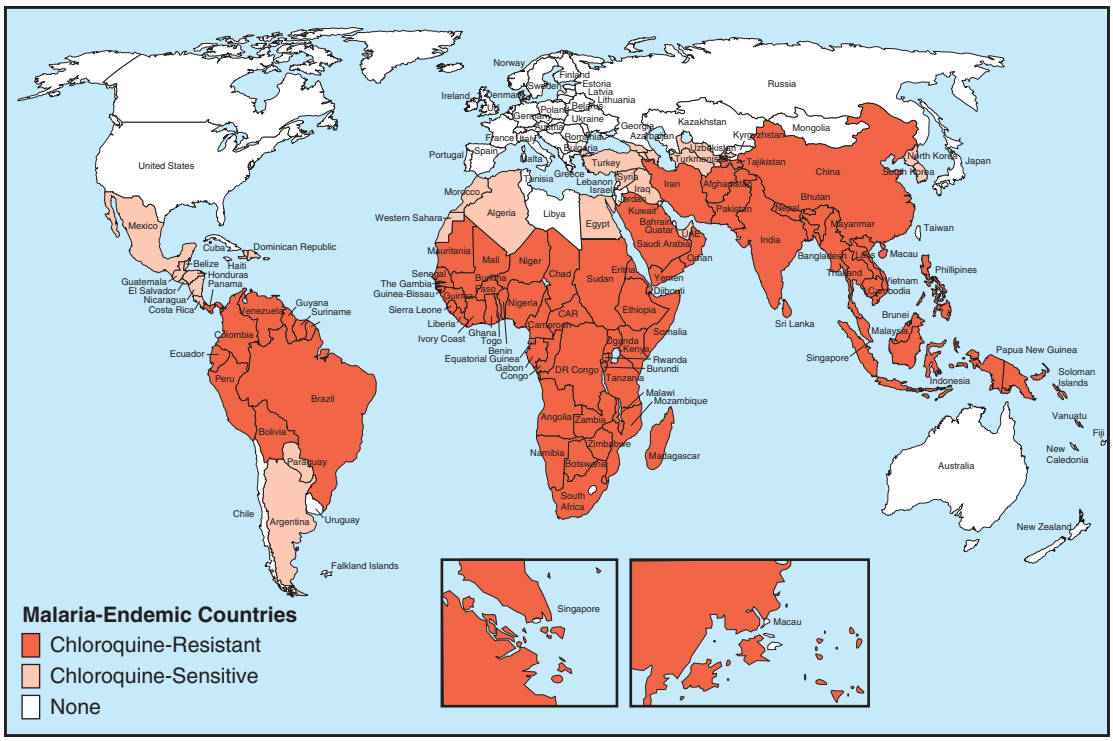
Pediculosis is also known as lice. Pediculosis infestations occur on the scalp (pediculosis capitis), trunk (pediculosis corporis), or pubic areas (pediculosis pubis). Each year, approximately 6 to 12 million children between the ages of 3 and 12 years are infested with head lice. Transmission is by direct contact with lice, particularly those on hats, combs, and body hair. Symptoms include pruritus with excoriation, nits on hair shafts, and lice on skin or clothes.

ANTIMALARIAL DRUGS

Drug therapy for malaria comprises three distinct types: suppressive therapy (prophylaxis), treatment of an acute attack (clinical cure), and prevention of a relapse (radical cure). Some drugs may be used in more than one type of therapy. Drug therapy is guided by three factors: the identity of *Plasmodium* species (laboratory confirmation necessary), the clinical status of the patient, and the geographic area where the infection was acquired (Figure 47.2).

Most cases of malaria, especially in the United States, are considered uncomplicated and are generally treated with oral antimalarial drugs. Patients with symptoms such as impaired consciousness/coma, severe normocytic anemia, renal failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, and repeated generalized convulsions have severe malaria and are treated with parenteral drugs.

Chloroquine (Aralen) is the prototype antimalarial drug. Table 47.1 presents a summary of selected antimalarial drugs.



• FIGURE 47.2 Malaria-endemic countries. (Source: Centers for Disease Control and Prevention, *http://www.cdc.gov/malaria/*.)

Nursing Management of the Patient Receiving P Chloroquine

Core Drug Knowledge

Pharmacotherapeutics

Chloroquine is indicated to suppress or treat acute attacks of malaria caused by *P. vivax, P. malariae, P. ovale,* and susceptible strains of *P. falciparum*. It does not prevent relapses because it is not effective against exoerythrocytic forms of the parasite. Also, it does not prevent infections caused by *P. vivax* or *P. malariae* when administered as a prophylactic. In addition to its use in treating malaria, chloroquine also is used to treat extraintestinal amebiasis, rheumatoid arthritis, and systemic lupus erythematosus.

Pharmacokinetics

Chloroquine is absorbed rapidly and completely from the gastrointestinal (GI) system. The drug concentrates in the erythrocytes (RBCs), liver, spleen, kidney, lung, melanin-containing tissues, and leukocytes (white blood cells). It penetrates the central nervous system (CNS) and crosses the placenta. Although chloroquine action peaks rapidly, its half-life is between 70 and 120 hours. About 70% of chloroquine is excreted unchanged by the kidneys. Any unabsorbed drug is excreted in feces. Small amounts of chloroquine have been detected in urine for months and even years after treatment stops.

Pharmacodynamics

Chloroquine, a 4-aminoquinoline, is classified as a blood schizonticide. In treating malaria, its direct effects are on the parasite. Chloroquine is taken up by plasmodia residing within the RBCs of the human host. Chloroquine is thought to increase blood pH and upset phospholipid metabolism in the parasite, thereby interrupting the synthesis of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). In patients with rheumatoid arthritis, chloroquine antagonizes histamine and serotonin, thereby inhibiting prostaglandin synthesis. The result is an anti-inflammatory effect. The drug's action in treating amebiasis is unknown.

Contraindications and Precautions

Chloroquine is contraindicated for patients with a hypersensitivity to any 4-aminoquinoline, such as hydroxychloroquine. Chloroquine also is contraindicated for patients with pre-existing eye disease because the drug can cause corneal opacities, keratopathy, or retinopathy. Retinopathy can lead to blindness and can progress even after the drug is discontinued.

Chloroquine is used with caution in patients with various pre-existing disorders. In patients with psoriasis or porphyria, chloroquine has precipitated severe attacks. Because chloroquine concentrates in the liver, it can produce toxic effects in patients with hepatic disease or alcoholism or in patients using other hepatotoxic drugs concurrently. The drug should be given with caution to patients with GI disorders, blood dyscrasias, dental disease, and neurologic disorders. Patients with these conditions may have exacerbations of disease because of the actions and potential adverse effects of chloroquine. Chloroquine has a black box

TABLE 47.1 Summary of Selected Antimalarial Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
chloroquine (Aralen)	Prophylaxis	*Adult:* PO, 500 mg (300-mg base) once a week on the same day for 1–2 wk before exposure and continuing until 4 wk after exposure *Child:* PO, 5 mg/kg base once a week on the same day for 1–2 wk before exposure and continuing 4 wk after exposure	*Onset:* Rapid *Duration:* 1 wk $t_{1/2}$: 3–5 d
	Acute malaria attack	*Adult:* PO, 1 g (600-mg base) initially, then 500 mg (300-mg base) at 6, 24, and 48 h *Child:* PO, 10-mg base/kg initially, then 5-mg base/kg at 6, 24, and 48 h	
	Extraintestinal amebiasis	*Adult:* IM, 160–200-mg base initially and 6 h later if needed; not to exceed 800 mg base/d *Child:* IM, 5-mg base/kg initially and 6 h later if needed	
	Rheumatoid arthritis/ systemic lupus erythematosus	*Adult:* PO, 1 g (600-mg base)/d for 2 d, then 500 mg (300-mg base)/d for 2–3 wk *Child:* PO, 10 mg/kg/d for 2-3 wk *Adult:* PO 150 mg daily	
atovaquone/proguanil (Malarone)	Prophylaxis	*Adult*: PO, 1 tablet (250 mg atovaquone/100 mg proguanil hydrochloride) per day; start 1–2 d before travel and continue until 7 d after return. *Child*: Based on weight; not recommended for children <11 kg	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: atovaquone, 2–3 d; proguanil, 12–21 h
	Acute malaria	*Adult*: PO, single dose of 4 tablets (total daily dose, 1 g atovaquone/400 mg proguanil hydrochloride)for 3 consecutive d *Child*: PO, based on weight	
Hydroxychloroquine (Plaquenil Sulfate)	Prophylaxis	*Adult*: PO, 310-mg base/wk on the same day each week, beginning 1–2 wk before exposure and continuing for 4 wk after leaving the malaria area *Child*: 5-mg base/kg/wk, then the same dosage regimen as for adults	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 50 d
	Acute malaria attack	*Adult*: PO, initial dose (day 1), 620-mg base; dose 2 (6 h after dose 1), 310 mg; dose 3 (day 2), 310 mg; dose 4 (day 3), 310 mg *Child*: PO, same as for adult in the following amounts, respectively: 10 mg/kg base, 5 mg/kg, 5 mg/kg, 5 mg/kg	
mefloquine (Lariam)	Prophylaxis	*Adult*: PO, 250 mg weekly beginning 1–2 wk before exposure and continuing for 4 wk after exposure *Child*: PO, based on weight, starting 1–2 wk before exposure and for 4 wk after exposure	*Onset*: Delayed *Duration*: Unknown $t_{1/2}$: 3 wk
	Acute malaria attack	*Adult*: PO, 750 mg initially, followed by 500 mg 6–12 h after initial dose *Child*: PO, 15 mg/kg initially, followed by 10 mg/kg 6–12 h after initial dose	
primaquine	Prophylaxis in special circumstances	*Adult*: PO, 30 mg daily beginning 1–2 d before exposure until 7 d after return *Child*: PO, 0.5 mg/kg beginning 1–2 d before exposure until 7 d after return *Adult*: PO, 30 mg base for 14 d *Child*: PO, 0.5 mg/kg base for 14 d	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 3.7–9.6 h
pyrimethamine/ sulfadoxine (Fansidar)	Suppression of malaria (used in conjunction with quinine) Toxoplasmosis	*Adult*: PO, 25 mg pyrimethamine/500 mg sulfadoxine (fixed dose), 2–3 tablets on the last day of quinine dosing *Child*: PO, Age 9–14 y: 2 tablets Age 4–8 y: 1 tablet Age <4 y: 1/2 tablet	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: 56–148 h
quinine	Chloroquine-resistant malaria Chloroquine-sensitive malaria	*Adult*: PO, 650 mg q8h, for 5–7 d *Child*: PO, 25 mg/kg/d in divided doses q8h for 5–7 d *Adult*: PO, 600 mg q8h for 5–7 d *Child*: PO, 10 mg/kg/d in divided doses q8h for 5–7 d	*Onset*: Varies *Duration*: Varies $t_{1/2}$: 4–5 h
quinidine gluconate	Severe *P. falciparum*	*Adult and child*: IV, 6.25 mg base/kg over 1–2 h, then 0.0125 mg base/mg/min for at least 24 h or 15 mg base/kg infused over 4 h, followed by 7.5 mg base/ kg infused over 4 h, q8h, starting 8 h after the loading dose	*Onset*: Rapid *Duration*: 6–8 h $t_{1/2}$: 6–7 h

warning that it should be administered only for malaria and extraintestinal amebiasis.

Chloroquine is a pregnancy category C drug. It should be given with extreme caution to infants and children because of potentially fatal toxicities.

Adverse Effects

Potential adverse effects of chloroquine may affect the cardiovascular, GI, hematologic, integumentary, and neurologic systems. The most common adverse effects are hypotension, cardiac changes reflected on an electrocardiogram (ECG), nausea, vomiting, diarrhea, and abdominal pain.

Infrequent but important potential adverse effects include blurred vision, difficulty focusing, changes in accommodation, irreversible retinal damage, tinnitus and reduced hearing in patients with pre-existing auditory damage, headaches or psychic stimulation, convulsive seizures, and neuromyopathy.

Potential adverse hematologic effects include agranulocytosis, aplastic anemia, pancytopenia, neutropenia, and thrombocytopenia. Potential integumentary effects are pruritus, skin discoloration, skin eruption, and hair bleaching or loss.

Patients who exhibit signs of toxicity may complain of headache, drowsiness, visual disturbances, nausea, or vomiting. Cardiovascular collapse, convulsions, and respiratory or cardiac arrest may rapidly follow. Patients suspected of experiencing toxicity should go to an emergency department.

Drug Interactions

Chloroquine may interact with cimetidine, penicillamine, cyclosporine, and methotrexate. With aluminum and magnesium-containing antacids, its absorption is decreased. Most patients remember any prescription drugs they are taking, but they may forget to mention over-the-counter (OTC) drugs, such as cimetidine or antacids. Therefore, it is important to remember to assess the patient's use of OTC drugs as well. See Table 47.2 for more information.

Assessment of Relevant Core Patient Variables

Health Status

Before administering chloroquine, assess for anemia, porphyria, psoriasis, ocular disease, neurologic disorders, liver and kidney diseases, and other conditions that contraindicate using the drug or that require close monitoring. Next, review the patient's drug history to identify substances that may interact with chloroquine and advise the patient to consult with the prescriber before taking any OTC drugs.

Because chloroquine may affect the eyes, arrange for the patient to have a complete baseline ophthalmologic examination, including visual acuity, slit-lamp, and funduscopic examinations. Similarly, because chloroquine may affect reflexes, muscle strength, and hearing, perform a physical examination and document baseline measurements of these factors. Additional baseline data include laboratory results related to liver function, kidney function, and complete blood count (CBC).

Life Span and Gender

In general, chloroquine may be administered to children to prevent or treat malaria. However, careful monitoring is needed because of the drug's potential for fatal toxicity in children. Assess the adult female patient for pregnancy or lactation. Breast-feeding women need to know that chloroquine enters breast milk. Although chloroquine is assigned to pregnancy category C, most prescribers believe the benefits of chloroquine therapy outweigh the risks associated with malaria.

TABLE 47.2 Agents That Interact with P Chloroquine

Interactants	Effect and Significance	Nursing Management
aluminum/magnesium antacids	Antacids containing aluminum or magnesium may decrease absorption and therapeutic effect of chloroquine; antacid activity may also be decreased.	Administer doses of chloroquine and antacids containing aluminum or magnesium at least 2 h apart.
cimetidine	Metabolism of chloroquine may be decreased, resulting in elevation of chloroquine serum concentration.	Monitor for possible chloroquine toxicity.
cyclosporine	Chloroquine may inhibit metabolism of cyclosporine, resulting in elevated cyclosporine serum concentration.	Monitor for signs of nephrotoxicity.
methotrexate	Chloroquine reduces the bioavailability of methotrexate.	Monitor for decreased efficacy of methotrexate.
penicillamine	Serum levels of penicillamine may be increased. This may induce hematologic, renal, or skin reactions to penicillamine.	During concurrent use of penicillamine and chloroquine, monitor patient closely for adverse effect to penicillamine. Avoid concurrent use if possible.

Lifestyle, Diet, and Habits

Determine the patient's willingness or ability to arrange activities and lifestyle to accommodate weekly therapy for suppression.

Environment

It is important to ensure that the patient understands the need for prophylactic drug therapy. People traveling to areas where malaria is endemic should begin drug prophylaxis 2 weeks before the trip begins and continue therapy for 4 to 6 weeks after returning. In addition to taking pharmacologic prophylaxis, the patient should implement activities, such as using insect repellent, protective clothing, and netting, that decrease exposure to disease-bearing mosquitoes.

Nursing Diagnoses and Outcomes

- Acute Pain related to headache and itching resulting from drug therapy
  Desired outcome: *The patient will use acetaminophen and take soothing oatmeal baths to relieve drug-related discomforts.*
- Risk for Deficient Fluid Volume related to drug-induced fluid losses from nausea, vomiting, diarrhea, and anorexia
  Desired outcome: *The patient will maintain adequate hydration despite the effects of drug therapy and minimize GI upset by taking the drug with food.*
- Ineffective Protection related to possible agranulocytosis, aplastic anemia, neutropenia, and thrombocytopenia resulting from drug therapy
  Desired outcome: *The patient will report signs and symptoms of blood abnormalities (bruising, unexplained fatigue) to the prescriber immediately.*
- Disturbed Sensory Perception, Auditory and Visual related to potential tinnitus, hearing loss, retinopathy, and blurred vision related to drug therapy
  Desired outcome: *The patient will report problems with hearing or vision to the prescriber immediately.*
- Risk for Injury: Cardiovascular Toxicity, Neuromyopathy, or Seizures related to drug therapy
  Desired outcome: *The patient will remain free of injury throughout therapy with chloroquine.*

Planning and Intervention

Maximizing Therapeutic Effects

The patient taking chloroquine on a weekly basis for prophylaxis should take the drug on the same day each week, usually by mouth. An intramuscular (IM) injection is given when the oral route is not possible. In such situations, the nurse or patient injects the drug into a large muscle mass, making sure to aspirate to avoid hitting a blood vessel. The IM route is unsuitable for children because of the risk for toxic effects. For children, the bitter-tasting tablets may be pulverized and mixed with a pleasantly flavored preparation, such as chocolate syrup or grape jam.

Minimizing Adverse Effects

The patient may take chloroquine with meals to minimize GI discomfort. After taking the drug, the patient may need to change positions slowly to minimize symptoms of dizziness or light-headedness, which signify a hypotensive response. The patient who experiences pruritus (itching) may be soothed by an oatmeal bath because antihistamines are ineffective in such cases. To relieve a headache, the patient may take acetaminophen. Patients with blood dyscrasias or myelosuppression should postpone dental work or other procedures that increase the risk for infection. Patients with these disorders have a higher risk for infection. Double-check pediatric doses to prevent toxicity.

Providing Patient and Family Education

- Teach patients how to take chloroquine to prevent or treat malaria.
- Prophylactic chloroquine therapy should begin about 1 to 2 weeks before entering the malarial area and should continue for 4 to 6 weeks after leaving the area.
- Tell patients to wear cover-up clothing as a barrier to mosquitoes (Box 47.1).
- Explain that if a fever develops within 2 months after a trip to a malarial area, the patient should notify the health care provider immediately.
- Point out potential adverse effects of chloroquine. For example, chloroquine use may discolor urine (red or brown). In addition, itching, nausea, vomiting, dizziness, and headaches may occur. Periodic ophthalmologic and audiometric examinations should be scheduled by patients taking prolonged therapy because the drug can cause vision and hearing problems. Instruct patients to contact the prescriber immediately if fever, sore throat, easy bruising, unusual fatigue, or problems with hearing or eyesight develop.
- Caution patients to avoid alcohol while taking chloroquine.
- Caution patients to notify the prescriber if nausea, vomiting, or diarrhea is persistent.

BOX 47.1 COMMUNITY BASED CONCERNS

Stop Malaria Before It Starts!

- In addition to prophylactic pharmacotherapy instructions, include the following when educating the patient about malaria:
- Be sure to use mosquito netting. Check for holes in the net.
- Always sleep in screened areas. Spray the area with permethrin-containing insecticide before the sun sets.
- Wear protective clothing. Use 30-mL DEET (N,N-diethyl metatoluamide) in 250 mL of water to impregnate cotton garments.
- Minimize nocturnal exposure; long-sleeved clothing and long pants should be worn outdoors after sunset.
- DEET insect repellents should be applied to exposed skin. Refined lemon eucalyptus oil also may be used on the skin but is not as effective.

Ongoing Assessment and Evaluation

Monitor patients taking chloroquine for episodes of misty or foggy vision, difficulty reading and complaints that words tend to disappear, and visual field changes (e.g., seeing half an object, light flashes or streaks, or pigmentation changes). Evaluate the patient's gross hearing, reflexes, and muscle strength throughout therapy. In addition, assess for irritability, excitability, and personality or behavioral changes and signs and symptoms of anemia and hepatic or renal dysfunction. Symptomatic patients or patients at high risk for hemolytic anemia should have periodic blood analyses. Institute seizure precautions as needed.

Drugs Closely Related to P Chloroquine

Hydroxychloroquine

Hydroxychloroquine (Plaquenil Sulfate) is very similar to chloroquine but is less toxic. Although it may be used to treat malaria, it is used more commonly to treat rheumatoid arthritis and lupus erythematosus. Higher dosages are needed for treating rheumatoid arthritis.

The pharmacokinetics and pharmacodynamics of hydroxychloroquine are the same as those of chloroquine, except that it is unknown whether it enters breast milk. Because the drugs are so similar and chloroquine does enter breast milk, the safest course is to refrain from its use in patients who are breast-feeding.

Hydroxychloroquine has the same extensive adverse effect profile as chloroquine. Like chloroquine, the most common adverse effects of hydroxychloroquine affect the GI tract. Patients should take hydroxychloroquine with food to minimize these effects.

Primaquine

Primaquine is an 8-aminoquinoline. It is classified as a tissue schizonticide. The exact mechanism of action is uncertain, although it is believed to interfere with the function of plasmodial DNA. Primaquine is the only tissue schizonticide available for the radical cure of *P. vivax* and *P. ovale* infection (killing dormant plasmodium in the liver). In addition to destroying exoerythrocytic (tissue) forms, primaquine prevents the development of erythrocytic (blood) forms, which cause relapses in *P. vivax* infection. Primaquine also is gametocidal for all four *Plasmodium* species.

Because of its potential toxicity, primaquine is not used as a first-line drug, except in cases of chloroquine-resistant malaria. Toxicity may occur when primaquine is given concurrently with other antimalarial drugs, such as quinacrine.

Primaquine is contraindicated for patients with known sensitivity. Patients with iodoquinol hypersensitivity may have cross-sensitivity to primaquine. Patients must be tested for glucose-6-phosphate dehydrogenase (G6PD) deficiency and have a documented G6PD level in the normal range before using primaquine. Those with pre-existing hematologic conditions secondary to G6PD deficiency are at risk for developing hemolytic anemia and methemoglobinemia.

Symptoms such as dark urine, anorexia, pallor, unusual tiredness or weakness, and back, leg, or abdominal pain may indicate that the patient is developing hemolytic anemia. Bluish fingernails, lips, or skin; dizziness; breathing difficulty; or unusual tiredness or weakness may indicate methemoglobinemia. This adverse effect occurs most frequently with high-dose therapy. If any of these adverse reactions occur, primaquine treatment must be discontinued immediately.

MEMORY CHIP

P Chloroquine

- Used primarily for malaria; secondarily for amebiasis, rheumatoid arthritis, and lupus
- Major contraindications: pre-existing eye diseases
- Most common adverse effects: hypotension, nausea, vomiting, diarrhea, and abdominal pain
- Most serious adverse effects: retinopathy and aplastic anemia
- Maximizing therapeutic effects: Administer medication on the same day each week.
- Minimizing adverse effects: Administer with meals to decrease potential GI effects.
- Most important patient education: Begin prophylaxis 2 weeks before entering any area where malaria is endemic and continue for 4 to 6 weeks after leaving the area.
- **Black box warning: Administer only for treatment of malaria and extraintestinal amebiasis**

Drugs Significantly Different From P Chloroquine

Artemether/lumefantrine

Artemether/lumefantrine (Coartem) is the newest drug approved for the treatment of malaria in the United States. It is approved for treatment of uncomplicated *P. falciparum* disease, but not for prevention. Artemether/lumefantrine is prescribed based on weight and is given over 3 days for a total of 6 doses: an initial dose, second dose after 8 hours, and then twice daily for the following 2 days. It should be administered with food to increase its absorption. Precautions for its use include patients with a history of QT prolongation, or those taking QT-prolongation drugs, and patients taking drugs using the same metabolic pathway (CYP3A4), such as antiretroviral agents. Artemether/lumefantrine should not be given within 1 month of halofantrine treatment. Adverse effects such as headache, anorexia, dizziness, asthenia, arthralgia, and myalgia occur commonly in adults. The most common adverse effects in children are pyrexia, cough, vomiting, anorexia, and headache. It is a pregnancy category C.

Atovaquone/Proguanil

Atovaquone/proguanil (Malarone) is used for the treatment of uncomplicated *P. falciparum* disease. The advantage of atovaquone/proguanil is that it is effective in regions where resistance to other antimalarial drugs has developed. Another

unique feature of atovaquone/proguanil is that it is not metabolized. It is eliminated by biliary excretion.

Atovaquone/proguanil therapy should be started 1 or 2 days before entering a malaria-endemic area and continued daily during the stay and for 7 days after return. It should be taken at the same time each day with food or milk to increase its bioavailability. In the event of vomiting, a repeat dose should be taken within 1 hour of dosing.

Among adults who receive atovaquone/proguanil for the treatment of malaria, adverse effects can include abdominal pain, nausea, vomiting, and headache. Among pediatric patients, vomiting and itching have been reported. This drug combination should not be used in infants less than 11 kg, pregnant women, women breast-feeding infants less than 11 kg, or patients with severe renal impairment (creatinine clearance less than 30 mL/min).

Mefloquine

Mefloquine (Lariam), a 4-quinolinemethanol derivative, is related chemically to quinine. Mefloquine is used for chloroquine-resistant and multidrug-resistant *P. falciparum*. Mefloquine prevents erythrocytic parasites from replicating but has no action on exoerythrocytic parasites. Its mechanism of action is unknown, but it may work by raising intravascular pH in parasite acid vesicles, causing death.

Despite its variable absorption, mefloquine is given orally because it is irritating to tissues. It is distributed widely, crosses the placenta, and may enter breast milk. It is highly bound to plasma proteins and concentrates in blood erythrocytes.

Mefloquine is contraindicated in persons with known hypersensitivity to the drug. It is also contraindicated in patients with seizure disorders, depression, acute anxiety disorder, or other psychiatric disturbances. Mefloquine is contraindicated during pregnancy because it is potentially teratogenic and embryotoxic.

The adverse effects of mefloquine when used in suppressive therapy are GI disturbance, headache, insomnia, abnormal dreams, visual disturbances, and dizziness. Psychiatric symptoms such as acute anxiety, depression, restlessness, or confusion may also occur during prophylaxis, but they are more frequent when the drug is given for acute malaria. When these symptoms occur while the patient is taking mefloquine as prophylaxis, the drug must be discontinued and an alternative drug substituted.

Several important drug–drug interactions can occur with mefloquine. Concurrent use of beta blockers, quinine, or quinidine can result in ECG abnormalities or cardiac arrest. Coadministration with chloroquine or quinine increases the risk of seizure activity. Concurrent use with valproic acid may decrease valproic acid concentrations, resulting in loss of seizure control.

Quinine Sulfate

Quinine sulfate has been used to treat malaria for more than 170 years. In combination with an adjunctive drug, quinine sulfate is the drug of choice for treatment against chloroquine-resistant plasmodia. Quinine is substantially more toxic than chloroquine. It is active against the asexual erythrocytic forms of *Plasmodium*. It does not provide a radical cure for malaria because it is not effective against exoerythrocytic forms of malaria.

Although the exact mechanism of action is unknown, quinine elevates the pH of parasitic acid vesicles and may upset molecular transport and phospholipase activity. Quinine is administered orally and distributes widely into the liver, lungs, kidneys, and spleen, with some distribution into the cerebrospinal fluid (CSF). Although it crosses the placenta and enters breast milk, the American Academy of Pediatrics considers quinine compatible with breast-feeding.

Quinine should not be used in patients with a known allergy to quinidine. Patients with quinidine hypersensitivity may have cross-sensitivity to quinine. Quinine is a pregnancy category X drug. Quinine can cause congenital malformation and has been associated with stillbirths. In addition to the potential effects on the fetus, quinine stimulates the release of insulin and may induce hypoglycemia in pregnant women.

In addition, quinine should be used cautiously in patients with G6PD deficiency, myasthenia gravis, or cardiac arrhythmias. Patients with G6PD deficiency have a higher than usual risk for developing hemolytic anemia. Quinine produces neuromuscular blockade and can exacerbate muscular weakness and cause respiratory distress and dysphagia in myasthenic patients. Patients with cardiac arrhythmias may be at risk for developing quinine-induced dysrhythmias. Patients treated with quinine have shown prolonged Q-T intervals.

Quinine should not be used for patients with optic neuritis or tinnitus because it can exacerbate these conditions. Even at therapeutic dosages, quinine may cause cinchonism (tinnitus, headache, nausea, vertigo, and vision impairment).

Quinine can cause several important drug–drug interactions. High doses of quinine can affect the clearance of digitalis glycosides and require dosage adjustment to avoid digoxin toxicity. Alkalinization of the urine by acetazolamide can decrease the renal clearance of quinine, resulting in an increased risk for toxicity. Conversely, rifampin has been shown to substantially accelerate quinine clearance and reduce its half-life. Higher doses of quinine may be required in patients who are receiving rifampin. Quinine can increase the hypoprothrombinemic (anticoagulant) effects of warfarin. The patient should be closely monitored for signs and symptoms of bleeding. Additionally, the possibility of cinchonism is increased if quinine and quinidine are administered concomitantly. Finally, quinine should not be used concomitantly with mefloquine because additive cardiac effects can produce arrhythmias and seizures.

Quinidine Gluconate

Quinidine gluconate is the only parenteral antimalarial drug in the United States. It is actually an antiarrhythmic drug that also slows or destroys the parasites in the red blood cells. Parenteral therapy is indicated for patients with life-threatening *P. falciparum* malaria who have symptoms such as impaired consciousness, severe normocytic anemia, renal

failure, pulmonary edema, acute respiratory distress syndrome, circulatory shock, disseminated intravascular coagulation, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, generalized seizures, and/or parasitemia more than 5%.

Quinidine gluconate has not been generally used in the United States; newer, less toxic antiarrhythmic drugs have been developed. It is contraindicated for patients with preexisting arrhythmias and myasthenia gravis. Because of the potential for cardiotoxicity, the drug is contraindicated for patients who have received 40 mg/kg of quinine in the preceding 48 hours or those who have received mefloquine within the preceding 12 hours.

Quinidine gluconate is administered in an intensive care setting. Continuous cardiac monitoring, blood pressure monitoring, and glucose monitoring are imperative. It is necessary to watch for hypotension and widening of the QRS complex or lengthening of the QTc interval. When the patient's parasitemia is less than 1% and the patient is able to tolerate oral medication, treatment is completed with oral quinine for 3 days (if exposure occurred in Africa or South America) and 7 days (if exposure occurred in Southeast Asia).

Several potential drug interactions, especially with other drugs that alter cardiac rhythm, are associated with quinidine gluconate.

Antibacterials

Doxycycline, tetracycline, and clindamycin are antibacterial agents used in combination with quinine or quinidine to treat malaria. Doxycycline is also used to prevent malaria in chloroquine-resistant areas. These three drugs are discussed in Chapter 40.

ANTIPROTOZOAN DRUGS

Antiprotozoan drugs are used to treat many human infections, including amebiasis, giardiasis, trichomoniasis, toxoplasmosis, and opportunistic infections such as PCP. The most frequently used drugs are metronidazole, iodoquinol, pentamidine, and atovaquone. Some drugs are effective for many types of infections, whereas others are effective for only one or two types of infections (Box 47.2). Because of an increase in the past decade in protozoan infections in the United States, many new antiprotozoan drugs are being developed. Several drugs are obtainable only from the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia.

• Drugs Affecting Amebiasis, Giardiasis, Trichomoniasis, and Toxoplasmosis

Metronidazole (Flagyl) is the prototype antiprotozoan drug for treating amebiasis, giardiasis, and trichomoniasis. In addition to its antiprotozoan effects, metronidazole has antibacterial effects and is extremely effective against the anaerobic bacteria that cause intra-abdominal infections and *Helicobacter pylori,* which is a cause of peptic ulcer disease. For a summary of selected antiprotozoal drugs, see Table 47.3.

Nursing Management of the Patient Receiving P Metronidazole

Core Drug Knowledge

Pharmacotherapeutics

Metronidazole is a synthetic antibacterial and antiprotozoan drug in a class called nitroimidazoles. As an antiprotozoan drug, it is the drug of choice for the treatment of trichomoniasis, amebiasis, and giardiasis. As an antibacterial drug, it is extremely effective against anaerobic infections. It also is useful in treating Crohn disease, antibiotic-associated diarrhea, and rosacea.

Pharmacokinetics

Metronidazole can be administered orally, intravenously, and topically. About 90% of metronidazole is absorbed orally, with food delaying but not interfering with absorption. Minimal amounts of metronidazole are absorbed systemically when it is used as an intravaginal drug. Both intravenous (IV) and oral metronidazole are distributed widely into most body tissues and fluids, including CSF. Metronidazole is metabolized in the liver and is a substrate of CYP3A4.

Pharmacodynamics

Metronidazole has no direct effects on the human body. It is taken up readily by anaerobic organisms and cells. Its selectivity for anaerobic bacteria results from the ability of these organisms to reduce metronidazole to its active form intracellularly because the electron transport proteins necessary

TABLE 47.3 Summary of Selected Antiprotozoal Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P metronidazole (Flagyl)	Bacterial prophylaxis Anaerobic bacterial infection Amebiasis Giardiasis Trichomoniasis Bacterial vaginosis Antibiotic-associated pseudomembranous colitis	*Adult:* IV, 15 mg/kg 1 h before surgery, then 7.5 mg/kg q6h ×2 *Adult:* IV, 15 mg/kg loading dose followed by 7.5 mg/kg every 6 h for 7–10 d; not to exceed 4 g/d *Child:* PO/IV, 7.5 mg/kg q48h *Adult:* PO, 500–750 mg 3×/d for 7–10 d *Child:* PO/IV, 35–50 mg/kg/d in 3 doses for 5–7 d *Adult:* PO, 250 mg 3×/d for 5–7 d *Child:* PO 15 mg/kg/d in 3 doses for 5-7 d *Adult:* PO, 2 g at one time or 500 mg 2×/d for 7 d *Child:* PO 15/mg/kg/d in 3 doses for 7 d *Adult:* PO, 750 mg extended release daily for 7 d; pregnant females: 500 mg 2×/d or 250 mg 3×/d for 7 d *Adult:* PO, 500 mg 3×/d for 7–14 d *Child:* PO, 30 mg/kg/d, divided, 4×/d for 7–10 d	*Onset:* PO, varies; IV, immediate *Duration:* Unknown $t_{1/2}$: 6–8 h
P pentamidine (NebuPent, Pentam 300)	PCP	*Adult and child*: Inhalational, 300 mg once every 4 wk with Respirgard nebulizer; IM/IV 4 mg/kg once daily for 14 d by deep IM injection or IV infusion over 60 min	*Onset*: Inhalation, rapid; IM, slow *Duration*: 6–8 wk $t_{1/2}$: 6.5–9.5 h
atovaquone (Mepron)	PCP	*Adult*: PO, 750 mg, tid for 21 d	*Onset*: Varies *Duration*: 3–5 d $t_{1/2}$: 2–3 d
iodoquinol (Yodoxin)	Amebiasis	*Adult*: PO, 650 mg tid before meals for 20 d *Child*: PO, 40 mg/kg/d in 3 divided doses before meals for 20 d, not to exceed 1.95 g/d	*Onset*: Minimal absorption *Duration*: Unknown $t_{1/2}$: Unknown
nitazoxanide (Alinia)	Cryptosporidiosis or giardiasis	*Adult*: PO, 500 mg 2×/d for 3 d *Child 1–3 y*: PO, 5 mL oral suspension q12h with food for 3 d *Child 4–11 y*: PO, 10 mL oral suspension q12h with food *Child >12 y*: PO, 500 mg q12h with food or 25 mL oral suspension q12h with food	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: 1–1.6 h
paromomycin (Humatin)	Amebiasis	*Adult and child*: PO, 25–35 mg/kg body weight daily, administered in 3 divided doses with meals, for 5–10 d	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: Unknown
pyrimethamine (Daraprim)	Toxoplasmosis	*Adult*: PO, initially 50–75 mg daily for 1–3 wk, then 25 mg daily for 4–5 wk with 1g of sulfadiazine, q6h *Child*: PO, 1 mg/kg daily in 2 equally divided doses for 2–4 d, then 0.5 mg/kg daily for 4 wk, with 100 mg sulfadiazine daily, divided in 4 doses	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: 4 d
tinidazole (Tindamax)	Trichomoniasis Giardiasis Intestinal amebiasis Amebic liver abscess	*Adult*: PO, 2 g as a single dose *Adult*: PO, 2 g as a single dose *Child >3 y*: PO, 50 mg/kg as a single dose *Adult*: PO, 2 g daily for 3 d *Child >3 y*: PO, 50 mg/kg daily for 3 d *Adult*: PO, 2 g daily for 3–5 d *Child >3 y*: PO, 50 mg/kg daily for 3–5 d	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: 12–14 h
trimetrexate (NeuTrexin)	Moderate to severe PCP not responding to other therapies; **must be given concurrently with leucovorin**	*Adult*: IV, 45 mg/m^2 daily over 60–90 min for 21 d Leucovorin: PO/IV, 20 mg/m2 4×/d; if IV, give over 5–10 min. Continue leucovorin for 3 d after the last dose of trimetrexate.	*Onset*: PO, 3 d; IV, immediate *Duration*: 12 wk $t_{1/2}$: 11–20 h

for this reaction are found only in anaerobic bacteria. Metronidazole acts against anaerobic bacteria by inhibiting DNA synthesis, which causes bacterial cell death.

Contraindications and Precautions

Major precautions are taken when using metronidazole in patients who are alcohol dependent or pregnant. Metronidazole enters fetal circulation rapidly. A theoretical risk remains for the fetus. Most prescribers prefer to postpone using metronidazole, a pregnancy B category drug, until after the first trimester. The drug also enters breast milk.

Because of the capacity for a disulfiram-like interaction (i.e., nausea, vomiting, headache, and chest pain), ingestion of metronidazole and alcohol should be separated by at least 1 day. Patients with hepatic dysfunction should be monitored for toxicity resulting from decreased clearance and possible accumulation of metronidazole. Dosage reduction may be necessary for patients with severe hepatic dysfunction. Because metronidazole can cause leukopenia, the drug should be used with caution in patients with active or previous depression of bone marrow function. Metronidazole carries a black box warning because it has been found to be carcinogenic in rodents.

Adverse Effects

The most common adverse effects of metronidazole are nausea and vomiting, dry mouth (xerostomia), altered sense of taste (dysgeusia), anorexia, and abdominal pain. Other consequences of xerostomia include periodontal disease and dental caries. Some patients report discolored (reddish brown) urine while taking metronidazole.

Other common adverse effects include CNS effects, such as dizziness, light-headedness, and headache. CNS toxicity has occurred and is exhibited as ataxia, mood changes, encephalopathy, or clumsiness. High dosages and prolonged use of metronidazole are associated with peripheral neuropathy and seizures.

As noted previously, patients receiving metronidazole who drink alcoholic beverages may experience disulfiram-like adverse effects. The flavor of alcoholic beverages may be altered as well.

Vaginal candidiasis occurs in some women because metronidazole can suppress natural bacteria, leading to an overgrowth of *Candida* organisms. Candidal overgrowth may also occur in the mouth. Symptoms include glossitis, stomatitis, and furry tongue.

IV metronidazole contains 28 mEq of sodium per gram of metronidazole, which may promote water retention and exacerbate pre-existing chronic heart failure (CHF) or peripheral edema. Oral preparations of the drug do not contain this large amount of sodium and can be used without jeopardy. Thrombophlebitis can occur from administration of IV metronidazole and is characterized as pain, redness, and swelling at the injection site. The potential for this adverse effect can be minimized by avoiding prolonged use of indwelling IV catheters.

Less common potential adverse effects include visual impairment, photophobia, and ocular motility disorders. Rare reports of optic neuritis have occurred. Additionally, using metronidazole may lead to blood dyscrasias and leukopenia. Pancreatitis is another serious, but rare, adverse reaction.

Drug Interactions

Metronidazole interferes with the metabolism of ethanol (alcohol), resulting in disulfiram-like effects, such as nausea, vomiting, and abdominal cramps. Patients taking disulfiram have reported psychotic reactions with concomitant use of metronidazole. Table 47.4 lists additional drugs that interact with metronidazole.

Assessment of Relevant Core Patient Variables

Health Status

Before administering metronidazole, assess the patient for potential medical conditions that contraindicate use or require close monitoring, such as alcoholism, cardiac disease, dental disease, hepatic disease, seizure disorders, and depressed bone marrow function.

Perform a baseline neurologic assessment because metronidazole may cause CNS toxicity or exacerbate peripheral neuropathy and seizure disorders. In addition, a baseline visual acuity assessment may be necessary. Other important assessments include liver function tests, because metronidazole is metabolized in the liver, and a CBC, particularly for patients with a history of depressed bone marrow function or severe anemia. Review the patient's drug history to identify drugs that may interact with metronidazole.

Life Span and Gender

Assess women for possible pregnancy because metronidazole, a pregnancy category B drug, is not recommended in the first trimester. Metronidazole enters breast milk and is not recommended for use in children or infants.

Lifestyle, Diet, and Habits

Determining the patient's typical intake of alcohol is important. Caution patients to refrain from alcohol ingestion for 48 hours after completing metronidazole therapy. They should also be reminded that because many OTC products contain alcohol, they should avoid using them without consulting their health care providers.

Environment

Be aware of the setting in which metronidazole will be administered. Hospitalized patients usually receive metronidazole by IV infusion. Monitor the patient's cardiovascular and respiratory status frequently because IV metronidazole may promote fluid retention, leading to an exacerbation of CHF or peripheral edema. Also, monitor the IV site frequently for signs of thrombophlebitis.

Nursing Diagnoses and Outcomes

- Risk for Deficient Fluid Volume: Anorexia, nausea, vomiting, and diarrhea related to drug administration
  Desired outcome: *The patient will maintain adequate hydration throughout therapy.*
- Risk for Disturbed Sensory Perception: Drug-induced dizziness, vertigo, syncope, and ataxia
  Desired outcome: *The patient will compensate for sensory-perceptual disturbances by moving slowly and carefully to prevent accidents and asking for help with ambulation as needed.*
- Disturbed Thought Processes: Acute confusional state related to potential disulfiram-like interaction
  Desired outcome: *The patient will refrain from alcohol consumption for 48 hours after completing drug therapy.*
- Risk for Injury: Potential teratogenic effects related to drug administration
  Desired outcome: *The patient will act to prevent conception while taking metronidazole.*

Planning and Intervention

Maximizing Therapeutic Effects

To avoid reinfection, patients taking metronidazole for *Trichomonas* infection need to understand that their sexual partners must be treated at the same time. To avoid early cessation of therapy, advise the patient that the drug may discolor the urine and reassure the patient that this discoloration is harmless.

Minimizing Adverse Effects

Because some patients downplay their intake of ethanol or neglect to mention they take disulfiram because of the social stigma attached to alcoholism, emphasize the importance of potential adverse effects resulting from the interaction of ethanol and metronidazole.

To minimize possible GI irritation, metronidazole may be administered with meals. Suggest to patients who experience dry mouth that they may use sugar-free hard candies or ice chips to moisten the mouth. Sugar-containing products

TABLE 47.4 Agents That Interact with P Metronidazole

Interactants	Effect and Significance	Nursing Management
amiodarone	Metronidazole may inhibit metabolism of amiodarone, resulting in increased risk of adverse effects or toxicity.	Monitor for QT interval prolongation and torsade de pointes.
anticoagulants	Hepatic metabolism of anticoagulants may be decreased by metronidazole, resulting in enhanced effects of anticoagulant. This may induce hemorrhage.	Monitor patients more frequently, and teach them to recognize signs and symptoms of bleeding. Notify the prescriber, who may need to prescribe a lower dose of anticoagulant.
barbiturates	Barbiturates may induce faster elimination of metronidazole, resulting in therapeutic failure of metronidazole.	Observe for treatment failure in patients receiving a barbiturate concurrently with metronidazole. Notify the prescriber, who may need to prescribe a higher dose of metronidazole.
busulfan	Coadministration may result in increased serum busulfan level.	Monitor for signs of veno-occlusive disease and hemorrhagic cystitis.
carbamazepine	Metronidazole may inhibit metabolism of carbamazepine, resulting in increased risk of adverse effects or toxicity.	Monitor carbamazepine level. Monitor for signs of toxicity. Monitor CBC, liver and renal status.
cyclosporine	Metronidazole may inhibit metabolism of cyclosporine, resulting in increased risk of adverse effects or toxicity.	Monitor cyclosporine level. Monitor for nephrotoxicity.
disulfiram	Coadministration of disulfiram and metronidazole may result in acute psychosis or confusional state. Mechanism of the interaction is unclear.	Monitor patients closely for signs of confusion or acute psychosis. Discontinue both agents if symptoms occur. Avoid coadministration.
ethanol	Metronidazole can inhibit alcohol dehydrogenase and other alcohol-metabolizing enzymes. This can lead to an accumulation of drug in the blood and the development of disulfiram-like side effects.	Caution patient to avoid ethanol during therapy and 1–2 d after therapy stops.
hydantoins	Metronidazole may inhibit metabolism of hydantoins, resulting in an increased risk of adverse effects or toxicity.	Monitor for signs of hydantoin toxicity.
lithium	Coadministration may result in increased serum lithium level.	Monitor for signs of lithium toxicity.
tacrolimus	Coadministration may result in increased serum tacrolimus level.	Monitor for signs of toxicity or transplant rejection.

tend to promote dental caries in dry mouth, an environment that is already friendly to decay-causing organisms. Infuse IV metronidazole slowly over 1 hour.

Providing Patient and Family Education

- Create teaching plans that focus on explaining the potential adverse effects (such as GI upset, altered taste, discolored urine), adapting to adverse effects (taking drug with meals to relieve GI upset), and identifying which effects to report to the prescriber. For example, candidal overgrowth, ataxia, easy bruising, or bleeding may represent adverse effects that require immediate intervention.
- Discuss the importance of refraining from ethanol or disulfiram use during metronidazole therapy.
- For patients taking metronidazole for giardiasis, stress the importance of treating sex partners simultaneously for trichomonal infections and of having follow-up stool examinations.
- Emphasize the need for birth control measures for women taking metronidazole long-term.

Ongoing Assessment and Evaluation

When administering IV metronidazole, monitor for thrombophlebitis and signs of edema or CHF. When administering oral metronidazole, monitor all patients for signs of oral candidiasis (white spots in the mouth) and women for symptoms of vaginal candidiasis. In addition, monitor for signs and symptoms of peripheral neuropathy (numbness and tingling of the extremities) and CNS toxicity (mood changes and irritability).

For patients on prolonged therapy, arrange for periodic CBCs and liver function tests as well as tests for visual acuity. Remind the patient to schedule frequent dental checkups.

For patients with giardiasis, arrange for testing of three stool specimens, taken several days apart. Three negative stool test results indicate successful metronidazole therapy.

MEMORY CHIP

P Metronidazole

- Used for *Trichomonas vaginalis,* amebiasis, giardiasis, and anaerobic infections
- Major contraindications: alcohol dependency and pregnancy
- Most common adverse effects: nausea, vomiting, xerostomia, and dysgeusia
- Most serious adverse effect: blood dyscrasias
- Maximizing therapeutic effects: Treat both partners at the same time.
- Minimizing adverse effects: Assess alcohol intake closely.
- Most important patient education: Reinforce the need to refrain from alcohol intake during therapy.
- **Black box warning: Carcinogenic in rodents – avoid unnecessary use.**

Drug Closely Related to Metronidazole

Tinidazole (Tindamax) is another nitroimidazole drug with the same indications as metronidazole. The drug has a longer half-life, which means that it may be given less frequently. Adverse effects are similar to metronidazole; however, tinidazole is generally better tolerated.

Tinidazole is also a substrate of CYP3A4 and may interact with drugs that inhibit or induce this substrate. Like metronidazole, tinidazole interacts with alcohol. Advise the patient to refrain from drinking alcohol while taking tinidazole.

Drugs Significantly Different From P Metronidazole

Iodoquinol

Iodoquinol (Yodoxin) is an oral antiprotozoan agent used to treat intestinal amebiasis. It exerts its action directly in the large intestine, although the exact mechanism of this action is unknown. Iodoquinol is active against both the trophozoite and encysted forms of the parasite. It can be used alone in mild cases or in asymptomatic carriers. In more severe cases, it should be used in combination with metronidazole or tinidazole.

Adverse effects associated with iodoquinol include mild GI disturbances, skin disorders, discoloration of hair and nails, thyroid enlargement, fever, chills, headache, vertigo, and malaise. Neurotoxicity may induce optic neuritis, optic atrophy, and peripheral neuropathy.

Protein-bound serum iodine levels may increase during iodoquinol treatment, and therapy may therefore interfere with certain thyroid function tests. These effects may persist for up to 6 months after therapy discontinues.

Nitazoxanide

Nitazoxanide (Alinia) is used to treat diarrhea in adults and children caused by *G. lamblia* or *C. parvum*. These conditions are also sometimes referred to as traveler's diarrhea. The drug has also been shown to be as effective as metronidazole in the treatment of *Clostridium difficile* colitis. Nitazoxanide works by interfering with the pyruvate:ferredoxin oxireductase (PFOR) enzyme-dependent electron transfer reaction that is essential to anaerobic energy metabolism. Nitazoxanide is used cautiously in patients who are immunocompromised and those with liver or kidney disease because it is not known how nitazoxanide will affect these conditions. Common adverse effects are GI distress, headache, and vomiting. The effects, if any, on the developing fetus are unknown. Until more information is available, nitazoxanide should be used during pregnancy only if the maternal condition justifies the potential risk to the fetus. Teach the patient with diabetes to increase the frequency of blood glucose monitoring, because 5 mL of nitazoxanide suspension contains 1.48 g of sucrose. Teach the patient to discard any opened suspension remaining after 7 days.

Paromomycin

Paromomycin (Humatin) is not an antiprotozoan drug; it is an oral aminoglycoside antibiotic with broad-spectrum

antibacterial and amebicidal activity. Paromomycin is used for extraintestinal amebiasis and cestode infestation. It is absorbed poorly from the GI tract and thus is used only for intestinal forms of amebiasis and helminths.

Adverse GI effects of paromomycin include anorexia, nausea, vomiting, gastric burning and pain, abdominal cramps, and diarrhea. Because of its antibacterial action, an overgrowth of nonsusceptible organisms, including fungi, may occur. The only important drug–drug interaction with paromomycin occurs with succinylcholine. When given in combination, paromomycin may potentiate the neuromuscular effects of succinylcholine.

Pyrimethamine

Pyrimethamine (Daraprim) is a folic acid antagonist that blocks the protozoal enzyme dihydrofolic reductase, thereby blocking the parasite's folic acid metabolism. It is used in combination with sulfadiazine for the treatment of toxoplasmosis.

After oral administration, pyrimethamine is distributed mainly into the kidneys, lungs, liver, and spleen, with concentrations in blood erythrocytes. It crosses the placenta and enters breast milk. Metabolism produces several unidentified metabolites that all are excreted in the urine. Urine excretion of this agent can persist for up to 30 days.

Pyrimethamine should be used cautiously in patients with anemia, folate deficiency, and suppressed bone marrow function. It is used cautiously in patients with pre-existing anemia because folic acid antagonism can potentiate anemias, especially megaloblastic anemia. Suppression of bone marrow function may result in myelosuppression, leading to leukopenia, agranulocytosis, or thrombocytopenia. Some clinicians routinely prescribe folic acid when treating toxoplasmosis because higher doses of pyrimethamine are necessary. Routine CBCs are also prudent. High doses of pyrimethamine may precipitate seizures.

In addition, pyrimethamine should be used with extreme caution during the first 14 to 16 weeks of pregnancy. Possible interference with folic acid metabolism could cause birth defects. If its use cannot be avoided, concurrent use of folinic acid is recommended. Use during breast-feeding should be avoided because the drug may interfere with the infant's folic acid metabolism.

Several adverse effects of pyrimethamine may occur. Common GI complaints include anorexia, nausea, vomiting, abdominal pain, and diarrhea. As with other antimalarials, taking the medication with food may decrease these symptoms. Potential dermatologic reactions include urticaria, toxic epidermal necrolysis, exfoliative dermatitis, and Stevens-Johnson syndrome. Pyrimethamine should be discontinued at the first sign of rash. CNS effects include weakness, ataxia, tremor, and, rarely, respiratory failure. In patients with pre-existing seizure disorders, pyrimethamine may precipitate seizures, especially in those on high-dose therapy.

Drug–drug interactions include the potential for the development of blood dyscrasias if pyrimethamine is used with other bone marrow depressants or folate antagonists. Bone marrow function may be more likely to be depressed with sulfonamide combination therapy. Other drugs that can interact with pyrimethamine in this manner include carbamazepine, clozapine, chloramphenicol, phenothiazines, procainamide, antiretroviral agents, antineoplastic agents, or antithyroid agents. Folic acid (vitamin B_9) can interfere with the action of pyrimethamine and therefore should not be used concomitantly with pyrimethamine.

• Drugs Affecting *Pneumocystis jiroveci* Pneumonia

Drugs used to treat PCP include pentamidine isethionate, atovaquone, primaquine, and sulfamethoxazole-trimethoprim (SMZ-TMP). SMZ-TMP, the drug of choice, is not an antiprotozoan drug but an antibiotic (see Chapter 42). Patients at high risk for PCP (low T-cell count or high viral load) and unable to take SMZ-TMP are maintained on a prophylactic dosage of pentamidine, atovaquone, or dapsone. The prototype antiprotozoan drug for prophylaxis and treatment of PCP is pentamidine isethionate (Pentam). Table 47.5 presents an overview of pentamidine.

Nursing Management of the Patient Receiving P Pentamidine Isethionate

Core Drug Knowledge

Pharmacotherapeutics

Historically, pentamidine was used only for trypanosomiasis (African sleeping sickness) and leishmaniasis. Currently, pentamidine is an important therapeutic drug for prophylaxis and treatment of PCP.

Pharmacokinetics

Pentamidine is absorbed readily and binds to body tissues. It is sequestered in the liver and kidneys and eliminated unchanged by the kidneys. Pentamidine can be detected in the urine up to 8 weeks after therapy has ended.

Pharmacodynamics

Pentamidine is administered by inhalation or parenterally. Its mechanism of action is unclear, but it appears to interfere with nucleotide, phospholipid, and protein synthesis of the parasite. It causes local tissue damage when given intramuscularly and is therefore usually given intravenously. For prophylaxis, pentamidine is delivered by inhalation through an aerosol device to the alveoli where *P. carinii* lodges.

Contraindications and Precautions

Pentamidine is contraindicated for use in patients with a history of an anaphylactic reaction to it. However, once the diagnosis of PCP is established, no absolute contraindications apply. The drug is given with caution to patients with asthma; hematologic disorders; cardiac, hepatic, and renal diseases; and diabetes mellitus.

TABLE 47.5 Overview of Pentamidine

pentamidine (NebuPent, Pentam)	Pneumocystis Jiroveci prophylaxis	Adult and child: IV 3–4 mg/kg/d for 21 d Adult and child >5 y: Aerosolized: 300 mg monthly with Respirgard II nebulizer;	Onset: Inhalation, rapid; IM, slow IV: rapid Duration: 6–8 wk $t_{1/2}$: 6.4–9.4 h

Adverse Effects

Sudden severe effects may develop after a single dose of pentamidine. Patients should be lying down and monitored closely during administration. Equipment for emergency resuscitation should be readily available.

The most frequent adverse effects from pentamidine are cough and bronchospasm, especially in patients with asthma. Another frequent adverse reaction to pentamidine is a sudden, severe hypotension.

Thrombocytopenia, leukopenia, and anemia are potential hematologic problems; arrhythmias, tachycardia, torsades de pointes, or other adverse cardiac effects may occur as well. Pentamidine is toxic to pancreatic cells. When receiving IV pentamidine, patients with diabetes mellitus can become acutely hypoglycemic immediately after the infusion. Additionally, pentamidine may precipitate pancreatitis. Pentamidine also can cause elevations in aspartate transaminase (AST), alanine transaminase (ALT), bilirubin, and alkaline phosphatase. Patients with pre-existing hepatic diseases are more vulnerable to these effects. Pentamidine can cause azotemia and acute renal insufficiency as well.

Drug Interactions

Concomitant use of other drugs associated with suppression of bone marrow function, electrolyte imbalance, pancreatitis, or nephrotoxicity may cause additive effects. Pentamidine also may interact with drugs that have similar adverse effects (Table 47.6).

Assessment of Relevant Core Patient Variables

Health Status

Assess for concurrent drug use that is potentially nephrotoxic. Obtain and review baseline measurements. These measurements include vital signs (especially blood pressure), CBC, hepatic and renal function values, and glucose and amylase levels.

Closely monitor administration of aerosolized pentamidine to patients with a history of asthma because the drug may induce bronchospasm and acute asthma.

Lifestyle, Diet, and Habits

It is important to assess lifestyle because patients at risk for PCP and diseases associated with compromised immune function include IV drug abusers, men who have sex with men, and people with multiple sex partners. Immunocompromised patients may be taking multiple drugs, placing them at risk for potential hematologic, renal, and hepatic toxicities. Because pentamidine also may affect these systems, monitor patients closely for adverse effects.

Environment

Note the environment in which pentamidine will be administered. Many patients receive IV or aerosolized pentamidine therapy at home.

Nursing Diagnoses and Outcomes

- Ineffective Protection: Risk for drug-induced leukopenia, thrombocytopenia, and anemia
  Desired outcome: *The patient will report any signs and symptoms of blood abnormalities (i.e., unusual fatigue, fever and infection, and bruising).*
- Risk for Deficient Fluid Volume related to drug-induced nausea, vomiting, and anorexia
  Desired outcome: *The patient will remain adequately hydrated throughout therapy.*
- Risk for Injury: Hypoglycemia, hyperglycemia, or acute renal failure related to drug therapy and bronchospasm, cough, hypotension, or cardiovascular complications related to drug administration
  Desired outcome: *The patient will remain free of injury or complications related to pentamidine administration.*

Planning and Intervention

Maximizing Therapeutic Effects

Protect IV pentamidine from the light and use it within 24 hours of preparation. Do not mix it with other drugs because of incompatibilities, and do not mix it with saline solutions because a precipitate will form. When administering pentamidine by inhalation, give a bronchodilator before treatment to reduce bronchospasm and increase drug effectiveness.

Minimizing Adverse Effects

Administer pentamidine with the patient lying down. Obtain baseline vital signs initially, and monitor them continuously during the infusion and then every 2 hours after the infusion until blood pressure stabilizes. Do not give IM injections to patients receiving pentamidine because the injections may cause bleeding, bruising, or hematomas as a result of thrombocytopenia secondary to pentamidine-induced depression of bone marrow function. Do not administer pentamidine at bedtime because hypoglycemia may occur at a time when the patient cannot respond to the symptoms.

TABLE 47.6 Agents that Interact with P Pentamidine

Interactants	Effect and Significance	Nursing Management
Bone Marrow Suppressants		
antineoplastic agents azathioprine carbamazepine clozapine cotrimoxazole phenothiazines zidovudine	Concomitant use of bone marrow suppressants and pentamidine has the potential to cause additive hemotoxicity.	Monitor for sore throat, easy bruising, or bleeding. Monitor CBC and platelet counts.
Diuretics		
loop diuretics thiazide diuretics	Diuretics and pentamidine can produce similar toxicities.	Monitor for hypokalemia, hypomagnesemia, and pancreatitis. Monitor serum electrolyte and amylase levels.
Drugs That May Cause Nephrotoxicity		
aminoglycosides amphotericin B cyclosporine vancomycin	Drugs associated with nephrotoxicity and pentamidine have the potential for causing additive renal toxicity.	Monitor for nephrotoxicity, hypokalemia, hypomagnesemia, and bone marrow depression.
Drugs That May Cause Pancreatitis		
azathioprine didanosine estrogens furosemide tetracycline valproic acid	Drugs associated with pancreatitis and pentamidine have the potential for causing additive pancreatic toxicity.	Monitor for signs of pancreatitis. Monitor amylase levels.

Take appropriate respiratory precautions to protect health care staff from contact with organisms, such as mycobacteria, that may be aerosolized if the patient coughs.

Providing Patient and Family Education

- Make sure that patients and families understand the therapeutic and adverse effects of pentamidine and the importance of monthly treatments for PCP prophylaxis. In addition, they need to realize that PCP infection is still possible despite pentamidine prophylaxis.
- Urge patients to contact the prescriber if fever or respiratory difficulties occur. Other conditions that necessitate contact with the prescriber include nausea, vomiting, or diarrhea that does not subside; persistent urinary frequency, inability to void, continual hunger and thirst, or unexplained weight loss; and abdominal pain, leg cramps, fever, sore throat, unexplained bruising, or extreme fatigue.
- Emphasize the need for small, frequent meals despite the patients' anorexia.

Ongoing Assessment and Evaluation

For hospitalized patients receiving pentamidine, monitor blood urea nitrogen, serum creatinine, serum calcium, and blood glucose levels; CBC and platelet counts; and liver function test results (including bilirubin, alkaline phosphatase, AST, and ALT levels) on a daily basis. Arrange for the scheduling of ECGs at regular intervals throughout therapy. It is important to measure daily fluid intake and output.

Drugs Significantly Different From Pentamidine

Atovaquone

Oral atovaquone (Mepron) is indicated for the acute treatment of mild to moderate *P. carinii* in patients who are intolerant to cotrimoxazole (SMZ-TMP). Atovaquone is approximately equivalent to IV pentamidine, but less effective than cotrimoxazole, for treating PCP.

Atovaquone is unique among agents used to manage PCP because it can kill *Pneumocystis* organisms rather than merely inhibiting their growth. Besides *Pneumocystis,* atovaquone is active against other protozoans, including *Plasmodium* species, *T. gondii, E. histolytica, T. vaginalis, Leishmania* species, and microsporidia. The antiprotozoan activity of atovaquone is probably related to its ability to selectively inhibit mitochondrial electron transport, leading to inhibition of pyrimidine synthesis.

Atovaquone is absorbed poorly from the GI tract. It is a highly lipophilic compound; thus, administering it with a

MEMORY CHIP

P Pentamidine

- Used for prophylaxis and management of PCP
- Major contraindication: previous anaphylactic reactions to the drug
- Most common adverse effects: cough and bronchospasm
- Most serious adverse effects: cardiac abnormalities, renal failure, and suppression of bone marrow function
- Maximizing therapeutic effects: Protect from light and administer within 24 hours of preparation.
- Minimizing adverse effects: Monitor blood pressure throughout administration.
- Most important patient education: Contact the health care provider if fever or respiratory difficulties occur; PCP may occur despite prophylactic treatment.

fatty meal improves its absorption. Because many patients who are treated with atovaquone have advanced HIV infection, distinguishing adverse effects caused by atovaquone from those caused by underlying medical conditions is often difficult. No life-threatening effects have yet been attributed to atovaquone.

Trimetrexate

Trimetrexate (NeuTrexin) is a parenteral drug used for moderate to severe PCP for immunocompromised patients who are not candidates for SMZ-TMP. Additionally, the agent is an off-label drug for the treatment of colorectal cancer. To avoid serious, life-threatening adverse effects, leucovorin ***must*** be given concurrently with trimetrexate and continued for 3 days after the completion of trimetrexate therapy.

Contraindications to trimetrexate include anemia, a low platelet count, or a low white blood cell count because the drug may cause these adverse effects. It is also contraindicated for patients with mouth or stomach ulcers and liver or kidney dysfunction because it may make these conditions worse.

The most common adverse effects of trimetrexate include abdominal pain or tenderness, black tarry stools, blood in urine or stools, clay-colored stools, dark urine, decreased appetite, fever and sore throat, headache, itching, loss of appetite, nausea and vomiting, pinpoint red spots on skin, skin rash, swelling of feet or lower legs, unusual bleeding or bruising, unusual tiredness or weakness, and jaundice.

Trimetrexate has many drug–drug interactions. Prior to administration, a careful history of current drug therapy is necessary. The patient should be advised to refrain from receiving any vaccines during therapy. During therapy, the CBC, as well as renal and hepatic function tests, should be monitored at least two times a week.

C ANTHELMINTHIC DRUGS

As discussed previously, helminthic infections result from cestodes, nematodes, and trematodes. The most commonly used anthelminthic drugs are mebendazole, albendazole, thiabendazole, niclosamide, pyrantel pamoate, diethylcarbamazine, oxamniquine, and praziquantel. Box 47.3 summarizes which drugs are used to treat the various types of helminths.

Box 47.3 WHICH DRUG FOR WHICH WORM?

	Ascariasis	Enterobiasis	Filarial	Schistosomiasis	Strongyloidiasis	Taeniasis	Trichuriasis	Trichinosis
albendazole	X	X	X		X	X	X	X
diethylcarbamazine			X					
ivermectin	X		X		X		X	
mebendazole	X	X	X				X	X
niclosamide						X		
praziquantel				X		X		
pyrantel		X						

Of all the drugs in the class, the prototype for treating most helminths is mebendazole (Vermox). Mebendazole is indicated to treat infection with cestodes and nematodes, such as pinworm, whipworm, common roundworm, common hookworm, and American hookworm. It also is used to treat enterobiasis. Mebendazole is usually the drug of choice in helminthic infections because mixed infections are common. Table 47.7 presents a summary of selected anthelminthic drugs.

Nursing Management of the Patient Receiving P Mebendazole

Core Drug Knowledge

Pharmacotherapeutics

Mebendazole is an oral, broad-spectrum, synthetic anthelminthic drug. It is particularly effective against susceptible GI nematodes, such as whipworms, pinworms, hookworms, and giant roundworms. Mebendazole is considered a drug of choice for treating infections caused by these nematodes.

Pharmacokinetics

Mebendazole is absorbed minimally from the GI tract because of substantial first-pass metabolism. It is metabolized to an inactive metabolite. Approximately 10% of the drug is excreted unchanged in the urine, and the remainder is excreted in the feces.

Pharmacodynamics

Direct pharmacodynamics occurs in the parasite. Mebendazole is a broad-spectrum anthelminthic, available in chewable tablets. It selectively damages cytoplasmic microtubules in the absorptive and intestinal cells of the helminth but not in those of the host. This microtubular deterioration is irreversible and leads to disruption of absorptive

TABLE 47.7 Summary of Selected Anthelminthic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P mebendazole (Vermox)	ascariasis or trichuriasis infection Enterobiasis Filarial infection Trichinosis infection	*Adult and child: 2:* PO, 100 mg bid for 3 consecutive d or 500 mg once *Adult and child:* PO, 100 mg;; repeat in 2 wk *Adult and child*: PO 100 mg 2× d for 30 d *Adult and child*: PO 200–400 mg 3×/d for 3 d then 400–500 mg/d for 10 d	*Onset:* <2 h *Duration:* 48 h $t_{1/2}$: 3–9 h
albendazole (Albenza)	Pinworm Hookworm, giant roundworm Chinese liver fluke Neurocysticercosis Hydatid disease	*Adult and child*: 400 mg; repeat in 2 wk *Adult and child*: 400 mg once only *Adult and child*: 10 mg/kg for 7 d *Adults >60 kg*: 3 cycles of 400 mg 2×/d for 28 d, with 14 d between cycles *Adults <60 kg*: 15 mg/kg/d, as scheduled above *Adult*: PO, 400 mg 2×/d for 8–30 d	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 8–12 h
diethylcarbamazine (Hetrazan)	Ascariasis Filariasis	*Adult*: PO, 13 mg/kg/d for 7–10 d *Child*: PO, 6–10 mg/kg tid for 7–10 d *Adult*: PO, 6–10 mg/kg tid for 3–4 wk	*Onset*: 1 h *Duration*: Variable $t_{1/2}$: 8 h
ivermectin (Stromectol)	Onchocerciasis Strongyloidiasis Scabies	*Adult and child >15 kg*: PO, 150 mcg/kg 1 h after breakfast *Adult and child >15 kg*: PO, 200 mcg/kg 1 h after breakfast *Adult and child >15 kg*: PO, 150–200 mcg/kg	*Onset*: Well absorbed *Duration*: Unknown $t_{1/2}$: 16–35 h
praziquantel (Biltricide)	Schistosomiasis Clonorchiasis and opisthorchiasis	*Adult*: PO, 60 mg/kg in three equally divided doses as a 1-d treatment, with 4–6 h between doses *Child*: Safety and efficacy not established *Adult*: PO, 75 mg/kg in three equally divided doses as a 1-d treatment *Child*: Safety and efficacy not established	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 0.8–1.5 h
pyrantel pamoate (Antiminth)	Pinworm and roundworm infections	*Adult*: PO, 11 mg/kg as a single dose; maximum dose, 1 g *Child >2 y*: PO, same as adults *Child <2 y*: Safety and efficacy not established	*Onset*: Poorly absorbed *Duration*: Unknown $t_{1/2}$: Unknown
thiabendazole (Mintezol)	Enterobiasis	*Adult <150 lb and child >30 lb*: PO, 10 mg/kg per dose *>150 lb PO, 1.5 g/dose; maximum daily dose, 3 g,* *2 doses/d for 1 d; repeat in 7 d to reduce risk of reinfection*	*Onset*: Rapid *Duration*: 24 h $t_{1/2}$: 1.2 h

and secretory functions of the cells that are essential to the helminth's survival. Efficacy varies, depending on preexisting diarrhea and GI transit time, degree of infection, and helminth strains.

Contraindications and Precautions

Mebendazole is contraindicated in patients with hypersensitivity to the drug, and it is used with caution in patients with inflammatory bowel disease or hepatic disease and during pregnancy, especially during the first trimester. In patients with Crohn disease or ulcerative colitis, drug absorption—and therefore the risk for toxicity—is increased. Mebendazole is metabolized primarily by the liver and can accumulate in patients with hepatic impairment, increasing the risk of adverse effects. Mebendazole is a pregnancy category C drug, and because it is not known whether mebendazole is excreted in breast milk, the drug is used with caution in breast-feeding mothers. It has not been evaluated for use in children younger than 2 years old.

Adverse Effects

Because of its poor absorption, mebendazole rarely causes systemic toxicity, except in patients with diseases that increase absorption of drugs from the bowel. Transient abdominal pain, diarrhea, dizziness, headache, and fever are common. However, these symptoms may result from expulsion of worms rather than from the drug. Other reported adverse effects include blood abnormalities, such as leukopenia, thrombocytopenia, and eosinophilia. Integumentary effects include pruritus, rash, and flushing. In the renal system, hematuria and crystalluria are possible. In addition, mebendazole may elevate liver enzyme levels.

Drug Interactions

Mebendazole may interact with antiepileptic drugs, such as carbamazepine and the hydantoins. Although the mechanism of interaction is unknown, mebendazole's pharmacologic effects may be decreased, resulting in failure to eradicate the helminth. However, no special precautions appear necessary. If an interaction is suspected, dosage may have to be increased.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for medical conditions that contraindicate or require close monitoring during therapy. Additional assessments should be made to prepare for potential drug interactions. Collect helminth specimens to ensure that mebendazole will be therapeutic. A baseline CBC is needed because mebendazole may cause blood abnormalities.

Monitor patients with a history of Crohn disease or ulcerative colitis closely. Patients in whom the bowel lumen is no longer intact may absorb mebendazole in toxic quantities.

Life Span and Gender

Assess for pregnancy and lactation, and determine the age of the patient, before administering mebendazole. Laboratory studies of mebendazole demonstrate birth defects in animals. Therefore, it should not be given during pregnancy. The drug is in pregnancy category C. Because it has not been adequately tested in children younger than 2 years of age, it should not be given to them or to breast-feeding women.

Environment

Evaluate the patient's close contacts because helminthic infections are highly contagious. Ideally, all family members are treated simultaneously, and care is taken to disinfect clothing and bedding.

Nursing Diagnoses and Outcomes

- Acute Pain related to headache, abdominal discomfort, rash, and perianal itching from drug therapy
  Desired outcome: *The patient will adopt measures to help tolerate therapy, including taking acetaminophen for headache, taking with food if GI distress occurs, and applying cream if indicated to sooth perianal itching.*
- Risk for Deficient Fluid Volume related to drug-induced diarrhea
  Desired outcome: *Unless contraindicated, the patient will maintain fluid intake to prevent dehydration.*

Planning and Intervention

Maximizing Therapeutic Effects

If necessary, crush and mix anthelminthic tablets with applesauce or other food. Chewing the drug offers the greatest effectiveness, as does taking the drug with fatty foods, such as milk, cheese, or ice cream. All family members and close patient contacts should be treated at the same time to avoid reinfection.

Minimizing Adverse Effects

Give mebendazole with small, frequent meals if GI distress occurs. Recommend soothing oatmeal baths to relieve pruritus or rash, because antihistamines are not effective. Relaxation techniques or acetaminophen may be used to manage headaches or constant GI distress. Unless contraindicated, increase fluid intake to at least eight 8-oz glasses of fluid daily to minimize the potential for crystalluria.

Providing Patient and Family Education

- Provide information about potential adverse drug effects, such as anemia and other blood problems signaled by sore throat, fever, and fatigue. In addition, stress the importance of contacting the prescriber if serious adverse effects occur. Explain that minor adverse effects, such as itching, may be relieved with oatmeal baths.
- Instruct women of childbearing age to contact the health care provider immediately should pregnancy occur while taking mebendazole.
- Urge patients to follow the instructions of the prescriber; printed directions may be given if appropriate.
- To prevent treatment failure, encourage patients to complete the full course of drug therapy.
- To prevent future infections, urge patients to wear shoes and wash all fruits and vegetables well before eating. Moreover, it is important to teach patients about hygiene (such as laundering infested bed linens and undergarments daily) and other measures that help prevent reinfection.

Ongoing Assessment and Evaluation

Evaluation of nursing care of patients taking mebendazole includes monitoring to ensure that the helminth has been eradicated and for complications of therapy, such as dehydration in instances of severe nausea and vomiting; sore throat, fever, and easy bruising; and hematuria or crystalluria. Ensure that periodic CBC counts and liver function tests are performed in patients at risk for hematologic or hepatic effects and in patients on long-term therapy.

Drugs Closely Related to P Mebendazole

Albendazole

Albendazole (Albenza) is used in the management of multiple parasites. Approved uses include hydatid disease (echinococcosis), *Gnathostoma* infection, and neurocysticercosis (pork tapeworm). Off-label uses include infestations of hookworm, pinworm, roundworm, and Chinese liver fluke.

Adverse effects to albendazole are generally mild. They include nausea, headaches, and fever. More serious potential adverse effects include elevation of liver transaminases and neutropenia. Obtain a baseline CBC and liver function tests, and arrange for periodic repeat laboratory testing throughout therapy.

MEMORY CHIP

P Mebendazole

- Used for management of helminthic infections
- Major contraindication: hypersensitivity
- Most common adverse effects: abdominal pain, diarrhea, dizziness, and headache
- Most serious adverse effect: blood dyscrasias
- Maximizing therapeutic effects: Treat all family members at the same time.
- Minimizing adverse effects: small, frequent meals to decrease GI effects
- Most important patient education: Wash all clothing and bed linens at the same time the whole family is being treated.

Like mebendazole, albendazole is considered teratogenic. Follow the same precautions and patient teaching as for mebendazole.

Thiabendazole

Thiabendazole (Mintezol) is a vermicidal drug related structurally to mebendazole. It has more limited usefulness than mebendazole because of its potential toxicity. The precise mechanism of action is not clear. It inhibits specific enzymes in the helminth and is used to treat pinworm, roundworm, threadworm, and hookworm infections.

Because thiabendazole is better absorbed than mebendazole from the bowel, adverse effects are more common than with mebendazole. It is used with caution in children weighing less than 15 kg, in patients with hepatic or renal dysfunction, and in patients with severe dehydration, malnutrition, or anemia.

Drugs Significantly Different From P Mebendazole

Diethylcarbamazine

Diethylcarbamazine (Hetrazan) is the only drug currently used for suppressing and curing bancroftian and brugian filariasis. It works in two ways. First, it decreases muscular activity in the microfilariae and eventually paralyzes them. Second, it causes changes in the microfilarial surface that make the parasite more susceptible to the host's immune responses.

Common adverse effects include nausea and vomiting, anorexia, and headache. Another reaction, caused by the dying parasite, is characterized by severe itching, papular rash, tachycardia, and intense headache.

Ivermectin

Ivermectin (Stromectol) is an oral drug used in managing onchocerciasis or strongyloidiasis. Although it is not approved to treat lice and scabies, ivermectin has been used successfully to treat these conditions. Ivermectin therapy for ectoparasites is used only when treatment with topical agents fails.

Ivermectin works by binding to glutamate-gated chloride ion channels in muscle and nerve cells of the parasite. This binding results in hyperpolarization of the cell, leading to paralysis and death of the parasite.

The most common adverse effects of ivermectin are pruritus and dizziness. Ivermectin may induce a mild to severe Mazzotti reaction when administered for onchocerciasis. This reaction is an inflammatory response to the death of microfilariae; it does not occur when treating strongyloidiasis. Symptoms include itching, rash, headache, joint pain, swollen lymph nodes, fever, tachycardia, vertigo, and hypotension.

Ivermectin should not be used during pregnancy or by women who breast-feed. It should be given cautiously to patients with severe illness such as hepatic, cardiovascular, renal, or pulmonary diseases.

Pyrantel

Like mebendazole, pyrantel pamoate (Antiminth) is used to treat pinworm and roundworm infections. Unlike mebendazole, pyrantel pamoate exhibits a selective depolarizing neuromuscular blocking action that causes spastic paralysis of worms.

Pyrantel is administered as an oral suspension that is absorbed poorly from the GI tract. Because of its poor absorption, it is well tolerated by patients older than 2 years. It is metabolized in the liver and excreted mainly in feces and secondarily in urine.

Pyrantel is used with caution in patients who have liver dysfunction, anemia, or both and in patients who are malnourished or dehydrated. Its safety has not been proved during pregnancy or for children younger than 2 years of age. Pyrantel and piperazine are mutually antagonistic and should not be given together because each blocks the other's activity.

Praziquantel

Praziquantel (Biltricide) is used in treating infection with schistosomes: flukes and tapeworms. It increases the helminths' permeability to calcium, thereby causing contracture and paralysis of the helminth.

Adverse effects are minimal; the most common include malaise, headache, dizziness, and abdominal discomfort. Patients should be warned not to drive a car or operate machinery on the day of treatment and the day after. Praziquantel did not exhibit mutagenicity, carcinogenicity, or teratogenicity in animal trials. However, prescribers advise breast-feeding women to refrain from nursing on the day of treatment and for 72 hours thereafter.

C ANTIECTOPARASITIC DRUGS

Antiectoparasitic drugs include permethrin, lindane, crotamiton, malathion,pyrethrins plus piperonyl butoxide and benzyl alcohol 5%. These are topical drugs with local action. Although they can eradicate the parasite, they have minimal effect on the pruritus that frequently accompanies ectoparasitic infections. Resistance is problematic with all of the topical drugs, even those that require a prescription. The use of

TABLE 47.8 Summary of Selected C Antiectoparasitic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P permethrin (Elimite, Nix)	Scabies Pediculosis	*Adult and child:* Topical cream, apply to clean, dry skin from the neck to the toes and rub in well; leave on skin for 8–12 h; wash skin well. *Adult and child:* Topical lotion, apply to the affected site and leave on for 10 min; rinse thoroughly.	*Onset:* 10 min *Duration:* Unknown $t_{1/2}$: 16 h
crotamiton (Eurax)	Scabies	*Adult*: Apply 10% preparation to the affected skin. Massage gently into skin until completely absorbed. Repeat as needed.	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: Unknown
lindane (Kwell, Scabene)	Scabies and pediculosis	*Adult and child*: Topical cream, apply to clean, dry skin from the neck to the toes and rub in well; leave on skin for 8–12 h; wash skin well. *Adult and child*: Topical shampoo, wash and dry the hair and allow to cool; apply shampoo to dry hair and rub into scalp;allow shampoo to remain in place for 4 min; use enough water to work up a good lather; rinse thoroughly and towel dry; use a fine-toothed comb when hair is thoroughly dry.	*Onset*: Rapid *Duration*: 3 h $t_{1/2}$: 18 h
malathion (Ovide)	Pediculosis	*Adult and child >6 y*: Apply approximately 30 mL and leave in place for 8–12 h; rinse thoroughly.	*Onset*: Rapid *Duration*: 2 d–2 wk $t_{1/2}$: 8–48 h

hot air (Louse Buster) is a nonchemical, effective treatment for lice and has the added benefit that lice cannot become resistant to it. However, this is a pharmacology text, and permethrin will be discussed as the prototype antiectoparasitic drug. Table 47.8 presents a summary of selected antiectoparasitic drugs.

Nursing Management of the Patient Receiving P Permethrin

Core Drug Knowledge

Pharmacotherapeutics

Permethrin is a topical scabicide and pediculicide. For lice, it is available OTC as a 1% cream (Nix). Scabies should be treated with the 5% prescription cream (Elimite).

Pharmacokinetics

Permethrin is applied topically. A small amount may be systemically absorbed, especially from abraded or denuded skin. It is excreted as inactive metabolites through the kidneys.

Pharmacodynamics

Direct effects of permethrin occur in the parasite. Permethrin disrupts the parasite's nerve cell membrane, resulting in paralysis and death. Permethrin also exhibits residual ovicidal activity for approximately 2 days. Generally, 70% to 80% of eggs are eradicated after one application.

Contraindications and Precautions

Permethrin should not be used in patients who have had previous hypersensitivity reactions to household insecticides because it contains similar substances. It is a pregnancy category B drug.

Adverse Effects

Common adverse effects include burning, itching, numbness, rash, redness, stinging, swelling, or tingling of the scalp. Pruritus, edema, and erythema caused by the parasite can be exacerbated during therapy. Inhaling substantial quantities of permethrin can aggravate bronchial asthma.

Drug Interactions

No drug–drug interactions are known to occur with permethrin.

Assessment of Relevant Core Patient Variables

Health Status

Evaluate the extent of infection. Lice that are visible in the eyebrows or eyelashes should not be treated by the patient at home.

Life Span and Gender

Permethrin is not approved for use in children younger than 2 years of age. Whether this pregnancy category B drug enters breast milk is unknown; however, the American Academy of Pediatrics recommends discontinuing breastfeeding during therapy.

Lifestyle, Diet, and Habits

Determine the patient's use of creams, ointments, or oils. Caution the patient not to use them during permethrin therapy.

Environment

Because permethrin is routinely used at home, the patient needs to clearly understand how to use the drug properly. Explain that the infection may take up to 2 weeks to resolve.

CRITICAL THINKING SCENARIO

HOME CARE CONCERNS IN ANTIECTOPARASITIC THERAPY

After treatment and recovery from status epilepticus, your patient, J. Colone, is discharged home on phenytoin (Dilantin) therapy. One of your assignments as a student nurse is to accompany the visiting nurse who will visit with Mr. Colone to assess his progress. When you arrive, you are surprised to learn that the whole family is being treated for head lice. Examine your concerns about Mr. Colone's current situation. In addition to teaching him about drug therapy, what other points will you emphasize in the teaching plan? What is especially important for Mr. Colone to know?

Nursing Diagnosis and Outcome

- Risk for Impaired Skin Integrity: Rash and pruritus related to drug therapy
  Desired outcome: *The patient will self-medicate with OTC diphenhydramine.*

Planning and Intervention

Maximizing Therapeutic Effects

Permethrin is for external use only, and encourage the patient to use it exactly according to directions. Prior to application, wash the hair with a nonconditioning shampoo. Apply the cream to the scalp and leave in place for 10 minutes. Rinse thoroughly with cool water. Because head louse eggs hatch in 5 to 11 days, apply a second treatment in 10 days.

Minimizing Adverse Effects

Tell the patient to follow the directions for using permethrin carefully to avoid potential adverse effects. Keep the drug out of the reach of children, who may ingest it accidentally.

Providing Patient and Family Education

- Emphasize the potential adverse effects of permethrin and the importance of contacting the provider should any such effects occur.
- Provide directions for using permethrin correctly. It is important to cover the following teaching points for use with scabies:
- Thoroughly wash and dry the skin.
- Massage the cream into the skin from the head to the soles of the feet, paying special attention to creases in the skin, hands, feet, underarms, and groin, and between fingers and toes.
- Scabies rarely infests the scalp of adults, although the hairline, neck, side of the head, and forehead may be infested in older people and in infants. Treat infants on the scalp, side of the head, and forehead.
- Leave the permethrin cream on the skin for 8 to 14 hours.
- Wash off by taking a shower.
- Change into clean clothes.
- It is important to cover the following teaching points for treatment against lice:
- Shampoo the hair and scalp using a nonconditioning shampoo.
- Rinse thoroughly and towel-dry the hair and scalp.
- Allow hair to air-dry for a few minutes.
- Shake the permethrin lotion well before applying.
- Wet the hair and scalp thoroughly with the permethrin lotion. Be sure to cover the areas behind the ears and on the back of the neck also. Allow the lotion to remain in place for 10 minutes.
- Rinse the hair and scalp thoroughly with cool water and dry with a clean towel.
- Remove nits only after the hair is completely dry.
- Instruct the patient how to eliminate nits (tiny, white, oval-shaped eggs of the adult louse, which lodge on hair close to the scalp):
- Buy a good metal lice or nit comb.
- Choose a well-lit area in the home to use as a lice-picking station.
- Comb through the hair a section at a time, using metal clips to divide sections—and a magnifying glass if one is handy.
- Remove lice and nits from the comb with a tissue after each stroke, or rinse the comb in sudsy hot water between strokes.
- Continue combing for at least 30 strokes or until the scalp and hair are nit free. Hand-pick any remaining nits.
- Repeat the procedure in 10 days.
- Additional information to reduce the potential for reinfection includes:
- Machine wash all clothing (including hats, scarves, and coats), bedding, towels, and washcloths in very hot water and dry them by using the hot cycle of a dryer for at least 20 minutes. Clothing or bedding that cannot be washed should be dry cleaned or sealed in an airtight plastic bag for 2 weeks.
- Shampoo all wigs and hairpieces.
- Wash all hairbrushes and combs in very hot soapy water (above 130°F) for 5 to 10 minutes and do not share them with other people.
- Clean the house or room by thoroughly vacuuming upholstered furniture, rugs, and floors.
- Wash all toys in very hot soapy water (above 130°F) for 5 to 10 minutes.
- Place all stuffed animals in sealed plastic bags for about a month. (Lice live only about 25 days.)

Ongoing Assessment and Evaluation

After-treatment evaluations consist of monitoring for signs of successful treatment (eradication) or failure (reinfection).

Drugs Closely Related to P Permethrin

Benzyl Alcohol

Benzyl alcohol 5% lotion is the newest drug approved by the FDA for the treatment of lice. It has a unique mechanism of action. Lice breathe though a system of spiracles that close

MEMORY CHIP

P Permethrin

- Used for scabies and pediculosis
- Major contraindications: hypersensitivity to household insecticides
- Most common adverse effects: skin irritation and pruritus
- Maximizing therapeutic effects: Apply only as directed.
- Minimizing adverse effects: Keep out of reach of children.
- Most important patient education: To minimize the risk for systemic absorption, do not leave on the scalp or body for longer than the recommended time.

upon contact with most liquids. This allows the lice to go into "suspended animation" and survive for hours without respiration. Benzyl alcohol prevents lice from closing their spiracles, thereby asphyxiating them within ten minutes. Adverse effects include itching, redness, or irritation. Advise the patient to ensure an adequate amount of lotion to completely cover the affected area and leave in place for 10 minutes. A second treatment is done 1 week later.

Crotamiton

Crotamiton (Eurax) is a prescription scabicidal and antipruritic drug used for treating *S. scabiei* (scabies) and relieving pruritus. The drug can be used with caution during pregnancy, and the only contraindication to its use is hypersensitivity. Pediatric safety has not been established. Crotamiton should not be applied in the eyes or around the mouth because it may cause irritation. It should not be applied to acutely inflamed skin or raw or weeping surfaces until the acute inflammation resolves. The only potential adverse reaction is rash.

Crotamiton should be applied from the chin to the toes after taking a routine bath or shower. A second application is advisable 24 hours later. A cleansing bath should be taken 48 hours after the last application. Clothing and bed linens should be changed the second day. Contaminated clothing and bed linen may be dry cleaned or washed in very hot water.

Lindane

Lindane (Kwell) is is highly effective; however, its use is highly controversial. In fact, many states have banned it as a pharmaceutical because of its potential for neurotoxicity.

In March 2003, the Food and Drug Administration (FDA) approved a Black Box warning stating that lindane be used only in patients who cannot tolerate first-line treatment with safer medications to treat lice or scabies infestation or in whom such treatment has failed. Lindane is contraindicated for patients with known seizure disorders and for individuals with known hypersensitivity. CNS toxicity may precipitate seizures. Lindane should not be used where skin rash, abrasion, or inflammation exists because such use can enhance systemic absorption and increase the possibility of CNS toxicity. Lindane also is contraindicated for children younger than 2 years of age, who have more permeable skin than adults do, and may therefore be at high risk for systemic absorption and resultant neurotoxicity. Caution should be used in administering this drug to children between 2 and 10 years of age, because the risk for toxicity is greater in this age group than in others.

Lindane is a pregnancy category C drug. It is not recommended for use while breast-feeding because it is secreted into breast milk. An alternative form of infant feeding should be used for at least 2 days after using lindane.

Malathion

Malathion (Ovide) is an organophosphate insecticide commonly known to the public as an aerosolized insecticide that is sprayed over vegetation. It was originally approved by the FDA in 1989, then removed from the market, and then reintroduced in 1999. It is used to manage human lice infections that are resistant to permethrin, although many providers feel it should be the first-line treatment.

Malathion works by enabling acetylcholine to overstimulate cholinergic receptor sites, which leads to rapid insect death. It is not recommended for children under the age of 6 years and is contraindicated for use in infants because their scalp is more permeable and allows more absorption. The topical formulation contains isopropyl alcohol, making it flammable. For that reason, it should not be used in proximity to any heat source, such as electric rollers, curling irons, and especially cigarettes, pipes, lighters, matches, and other smoking-related items.

If ingested, malathion is a poison. The most serious symptom of organophosphate poisoning is respiratory distress, including potential respiratory arrest. Other respiratory symptoms include rhinorrhea, chest tightness, and wheezing. In addition to affecting the respiratory system, organophosphate poisoning can induce gastrointestinal peristalsis, diarrhea or fecal incontinence, and abdominal pain or cramps. It can also cause miosis, loss of ocular accommodation, blurred vision, and ocular pain. In the cardiovascular system, potential symptoms include bradycardia or hypotension. CNS symptoms include confusion, drowsiness or lethargy, and seizures. The patient may also experience weakness or muscle paralysis. Atropine and pralidoxime are the antidotes to organophosphate poisoning.

Malathion is a pregnancy category B drug; whether it is excreted into breast milk is unknown.

Pyrethrins Plus Piperonyl Butoxide

Pyrethrins plus piperonyl butoxide (Rid) constitute an OTC medication for treating both lice and scabies. It is available in liquid, gel, and shampoo forms. Pyrethrins are absorbed through the exoskeletons of arthropods and block nerve impulse transmissions from the parasite's nervous system, resulting in its paralysis and death. Piperonyl butoxide has little or no insecticidal activity but inhibits the enzymes responsible for metabolism of pyrethrins in arthropods; this increases the insecticidal activity of pyrethrins by 2 to 12 times.

Patients should be instructed to use enough medication to cover the affected hairy area and adjacent areas and to wash the

medication off their hands after application. The medication is left on the affected area for exactly 10 minutes, and then the area should be washed with warm water and soap or regular shampoo. The drug should not be used near the eyes, mouth, nose, or vagina. If accidental contact with the eyes occurs, patients should thoroughly rinse the eyes for at least 5 minutes.

Pyrethrins plus piperonyl butoxide are contraindicated for patients who are allergic to either ragweed or chrysanthemums. Pyrethrin is a pregnancy category C drug. Piperonyl butoxide's pregnancy category is unknown.

CHAPTER SUMMARY

- Parasites include protozoa, helminths, and arthropods.
- Helminths include cestodes, nematodes, and trematodes.
- Arthropods include ectoparasites, such as scabies and lice.
- Pharmacologic intervention for parasites must be specific not only to the type of parasite but also to the stage of its life cycle.
- Chloroquine is the prototypical antimalarial drug. Additional drugs used in treating malaria include hydroxychloroquine, mefloquine, primaquine, atovaquone/proguanil, pyrimethamine/sulfadoxine, and quinine.
- Metronidazole is the prototypical antiparasitic drug. Additional antiprotozoan drugs include tinidazole, iodoquinol, paromomycin, and pyrimethamine.
- PCP occurs most often in immunocompromised patients. Drug treatment for PCP includes pentamidine, atovaquone, trimetrexate, and SMZ-TMP.
- Mebendazole is the prototypical anthelminthic drug. However, the choice of anthelminthic therapy depends on the type of helminth. Other anthelminthic drugs include albendazole, thiabendazole, pyrantel, diethylcarbamazine, and praziquantel.
- Permethrin is the prototypical antiectoparasitic drug. Drugs closely related to permethrin include benzyl alcohol, crotamiton, lindane, malathion, and pyrethrins plus piperonyl butoxide.

QUESTIONS FOR STUDY AND REVIEW

1. Why should patients who undergo chloroquine therapy continue to have their eyes examined after completing therapy?
2. Why is chloroquine used cautiously in children?
3. What baseline evaluations should be done for a patient on long-term antimalarial therapy?
4. Why would a patient with alcoholism need to be monitored closely during antiparasitic therapy?
5. Why should you take respiratory protective measures during the administration of inhaled pentamidine?
6. How can you intervene to minimize potential severe adverse effects from the administration of pentamidine?
7. Why is mebendazole contraindicated for women who are pregnant?

UNIT 11
Endocrine Drugs

48

Drugs Affecting Corticosteroid Levels

Learning Objectives

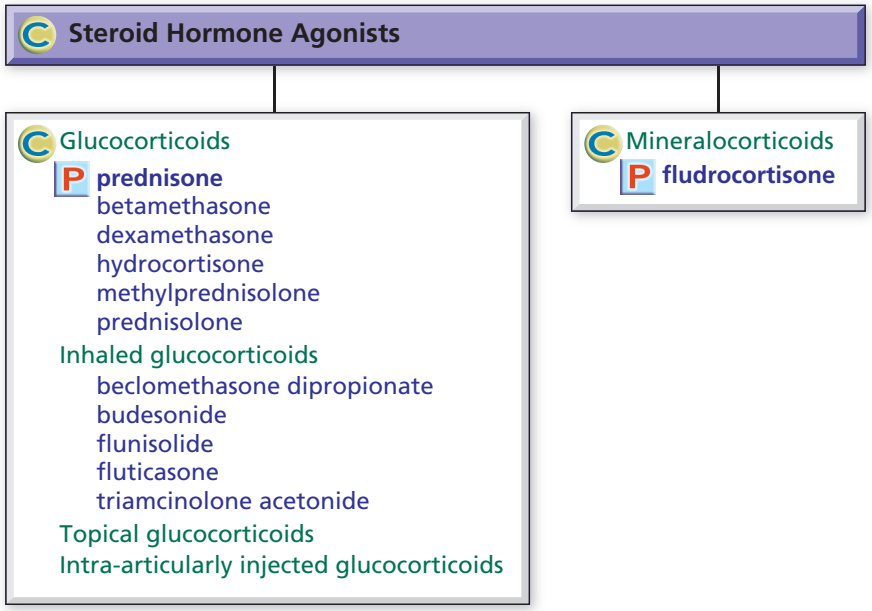
At the completion of this chapter the student will:

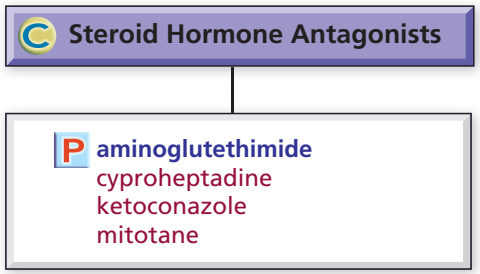
1. Describe the physiologic effects of and clinical indications for mineralocorticoids and glucocorticoids.
2. Discuss complications associated with glucocorticoids.
3. Discuss nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect corticosteroid hormone levels and have anti-inflammatory action.
4. Describe the most frequently encountered adverse effects associated with the glucocorticoids and mineralocorticoids.
5. Identify dosing strategies that may minimize glucocorticoid-related adverse effects.
6. Determine key points for patient and family education for drugs that affect corticosteroid hormone levels and have anti-inflammatory action.
7. Discuss the clinical indications of drugs referred to as steroid hormone antagonists.

Key Terms

Addison disease
addisonian crisis
adrenal insufficiency
aldosterone
cortisol
Cushing syndrome
glucocorticoid
hyperaldosteronism
mineralocorticoid
salt-losing adrenogenital syndrome
steroid hormone inhibitors

Drugs Affecting Corticosteroid Levels





The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Synthetic corticosteroids are used for replacement therapy to maintain adequate levels of hormones in patients with inadequate adrenal function and diminished natural corticosteroid production. Corticosteroids are also used for their anti-inflammatory properties by reducing irritation and swelling; antiallergenic by minimizing and or preventing the body's response to allergens; and immunosuppressive effects by decreasing the body's harmful response to diseases that affect the immune system (Box 48.1).

The benefits derived from chronic use of corticosteroids, also known as steroids in lay terminology, are often accompanied by a number of risks (adverse effects). Corticosteroid complications vary from mild to life threatening and are a function of the dosage, route of administration, and duration of therapy and results from the body's altered natural endogenous production of corticosteroid during the course of receiving exogenous corticosteroid therapy. With this in mind, the benefit–risk of corticosteroid therapy requires careful deliberation. Furthermore, the use of the smallest dose, the shortest treatment duration, and as necessary, gradual dose tapering prior to its discontinuance are important considerations.

Box 48.1 THERAPEUTIC USES FOR THE CORTICOSTEROIDS

Glucocorticoid and Mineralocorticoid Effects at Physiologic Doses

Adrenocortical insufficiency
Adrenogenital syndrome (salt-losing)

Glucocorticoid Effects at Supraphysiologic (Pharmacologic) Doses

Acute allergic conditions (e.g., bronchial asthma, serum sickness)
Acute spinal injury
Cerebral edema
Collagen diseases, rheumatic disorders (e.g., systemic lupus erythematosus, acute rheumatic carditis)
Dermatologic diseases (e.g., seborrheic dermatitis, severe psoriasis)
Gastrointestinal diseases (e.g., Crohn disease, intractable sprue, ulcerative colitis)
Hematologic disorders (e.g., autoimmune hemolytic anemia, thrombocytopenia)
Hepatic diseases (e.g., liver cirrhosis with ascites)
Joint inflammation (e.g., bursitis)
Meningitis
Neoplastic diseases (e.g., leukemias, lymphomas)
Nephrotic syndrome
Ocular disorders (e.g., allergic conjunctivitis, chorioretinitis, iritis, keratitis)
Organ transplantations
Respiratory diseases (e.g., interstitial pulmonary fibrosis, pulmonary emphysema with bronchial edema)
Thyroiditis

PHYSIOLOGY

The hormones of the endocrine system are important messengers in the communication between cells. The nervous system, adrenal glands, and other endocrine glands contribute to homeostasis, thus allowing physical and emotional adaptation to internal and external changes.

There are two adrenal glands, one at the top of each kidney. Each gland is composed of two distinct parts—the medulla and the cortex.

The medulla and cortex are crucial to metabolism, the body's stress response, and fluid and electrolyte balances. The adrenal medulla synthesizes and secretes catecholamines—epinephrine and norepinephrine. These hormones are important in counteracting short-term stress.

The adrenal cortex is involved primarily in the synthesis and secretion of **glucocorticoids** and **mineralocorticoids** (collectively referred to as the corticosteroids or corticoids) from plasma-derived, low-density lipoproteins and high-density lipoproteins (cholesterol). Corticosteroids are characterized by mineralocorticoid and glucocorticoid effects, depending on the predominant pharmacologic action of the agent. Adrenal corticosteroids exert effects on almost every organ in the body. Their pharmacologic actions are generally an extension of their physiologic effects. Their primary actions include carbohydrate, protein, and fat metabolism; electrolyte and water metabolism; cardiovascular functions; and immune effects. The zona reticularis region of the adrenal cortex produces and secretes other steroid hormones, including adrenal androgens, progesterone, and the estrogens.

Glucocorticoids

The glucocorticoids acquired their name from their role in glucose metabolism; they increase blood glucose concentrations by:

- Stimulating gluconeogenesis and glucose secretion by the liver
- Increasing the hepatic sensitivity to the gluconeogenic actions of glucagon and catecholamines
- Decreasing glucose uptake and utilization by peripheral tissue
- Increasing proteolysis and decreasing protein synthesis in muscles to support the gluconeogenesis activities

Glucocorticoids exert potent and diverse actions on glucose, protein, and bone metabolism and possess anti-inflammatory, antiallergenic, and immunosuppressant actions. Metabolic effects of glucocorticoids include gluconeogenesis, mobilization of amino acids from protein in striated muscle, protein catabolism, fat synthesis and lipolysis, and hepatic enzymatic activities that convert amino acids to glucose, with most of the excess glucose stored in the liver as glycogen. The metabolic effects of the glucocorticoids result in the following:

- An increase in circulating amino acid levels
- An overall depletion of muscle protein
- A negative nitrogen balance
- A mobilization of fatty acids, converting cell metabolism from using glucose for energy to using fatty acids for energy

Other physiologic effects of the glucocorticoids include:

- An antagonistic effect on antidiuretic hormones to maintain water balance
- A lowering of the threshold for electrical excitation in the brain
- A reduction in the amount of new bone synthesis

In addition, glucocorticoids have actions that allow the body to cope effectively with physiologic or psychological stress (e.g., overwhelming illness or trauma). For example, the natural glucocorticoid **cortisol** sensitizes the arterioles to norepinephrine for vasopressor effects and allows epinephrine and glucagon to activate gluconeogenesis and glycogenolysis.

Hypothalamic corticotropin-releasing factor (CRF) stimulates the release of pituitary adrenocorticotropic hormone (ACTH). The hypothalamic-pituitary-adrenal (HPA) axis regulates and stimulates cortisol synthesis release by the adrenal cortex. Each of these substances is regulated by a complex feedback loop because the production of each substance is regulated by the plasma concentrations of the other two. Glucocorticoid, androgen, and estrogen secretion depend on adrenocortical stimulation by ACTH from the anterior pituitary. CRF controls ACTH release into the bloodstream (Figure 48.1).

Three factors are important in regulating ACTH secretion:

- Circulating cortisol levels
- Stress levels
- Circadian (diurnal) rhythms

Pituitary production of ACTH is very sensitive to suppression by exogenous glucocorticoids. Long-term or chronic administration may result in adrenocortical atrophy and its subsequent reduction in the secretory ability to produce these hormones.

Mineralocorticoids

The mineralocorticoids (**aldosterone** is the most prevalent naturally occurring mineralocorticoid) exert a major influence on regulating potassium, sodium, and water balance. Mineralocorticoids are produced in the outer layer of cells of the adrenal cortex (zona glomerulosa). Numerous systemic factors affect the synthesis and secretion of aldosterone. Angiotensin II is the most potent of these factors. In the distal renal tubules, aldosterone promotes the reabsorption of sodium into the blood in exchange for potassium secreted into the renal tubules for urinary excretion.

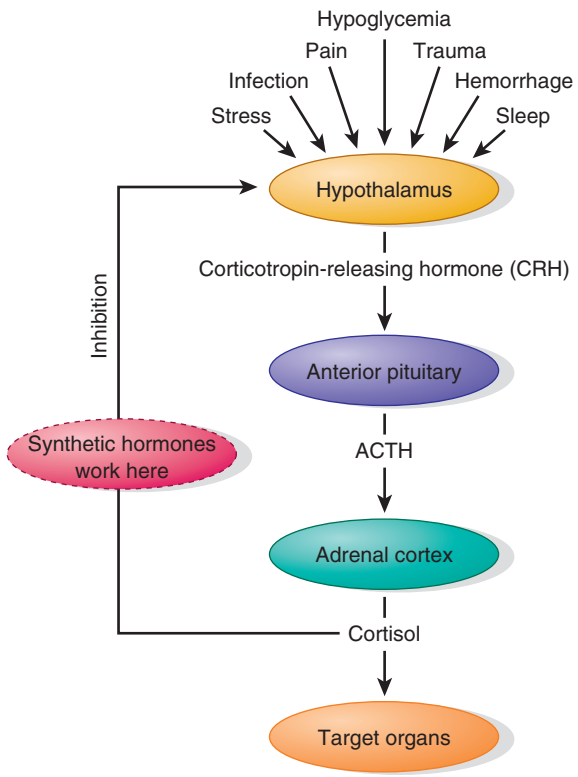
Several mechanisms control aldosterone levels:

- Extracellular sodium and potassium levels—when serum sodium levels are low or potassium levels are high, aldosterone levels rise.
- Renal renin release—a reduction in renal blood flow increases aldosterone levels by the renin-angiotensin-aldosterone system.
- Pituitary ACTH—the glucocorticoid hormones produced in the adrenal cortex have mineralocorticoid effects.

Sex Steroids

The adrenal cortex produces small amounts of sex steroids (e.g., testosterone and estrogens) and some weak anabolic androgens (e.g., dehydroepiandrosterone and androstenedione). These hormones are produced by the adrenal glands in males and females. The amounts are usually insignificant compared with the hormone amounts secreted by the gonads. However, under certain conditions (e.g., tumors, cushingoid effects), their excess may cause a substantial endocrine imbalance. These gonadal hormones are discussed in depth in Chapters 53 and 54.

PHYSIOLOGY



• FIGURE 48.1 The hypothalamic-pituitary-adrenal (HPA) feedback system regulates and stimulates cortisol synthesis and release by the adrenal cortex. Each hormone in the HPA axis is influenced by a complex feedback loop because synthesis of one substance is regulated by plasma concentrations of the others. For instance, secretion of glucocorticoid, androgen, and estrogen depends on adrenocortical stimulation by adrenocorticotropic hormone (ACTH) from the anterior pituitary. Corticotropin-releasing factor, produced by the hypothalamus, controls ACTH release into the bloodstream. Circulating cortisol levels, stress, and circadian rhythms are also important in regulating ACTH secretion. ACTH in turn regulates cortisol release. The objectives of replacement and pharmacologic drug therapy involve maintaining balance in the HPA feedback system.

PATHOPHYSIOLOGY

Adrenal Insufficiency

There are two forms of **adrenal insufficiency**—primary and secondary. Primary adrenal insufficiency (**Addison disease**) results from the destruction of the adrenal cortex caused by infection or hemorrhage, which results in hyposecretion of all adrenocortical hormones—most importantly, the glucocorticoid *cortisol* and the mineralocorticoid *aldosterone*.

Characteristics of Addison disease include those related to glucocorticoid deficiency, such as hypoglycemia, anorexia, nausea, vomiting, flatulence, diarrhea, hyperpigmentation of skin, anxiety, depression, and loss of mental acuity; and those related to mineralocorticoid deficiency, such as fluid and electrolyte imbalance, orthostatic hypotension, hyponatremia, hyperkalemia, general malaise, muscle weakness, muscle pain, and cardiac arrhythmias.

The major complication of Addison disease is a sudden, life-threatening exacerbation called **addisonian crisis** (adrenal crisis). The patient experiences severe hypotension, hyponatremia, dehydration, hyperkalemia, and hyperthermia in the absence of another cause. A stressor is often the trigger for an addisonian crisis. These physiologic responses are initially treated with standard resuscitative therapy (e.g., vasopressors, plasma expanders). When the source of these symptoms is adrenal hypofunction, the treatment includes immediate replacement of adrenocortical hormone (e.g., intravenous [IV] hydrocortisone [Solu-Cortef]), salt, and fluids to restore normal blood volume and blood pressure.

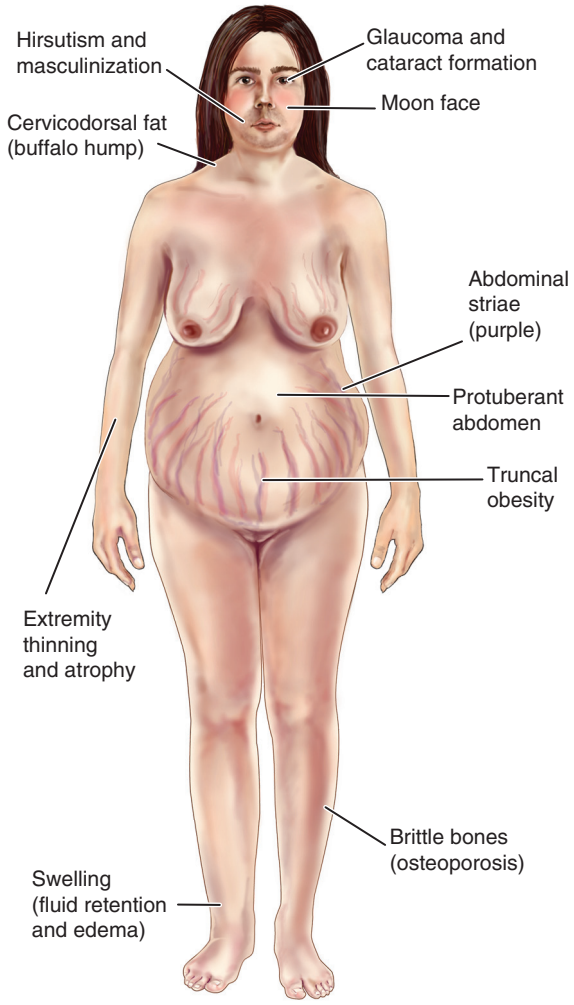
In secondary adrenal insufficiency, the deficiency of cortisol secretion is secondary to insufficient secretion of ACTH by the anterior pituitary. Little or no alteration in aldosterone secretion occurs. Thus, glucocorticoid insufficiency occurs without affecting mineralocorticoid levels. The most common cause of secondary adrenal insufficiency is long-term treatment of nonendocrine disorders with pharmacologic doses of glucocorticoid drugs. Because it bypasses the negative feedback loop, this treatment results in gradual loss of adrenal and pituitary hormonal reserves and some degree of atrophy of the ACTH-secreting cells of both the pituitary and the adrenal cortex. Sudden withdrawal of the glucocorticoid drug may result in secondary adrenal insufficiency, manifested clinically by acute adrenal insufficiency. HPA axis suppression resulting from glucocorticoid therapy may last for as long as 1 year after drug therapy has been discontinued.

A patient receiving pharmacologic doses of glucocorticoids for more than 2 weeks may have some degree of HPA axis suppression. Prevention of secondary adrenal insufficiency following prolonged administration of glucocorticoid drugs can be avoided by "weaning" the patient from the drug over weeks or months.

Cushing Syndrome

Cushing syndrome is a rare disorder resulting from increased adrenocortical secretion of cortisol, resulting in chronic elevation in glucocorticoid and adrenal androgen hormones. Mineralocorticoid hormone levels are usually not affected because increased ACTH production is usually the causative agent. Cushing syndrome may be caused by any one of the following sources:

- ACTH-dependent adrenocortical hyperplasia
- Tumor
- ACTH-secreting tumor
- Long-term administration of large doses of any steroid that is a potent glucocorticoid (iatrogenic Cushing syndrome)



• FIGURE 48.2 Cushingoid characteristics.

The term *cushingoid* refers to the variable number of the physiologic changes associated with Cushing syndrome (Figure 48.2).

Salt-Losing Adrenogenital Syndrome

Salt-losing adrenogenital syndrome, a congenital condition, is characterized by an inherited enzymatic interference with the normal biosynthesis of glucocorticoids and mineralocorticoids. The resulting low levels of these corticosteroids stimulate the body's feedback mechanism to produce large amounts of corticotropin (ACTH). The adrenal glands are only able to respond to the increased ACTH by increasing their production of adrenal androgens. Consequently, testosterone levels are abnormally high, which results in masculinization.

Hyperaldosteronism

Hyperaldosteronism is another abnormality of adrenal hormone production. Certain tumors of the adrenal cortex produce excessive amounts of aldosterone (or occasionally another mineralocorticoid). Two problems occur as a result of hyperaldosteronism: hypertension secondary to sodium

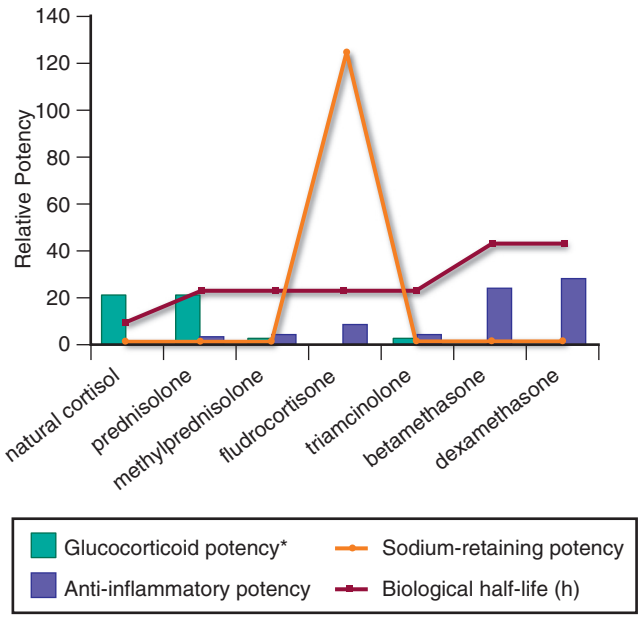
and water retention and hypokalemia-induced muscle weakness. Both problems represent excessive aldosterone actions on the distal renal tubule. Treatment ultimately involves surgical removal of the tumor.

C STEROID HORMONE AGONISTS

• C GLUCOCORTICOIDS

The primary endogenous glucocorticoids produced by the adrenal gland are cortisol (hydrocortisone) and cortisone. Cortisol and cortisone are used for replacement therapy in patients with adrenal insufficiency. They have no role in any systemic anti-inflammatory therapeutic regimen because of their high mineralocorticoid activity relative to their anti-inflammatory activity.

All natural and synthetic glucocorticoids act by binding to a specific cytoplasmic glucocorticoid receptor. Currently, glucocorticoids are available in numerous formulations, including oral, topical, ophthalmic solutions and ointments, oral inhalers, nasal formulations, parenteral, and rectal preparations. Glucocorticoids are used mainly therapeutically as anti-inflammatory agents, immunosuppressive agents, replacement therapy for individuals with adrenal insufficiency, and adjunctive treatment in selected malignant disorders. Synthetic glucocorticoids include prednisone, betamethasone, dexamethasone, methylprednisolone, and prednisolone (Figure 48.3). These potent synthetic glucocorticoids have little mineralocorticoid, androgenic, or estrogenic activities and as a result, the major systemic side effects are those associated with hypothalamic-pituitary-adrenal function suppression. Table 48.1 presents a summary of selected glucocorticoids.



*Glucocorticoid activity signifies the stimulation of glucose formation, a reduction in its utilization, and the promotion of its storage as glycogen.

• FIGURE 48.3 Comparison of glucocorticoids.

A common adverse effect of synthetic glucocorticoids administered in high doses for anti-inflammatory and immunosuppressant effects (combined or separately) is suppression of the HPA axis and may lead to secondary adrenal insufficiency. This effect appears within days of beginning glucocorticoid therapy. The time needed for the HPA axis to recover depends on the type of glucocorticoid given, the dose and frequency of administration (daily dosing or alternate-day dosing), and the duration of treatment. Occasionally, the patient's HPA axis remains permanently suppressed by glucocorticoid anti-inflammatory therapy. Consequently, the corticosteroid therapy reverts to replacement therapy.

Abrupt discontinuation of a glucocorticoid following prolonged administration may result in acute adrenal insufficiency because of a lack of both exogenous and endogenous glucocorticoids. To prevent acute adrenal insufficiency, exogenously administered glucocorticoids must be withdrawn gradually (tapered) so that the HPA axis can resume secretion of cortisol at a normal level and rate.

Prednisone (Deltasone, Prednicot), a synthetic analogue of cortisone, is the prototype glucocorticoid. It is four times more potent than naturally occurring cortisol; thus, its results are longer acting and have a more potent anti-inflammatory effect. Prednisone and its derivatives are the most commonly used glucocorticoids for the treatment of inflammatory conditions and a variety of autoimmune diseases.

Nursing Management of the Patient Receiving P Prednisone

Core Drug Knowledge

Pharmacotherapeutics

Prednisone is used for both its anti-inflammatory effects and immunosuppressive effects. It may be used as replacement therapy for adrenal insufficiency; however, hydrocortisone is preferred because of its glucocorticoid and mineralocorticoid activity. Therapeutic uses of prednisone are extensive and include anti-inflammatory treatment for conditions such as asthma, allergies, rheumatoid arthritis, inflammatory bowel disease (such as ulcerative colitis), skin disorders, and neoplasms (such as leukemia and lymphoma); for other inflammatory conditions such as tendonitis or bursitis; and increasingly for acute gout on patients intolerant of, or poor candidate for, NSAIDs. Prednisone is also used for its immunosuppressive effects to prevent organ transplant rejection, cerebral edema, and spinal cord injuries. Prednisone also has unlabeled investigational use such as adjunctive treatment for pneumocystis jiroveci, autoimmune hepatitis, and as adjunct for pain management of immunocompetent patients with herpes zoster.

Prednisone may be used as either short- or long-term therapy. Short-term therapies include during acute allergic reactions, during periods of acute exacerbation of chronic diseases such as chronic obstructive pulmonary disease,

TABLE 48.1 Summary of Selected Glucocorticoids

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
prednisone (Deltasone, Prednicot)	Adrenal insufficiency Inflammatory disorders Multiple sclerosis, relapsing Pneumocystis pneumonia Nephrotic syndrome Asthma	*Adult and Child:* PO, 4–5 mg/m^2 daily *Adult:* PO, 5–60 mg daily *Child:* PO, 0.05–2 mg/kg daily *Adult:* PO, 200 mg daily ×7 d, then 80 mg every other day ×1 mo *Adult:* PO, 40 mg daily ×5 d, then 20 mg daily *Child:* PO, 2 mg/kg daily *Child:* PO, 1–2 mg/kg daily	*Onset:* Varies *Duration:* 1–1.5 d $t_{1/2}$: 3.5 h
betamethasone (Celestone)	Anti-inflammatory Adrenal Insufficiency	*Adult*: PO, 0.6–7.2 mg/d *Child*: PO, 62.5–250 mcg/kg in 3 divided doses *Child*: PO, 17.5 mcg/kg in 3 divided doses	*Onset*: Varies *Duration*: 3 d $t_{1/2}$: 36–54 h
betamethasone sodium phosphate	Anti-inflammatory Adrenal insufficiency	*Adult*: IM, IV, up to 9 mg *Child*: IM, 20.8–125 mcg/kg every 12–24 h *Child*: IM, 5.8–8.75 mcg/kg daily	
betamethasone sodium phosphate/betamethasone acetate (Celestone Soluspan)	Anti-inflammatory Prevention of respiratory distress syndrome in preterm infants Intralesional, intrabursal, intra-articular	*Adult*: IM, 0.5–9 mg *Adult*: IM, 12 mg daily ×2–3 d before delivery *Adult*: IL, 0.25–2 mL	
dexamethasone (Decadron)	Adrenocortical insufficiency Suppression test Cerebral edema Anti-inflammatory	*Adult*: PO, 0.5–9 mg daily *Child*: PO, 23.3 mcg/kg in 3 divided doses *Adult*: PO, 2 mg every 6 h ×2 d *Adult*: IM, IV, 10 mg IV then 4 mg IM every 6 h *Adult*: PO, 0.5–9 mg daily *Child*: PO, 83.3–333.3 mcg/kg	*Onset*: Oral, slow; IM, IV, rapid *Duration*: 2–3 d $t_{1/2}$: 110–210 min
hydrocortisone (Cortef)	Adrenal insufficiency Anti-inflammatory Congenital adrenal hyperplasia	*Adult*: PO, 25–30 mg daily in divided doses *Child*: PO, 0.5–0.7 mg/kg daily in divided doses *Adult*: PO, 20–240 mg daily in divided doses *Child*: PO, 2.5–10 mg/kg daily in divided doses *Child*: PO, 20–25 mg/m2 daily in divided doses	*Onset*: Oral, 1–2 h; IM, rapid; IV, immediate *Duration*: 1–1.5 d $t_{1/2}$: 80–120 min
hydrocortisone sodium succinate (Solu-Cortef)	Acute adrenal insufficiency Anti-inflammatory Status asthmaticus Shock	*Adult*: IV: 100 mg every 6–8 h *Child*: IV, 1–2 mg/kg once, then 25–150 mg daily in divided doses *Adult*: IM, IV, 20–240 mg daily in divided doses *Child*: IM, IV, 1–5 mg/kg every 12–24 h *Adult*: IV, 300–400 mg divided every 6 h *Child*: IV, 4–8 mg/kg once, then 2 mg/kg every 6 h *Adult*: IV, 200–300 mg, divided, every 6–8 h ×5–10 d	
methylprednisolone (Medrol)	Anti-inflammatory	*Adult*: PO, 2–60 mg/d *Child*: PO, 0.5–0.7 mg/kg daily	*Onset*: IM, IV, rapid *Duration*: IM, 1–5 wk; IV, unknown $t_{1/2}$: 78–188 min
methylprednisolone acetate (Depo-Medrol)	Anti-inflammatory Congenital adrenal hyperplasia Multiple sclerosis exacerbation Interarticular/interlesional	*Adult*: IM, 40–20 mg every 1–4 wk *Adult*: IM, 40 mg every 2 wk *Adult*: IM, 160 mg daily ×7 d, then 64 mg every other day ×1 mo *Adult*: IM/IL, 4–80 mg every 1–5 wk	

(*Continued*)

TABLE 48.1 Summary of Selected Glucocorticoids *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
methylpred-nisolone sodium succinate (Solu-Medrol)	Anti-inflammatory	*Adult*: IM, IV, 10–250 mg every 4 h *Child*: IM, IV, 0.5–1.7 mg/kg daily, divided, every 6–12 h	
	Aplastic anemia	*Adult*: IV, 1 mg/kg daily ×4	
	Lupus nephritis	*Adult*: IV, 1 g daily ×3 d *Child*: IV, 30 mg/kg every other day ×6 doses	
		Adult: IM, IV, 100–250 mg every 4 h	
	Shock	*Adult*: IV, 5.4 mg/kg/h daily	
	Spinal cord injury	*Child*: IV, 30 mg/kg over 15 min, then 5.4 mg/kg daily	
	Status asthmaticus	*Adult and Child*: IM, IV, 2 mg/kg once, then 0.5–1 mg/kg every 6 h	
prednisolone acetate (Orapred, Orapred [ODT])	Adrenal insufficiency	*Adult and Child*: IM, IV, 4–5 mg/m^2 daily	*Onset*: Rapid *Duration*: IV, 1.5 d; IM, 4 wk $t_{1/2}$: 3.5 h
	Anti-inflammatory	*Adult*: IM, IV: 5–60 mg/d *Child*: IM, IV, 1–2 mg/kg/d, divided up to 4×/d	
	Intra-articular	*Adult*: IL, 2–30 mg every 3 d to every 3 wk	
	Multiple sclerosis exacerbation	*Adult*: IM, IV 80 mg every other day ×7 d	
	Asthma exacerbation	*Child*: IV, 1–2 mg/kg every 6 h ×2 d	

asthma, or ulcerative colitis, and at the beginning of treatment for a chronic condition to manage symptoms until other drugs become effective. Long-term high-dose or low-dose therapy may be indicated, depending on the underlying condition (e.g., transplantation) or disease (e.g., rheumatoid arthritis) being treated (see Table 48.1).

Pharmacokinetics

Prednisone, like other glucocorticoids, is absorbed readily from the gastrointestinal (GI) tract because of its lipophilic nature. Glucocorticoids also are absorbed at a moderate rate from the synovial and the conjunctival spaces and very slowly through the skin. Consequently, topical administration is used for a localized action. Excessive and prolonged local application of certain drugs may result in enough absorption to cause systemic effects. In contrast to oral dosage forms, injectable preparations (e.g., esters, suspensions) have greatly altered onsets and durations of action; they are, however, absorbed slowly and completely. Prednisone—inactive on its own—must be metabolized in the liver into pharmacologically active prednisolone. Prednisolone is excreted in the urine, crosses the placenta, and enters the breast milk.

Metabolic factors can increase or decrease the levels of prednisone in the blood. The liver and kidney are the major sites of glucocorticoid inactivation. Drugs that are cyproheptadine inducers (e.g., phenobarbital, phenytoin, rifampin) may accelerate the hepatic biotransformation of glucocorticoids. Conditions such as hypothyroidism may cause the hepatic metabolism to be decreased.

Pharmacodynamics

Prednisone has primarily glucocorticoid activity, although some mineralocorticoid activity is present and more apparent when the drug is administered in high doses (see Figure 48.3). Prednisone may cause salt and water retention, resulting in edema and hypertension. Prednisone affects virtually all body cells but not in the same way. Anti-inflammatory effects include retardation of the migratory polymorphonuclear leukocytes, suppression of tissue repair and granulation, reduction in the erythrocyte sedimentation rate, decrease in fibrinogenesis, and diminished C-reactive protein. However, prednisone does not affect antigen-antibody reactions or immediate hypersensitivity reactions.

Its immunosuppressant effects are attributable to suppression of phagocytosis, decrease in the number of circulating eosinophils and lymphocytes, suppression of delayed hypersensitivity reactions, decrease in antigen–antibody tissue reactions, and a decrease in plasma immunoglobulins.

The effects of glucocorticoid on carbohydrate, fat, and protein metabolism are responsible for both the beneficial and adverse results. The normal physiologic action of systemic glucocorticoids, including prednisone, is increased gluconeogenesis and decreased glucose use. These actions provide for glucose production (and energy) during periods of stress or decreased carbohydrate intake (Box 48.2).

Contraindications and Precautions

Contraindications to prednisone use are a hypersensitivity to the drug and systemic fungal infections or administration of live virus or live attenuated vaccines with immunosuppressive doses of prednisone. It may enhance the adverse effects and/or diminish the effectiveness of a live vaccine, or may bring about vaccine-associated infection. Precautions include closely monitored use for individuals with sensitivity to additives such as tartrazine or sulfites, because they may develop severe allergic or anaphylactic

Box 48.2 PHARMACODYNAMIC EFFECTS OF GLUCOCORTICOIDS

Metabolic

- Increased glycogenolysis and gluconeogenesis
- Increased protein catabolism and decreased protein synthesis
- Decreased gastrointestinal absorption of calcium
- Decreased secretion of thyroid-stimulating hormone (TSH)
- Decreased activity and formation of osteoblasts

Anti-inflammatory (systemic and local effects)

- Decreased production of prostaglandins, cytokines, and interleukins
- Decreased proliferation and migration of lymphocytes and macrophages

reactions to some preparations. Caution is also necessary in patients with hypertension, myasthenia gravis, GI disorders, diabetes mellitus, osteoporosis, cataract, glaucoma, increased intra-ocular pressure, peptic ulcer, and renal insufficiency because the actions of the drug may increase the risk of the complications of these disorders, and or exacerbate or induce these conditions.

Prednisone is a pregnancy category C drug. It is secreted in breast milk and may suppress growth or cause other adverse effects in nursing infants.

Adverse Effects

Treatment with prednisone may produce adverse effects. These effects include the central nervous system (CNS) stimulation with anxiety, mood swings, insomnia, and headache. GI complaints include nausea, vomiting, increased appetite, weight gain, and dyspepsia. Prednisone should be used with caution for patients at risk for gastrointestinal perforation, such as those with diverticulitis, ulcerative colitis, and peptic ulcer. Endocrine changes of menstrual irregularities, alteration with glucose regulation and production leading to hyperglycemia, and suppression of pituitary ACTH release (after 2 to 3 days) are common with continued prednisone use. In addition, dermatologic and integumentary adverse effects include acne, suppression of skin test reactions, and delayed healing of wounds. Other effects of continued prednisone use include muscle weakness, prolonged, or exacerbation, or increased susceptibility to infections (especially those due to herpes virus, varicella virus, and *Candida* and *Mycobacterium* species), suppression and/or masking of physiologic responses to infection; also sodium and fluid retention, fatigue, and malaise. Caution should be exercised for patients at risk for congestive heart failure. Similarly, corticosteroids have been associated with myocardial rupture following acute infarction. Also, use of prednisone may enhance hepatic impairment for patients with cirrhosis.

Administration of prednisone produces a negative feedback effect on the HPA axis; this effect results in the suppression of endogenous cortisol production. Suppression of ACTH release and cortisol secretion has been shown to occur with 50 mg/day of oral prednisone for as few as 5 days. Although long believed to be important, high doses and long-term use of glucocorticoids are no longer thought to be reliable predictors of a probable HPA axis deficiency. There appears to be considerable patient variability in responses to dosages and duration of therapy. Acute adrenal insufficiency caused by HPA axis suppression following drug withdrawal is one of the most serious complications of prednisone therapy (Box 48.3).

Adverse reactions occur with long-term administration of supraphysiologic (pharmacologic) doses of prednisone. Cushingoid characteristics include redistribution of fat deposits (e.g., buffalo hump, moon face, and truncal obesity). Signs of protein catabolism, such as loss of muscle mass and thinning of the extremities, muscle aches, and weakness may also develop. Visual acuity may be affected by the development of cataracts and glaucoma. Hyperlipidemia and thrombus formation also may occur. Other adverse effects from long-term therapy (doses above 5 mg/d) include undesired dermatologic responses of acne, hirsutism, delayed wound healing, skin atrophy, tearing, and striae. Women and the elderly of both genders are more prone to these effects.

A clinically important adverse effect of long-term or high-dose prednisone therapy is osteoporosis due to its association with increased bone mineral density loss putting the patient at increased risk for fracture, which is often considered to be a major limitation of long-term prednisone therapy. Long-term prednisone therapy (doses over 7.5 mg/d) enhances calcium loss and increases parathyroid hormone levels. Calcium loss from bone substance resorption decreases bone mineral density, thereby promoting an osteoporotic condition that increases the risk for hip, pelvic, rib, or vertebral fractures.

Substantial bone effects (e.g., suppression of bone growth) may occur when corticosteroid drugs are used in long-term or intermittent treatment of a variety of diseases. The bones most often affected are the vertebrae, ribs, and long bones, although all bones are at risk. A high incidence of vertebral compression fractures exists in both male and female patients who receive extended prednisone treatment.

There appears to be a direct correlation between the extent of bone loss and the duration of prednisone therapy; research suggests that the majority of bone loss occurs within the first 3 to 12 months, with a slowing of bone loss thereafter. Although alternate-day therapy has been shown to delay some of the adverse effects of long-term prednisone therapy, it does not appear to decrease the risk of osteoporosis. The prevalence of osteoporosis is difficult to assess when corticosteroids are used in diseases in which the risk of osteoporosis is already increased (e.g., rheumatoid arthritis and renal disease).

Finally, glucose tolerance is affected by prednisone. This reaction occurs in as many as 15% of individuals on long-term therapy. The risk for iatrogenic diabetes mellitus

Box 48.3 POTENTIAL ADVERSE EFFECTS OF PREDNISONE (AND OTHER GLUCOCORTICOID THERAPY)

Central Nervous System Problems

- Emotional lability
- Anxiety
- Paresthesias
- Seizures
- Increased intracranial pressure with papilledema
- Insomnia
- Psychosis
- Paradoxical suicidal depression
- Aggravation of preexisting psychiatric disorders

Endocrine/Metabolic Problems

- Antagonistic effects on insulin, parathyroid, and thyroid hormones
- Glucose intolerance
- Hirsutism
- Suppression of HPA axis
- Hyperglycemia
- Hyperlipidemia
- Iatrogenic diabetes
- Obesity
- Increased serum lipids
- Increased serum triglycerides (in transplant and asthmatic patients and those with organ transplantation treated with >5 mg/d of prednisone)
- Protein wasting
- Amenorrhea
- Postmenopausal bleeding

Cardiovascular Problems

- Thromboembolism (fat embolism)
- Arrhythmias secondary to K+ alterations
- Hypertension
- CHF

Gastrointestinal Problems

- Fatty liver infiltrates
- Pancreatitis
- Increased appetite (which leads to weight gain)
- Ulcerative esophagitis
- Nausea and vomiting
- Peptic ulceration with perforation or hemorrhage

Fluid and Electrolyte Problems

- Fluid retention
- K+ loss (hypokalemia)
- Na+ retention (hypernatremia)
- Ca++ loss (hypocalcemia)

Hematologic and Immunologic Problems

- Altered inflammatory response
- Eosinopenia
- Leukocytosis
- Opportunistic infections
- Leukopenia

Musculoskeletal Problems

- Aseptic necrosis (femur, humerus head)
- Growth failure
- Myopathy
- Osteopenia
- Osteoporosis

Ophthalmic Problems

- Increased intraocular pressure
- Cataracts
- Glaucoma
- Exophthalmos

Integumentary Problems

- Acne
- Ecchymoses
- Petechiae
- Skin atrophy
- Striae purpura
- Subcutaneous fat atrophy

General Problems

- Cushingoid characteristics
- Withdrawal syndrome

increases with age, obesity, a previous history of glucose intolerance, and a family history of diabetes. Even low-dose therapy can impair glucose tolerance in patients with type 1 and 2 diabetes. Patients with diabetes may need changes in diet or hypoglycemic therapy (e.g., insulin, oral drugs) to maintain control of blood sugar.

Drug Interactions

Major interactions may occur between prednisone and a variety of drugs. Prednisone also causes some interactions with laboratory measurements. Urine glucose and serum cholesterol levels may be increased. Serum levels of K^+ may be decreased. Triiodothyronine (T_3), thyroxine (T_4), thyroid iodine-131 (I-131) uptake, and protein-bound iodine concentrations may be decreased, making it difficult to monitor the therapeutic response of patients receiving the drugs for thyroiditis or assessing patients for thyroid dysfunction. Prednisone also may produce a false-positive result in some tests for systemic bacterial infections. In addition, reactions to skin tests may be suppressed. Prednisone alters glucose tolerance tests. Patients with diabetes should be monitored closely and adjustments in dosage of insulin or oral antidiabetic drugs made accordingly. Table 48.2 lists drugs that interact with prednisone.

Assessment of Relevant Core Patient Variables

Health Status

Before administering prednisone, review the patient's drug history for use of prescription, over-the-counter (OTC),

TABLE 48.2 Agents That Interact with P Prednisone

Interactants	Effect and Significance	Nursing Management
anticholinesterases	Corticosteroids antagonize the effects of anticholinesterases in patients with myasthenia gravis, resulting in profound muscle depression.	Monitor patient's muscle strength. Ensure safety.
azole antifungal agents	Prednisone clearance possibly decreased	Monitor for increased adverse effects of prednisone.
barbiturates	Barbiturates induce hepatic metabolism of prednisone, resulting in subtherapeutic serum concentrations of prednisone.	Monitor for exacerbation of presenting symptoms. Discuss dosage adjustment of prednisone with health care provider.
hydantoins	Hydantoins induce hepatic metabolism of prednisone, resulting in subtherapeutic serum concentrations of prednisone.	Monitor for exacerbation of presenting symptoms. Discuss dosage adjustment of prednisone with health care provider
oral anticoagulants	Anticoagulant dose requirements possibly reduced; conversely, prednisone may oppose the anticoagulant action.	Monitor PT/INR. Monitor for signs of bruising or bleeding. Monitor for signs of hypercoagulability.
oral contraceptives/ estrogens	Possible increased prednisone half-life and concentration and decreased clearance	Monitor for corticosteroid adverse effects. Discuss dosage adjustment of prednisone with health care provider.
potassium-depleting agents (diuretics)	May increase depletion of potassium	Observe patients for muscular and systemic effects of hypokalemia.
rifamycins	Rifamycins induce hepatic metabolism of prednisone, resulting in subtherapeutic serum concentrations of prednisone.	Avoid coadministration if possible. Monitor for exacerbation of presenting symptoms. Discuss dosage adjustment of prednisone with health care provider.
salicylates	Prednisone stimulates the metabolism of salicylates, resulting in decreased serum salicylate levels, and may decrease their effectiveness.	Monitor for effectiveness of salicylates.
tacrolimus	Prednisone may decrease tacrolimus serum concentration.	Monitor for signs of transplant rejection.
theophylline	Alterations in the pharmacologic activity of either agent are possible.	Monitor for theophylline toxicity. Discuss dosage adjustment of theophylline with health care provider.
warfarin	Prednisone may reduce warfarin dose requirements. Conversely, prednisone may occasionally induce a hypercoagulable state that could oppose warfarin action.	Monitor PT/INR closely, especially when starting or stopping prednisone therapy. Discuss potential dosage adjustments with the health care provider.

and herbal medications and recreational drugs. In addition, it is important to review the patient's medical history for GI problems. Assess the patient's nutritional status, weight control, and disease or trauma history to correlate risk for fall and fracture. Perform a complete physical examination and review current laboratory data. In addition, muscle strength and body proportions should be observed, as should patterns of hair growth and distribution. Depending on the findings, further testing (e.g., hepatic and renal function studies) may be indicated. Throughout therapy, continue to assess the patient for signs of adrenal insufficiency.

Life Span and Gender

Determine whether the patient is pregnant or lactating, because prednisone is a pregnancy category C drug and enters breast milk. Growth suppression can occur in children receiving prolonged prednisone therapy. Growth suppression is proportional to the duration, dose, and frequency of prednisone administered. Divided daily doses are more growth inhibiting than a single daily dose.

Assess the age of the patient. Elderly patients are more prone to adrenal suppression from prolonged prednisone administration. They may require lower doses because of physiologic changes resulting from aging, such as decreased

muscle mass and plasma volume or impairment of hepatic or renal functions. Monitor blood pressure, blood glucose, and electrolyte levels regularly.

Lifestyle, Diet, and Habits

Assess the patient's typical diet. The patient's diet plan should include low sodium and high potassium. A diet that controls carbohydrate and calorie intake is important (unless contraindicated) because of the increased gluconeogenesis, decreased glucose use, increased appetite, and weight gain effects of pharmacologic glucocorticoid therapy. Encourage increased protein intake to decrease the risk of protein deficiency.

Assess the patient's typical daily activities and fall risk. The weak muscles and easily fatigued state characteristic of unintentional glucocorticoid excess secondary to therapy predispose the patient to accidents such as a fall injury. With this in mind, assessment and discussion of environmental elements that may predispose the patient to a fall injury and implementation of necessary preventive measures are warranted. Osteoporosis and vertebral-compression effects of prolonged, thus, excessive glucocorticoid therapy may make bone fractures more likely. It is important to encourage passive and active range-of-motion exercises, and anaerobic forms of exercises such as weightlifting and resistance training may help to offset the tendency toward muscle weakness and atrophy. Similarly, medications such as calcium, vitamin D, and bisphophonates, e.g., Fosamax, may help prevent and/or arrest the risk of glucocorticoid-induced osteoporosis. Physical or occupational therapy referrals may be necessary.

Nursing Diagnoses and Outcomes

- Excess Fluid Volume related to sodium and water retention secondary to corticosteroid therapy
  Desired outcome: *The patient will relate causative factors and methods of preventing edema and exhibit decreased peripheral and sacral edema.*
- Risk for Infection or Risk for Injury related to anti-inflammatory, immunosuppressive, dermatologic, and metabolic effects of chronic corticosteroid therapy
  Desired outcome: *The patient will demonstrate knowledge of risk factors associated with potential for infection or injury and will practice appropriate precautions for prevention.*
- Imbalanced Nutrition: More than Body Requirements related to increased appetite secondary to corticosteroid medications
  Desired outcome: *The patient will maintain a healthy weight, discuss current nutritional needs, and discuss the effects of exercise on weight control.*
- Altered Body Image related to cushingoid characteristics or physical changes secondary to glucocorticoid therapy
  Desired outcome: *The patient will verbalize and demonstrate acceptance of appearance (grooming, dress, posture, presentation of self), verbalize and demonstrate increased positive feelings, and demonstrate healthy adaptation and coping skills.*

Planning and Intervention

Maximizing Therapeutic Effects

Hormone production by the adrenal gland is influenced by many factors. Normal cortisol production follows a diurnal cycle. Levels peak in the early morning hours (6 AM to 8 AM) and decline throughout the day with a second, lower peak in the late afternoon (4 PM to 6 PM). Cortisol secretion increases in response to stress (physical or emotional) and low endogenous glucocorticoid levels. Thus, the most opportune time for administration of daily doses or alternate-day doses of glucocorticoids is early in the morning.

When prednisone is prescribed for replacement therapy, teach the patient about:

- Signs and symptoms of glucocorticoid imbalances
- Monitoring the response to therapy
- Drug schedule
- Identifying factors that increase adrenal stress (e.g., physical illness, injury, trauma, or emotional upset)
- Stress management
- Dosage changes during periods of stress or illness
- Prevention of injury and infection
- Drug interactions

Alert the patient that following intra-articular injection, the injected joint should not be overused. Weight-bearing joints, such as the knee, should be rested 24 to 48 hours after the injection.

Minimizing Adverse Effects

Monitor the patient, especially the surgical patient, carefully for signs of infection, because prednisone's immunologic activity may mask the symptoms of infection. Advise the patient to stay away from those with cold or flu-like symptoms or situations that increase the risk of exposure to potential infections. Emphasize the importance of adherence to the drug regimen, especially the adverse consequences of stopping therapy abruptly, such as the danger of adrenal insufficiency, without consultation with their health provider. Administration of prednisone can lead to peptic ulcer disease, as can the use of other anti-inflammatory drugs. Therefore, teach the patient to reduce gastric irritation from prednisone use by consuming milk (unless contraindicated), food, or appropriately timed taking of nonsystemic antacids (e.g., Al^{+}, Ca^{2+}, or Mg^{+} salts), taken 2 hours before or after prednisone dose, or by using adjunct antiulcer drug therapy (e.g., H_2-receptor antagonists, proton pump inhibitors) when taking the medication. Caffeine, alcohol, and products containing aspirin interact with prednisone, increasing the secretion of gastric acid irritating the gastric mucosa and leading to an increased risk of GI bleeding.

Altered growth and development is a risk with systemic glucocorticoid therapy. Inhaled glucocorticoids may cause

hoarseness, fungal infections, throat irritation, and dry mouth. Teach the patient to rinse the mouth or brush the teeth following use of the inhaled steroids to minimize the risk for oral, laryngeal, or pharyngeal fungal infections. Carefully monitor patients who are transitioning from systemic prednisone to an inhaled glucocorticoid. When systemic glucocorticoids are withdrawn too quickly after beginning inhalation therapy, a corticosteroid withdrawal syndrome (e.g., malaise, myalgia, nausea, headache, and low-grade fever) and asthma relapse may develop.

Alternate-day administration (glucocorticoids given every other day instead of daily) of long-term, systemic glucocorticoids has been used to lessen the suppression of the hypothalamus, the anterior pituitary, and the rate of bone loss. However, alternate-day dosing does not minimize the risk of osteoporosis or cataract formation. Intermediate-acting glucocorticoids, such as prednisone, are most appropriate for alternate-day therapy. Ensure that the change from daily to alternate-day administration does not occur abruptly, because this abrupt change may cause signs and symptoms of adrenal insufficiency (e.g., fatigue, nausea, vomiting, and hypotension) on the days between doses.

When a patient receiving ongoing corticosteroid therapy requires surgery, review the preoperative orders to ensure a dose of a rapid-acting corticosteroid has been added to the patient's daily dose of corticosteroid. If not, obtain the order from the prescriber. To promote recovery after the stress of surgery, an increased dose of steroid should be continued postoperatively in decreasing doses over several days, returning to the patient's baseline dose of corticosteroid.

Providing Patient and Family Education

- Discuss taking the drug exactly as prescribed.
- Discuss not stopping the drug abruptly because of the risk of acute adrenal insufficiency.
- Discuss dealing with missed doses and the dosing strategy (Box 48.4).
- Discuss the purpose of the medication therapy and the need for maintaining therapy.
- Teach that prednisone replacement therapy is used to treat the chronic, lifelong conditions of adrenal cortical insufficiency.
- Provide emotional support and assistance in the grieving process over loss of health and loss of control, as needed (PRN).
- Advise patients to wear a medical identification device with the diagnosis and drug therapy clearly indicated.
- Emphasize the importance of patients' notifying all health care providers about glucocorticoid therapy when seeking medical treatment.
- Discuss the adverse effects of drug therapy and identify symptoms that should be reported to the prescriber.
- Discuss alterations in appearance that may cause disturbances in self-concept from long-term therapy.

BOX 48.4 COMMUNITY BASED CONCERNS

Home Dosing Strategies

One Dose Every Other Day

If a dose is missed, take the missed dose as soon as possible. If the medication is remembered the same morning, take it and then go back to the regular dosing schedule.

If the dose is remembered several hours late, then wait and take it the following morning. Skip the next day and start the regular dosing schedule the day after.

One Dose Every Day

If a dose is missed, take the missed dose as soon as possible, then go back to the regular schedule.

If the missed dose is not remembered until the next day, skip it and do not double the next dose.

Several Doses Every Day

If a dose is missed, it is important to take the missed dose as soon as possible, then go back to the regular schedule.

If the missed dose is not remembered until the next dose is due, double the next dose.

Periods of Stress, Illness, Injury, or Surgery

Make sure that the directions for dosage adjustment are clearly indicated on the drug label.

- Discuss strategies to deal with the changes that occur (e.g., truncal obesity, acne, hair growth, stretch marks, thinning of extremities, weight gain, or "buffalo hump" may be camouflaged with loose clothing).
- Discuss bone health (supplemental daily intake of 1,500 mg of oral calcium and 510 IU of vitamin D, or bisphosphonates, is recommended).
- Teach how to identify signs and symptoms of acute adrenal insufficiency, including symptoms of anorexia, hypoglycemia, lethargy, malaise, nausea, psychological despondency, restlessness, and weakness, and to report symptoms to the prescriber.
- Discuss the importance of rest, sleep, and health-maintenance behaviors.
- Teach ways to avoid infection and how to recognize signs of infection.
- Discuss self-medication for minor illnesses handled at home (e.g., flu with vomiting and diarrhea) that may require dosage adjustments, medical intervention, or hospitalization.
- Provide patients and their caregivers with written instructions on what to do on sick days.
- Discuss safety issues and fall preventions. Emphasize the possible occurrence of osteoporosis and encourage patients and caregivers to report all bone pain.
- Evaluate the safety of the home environment. Stress the importance of reporting bone pain, because aseptic necrosis or pathologic fractures may occur spontaneously.
- Explain the importance of serial ophthalmologic examination and may include continued screening for cataract, glaucoma, intraocular pressure, and or eye infections.

Ongoing Assessment and Evaluation

During prednisone therapy, the patient must be monitored for therapeutic drug response, adverse drug reactions, and indications of drug toxicity. Monitor for periods of stress (e.g., trauma, surgery, or severe illness) in order to coordinate medication adjustment of prednisone dosage to avoid drug-induced adrenal insufficiency. Assess for appropriate healing of all wounds and infections during and after hospitalizations or minor surgery because prednisone delays wound healing and increases the risk for infection. Common indicators of infection (including temperature elevation, erythema, and leukocytosis) are repressed because corticosteroids block the inflammatory responses. Also, assess for changes in energy level, activity level, and appetite as indicators of infection.

Glucocorticoids cause an increase in gluconeogenesis and a decrease in glucose utilization, causing hyperglycemia to occur. Monitor patients for the development of iatrogenic diabetes mellitus. Patients with existing diabetes may require an adjustment in therapy to maintain glucose control. Prophylactic antitubercular drug therapy may be required in infected persons because high glucocorticoid levels are likely to reactivate encapsulated tuberculosis.

Maintain vigilance in assessing patients receiving long-term therapy with prednisone (and other glucocorticoids). Adrenal suppression may occur, whereas effects of endogenous glucocorticoid hormones on the body may be exaggerated. Indications of adrenal suppression include anorexia, diarrhea, fluid and electrolyte imbalances (especially decreased Na^+, decreased glucose, and increased K^+), fatigue, nausea, vomiting, and weight loss. If fluid volume deficit occurs, it is important to assess for hypotension, pyrexia, tachycardia and tachypnea, dry skin, and dry mucous membranes. Also, assess for adverse reactions from prednisone (and other glucocorticoids), such as changes in mood or affect (e.g., agitation, depression, euphoria, and insomnia), edema, muscle weakness, nausea, vomiting, and weight gain.

While caring for a patient on glucocorticoid therapy, monitor specific laboratory tests results. Actual serum levels of cortisol and ACTH may be determined by a 24-hour urine collection. Electrolytes are measured with a metabolic panel. Lymphocyte levels (primarily T_4) should decrease when glucocorticoids are being used for immunosuppressive effects. In addition, monitor patients receiving digoxin or other digitalis-based drugs for toxicity.

Evaluate for the effectiveness of the therapy and assess signs and symptoms that precipitated the use of glucocorticoid drugs. When prednisone is used as replacement therapy, the patient should report an increased state of health (e.g., absence of fatigue, hypoglycemia, hypovolemia, and weakness) and a feeling of well-being. When prednisone is used for chronic inflammatory conditions (e.g., rheumatoid arthritis), the patient should experience less pain and discomfort and increased joint mobility.

MEMORY CHIP

Prednisone

- Anti-inflammatory or immunosuppressive therapy
- Hepatic dysfunction may impair prednisone conversion into active prednisolone.
- Prednisone may cause HPA axis suppression if given for more than 2 weeks and then withdrawn too abruptly, placing the patient at risk for acute adrenal insufficiency.
- Major contraindications: hypersensitivity to prednisone; systemic fungal infections
- Most common adverse effects: CNS complaints of euphoria, headache, and vertigo; GI complaints of nausea, vomiting, increased appetite, weight gain, and dyspepsia
- Most serious adverse effect: acute adrenal insufficiency due to HPA axis suppression following prednisone withdrawal
- Maximizing therapeutic effects: Administer prednisone according to established schedule (preferably one that follows the normal diurnal pattern of cortisol secretion); increase the dosage in times of stress to prevent drug-induced adrenal insufficiency.
- Minimizing adverse effects: Give prednisone with meals and/or antacids.
- Most important patient education: Advise the patient to wear medical identification so that any emergency medical personnel will know about this drug therapy.

CRITICAL THINKING SCENARIO

CONCERNS RAISED BY METHYLPREDNISOLONE AND OTHER GLUCOCORTICOIDS

Mr. Vito, 62 years old, is admitted to the emergency department with acute respiratory distress related to chronic obstructive pulmonary disease. Emergency treatment consists of respiratory inhalation therapy and IV methylprednisolone sodium succinate (Solu-Medrol), after which Mr. Vito is transferred to the telemetry unit. The nursing history that accompanies him discloses that he has type 2 diabetes that is controlled by diet and oral antidiabetic drugs.

1. Discuss assessment data needed to ensure safe administration of methylprednisolone to Mr. Vito, identifying any condition that represents a need for particularly cautious drug administration.
2. Define any concerns related to respiratory therapy and diabetes control. As Mr. Vito recovers, plans are made for him to begin long-term, anti-inflammatory corticosteroid therapy. At discharge, he will be on a tapering dose of oral prednisone and a beclomethasone (Vanceril) inhaler as needed.
3. Identify any important assessments that should be done to ensure safe administration of prednisone. In addition, propose important points to include in a patient education program.

Drugs Closely Related to Prednisone

Betamethasone

Betamethasone (Celestone) is available as an oral, effervescent, or extended-release tablet, or as a syrup. Betamethasone sodium phosphate/betamethasone acetate (Celestone Soluspan) is a solution for intramuscular (IM) administration when the oral form cannot be given. Clinical uses and adverse effects are similar to those for dexamethasone and methylprednisolone (see below). In addition, betamethasone sodium phosphate/betamethasone acetate may be used to prevent respiratory distress syndrome in premature infants. Betamethasone dipropionate combined with calcipotriene or clotrimazole is available as a lotion or ointment for disorders of the skin.

Dexamethasone

Dexamethasone (Decadron) exhibits essentially no mineralocorticoid activity and maximal anti-inflammatory activity with a prolonged plasma half-life (see Figure 48.3). Indications are similar to those for prednisone; however, it is most frequently used in short-term situations that require maximum anti-inflammatory activity (e.g., cerebral edema and septic shock) or as replacement therapy, or as an anti-emetic. Also, it is used for steroid-responsive ophthalmologic inflammatory conditions, such as allergic conjunctivitis, iritis, and also for symptomatic treatment of corneal injuries associated with trauma, such as thermal or chemical burns, and also foreign body eye penetration. Dexamethasone is also used to diagnosis Cushing disease (idiopathic adrenocortical hyperfunction). Patients are given a dexamethasone suppression test. In normal patients, dexamethasone suppresses the release of ACTH, resulting in a decreased release of cortisol. In patients with Cushing disease, there is little or no change in the release of cortisol. Off-label uses of dexamethasone include acute mountain sickness, bacterial meningitis, bronchopulmonary dysplasia in preterm infants, diagnosis of depression, hirsutism, and for antiemetic purposes. Contraindications, adverse effects, drug–drug interactions, and patient management are similar to those for prednisone.

Hydrocortisone

Hydrocortisone (Cortef) is structurally identical to natural cortisol. It is available in many forms, including oral tablets, rectal cream or enema, ophthalmic drops, and topical cream, lotion, gel, ointment, spray, and even a stick. Hydrocortisone sodium succinate (Solu-Cortef, A-Hydrocort) is administered parenterally for acute adrenal insufficiency or when oral administration is not possible for other indications. Because of its glucocorticoid and mineralocorticoid activity, as well as its salt-retaining properties, hydrocortisone is the treatment of choice for adrenal insufficiency replacement therapy. The drug is bound reversibly to corticosteroid-binding albumin and globulin. It is metabolized by the liver and excreted in the urine. Rectal preparations of hydrocortisone (Anusol HC, Colocort) are absorbed as much as 50% and used as adjunctive therapy in patients with ulcerative colitis and other steroid-responsive conditions. Contraindications to rectal preparations are systemic fungal infections, recent ileocolostomy or intestinal anastomoses, abscess, obstruction, peritonitis, and perforation. Contraindications, adverse effects, drug–drug interactions, and patient management of oral hydrocortisone are similar to those for prednisone. In addition, its intramuscular injection is contraindicated on patients with idiopathic thrombocytopenia purpura (ITP).

Methylprednisolone

Methylprednisolone (Medrol) and its derivatives, methylprednisolone acetate (Depo-Medrol) and methylprednisolone sodium succinate (Solu-Medrol), are synthetic glucocorticoids characterized by potent anti-inflammatory and immunosuppressive effects. These drugs have little mineralocorticoid activity and usually are not used to manage adrenal insufficiency unless a more potent mineralocorticoid is administered concomitantly.

Methylprednisolone is administered orally, whereas methylprednisolone sodium succinate may be given by IM or IV injection. Methylprednisolone acetate may be administered by IM, intra-articular, intralesional, or soft-tissue injection. Avoid IM injections of acetate to deltoid area due to high incidence of subcutaneous atrophy because of its low solubility and sustained IM effect. Also, avoid injections on areas with acute local infection. As in prednisone therapy, systemic methylprednisolone must be discontinued gradually or changed to an oral form of a glucocorticoid to prevent acute adrenal insufficiency. Contraindications, adverse effects, drug-drug interactions, and patient management are similar to those for prednisone.

Prednisolone

Prednisolone sodium phosphate (Pediapred, Orapred) is primarily a glucocorticoid. It is available for parenteral and ophthalmic administration. Prednisolone has indications similar to those for prednisone, although it is not approved for adrenal insufficiency. Non–Food and Drug Administration (FDA)-approved uses include breast cancer, malignancy-induced fever, primary intracranial tumor, nerve injury due to leprosy, multiple myeloma, and prostate cancer. Prednisolone acetate (Pred Forte, Pred Mild) is an ophthalmologic drug for inflammatory disorders of the eye. For a comparison of glucocorticoids, see Figure 48.3.

Inhaled Glucocorticoids

Beclomethasone, budesonide, flunisolide, fluticasone, and triamcinolone acetonide constitute a class of pulmonary and intranasal steroids possessing enhanced topical anti-inflammatory activity and low systemic potency. Inhaled glucocorticoids are metabolized in the lung before they are absorbed, thereby reducing their systemic effects. These drugs are relatively equal in potency and clinical effectiveness and are thought to have variable systemic activity and complications. The intranasal and inhaled glucocorticoids are covered in depth in Chapters 48 and 49.

Topical Glucocorticoids

Topical steroids are effective therapy for a variety of inflammatory skin conditions. They are ranked according to their potency, from very high to very low (Table 48.3). Available formulations include lotions, creams, solutions, ointments, gel, or foams. Ointments are often preferred, are most potent because of its occlusive effect as they facilitate steroid absorption and penetration by trapping the moisture in the epidermis. However, its greasy effect may not enhance patient's compliance. Lotions are best for hairy and large surface areas and provide coolness and drying effect that is excellent for moist dermatoses or pruritus. Foams, on the other hand, are readily and easier to apply especially on an inflamed skin and scalp. It is the most cosmetically acceptable and thus increases compliance, but tend to be more expensive. Topical steroids are best applied when skin is moist, such as after taking a bath.

The primary therapeutic effects of the topical corticosteroids are their nonspecific anti-inflammatory activity on most causes of inflammation, including chemical, immunologic, mechanical, and microbiologic etiologies. When the glucocorticoids are applied to inflamed skin, they inhibit the migration of macrophages and leukocytes into the area by reversing the vascular dilation and permeability. The clinical result is a decrease in edema, erythema, and pruritus.

Topical application of corticosteroids rarely produces systemic effects. Topical steroids may be absorbed systemically if applied to the nasal mucosa or large areas of abraded skin, inhaled excessively for prolonged periods, or used in large doses. Optic and otic steroid preparations are not absorbed systemically.

Adverse effects with topical application are usually milder and more transient than those seen after systemically administered steroids. However, adrenal function may be suppressed when potent topical agents are used in large amounts for long periods especially when the skin surface is denuded or when occlusive dressings are used. Occlusive dressings substantially increase percutaneous absorption, increasing the risk for local adverse effects (e.g., skin atrophy) and systemic adverse effects. Increased skin temperature, hydration, and application to skin with a thin surface layer also enhance absorption. Duration of potent topical corticosteroid should not exceed 3 weeks, but is alright for persistent small areas. Intermittent treatment is preferable over continuous therapy to avoid tachyphylaxis. Also, weaker form of topical steroids should be used on intertriginous areas, the face, and genitalia as they are most susceptible to corticosteroid-induced atrophy and telangiectasia.

Intra-articularly Injected Glucocorticoids

Intra-articular injection produces localized effects for symptomatic relief of joint pain and increase joint mobility. Patients receiving this form of the drug need to be cautioned to allow time for the treated area to heal, about 24 to 48 hours. The pain-induced limitation may be eliminated, but overusing the joint may still aggravate the active inflammatory process. Frequent intra-articular injections may damage joint tissues.

TABLE 48.3 Comparative Potency of Topical Glucocorticosteroids

Very High Potency	High Potency	High/Medium Potency	Medium Potency	Medium/Low Potency	Low Potency	Lowest Potency
betamethasone dipropionate augmented (0.05% G,O) clobetasol (0.05% C,G,F, L,O,S) halobetasol (0.05% C,O)	amcinonide (0.1% O) betamethasone dipropionate augmented (0.05% C,L) betamethasone dipropionate (0.05% O) desoximetasone (0.25% C,O; 0.05% G) diflorasone (0.05% O) diflorasone emollient (0.05% C,O) fluocinonide (0.05% C,G, O,S) halcinonide (0.1% C) mometasone (0.1% O)	amcinonide (0.1% C,L) betamethasone dipropionate (0.05% C) betamethasone valerate (0.1% O) desoximetasone (0.05% C) diflorasone (0.05% C,L) fluocinonide emollient (0.05% C) fluticasone (0.005% O) halcinonide (0.1% O,S) triamcinolone (0.1% O, 0.5% C, aerosol)	betamethasone valerate (0.12% F) clocortolone (0.1% C); fluocinolone (0.025% O) flurandrenolide (0.05% O) hydrocortisone valerate (0.2% O) mometasone (0.1% C,L) prednicarbate (0.1% O) triamcinolone (0.1% C,O)	betamethasone dipropionate (0.05% L) betamethasone valerate (0.1% C) desonide (0.05% O) fluocinolone (0.025% C, 0.01% Shmp) flurandrenolide (0.05% C) fluticasone (0.05% C,L) hydrocortisone butyrate (0.1% C,O,S) hydrocortisone valerate (0.2% C) prednicarbate (0.1% C) triamcinolone (0.025% O; 0.1% L)	alclometasone (0.05% C,O) betamethasone valerate (0.1% L) desonide (0.05% C,F,G,L) fluocinolone (0.01% C,S) triamcinolone (0.025% C,L; 0.1% C)	hydrocortisone (0.5%,1% C,L,O; 2.5% C,L,S) methylprednisolone (0.25% O)

C, cream; F, foam; G, gel; L, lotion; O, ointment; S, solution; Shmp, shampoo.

• Mineralocorticoids

Aldosterone, the naturally occurring mineralocorticoid, is expensive and requires parenteral administration. Therefore, fludrocortisone (Florinef Acetate) is the prototype exogenous mineralocorticoid. This adrenal corticosteroid has both high mineralocorticoid and glucocorticoid activity (its glucocorticoid potency is 15 times greater than that of hydrocortisone). However, when used as replacement therapy in adrenocortical deficiency, its therapeutic effect is the mineralocorticoid activity.

Nursing Management of the Patient Receiving P Fludrocortisone

Core Drug Knowledge

Pharmacotherapeutics

Fludrocortisone is used for partial replacement therapy for primary and secondary adrenocortical insufficiency in Addison's disease and for treating salt-losing adrenogenital syndrome.

Pharmacokinetics

Orally administered, fludrocortisone is absorbed readily from the GI tract, with peak concentration in 1.7 hours. It is metabolized in the liver and excreted by the kidney. Plasma half-life is approximately 3.5 hours, but biologic half-life ranges from 18 to 36 hours. Fludrocortisone crosses the placenta and is secreted in breast milk. The usual adult dosage is 0.1 mg/day (range, 0.1 mg three times a week, up to 0.2 mg/day). See Table 48.4.

Pharmacodynamics

Fludrocortisone acts on the distal renal tubule to enhance the reabsorption of sodium and to increase the urinary excretion of both potassium and hydrogen ions. In small oral doses, the mineralocorticoid effects of fludrocortisone predominate: urinary excretion of potassium, marked sodium retention, and a rise in blood pressure as a result of the physiologic effects of these electrolyte levels. Larger doses of fludrocortisone result in predominance of glucocorticoid effects such as endogenous adrenal cortical secretion, thymic activity, and corticotropin excretion.

Contraindications and Precautions

Fludrocortisone hypersensitivity, systemic fungal infections, and conditions not requiring intense mineralocorticoid activity are contraindications to use. Fludrocortisone is a pregnancy category C drug, and it should be used cautiously during lactation because it is secreted into breast milk. Safety and efficacy are not established in children. It should also be used cautiously in patients with cardiovascular disease because it can elevate sodium and fluid levels.

Adverse Effects

In small oral doses, fludrocortisone produces marked sodium retention and increased urinary potassium excretion, causing a rise in blood pressure. In larger doses, fludrocortisone inhibits endogenous adrenal cortical secretion and pituitary corticotropin excretion. It promotes the deposition of liver glycogen. It induces negative nitrogen balance when protein intake is inadequate. Adverse effects usually occur when the dosage is too high or when the drug is withdrawn too rapidly. Cardiovascular adverse effects may include edema, hypertension, chronic heart failure, and cardiomegaly. Dermatologic adverse effects may include bruising, diaphoresis, urticaria, or allergic skin rash. Hypokalemic alkalosis may occur. Additionally, fludrocortisone may cause adverse effects similar to those seen with the glucocorticoids.

Drug Interactions

Fludrocortisone interacts with many of the same drugs as prednisone because of its high glucocorticoid activity. The drugs with which fludrocortisone interacts include barbiturates, hydantoins, rifampin, anticholinesterases, and salicylates. Table 48.5 lists agents that interact with fludrocortisone.

Assessment of Relevant Core Patient Variables

Health Status

Review the patient's history for pre-existing conditions that require cautious use of fludrocortisone (e.g., diabetes mellitus, hypertension, osteoporosis, or impaired renal function).

Report any positive findings to the health care provider. Before administering fludrocortisone, assess the patient's fluid and electrolyte balance, nutritional status, and weight control history. Depending on the patient's condition before drug administration, assess appropriate laboratory or diagnostic tests to manage the adverse events associated with fluid and electrolytes (particularly hypertension).

Life Span and Gender

Determine whether the patient is pregnant or lactating, because fludrocortisone is a pregnancy category C drug, which means that safety for use during pregnancy has not been established. If fludrocortisone is given during pregnancy, observe the newborn for signs of adrenocortical insufficiency because of adrenal suppression.

TABLE 48.4 Overview of P Fludrocortisone

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P fludrocortisone	Adrenal insufficiency	Adult PO: 0.1–0.2 mg daily Child: safety and efficacy not established.	*Onset:* gradual *Duration:* 18–36 h $t_{1/2}$: 3.5 h

TABLE 48.5 Agents That Interact with P Fludrocortisone

Interactants	Effect and Significance	Nursing Management
Anticholinesterases	Corticosteroids antagonize the effects of anticholinesterases in patients with myasthenia gravis, resulting in profound muscle depression.	Monitor patient's muscle strength. Ensure safety.
Barbiturates	Barbiturates induce hepatic metabolism of prednisone, resulting in subtherapeutic serum concentrations of prednisone.	Monitor for exacerbation of presenting symptoms. Discuss dosage adjustment of prednisone with health care provider.
Hydantoins	Hydantoins induce hepatic metabolism of prednisone, resulting in subtherapeutic serum concentrations of prednisone.	Monitor for exacerbation of presenting symptoms. Discuss dosage adjustment of prednisone with health care provider.
Oral anticoagulants	Anticoagulant dose requirements possibly reduced; conversely, prednisone may oppose the anticoagulant action.	Monitor PT/INR. Monitor for signs of bruising or bleeding. Monitor for signs of hypercoagulability.
Rifamycins	Rifamycins induce hepatic metabolism of prednisone, resulting in subtherapeutic serum concentrations of prednisone.	Avoid coadministration if possible. Monitor for exacerbation of presenting symptoms. Discuss dosage adjustment of prednisone with health care provider.
Salicylates	Prednisone stimulates the metabolism of salicylates, resulting in decreased serum salicylate levels, and may decrease their effectiveness.	Monitor for effectiveness of salicylates.

Fludrocortisone is secreted in breast milk. Therefore, use caution when giving it to lactating women. It is important to note the patient's age before administering fludrocortisone. Monitor growth and development of infants and children on long-term therapy.

Lifestyle, Diet, and Habits

Assess the patient's diet because fludrocortisone-mediated sodium retention and potassium loss are affected by food choices. Teach the patient about foods that are low in sodium or high in potassium.

Environment

Fludrocortisone may be given in any setting, including the home environment.

Culture and Inherited Traits

Traditional foods and herbal and home remedies consumed by patients of various ethnic or cultural groups may be high in sodium. For example, Chinese foods are traditionally prepared with high-sodium soy sauce and monosodium glutamate (MSG). Many other preserved and fermented foods are high in sodium. Take a complete dietary history, including usual dietary intake, food preferences and intolerances, and use of home remedies. This information allows you to assess the patient's risk of weight gain or edema and also provides the knowledge to use when teaching the patient, family, and caregivers.

Nursing Diagnoses and Outcomes

- Excess Fluid Volume related to mineralocorticoid-induced sodium and water retention
  Desired outcome: *The patient will relate causative factors and methods of preventing fluid retention and exhibit decreased peripheral and sacral edema.*
- Risk for Infection or Risk for Injury related to immunosuppressive effects of chronic corticosteroid therapy
  Desired outcome: *The patient will demonstrate knowledge of risk factors associated with potential for infection and will practice appropriate precautions for prevention.*
- Risk for Injury related to adrenocortical insufficiency
  Desired outcome: *The patient will demonstrate knowledge of risk factors associated with potential for injury and will practice appropriate precautions for prevention.*

Planning and Intervention

Maximizing Therapeutic Effects

Assess for drugs that may interact with fludrocortisone and decrease its efficacy. These drugs include barbiturates, cholestyramine, oral contraceptives, and salicylates. As with prednisone, evaluate the need for an increased dose of fludrocortisone during times of injury, stress, or infection, or during surgery.

Minimizing Adverse Effects

Monitor blood pressure, fluid balance, signs of edema, serum electrolyte status, and serum renin activity. Patients with a history of renal or cardiovascular dysfunction are at risk for adverse effects from fludrocortisone. Review the importance of following a diet high in potassium-rich foods in order to prevent potassium loss and low sodium intake to reduce the risk for hypertension, weight gain, and edema.

MEMORY CHIP

P Fludrocortisone

- Fludrocortisone is given for adrenal insufficiency (Addison disease)
- Fludrocortisone may cause HRA axis suppression if given for more than 2 weeks and withdrawn too abruptly; abrupt withdrawal places the patient at risk for acute adrenal insufficiency.
- Major contraindications: hypersensitivity to fludrocortisone; conditions not requiring intense mineralocorticoid activity
- Most common adverse effects: sodium retention and increased urinary potassium excretion
- Most serious adverse effects: chronic heart failure, cardiomegaly, and hypokalemic alkalosis
- Maximizing therapeutic effects: Increase the dosage in times of stress to prevent drug-induced adrenal insufficiency.
- Minimizing adverse effects: Monitor fluid balance.
- Most important patient education: Eat potassium-rich foods and moderate sodium intake.

Providing Patient and Family Education

- Instruct patients to adhere to drug therapy as prescribed, stressing the importance of regular follow-up visits with the prescriber.
- Encourage patients to wear a medical identification bracelet stating their medical condition and the specific drug therapy.
- Teach patients to report unusual weight gain, lower extremity edema, muscle weakness, and severe or continuing headache.
- Teach patients to monitor blood pressure.
- Schedule follow-up appointments to monitor serum electrolytes (including calcium) regularly to prevent fludrocortisone overdosage.
- Help patients develop a low-sodium and high-potassium dietary plan.
- Teach patients to weigh themselves daily; any sudden weight increase indicates fluid retention.
- Teach signs and symptoms for self-monitoring adverse effects to drug therapy.

Ongoing Assessment and Evaluation

Monitor for edema, weight gain, hypertension, cardiac arrhythmias, or muscular weakness that may develop because of fludrocortisone's sodium-retaining effects. Potassium supplementation may be necessary related to potassium loss. Periods of stress (e.g., those related to trauma, surgery, or severe illness) may require medication adjustment of mineralocorticoid and glucocorticoid dosage to avoid drug-induced adrenal insufficiency.

Assess the patient for adverse reactions to fludrocortisone, including fluid retention (e.g., increased blood pressure, sudden weight gain), ankle edema, and respiratory crackles. Additionally, monitor for acute adrenal insufficiency or characteristic adverse glucocorticoid reactions. Fludrocortisone replacement therapy is effective when the patient exhibits a normal blood pressure, and fluid and electrolyte balance is within normal limits. The patient should be able to explain the importance of self-monitoring for adverse effects.

C STEROID HORMONE ANTAGONISTS

Steroid hormone antagonists, otherwise known as adrenal **steroid hormone inhibitors,** act to inhibit or suppress the steroidogenesis by the adrenal cortex, thus controlling the symptoms of Cushing syndrome. Drugs within this class include aminoglutethimide, cyproheptadine, ketoconazole, mifepristone, and mitotane. Aminoglutethimide, which suppresses adrenal cortical function, is the prototype steroid hormone antagonist.

Nursing Management of the Patient Receiving P Aminoglutethimide

Core Drug Knowledge

Pharmacotherapeutics

Aminoglutethimide is used to treat hypercortisolism (Cushing syndrome). It does not affect the underlying pathology of the hypercortisolism and is used for a short period (less than 3 months) until more definitive therapy (e.g., surgery or pituitary radiation) can be initiated. Non-FDA-approved uses include advanced breast cancer in postmenopausal women and metastatic prostate cancer.

Pharmacokinetics

Aminoglutethimide is well absorbed orally and is bound minimally to plasma proteins. Its plasma half-life of 5 to 9 hours (initially, 11 to 16 hours) decreases following 1 to 2 weeks of therapy because of its action as a hepatic enzyme inducer. Aminoglutethimide crosses the placenta and is secreted in breast milk. It is excreted in the urine. The usual adult dosage for Cushing syndrome is 250 mg every 6 hours, up to a maximum of 2 g/d (see Table 48.6).

TABLE 48.6 Overview of P Aminoglutethimide

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P aminoglutethimide	Cushing syndrome	Adult PO: 250 mg every 6 h to a maximum of 2 g/d Child: Safety and efficacy not established	Onset: gradual Duration: unknown T ½: 11–16 h
	Breast cancer	Adult PO: 250 mg 2×/d for 2 wk then increase to 250 mg 4×/d. Given in combination with hydrocortisone.	

Pharmacodynamics

Aminoglutethimide inhibits enzymatic conversion of cholesterol to pregnenolone, which is the first step in steroid syntheses pathway. This reduces the synthesis of all adrenal steroids. The decrease in adrenal steroids induces a compensatory increase in secretion of ACTH, necessitating coadministration of hydrocortisone to maintain aminoglutethimide's effect. Aminoglutethimide also blocks the aromatase enzyme, which decreases estrogen production from androgens in peripheral tissues.

Contraindications and Precautions

Hypersensitivity to glutethimide (a nonbarbiturate sedative-hypnotic) or aminoglutethimide is a contraindication for use. A pregnancy category D drug, aminoglutethimide is used cautiously during pregnancy.

Adverse Effects

Common adverse reactions to aminoglutethimide include drowsiness, dizziness, skin rash, nausea, and anorexia. These effects usually disappear spontaneously within 1 to 2 weeks of therapy. Aminoglutethimide may suppress aldosterone production by the adrenal cortex, resulting in hypotension and compensatory tachycardia. Additional adverse effects include headache, myalgias, and blood dyscrasias such as granulocytosis, leukopenia, neutropenia, and pancytopenia. Rarely, elevated liver enzymes or hepatotoxicity may occur.

Drug Interactions

Drug interactions with aminoglutethimide occur because of its action as an enzyme inducer. Aminoglutethimide interacts with coumarin, warfarin, other oral anticoagulants, theophylline, digoxin, medroxyprogesterone, and dexamethasone. Table 48.7 lists agents that interact with aminoglutethimide.

Assessment of Relevant Core Patient Variables

Health Status

Review current laboratory data because hypothyroidism and hematologic abnormalities may occur with aminoglutethimide use. These tests include a CBC, serum electrolyte levels, thyroid function studies, kidney and liver function, glucose tolerance test results, electrocardiogram, x-ray films of spine and chest, and tuberculin skin test results. Assess the patient's history of prescription, OTC, recreational, or illicit drug use; GI upset; ulcers; or epigastric pain. Also assess nutritional status, weight control, concurrent disease, and trauma history. Include orthostatic vital signs in the physical assessment. Observe muscle strength and body proportions as well as hair growth and distribution patterns. Throughout therapy, continue to assess for signs of adrenal insufficiency.

Life Span and Gender

Determine whether the patient is pregnant. Aminoglutethimide is a pregnancy category D drug and should be avoided during pregnancy. It is unknown whether it is secreted in breast milk; safety in lactation and safety and efficacy in children have not been established. It is important to note the patient's physical condition and age before administering aminoglutethimide. Geriatric patients may have increased sensitivity to CNS effects and may become lethargic.

Lifestyle, Diet, and Habits

Assess the patient's typical daily activities. Dizziness and drowsiness may occur with aminoglutethimide use, and caution when performing activities requiring alertness and concentration is necessary until drug effects are known. It also is important to determine the patient's alcohol intake because alcohol potentiates aminoglutethimide's effect.

Environment

Aminoglutethimide may be given in any setting, including the home environment.

Nursing Diagnoses and Outcomes

- Risk for Injury related to CNS effects of hypotension and sedation, endocrine effects of hypothyroidism, or hematologic effects of agranulocytosis, leukopenia, and thrombocytopenia

TABLE 48.7 Agents That Interact with P Aminoglutethimide

Interactants	Effect and Significance	Nursing Management
oral anticoagulants	Aminoglutethimide increases warfarin metabolic clearance, reducing action of warfarin.	Monitor PT/INR. Monitor for signs of bruising or bleeding. Discuss dosage adjustment of warfarin with health care provider.
corticosteroids	Aminoglutethimide may induce loss of dexamethasone-induced adrenal suppression, resulting in unsuccessful chemical adrenalectomy.	Doses of dexamethasone higher than usually required may be necessary. Discuss substituting hydrocortisone for dexamethasone with health care provider.
theophyllines	Aminoglutethimide is a potent inducer of hepatic enzymes responsible for the metabolism of theophylline.	Monitor serum theophylline levels. Monitor respiratory status. Discuss dosage adjustment of theophylline with health care provider.

Desired outcome: *The patient will remain injury free during aminoglutethimide therapy.*

- Imbalanced Nutrition: Less than Body Requirements related to adverse effects of anorexia and nausea
  Desired outcome: *There will be no change or an improved nutritional status.*
- Disturbed Body Image related to hirsutism and masculinization (in females)
  Desired outcome: *The patient will identify and incorporate methods for camouflaging the adverse hormonal effects of aminoglutethimide therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Advise the patient to carry medical identification and to inform health care professionals that aminoglutethimide is being taken. It is important to remind the patient that an injury, infection, or illness may cause adrenocortical insufficiency, and the patient may require a medication dose adjustment.

Minimizing Adverse Effects

Suppression of aldosterone production may cause orthostatic or persistent hypotension. Teach the patient to change positions slowly and to avoid situations or environments that enhance hypotension (e.g., consumption of alcohol, overheated areas) to decrease the risk of accidental injury from postural hypotension.

Providing Patient and Family Education

- Discuss the adverse reactions of aminoglutethimide, including dizziness or drowsiness, nausea, anorexia, headache, orthostatic hypotension, and hirsutism.
- Caution patients about driving or performing other tasks that requires alertness, coordination, or physical dexterity until the effects of the drug are known.
- Teach patients that small, frequent meals of bland foods may reduce the symptoms of nausea.
- Teach patients to change positions slowly to reduce fall risk caused by orthostatic hypotension.
- Teach patients to report skin rash, severe drowsiness or dizziness, headache, or severe nausea.
- Teach patients to avoid pregnancy, alcohol consumption, and overheated environments while taking this drug.

Ongoing Assessment and Evaluation

Continuously assess for adrenal insufficiency because adjustment of the aminoglutethimide dose may be necessary. Monitor blood pressure and assess for hematologic abnormalities and physical and mental changes associated with hypothyroidism. Thyroid hormone replacement may be necessary.

Nursing management of aminoglutethimide therapy is considered successful when the patient sustains a reduced plasma cortisol level. The patient should be able to state the importance of self-monitoring for adverse effects and of reporting symptoms to the prescriber.

MEMORY CHIP

P Aminoglutethimide

- Used to treat adrenocortical hormone excess (Cushing syndrome); it suppresses adrenal cortical function
- Major contraindication: hypersensitivity to glutethimide
- Most common adverse effects: drowsiness, skin rash, nausea, headache, myalgia, and anorexia
- Most serious adverse effects: orthostatic hypotension and tachycardia
- Maximizing therapeutic effects: Provide supplemental doses of steroids during times of injury, infection, or illness.
- Minimizing adverse effects: Help the patient change positions slowly to decrease the risk of injury related to orthostatic hypotension.
- Most important patient education: Take the drug with small, frequent meals to lessen GI effects; do not drive or perform other tasks that require alertness, coordination, or physical dexterity until the effects of the drug are known.

Drugs Significantly Different From P Aminoglutethimide

Cyproheptadine

Cyproheptadine (Periactin) is a potent serotonin and cholinergic antagonist that inhibits secretion of ACTH from pituitary microadenoma cells. It is used for treatment of ACTH hypersecretion and Cushing syndrome secondary to pituitary disorders. Remission of Cushing syndrome usually occurs 1 to 3 months after beginning therapy.

Ketoconazole

Ketoconazole (Nizoral) is an antifungal that strongly inhibits all gonadal and adrenal steroid hormone synthesis. It is used in conjunction with surgery or radiation to inhibit glucocorticoid synthesis. The dose required for adrenal suppression is much higher than when ketoconazole is used as an antifungal agent. Ketoconazole is also discussed in Chapter 44.

Mitotane

Mitotane (Lysodren) is an adrenal cytotoxic agent, although it can cause adrenal inhibition without cellular destruction. It is used for palliative treatment of inoperable adrenal cortical carcinoma. Its biochemical action is unknown, but it reduces production of adrenal steroids and is thought to modify the peripheral metabolism of steroids and directly suppress the adrenal cortex. Approximately 40% of oral mitotane is absorbed; it is primarily stored in fat and undergoes hepatic metabolism. It is excreted in the urine and feces. Its blood levels, detectable for up to 10 weeks after discontinuation of therapy because of the drug's lipophilic nature, does not appear to be related to therapeutic or toxic effects. This may require that the patient be tapered to the usual replacement dose for several weeks after the patient is cured or mitotane is discontinued.

Mitotane is assigned to pregnancy category C. Reliable contraceptive measures are recommended during therapy.

Precautions include concomitant drug therapy, hepatic enzyme induction, and the probability that adrenal insufficiency may develop. Adverse reactions include GI distress such as nausea, diarrhea, vomiting, lethargy and somnolence, transient skin rashes, and hypercholesterolemia and hypouricemia. It is also hepatotoxic and requires monitoring of serum alkaline phosphatase concentration. The drug has a black box warning that the drug be used under the supervision of a physician experienced in the use of cancer chemotherapeutic agents. Also, the drug should temporarily be discontinued following shock or severe trauma as adrenal suppression is its prime action.

CHAPTER SUMMARY

- Corticosteroids affect every body system and have the potential to cause severe adverse effects. Prolonged high-dose corticosteroid therapy increases the incidence of disabling and lethal effects.
- Glucocorticoids occupy an important role in the pharmacologic management of various inflammatory diseases despite the numerous complications that may occur from therapy. Uses of the corticosteroids include replacement, anti-inflammatory, and immunosuppressive therapies. Glucocorticoids are used as replacement therapy in Addison disease, as pharmacologic anti-inflammatory drugs for serious inflammatory disorders and autoimmune diseases, and for a chemotherapeutic effect in certain malignant neoplasms.
- Glucocorticoids are potentially useful in many situations when used with caution. To prevent or manage adverse effects, the nurse, the patient, and the family need a clear understanding of the drugs' actions and uses.
- Glucocorticoids used therapeutically are usually synthetic analogues of the naturally occurring adrenal corticosteroid cortisol, also known as cortisone. The prototype glucocorticoid is prednisone.
- Some patients are at high risk for the serious adverse or toxic effects of the glucocorticoids. Use precautions to avoid viral infections and live virus vaccines. Use with caution in children, pregnant or lactating women, and patients with diseases and disorders, such as cardiovascular disease, renal impairment, peptic ulcer disease, diabetes mellitus, osteoporosis, and treatment-resistant infections.
- Adverse effects, also known as cushingoid effects or characteristics, may be debilitating and life threatening. Cushingoid effects occur with long-term high dosages of systemic glucocorticoids.
- Acute adrenal insufficiency (addisonian crisis) may occur after abrupt withdrawal of pharmacologic dosages of glucocorticoids. A patient experiencing acute adrenal insufficiency is in a potentially life-threatening situation because of the multiple body systems involved.
- During steroid therapy, the underlying disease or condition and its extent suggest the therapeutic goals that direct the nursing care. Patient and family education is fundamental to nursing management.
- Mineralocorticoids are essential for fluid, sodium, and potassium homeostasis.
- Fludrocortisone is the prototype mineralocorticoid. It is used therapeutically with a glucocorticoid for treating patients with adrenocortical insufficiency (Addison disease).
- Episodes of acute stress (e.g., surgery or trauma) may require a dosage adjustment of the corticosteroids to prevent acute adrenal insufficiency.
- Aminoglutethimide, an adrenal steroid inhibitor, suppresses adrenal cortical function. It is used for disorders chiefly characterized by adrenocortical hormone excess (Cushing syndrome).

QUESTIONS FOR STUDY AND REVIEW

1. What are the main effects of glucocorticoids on metabolism?
2. What are the physiologic changes that occur as a result of untreated acute and chronic adrenal insufficiency (Addison disease)?
3. What is Cushing syndrome? What is the physiologic effect of chronic pharmacologic dosage of glucocorticoids? How is Cushing syndrome different from "cushingoid" characteristics?
4. What are the three major actions of the adrenal steroids?
5. What are the two major clinical uses of adrenal steroids?
6. Why should glucocorticoid therapy never be stopped suddenly in a patient who has been receiving long-term therapy?
7. What are the advantages and disadvantages of glucocorticoid alternate-day therapy?
8. What drug interactions commonly occur with glucocorticoids?
9. What is the major clinical use of fludrocortisone? What steroid characteristics does it possess?
10. What patient teaching should be done with patients taking fludrocortisone?
11. What is the major clinical indication for use of the adrenal steroid inhibitors? Name the prototype adrenal steroid inhibitor. Explain its function.

Drugs Affecting Blood Glucose Levels

Learning Objectives

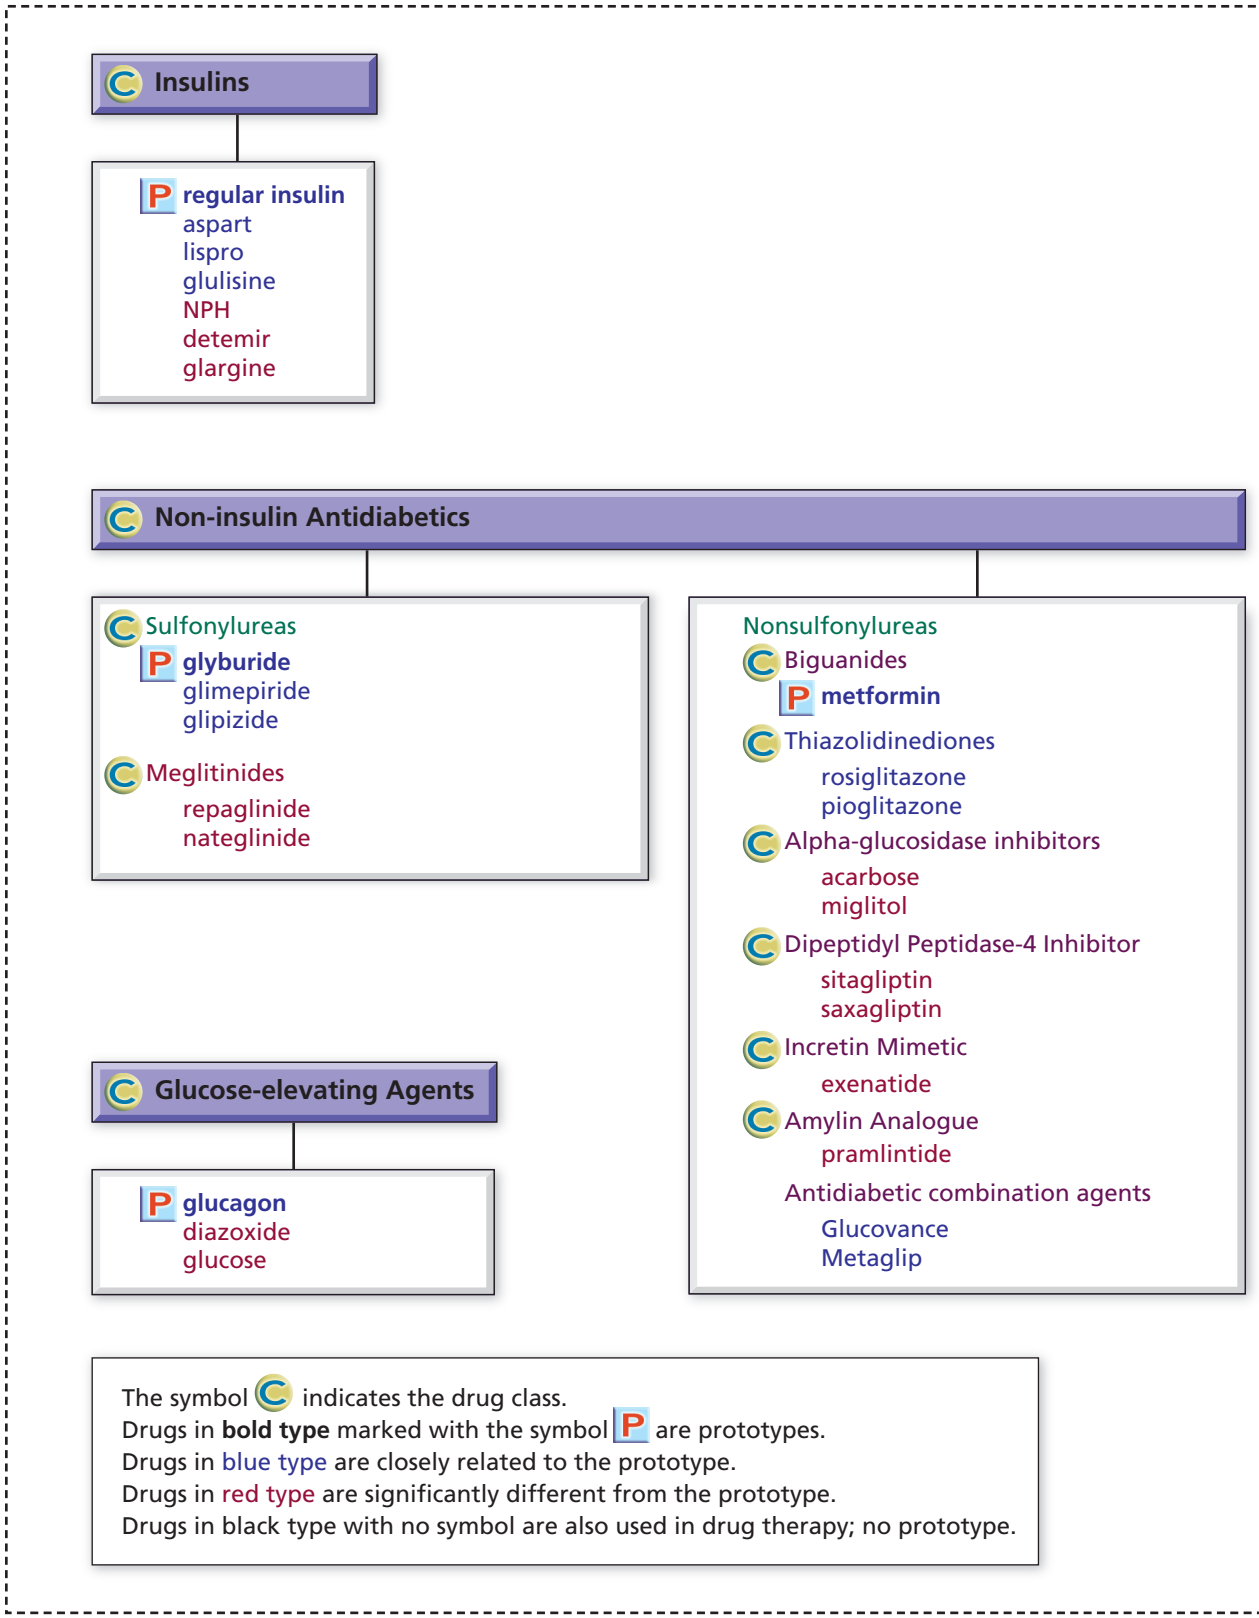
At the completion of this chapter the student will:

1. Discuss the importance of diabetes in terms of prevalence and costs.
2. Compare the characteristics of type 1, type 2, and gestational diabetes; describe their pathophysiologic processes.
3. Explain the current principles of insulin therapy, which guide care of the diabetic patient.
4. Identify core drug knowledge and core patient variables for the various insulins and for the oral antidiabetic drugs.
5. Identify the peak action time for the four types of insulin and determine when a hypoglycemic episode is most likely to occur with the use of each type.
6. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect blood glucose.
7. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for the drugs that lower blood glucose.
8. Describe treatment for hypoglycemia and hyperglycemia
9. Determine key points for patient and family education for insulin and the oral antidiabetic drugs that affect blood glucose levels.

Key Terms

basal insulin
correctional insulin
dawn phenomenon
diabetes mellitus
diabetic ketoacidosis
gestational diabetes mellitus
gluconeogenesis
glycogenolysis
glycosylated hemoglobin
hyperglycemia
hypoglycemia
insulin
lipodystrophy
metabolic syndrome
nonketotic hyperglycemia
prandial insulin
Somogyi effect
supplemental insulin
type 1 diabetes
type 2 diabetes

Drugs Affecting Blood Glucose Levels



Diabetes mellitus is a common chronic disease that affects 23.6 million people in the United States, or 7.8% of the population (CDC, 2007). Although an estimated 17.9 million people are diagnosed with diabetes, 5.7 million are unaware they have the disease (CDC, 2010a). Approximately 5% to 10% of Americans diagnosed with diabetes have type 1 (lack of endogenous insulin), whereas 90% to 95% have type 2 (diminished insulin effectiveness) (CDC, 2010a). In the United States, diabetes is the sixth leading cause of death by disease, although it is believed to be underreported as a cause of death (Heron, Hoyert, Murphy, et al. 2009; CDC, 2010a).

People with diabetes are at increased risk for cardiovascular disease (hypertension, heart disease, stroke), kidney failure, blindness, nervous system disease, extremity amputations, dental disease, and complications of pregnancy. These morbidities add to the cost of care for diabetes. In 2007, the total annual economic cost of diabetes was estimated to be $174 billion (CDC, 2010a). Diabetes has serious consequences that require patient self-management education and continuing medical care provided by an interdisciplinary team of health care professionals. Although research is exploring how to correct the pathologies in the pancreas that produce diabetes (e.g., transplantation of islets of Langerhans cells), at this time, diabetes is normally controlled by drug therapy and cannot be cured.

Exogenous insulins (manufactured versions of the protein hormone that helps regulate the use of sugar and other carbohydrates) are used to replace deficient intrinsic insulins. The prototype insulin is regular insulin. There are several other types of insulin. Oral antidiabetic drugs are used to control type 2 diabetes, in which there is insulin resistance. These agents belong to several chemical classes, but can generally be considered in two groups: sulfonylureas and nonsulfonylureas (also known as antiglycemics or antihyperglycemics). The prototype sulfonylurea is glyburide; the prototype nonsulfonylurea is metformin.

PHYSIOLOGY

Glucose is made available to the body from food that is ingested and from the production of glucose by the liver. Unable to store or synthesize glucose, the brain depends on a steady supply of glucose from the circulation and extracts its energy on a nearly continuous basis.

Three body systems are involved in the regulation and use of glucose—the liver, pancreas, and skeletal muscle tissue. The liver synthesizes its own glucose supply (a process called **gluconeogenesis**) in addition to storing and releasing glucose that has been converted from dietary carbohydrates. Normally, the liver releases some of its stored or synthesized glucose when blood levels are low and stops producing and releasing glucose when blood levels are high.

The pancreas is both an exocrine and endocrine gland. Its exocrine pancreatic function is to produce digestive enzymes. Its endocrine function is to synthesize and secrete peptide hormones—insulin, glucagon, and somatostatin—by the islets of Langerhans. The islets of Langerhans are cellular structures that lie in the interstitial tissue of the pancreas and are richly innervated by adrenergic and cholinergic nerves. Insulin, glucagon, and somatostatin play an important role in regulating the metabolic activities of the body as well as in regulating and maintaining the homeostasis of blood glucose. The islets of Langerhans contain the following types of cells:

- Beta cells, which secrete the hypoglycemic hormone insulin
- Alpha cells, which secrete the hyperglycemic hormone glucagon
- Delta cells, which release somatostatin, a hormone that inhibits both glucagon and insulin secretion
- F cells, which synthesize and secrete pancreatic polypeptides used in digestion

The muscle tissue is the target organ for the action of insulin; it contains the majority of insulin receptor sites. When insulin binds with receptor sites on the skeletal muscle, glucose is able to cross over the membrane and enter the cell. When muscle tissue has fewer available receptor sites than are needed by the cells for glucose entry, a condition called insulin resistance occurs. Insulin resistance plays a major role in the development of type 2 diabetes.

Insulin

Insulin is a small protein, consisting of two polypeptide chains, which is synthesized as a precursor protein (proinsulin) that then undergoes enzymatic splitting to form insulin and peptide C—both of which are secreted by the pancreatic beta cells. Measurement of circulating C peptide provides an index of insulin levels.

Insulin secretion is regulated tightly by a coordinated interaction of blood glucose levels, gastrointestinal (GI) and pancreatic hormones, and autonomic neurotransmitters. Insulin secretion is most commonly triggered by high blood glucose. Glucose is one of the body's most important energy sources, and some tissues—especially those in the brain—are highly dependent on glucose for energy, particularly the glucose extracted from the blood. Therefore, careful regulation of blood glucose levels and cellular uptake is essential.

Numerous hormones are involved in regulating blood glucose levels. However, two hormones—insulin and glucagon, secreted by the pancreas—exert the most direct influence.

Functions of Insulin

Insulin has a number of important actions. Primarily, it regulates carbohydrate metabolism, but it also plays an important role in metabolizing fats and proteins. Insulin and its analogues lower blood glucose levels by stimulating peripheral glucose uptake, especially by skeletal muscle and fat. Insulin works at specific receptors to allow the glucose to enter the cells. It is normally released rapidly in response to elevations of circulating glucose. Insulin resistance leads to an inappropriately elevated hepatic glucose output and impaired glucose uptake by the muscle tissue. In the liver, insulin has several functions; it promotes the uptake and storage of glucose in

the form of glycogen, promotes the conversion of excess glucose into fat, and suppresses hepatic gluconeogenesis (production of glucose) and **glycogenolysis** (breakdown of glycogen to glucose). Most tissues in the body need insulin so that glucose can enter their cells (Figure 49.1). However, the tissues of the brain, nerves, intestine, liver, retina, erythrocytes, and renal tubules do not.

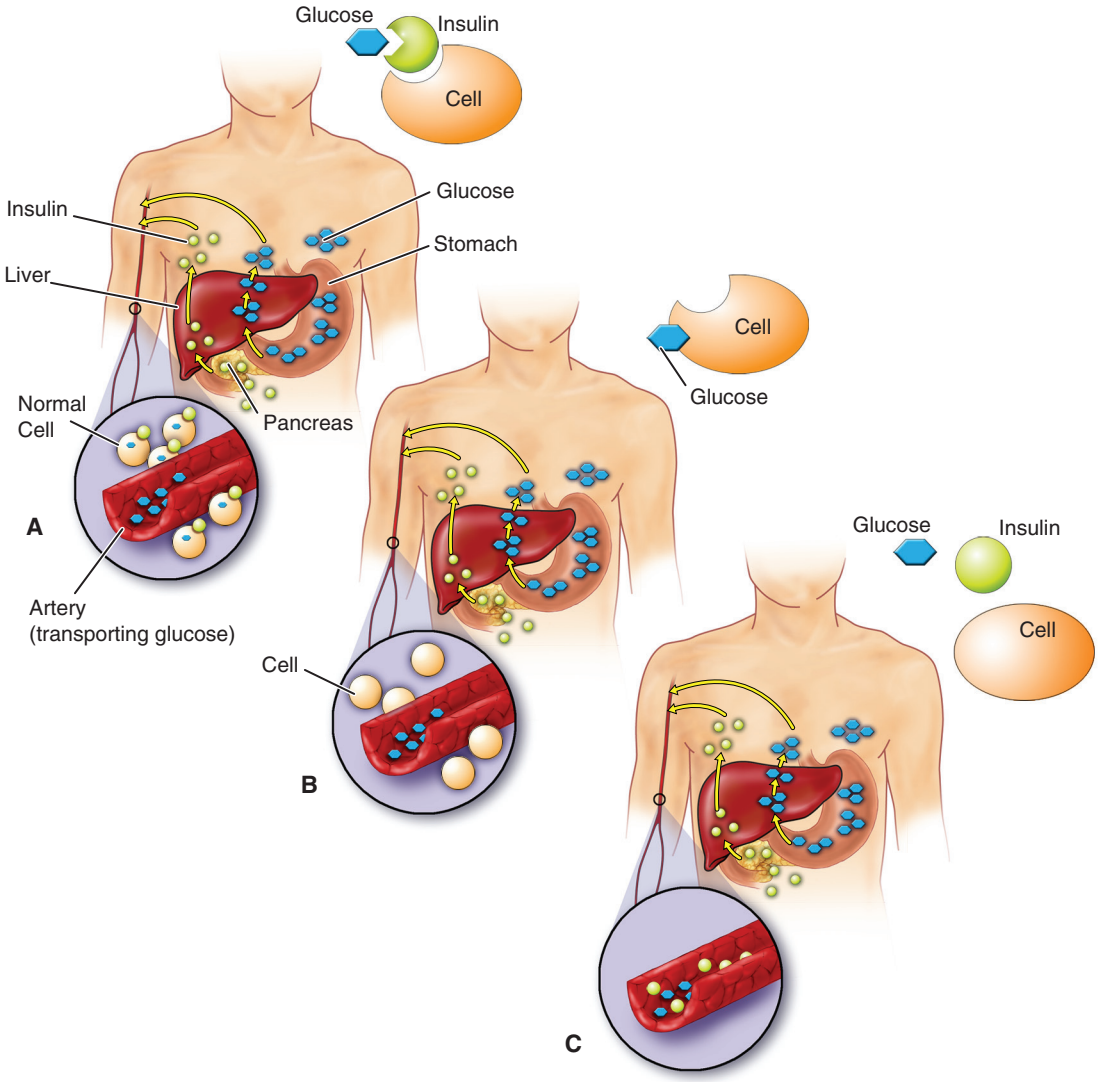
Insulin Synthesis and Release

The plasma glucose level is the single most important factor in controlling the rate of insulin synthesis and release. Other factors that directly or indirectly influence insulin release or its action include blood levels of sugars (fructose, sucrose, and others), levels of free fatty acids, growth hormone, thyroid-stimulating hormone, glucagon, sympathetic and parasympathetic stimulation, adrenocorticotropic hormone, and cortisol.

Stimulated by plasma glucose levels, insulin secretion occurs in two phases. During the first phase, insulin secretion peaks after 1 to 2 minutes and is short lived. Delayed onset and a longer duration of action characterize the second phase. The exact mechanism by which glucose stimulates insulin release is not fully understood.

Blood glucose levels may be influenced by several factors other than insulin secretion. Any of the following can cause changes in blood glucose levels:

- Stress or illness
- Secretion of insulin-antagonistic hormones (counter-regulatory hormones) that affect glucose metabolism



• FIGURE 49.1 (**A**) Normally, glucose is made available to the body from the food that is ingested and from glucose production by the liver. Insulin secreted by beta cells in the pancreas binds to the skeletal muscle cells, allowing glucose to cross the plasma membrane and enter the cell. As depicted in the enlargement, insulin provides the key that unlocks the cellular membrane to allow glucose to enter. (**B**) In type 1 diabetes, the pancreas does not produce insulin, so glucose cannot refuel the cells. Without insulin (the key), glucose is unable to enter the cell. (**C**) In type 2 diabetes, insulin is produced by the pancreas but it does not work properly and the glucose is not absorbed by the cell. Both types of diabetes have the same result: failure of glucose to be absorbed into the cells, leading to hyperglycemia.

(e.g., cortisol, epinephrine, growth hormone, glucagon, and somatostatin)
- Rates of hepatic synthesis of glucose (gluconeogenesis) or conversion of glycogen to yield glucose (glycogenolysis)
- Presence and levels of insulin antibodies
- Use of glucose by peripheral cells or tissues
- Number of cellular insulin receptors

In response to postprandial elevations of blood glucose levels (those that occur after a meal), insulin is released into the bloodstream by the beta cells. A prompt increase in insulin release occurs so that absorbed carbohydrates are transported rapidly to the liver and other tissues where carbohydrates are stored or used, preventing the serum glucose level from rising too much. As a result, blood glucose levels decline, and the stimulus for insulin secretion is suppressed. When the level of serum glucose decreases, the alpha cells release glucagon into the bloodstream, raising the blood glucose level by stimulating the release of glycogen from hepatic storage sites and thus preventing the serum glucose level from falling too low.

Between periods of food intake, insulin levels remain low, and sources of stored glucose and amino acids are mobilized to meet the energy needs of glucose-dependent tissues. Hepatic glycogen stores are depleted within 6 hours after a meal. If additional food is not ingested by this time, muscles begin to release amino acids that are converted to glucose. Lipolysis occurs in adipose tissue, and serum levels of free fatty acids rise. Free fatty acids are used for energy by muscle and liver cells, thus conserving glucose for use by the brain.

Glucagon

Glucagon also plays a role in regulating the blood glucose level. Glucagon is a small protein hormone, and declining blood glucose levels stimulate its release from pancreatic islet alpha cells. Sympathetic nerve impulses, exercise, infection, and trauma also stimulate its release. In the liver, glucagon stimulates glycogenolysis and gluconeogenesis, resulting in a release of glucose into the blood.

PATHOPHYSIOLOGY

Diabetes mellitus is a serious chronic disease that affects people of all ages and ethnic groups. Most cases of diabetes fall into two broad categories—type 1 and type 2. Another type of diabetes, gestational diabetes mellitus, is a condition characterized by glucose intolerance with onset during pregnancy. Some other conditions can induce a diabetes-like state with hyperglycemia, including diseases such as carcinomas, pancreatitis, and infections; hormonal abnormalities such as acromegaly and Cushing syndrome; drugs such as corticosteroids; and genetic defects of the beta cell. A different type of diabetes, termed diabetes insipidus, is a metabolic disorder in which high amounts of dilute urine are formed because of deficient production of antidiuretic hormone (ADH) or inability of the kidney tubules to concentrate urine (see Chapter 53). This type of diabetes does not alter blood glucose levels and is not treated by insulin or oral antidiabetic drugs. For simplicity, this text will use the term *diabetes* to refer to diabetes mellitus.

Type 1 Diabetes Mellitus

Type 1 diabetes is an autoimmune disorder characterized by the destruction of the insulin-secreting beta cells in the pancreas, leading to absolute insulin deficiency (see Figure 49.1). The body's reserve of insulin is depleted, resulting in **hyperglycemia** (abnormally high blood glucose). Because the circulating glucose is not accessible to the cells, the body mistakenly interprets this to mean that there is not enough glucose and thus initiates two other processes to gain energy: breaking down lipids and breaking down proteins. The increase in lipid metabolism leads to an increase in ketoacids, causing ketoacidosis (metabolic acidosis of diabetes). The breaking down of proteins leads to muscle wasting, constant weakness, and weight loss. By the time the signs and syfmptoms of type 1 diabetes appear, most pancreatic beta cells have been destroyed. Although the pathogenesis is unclear, considerable evidence (e.g., the presence of islet cell and insulin autoantibodies) suggests that the destructive process is autoimmune, with some genetic and environmental components. The autoimmune destruction of the pancreatic beta cells may occur over a period of months to several years before the onset of clinical disease is observed. The final result of type 1 diabetes is an extensive and selective loss of pancreatic beta cells and a state of absolute insulin deficiency (insulinopenia). Therefore, insulin therapy is indicated in all cases of type 1 diabetes. Insulin is used as replacement therapy by supplementing the deficient endogenous levels and temporarily restoring the ability of the body to use carbohydrates, fats, and proteins properly.

The onset of type 1 diabetes commonly occurs during childhood or puberty; however, it can develop at any age. In fact, another small peak of onset is seen during midlife.

Type 2 Diabetes Mellitus

Type 2 diabetes is the result of insulin resistance by the tissues and usually a decrease in insulin production (see Figure 49.1). Abnormalities of carbohydrate, fat, and protein metabolism occur in type 2 diabetes. Type 2 diabetes is linked closely to obesity, sedentary lifestyle, and lack of physical activity; scientific experts declare that the dramatic rise in the number of patients with this type of diabetes is attributable, in great part, to America's weight problem. More than two thirds of the U.S. adult population is either overweight or obese (Centers for Disease Control and Prevention, 2010b)

No appreciable loss of pancreatic beta cells or cellular activity from the islets occurs in type 2 diabetes. Plasma concentrations of insulin are essentially normal or may even be increased because the pancreas tries to overcome the resistance by producing more insulin; because the peripheral tissue is resistant to insulin, the insulin does not enter the cells but stays in the bloodstream.

Historically, type 2 diabetes was rare in children, adolescents, and young adults. However, this is no longer the case because type 2 diabetes is increasing in these younger age groups as the childhood population becomes increasingly overweight. Almost one in five American children is overweight (American Obesity Association, 2010c). Type 2 diabetes is now seen as an emerging epidemic in the pediatric population. Obesity and diabetes are also risk factors for cardiovascular disease, and as the incidence of diabetes increases in the pediatric population so does the risk for cardiovascular disease.

Race also appears to be a risk factor for developing type 2 diabetes. Type 2 diabetes occurs in a disproportionately higher prevalence in some racial groups in the United States, including African Americans, Hispanic Americans, and Native Americans. Other factors (besides obesity, race/ethnicity, and impaired glucose metabolism) are associated with type 2 diabetes, including older age, family history of diabetes, and history of gestational diabetes.

Insulin resistance can be considered the primary defect in type 2 diabetes. An insulin-resistance syndrome known as **metabolic syndrome** (or Syndrome X) is a precursor to the development of type 2 diabetes. This syndrome is a combination of conditions, namely insulin resistance with a compensatory hyperinsulinemia to maintain glucose homeostasis; obesity (especially abdominal or visceral obesity); dyslipidemia characterized by high triglycerides, low high-density lipoproteins (HDLs), or both; prothrombotic state (e.g., high fibrinogen or plasminogen activator inhibitor); proinflammatory state (e.g., elevated high-sensitivity C-reactive protein in the blood); and hypertension (130/85 mm Hg or greater). Approximately 33% to 35% of American adults have metabolic syndrome (American Heart Association, 2010d). The focus of these signs and symptoms is an increasing inability to use insulin. Hyperlipidemia linked to insulin abnormalities leads to atherosclerotic plaques in the vessels. Metabolic syndrome increases the risk of cardiovascular disease. Patients with undiagnosed type 2 diabetes (which is fairly common) are at greatly increased risk for coronary heart disease, stroke, and peripheral vascular disease.

In many cases, type 2 diabetes can be controlled with weight reduction, age-appropriate physical activity, dietary modifications, and oral drug therapy or injections of insulin.

Table 49.1 compares type 1 with type 2 diabetes.

TABLE 49.1 Comparison of Type 1 and Type 2 Diabetes Mellitus

Patient Characteristics	Type 1 (Absolute Insulin Deficiency)	Type 2 (Relative Insulin Deficiency)
Age at onset	Usually before 20 y; onset sudden	Usually after 40 y with incidence increasing as age and weight increase; gradual onset; may occur in youth
Incidence	5%–10%	90%–95%
Body weight	Usually thin/underweight or normal weight	Usually overweight/obese
Endogenous insulin production/activity	Significantly decreased/absent	Slightly decreased; normal or may be increased; insulin effects reduced by inadequate tissue (receptor) response
Insulin receptors/resistance	Normal receptors/no resistance	Decreased or defective receptors/definite insulin resistance
Dietary modifications	Necessary	Beneficial for blood glucose and weight control
Exogenous insulin requirement	Required for all patients with type 1 diabetes	May be necessary for patients with type 2 diabetes
Clinical signs/symptoms	Hyperglycemia, significant polyphagia/ polydipsia/ polyuria, weight loss	Hyperglycemia, fatigue, weakness, mild polyphagia/ polydipsia/polyuria, fungal infections (especially skin, vaginal), blurred vision
Complications		
Acute—ketoacidosis	Likely	Unlikely; may occur in the presence of severe illness/ stress
Chronic—microvascular and macrovascular disorders	Frequent	Frequent
Etiology/genetic susceptibility	Not fully known; related to human leukocyte antigen (HLA-DR3, HLA-DR4), proposed beta-cell destruction by viral infection or autoimmune process	Not fully known; strong familial component
Clinical management	Insulin injections, dietary controls, exercise regimen	Weight reduction, dietary controls, exercise regimen, oral drug therapy, insulin

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) occurs when a woman's pancreatic function is not sufficient to overcome the insulin resistance created by the anti-insulin hormones secreted by the placenta (e.g., estrogen, prolactin, cortisol, and progesterone), as well as the increased fuel consumption needed for the mother and the fetus. Diagnosis and treatment are essential because the severe hyperglycemia that can result is associated with increases in the incidence of preeclampsia, fetal macrosomia (i.e., large infants), birth trauma, and perinatal mortality. GDM complicates approximately 4% of all pregnancies in the United States (American Diabetes Association, 2010). This rate may be much higher in certain populations, such as Asians, Hispanics, Native Americans, and Pacific Islanders, than in the general population. If the patient is at high risk for GDM (from obesity or because of GDM in a previous pregnancy for example) and is found to be positive for diabetes on initial screening when entering prenatal care these patients are now considered to have "overt diabetes" rather than GDM (American Diabetes Association, 2010). Treatment for GDM may include diet, exercise, and insulin. One research study of 958 pregnant women with mild gestational diabetes (an abnormal OGTT but a fasting glucose of 95 mg/dL or less) found that treating mild GDM with diet and if needed insulin (as opposed to standared prenatal care) decreased the incidence of excessive weight of the newborn (over 4,000 g), shoulder dystocia, cesarean delivery, and hypertensive disorders (gestational hypertension and preeclampsia). Rates of stillbirth or perinatal deaths were not altered by treatment (Landon et al., 2009). Generally, glucose regulation in GDM returns to normal following delivery, although 5% to 10% of women with a history of GDM are found to have type 2 diabetes. The long-term risk of developing type 2 diabetes also exists; women who have had GDM have a 20% to 50% chance of developing diabetes within the next 5 to 10 years (CDC, 2010).

Other Causes of Diabetes Mellitus

Some other factors, some endogenous some exogenous, may cause the person to develop diabetes. Endogenous sources which may produce diabetes mellitus include genetic defects in Beta cell function or insulin action or diseases of the pancreas such as cystic fibrosis. Exogenous causes of diabetes include surgical removal of the pancreas, or ingestion of certain drugs or chemicals (example: glucocorticoid steroids) (American Diabetes Association, 2010).

Criteria for Diabetes Mellitus Diagnosis

Four criteria are used to diagnose diabetes:

1. Plasma glucose = 126 mg/dL after fasting for 8 hours, or
2. Plasma glucose = 200 mg/dL during an oral glucose tolerance test (OGTT) in which 75 g of glucose dissolved in water is ingested or
3. An A1C level of ≥6.5%. (A1C is a blood test that measure long term mean glucose 6 is equal to a mean plasma glucose level of 126) or
4. Symptoms of diabetes and hyperglycemia or hyperglycemic crisis (plasma glucose ≥200 mg/dL at any time of day, regardless of time since last meal,)

Between the fasting and the oral glucose tolerance tests, the preferred screening and diagnostic test is measuring the fasting plasma glucose (FPG) because it is less expensive and easier to perform than the OGTT. The OGTT is more sensitive and more specific than the FPG, yet it is poorly reproducible and rarely used in clinical practice. A random screening is more likely to vary because of dietary intake and is not conclusive by itself. If a random screening is unexplainably elevated, a fasting specimen is ordered to confirm or disprove the diagnosis of diabetes.

A1C blood tests measure the average blood glucose level from the last 2 to 3 months. This test is being used more and more frequently in diagnosis of diabetes. Hemoglobin molecules react with glucose molecules and form glycosylated hemoglobin. This process is increased when blood glucose levels are elevated, such as in diabetes. Because this reaction of glucose with hemoglobin will last the life of the red blood cell it is possible to determine a patient's blood glucose level over time as opposed to a "snap shot view" that measures the level at a given time. Because the glucose molecule is attached to the hemoglobin molecule the lab test is sometimes referred to as an HbA1C.

When a patient's blood glucose levels are higher than normal but do not meet the criteria for diabetes they are at increased risk for developing diabetes (this was formerly termed prediabetes). Under guidelines established by the American Diabetes Association (ADA), an FPG of less than 100 mg/dL is normal, and 100 to 125 mg/dL is considered Impaired Fasting Glucose and a risk for diabetes. Impaired Glucose Tolerance where 2 hour OGTT readings are 140 to 199 mg/dl is also considered a risk factors. IFG and IGT are associated with obesity (especially abdominal or visceral obesity), dyslipidemia with high triglycerides and/or low HDL cholesterol, and hypertension. Elevated A1C of 5.7%–6.4% (normal is 6% or less) may also be recognized as a high risk for future diabetes. Chronic elevated glucose is almost always a precursor to type 2 diabetes, unless lifestyle modifications are instituted (American Diabetic Association, 2010).

Complications of Diabetes

The consequences of uncontrolled diabetes are serious and can result in acute or chronic complications.

Acute Complications

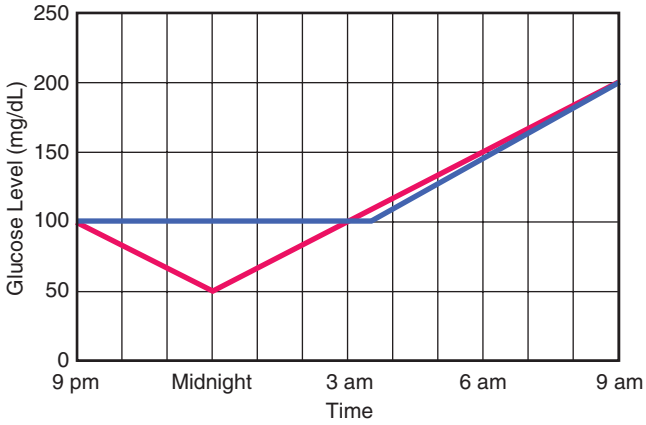
Hyperglycemia is an abnormally high concentration of glucose in the circulating blood. According to the ADA guidelines, hyperglycemia is a fasting plasma glucose value of more than 126 mg/dL. The classic signs of hyperglycemia include excessive urination (polyuria) and excessive thirst (polydipsia) caused by the osmotic pull of glucose. Other symptoms include fatigue, dry or itchy skin, poor wound healing, and vision changes (often blurred vision).

Diabetic ketoacidosis and **nonketotic hyperglycemia,** also known as hyperosmolar hyperglycemic nonketotic syndrome, are two serious acute complications of diabetes that greatly contribute to the morbidity and mortality among patients with diabetes. These disorders are extreme manifestations of impaired carbohydrate regulation that can occur in diabetes.

Diabetic ketoacidosis occurs primarily in type 1 diabetes. It occurs when ketone production by the liver outpaces ketone loss through the kidneys. Lack of insulin is usually the cause of the ketone imbalance. The onset of diabetic ketoacidosis is slow and gradual. The major metabolic imbalances present in diabetic ketoacidosis are hyperglycemia, ketosis, and metabolic acidosis. Glucose levels are more than 250 mg/dL and can potentially be more than 1,000 mg/dL. These elevated glucose levels can cause loss of consciousness. Other symptoms that may occur include osmotic diuresis, dehydration, electrolyte imbalance, tachycardia, acetone smell to the breath (sometimes referred to as a fruity breath), and hypotension. Treatment for diabetic ketoacidosis is regular insulin administered by intravenous (IV) infusion and IV replacement of fluids and electrolytes.

Nonketotic hyperglycemia also has a slow, gradual onset, but unlike diabetic ketoacidosis, it occurs primarily in type 2 diabetes. In nonketotic hyperglycemia, insulin is present, but it is not as effective as it should be. This circulating insulin prevents the formation of ketones yet is ineffective in moving the glucose from the blood into the cells. The two primary factors that contribute to nonketotic hyperglycemia are the body's increased resistance to insulin and high dietary carbohydrate consumption. The symptoms of nonketotic hyperglycemia are severe hyperglycemia (glucose level, greater than 600 mg/dL), hyperosmolarity of the blood (≥310 mOsm/L), and dehydration. The severe hyperosmolarity pulls water out of cells, including brain cells, causing neurologic changes such as altered reflexes (presence of Babinski sign), grand mal seizures, aphasia, hyperthermia, visual hallucinations, and hemiparesis. Nonketotic hyperglycemia may initially be misdiagnosed as stroke because of the overlap of some of the neurologic changes. Treatment involves careful rehydration and drug therapy to lower blood glucose.

Two types of fasting hyperglycemia can occur in diabetics receiving insulin treatment: the **dawn phenomenon** and the **Somogyi effect** (Figure 49.2). In the dawn phenomenon, blood glucose levels are at their highest between 5 AM and 6 AM. The release of growth hormone overnight is believed to produce this increase in blood glucose. Dawn phenomenon is treated by providing larger doses of intermediate-acting insulin at bedtime to prevent early-morning elevations of glucose. The Somogyi effect also produces early-morning hyperglycemia, but the precipitating factor is actually a hypoglycemic event sometime after midnight. The body compensates for the low blood glucose by using counter-regulatory hormone release, directing the liver to release glucose to restore the glucose level to normal. When the body overcompensates, rebound hyperglycemia occurs. The Somogyi effect is treated by lowering the insulin dose, increasing dietary intake at bedtime, or both. The patient's exercise habits should also be evaluated to determine the appropriate balance between calorie intake and insulin needs.



• FIGURE 49.2 Blood glucose levels characteristic of unusual phenomena: the Somogyi effect (*red line*) and the dawn phenomenon (*blue line*). In the Somogyi effect, the blood glucose dips around midnight but rises significantly in the morning before breakfast. In the common problem known as the dawn phenomenon, the blood glucose level is stable until about 3 AM but begins rising after dawn. These kinds of problems illustrate why diabetic drug dosages are tailored to meet the individual patient's needs. They present the health care practitioner with challenges and opportunities to mix insulins and adjust dosage regimens to benefit the patient.

Chronic Complications

The chronic complications of diabetes are usually classified as microvascular or macrovascular, according to the type of blood vessel damage that underlies the problem. Among the macrovascular chronic complications are atherosclerotic vascular disease, myocardial infarction, and cerebrovascular accident. Among the microvascular complications are cataracts, glaucoma and blindness from retinopathy, lower-extremity infections and gangrene, foot ulcers and Charcot joints resulting in amputation, renal failure from nephropathy and gastroparesis, and sexual dysfunction as a result of autonomic neuropathy.

Chronic complications can be prevented by a closer control of chronic glucose levels; the lab value that measures this is the hemoglobin A_{1C} level. Lowering the hemoglobin A_{1C} has been associated with a reduction of microvascular and neuropathic complications of diabetes, and it may also lower macrovascular disease. Current clinical guidelines recommend that the target hemoglobin A_{1C} is around or below 7 (American Diabetes Association, 2010). Reducing A1C to one percentage point greater than normal has been found to reduce microvascular and neuropathic complications of type 1 and type 2 diabetes. Research that studied the effect of lowering A1c closer to 6 (normal) has been mixed. Two large clinical trials that examined type 1 diabetics: Diabetes Control and Complications Trial (1993) and Association of glycaemia with macrovascular and microvascular complications of type 2 diabetes (UKPDS) (Stratton et al., 2000) showed that reducing the A1C closer to 6 further reduces the risk of

microvascular complications from diabetes. Yet, a large clinical trial Action to Control Cardiovascular Risk in diabetes (ACCORD) found that trying to decrease the A1C to 6 or less in type 2 diabetics who were at high risk for cardiovascular events actually increased the risk of cardiovascular events. Based on these findings the current recommendation is to lower A1C to around 7.

The danger of keeping tight control of blood glucose levels is **hypoglycemia,** a condition in which blood glucose levels are abnormally low. Severe hypoglycemia can result in altered consciousness or coma. The risk of hypoglycemia can be reduced by frequent blood glucose monitoring, adjusting the insulin regimen, and altering the time, frequency, and content of the patient's meals. Recent research suggests that achieving appropriate glycemic control can be particularly challenging when patients have limited access to health care (Box 49.1).

In addition to controlling glucose levels, chronic cardiovascular complications can be minimized by treating hypertension with a goal being less than 130/80, treating hyperlipidemia (In individuals without overt CVD, the primary goal is an LDL cholesterol less than 100 mg/dL, in those with overt CVD, a lower LDL cholesterol goal of less than 70 mg/dl from using statin drug therapy) encouraging weight loss and exercise (150 minutes of moderate exercise per week), and encouraging dietary changes to include a low fat low sodium foods. Aspirin therapy (75 to 162 mg/d) can be used a primary prevention for coronary vascular disease in those with increased cardiovascular risk. A similar dosing of aspirin can also be used as secondary prevention for those with diabetes who have a history of CVD (American Diabetic Association, 2010).

Diabetic Therapy

The treatment for type 1 diabetes includes two different insulin regimens. The nonphysiologic regimen does not mimic normal beta-cell secretion and is ideal for those newly diagnosed patients who still produce some endogenous insulin and have not progressed to complete beta-cell failure. This regimen includes one or two daily injections of long-acting insulin. The physiologic regimen, used in complete beta-cell failure when glucose control cannot be achieved with the nonphysiologic regimen, attempts to mimic normal insulin secretion, consisting of basal and prandial insulin. **Basal insulin** is the continuous secretion that maintains glucose homeostasis, that is, the body's baseline level of insulin. **Prandial insulin** is the insulin secretion stimulated in response to meals. A regimen that meets both basal and prandial needs combines quick-onset, short-duration insulin with slower-onset, longer-duration insulin. Typically, this mixed basal and prandial regimen includes giving intermediate- to long-acting insulin (such as NPH or glargine) daily and short-acting (regular) or rapid-acting (aspart or lispro) insulin before each meal. Meal timing and consistency are very important to avoid hypoglycemic episodes. The physiologic regimen has several variations. Overall, the main goal of this therapy is to avoid hypoglycemic episodes and improve hemoglobin A_{1C} levels yet maintain a simple regimen to which the patient can adhere.

Hospitalized patients with type 1 diabetes who are not eating regularly should be receiving other forms of nutrition such as IV fluids with dextrose, total parenteral nutrition, or partial parenteral nutrition, tube feedings, in addition to some oral feedings. They need to receive enough glucose to prevent

BOX 49.1 FOCUS ON RESEARCH

Diabetes Case Management Among Low-Income Ethnic Minority Populations

Jovanovic, L., Wollitzer, A. O., Gorke, K., et al., The California Med-Cal Type 2 Diabetes Study Group. (2004). Closing the gap: Effect of diabetes case management on glycemic control among low-income ethnic minority populations. *Diabetes Care,* 27(1):95–103.

The Study

A primary objective of diabetes management is to improve glycemic control. When normal glycemic control can be achieved in patients with diabetes, microvascular and macrovascular complications are reduced. Therefore, it is cost effective to monitor glycemic control by measuring hemoglobin A_{1C} levels periodically and by self-monitoring blood glucose daily. However, research indicates that many patients with diabetes have poor glycemic control. In particular, disparities exist among low-income ethnic minority populations relative to other groups. Barriers to care include high cost of glucose monitoring strips and medications, lack of English language skills, and poor cultural sensitivity of health care providers.

In this study, 362 participants were randomized into two groups: a control group that continued to receive usual care from their primary care provider, and an intervention group that received individualized education from registered nurses and dietitians. The intervention group was assessed for diet, exercise, and self-care behaviors, and strategies to improve self-care education and management were used throughout the study in this group. The strategies considered the patient's level of education, literacy, and functional understanding and also his or her treatment goals, general health status, cultural beliefs, and support network. All interactions occurred in a clinic setting or by telephone; appointments were monitored and were rescheduled if missed. Transportation issues were also addressed to ensure visits were completed. Both groups had similar mean hemoglobin A_{1C} levels at baseline. During the 2 years of study, a progressive reduction in hemoglobin A_{1C} levels was seen in both groups; however, the reduction in the intervention group was significantly greater at each time (p <0.01). By the end of the study, the mean difference from baseline in hemoglobin A_{1C} levels in the intervention group was 0.87 greater than that in the control group. The authors conclude that diabetes case management, added to primary care, substantially improves glycemic control.

Nursing Implications

Registered nurses play a vital role in patient education and diabetic management for people with diabetes. Diabetes management can help reduce disparities among low-income ethnic populations but also can improve diabetic health status in all populations. You need a clear understanding of drug therapies and management strategies for diabetes to ensure that patients receive high-quality, accurate patient education that will lead to better control of their diabetes

starvation ketosis and hypoglycemia; usually 5 to 10 g of glucose/hour is sufficient. Some insulin coverage is also necessary, so that this essential glucose can enter the cells. The term *nutritional dose* (as opposed to prandial dose) may be used in these circumstances. In addition to the basal and prandial doses, patients with diabetes who are ill and hospitalized may also require some **correctional** (or **supplemental**) **insulin** doses to correct any elevations in blood glucose, with the goal of keeping the blood glucose close to normal at all times, because the physiologic stress of illness increases glucose levels. Some medications can also increase glucose levels. Preprandial glucose levels greater than 110 mg/dL should be treated with a correctional dose of short-acting or rapid-acting insulin (in addition to their normal prandial dose). The correctional dose is administered before the meal. In contrast, the prandial dose may be given either before the meal, or if it is adjusted based on precise amount eaten, immediately after eating. The goal for non-critically ill hospitalized patients is a pre-meal glucose level of less than 140 mg/dL.

When a patient is critically ill and in an intensive care unit control of blood glucose levels warrants special treatment goals as patients have been found to have better hospital outcomes if their glucose is better controlled. However, intensive controlling of glucose levels have been found to increase mortality rates (Griesdale, de Souza, van Dam, et al., 2009) Critically ill patients may receive IV insulin infusions when their glucose levels are greater than 180 mg/dL which should be titrated to maintain their glucose levels between 140 and 180) instead of subcutaneous (SC) injections.

Patients who are at risk for diabetes are treated with lifestyle modifications (e.g., weight reduction, exercise, diet modification). If they have other significant risk factors, they may also be treated with oral antidiabetic drugs. The first line of treatment for diagnosed type 2 diabetes consists of oral antidiabetic agents in addition to lifestyle modifications. Starting insulin therapy is recommended if hemoglobin A_{1C} approaches 8% despite optimal oral therapy. The best regimen uses bedtime long-acting basal insulin (such as NPH or glargine) while continuing one or two daytime oral antidiabetic medications. Because of the insulin resistance associated with type 2 diabetes, the patient may require large doses of exogenous insulin; therefore, the goal of therapy is to lower the hemoglobin A_{1C} level, not the insulin dose. Patients with type 2 diabetes require insulin if they become pregnant, have major surgery, or experience severe trauma, infections (including gangrene), fever, hepatic or renal dysfunction, and hyperthyroidism or other endocrine dysfunction. Table 49.2 presents a summary of selected antidiabetic drugs.

INSULINS

Synthetic insulin (exogenous; i.e., not produced within a person's body) acts in the same manner as endogenously produced insulin. Sources of exogenous insulin historically included pork and beef pancreas, but now only recombinant DNA technology or genetic engineering is used to create human-like insulin. Modifying the amino acid sequence of the human insulin molecule has resulted in new, rapid-acting insulin analogues, such as aspart, lispro, or glulisine (produced by rDNA technology). Human-sourced insulin is considered the standard therapy.

Insulin is available as rapid-, short- (also known as "regular"), intermediate-, and long-acting types. Type usually refers to the action time of a particular product, which includes the onset, peak, and duration of effects. Some insulins are injected separately, whereas others may be mixed together in a syringe. Other insulins are available premixed in standard concentrations in one vial.

The potency of insulin is expressed in the *United States Pharmacopeia* (USP) or international units. The standard concentrations of insulins are solutions of 100 U/mL. A 500 U/mL of regular insulin is also available. The numbers after the "U" indicate the number of units per milliliter (e.g., U-100). A special insulin syringe that has been calibrated to 100 U/mL is used to administer insulin; markings show the units. The standard insulin syringe measures up to a maximum of either 50 or 100 U of insulin, and some very-low-dose syringes hold a maximum of 25 U. Regular (U-100) and NPH insulins are sold as over-the-counter (OTC) drugs, but other forms require a prescription. Consequently, the type of insulin—as well as injection technique, presence of insulin antibodies, site of injection, and individual patient response differences—can all affect the onset, peak, degree, and duration of insulin activity.

Short-acting regular insulin is the prototype insulin. Regular insulin is sold OTC under the trade names Novolin-R and Humulin-R; the R stands for regular. There are also longer-acting insulins. Combinations of some of these drugs also exist.

Nursing Management of the Patient Receiving P Regular Insulin

Core Drug Knowledge

Pharmacotherapeutics

Insulin therapy is indicated for all patients with type 1 diabetes and for those patients with type 2 diabetes whose hyperglycemia cannot be controlled properly by diet, exercise, weight reduction, oral antidiabetic drugs, or a combination of these interventions. Regular insulin is used only to correct a current glucose elevation or an expected rise after eating, it is not used to control the glucose level all day (i.e., basal dosing) due to its short duration of action (see pharmacokinetics below). Regular insulin is also indicated for patients with hyperkalemia because an infusion of glucose and insulin produces a shift of potassium into cells and lowers serum potassium levels. Like all insulins, regular insulin is administered subcutaneously. It can also be administered intravenously and subcutaneously through an implantable insulin pump.

Subcutaneous insulin therapy for type 1 diabetes frequently consists of daily injections of mixtures of short-acting regular

TABLE 49.2 Summary of Selected Antidiabetic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Insulins			
Short Acting			
P regular insulin (Humulin R, Novolin R)	**All insulin preparations,** types 1 and 2 diabetes mellitus	**All insulin preparations** *Adult and child:* SC, dosages determined and adjusted depending on plasma glucose, diet, activity, and health status	*Onset:* 0.5–1 h *Duration:* 8–12 h $t_{1/2}$: Varies with preparation
Rapid Acting			
insulin lispro (Humalog)			*Onset:* 0.25 h *Duration:* 6–8 h $t_{1/2}$: 1 h
insulin aspart (Novolog)			*Onset:* 5–10 min *Duration:* 3–5 h $t_{1/2}$: 1.5 h
Intermediate Acting			
isophane insulin suspension, NPH (Humulin N, NPH Iletin I, *Canadian:* Novolin ge)			*Onset:* 1–1.5 h *Duration:* 18–24 h $t_{1/2}$: Unknown
Long Acting			
glargine (Lantus)			*Onset:* 1 h *Duration:* 24 h $t_{1/2}$: Unknown
Combination			
isophane insulin suspension (NPH) and insulin injection (70% NPH and 30% regular insulin) (Novolin 70/30)			*Onset:* 30 min *Duration:* 24 h $t_{1/2}$: Unknown
50% lispro protamine suspension and 50% lispro (Humalog Mix 50/50)			*Onset:* 15 min *Duration:* 10–12 h $t_{1/2}$: Unknown
70% aspart protamine suspension and 30% aspart (Novolog Mix 70/30)			*Onset:* 15 min *Duration:* Up to 24 h $t_{1/2}$: Unknown
Oral Antidiabetics			
Sulfonylureas			
P glyburide (Diabeta)	**All oral antidiabetics,** type 2 diabetes mellitus	*Adult:* PO, initially 2.5–5 mg with breakfast; maintenance, 1.25–20 mg/d *Child:* Safety and efficacy not determined	*Onset:* 1–2 h *Duration:* 16–24 h $t_{1/2}$: 10 h
glipizide (Glucotrol)		*Adult:* PO, initially 5 mg before breakfast; then increase in increments of 2.5–5 mg, not to exceed 15 mg/d *Child:* Safety and efficacy not determined	*Onset:* 1–3 h *Duration:* 10–24 h $t_{1/2}$: 2–4 h
chlorpropamide (Diabenese;)		*Adult:* PO, 200–500 mg/d; maximum dose, 750 mg/d	*Onset:* 1 h *Duration:* 24–60 h $t_{1/2}$: 36 h
Meglitinides			
repaglinide (Prandin)		*Adult and child:* PO, 0.5–4 mg before meals; maximum dose, 16 mg/d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 1 h
nateglinide (Starlix)		*Adult and child:* PO, 120 mg tid (60 mg tid if HbA_{1C} is near therapeutic goal), 1–30 min before meals	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 1.5 h

TABLE 49.2 Summary of Selected Antidiabetic Drugs *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Biguanide **P** metformin (Glucophage)		*Adult:* 500–2,000 mg/d in divided doses *Child:* Safety and efficacy not determined	*Onset:* 2–2.5 h *Duration:* 10–16 h $t_{1/2}$: 1.5–6.2 h
C Alpha-Glucosidase Inhibitors acarbose (Precose)		*Adult:* PO, 50–100 mg tid with the first bite of each main meal *Child:* Safety and efficacy not determined	*Onset:* <30 min *Duration:* 4–6 h $t_{1/2}$: 2 h
miglitol (Glyset)		*Adult and child:* PO, initial dose of 25 mg tid at first bite of meal; may start at 25 mg/d if GI effects are severe. Maintenance dose of 50 mg/tid; maximum dose of 100 mg tid	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 2 h
C Thiazolidinediones rosiglitazone (Avandia)		*Adult and child:* PO, 4 mg/d as single dose or divided into two doses; may increase to maximum of 8 mg/d after 8 wk	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 3–4 h
C Amylin analogue pramlintide (Symlin)		*Adult:* type 2 diabetes: SC, initially 60 mcg; increase to 120 mcg; type 1 diabetes: SC, initially 15 mcg; increase to 30–60 mcg	*Onset:* Rapid *Duration:* about 3 h $t_{1/2}$: 48 min
C Dipeptidyl peptidase-4 (DPP-4) enzyme inhibitor sitagliptin (Januvia)		*Adult:* PO, 100 mg once daily *Child:* Safety and efficacy not established	*Onset:* Unknown *Duration:* 24 h $t_{1/2}$: 12.4 h
C Incretin Mimetic exenatide (Byetta)		*Adult:* SC, 5 mcg twice daily, no more than 60 min before a meal; may increase up to 10 mcg twice daily *Child:* Safety and efficacy not established	*Onset:* <1 h *Duration:* 5 h $t_{1/2}$: 2.4 h
P Glucose-Elevating Agent			
P glucagon (GlucaGen)	Reverse severe hypoglycemia resulting from insulin overdosage	*Adult and child (>20 kg):* SC, IM, IV, 1.0 mg; dose may be repeated once or twice *Child (=20 kg):* 0.5 mg	*Onset:* IM, 8–10 min; IV, 1 min *Duration:* IM, 19–32 min; IV, 9–20 min $t_{1/2}$: 3–10 min

insulin with intermediate-acting insulins; multiple doses of regular insulin before each meal (i.e., prandial) in association with one or two daily doses of long-acting insulin may also be used. Combining the two types of insulin allows for rapid adjustment to elevated glucose levels as well as for prolonged control, such as all day or overnight. Some premixed combinations are also available.

Regular insulin may be used on a correctional (or supplemental) basis (previously termed "sliding scale"). When administered as a correctional dose, it is given in addition to basal insulin (with a long-acting preparation) or in additions to regimens of basal insulin and prandial insulin. In correctional doses, the number of units of regular insulin administered is based on blood glucose levels, according to guidelines provided in a specific medication order. Correctional insulin may be used before meals and at bedtime or every 4 to 6 hours if a patient is receiving continuous total parenteral nutrition. Correctional insulin is ordered frequently for hospitalized diabetic patients when insulin needs may be greatest, for example, with fever, infection, or internal stress, or after surgery or trauma.

Pharmacokinetics

Regular insulin, like all insulins, is destroyed by gastric acids and cannot be given orally. The SC route usually produces slow, steady absorption. The rate of absorption is affected by the site of administration. The most rapid absorption occurs when administration is into the abdominal SC layer (as much as 50% faster than other routes). The next most rapid is into the arm, followed by the thigh, and finally the buttocks.

When regular insulin is given by IV infusion, some of the drug—usually between 20% and 30%—is absorbed into the plastic tubing set. Up to 80% loss has occasionally

been reported. Close monitoring of the therapeutic effect is necessary because it is not possible to determine the exact amount that will be lost and never received by the patient.

Regular insulin has a quick onset and a short duration of action; therefore, it can be administered to a patient several times a day. In comparison to regular insulin, some other forms of insulin have slower onsets but longer durations of action, although insulin analogues have a more rapid onset (see Table 49.2). Insulin deteriorates if exposed to excessive heat or light. Regular insulin is stable at room temperature for 1 month. For longer storage, place insulin in the refrigerator.

Insulin is filtered at the glomerulus, with most of the dose (98%) reabsorbed in the proximal renal tubule. Slightly more than half of the reabsorbed insulin is metabolized and excreted; the remaining insulin is returned to the venous blood. Renal function impairment occurs commonly in diabetic patients because of vascular insufficiency. Renal function impairment reduces the amount of insulin excreted, thus reducing the amount of insulin required.

Pharmacodynamics

Insulin is the principal hormone required for proper glucose use in normal metabolic processes. Most of the body's cells require insulin to facilitate entry of glucose. Insulin's effects are tissue specific; it facilitates membrane transport of glucose (and some other amino acids and ions) into muscle, adipose, and connective tissue cells and into leukocytes. Nerve tissues, erythrocytes, kidney epithelium (tubules), and cells of the brain, intestines, liver, and retina do not require insulin to absorb glucose.

Injected insulin mimics the effect of endogenous insulin. Serum glucose level is regulated by insulin control over the metabolism of carbohydrates, fats, and proteins. At the cellular level, insulin increases the cell membrane permeability to glucose, amino acids, and fatty acids and maintains a constant glucose level by changing glycogen into glucose. In addition, insulin converts excess glucose into glycogen and promotes the storage of fat by combining alpha-glycerophosphate (a product of glucose metabolism) with fatty acids to form triglycerides. Consequently, one effect of insulin on metabolism is weight gain.

Contraindications and Precautions

Regular insulin is contraindicated in times of hypoglycemia or if the patient has any sensitivity to any of its components. When changing the type of insulin (e.g., from short acting to rapid acting or to intermediate acting, or vice versa), caution should be used and the patient monitored carefully for hypoglycemia or hyperglycemia, either of which may occur as the body adjusts to the different pharmacokinetics of the preparation.

Insulin is a pregnancy category B drug.

Adverse Effects

Hypoglycemia, the most common adverse effect of insulin therapy, may result from an excessive insulin dose or from increased physical activity without eating. Hypoglycemia is a substantial drop in blood glucose level (to less than 70 mg/dL) that may result from excessive insulin entering the bloodstream or from insufficient glucose levels to meet tissue demands. The earliest signs of hypoglycemia are neurologic in nature because the brain uses only glucose for fuel. They include fatigue and malaise, trembling, irritability, headache, nausea, numbness, paresthesias, muscle weakness, blurred vision, confusion, and ultimately convulsions, stupor, coma, and death. Hypoglycemia may cause increased sympathetic activity and manifest as hunger, tachycardia, sweating, and nervousness.

Repetitive SC injections into the same injection site can cause disturbances in fat metabolism. This adverse effect, known as **lipodystrophy,** can present as either as lipoatrophy or lipohypertrophy. In lipoatrophy, SC fat breaks down because of repeated insulin injections into the same site and causes a depression in the skin; in lipohypertrophy, there are additional lipid deposits at a particular site, causing a spongy area. Both forms of lipodystrophy may delay insulin absorption, adversely affecting pharmacotherapeutics.

Drug Interactions

Table 49.3 lists important drug interactions with insulin.

Assessment of Relevant Core Patient Variables

Health Status

Assess patients for allergies and for immunocompromised states and determine whether the patient has been receiving daily insulin, either as a lifelong therapy or as short-duration

TABLE 49.3 Agents that Interact with P Regular Insulin

Interactants	Effect and Significance	Nursing Management
acetazolamide, AIDS antivirals, calcitonin, corticosteroids, diazoxide, diltiazem, thiazide diuretics, dobutamine, epinephrine, estrogens (including oral contraceptives), isoniazid, lithium carbonate, morphine sulfate, niacin, phenothiazines, phenytoin, nicotine, thyroid hormones	Decreased hypoglycemic effect of insulin	Monitor plasma glucose and A_{1C} levels. Observe for hyperglycemic complications.
ACE inhibitors, alcohol, beta blockers, calcium, chloroquine, clofibrate, guanethidine, lithium carbonate, MAO inhibitors, mebendazole, octreotide, pentamidine, phenylbutazone, pyridoxine, salicylates, sulfinpyrazone, sulfonamides, tetracyclines	Increased hypoglycemic effect of insulin	Monitor blood glucose level. Observe for hypoglycemic complications.

therapy (such as that needed during acute infections). When the patient has been receiving regular insulin at home, determine the type, amount, and usual time of administration, who administers it, and what sites are used. Also, determine the frequency of hypoglycemic reactions and how the patient or family handles these reactions. This information helps the health care team assess knowledge, usual practices, and teaching needs.

Complete a thorough history and physical assessment from which to establish a baseline. Solicit current drug history, including information on all prescription and OTC drugs, from the patient or family. A careful review of this information may identify drugs that can alter the action of insulin. Drugs taken for other disorders (e.g., thiazide diuretics, corticosteroids, and estrogens) may cause hyperglycemia, which complicates diabetic control and requires higher dosages of an antidiabetic medication or insulin.

Assess for complications related to diabetes, such as neuropathy, nephropathy, or retinopathy, and for the patient's ability to perform psychomotor skills such as self-monitoring of blood glucose or self-injection of insulin.

Assess the integumentary system and inquire into the patient's general health practices, especially in regard to the skin. For example, assess for lipoatrophy or lipohypertrophy at injection sites, color and temperature of the lower extremities, presence of calluses and ulcers on feet, delayed healing of wounds, and signs of peripheral neuropathy.

It is important to obtain baseline and periodic assessments of blood glucose levels, blood cell counts, electrolytes (especially potassium), blood lipid levels (e.g., cholesterol and triglycerides), and hemoglobin A_{1C} levels. Assess the patient's knowledge of diabetes and basics of self-care.

Patients who are critically ill and hospitalized in an intensive care unit require close assessment of their glucose levels.

Life Span and Gender

Assess the patient for pregnancy. Human insulin is preferred for use during gestation as opposed to an oral antidiabetic drug (both in gestational diabetes and in women who have diabetes before becoming pregnant). Human insulin is also recommended for women with diabetes who are considering pregnancy. Insulin is a pregnancy category B drug. Inquire about breast-feeding status. Although the hormone does not pass into breast milk, lactation may decrease insulin requirements despite the increase in caloric intake necessitated by it.

Adjust care to meet the patient's chronologic and developmental age. Assess infants and toddlers carefully to avoid hypoglycemic episodes, which could have harmful effects on the developing brain and spinal column. With adolescents, monitor growth spurts, which can cause a substantial increase in insulin requirements. Also, assess the adolescent's acceptance of and actual adherence to therapy. Adolescents with type 1 or 2 diabetes may resist medication, especially insulin injections. They may delay or omit their insulin dosages to fit in socially or to control their weight.

With older adults, assess for changes in the management and control of diabetes and glucose levels. Changes in the diet and activity level of elderly patients pose challenges to control of blood glucose levels. Examples of these changes include ill-fitting dentures, difficulty chewing and swallowing, decreased ability and interest in cooking, age-related changes in taste perception, reluctance to change long-established eating patterns, limited finances, and reliance on others for meals. Furthermore, decreased motor coordination and visual acuity may impair patients' ability to perform self-monitoring of blood glucose levels and self-injection of insulin. Older adults may have impaired vision, decreased motor coordination, or other health problems that affect their ability to perform tasks needed for diabetic control, such as fingersticks, self-administration of insulin, and managing diet and exercise.

Lifestyle, Diet, and Habits

An assessment of psychosocial aspects of diabetes, such as role changes and financial concerns, may help ascertain the patient's ability to cope with a chronic illness that involves major changes in lifestyle.

Exercise increases the permeability of the cell membrane to glucose, decreasing the need for insulin to transport glucose into the cell. Therefore, determine the activity and exercise patterns of the patient, which can be accomplished by asking about the patient's usual activity level, occupation, amount and type of recreational activities, and daily exercise patterns. Also, assess the patient's typical eating habits because these also alter the individual response to regular insulin.

The patient's typical alcohol intake is also a factor because consuming alcohol may cause hypoglycemia or hyperglycemia. Alcohol has no nutritional value, although if consumed, it must be included in the fat allowances of the diabetic diet plan. A patient taking insulin and consuming alcohol may need to adjust the insulin dosage because alcohol potentiates the hypoglycemic effect of insulin. Also, assess for the use of dietary supplements and herbal products because they may alter glucose production or storage or interact with insulin.

Environment

Note the environment in which regular insulin will be administered. Insulin is most commonly self-administered by the patient in the home. Proper needle disposal is a growing concern because of the large number of patients administering medications with syringes in the home care setting. Current Environmental Protection Agency (EPA) guidelines recommend that syringes, lancets, and other sharp objects be placed in a hard plastic or metal container with a screw-on or other tight-fitting lid. Patients should check local regulations regarding sharps disposal. For information on patients who use an insulin pump at home, see Box 49.2. Insulin given by intravenous infusion should be done in a critical care setting.

BOX 49.2 COMMUNITY BASED CONCERNS

Understanding How an Insulin Infusion Pump Works

Patients who have type 1 diabetes and require frequent insulin injections throughout the day to control their elevated blood glucose levels may have their insulin delivered by an insulin pump. An insulin pump is a small (2- × 3-in), precise computerized device that consists of a reservoir filled with insulin. The reservoir is connected by an infusion set (a thin plastic tube) to a subcutaneous (SC) catheter or needle. The catheter is changed every 2 to 3 days. An insulin pump can be programmed to deliver a basal infusion of insulin (microdoses; about 0.1 U) 24 hours a day. Continuous delivery of insulin helps maintain blood glucose concentrations between meals and overnight. Insulin dosing adjustments require little or no patient effort. When the patient eats, a predetermined prandial bolus dose of insulin is delivered that is matched to the estimated caloric intake. The bolus mode requires the patient to determine the dose and push a button to administer insulin before or after each meal. Pump devices help patients achieve tighter blood glucose control, thus minimizing potential complications. The pumps have an alarm system that alerts the patient if insulin delivery is interrupted. Some patients may find the pump complicated to use. The individual needs to be very motivated and adherent to therapy. The pump is not automatic; the user must decide how much insulin to give.

Some combinations of pumps and glucose monitors are available. A combination of a glucose monitor and an insulin pump with a dose calculator is manufactured by Medtronic MiniMed, Inc., and Becton Dickinson. The combination of these two products allows for better interchange of data between the two. Glucose values are automatically sent to the insulin pump, thus preventing possible errors that can result when the patient inputs the glucose data manually into the pump. The software that ac companies this glucose monitor–insulin pump also allows for transfer of data to a personal computer fitted with the appropriate software program.

Nursing Diagnoses and Outcomes

- Deficient Knowledge related to insulin pharmacotherapeutics
  Desired outcome: *The patient (or family) will state brand, type, onset, peak, duration, and dose of insulin.*
- Risk for Nonadherence to Self-Care related to the complexity and chronic nature of the insulin regimen.
  Desired outcome: *The patient will adhere to the treatment regimen and communicate an understanding of the insulin regimen and its importance (i.e., demonstrate techniques for administering insulin and verbalize recommendations for site rotation, storage of insulin, and disposal of syringes).*
- Potential Complication: Hypoglycemia related to administration of too much insulin.
  Desired outcome: *The patient will assess for and report signs and symptoms of hypoglycemia and if an episode should occur will implement the appropriate treatment.*
- Pain related to insulin injections and self-monitoring blood glucose testing via fingerstick.
  Desired outcome: *The patient will state two nonpharmacologic methods used to control pain and will demonstrate proper subcutaneous injection and fingerstick techniques to minimize pain.*

Planning and Intervention

Maximizing Therapeutic Effects

Store opened vials of regular insulin at room temperature. Extra supplies are stored in the refrigerator, but not the freezer. Extreme temperatures (less than 28C or greater than 308C) should be avoided to prevent loss of maximum function.

Administer regular insulin with an insulin syringe into an appropriate subcutaneous site. Regular insulin is administered about 30 to 60 minutes before eating. To promote regular absorption, one anatomic area should be selected for regular insulin injections (e.g., the abdomen). Serial locations within that anatomic area are chosen to rotate the exact injection site. This practice is sometimes called intrasite rotation. Do *not* rotate injection sites by using the arm one day, the stomach the next day, and the thigh the next day because this practice will substantially change the absorption of the insulin and the blood glucose levels of the patient. If the patient routinely receives regular insulin in the morning and in the evening, one anatomic area may be selected for each time of day (e.g., use the abdomen for all morning injections and the thighs for all evening injections).

Frequent monitoring of blood glucose by fingersticks and periodic determinations of hemoglobin A_{1C} levels help determine the therapeutic effect of insulin and overall consistency of diabetic control. Such monitoring also provides the necessary data to change the insulin regimen (if necessary) so that maximal effects are achieved. When supplemental doses are based on a current glucose level obtained from a glucometer, it is important that the reading achieved with the measurement is accurate. Calibrate the glucometer per manufacturer recommendations or hospital protocol, and perform quality control checks per protocol. Use the appropriate technique for obtaining the specimen. Assess for physiologic conditions, which may cause inaccurate bedside blood glucose readings. See Box 49.3 for factors that may alter glucometer accuracy.

Most diabetic patients (those at home and those in the hospital) can have their glucose levels effectively controlled with subcutaneous injections. Some patients at home may use an implantable subcutaneous insulin pump to administer their insulin. A review of the literature (Misso, Egberts, Page, et al., 2010) found that continuous subcutaneous insulin infusion (via an insulin pump) may provide better control of glucose levels than multiply subcutaneous injections in a day. Subcutaneous infusion pumps did not appear to provide any benefit in reducing non severe hypoglycemic events.

When a patient receives regular insulin intravenously, carefully monitor blood sugar levels to account for varying absorption of the drug into the plastic tubing. Patients who are hospitalized and critically ill will require insulin by drip infusion if their glucose level exceeds 180 mg/dL. The infusion should be titrated to achieve a blood glucose level between 140 and 180 mg/dL. Avoiding significant hyperglycemia promotes positive outcomes for the patient.

Box 49.3 FACTORS THAT ALTER THE ACCURACY OF BEDSIDE BLOOD GLUCOSE RESULTS

As regular insulin or the rapid-acting analogues are frequently dosed based on the current blood glucose level, an accurate reading is essential. Errors in glucometer readings have two sources: users or intrinsic patient factors.

Common User Errors:

- Inadequate meter calibration or meter maintenance
- Inadequate quality control testing
- Using a test strip that does not match the meter code or that has expired
- Poor technique in performing a fingerstick
- Insufficient size of blood droplet
- Poor technique in applying blood droplet to test strip
- Failure to record result in patient chart
- Inability to correctly interpret medication order and administer the appropriate amount of insulin based on current glucose level

Potential Patient Factors:

- Low hematocrit (falsely higher readings)
- High hematocrit (falsely lower readings)
- Shock and dehydration (falsely lower readings)
- Hypoxia (either falsely higher or falsely lower readings)
- Hyperbilirubinemia, severe lipemia (falsely higher readings)
- Sodium fluoride as specimen additive (falsely lower readings)
- Use of these drugs: acetaminophen overdose, ascorbic acid, dopamine, fluorescein, mannitol, salicylate (either falsely higher or falsely lower readings)

Minimizing Adverse Effects

Avoid administering cold insulin to help limit local irritation (e.g., lipodystrophy) at the injection site. Injection-site rotation also helps prevent lipodystrophy. Prevention is especially important in infants and children.

Assess the current blood sugar level of the patient before administering regular insulin. Caution is necessary if the blood glucose level is below 70 mg/dL before administration. Usually, the dose is withheld until the blood sugar level has risen to normal levels (at least 70 mg/dl). Consult with the physician or nurse practitioner before administering regular insulin if the blood sugar is low. Regular insulin can be used in a prandial dose where a set number of prescribed units are administered when the patient eats. Regular insulin could also be used for correctional doses, where the blood glucose is monitored before meals and bedtime, and the number of units of regular insulin given is according to the degree of glucose detected. The patient should receive a basal dose of a long acting insulin (NPH, glargine, or determir, described below) in addition to receiving prandial doses and/or correctional doses. Use of regular insulin as a correctional dose without a basal insulin should be avoided for most diabetic patients as this method creates recurring episodes of hyperglycemia which lead to poorer patient outcomes (American College of Endocrinology and American Diabetes Association Consensus Statement on Inpatient Diabetes and Glycemic Control, 2006).

Determining the correct dose of insulin for a patient requires adjustments based on the individual patient's needs. Much like Goldilocks who was looking for something "just right," the correct insulin dose will prevent hyperglycemia but avoid hypoglycemia. Each of these can be dangerous to the patient. Severe hypoglycemia is an acute life threatening event. Hyperglycemia contributes to poor outcomes for the hospitalized patient and long term sequela, such as cardiovascular disease, for the diabetic at home. The nurse must monitor the patient closely for hypoglycemic reactions, especially near the peak action time of the insulin (see Table 49.2). Reassess the patient's blood glucose level if signs or symptoms of hypoglycemia occur. The fear of hypoglycemia may prevent nurses and other health care providers from treating diabetes appropriately. To minimize this risk explicit guidelines should be developed and followed so that the appropriate treatment for hypoglycemic episodes occurs (American College of Endocrinology and American Diabetes Association Consensus Statement on Inpatient Diabetes and Glycemic Control, 2006). Treat hypoglycemic episodes by following the institutional guidelines or by administering one of the following: 4 ounces of juice or a regular soda (not diet), 4 oz of water with four sugar packets (i.e., 4 teaspoons), or 8 oz of low fat milk if the patient is hypoglycemic and able to swallow. Administer 50% IV dextrose or glucagon if the hypoglycemic patient is not able to swallow.

If the regular insulin dose is too low for the patient's current metabolic needs, hyperglycemia may occur. Monitor the patient for signs and symptoms of hyperglycemia and re-evaluate blood glucose levels as appropriate. If the patient has frequent hyperglycemia the nurse should consult with the physician or nurse practitioner concerning adjusting the basal insulin dose.

When drawing up insulin, always have the dose double-checked by another nurse to prevent accidental overdosage, because insulins are very potent. A small dose produces a big effect and could cause serious and even life-threatening consequences to the patient. Read labels very carefully, because many forms of insulin have similar-sounding trade names. *When referring to insulins, use generic names rather than trade names.*

Use special consideration when caring for infants and toddlers with type 1 diabetes. Infants and toddlers require low dosages of insulin to maintain a goal serum glucose level of 100 to 200 mg/dL. Hypoglycemia may occur because of unpredictable food intake and activity levels in preschool-aged children. The brain and spinal column do not develop normally without an adequate and available source of glucose. Therefore, hypoglycemia must be avoided in infants and young children because it can have potentially damaging effects on growth and development.

Box49.4 PATIENT AND FAMILY EDUCATION COMMON TO DIABETIC DRUG THERAPY

In addition to receiving routine medical care provided by health care professionals, patients and their families need to be educated on important topics of self-management and drug therapy for diabetes if their management is going to be successful. People with diabetes need to understand:

- What diabetes is and why treatment is necessary
- How to administer and store insulin
- How and when to test their blood glucose
- How and when to take oral medications if they have type 2 diabetes

Emphasize that drug therapy is not a substitute for diet control, exercise, and weight loss. The patient must understand the balance among exercise, diet, and drug therapy, realizing that changes in dietary intake and exercise will result in a change in drug therapy.

Caution the patient against consuming alcohol because of its hypoglycemic or hyperglycemic effects with insulin and other antidiabetic drugs, and because of the possibility of a disulfiram-like reaction when alcohol is combined with some sulfonylureas.

Teach the patient to recognize and report symptoms of hypoglycemia (e.g., fatigue, excessive hunger, diaphoresis, and numbness or tingling of extremities), or hyperglycemia (e.g., excessive thirst or urination, urinary glucose, or ketones) to the health care team.

Teach the patient and the family to treat symptoms of hypoglycemia by taking 4 oz of juice or non diet soda, 4 oz of water with 4 teaspoons of sugar in it, 8 oz of non fat milk,. If the patient is receiving acarbose or miglitol for type 2 diabetes they cannot take a dietary sugar but should take glucose tablets

Teach the patient to notify the prescriber when his or her blood sugar is consistently outside of the set parameters (too high or too low), so that changes in the drug regimen can be made.

Encourage the patient to carry some type of medical identification (e.g., a Medic Alert bracelet) and to inform all health care providers of current drug therapy.

Providing Patient and Family Education

In addition to the information provided within this section, which is specific to insulin therapy, see Box 49.4.

DISCUSSING DIET

- Emphasize the importance of eating the prescribed diet after insulin dosing. Warn patients that hypoglycemia may occur from omission of a meal or from altered absorption of food if a meal is postponed.
- Counsel patients not to take any nonprescription or OTC preparations, including herbs or alcohol, without first consulting the prescriber, because these substances may interact with regular insulin and alter its effectiveness.

UNDERSTANDING ACTIVITY AND REST

Emphasize that changing the daily exercise or activity pattern will vary the hypoglycemic effect from insulin. If patients are more active than usual, they will use more glucose, thus lowering the available glucose for insulin to act on. The molecules of insulin administered in the ordered dose each have the pharmacodynamic ability to move a certain number of molecules of glucose. If less glucose is available in the bloodstream than is usual for that particular patient, when insulin moves the set number of glucose molecules into the cells, hypoglycemia will result. Therefore, the patient may need to eat more to offset the glucose burned by exercising. If the increase in exercising is a permanent change, the insulin dose may need to be adjusted.

RECOGNIZING THE ROLE OF STRESS

- Teach patients and families that stress, both physiologic (e.g., from illness, surgery, and trauma) and psychological (e.g., from death in the family, divorce, and job changes), may change insulin requirements because the hormones released in stressful situations are antagonistic to insulin.
- In cases of stress, urge patients to consult the prescriber to see whether a change is needed in the insulin dosage or regimen.

MONITORING THE BLOOD GLUCOSE LEVEL

- Most patients with diabetes learn to test their own blood to measure the level of circulating glucose. Various kits and devices are commercially available for this task.

ADMINISTERING INSULIN

- Most patients with type 1 diabetes administer their own insulin with disposable needle and syringe injection devices or with a special injection pen device. Teach patients to use aseptic technique, select the appropriate type of insulin, mix insulin properly (if necessary), administer insulin correctly by SC injection (see Chapter 3 on injection technique), rotate sites serially in an anatomic location (intrasite rotation), and store insulin carefully (Box 49.5). If an acute infection is present or resistance to infection is impaired, the needles should not be reused.
- Manufacturers of disposable syringes recommend a single use. However, some patients prefer to reuse a syringe until its needle becomes dull, usually up to three or four times. Reuse reduces the cost of injections, which may be important for patients with limited financial resources. Most insulin preparations have bacteriostatic additives that inhibit the growth of bacteria commonly found on the skin. If reuse is planned, the needle must be carefully recapped by the patient after each use. Aseptic technique should be followed. The patient who reuses a syringe should be taught to inspect the skin around the injection sites for unusual redness or signs of infection.
- Teach patients thoroughly about safe insulin administration. Needles or syringes should never be shared with anyone

Box 49.5 INSULIN ADMINISTRATION

American Diabetes Association Guidelines for Preparing and Administering a Subcutaneous Dose of Insulin

- Check the type of insulin and the expiration date.
- Inspect the solution for visible changes (e.g., solid clumps) that indicate deterioration of the drug.
- If possible, verify Dose, Expiration date, Concentration, and Type with another individual (nurse if in health care setting).
- Wash hands.
- Cleanse injection site and insulin vial by wiping with alcohol.
- If using suspension (cloudy solution), roll gently between palms of hands to resuspend the insulin.
- Inject an amount of air into the vial (each vial, if using two) that is equal to the dose of insulin.
- When mixing two types of insulin in one syringe, the short-acting clear insulin should be drawn into the syringe first.
- Eliminate air bubbles from the syringe to ensure an accurate dose.
- Injection sites—in their order of rapidity of absorption—include the (1) abdomen (excluding 2 inches around the umbilicus), (2) subcutaneous tissue of the upper arm, (3) anterior and lateral aspects of the thigh, and (4) buttocks.*
- Insulin injections are made into SC tissue, so it is not necessary to aspirate for blood routinely before injecting the insulin.
- The needle angle during the injection (45 to 90 degrees) should be individualized to avoid IM injection; the needle length is usually 5/8 inches. Gently pinch a skin fold to determine the angle that will deliver an SC injection.

Other Considerations

- Insulin vials in current use may be stored at room temperature; avoid exposure to direct sunlight and high temperatures. Some potency of product may be lost after 30 days.
- Spare insulin vials should be stored in the refrigerator. No potency is lost when stored in the refrigerator.
- Prefilled syringes:
  - Are stable up to 30 days when stored in the refrigerator.
  - Filled with an insulin suspension (cloudy solution) should preferably be stored with the needle pointed up (vertical position) to avoid clumping of suspended insulin molecules in the needle.
  - Insulins that cannot be mixed with any other type of insulin: glargine and detemir
- Injection pens:
  - Are unique because they combine the insulin container and the syringe into a single modular unit.
  - Are available in a variety of types and styles (e.g., prefilled single use or reusable), but generally, they have a characteristic design—the patient must attach a needle, prime the pen, dial the dose, and depress a plunger to deliver the dose.
  - Add lifestyle flexibility (because pens are pocket sized and easy to carry) and confidentiality (because some look like fountain pens, not a medical device) and may lead to improved glycemic control.
  - Many of the rapid-acting insulins come in insulin pens.
- Adaptive equipment—several products are available for patients with diabetes who are visually or functionally impaired. Some of the commonly used assistive devices include:
  - Syringe magnifiers to enlarge the measurements on the syringe barrel.
  - Needle guides to help direct the needle into the vial stopper.
  - Vial stabilizers mounted on a surface to hold the vial in place during needle insertion.
  - Insertion aids add bulk to the syringe for patients unable to hold a small syringe.
  - Dose-measuring devices assist the visually impaired patient to draw up the recommended insulin dosage into a syringe.
  - "Talking" blood glucose meters produce audible test results with tactile guides for test strip insertion.

*Site selection affects absorption; it is recommended that site rotation for insulin injection take place within the same anatomic area.

else because this practice may cause transmission of blood-borne infections (e.g., hepatitis B or C, or HIV infection).
- Nearly as important as learning about injection techniques is learning about safe and proper disposal of insulin injection equipment. The EPA recommends that insulin needles and lancets be discarded whole in opaque, puncture-resistant containers to avoid the hazards of exposed or broken needles and that the lid be taped on tightly before the container is put in the trash. For example, a plastic milk container or a coffee can is preferable to a glass jar, which can break.

EXPLAINING OTHER SAFETY MEASURES

- Encourage patients to wear diabetic identification, such as a MedicAlert bracelet, so that appropriate treatment can be given if complications, such as diabetic coma, occur away from home.
- Also, caution patients that changing the kind of insulin normally used may affect blood glucose control and should be done only under the supervision of the health care professional.
- Advise patients always to carry a spare vial of each type of insulin used and to pay attention to the expiration date stamped on the vial.

Ongoing Assessment and Evaluation

It is important to evaluate the technical skills (e.g., insulin injection) that will be used by the patient for self-care at home. Specific assessment and evaluation criteria may include the patient's stated willingness to adhere to recommended drug therapy and management techniques for diabetes and may also include blood glucose levels that remain within normal limits as specified by the prescriber.

Fasting blood glucose and hemoglobin A_{1C} levels are valuable in monitoring the patient's response to therapy.

Nursing management of drug therapy is considered successful if the patient experiences few episodes of

hypoglycemia or hyperglycemia, demonstrates the ability to correctly perform the technical tasks necessary for managing diabetes at home, follows the ADA diet and incorporates it into his or her lifestyle, incorporates an exercise regimen to attain or maintain normal body weight, and recognizes situations in which knowledge deficit may require the guidance of a diabetes health care professional for additional information or follow-up care.

Drugs Closely Related to P Regular Insulin

Rapid-acting Insulins: Aspart, Lispro, and Glulisine

Three rapid-acting insulins that are analogues of rapid-acting regular insulin are now available: aspart (NovoLog), lispro (Humalog), and glulisine (Apidra). The use of these drugs is becoming preferred over the use of regular insulin. Like regular insulins, these are clear insulins. Caution should be used so as not to confuse the trade names for aspart and lispro with the trade names for regular insulin. These rapid-acting insulins may be used in type 1 diabetes (in combination with an intermediate- or long-acting insulin), or in type 2 diabetes, where glucose control cannot be achieved solely from oral therapy. Compared with regular insulin, the pharmacodynamically rapid-acting (rDNA) insulins have a faster onset of glucose-lowering activity, an earlier peak glucose-lowering effect, and a shorter duration of action after SC administration. The rapid onset of action allows patients more flexibility in taking insulin and preparing and consuming meals. All rapid-acting insulins are well suited for use in implantable pumps because their short duration of action mimics endogenous insulin more closely than regular insulin. These insulins are also used as either prandial doses or supplemental doses when combined with a basal dose of an intermediate- or long-acting insulin. Unlike regular insulin, these rapid-acting insulins should be administered closer to the time a meal is started because of their onset of action. The pharmacologic and pharmacokinetic features of these analogues are quite similar. To compare pharmacokinetics of various insulins, see Table 49.4. These newer analogues are less likely to cause hypoglycemia than human formulations of regular or NPH (Moghissi, 2010). Other adverse effects and patient education are similar to those for regular insulin with the exception of the timing of the dose. All of the rapid-acting insulins are sold by prescription, in contrast to regular insulin, which may be obtained OTC.

In patients with type 1 diabetes, insulin lispro is used in regimens that include a longer-acting insulin. However, in patients with type 2 diabetes, lispro may be used without a longer-acting insulin when used in combination therapy with an oral antidiabetic drug. It may also be used in adults and children older than three years of age. Lispro is administered no more than 15 minutes before a meal; in some situations (e.g., when a patient needs to adjust a prandial dose based on how much is eaten), it may be administered immediately after a meal (Magee & Clement, 2004). This insulin analogue produces a smaller postprandial glucose increase than regular insulin. Lispro is administered subcutaneously, either by direct injection (via needle and syringe or special injector pen) or by infusion via an insulin pump—never intravenously. It *can be* mixed with NPH insulin for administration in a syringe but *cannot* be mixed with NPH for SC administration via an external insulin pump. Lispro is a pregnancy category B drug.

MEMORY CHIP

P Regular Insulin

- Used primarily to treat type 1 diabetes mellitus; only type of insulin used for intravenous administration, in external insulin pumps, and for "sliding scale" coverage for hypoglycemia
- Most common adverse effect: hypoglycemia
- Most serious adverse effects: anaphylaxis and hypersensitivity
- **Patient safety alert: Sound-alike names for various types of insulin and the high potency of insulins are both common sources of medication errors**
- Maximizing therapeutic effects: Protect insulin from excessive heat and light to avoid deterioration.
- Minimizing adverse effects: Use the same type and brand of syringe to avoid dosage errors; rotate injection sites to prevent tissue damage; have second nurse check dose; read labels carefully.
- Most important patient education: thorough teaching regarding dosage, administration techniques for subcutaneous injection, delivery devices, diet and exercise, and capillary blood glucose testing; wear medical alert tag identifying diabetic condition treated with insulin to alert emergency medical personnel

TABLE 49.4 Pharmacokinetics of Insulins

Nurses should be familiar with the onset, peak, and duration of insulins, because this affects the time of administration and the time to assess the patient for therapeutic and adverse effects.

	Number of Hours		
Insulin	**Onset**	**Peak**	**Duration**
Regular (short-acting)	0.5–1	2–3	8–12
lispro (rapid-acting)	0.25	0.5–1.5	3–4
aspart (rapid-acting)	0.15	0.75–1.5	3–5
glulisine (rapid-acting)	0.3	1.5	Up to 5.3
50% lispro protamine suspension and 50% lispro (mixed intermediate-acting and rapid-acting)	0.25	0.75–2	10–12
70% aspart protamine suspension and 30% aspart (mixed intermediate-acting and rapid-acting)	0.15	1–4	Up to 24
NPH (intermediate-acting)	1–1.5	4–12	18–24
Levemir (long-acting)	Unknown	3–14	5.7–23.2
70% NPH with 30% regular (mixed-acting)	0.5–1	2–12	24
glargine (long-acting)	1	—	24

Aspart should be administered just before starting a meal, no more than 5 to 10 minutes before eating. This insulin analogue can be given intravenously or subcutaneously, either via needle and syringe, via special injection pen (NovoLog FlexPen), or by infusion via an external insulin pump. Aspart can be mixed with NPH in one syringe (draw up the aspart first, then the NPH) and administered subcutaneously. However, aspart–NPH mixtures should not be subcutaneously administered via an insulin pump. Aspart is a pregnancy category B drug, and it is approved for use in children 6 years of age and older.

Glulisine is almost identical to lispro in terms of its pharmacokinetics, clinical indications, and adverse effects. It also is administered subcutaneously and as an SC infusion via an insulin pump. No other insulins should be mixed with it for SC infusion. Glulisine should be administered within 15 minutes of the start of a meal. Unlike regular insulin and the other rapid-acting insulins, glulisine is a pregnancy category C drug and is not approved for use in children.

Drugs Significantly Different From P Regular Insulin

Insulin is available in a variety of forms, with the different forms made by adding protamine, zinc, or isophane with a buffer. These modifications delay the absorption of the insulin from a subcutaneous site, resulting in a later onset of action, peak action, and an extended duration of action. Thus, insulin preparations may be rapid-, short-, intermediate-, or long-acting, depending on whether an additive is mixed into the insulin. Drugs significantly different from regular insulin are NPH (a suspension of isophane), detemir, glargine, and the human insulin Exubera. To compare pharmacokinetics of these insulins, see Table 49.4.

Preparations of Aspart or Lispro with Protamine

Some forms of the rapid-acting insulins, aspart or lispro, are available as mixtures with protamine added to the drug. This provides some rapid action as well as some prolonged action from the insulin. Mixtures of insulins always list the longer-acting component first. The aspart combination is sold under the trade name of NovoLog Mix 70/30 and contains 70% aspart protamine and 30% aspart. The lispro combination is sold under the name Humalog Mix 75/25 or Humalog Mix 50/50 and contains 75% lispro protamine and 25% lispro, or 50% lispro protamine and 50% lispro, respectively. The similarity of the trade names compared with each other and regular insulin (Novolin or Humulin), as well as with each other, makes these combination insulins extremely easy to confuse; and this is a major source of drug errors (Paparella, 2006). *To avoid confusion, the drugs should be referred to by their generic names, not their trade names*.

NPH

Although the full chemical name of NPH (Humulin N) insulin is Neutral Protamine Hagedorn insulin, it is known and referred to in clinical practice as NPH. Protamine is added to insulin to create NPH insulin and lengthen its duration of action. Onset of action is 1 to 1.5 hours, peak action occurs in 4 to 12 hours, and duration of action is up to 24 hours. The N on the label signifies NPH. NPH differs from regular insulin primarily in terms of duration of action, appearance, and frequency of administration. It is considered intermediate acting. Cloudy in appearance, NPH is now the only insulin that is not clear. NPH is administered once or twice daily via SC injection, never by IV infusion or SC insulin pump. It is never used for supplemental coverage. Because NPH insulin is a suspension and tends to separate inside the vial, it must be mixed by rolling the vial between the palms of both hands before withdrawing the mixture into the insulin syringe. Excessive agitation should be avoided to prevent damaging the additive used to create a long-term drug action.

NPH insulin is the most widely used intermediate-acting insulin. Occasionally, a white precipitate (flocculus) may appear as frosting that adheres to the vial. This effect, called flocculation, occurs for unknown reasons, although vigorous mixing of the vial is thought to contribute. Flocculation decreases the potency of the insulin; if it is present, the insulin should be discarded. NPH insulin may be mixed with regular insulin; premixed solutions of NPH and regular insulin are also available in ratios of 70/30 (sold as Novolin 70/30 or Humulin 70/30) and 50/50 (sold as Humulin 50/50). The proportion of insulin for these preparation means that for every 100 U of insulin, there are 70 of NPH and 30 of regular insulin, or 50 of NPH and 50 of regular insulin, respectively. Use of premixed insulin is especially useful for patients who are visually impaired or have difficulty with fine motor skills and may reduce the number of errors that might occur using the standard mixing technique. A limitation of the premixed solutions is that the patient's insulin requirements must match the fixed ratio of the premixed preparations.

Nursing interventions specific for intermediate-acting insulin include observing patients for adequate nutritional intake and monitoring for hypoglycemia during mid to late afternoon (after an early-morning dose), because the lengthy peak action time produces additional risks for hypoglycemic reactions. The onset of hypoglycemia with the intermediate-acting insulin is insidious and more prolonged. Adverse effects, nursing actions, and patient education are also similar to those for regular insulin.

Detemir

Detemir (Levemir) is a long-acting insulin that differs from human insulin by slight chemical modification (deletion of one amino acid and addition of one fatty acid chain). These changes cause the insulin particles to be more slowly absorbed from the SC injection site than NPH insulin and to distribute to the target sites in the peripheral tissues more slowly, preferring to be highly protein bound once absorbed. Detemir is used in the treatment of type 1 and type 2 diabetes. The drug is administered once or twice a day by SC injection. Detemir cannot be administered intravenously or subcutaneously via insulin infusion pumps. It should not be mixed with any other insulins, because this will decrease its effectiveness. Unlike NPH, detemir is a clear insulin, similar to regular insulin.

Caution must be used not to confuse detemir for regular insulin. Detemir comes in a multidose vial and in cartridges to use with an injection pen. This insulin provides glycemic control similar to that of NPH, with a slightly greater reduction in FPG. Detemir may be associated with less weight gain and a lower risk of nocturnal hypoglycemia than NPH.

Glargine

Insulin glargine (rDNA) is characterized by a chemical structure that regulates its release from the SC tissue into the circulation, providing a relatively constant glucose-lowering effect with no pronounced peak of action over a 24-hour period. Glargine, unlike NPH, is a clear insulin, similar to regular insulin in its appearance. Extreme caution must be used not to confuse glargine for regular insulin because serious adverse effects, including hypoglycemia, can occur. Glargine must not be diluted or mixed with any other insulin or solution because its onset of action may be delayed, and the solution will become cloudy. Insulin glargine is administered subcutaneously once daily at bedtime. This timing of administration is unique for glargine. Patients who have previously received twice-daily injections of NPH insulin may be switched over to glargine's once-daily regimen under medical supervision. The initial dose of glargine is usually 20% less than the previous NPH dose. Taking one injection daily instead of two may be viewed as an improvement in quality of life for some patients. Adverse effects, administration techniques, and patient education are similar to those for regular insulin.

NON-INSULIN ANTIDIABETIC MEDICATIONS

Until the mid-1990s, the sulfonylurea drugs were the only class of antidiabetic agents available to manage type 2 diabetes. Currently, five chemical classes of oral antidiabetic agents are available for treating type 2 diabetes, and two classes of subcutaneous antidiabetic agents. For simplicity, they are grouped here, based on chemical composition, into sulfonylureas and nonsulfonylureas.

• C SULFONYLUREAS

The sulfonylureas consist of first- and second-generation drugs. The terms *first generation* and *second generation* are applied to groups of drugs that are in the same class but are developed at different times and have some different characteristics. The first-generation drugs are the original group of drugs in the class, and the second-generation drugs are those that are developed to overcome recognized limitations of the first generation. For example, second-generation sulfonylurea drugs have fewer drug interactions than those in the first generation. The first-generation sulfonylureas—acetohexamide, chlorpropamide, tolazamide, and tolbutamide—are rarely used today. Glyburide (Diabeta), a second-generation drug, is the prototype sulfonylurea hypoglycemic. See Table 49.2 for a summary of selected sulfonylureas.

Nursing Management of the Patient Receiving P Glyburide

Core Drug Knowledge

Pharmacotherapeutics

Glyburide is a potent second-generation oral sulfonylurea that is indicated as an adjunctive treatment to lower blood glucose levels in patients with type 2 diabetes in whom hyperglycemia cannot be controlled by diet and exercise alone.

Combination administration of a sulfonylurea and insulin has been used with some success in patients with type 2 diabetes whose disease is difficult to control with diet and sulfonylurea therapy alone. One such method is the "BIDS" system—*B*edtime *I*nsulin (usually NPH) in combination with a *D*aytime (morning only or morning and evening) *S*ulfonylurea. Temporary use of insulin in addition to glyburide may be necessary during periods of physiologic stress (e.g., from systemic infection, trauma, surgery, or fever); stress can induce alterations in glucose regulation that can be controlled only with exogenously administered insulin.

Pharmacokinetics

Administered orally, glyburide is absorbed rapidly and completely from the GI tract. The onset of action occurs within 2 hours, with a maximal decrease in serum glucose occurring within 3 to 4 hours. Like other second-generation sulfonylureas, glyburide is highly protein bound by nonionic binding, which differs from the ionic protein binding observed with first-generation sulfonylureas. Therefore, first-generation sulfonylureas are more likely to be displaced by drugs that competitively bind to proteins (e.g., warfarin), resulting in greater hypoglycemic response.

Glyburide is metabolized completely in the liver by the CYP3A3/4 isoenzyme to two metabolites, both of which are only weakly active. Both unchanged drug and metabolites are excreted equally in the urine and feces. The elimination half-life of the drug is 10 hours, and the duration of action is 24 hours in patients with normal renal function.

There are two forms of glyburide—micronized and nonmicronized. The two forms differ in absorption, onset of action, and delivery system, and consequently also differ in their bioavailability. Patients transferring to micronized glyburide from conventional glyburide or other oral antidiabetic agents should have their dosages adjusted.

Pharmacodynamics

The hypoglycemic action of glyburide results from the stimulation of pancreatic beta cells, leading to increased insulin secretion. Glyburide, like other sulfonylureas, is ineffective in type 1 diabetes, in which no endogenous release of insulin occurs, and in severe cases of type 2 diabetes, in which the release of insulin is severely impaired. Glyburide also reduces the glucose output from the liver by decreasing liver glycogenolysis (breakdown of glycogen stored in liver into glucose) and gluconeogenesis (formation of glycogen from fatty acids and proteins rather than from carbohydrates).

Glyburide also increases insulin sensitivity at cellular sites. These mechanisms lower blood glucose levels.

Contraindications and Precautions

Glyburide is contraindicated in patients with a known hypersensitivity to sulfa drugs because the sulfonylureas are related chemically to the antimicrobial sulfonamides (although they do not demonstrate any antimicrobial activity). Glyburide should not be used in type 1 diabetes and should be used cautiously in individuals with renal or hepatic disease.

Glyburide is a pregnancy category B drug.

Adverse Effects

Glyburide and other sulfonylureas are generally well tolerated. The primary adverse effect associated with glyburide (and the other sulfonylureas) is hypoglycemia. Renal or hepatic insufficiency may elevate drug blood levels, and hepatic insufficiency may also diminish gluconeogenic capacity. Both effects increase the risk of serious hypoglycemic reactions. In addition to excessive dosage, other factors that result in hypoglycemia include altered hepatic metabolism and renal excretion, improper diet, excessive physical activity, ingestion of alcohol (more of a problem with first-generation sulfonylureas), or concomitant use of more than one glucose-lowering drug. The hypoglycemia induced by glyburide and other sulfonylureas, although typically mild, may occasionally be severe and require immediate re-evaluation and adjustment of the drug dosage and the patient's lifestyle (e.g., diet and activity). Elderly, debilitated, or malnourished patients and those with adrenal or pituitary insufficiency are particularly susceptible to the hypoglycemic action of glucose-lowering drugs.

Glyburide may also cause GI effects, including anorexia, nausea, vomiting, heartburn, and a metallic taste in the mouth. Sulfonylurea drugs like glyburide result in weight gain, which may be a problem for some patients with diabetes who are already overweight. Signs of allergic reactions to glyburide therapy can include maculopapular rash, urticaria, pruritus, and erythema. These reactions are usually mild, but if they persist or become severe, the drug should be discontinued. Photosensitivity reactions also may occur with sulfonylureas. Rarely, blood dyscrasias occur (e.g., leukopenia, thrombocytopenia, pancytopenia, agranulocytosis, aplastic anemia, hemolysis) that may lead to hemolytic anemia. These effects typically subside once the drug is stopped, assuming the condition is detected early after its onset; if undetected and untreated, these conditions may progress and be fatal.

Hyponatremia and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) have occurred in patients receiving sulfonylureas. As the medication stimulates ADH release, the normal feedback mechanism that controls ADH release is overridden, making the kidneys more permeable to water. This effect results in an increased plasma volume and dilutional hyponatremia. Signs and symptoms of SIADH include water intoxication characterized by mental confusion, nausea, anorexia, dizziness, decreased sodium concentration, increased urinary osmolality, and decreased serum osmolality.

Research performed in the 1970s demonstrated a higher rate of cardiovascular death in patients who received a first-generation sulfonylurea than patients treated with placebo or diet plus insulin. Although the question has always lingered concerning second-generation sulfonylurea drugs, a recent review of the literature indicates that glyburide or other second-generation sulfonylureas cause no cardiovascular effects of any clinical consequence (Riveline, Danchin, Ledru, et al., 2003). Recent comparisons of sulfonylureas with other antidiabetic drugs (pioglitazone and metformin) have shown similar cardiovascular outcomes with all treatments (Belcher, Lambert, Edwards, et al., 2005).

Drug Interactions

As with other first- and second-generation sulfonylureas, a synergistic drug interaction occurs between glyburide (which stimulates insulin release) and the "insulin sensitizers" metformin and rosiglitazone (which improve tissue use of insulin). Hypoglycemia may occur. A disulfiram-like reaction (see Chapter 5) may occur when glyburide or other sulfonylureas are administered with alcohol. This disulfiram-like reaction is characterized by facial flushing

CRITICAL THINKING SCENARIO

UNEXPECTED HYPOGLYCEMIA

At the beginning of your 7 am shift, Mr. B., an 81-year-old African American male, is unresponsive when brought to the emergency department by ambulance. He is accompanied by his wife. She states she was unable to wake him up this morning. Mr. B. is found to have a serum glucose level of 8 mg/dL. One amp of D_{50} (50% dextrose) is administered, and his glucose level increases to 40 mg/dL and is closely monitored. He becomes responsive, alert, and oriented. Mr. B. has a past medical history of hypertension, chronic heart failure (CHF), and end-stage renal disease, for which he undergoes hemodialysis three times a week. He does not have diabetes, and there is no family history of diabetes, although his wife has type 2 diabetes. He and his wife are able to care for one another and live in their own home. Throughout your 12-hour shift, you continue to administer amps of D_{50} after checking his blood glucose every hour. His blood sugar continues to fluctuate and remains low, never getting above 60 mg/dL. A computed tomography scan of his head is negative, and his cardiac enzymes are also negative, indicating there has been no heart damage. After all of the fluid is administered, you notice crackles in the bases of his lung, leading to fluid overload and exacerbation of his CHF. By the end of your shift, you start a continuous infusion of D_{50} at 75 mL/h while continuing to check his blood glucose levels every hour. Without the D_{50}, Mr. B.'s blood glucose will drop.

1. After analyzing all of this information, how do you account for Mr. B.'s symptoms?
2. What further information might be helpful to fully assess Mr. B.'s condition?

TABLE 49.5 Agents that Interact with P Glyburide

Interactants	Effect and Significance	Nursing Management
antacids (MG+ salts)	Increased glyburide serum levels due to increased glyburide absorption	Monitor blood glucose level for hypoglycemia.
sulfonamides, chloramphenicol, phenylbutazone, salicylates, clofibrate, anticoagulants, fluconazole, H_2 antagonists (e.g., cimetidine), MAOIs, probenecid, sulfonamides, tricyclic antidepressants	Increased risk for hypoglycemia	Monitor blood glucose level for hypoglycemia. Teach patient to recognize signs of hypoglycemia, and to carry food with sugar to eat if necessary.
diazoxide, beta blockers, cholestyramine, hydantoins, thiazide diuretics, rifampin	Decreased hypoglycemic effect	Monitor blood glucose level for hyperglycemia. Monitor A_{1C} levels.
digitalis	Increased serum digitalis levels	Monitor serum digitalis levels and heart rate and rhythm. Observe for symptoms of digitalis toxicity.
alcohol	Disulfiram-like reaction with some sulfonylureas; may cause hypoglycemia or hyperglycemia	Avoid concomitant use.

and occasional breathlessness but without the nausea, vomiting, and hypotension seen with a true alcohol–disulfiram reaction. A number of drug interactions are possible because these drugs are metabolized by the CYP3A3/4 system. Table 49.5 lists drugs that interact with glyburide.

Concomitant use of some alternative therapies (e.g., juniper berries, ginseng, garlic, fenugreek, coriander, dandelion root, or celery) increases the risk of hypoglycemia.

Assessment of Relevant Core Patient Variables

Health Status

Assessments to be made before therapy with glyburide are similar to those necessary with insulin. Because glyburide undergoes hepatic metabolism and renal excretion, impairment in these functions can result in elevated serum concentrations of glyburide and increase the risk of hypoglycemia. Therefore, assess renal and hepatic function. To detect or prevent possible adverse drug interactions, additional assessments should include a review of all other drugs—prescription and OTC, including herbal products and dietary supplements—used by the patient. If hypoglycemic reactions occur, it is important to determine their frequency and how the patient or family handles these reactions. This information helps assess knowledge, usual practices, and teaching needs.

Life Span and Gender

Assess the patient for pregnancy or lactation. Glyburide is in pregnancy category B. Animal reproduction studies have shown adverse fetal effects with glyburide; thus, insulin is recommended instead to maintain blood glucose levels during pregnancy. Prolonged severe neonatal hypoglycemia may occur if glyburide is administered near the time of delivery. Whether glyburide is excreted in breast milk is unknown; however, some first-generation sulfonylureas are excreted in breast milk. Because of the possibility of hypoglycemia in breast-fed infants, lactating women should avoid use of glyburide.

Note the age of the patient before administering glyburide. The drug's safety and efficacy have not been established in children. Although the Food and Drug Administration has not approved any of the oral antidiabetic drugs for use in children with type 2 diabetes, they are frequently prescribed by physicians who treat this population. Elderly patients may be more susceptible to the hypoglycemic effects of glyburide because of age-related decline in renal function that slows down the drug excretion. Rapid and prolonged hypoglycemia (less than 12 hours), despite hypertonic glucose injections, has been reported. Hypoglycemic reactions may be more difficult to recognize in elderly individuals because they may be obscured by other pathologies or drug therapies.

Lifestyle, Diet, and Habits

It is a good idea to assess the patient's willingness or ability to adhere to strict drug therapy. Tell the patient to take the pills daily and at the same time each day. Note the patient's weight and typical alcohol consumption before therapy is initiated. An obese patient (those more than 20% over ideal body weight) may not respond to glyburide. Concomitant alcohol use increases the rate of glyburide metabolism and may cause a disulfiram-like reaction. Also, assess for use of herbs that might interact with glyburide.

Environment

Be aware of the environment in which glyburide will be administered. Glyburide is most commonly self-administered by the patient in the home setting.

Nursing Diagnoses and Outcomes

- Ineffective Health Maintenance related to glyburide-induced nausea, vomiting, abdominal pain, and disulfiram-like reaction secondary to alcohol ingestion
  Desired outcome: *The patient will follow American Diabetes Association dietary guidelines and avoid consuming alcohol.*

- Imbalanced Nutrition: More than Body Requirements, related to weight gain secondary to glyburide/sulfonylurea therapy
  Desired outcome: *The patient will follow American Diabetes Association dietary guidelines and not experience a weight gain.*
- Ineffective Protection related to leukopenia secondary to bone marrow depression associated with glyburide use
  Desired outcome: *The patient will be free from infection while taking glyburide.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer glyburide before breakfast or the first main meal of the day in order to stimulate insulin production. In addition, glyburide should be stored in a tightly capped container at room temperature.

Minimizing Adverse Effects

Monitor the patient's blood glucose levels periodically throughout therapy to detect hypoglycemia. Assess blood glucose levels most closely at the start of therapy and whenever the dose is increased. Because older adults are more sensitive to the hypoglycemic effects of glyburide, administer the drug cautiously at a reduced dosage until the effects on the patient are known. More frequent monitoring of blood glucose levels may be required with older adults.

Monitor patients with renal and hepatic impairment for signs of adverse effects. General blood work should also be monitored periodically throughout therapy to detect blood dyscrasias.

Providing Patient and Family Education

In addition to general teaching on diabetes and diabetic management (see Box 49.4), teach specific information about glyburide.

- Teach patients and families the signs and symptoms of hypoglycemia (irritability, confusion, nervousness, weakness, hunger), which is a common adverse effect of glyburide. They should know to treat hypoglycemia with a small amount of quickly absorbed carbohydrate, such as a hard candy, orange juice, or a teaspoon of sugar.
- Alert patients and families to the signs and symptoms of out-of-control diabetes, such as hyperglycemia, polydipsia, polyphagia, and polyuria. Persistent hyperglycemia may indicate a need to adjust the glyburide dose or some other aspect of the therapeutic regimen, such as diet.
- Teach patients to avoid alcohol while using glyburide.
- It is important to caution patients to avoid OTC medications and herbal or dietary supplements without first consulting the prescriber. Drug interactions may occur; for example, cough syrups containing alcohol and sugar may cause an unintended effect.
- Provide patients with oral and written information about amount and timing of the doses to be taken.

MEMORY CHIP

P Glyburide

- Oral hypoglycemic that stimulates insulin release and increases peripheral tissue sensitivity to insulin effects; used as adjunct with dietary restrictions to treat type 2 diabetes mellitus; is available commercially, combined with metformin, to manage type 2 diabetes (e.g., Glucovance)
- Major contraindications: severe hepatic or renal impairment; allergy to sulfa drugs
- Most common adverse effects: nausea, epigastric fullness, heartburn
- Most serious adverse effect: hypoglycemia
- **Life span alert: Older adults may be at greater risk for hypoglycemia related to drug accumulation from age-related decline in hepatic and renal functions.**
- Maximizing therapeutic effects: Daily dosage of greater than 10 mg should be divided into two doses and taken 30 minutes before the meal.
- Minimizing adverse effects: Avoid taking glyburide with certain alternative dietary therapies, supplements, or herbs because of increased risk for hypoglycemia.
- Most important patient education: signs and symptoms of out-of-control diabetes, such as hyperglycemia, polydipsia, polyphagia, and polyuria; dietary restrictions for serum glucose control and weight loss

Ongoing Assessment and Evaluation

Interview the patient and family and observe for therapeutic and adverse responses to glyburide and adherence to prescribed treatments. When assessing the success of nursing management, be alert for adverse drug effects (especially hypoglycemia) and appropriately refer the patient to the prescriber for re-evaluation of pharmacotherapy if pertinent symptoms are identified. Blood tests monitoring glucose levels (e.g., fasting, 2-hour postprandial, and hemoglobin A_{1C}) are as important as they are for patients taking exogenous insulin. Review the patient's hepatic and renal function periodically, particularly if he or she has pre-existing liver or kidney impairment. Drug therapy with glyburide is considered effective if blood glucose levels are controlled and the patient does not experience appreciable adverse effects.

Drugs Closely Related to P Glyburide

There are two other second-generation sulfonylurea drugs, glipizide (Glucotrol or Glucotrol XL) and glimepiride (Amaryl). Glipizide has a slight variation from glyburide in the recommended time of administration. Because the absorption of glipizide is delayed by approximately 40 minutes when taken with food, it is more effective when given approximately 30 minutes before a meal. Like glyburide, glipizide and the other sulfonylureas may be taken with food. Glipizide is a pregnancy category C drug, unlike glyburide, which is in category B. Otherwise, glipizide is very similar to glyburide.

Glimepiride is much like glipizide, with two major differences: it is metabolized in the liver via the CYP2C9 pathway, and it is excreted via two routes, fecal and renal.

Drugs Significantly Different From P Glyburide

The meglitinides, consisting of repaglinide and nateglinide, are significantly different from the prototype glyburide. These drugs act similarly to the sulfonylureas but have a different chemical structure.

Repaglinide

Repaglinide (Prandin), which belongs to the meglitinide class, is an oral hypoglycemic agent. This class shares many of the pharmacologic actions and adverse effects of the sulfonylureas. In lowering blood glucose levels, repaglinide has a mechanism of action much like that of the sulfonylureas. Similar to glyburide, it stimulates the secretion of insulin from the pancreatic beta cells by binding to the beta cell sites. In contrast to the sulfonylureas, this agent is absorbed rapidly and undergoes minimal renal excretion, making it suitable for elderly patients or others with decreased kidney function. Peak action occurs within 1 hour of ingestion; the drug is metabolized completely in 3 to 4 hours. Administered orally before each meal, repaglinide is effective in lowering postprandial glucose levels, as the amount of insulin released from the pancreas increases during and just after a meal, mimicking the normal blood glucose response to eating. Because of its rapid elimination in contrast to the sulfonylureas, repaglinide does not cause the beta cells to continuously release insulin for long periods of time. Therefore, insulin levels return to normal before the next meal. The number of meals eaten is equivalent to the number of doses taken; for example, if a meal is missed, the corresponding dose of medication also is skipped. Conversely, a dose is added when an extra meal or large snack is taken.Weight gain (up to three kg in three months) occurred more frequently from repaglinide compared to metformin. (see below for discussion of metformin) (Black, Donnelly, McIntyre et al. 2007)

Nateglinide

Nateglinide (Starlix) is a meglitinide that may be used alone or in combination therapy with metformin. It lowers blood glucose by stimulating insulin secretion from the pancreas within 20 minutes following oral administration; the extent of pancreatic insulin release is glucose dependent and diminishes at low glucose levels. Used before meals, it causes a rapid rise in plasma insulin, with peak levels occurring within 1 hour and a fall to baseline by 4 hours. Nateglinide is metabolized predominantly by the CYP450 system and is rapidly and completely eliminated renally. Nateglinide is a category C drug and is contraindicated in pregnancy and lactation. It should be used with caution in chronic hepatic disease, and its safety and efficacy in children is not established. Although hypoglycemia occurs infrequently, it is the most common adverse reaction. Drug interactions that potentiate the hypoglycemic effect of nateglinide include nonsteroidal anti-inflammatory drugs, salicylates, and nonselective beta-adrenergic blockers. Drug interactions that reduce the hypoglycemic effect of nateglinide include thiazides, corticosteroids, thyroid products, and sympathomimetics. Like repaglinide, weight gain (up to three kg in three months) occurred more frequently from nateglinide compared to metformin. (see below for discussion of metformin) (Black, Donnelly, McIntyre et al. 2007)

• Nonsulfonylureas

The nonsulfonylurea antidiabetics comprise three different classes grouped by their chemical structure: biguanides, thiazolidinediones, and alpha-glucosidase inhibitors. However, more commonly, these drugs are considered by their mode of action, which is either improving insulin action or delaying the digestion of carbohydrates; thus, the terms *antiglycemic* or *antihyperglycemic* may also be used. Metformin (Fortamet, Glucophage), a biguanide, works by improving insulin action and is the prototype drug.

Nursing Management of the Patient Receiving P Metformin

Core Drug Knowledge

Pharmacotherapeutics

Metformin is used as an adjunct to diet and exercise to lower blood glucose in type 2 diabetes (see Table 49.2) and is usually the drug of first choice to use in type 2 diabetes. Metformin is not a hypoglycemic agent because it does not stimulate insulin secretion; rather, it is an antihyperglycemic or "insulin sensitizer" agent. Metformin works by suppressing hepatic glucose production (reducing glyconeogenolysis) while enhancing insulin sensitivity in adipose and skeletal muscle tissue, increasing glucose uptake into those cells. As a result, insulin resistance is lessened. Metformin is ineffective if patients are without some residual functioning pancreatic islet cells.

In addition, metformin lowers triglyceride levels and total and low-density lipoprotein (LDL) cholesterol levels, and it promotes weight loss. Metformin may be used with a sulfonylurea or with insulin to control glucose levels in type 2 diabetes. When it is necessary to give insulin as well as an oral antihyperglycemic, metformin combined with insulin appears to be the best regimen for most patients with type 2 diabetes because this combination has resulted in fewer hypoglycemic episodes, lower insulin doses, and less weight gain than other combinations of sulfonylureas and insulin.

Pharmacokinetics

Administered in oral tablet form, metformin is absorbed slowly but incompletely from the GI tract; this incomplete absorption results in a bioavailability of only 50% to 60%. Food slightly delays and decreases the extent of its absorption. The absorbed drug is distributed rapidly into peripheral body tissues and fluids, and peak serum levels are achieved in 2 to 3 hours after administration. Metformin does not bind to plasma proteins and does not undergo hepatic metabolism. Metformin is excreted mostly unchanged by

the kidneys; 90% of the absorbed drug is eliminated renally within the first 24 hours, with a plasma elimination half-life of 6.2 hours. Half-life is longer in patients with impaired renal function.

Pharmacodynamics

Metformin decreases hepatic glucose production, decreases intestinal absorption of glucose, and improves insulin sensitivity by increasing peripheral glucose uptake and use in skeletal muscle and adipose tissue through increased transport of glucose across the cell membrane.

Unlike the sulfonylureas, metformin rarely causes hypoglycemia when used alone because it does not stimulate insulin secretion. In fact, insulin secretion remains unchanged, whereas fasting insulin levels and day-long plasma insulin response may actually decrease. In addition, metformin lowers triglyceride levels and promotes weight loss. Metformin lowers fasting and postprandial hyperglycemia. Full therapeutic effect from a given dose takes up to 2 weeks to occur; thus, when the dose is being titrated upward, increases should occur no more frequently than every 1 to 2 weeks.

Contraindications and Precautions

Metformin is contraindicated in patients with hepatic disease, alcoholism, acute or chronic metabolic acidosis, chronic heart failure, clinical situations that predispose to hypoxemia, and renal impairment (creatinine clearance, less than 40 mL/min) because these conditions may predispose the patient to lactic acidosis. This risk of lactic acidosis is highlighted in a Black Box warning for metformin.

Metformin is a pregnancy category B drug.

Adverse Effects

Minor but common side effects of metformin include GI disturbances such as anorexia, nausea and vomiting, weight loss, abdominal discomfort, dyspepsia, flatulence, diarrhea, and a metallic taste sensation. These adverse effects tend to decline with continued use and can be minimized by initiating therapy with lower doses of metformin. Hypoglycemia can occur if metformin is combined with a sulfonylurea drug or with insulin.

Serious adverse effects are rare and usually occur in individuals with impaired renal or hepatic function. Lactic acidosis is listed in the drug label information as a very rare serious, potentially lethal adverse effect. Lactic acidosis is a metabolic complication characterized by an increased anion gap, elevated blood lactate levels, decreased blood pH, and electrolyte disturbances. The onset of lactic acidosis is often subtle and presents with nonspecific symptoms such as malaise, myalgias, respiratory distress, increasing somnolence, and nonspecific abdominal distress Hypothermia, hypotension, and bradyarrhythmias may be present with more marked acidosis. However, despite its black box warning, a recent "review from all known comparative and observational studies lasting at least one month found no cases of fatal or nonfatal lactic acidosis in 70,490 patient-years of metformin use, Average lactate levels measured during metformin treatment were no different than for placebo or for other medications used to treat diabetes" (Salpeter, Greyber, Pastemak, et al., 2010). It appears that the cases of lactic acidosis noted during original drug trials were related to normal occurrence of this condition in the general population and not secondary to the drug itself. Other rare, serious adverse effects associated with metformin include blood dyscrasias such as aplastic anemia, agranulocytosis, and thrombocytopenia.

Drug Interactions

Metformin, which improves insulin use, interacts synergistically with the sulfonylureas, which stimulate insulin production. This interaction causes hypoglycemic adverse effects. Metformin may react with contrast media used for radiographic procedures. Table 49.6 lists drugs that interact with metformin.

Assessment of Relevant Core Patient Variables

Health Status

Assessments to be made before therapy with metformin are similar to those necessary with insulin. Assess current health status, including diet, activity, medication, any adverse effects from medications, and methods used for monitoring blood glucose. Ensure that the patient receiving metformin has periodic renal and hepatic function tests. Metformin's half-life is prolonged and its excretion is decreased in patients with impaired renal function, especially those with decreased creatinine clearance. Impaired hepatic function

TABLE 49.6 Agents That Interact with P Metformin

Interactants	Effect and Significance	Nursing Management
cimetidine	Increased risk for hypoglycemia	Monitor blood glucose levels.
sulfonylureas	Synergistic reaction between metformin and sulfonylurea that improves insulin use; may increase risk for hypoglycemia	Monitor blood glucose levels. Observe for hypoglycemic complications.
glucocorticoids, alcohol	Increased risk of lactic acidosis	Monitor serum lactate levels.

may increase the risk of lactic acidosis. Also, ensure that the patient has periodic blood tests, because blood dyscrasias are rare but possible. Assess the patient's weight during therapy, because weight loss—a beneficial side effect for overweight patients with type 2 diabetes—may occur. Monitor lipid levels because metformin decreases LDL cholesterol; again, this result is usually a positive effect for the patient with diabetes.

Life Span and Gender

Assess whether the patient is pregnant or breast-feeding. Metformin is in pregnancy category B. Animal studies demonstrate metformin excretion into breast milk, but studies in lactating women have not been performed. It is important to determine the age of the patient before administering metformin. Safety and efficacy in children have not been established. Age-related changes in renal function account for altered pharmacokinetics; metformin should be used cautiously in elderly patients because of the prevalence of decreased renal function in this age group. In general, elderly patients are better able to tolerate lower doses of metformin.

Lifestyle, Diet, and Habits

Ask patients about their typical diet and exercise habits and about alcohol intake. Hypoglycemia is more common when metformin is administered concomitantly with other oral hypoglycemic agents, if caloric intake is deficient, or if the patient exercises strenuously. Caution patients against excessive alcohol intake while taking metformin because alcohol use increases the risk of lactic acidosis. Concurrent use with chromium, garlic, gymnema, or alcohol may increase the risk for hypoglycemia.

Environment

Note the environment in which metformin will be administered. Metformin is an oral drug that is easily self-administered in the home setting.

Culture and Inherited Traits

In controlled clinical studies of metformin in individuals with type 2 diabetes, the antihyperglycemic effect was comparable among whites, African Americans, and Hispanics.

Nursing Diagnosis and Outcome

- Risk for Imbalanced Nutrition: Less than Body Requirements, related to anorexia secondary to adverse GI effects of weight loss, diarrhea, and anorexia from metformin
  Desired outcome: *The patient will ingest daily nutritional requirements in accordance with activity level and metabolic needs and relate the importance of good nutrition.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer metformin twice a day, with the morning and evening meals. The dosage is individualized on the basis of both effectiveness and tolerance. FPG and hemoglobin A_{1C} (**glycosylated hemoglobin**) are used to identify the minimum effective dose of metformin, when used either as monotherapy or in combination with a sulfonylurea or insulin. Adherence with the recommended diabetic diet and daily exercise help in the control of type 2 diabetes, when used in conjuncture with metformin.

Metformin is frequently prescribed with other oral antidiabetic drugs, especially a sulfonureas drug. When patients have difficulty achieving control on oral medication, an insulin can be added to the drug thereapy. Recent research that examined the A1C level of patients who received metformin and a sulfonureas drug and one of three insulin regimens: aspart twice a day, aspart with each meal, or basal detemir once or twice a day. Patients who received either the prandial (mealtime) dose with aspart or the basal dose of detemir were more likely to achieve an A1C level of 6.5% or less than those who received aspart twice a day. Using basal dosing of detemir created fewer hypoglycemic episodes and allowed for less weight gain than the other methods (Holman, Farmer, Davies, et al for the 4-T study group, 2009).

Minimizing Adverse Effects

Adverse GI effects during initiation of metformin therapy appear to be dose related. Taking the drug at mealtimes and using gradual dosage increments minimize these effects. Because it is excreted renally, metformin should be withheld temporarily when patients undergo any procedure using iodinated contrast dye, which is also excreted renally. Lower doses are usually indicated in older adults to prevent adverse effects. If the patient is having any surgical procedure (except for minor procedures), metformin should be temporarily withheld until oral intake has resumed and renal function has returned to normal.

Providing Patient and Family Education

- Teach patients to take metformin with meals, morning and evening.
- Emphasize that patients should not use alcohol while taking metformin.
- Advise patients not to take any OTC preparations, including dietary and herbal supplements, without first consulting the prescriber.
- For general teaching, see Box 49.4.

Ongoing Assessment and Evaluation

Monitor blood glucose levels (fasting and hemoglobin A_{1C}) throughout metformin therapy. Periodic screening for hematologic changes is recommended during therapy because blood dyscrasias may occur. Metformin therapy is effective when glucose levels are controlled and the patient does not experience any important adverse effects (see also the "Ongoing Assessment and Evaluation" section in the "Insulin" discussion).

MEMORY CHIP

P Metformin

- Oral antihyperglycemic that increases peripheral tissue sensitivity to the effects of insulin and decreases hepatic glucose production. Is available commercially, combined with glyburide, to manage type 2 diabetes (e.g., Glucovance)
- Major contraindications: serious hepatic or renal function impairment
- Most common adverse effects: nausea, diarrhea, abdominal bloating, flatulence, and anorexia; GI adverse effects appear to be dose related
- Most serious adverse effects: lactic acidosis and hypoglycemia
- **Life span alert: Older adults may be at greater risk for lactic acidosis from age-related decline in renal function.**
- Maximizing therapeutic effects: Individualize the dosage on the basis of both effect and tolerance, while not exceeding the maximum recommended daily dose.
- Minimizing adverse effects: Daily dosage of greater than 2 g should be divided into three doses taken at each meal; the drug should be taken with food to decrease adverse GI effects.
- Most important patient education: dietary restrictions for serum glucose control and weight loss

Drugs Closely Related to P Metformin

Drugs closely related to metformin are the thiazolidinediones, including rosiglitazone and pioglitazone. These drugs also enhance the effectiveness of insulin.

C Thiazolidinediones: Rosiglitazone and Pioglitazone

The pharmacodynamic actions of the thiazolidinedione oral antihyperglycemic drugs are similar to those of the biguanides; they are antihyperglycemics and "insulin sensitizers." Thiazolidinedione antidiabetic drugs include rosiglitazone (Avandia) and pioglitazone (Actos). Rosiglitazone and pioglitazone are both indicated as an adjunct to diet and exercise to lower blood glucose in patients with type 2 diabetes. They are prescribed in combination with a sulfonylurea, metformin, or insulin when adequate glycemic control is not achieved."Although these drugs are quite effective in helping to maintain normal blood glucose levels, the class of drugs has been dogged, almost since first brought to market, with concerns that they may create serious adverse effects. The first drug in this class troglitazone was taken off the market in March 2000 after it was found in post-marketing use to cause acute liver failure"(Aschenbrenner, 2011). Thiazolidinedione drugs cause weight gain.Weight gain is important to note, because this adverse effect differentiates this class from metformin, which causes weight loss. Both drugs are absorbed rapidly after oral administration.

Rosiglitazone

Rosiglitazone, while an effective antidiabetic drug, now has limitations as to its use. The restrictions limit the initiation of rosiglitazone to second line therapy for those who have not been able to achieve glycemic control from other antidiabetic drugs and in whom the drug appears to be a medical necessity. Patients who were prescribed rosigllitazone prior to the label changes in 2011 may also continue to receive the drug, if they choose. All patients must receive documented education concerning potential risks from the therapy (Aschenbrenner, 2011).

The restrictions are based on meta-analysis of clinical trials that indicate rosiglitazone may potentially increase the risk of myocardial infarction and other cardiovascular events. Unfortunately, these clinical trials were never designed to assess cardiovascular risk, so this makes it difficult to accurately draw conclusions about the findings from these trials. Other clinical trials did not find that there was an increased risk of myocardial infarction from rosiglitazone. Uncontrolled diabetes is in itself a risk factor for cardiovascular disease and this complicates the interpretation of some of the clinical trial findings. More research must be done to determine conclusively what effects rosiglitazone have on the cardiovascular system. (Aschenbrenner, 2011).

One large multicentered clinical trial that examined the risks of rosiglitazone was the RECORD trial (Rosiglitazone Evaluated for Cardiac Outcomes and Regulation of Glycaemia in Diabetes) RECORD examined the effect of adding rosiglitazone to oral monotherapy with either metformin or a sufuonureas drug compared to receiving combination therapy with metformin and a sulfonureas This trial found that the addition of rosiglitazone increases the risk of heart failure (most likely due to the increase in fluid retention) as well as increasing the risk of upper and distal lower limb fractures, mostly in women. Rosiglitazone's effect on myocardial infarction is inconclusive from this study, although cardiovascular morbidity or mortality from all sources did not increase (Home, Pocock, Beck-Nielsen, et al., for RECORD study team, 2009). The findings from this trial contributed to the FDA's decision to include a black box warning stating that rosiglitazone may increase the risk of congestive heart failure, most likely from fluid retention, and that it may increase the risk of myocardial infarction.

Rosiglitazone is highly protein bound and undergoes hepatic metabolism through the P-450 system. Rosiglitazone is metabolized by P-450 2C8 and 2C9. These are not major pathways for most other drugs; therefore, drug interactions are minimal. Rosiglitazone is excreted in the urine and feces. The elimination half-life of rosiglitazone is much shorter than the half-life of pioglitazone (3 to 4 hours, compared with 16 to 24 hours).

Rosiglitazone should not be given to patients with symptomatic heart failure(based on the black box warning) or those with active liver disease or increased serum transaminase or aminotransferase levels (ALT or AST more than 2.5 times the upper limits of normal) (based on the earliest drug in this class increasing the risk of hepatic failure). Patients treated with these drugs should undergo periodic monitoring of liver enzymes. Hepatic enzymes should be measured before therapy begins. In patients with normal baseline liver

enzymes, liver enzymes should be monitored every 2 months for the first 12 months and periodically thereafter. Rosiglitazone therapy is generally well tolerated despite its black box warnings; the few adverse effects include fluid retention (while it may be significant enough to exacerbate CHF or to induce it in susceptible individuals, generally it is a minor effect), headache, and weight gain (likely from fluid retention). Plasma volume expansion may occur with rosiglitazone therapy. As a result, small decreases in hemoglobin, hematocrit, and neutrophil counts (within the normal range) have occurred

Triglyceride levels can significantly increase with rosiglitazone therapy. HDLand LDL cholesterol will also increase from baseline levels.

The assessment of current health status for rosiglitazone is the same as for metformin. Particular attention to hepatic function blood tests is needed because of the risk of hepatotoxicity. It is necessary to emphasize the importance of follow-up blood work and to teach patients to report signs of early liver impairment (e.g., nausea, vomiting, malaise, and dark urine). Premenopausal, anovulatory women with diabetes taking rosiglitazone are at risk for resuming ovulation with drug therapy and so are at risk for pregnancy. Female patients should be counseled to consider an alternative method of contraception or be referred to their prescribers to discuss a dosage increase in the oral contraceptive. Rosiglitazone is a pregnancy category C drug.

Pioglitazone

Pioglitazone is very similar in action to rosiglitazone. At this time there is still unrestricted access to prescribing piolglitazone, unlike for rosiglitazone. The decision to allow unrestricted access to the other drug in the same class, pioglitazone, is considered controversial even among FDA officials and should not be construed by providers that pioglitazone is without risk. Rosiglitazone and pioglitazone have never been tested head to head in a clinical trial comparing cardiovascular risk from each drug. The FDA's decision to encourage the use of pioglitazone before the use of rosiglitazone was based on data that some scientists believe is without strong scientific basis (Parks, 2010).

Like rosiglitazone, however, pioglitazone carries a black box warning that it may cause congestive heart failure from fluid retention.

Like rosiglitazone, pioglitazone is highly protein bound and undergoes hepatic metabolism through the P-450 system, although they are metabolized by different isoenzymes. Pioglitazone is metabolized hepatically by P-450 2C8 and 3A4. Isoenzyme 3A4 is an important pathway for metabolism of some drugs; therefore, drug interactions can occur. Drugs that are metabolized by CYP3A4, such as erythromycin, calcium channel blockers, cortical steroids, cyclosporine, the statins, tacrolimus, triazolam, and trimetrexate, may have their metabolism impaired by pioglitazone, and caution should be used. Drugs that inhibit CYP3A4, such as ketoconazole, appear to increase the metabolism of pioglitazone. Additionally, pioglitazone is metabolized by the P-450 isoenzyme 1A1 via extrahepatic pathways. Like rosiglitazone,pioglitazone is excreted in the urine and feces. The elimination half-life of pioglitazone is much longer than that for rosiglitazone (16 to 24 hours compared with 3 to 4 hours).

Like rosiglitazone, pioglitazone should not be given to patients with symptomatic heart failure or those with active liver disease or increased serum transaminase or aminotransferase levels (ALT or AST more than 2.5 times the upper limits of normal). Monitoring for liver adverse effects is identical. Pioglitazone therapy has the same adverse effects as rosiglitazone, except pioglitazone may cause its own unique adverse effects as animal and human research indicates that it may increase the risk of bladder cancer.

Pioglitazone will also alter lipid levels. Triglyceride levels were significantly decreased with pioglitazone therapy and (while significantly increased with rosiglitazone therapy). Although both these drugs increase HDL cholesterol, pioglitazone provides significantly greater increases from the baseline. Both pioglitazone and rosiglitazone also increase LDL cholesterol, but mean changes from baseline are significantly less with pioglitazone.

The assessment of current health status for rosiglitazone and pioglitazone is the same as for metformin. Hepatic function needs to be assessed and monitored for pioglitazone as done for rosiglitazone. Similarly to those taking rosiglitazonen, premenopausal, anovulatory women with diabetes taking pioglitazone are at risk for resuming ovulation with drug therapy and so are at risk for pregnancy. Female patients should be counseled to consider an alternative method of contraception or be referred to their prescribers to discuss a dosage increase in the oral contraceptive. Pioglitazone is a pregnancy category C drug. Pioglitazone has been found to increase a woman's risk of fractures in distal upper limbs (forearm, hand, and wrist) or distal lower limbs (foot, ankle, fibula, and tibia) (Food and Drug Administration MedWatch, 2007). It is necessary to assess the risk of fracture when initiating therapy with pioglitazone in women, as well as the risk of falls, which may increase the risk of fractures.

Drugs Significantly Different From P Metformin

C Alpha-Glucosidase Inhibitors: Acarbose and Miglitol

Alpha-glucosidase inhibitors provide yet a different mechanism of action for patients with type 2 diabetes. These medications do not enhance insulin secretion, nor are they insulin sensitizers like metformin. Rather, the antihyperglycemic activity results from a substantial reduction in postprandial glucose levels. Alpha-glucosidase inhibitors slow down enzymes needed to digest carbohydrates; specifically, they inhibit alpha-glucosidase enzymes in the brush border of the small intestine and inhibit pancreatic alpha-amylase. Pancreatic alpha-amylase hydrolyzes complex starches to oligosaccharides in the lumen of the small intestine, whereas

the membrane-bound intestinal alpha-glucosidases hydrolyze oligosaccharides, trisaccharides, and disaccharides to glucose and other monosaccharides in the small intestine. Inhibition of these enzyme systems reduces the rate of digestion of complex carbohydrate. Less glucose is absorbed because the carbohydrates are not broken down into glucose molecules. In patients with diabetes, the short-term effect of these drug therapies is to decrease current blood glucose levels; the long-term effect is a small reduction in the hemoglobin A_{1C} level. Alpha-glucosidase inhibitors are an ideal alternative therapy for patients with type 2 diabetes who have mild to moderate hyperglycemia and who are at risk for hypoglycemia or lactic acidosis (see Table 49.2).

Acarbose (Precose) and miglitol (Glyset), two alpha-glucosidase inhibitors, effectively lower postprandial serum glucose when administered alone or in combination with insulin, metformin, or a sulfonylurea. Both these drugs should be administered orally with the first bite of food. The drugs differ in their metabolism and excretion. Acarbose undergoes exclusive metabolism within the GI tract—principally by intestinal bacteria but also by digestive enzymes. An active metabolite is created that produces the therapeutic effects of acarbose. Little of the active metabolite is absorbed; only about 35% of the dose is converted and then absorbed. Miglitol, on the other hand, does not undergo any metabolism, so the therapeutic effect comes directly from the drug. The elimination half-life of acarbose and miglitol is about 2 hours. Acarbose is eliminated through the kidneys and the GI tract, whereas miglitol is eliminated unchanged by renal excretion.

Acarbose and miglitol are contraindicated in patients with diseases of the bowel (e.g., inflammatory bowel disease, absorptive disorders, colonic ulceration, and history of bowel obstruction). They should be used cautiously in patients with hiatal hernia or other conditions that might be exacerbated by increased formation of gas, which is an adverse effect of acarbose. The drugs are also contraindicated in patients with chronic liver diseases and substantial renal impairment (serum creatinine, greater than 2 mg/dL). Acarbose and miglitol are in pregnancy category B. They are excreted into breast milk and should not be given to lactating women.

Adverse effects of acarbose and miglitol are primarily GI in nature and include flatulence, diarrhea, and abdominal distention. These effects occur because the delay in carbohydrate absorption increases fermentation and formation of intestinal gases.

Assessments to be made before starting therapy with the alpha-glucosidase inhibitors are similar to those necessary with insulin. In addition, 1-hour postprandial blood glucose and serum transaminase levels should be obtained as baseline data. It is necessary to stress the importance of notifying the health care team if unusual fatigue or muscle pain, difficulty breathing, GI distress, dizziness, light-headedness, or irregular heartbeat occurs, because these symptoms may indicate the onset of lactic acidosis, which is often insidious. Initial education of the patient should involve telling him or her that acarbose and miglitol inhibit the absorption of regular cane sugar (such as in candy or orange juice). The most important difference between these drugs and insulin or metformin therapy is that if a hypoglycemic reaction occurs, *the patient must not use cane or table sugar products because the sugar will not be absorbed*. It should be emphasized that he or she should use oral glucose tablets instead to increase blood glucose levels. (See Box 49.4.)

Dipeptidyl Peptidase-4 Inhibitor

Sitagliptin (Januvia) and saxagliptin (Onglyza) are antidiabetic drugs that works in a unique way to lower blood glucose in type 2 diabetes. Saxagliptin is more potent, but not more effective. Both sitagliptin and saxagliptin are dipeptidyl peptidase-4 (DPP-4) enzyme inhibitors, which work by protecting the endogenous incretin hormones and enhancing their actions. Incretin hormones (glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1) are released in response to glucose elevations that occur after a meal to maintain normal levels of glucose. These incretin hormones increase insulin synthesis and its release from pancreatic beta cells by intracellular signaling pathways. Glucagon-like peptide-1 also lowers glucagon secretion from the pancreas, thus reducing hepatic glucose production. However, incretin hormones are metabolized rapidly by the special enzyme DPP-4, leading to a decrease of insulin production and an increase in glucagons levels. As the result of sitagliptin's and saxagliptin's inhibition of the breakdown of incretin hormones by DPP-4, incretin hormone activity is more pronounced; therefore, insulin release continues and glucagon levels decrease. Both of these factors result in lower blood glucose levels. Incretin hormones function only when the blood glucose level is high. Because of this, sitagliptin and saxagliptin only rarely cause hypoglycemia if they are used in monotherapy.

The most common adverse effects are central nervous system (CNS)–related (headache), GI (abdominal pain, diarrhea, nausea), and respiratory (nasopharyngitis, upper respiratory infections). Saxagliptin may also cause peripheral edema and urinary tract infections. Infections from all causes increase significantly with sitagliptin for an unknown reason. No long term data regarding the drug's effect on the immune function is currently available (Richter, Bandeira-Echtler, Bergerhoff, et al. 2008). Both drugs are pregnancy category B drugs.

The only known drug interaction with sitagliptin is with digoxin. Coadministration increases digoxin levels, but no dose adjustment is recommended. However, the patient should be monitored for any adverse effects from this combination. It is unknown what effect sitagliptin will have on cardiovascular disease in diabetics (Richter, Bandeira-Echtler, Bergerhoff, et al. 2008).

Saxagliptin has a drug interaction with the following drugs: atazanavir, clarithromycin, indinavir, itraconazole, ketoconazole, nefazodone,nelfinavir, ritonavir, saquinavir, and telithromycin. All of these drugs will increase the circulating level of saxagliptin.

Incretin Mimetic

Exenatide (Byetta) is a synthetic incretin mimetic. By mimicking the actions of incretin hormones, the drug decreases blood glucose levels, helping them to return to normal. Exenatide works at the glucagon-like peptide-1 receptors and produces effects similar to glucagon-like peptide-1. However, all observed pharmacodynamic effects of exenatide have not been consistent with those of glucagon-like peptide-1, suggesting that the drug may also produce some actions via functionally different receptors not yet identified. Actions of exenatide include enhancement of insulin secretion in the presence of glucose, decrease in glucagon secretion, slowing of gastric emptying, reduction of food intake, promotion of beta-cell proliferation and neogenesis, reduction in adiposity, and insulin-sensitizing effects (this was seen only in animal models; natural exendin-4 was first isolated from the saliva of *Heloderma suspectum* [Gila monster]). Exenatide is a gene product that is distinct from glucagon-like peptide-1. Although it shares more than half of the amino acid sequence with that found in mammalian glucagon-like peptide-1, exenatide is not an analogue of, or a modified form of, glucagon-like peptide-1. Unlike endogenous glucagon-like peptide-1, exenatide is relatively resistant to degradation by dipeptidyl peptidase-4; thus it has a longer half-life.

Exenatide is used as an adjunct in treating patients with type 2 diabetes (i.e., those who are taking metformin, a sulfonylurea, a thiazolidinedione, a combination of metformin and a sulfonylurea, or a combination of metformin and a thiazolidinedione but have not achieved adequate glycemic control). It reduces hemoglobin A_{1C}, fasting plasma glucose, and body weight. Weight loss is probably related to slower gastric emptying.

Exenatide is administered by subcutaneous injection up to one hour before breakfast and dinner. It should always be given before a meal, not afterward. The dose does not need to be adjusted based on size of meal or amount of exercise. Because weight loss is expected from exenatide therapy, the dose should not be decreased based on weight. Exenatide is not an insulin and must not be confused with an insulin, although it is administered subcutaneously. The drug comes in a special prefilled injection "pen," and the lancets must be purchased separately. Until the injection pen is used for the first time, it should be kept refrigerated; after first use, it may be kept at room temperature.

Hypoglycemia can occur, especially if exenatide is given in combination with a sulfonylurea drug. Other common adverse effects are GI (diarrhea, indigestion, nausea, vomiting); immunologic (antibody development); and neurologic (dizziness, headache, nervousness). Serious adverse effects are rare but include anaphylaxis; pancreatitis; and acute renal failure, which may be related to dehydration from severe vomiting and diarrhea. Acute renal failure is reversible with appropriate treatment. Exenatide is a pregnancy category C drug. Because exenatide slows gastric emptying, drugs that require absorption at a certain rate in order to achieve a therapeutic level may be effected by exenatide use. For this reason, if the patient is taking birth control pills or antibiotics, he or she should be taught to take these medications at least one hour before taking exenatide. Exenatide may also slow the absorption of acetaminophen, so this drug should also be taken 1 hour prior to exenatide. Exenatide, when coadministered with lovastatin, an antihyperlipidemic, may decrease lovastatin's bioavailability and possibly decrease the lipid-lowering ability of lovastatin. Lipid serum levels should be monitored, and the dose should be adjusted if necessary.

Amylin Analogue

Pramlintide (Symlin) is an antihyperglycemic used as an adjunct in the treatment of type 1 and type 2 diabetes when glucose levels cannot be controlled by insulin therapy. It is an analogue of endogenous amylin and sometimes is classified as an amylinomimetic. Endogenous amylin is secreted, like insulin, from the pancreatic beta cells in response to food intake. Amylin affects the rise of postprandial glucose levels by slowing gastric emptying without altering overall absorption of nutrients. Amylin also suppresses glucagon secretion so that the liver does not release glucose. Amylin has an additional role in suppressing feelings of hunger. Amylin, similar to insulin, is absent or deficient in patients with diabetes. Like endogenous amylin, pramlintide delays gastric emptying, prevents a postprandial rise in plasma glucagon, and promotes feelings of satiety so that the patient eats less. Pramlintide is *not* an insulin, but like the prototype metformin, it is used as a supplement to insulin therapy. Unlike the prototype metformin, it is administered subcutaneously immediately before meals. Pramlintide should be administered using an insulin syringe, but it should never be mixed in the same syringe as insulin. The abdomen or the thighs are the preferred injection sites because absorption is erratic in the arms.

An adverse effect of pramlintide is hypoglycemia; this appears to be a drug interaction with any insulin the patient is receiving. Pramlintide carries a Black Box warning that hypoglycemia can occur. When hypoglycemia is significant it will occur within 3 hours after administration of pramlintide. Because of this risk, any dose of a short-acting insulin also administered before a meal should be decreased by 50% initially when beginning pramlintide therapy.

GI complaints, including nausea, vomiting, anorexia, and abdominal pain, are also fairly common adverse effects of pramlintide. Because of these adverse effects, patients who require drugs that stimulate gastrointestinal motility should *not* be considered for pramlintide therapy. Central nervous system adverse effects include headache, dizziness, and fatigue. Allergic reactions are also possible. Pramlintide is a pregnancy category C drug.

Effectiveness of pramlintide therapy is assessed by control of daily blood glucose levels and improved hemoglobin A_{1C} values.

Antidiabetic Combination Agents: Glucovance and Metaglip

Glucovance and Metaglip are both combination antidiabetic agents consisting of a sulfonylurea and a biguanide. Glucovance is a combination of glyburide and metformin, and Metaglip is

a combination of glipizide and metformin. Both are indicated as an adjunct to diet and exercise to improve glycemic control. They are also indicated as a second-line therapy when initial treatment with a sulfonylurea or metformin does not result in adequate glycemic control in type 2 diabetes. For patients taking Glucovance who require additional therapy, a thiazolidinedione can be added. Both medications are administered once or twice daily with meals to avoid hypoglycemia (largely because of glyburide or glipizide) and to reduce GI side effects (largely because of metformin). These agents are not recommended for use during pregnancy or in children. Careful consideration is needed in the elderly population and those with renal function impairment. One of the advantages of a combined drug is that it helps to promote adherence to drug therapy because the patient has to take fewer pills daily. For other information, please refer to the individual prototype drugs (see Table 49.2).

GLUCOSE-ELEVATING AGENTS

Glucagon is a hyperglycemic polypeptide hormone produced by the alpha cells of the pancreatic islets of Langerhans. Its physiologic effect is generally the opposite of that of insulin. Glucagon is the body's first line of defense against hypoglycemia. Whether endogenous or exogenous, it reduces the effectiveness of insulin and some commonly used drugs.

The main stimulus to glucagon secretion is a decrease in intracellular glucose concentrations that usually occurs as a result of a drop in serum blood sugar. Patients with diabetes have been shown to have high levels of glucagon, although the cause-and-effect relationship is uncertain. Theoretically, glucagon imbalances could contribute to many of the diabetic patient's problems with glucose metabolism.

Nursing Management of the Patient Receiving P Glucagon

Core Drug Knowledge

Pharmacotherapeutics

Most commonly, glucagon (GlucaGen) is used in unconscious patients with diabetes to reverse the severe hypoglycemia resulting from insulin overdosage. Glucagon is effective in hypoglycemia only if liver glycogen is available. It is administered by the intramuscular (IM), IV, or SC route. Glucagon also is used to induce intestinal relaxation before radiographic examinations. Off-label uses for glucagon include treatment for propranolol (beta-adrenergic antagonist) overdose and cardiovascular emergencies.

Pharmacokinetics

Glucagon has a plasma half-life of 3 to 10 minutes (see Table 49.2). The hormone undergoes hepatic metabolism and is excreted in urine and bile.

Pharmacodynamics

Glucagon increases blood glucose levels by stimulating glycogenolysis in the peripheral tissues, exerts a positive inotropic and chronotropic effect on the heart (increasing heart contraction and heart rate, respectively) by increasing cyclic adenosine monophosphate, and relaxes the GI smooth muscle. After parenteral injection of glucagon, the maximum hyperglycemic effect occurs within 30 minutes. The duration of action is about 1 to 2 hours. GI smooth muscle relaxation occurs within 15 minutes and lasts for approximately 30 minutes. The mechanism by which glucagon relaxes GI smooth muscle is not known.

Contraindications and Precautions

A hypersensitivity to glucagon contraindicates its use. Glucagon causes insulin release and is contraindicated in cases of insulinoma (also known as hyperinsulinism) related to a tumor of the functional islet cells. It causes catecholamine release and is contraindicated in pheochromocytoma. Glucagon is a pregnancy category B drug. It should be used cautiously in pregnancy and lactation.

Adverse Effects

Glucagon may cause hypotension, respiratory distress, nausea and vomiting, hypersensitivity reactions of urticaria, and hypokalemia in overdosage.

Drug Interactions

Glucagon increases the hypoprothrombinemic effect of oral anticoagulants and may cause bleeding. The interaction appears to be dose related.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient's blood sugar levels and level of consciousness. After emergency use of glucagon, assess the patient's level of adherence to the therapeutic regimen and the patient's level of understanding of the disease and its treatment.

Life Span and Gender

Note whether the patient is pregnant or breast-feeding. Glucagon, a pregnancy category B drug, crosses the placental barrier and enters breast milk. However, emergency use overshadows concerns regarding breast-feeding.

Lifestyle, Diet, and Habits

Review the patient's adherence to the diabetic treatment plan. It is important to assess whether the patient is administering the insulin and monitoring blood glucose correctly, and whether he or she is adhering to the prescribed dietary and exercise regimens. Adherence to the treatment plan helps prevent episodes of hypoglycemia.

Environment

Be aware of the environment in which glucagon will be administered. Glucagon is usually administered as an emergency treatment. Although it most frequently is administered in an acute care setting, it may be administered in extended care settings or in the home. Home use is limited to patients at high risk for experiencing severe hypoglycemia when a family member or caregiver can be taught how to assess for hypoglycemia and administer the drug.

Nursing Diagnosis and Outcome

- Risk for Injury related to hypotension from the adverse effects of glucagons
  Desired outcome: *Substantial hypotension will not result from glucagon treatment.*

Planning and Intervention

Maximizing Therapeutic Effects

Glucagon is dispensed in a powder form and must be reconstituted to a concentration of 1 mg/mL using the diluent supplied by the manufacturer. Use reconstituted glucagon immediately, although refrigerated solution may be kept for 48 hours. If the solution is not clear after dilution, discard it. A dose of 0.5 to 1.0 mg is usually effective. Reconstitute doses exceeding 2 mg with sterile water and use them immediately. Administer an additional dose if the patient's response is inadequate or incomplete after 20 minutes.

Minimizing Adverse Effects

Administer supplemental carbohydrates as soon as possible once consciousness has been achieved to restore liver glycogen and prevent secondary hypoglycemia.

Providing Patient and Family Education

- Emphasize to patients and family members measures to prevent hypoglycemic reactions from insulin (reasonable uniformity from day to day with regard to diet, insulin, and exercise; routine blood glucose self-monitoring; and carrying sugar, candy, or other readily absorbable carbohydrate so that it may be taken at the first warning of hypoglycemia).
- Teach family members the importance of quick intervention if severe hypoglycemia occurs, to prevent CNS damage.
- Instruct family members in the proper technique for emergency administration of glucagon, if appropriate.

Ongoing Assessment and Evaluation

Blood glucose levels should be monitored before, during, and after glucagon administration, and the patient's emergency supply of glucagon should be restored (if appropriate) as soon as possible. Survival and return to normal function are signs of effective nursing management.

Drugs Significantly Different From P Glucagon

Diazoxide

Administered orally, diazoxide (Proglycem) produces a prompt, dose-related increase in blood glucose levels. Its hyperglycemic effects occur because it inhibits insulin release from the pancreas and has an extrapancreatic effect. Its clinical indications are hyperinsulinism caused by an inoperable islet cell cancer, islet cell hyperplasia, or an extrapancreatic cancer. Diazoxide administered intravenously will quickly lower blood pressure in a hypertensive emergency. See Chapter 28 for a discussion of this use of the drug.

MEMORY CHIP

P Glucagon

- Glucose-elevating agent that accelerates hepatic glyconeogenesis, increasing blood glucose levels
- Major contraindications: insulinoma and pheochromocytoma
- Most common adverse effects: nausea, vomiting, generalized allergic reactions, including urticaria, respiratory distress, and hypotension
- Most serious adverse effect: hypokalemia
- Maximizing therapeutic effects: Use the diluent provided in preparation of glucagons for parenteral injection (SC, IM, or IV). Reconstituted glucagons should be clear, watery, and used immediately. Any unused portion should be discarded. Provide supplemental carbohydrates as soon as possible after drug injection to restore liver glycogen and prevent secondary hypoglycemia.
- Minimizing adverse effects: Teach the patient and family members preparation and administration techniques for glucagons before an emergency arises.
- Most important patient education: Teach the patient and family members measures to prevent hypoglycemic reactions due to insulin; convey importance of early recognition and treatment of hypoglycemic episodes.

Diazoxide is absorbed rapidly. Onset of action occurs within 1 hour. It is highly protein bound (more than 90%), has an 8-hour duration of effect, and has a half-life that ranges from 24 to 36 hours. Diazoxide undergoes hepatic metabolism and renal elimination. Diazoxide is in pregnancy risk category C.

The most common adverse effects from oral dosing are sodium and fluid retention, hyperglycemia, and glycosuria. In some patients, chronic heart failure may develop secondary to sodium and fluid retention.

Other adverse effects can include dizziness and weakness, GI discomfort (e.g., nausea, vomiting, anorexia, abdominal pain, and constipation), and taste alterations.

The usual dosage of diazoxide (adult or child) is 3 to 8 mg/kg/d divided into two or three doses every 8 or 12 hours. Infants and newborns may be given 8 to 15 mg/kg/d every 8 to 12 hours. The total daily dose is divided equally, and administration times also are evenly spaced within the 24-hour day.

Glucose

Glucose, a monosaccharide, is absorbed directly from the intestine, resulting in a rapidly increased blood glucose concentration. It is indicated for managing hypoglycemia. The dosage is 10 to 20 g orally, repeated in 10 minutes if necessary. An occasional adverse effect is nausea. Glucose is not absorbed from the buccal mucosa. It must be swallowed to be effective. It should be used with caution in children younger than 2 years of age. IV glucose (dextrose) is also used to treat hypoglycemia. Solutions with a concentration of 25% dextrose are used in neonates and infants, and solutions of 50% dextrose are used in other age groups.

CHAPTER SUMMARY

- Diabetes is primarily a disorder of carbohydrate metabolism, although it is associated with derangements of protein and fat metabolism and a series of vascular disorders.
- The patient with type 1 diabetes has an absolute insulin deficiency, cannot maintain a normal blood glucose level, and depends on exogenous insulin for survival. Combinations of short- or rapid-acting and longer-acting insulins may be administered to fully manage and control glucose levels. Basal and preprandial doses may be required to control glucose levels. During times of physiologic stress, when glucose levels are elevated (such as after surgery), the patient with diabetes may also require additional correctional doses of short-acting or rapid-acting insulins. Critically ill patients may need to receive an insulin drip to maintain glucose levels as close to normal as possible.
- The patient with type 2 diabetes has a developed insulin resistance. Although insulin is produced, it is not effective in moving glucose into the cells. Oral antidiabetic agents are used to improve glucose control. Occasionally, this patient may also need insulin to achieve glucose balance during times of stress, such as illness, or to achieve maximum control of blood sugar.
- All insulins manage hyperglycemia by promoting cellular glucose uptake and metabolism. Insulins vary in peak, onset, and duration of action; they are similar in absorption, distribution, metabolism, and excretion.
- Hypoglycemia is the most common adverse effect of insulin therapy. Severe hypoglycemia may produce loss of consciousness and is termed insulin shock.
- Regular insulin has a quick onset and peak, and a short duration of therapy. Because of these pharmacokinetic features, it can be used multiple times a day, usually before meals and at bedtime. Regular insulin can be used in addition to long-acting insulin. The dose of regular insulin is often variable and based on the current blood glucose reading. This approach is known as correctional or supplemental dosing (previously referred to as sliding-scale insulin).
- Rapid-acting insulins, lispro, aspart, and glulisine, have a more rapid onset of action than regular insulin. When administered subcutaneously, they are administered closer to the time of a meal than regular insulin. These insulins can also be administered by an insulin pump. When used as prandial doses, they may be administered immediately after a meal if the dose varies, depending on the amount and type of food eaten.
- Intermediate-acting insulins, such as NPH and detemir, have a slower onset with a peak effect occurring later than with regular insulin. Their effects also last longer than those of regular insulin. These longer-acting insulins are normally assigned a standard daily dosage that the patient takes once or twice a day. Intermediate- acting insulins may be used in combination with regular insulin or rapid-acting insulins to meet both the current and long-term glucose levels of the patient. NPH can be mixed in a syringe with other insulins, but detemir cannot be mixed with any other insulin. Intermediate- or long-acting insulins are not administered by the IV route or by SC insulin pumps, or used as correctional-dose insulin. NPH is a suspension, and it is the only insulin that appears cloudy.
- Long-acting glargine does not create the peak and trough in blood insulin levels that NPH does. It has a more flat, sustained effect, which lasts for 24 hours. It is taken subcutaneously once daily at bedtime.
- Combinations of NPH and regular insulins or rapid-acting insulins as well as rapid-acting insulins and protamine are available. The trade names of these products are very similar and may cause medication errors. Avoiding referring to these drugs by their trade names minimizes the risk of serious medication errors.
- Insulins are very potent (a small dose creates a big effect). When drawing up insulin, the dose should always be double-checked by another nurse to prevent accidental overdosage, which could cause serious, even life-threatening, consequences to the patient.
- Nursing care of the patient receiving insulin therapy calls for balancing diet, exercise, and insulin requirements; preventing and monitoring for complications of therapy; and teaching the patient how to do the same.
- Glyburide is the prototype oral antidiabetic sulfonylurea drug. It is used to treat type 2 diabetes. It works by stimulating insulin release from the beta cells of the pancreas and by reducing glucose output from the liver. It also increases the sensitivity of the peripheral cells to insulin. The patient must make some endogenous insulin for glyburide to work. The most common adverse effect is hypoglycemia.
- Other antidiabetic drugs work in different ways than the sulfonylureas. Metformin is the prototype for these drugs. Metformin decreases intestinal absorption of glucose and improves insulin sensitivity in type 2 diabetes. It rarely causes hypoglycemia when used alone.
- Alpha-glucosidase inhibitors (acarbose and miglitol) inhibit enzymes needed to digest carbohydrates; thus, they produce a slower postprandial rise in glucose in type 2 diabetes. Because of how they work, if hypoglycemia does occur during their use, do not use dietary sugars (orange juice, cane sugar) but use glucose tablets.
- The thiazolidinedione oral antihyperglycemic drugs rosiglitazone and pioglitazone are similar to those of the biguanides; they are antihyperglycemics and "insulin sensitizers" and are used in type 2 diabetes.Both drugs carry a black box warning that they may induce or exacerbate heart failure. Rosiglitazone now carries a black box warning that it may increase the risk of myocardial infarction. Its use is now restricted to those who cannot be controlled on other anti diabetic therapy.
- Sitagliptin is a dipeptidyl peptidase-4 (DPP-4) enzyme inhibitor; it works by enhancing the action of endogenous incretin hormones. Incretin hormones are released in response to glucose elevations that occur after a meal in

order to maintain normal levels of glucose. These incretin hormones increase insulin synthesis and its release from pancreatic beta cells by intracellular signaling pathways as well as lowering glucagon secretion from the pancreas. Sitagliptin may be used as monotherapy or in combination with other oral antidiabetic drugs to treat type 2 diabetes.

- Exenatide is an incretin mimetic drug and is used as an adjunct in treating patients with type 2 diabetes. Administered subcutaneously, it increases insulin synthesis, lowers glucagon secretion, slows gastric emptying, and promotes weight loss. Exenatide is not an insulin, and care must be used not to confuse it with insulin.
- Pramlintide is an analogue of endogenous amylin, a hormone secreted like insulin from pancreatic beta cells. It is used as a subcutaneous supplement to insulin therapy in patients with type 1 or type 2 diabetes who have not been able to achieve sufficient glucose control on insulin alone. It is not an insulin and cannot be mixed with an insulin. Like endogenous amylin, pramlintide delays gastric emptying, prevents postprandial rise in plasma glucagon, and promotes feelings of satiety so that the patient eats less. Adverse effects that can occur include hypoglycemia and GI distress.
- Glucagon is a protein made by the pancreas that is used for emergency treatment of severe hypoglycemia. It regulates the rate of glucose production through glycogenolysis, gluconeogenesis, and lipolysis.
- The management of type 1 and type 2 diabetes has become more complicated in recent years because of the variety of new drugs available to control elevated glucose levels, but these new therapies mean that patients who have previously been unsuccessful in controlling their glucose levels may be able to achieve glucose control. Long-term glucose control is important, as it prevents the serious sequelae that accompany uncontrolled diabetes.

QUESTIONS FOR STUDY AND REVIEW

1. What effect does insulin have on blood glucose levels?
2. What effect does glucagon have on glucose metabolism? What effect does it have on the effect of insulin?
3. How do the characteristics of type 1 and type 2 diabetes compare?
4. Why can insulin not be given orally?
5. What effect would be expected from too much insulin? How would this effect be recognized?
6. Why is regular insulin often combined with a longer-acting insulin?
7. Which insulins are used to provide supplemental doses (insulin dose based on current blood glucose level)?
8. What is the difference between NPH and glargine insulins?
9. What is the most common adverse effect of glyburide, a sulfonylurea oral antidiabetic drug?
10. How does acarbose produce its therapeutic effect?
11. What patient and family education should be given if the patient is prescribed glucagons for emergency home use?

Drugs Affecting Pituitary, Thyroid, Parathyroid, and Hypothalamic Function

Learning Objectives

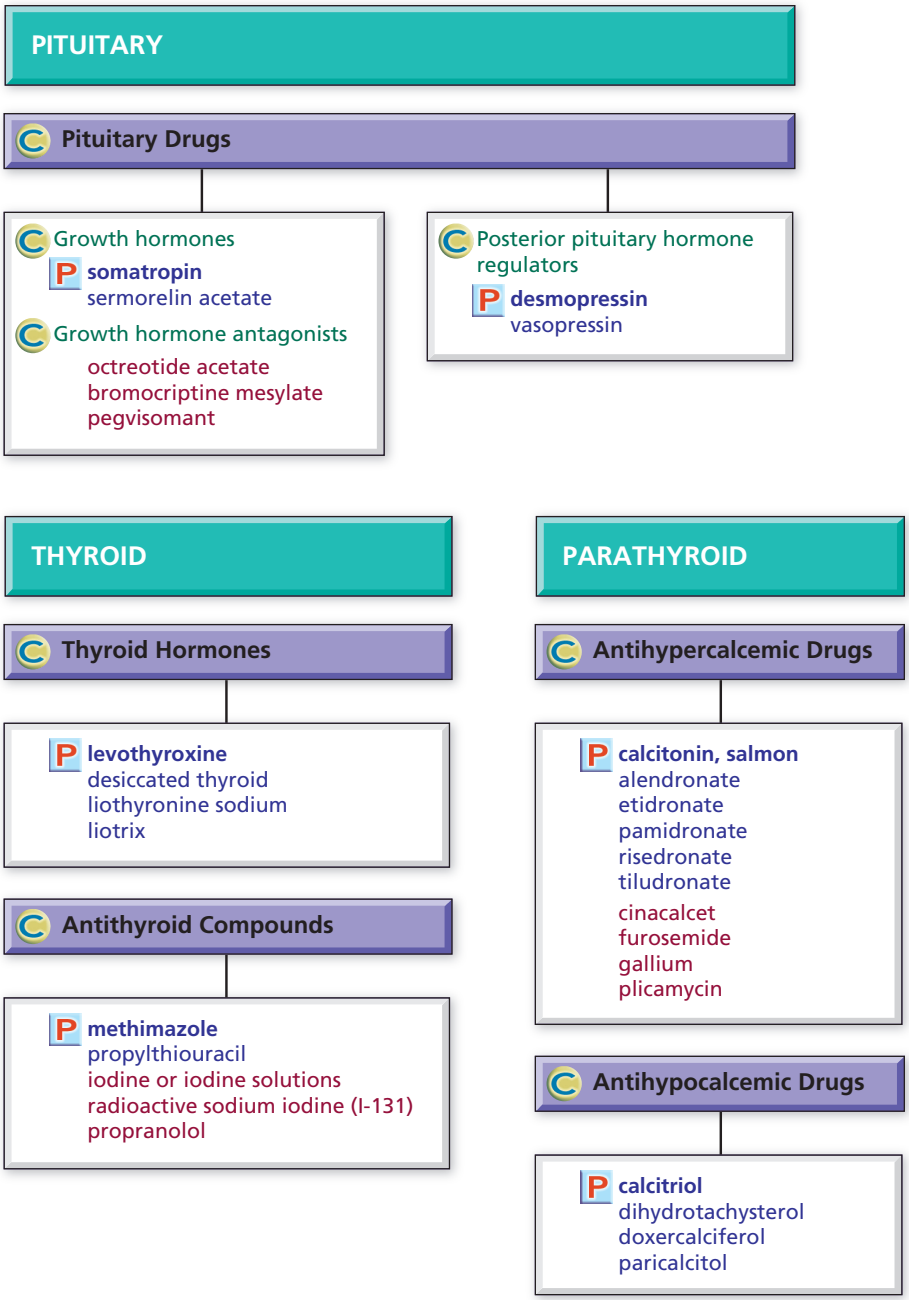
At the completion of this chapter the student will:

1. Identify drugs commonly used for pituitary hypofunction and hyperfunction, thyroid hypofunction and hyperfunction, and parathyroid hypofunction and hyperfunction.
2. Identify core drug knowledge about drugs affecting the pituitary gland and its hormones, the thyroid gland and its hormones, and the parathyroid glands and their hormones.
3. Identify core patient variables relevant to drugs affecting the pituitary gland and its hormones, the thyroid gland and its hormones, and the parathyroid glands and their hormones.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs affecting the pituitary gland and its hormones, the thyroid gland and its hormones, and the parathyroid glands and their hormones.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs affecting the pituitary gland and its hormones, the thyroid gland and its hormones, and the parathyroid glands and their hormones.
6. Determine key points for patient and family education for drugs affecting the pituitary gland and its hormones, the thyroid gland and its hormones, and the parathyroid glands and their hormones.

Key Terms

acromegaly
bone resorption
cretinism
diabetes insipidus
effector hormones
gigantism
Graves disease
hyperthyroidism
hypothyroidism
myxedema coma
Paget disease
syndrome of inappropriate antidiuretic hormone
thyroid crisis
thyrotoxicosis
tropic hormones

Drugs Affecting Pituitary, Thyroid, Parathyroid, and Hypothalamic Function



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

The endocrine system works with the central nervous system (CNS) to integrate and regulate all aspects of body function, including energy metabolism, growth and development, sexual development, fluid and electrolyte balance, muscle and adipose tissue distribution, and inflammation and immune responses. This system has three major components: glands, hormones, and receptors. The glands—pineal, pituitary, thyroid, parathyroid, thymus, adrenal, pancreas, and gonads (ovaries and testes)—are specialized organs or cell clusters that synthesize hormones. Hormones are substances that are manufactured by a dedicated cell type and that, released into the circulation, produce a physiologic or biochemical response. Most hormones are always present in the body fluids, but the amounts present vary, depending on the body's needs. Receptors are molecules that initiate specific changes in a target cell in response to stimulation by the hormones. Homeostasis is accomplished through coordination of glandular activities that either suppress or stimulate hormones. Specific disorders occur when the endocrine glands are either hyperactive or hypoactive. Drugs discussed in this chapter are used to manage the disorders that occur from either hyperactivity or hypoactivity of the pituitary, thyroid, and parathyroid glands.

Agents that affect pituitary function are mainly used to mimic or antagonize the effect of the pituitary hormones. Replacement therapy is indicated for conditions that occur from an underactive pituitary gland. The prototype drug for the anterior pituitary is somatropin (Genotropin, Humatrope, Norditropin, Nutropin, Omnitrope, Saizen, and Serostim). The prototype drug for the posterior pituitary is desmopressin.

Agents that affect thyroid function are used either to antagonize an overactive thyroid gland or to replace hormones as a result of an underactive gland. The prototype drug for thyroid replacement is levothyroxine. The prototype drug for treating an overactive thyroid is methimazole.

Serum calcium and phosphate are regulated by parathyroid hormone (PTH), vitamin D, and calcitonin. Agents used to regulate serum calcium do so by either increasing or decreasing serum calcium levels. The prototype drug to decrease serum calcium is calcitonin, salmon. The prototype drug to increase serum calcium is calcitriol.

PHYSIOLOGY

To remain healthy, the body ensures that hormones are present in adequate concentrations in the areas in which they are needed. This distribution is accomplished by controlling the rate of production of a hormone, the time of release from its storage site, the speed of clearance from the body, or the breakdown of the hormone. Both the rate of production of many hormones and the time of their release is regulated by a negative feedback system. In this system, when sensors detect a change in a particular hormone level, the amount of hormone secreted is adjusted to maintain homeostasis. When a hormone is present in excessive amounts, the sensors decrease production and prevent further release of that hormone, so that levels remain within an appropriate range. Conversely, an increase in levels of a particular hormone stimulates the feedback system to decrease the amount produced and released. For example, if thyroid hormone levels increase, sensors in the hypothalamus or anterior pituitary gland detect the increase. This interaction triggers a reduction in secretion of thyroid-stimulating hormone (TSH), which in turn causes a decrease in the release of thyroid hormone from the thyroid gland. The combined sequence of events maintains homeostasis.

The hypothalamus is an area of the brain that exerts direct effects on the neurologic and endocrine systems (Figure 50.1), including temperature regulation, catecholamine secretion, growth and development, fluid volume regulation, perspiration, gastrointestinal (GI) activity, appetite and thirst regulation, blood pressure, respiration, regulation of basic body rhythms (e.g., sleep and menstrual cycles), and complex behavioral and emotional reactions (e.g., sexual behavior and defensive reactions of fear and rage). It is the coordinating center of the endocrine system and produces hormones that are stored and later secreted by the pituitary gland. To promote homeostasis, the hypothalamus transmits stimuli to the pituitary gland, causing hormonal release or inhibition.

The pituitary gland is approximately the size of a pea and rests in the bony sella turcica (Turkish saddle) under a layer of dura mater at the base of the brain. This gland consists of two main regions: the anterior (adenohypophysis) and posterior (neurohypophysis) pituitary lobes, which are connected to the hypothalamus by a stalk of neurosecretory fibers. Groups of releasing hormones (or factors) have controlling effects on the anterior lobe of the pituitary. These hormones and their actions include the following:

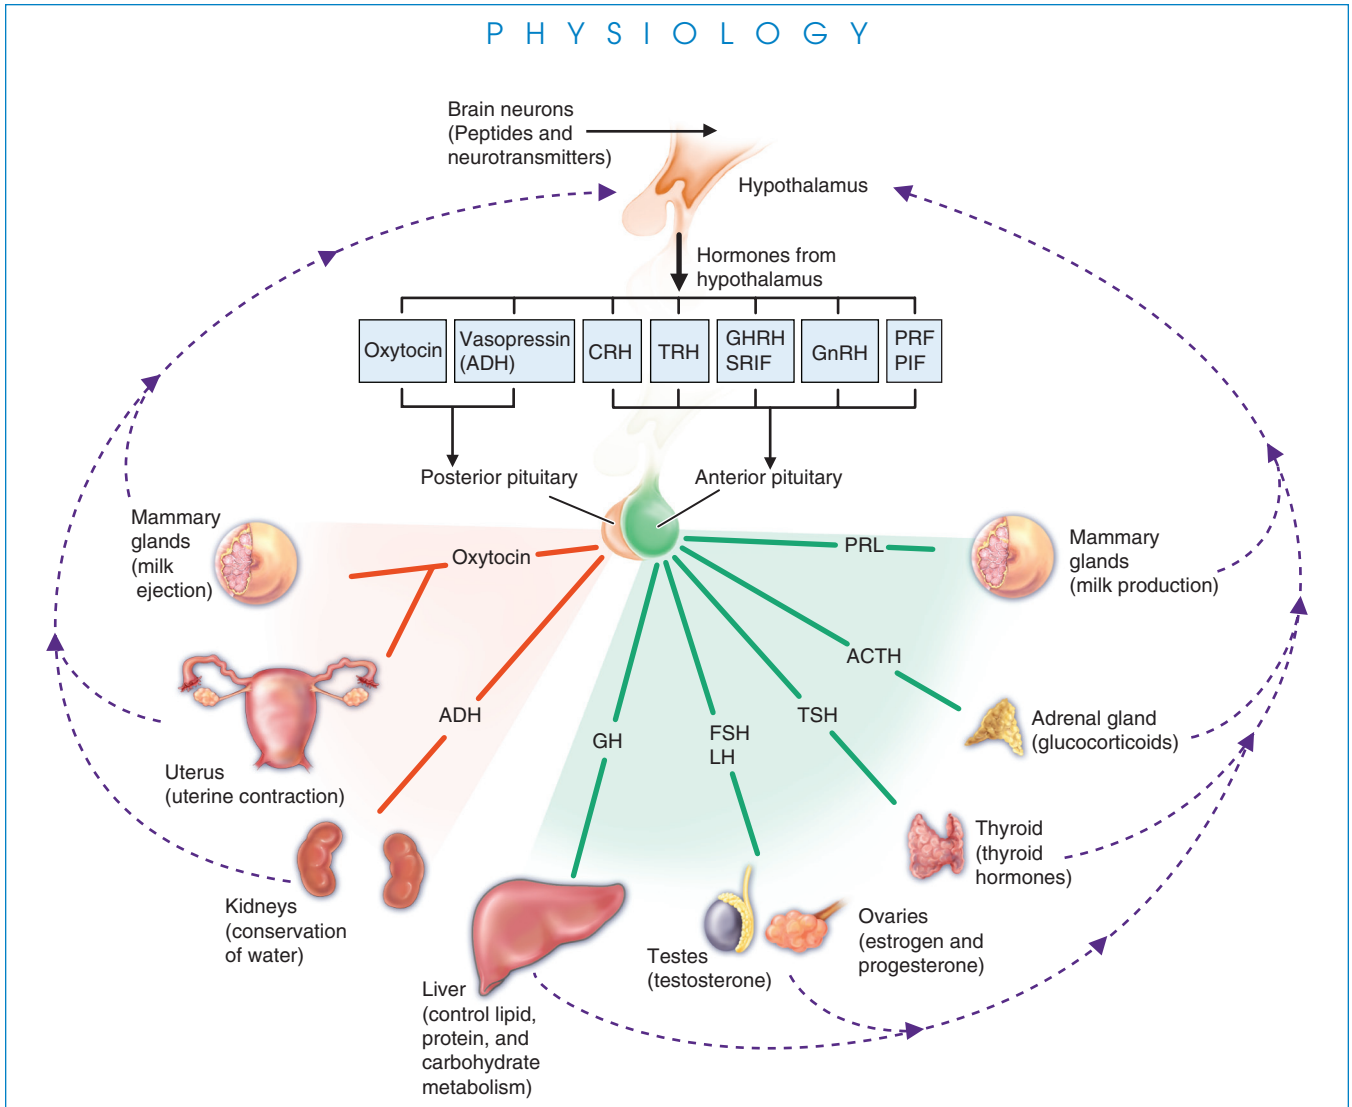
- Growth hormone–releasing hormone (GHRH), also known as sermorelin, stimulates anterior pituitary release of growth hormone (GH).
- Thyroid-releasing hormone (TRH), also known as protirelin, stimulates the anterior pituitary to produce thyrotropin (TSH), which in turn stimulates the thyroid to produce thyroxine.
- Gonadotropin-releasing hormone (GnRH) controls the release of the gonadotropins: follicle-stimulating hormone (FSH) and luteinizing hormone (LH).
- Corticotropin-releasing factor (Xerecept) stimulates release of adrenocorticotropic hormone (ACTH).

The pituitary gland also has a small region between the anterior and posterior lobes, known as the intermediate lobe (pars intermedia). The hormones of this lobe stimulate synthesis of melanin, which affects skin pigmentation.

Pituitary Gland Function

Anterior Lobe of the Pituitary Gland

The pituitary gland was previously considered to be the master gland because its hormones control the function of many cells and glands, such as glucocorticoid hormone levels (ACTH), body growth and metabolism (GH), function of the thyroid gland (TSH), gonadal function (FSH and LH), and milk production and breast growth (prolactin). The hypothalamus is



• FIGURE 50.1 Control of hormone production by hypothalamic-pituitary-target cell feedback mechanism. Hormone levels from the target glands regulate the release of hormones from the anterior pituitary by means of a negative feedback system. The *dashed line* represents feedback control. (CRH, corticotropin-releasing hormone; TRH, thyrotropin- releasing hormone; GHRH, growth hormone–releasing hormone; SRIF, somatropin release-inhibiting hormone; GnRH, gonadotropin-releasing hormone; PRF, prolactin-releasing hormone; PIF, prolactin-inhibiting factor; ADH, antidiuretic hormone; GH, growth hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone; ACTH, adrenocorticotropic hormone; PRL, prolactin.)

now recognized as the coordinating center of the brain that stimulates the pituitary gland to release specific hormones when indicated. The first five hormones listed are **tropic hormones,** which means that they stimulate other organs or glands to secrete substances that are hormonally active. Secretionvaries with physiologic activity (such as exercise) or with the time of day. Various drugs, the CNS, hypothalamic hormones, some diseases, and hormones of the peripheral endocrine system affect their synthesis and release. Prolactin acts directly on breast tissue to stimulate milk production.

GH does not have a specific target gland. Its rate of production in adulthood is almost equal to that of childhood. GH is necessary for linear bone growth. It regulates cellular metabolism, facilitates protein synthesis, enhances amino acid transport across cell membranes (which stimulates an anabolic effect), decreases the rate of carbohydrate use in cells, increases the rate of fatty acids for fuel, and maintains or increases blood glucose levels in both children and adults. Many of the effects of GH depend on the production of insulin-like growth factor-1 (IGF-1), which is mainly produced by the liver.

GH is the most apparent of the pituitary hormones. Its secretion is regulated by two hypothalamic hormones: GHRH (GH-releasing hormone), which increases the release of GH; and somatostatin, which inhibits GH release. GH secretion fluctuates over a 24-hour period, with peak levels occurring during sleep stages 3 and 4 (1 to 4 hours after the onset of sleep). GH is also released during periods of hypoglycemia, stress, exercise, and excitement, and in response to levodopa and arginine.

Posterior Lobe of the Pituitary Gland

The posterior pituitary stores and secretes two **effector hormones** (hormones that produce an effect when stimulated): oxytocin and vasopressin (also known as antidiuretic hormone [ADH]). Both are synthesized in the hypothalamus and transported to the posterior lobe for future use.

Oxytocin stimulates uterine smooth muscle contraction in the later part of pregnancy and causes the milk let-down reflex in lactating women. Vasopressin controls the concentration of body fluids. It is released in response to decreases in blood volume, hypotension, or increases in plasma osmolarity (concentration). Vasopressin release can also be stimulated by stress, pain, trauma, nausea, use of tranquilizers or morphine, a positive-pressure apparatus, and some anesthetics. Vasopressin alters the permeability of the distal renal tubules and collecting ducts in the kidneys to conserve water.

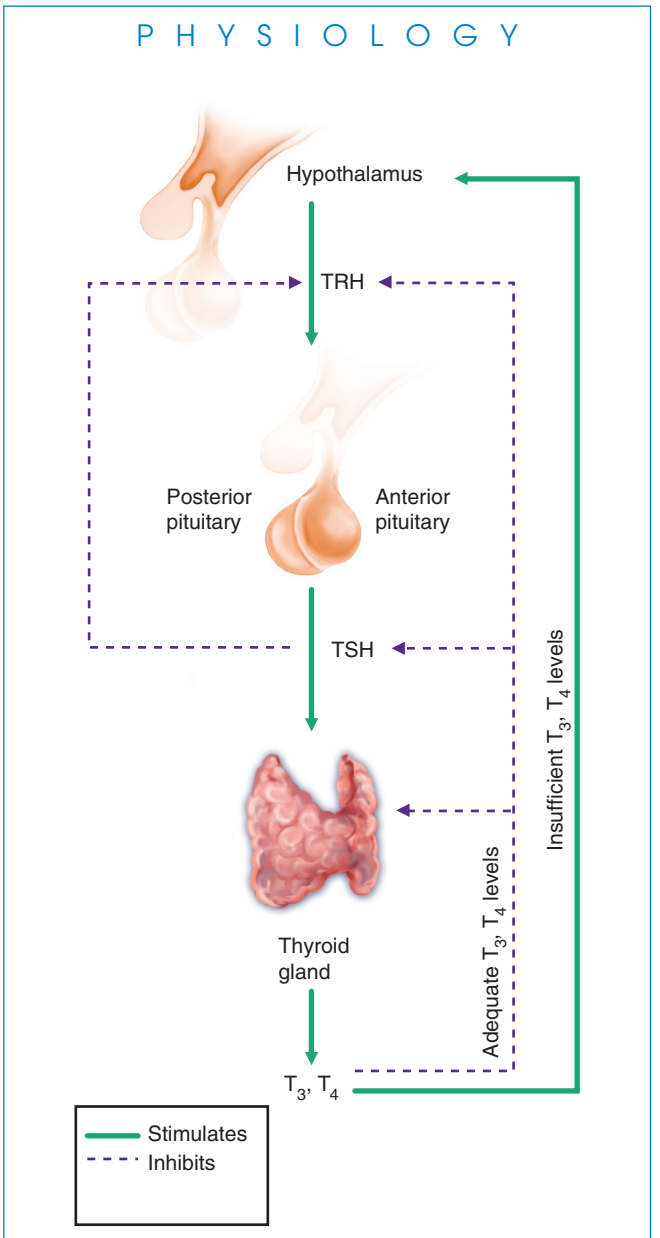
Thyroid Gland Function

The bilobar thyroid gland is a shield-shaped gland located in the anterior middle portion of the neck, between the larynx and the trachea. The gland is composed of a series of circular follicles containing a material called colloid in the center. The colloid consists largely of thyroglobulin, which is a glycoprotein–iodine complex. It is synthesized in the thyroid cells and secreted into the follicle, where the thyroid hormone is stored. In making thyroid hormone, the thyroid gland is very efficient in its use of iodide, which it receives from food, water, or medications.

A daily dietary absorption of 100 to 200 mcg of iodide is adequate for the thyroid gland to make normal quantities of thyroid hormone. Iodide is pumped into the follicular cells against a concentration gradient in the process of removing it from the blood for storage. Because of this mechanism, the concentration of iodide in the normal thyroid gland is much higher than in the blood.

Once the iodide is in the follicle, it is oxidized by an enzyme called peroxidase in a reaction with a tyrosine molecule to form monoiodotyrosine and diiodotyrosine. Thyroxine (T_4) is formed when two diiodotyrosine residues are coupled. Triiodothyronine (T_3) is formed when a monoiodotyrosine and a diiodotyrosine are coupled. Collectively, these two hormones are referred to as thyroid hormone. When thyroid hormone is needed, T_4 and T_3 are released into the bloodstream. Once in the bloodstream, both $_4$ are more than 99% bound to thyroid-binding globulin and other plasma proteins for transport. The three major thyroid-binding proteins are thyroid hormone-binding globulin, thyroxine-binding prealbumin, and albumin. Some medications, systemic diseases, and congenital diseases can affect either the amount of binding protein in the blood or the binding ability of the hormone.

The hypothalamic-pituitary-thyroid feedback system regulates secretion of thyroid hormone. The hypothalamus produces TRH, which controls the release of TSH from the anterior pituitary gland. TSH increases the release of thyroid hormone from the follicles into the bloodstream and thyroglobulin breakdown, which increases thyroid activity. This increased activity activates the iodide pump. Activation of the pump increases the oxidation of iodide and the size and number of follicle cells. The increase in thyroid hormone levels sends a message to the hypothalamus to decrease TRH release and to the pituitary to decrease TSH. The decrease in TRH levels causes a decrease in TSH levels, which in turn causes the thyroid hormone levels to drop. The drop in thyroid hormone is sensed by the hypothalamus and pituitary, which respond by once again increasing TRH and TSH release (Figure 50.2).



• FIGURE 50.2 Thyroid-releasing hormone (TRH) from the hypothalamus stimulates the anterior pituitary to release thyroid-stimulating hormone (TSH). TSH stimulates the thyroid gland to release T_3 and T_4. It also inhibits the hypothalamus from releasing TRH and the anterior pituitary from releasing more TSH. The release of T_3 and T_4 from the thyroid gland inhibits TRH release from the hypothalamus, TSH release from the pituitary, and further T_3 and T_4 release from the thyroid gland. Falling T_3 and T_4 levels will stimulate the hypothalamus to release TRH, and the process repeatedly continues to maintain effective hormone levels.

TABLE 50.1 Effect of Thyroid Hormones

Target Physiologic Process or Body System	Primary Effects
Carbohydrate metabolism	Increases cellular glucose uptake Increases gluconeogenesis and glycolysis Increases GI carbohydrate absorption Increases insulin secretion
Cardiovascular system	Increases heart rate, cardiac output, arterial pressure
Central nervous system	Increases mental processes Increases activity in spinal cord areas controlling muscle tone
Fat metabolism	Increases fat metabolism, including lipid mobilization from fat tissues and free fatty acid oxidation
GI function	Increases appetite, food absorption, digestive enzyme secretions, GI motility
Growth metabolism	Accelerates growth (in children) Accelerates food use for energy, speeds protein synthesis and catabolism, excites mental processes Increases other endocrine gland functions

Thyroid hormones control cellular metabolism and promote normal growth and development. They regulate heat and energy production, blood volume, cardiac output, oxygen consumption, and metabolism of fats, carbohydrates, and proteins (Table 50.1). All major organs are affected by disorders of the thyroid gland.

The thyroid gland also produces calcitonin, which maintains the serum calcium level by preventing release of calcium from the bone.

Parathyroid Gland Function

The four tiny, highly vascular parathyroid glands work together as a single gland to produce PTH, which helps to regulate serum calcium and phosphate. These glands are located on the dorsal surface of the thyroid. In the healthy individual, plasma calcium concentration is maintained within narrow limits.

PTH affects three target organs: bone, kidneys, and GI tract. The primary storage site for calcium is in the bone. The major controlling factor for PTH secretion is serum calcium. When serum calcium levels are low, the parathyroid gland stimulates the release of PTH. Release of this hormone promotes increased bone resorption, which increases the serum calcium level. PTH also activates vitamin D in the kidney, which boosts absorption of phosphate and calcium from the GI tract. When serum calcium levels are elevated, PTH secretion decreases. Magnesium and phosphate levels also affect PTH secretion.

PATHOPHYSIOLOGY

Pituitary Gland Dysfunction

Pituitary dysfunction may occur from many causes, such as congenital defects, developmental abnormalities, acute or chronic inflammation, invasive tumors, circulatory disturbances (infarction or hemorrhage), surgery, radiation therapy, injury (head trauma), or infection. These conditions may cause either a decrease or increase in hormonal secretions. A single hormone or multiple hormones may be affected.

Anterior Pituitary Gland Dysfunction

Conditions of anterior pituitary dysfunction include growth hormone deficiency and excess.

Growth Hormone Deficiency

Several forms of GH deficiency can occur in children, including idiopathic and congenital. Idiopathic is the most common. Children with idiopathic GH deficiency have adequate somatotropes but inadequate GHRH, leading to short stature or dwarfism. Those with congenital GH deficiency have a normal birth length but are noted to have a decreased growth rate within the first year or two of life.

Adults with GH deficiency also fit into two categories: those who manifest GH deficiency as children, and those who develop GH deficiency in adulthood secondary to a pituitary tumor or its treatment. Aging can cause decreases in GH levels (termed somatopause); the effects of decreasing GH levels in the elderly are being investigated. It is unclear whether GH replacement for somatopause is beneficial, however metabolic disorders that affect mobility, energy levels and socialization, and cardiovascular mortality are all associated with GH deficiency in adults.

Growth Hormone Excess

When GH excess occurs before puberty and the fusion of the epiphysis of the long bones, linear skeletal growth is accentuated and causes **gigantism.** Gigantism is an uncommon condition, caused by excessive secretion of GH by somatotrope adenomas. These children have normal body proportions but grow to be 7 ft or taller.

Acromegaly is the term used to describe excessive GH secretion that occurs in adulthood, after puberty and the closure of the epiphyseal plate. This is an uncommon condition with an annual incidence estimated at three to four cases per 1 million people. The most common cause of acromegaly is somatotrope adenoma. It can also be caused by hypothalamic or some nonendocrine tumors (such as small cell lung cancer). Because the epiphysis of the long bones has closed, these people cannot grow taller, but soft tissues continue to grow. As a result, small bones of the feet and hands and membranous bones of the skull and face enlarge. This enlargement causes the hands and feet to grow and gives the face coarse features, such as a broadening nose, slanting forehead, and protruding jaw. All body organs are affected, leading to

an enlarged heart, hypertension, accelerated atherosclerosis, peripheral neuropathies, and muscle weakness.

Posterior Pituitary Gland Dysfunction

Two major disorders that arise from posterior pituitary gland dysfunction are **diabetes insipidus** (DI) and **syndrome of inappropriate antidiuretic hormone** (SIADH). DI is caused by either a deficiency in or a decreased response to ADH. SIADH is caused from excessive ADH secretion secondary to a failure of the negative feedback system responsible for its release and inhibition. Most disorders of the posterior pituitary gland are secondary to lymphoma, metastatic cancer, septicemia, or disseminated intravascular coagulation.

Diabetes Insipidus

Increases in plasma osmolarity or decreases in blood volume stimulate the release of ADH. ADH is produced in the kidney, causing areas of the collecting duct to become more permeable to water and allowing water reabsorption to increase. Increased water reabsorption increases both plasma osmolarity and blood volume.

DI occurs when there is either a decreased response to ADH (termed nephrogenic DI), or a deficiency in the synthesis or release of ADH (termed central or neurogenic DI). In either case, the person is unable to concentrate urine at times when water is restricted and often excretes large amounts of urine (as much as 3 to 20 L/d). Excessive thirst accompanies the large amount of urine output. As long as the thirst mechanism is normal and fluids are replenished, fluid levels are not altered. However, if the person with DI is unable to communicate a need for water or does not have access to fluids, hypertonic dehydration and increased serum osmolality occur. Nephrogenic DI may have a genetic cause or may occur secondary to lithium ingestion, chronic hypercalcemia, or potassium depletion. Neurogenic DI may occur following surgery near the hypothalamus or from head injury. DI can be an acute or chronic problem.

Syndrome of Inappropriate Antidiuretic Hormone

SIADH is a condition in which ADH secretion continues, regardless of decreased serum osmolarity, which causes dilutional hyponatremia and marked water retention. It results from a failure of the negative feedback system that regulates the release and inhibition of ADH. SIADH may be chronic (secondary to tumors or CNS disorders) or acute (secondary to stress, pain, or surgery). A variety of drugs can also cause SIADH (Box 50.1). Clinical manifestations seen in SIADH (as a result of the dilutional hyponatremia) include lethargy, anorexia, muscle cramps, nausea, vomiting, seizure, coma, and death.

Thyroid Gland Dysfunction

Thyroid function alterations can occur from a hyperfunctioning or hypofunctioning gland, which are malfunctions that may be caused by either a congenital defect or by a problem that occurs later in life. Dramatic changes in patterns of growth and development, and in functions of the cardiovascular, respiratory, GI, neuromuscular, skeletal, and reproductive systems, can result.

Box 50.1 DRUGS THAT MAY CAUSE SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION (SIADH)

- carbamazepine (Tegretol)
- chlorpropamide (Diabinese)
- clofibrate (Atromid-S)
- cyclophosphamide (Cytoxan)
- isoproterenol (Isuprel)
- morphine
- oxytocin (Pitocin)
- phenothiazines
- prostaglandins
- thiazide diuretics
- tricyclic antidepressants
- vasopressin
- vincristine (Oncovin)

An increase in the size of the thyroid gland (goiter) can occur in hyperthyroid, euthyroid, and hypothyroid states. Goiters may be toxic or nontoxic. Toxic goiters cause signs of extreme hyperthyroidism or thyrotoxicosis, described later in this section. The amount of thyroid gland enlargement is proportional to the extent and/or duration of thyroid deficiency. Some goiters grow so large that they can cause difficulty breathing or swallowing. Table 50.2 compares the clinical manifestations of hypothyroidism and hyperthyroidism.

Hypothyroidism

Congenital **hypothyroidism** is present at birth, and acquired hypothyroidism occurs later in life as a result of either a primary or secondary disorder of the hypothalamus or pituitary gland.

Untreated congenital hypothyroidism (which affects approximately 1 out of every 5,000 infant births) can have devastating effects, such as mental retardation and impaired physical growth. Congenital hypothyroidism occurs from abnormal biosynthesis of thyroid hormone, deficient TSH hormone, or an absence of the thyroid gland. **Cretinism,** the term used for the condition of untreated hypothyroidism, does not apply to the normally developing infant, born with hypothyroidism, who receives thyroid hormone replacement therapy soon after birth. Fortunately, a very effective screening test for hypothyroidism is readily available. A drop of blood is taken from the infant's heel and analyzed for thyroid hormones and TSH, and treatment can be instituted immediately if hypothyroidism is detected.

Hypothyroidism that is evident in older children and adults occurs as a result of either dysfunction or destruction of the thyroid gland (primary hypothyroidism) or of impaired hypothalamic or pituitary function (secondary hypothyroidism). Primary hypothyroidism may result from surgical removal of the thyroid gland (thyroidectomy) or from radiation, which ablates the gland. Certain drugs (e.g., lithium carbonate, used for manic depression, and propylthiouracil and methimazole, which are antithyroid drugs) can block hormone synthesis causing hypothyroidism with a goiter. Thyroid hormone production can be blocked by drugs containing iodine (e.g., kelp tablets, radiographic contrast media, and cough syrups containing iodide). Thyroid problems are also being reported

TABLE 50.2 Clinical Comparison of Hypothyroidism and Hyperthyroidism

Body System	Clinical Picture of Hypothyroidism	Clinical Picture of Hyperthyroidism
Central nervous system	General slowing of mental processes Lethargy Neuropathies	Emotional lability Hyperkinesia Nervousness
Cardiovascular system	Decreased peripheral vascular resistance, heart rate, stroke volume, cardiac output, pulse pressure ECG changes: bradycardia, increased PR interval, flat T wave, low voltage Low-output congestive heart failure Pericardial effusion	Increased peripheral vascular resistance, heart rate, stroke volume, cardiac output, pulse pressure High-output congestive heart failure Increased inotropic and chronotropic effects Angina Arrhythmias
EENT	Enlarged tongue Eyelid drooping Periorbital edema Puffy, nonpitting face	Diplopia (Graves disease) Exophthalmos (Graves disease) Periorbital edema Retraction of upper lid with wide stare
Gastrointestinal system	Decreased appetite Decreased frequency of bowel movements Ascites	Increased appetite Increased frequency of bowel movements Hypoproteinemia
Hematopoietic system	Decreased erythropoiesis Anemia	Increased erythropoiesis Anemia
Metabolic system	Decreased basal metabolic rate with slight positive nitrogen balance Delayed degradation of insulin with increased insulin sensitivity Increased cholesterol and triglycerides Decreased hormone degradation Decreased requirements for fat- and water-soluble vitamins Decreased drug detoxification	Increased basal metabolic rate with negative nitrogen balance Hyperglycemia Increased free fatty acids Decreased cholesterol and triglycerides Increased hormone degradation Increased requirements for fat- and water-soluble vitamins Increased drug detoxification
Musculoskeletal system	Stiffness and muscle fatigue Decreased deep tendon reflexes Increased alkaline phosphatase, LDH, AST	Weakness and muscle fatigue Increased deep tendon reflexes Hypercalcemia Osteoporosis
Renal system	Impaired water excretion Decreased renal blood flow Decreased glomerular filtration rate	Mild polyuria Increased renal blood flow Increased glomerular filtration rate
Reproductive system	Hypermenorrhea Infertility* Decreased libido* Men: impotency, oligospermia decreased gonadal steroid metabolism*	Women: menstrual irregularities decreased fertility, decreased gonadal steroid metabolism*
Respiratory	Pleural effusions Hypoventilation Hypercarbia	Dyspnea Decreased vital capacity
Skin	Pale, cool, puffy skin (myxedema) Dry, brittle hair Brittle nails Cold intolerance	Warm, moist, diaphoretic skin Fine, thin hair Heat intolerance

*Both men and women

from the use of the antiarrhythmic medication amiodarone, because of its high iodine content. In the United States, the use of iodized salt and other dietary iodide sources has decreased the incidence of iodine deficiency, which causes hypothyroidism and goiter. The major cause of goiter and hypothyroidism is Hashimoto thyroiditis, an autoimmune disorder that damages the thyroid. This is a condition that affects females to males at a 5:1 ratio.

Clinical manifestations of hypothyroidism can vary widely. Subclinical hypothyroidism can cause nonspecific complaints. Overt manifestations of hypothyroidism occur as a result of decreased cellular metabolism secondary to thyroid hormone deficiency and myxedematous involvement of the body tissues. These manifestations include lethargy, hypoactive reflexes, weight gain, anxiety, impaired memory, constipation, hypotension, bradycardia, intolerance to cold, loss of hair, decreased sexual function, menstrual irregularities, infertility, edema of the hands, feet, and face, pale and rough skin, thickened tongue, and husky voice.

Hyperthyroidism

An excessive amount of thyroid hormone in the peripheral tissues results in **hyperthyroidism,** or **thyrotoxicosis.** Patients with hyperthyroidism exhibit signs and symptoms of overactive cellular metabolism of all body systems, tachycardia, palpitations, hypertension, increased body temperature, heat intolerance, weight loss, amenorrhea, and goiter (see Table 50.2). These manifestations result from increased oxygen consumption and increased sympathetic nervous system activity. Graves disease, the most common cause of hyperthyroidism, is accompanied by goiter and exophthalmos (bulging of the eyeballs). Other causes of hyperthyroidism include thyroid gland adenoma, multinodular goiter, and ingestion of excessive thyroid hormone.

Graves disease is an autoimmune disorder that arises from sustained overactivity of the thyroid gland, caused by thyroid-stimulating antibodies and growth of the entire thyroid gland (goiter). Infiltrative ophthalmopathy (exophthalmos) occurs in as many as 50% of all patients with Graves disease Skin lesions (dermopathy) may also occur. Patients with exophthalmos appear to have protruding eyes. Even with treatment, once exophthalmos exists, it remains essentially unchanged. Vision loss (secondary to involvement of the optic nerve) and corneal ulceration (secondary to the eyelids not closing tightly) also occur.

An extreme, life-threatening form of thyrotoxicosis is called **thyroid crisis** (also known as thyroid storm). It is seen in patients who are not adequately treated for their hyperthyroidism or who are undiagnosed. Thyroid crisis is frequently precipitated by infection (usually respiratory), diabetic ketoacidosis, stress, manipulation of a hyperactive thyroid gland during thyroidectomy, or emotional or physical trauma. Manifestations of thyroid crisis include severe CNS effects (e.g., restlessness, agitation, or delirium), extreme cardiovascular effects (e.g., angina, heart failure, or tachycardia), and high fever. Treatment must be implemented immediately; it includes administration of methimazole (MMI), beta blockers, corticosteroids, fluids and electrolytes, measures to control hyperthermia, and oxygen.

Parathyroid Gland Dysfunction

PTH is secreted by the parathyroid glands. This hormone is a major regulator of serum calcium and phosphate. A decrease in serum calcium concentration is the dominant regulator of PTH, with a response rate of just a few seconds. A decrease in phosphate causes an indirect effect on PTH by combining with calcium and decreasing serum calcium concentrations. Magnesium also affects the secretion, synthesis, and action of PTH; severe and prolonged hypomagnesemia can have a marked effect on the inhibition of PTH levels. Hypocalcemia can cause tetany, convulsions, muscle spasm, and neuromuscular excitability. Hypercalcemia has been associated with life-threatening cardiac dysrhythmias, CNS abnormalities, renal damage, and soft tissue calcification. For these reasons, maintaining calcium at the desired level is important. Table 50.3 summarizes disorders of bone and calcium metabolism.

TABLE 50.3 Disorders of Bone and Calcium Metabolism

Disorders	Examples	Management
Hypocalcemia	• Inadequate dietary intake of Ca++ and/or vitamin D • Malabsorption caused by vitamin D lack or end-organ resistance • Hypoparathyroidism, pseudohypoparathyroidism • Renal failure	• Treatment with calcium and vitamin D compounds
Hypercalcemia	• Hyperparathyroidism • Hypervitaminosis D • Neoplasia • Hyperthyroidism • Immobilization	• Treatment with fluids, low-calcium diet, calcitonin, bisphosphonates, glucocorticoids, loop diuretics
Impaired bone remodeling	• Osteoporosis	• Treatment with bisphosphonates, calcitonin, calcium, estrogen (female)

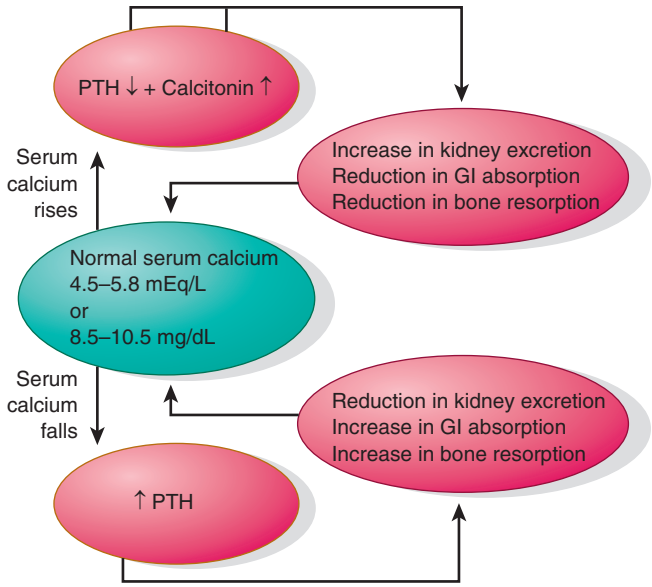
Hypoparathyroidism

Hypoparathyroidism (inadequate PTH levels) can be either inherited or acquired. This condition is characterized by hypocalcemia and frequently by hypophosphatemia. As stated previously, hypocalcemia can cause tetany, convulsions, muscle spasm, and neuromuscular excitability. Acquired hypoparathyroidism occurs most commonly as a result of surgery in the neck, but this adverse outcome has become less common with the advent of improved surgical techniques and the increased use of nonsurgical therapy. Lack of PTH can cause vitamin D deficiency, leading to osteomalacia (softening and bending of the bones) in adults and rickets (skeletal deformities) in children.

Hyperparathyroidism

Hypersecretion of PTH leads to hyperparathyroidism. Primary hyperparathyroidism is most common in women older than 50 years and is caused by an adenoma, a carcinoma of the parathyroid gland, or hyperplasia. Hyperparathyroidism causes excessive levels of calcium in both serum (hypercalcemia) and urine (hypercalciuria). Urine phosphate levels are also high, and serum phosphate levels are normal to low. Potential complications of these imbalances include nervous system complaints, pancreatitis, peptic ulcers, kidney stones, severe osteoporosis and osteopenia, and pathologic bone fractures. These complications can be remembered by the rhyme, "moans, groans, stones, and bones." Secondary hyperparathyroidism occurs primarily in persons with renal failure, but it can also occur with multiple myeloma, bone metastasis, and Paget disease. Regardless of the cause, hyperparathyroidism is characterized by deposits of calcium salts in body tissues and bone decalcification. In primary hyperparathyroidism, the severity of hypercalcemia reflects the quantity of hyperfunctioning tissue. Excessive quantities of PTH stimulate transport of calcium into the serum from the kidneys, bones, and intestines. Nephrolithiasis (formation of kidney stones) can occur secondary to calcium deposits in the soft tissues of the kidney.

The influence of PTH on the cells of the bones is very strong and causes them to release calcium into the serum. Under normal conditions, the amount of calcium in the bones remains at a constant level, but in the presence of too much PTH, the bones release their calcium into the bloodstream at a high rate, resulting in osteopenia and osteoporosis (Figure 50.3). PTH also influences the lining of the intestine to absorb more calcium from the diet (Table 50.4).



• FIGURE 50.3 Regulation of serum calcium. Parathyroid hormone (PTH) and calcitonin regulate normal serum calcium. As serum calcium rises, PTH is inhibited by calcitonin. The kidney then excretes more calcium, the GI system absorbs less, and a reduction in bone resorption occurs. As serum calcium falls, PTH is secreted and raises the calcium level by decreasing the amount of calcium lost in the kidney, increasing the amount absorbed in the GI tract, and increasing bone resorption.

Secondary hyperparathyroidism is caused most often by corticotropin-releasing factor and hyperphosphatemia. There is an inverse relationship between the glomerular filtration rate and serum phosphate levels: as the glomerular filtration rate decreases, serum phosphate levels increase. In turn, this increase decreases serum calcium levels, and this drop then stimulates secretion of PTH.

As the serum calcium level rises, neuromuscular irritability decreases, because of the sedative effect of serum calcium on the body. Hypercalcemia is commonly associated with hyperparathyroidism, but it can also occur secondary to neoplastic disease or immobilization, during which

TABLE 50.4 Actions of Parathyroid Hormone (PTH) and Vitamin D

	PTH	Vitamin D (and Metabolites)
Bone	• High doses—calcium and phosphate resorption increased • Low doses—may increase bone formation	• Increased calcium and phosphate resorption by calcitriol • Increased bone formation
Kidney	• Decreased calcium excretion • Increased phosphate excretion	• Calcium and phosphate excretion may be decreased by calciferol and calcitriol.
Intestine	• Increased calcium and phosphate absorption by increased calcitriol production	• Increased calcium and phosphate absorption by calcitriol
Effect on serum levels	Serum calcium is increased and serum phosphate is decreased	Serum calcium and serum phosphate are both increased

movement of calcium out of the bones increases. Renal failure also decreases renal excretion of calcium and thus also leads to hypercalcemia.

C PITUITARY DRUGS

The primary effects of drugs used to affect pituitary function are to either mimic or antagonize the pituitary hormone. GH, somatostatin, ADH, and oxytocin are the most frequently used drugs. Table 50.5 presents a summary of selected pituitary drugs.

• C GROWTH HORMONES

GH deficiency, leading to short stature, was initially treated with GH injections extracted from the pituitary glands of cadavers. Because cadavers were the only source, the availability of the treatment was limited. Additionally, several cases of Creutzfeldt-Jakob disease (a neurologic disturbance that progresses to coma and death, caused by encephalopathy) secondary to an infectious agent in the GH put an end to this practice. Presently, synthetic human GH (rhGH), produced from recombinant DNA, is available. Although rhGH therapy is very expensive, it has been shown to be effective in treating children and adolescents with GH deficiencies. Somatropin (Humatrope) is the prototype rGH discussed in this chapter (see Table 50-5). Somatropin is produced by many pharmaceutical laboratories, and each preparation has a different trade name. They do not all share the same Food and Drug Administration (FDA) indications.

Nursing Management of the Patient Receiving P Somatropin

Core Drug Knowledge

Pharmacotherapeutics

Somatropin is a recombinant DNA formulation of GH (rGH) that has an amino acid sequence identical to that of pituitary-derived GH. It is used as long-term replacement

TABLE 50.5 Summary of Selected C Pituitary Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range
C Growth Hormones		
P somatropin (Humatrope) Genotrope, Norditropin, Nutropin Omnitrope Saizen Serostim Tev-Tropin Zorbtive	Treatment of growth failure from growth-hormone deficiency or chronic renal failure (prior to transplant) Turner syndrome AIDS wasting syndrome Treatment (long-term) of growth failure in children Short stature of Turner syndrome (orphan use) Short-bowel syndrome	Dosing is dependent on specific type of growth hormone and on individual patient requirements.
Growth Hormone Antagonists		
octreotide acetate (Sandostatin)	Acromegaly (reduce growth hormone levels), severe diarrhea	*Adult*: SC, 50–600 mcg bid–qid *Child*: Safety and efficacy not established
bromocriptine mesylate (Parlodel)	Acromegaly Parkinson disease (idiopathic) Suppression of physiologic lactation following parturition Hyperprolactinemia	*Adult*: PO, 1.25–30 mg/d *Adult*: PO, 2.5–100 mg/d; efficacy for >2 y not established *Adult*: PO, 2.5 mg bid × 14–21 d *Adult*: PO, 5–10 mg/d
C Posterior Pituitary Hormone Regulators		
desmopressin (DDAVP, Stimate*)	Neurogenic diabetes insipidus	*Adult:* Intranasal, 0.1–0.4 mL/d daily or bid, 1 spray (300 mg)/nostril; SC, IV, 0.5–1.0 mL/d bid; PO, 0.05 mg bid *Child, 3 mo–12 y:* Intranasal, 0.05–0.3 mL/d qd or bid, 1 spray (300 mg)/nostril; SC, IV, 0.5–1.0 mL/d bid; PO, 0.05 mg bid (*dosage adjusted according to water turnover pattern*)
	Primary nocturnal enuresis	*Adult and child >6 y:* Intranasal, 20–40 mcg at bedtime
Vasopressin (Pitressin)	Neurogenic diabetes insipidus Abdominal distention Antiflatulent effect for abdominal roentgenography	*Adult*: IM, SC, intranasal; 5–10 U repeated bid to tid *Adult*: IM, 5–10 U repeated q3–4h *Adult*: IM, SC, 10 U at 2 h and 10 U 30 min before procedure *Child*: Decrease dosage proportionately
	Ventricular fibrillation, ventricular tachycardia	*Adult*: IV, 40 U

therapy for children who have growth failure because of inadequate endogenous GH secretion and those with short stature caused by Turner syndrome. Somatropin stimulates linear growth in such patients, resulting in an increase in skeletal growth. Therefore, it is given for short stature only when the epiphyses are not closed. Somatropin is also indicated for use in patients with idiopathic short stature (non–GH-deficient short stature). The American Association of Clinical Endocrinologists and Growth Hormone Research Society defines short stature as height more than 2 standard deviations (SDs) below the mean for sex and age. Patients more than 2.25 SD below the mean for sex and age are treated with somatropin.

Pharmacokinetics

Somatropin is well absorbed and distributed. The absolute bioavailability of somatropin is 75% and 63% after subcutaneous (SC) and intramuscular (IM) administration, respectively. GH localizes to the liver and kidney. It is filtered by the glomerulus in the kidney, reabsorbed in the proximal tubule, and broken down within renal cells into amino acids. A portion of the breakdown products is returned to the systemic circulation. Intravenous (IV) somatropin has a mean half-life of 0.36 hours, whereas SC- and IM-administered somatropin doses have mean half-lives of 3.8 and 4.9 hours, respectively. The longer half-life of SC and IM administration is attributable to slower absorption from the injection site. The liver and kidney are the major elimination organs for exogenously administered GH. Caution must be used in administering somatropin to patients with severe hepatic and renal function because reduced clearance occurs.

Pharmacodynamics

Treatment with GH has powerful effects on growth and metabolism. It stimulates cell growth and cellular mitosis, facilitates cellular uptake of amino acids for protein synthesis, and promotes use of fatty acids for energy. These effects are caused indirectly by an increase in IGF-1, an intermediary peptide. In vitro and clinical testing has demonstrated that somatropin is equivalent therapeutically to GH of pituitary origin in adults.

Contraindications and Precautions

Somatropin is contraindicated for growth promotion in children with closed epiphyses. It is also contraindicated in patients with intracranial tumors until the antimalignancy treatment is completed. Somatropin is not indicated for patients with acute critical illness due to complications following open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure because of an increased risk of mortality with these conditions.

Pediatric patients with endocrine disorders, including GH deficiency, are more likely to develop slipped-capital epiphysis. For this reason, if a pediatric patient taking GH begins to limp or complain of hip or knee pain, the patient must be evaluated. Patients with a history of scoliosis who are being treated with GH are at elevated risk for developing more severe scoliosis, which occurs more frequently if rapid growth occurs. Patients with Turner syndrome have an increased risk of otitis media or hearing disorders. They are also at a greater risk for cardiovascular disorders (aortic aneurysm, stroke, and hypertension). Somatropin is a pregnancy category C drug. It should be given only when clearly needed because it is not known whether it can cause fetal harm or is excreted in breast milk. Cautious use also is advised in patients with diabetes because insulin resistance resulting in hyperglycemia may develop. Some product formulations contain diluent preservatives that may cause hypersensitivity.

Adverse Effects

Adverse effects with high-dose somatropin include headache, hypertension, joint and back pain, peripheral edema, muscle aches, and rhinitis. Many of these adverse effects occur initially and then resolve spontaneously or in response to dosage adjustments. Others include hypothyroidism, hyperglycemia, glycosuria, and pain at the injection site. Recurrent growth of an intracranial tumor also may occur. Leukemia has occurred in a small number of children receiving somatropin or somatrem, but its relation to therapy is uncertain.

A small percentage of patients (approximately 2%) may develop antibodies to the rGH protein molecule. However, GH antibody–binding capacities (2 mg/L) have not been associated with any growth reduction.

Drug Interactions

GH reduces the activity of hepatic mixed-function oxidases. This reduction may alter the metabolism of many drugs (Table 50.6). Glucocorticoid or other corticosteroid therapy may inhibit the growth-promoting effect of rGH. Patients with coexisting ACTH deficiency may need their glucocorticoid replacement dosages adjusted carefully to avoid an inhibitory effect on growth. Therefore, patients should be monitored closely if this combination must be used. Use of somatropin with anabolic steroids, androgens, estrogens, or thyroid hormones may accelerate epiphyseal maturation.

Assessment of Relevant Core Patient Variables

Health Status

Before administering somatropin, review the patient's record to determine whether it can be administered safely. A physical assessment establishes baseline data from which to monitor the effects of the drug. This assessment should include height and weight measurements, bone age determinations, thyroid function tests, blood glucose tests, and levels of GH. Monitor these data, and review them periodically during treatment. If the growth rate does not meet or exceed the pretreatment rate by at least 2 cm/y, consider nonadherence to therapy, antibody formation, malnutrition, or hypothyroidism as possible causes. X-rays of the hip and funduscopic examination are recommended before starting and periodically during the course of GH therapy.

TABLE 50.6 Agents That Interact with P Somatropin

Interactants	Effect and Significance	Nursing Management
Antiarrhythmics disopyramide dofetilide	Somatropin induces metabolism of antiarrhythmics.	Monitor antiarrhythmic drug levels. Monitor for cardiac arrhythmias. Discuss adjustment of antiarrhythmic drugs with health care provider.
anti-impotence drugs sildenafil tadalafil vardenafil	Somatropin induces metabolism of anti-impotence drugs.	Instruct patient of potential drug interaction.
antipsychotic drugs clozapine pimozide	Somatropin induces metabolism of some antipsychotic drugs.	Monitor antipsychotic drug levels. Monitor for psychotic symptoms. Discuss adjustment of antipsychotic drugs with health care provider.
antiseizure drugs carbamazepine felbamate tiagabine	Somatropin induces metabolism of some antiseizure drugs.	Monitor for seizure activity. Ensure safety. Monitor antiseizure drug levels. Discuss adjustment of antiseizure drugs with health care provider.
corticosteroids	Corticosteroids have antagonistic effect on GH.	Monitor GH levels. Monitor for efficacy of GH. Discuss adjustment of GH with health care provider.
Hormones oral contraceptives hormone replacement testosterone	Somatropin induces metabolism of certain hormones.	Advise patient to use other form of birth control. Monitor for signs of estrogen deficiency. Monitor for signs of testosterone deficiency. Discuss adjustment of hormonal drugs with health care provider.
hypoglycemic drugs acarbose insulins metformin meglitinides nateglinide repaglinide sitagliptin sulfonylureas thiazolidinediones	Somatropin induces metabolism of many oral and parenteral hypoglycemic drugs.	Monitor blood glucose. Monitor Hb A_{1C}. Monitor for signs of hyperglycemia. Discuss adjustment of hypoglycemic drugs with health care provider.
Immunosuppressants cyclosporine sirolimus tacrolimus	Somatropin induces metabolism of some immunosuppressant drugs.	Monitor for signs of transplant rejection. Monitor immunosuppressant drug levels. Discuss adjustment of immunosuppressant drugs with health care provider.
methadone	Somatropin induces metabolism of methadone.	Monitor for pain. Monitor for opioid withdrawal. Discuss adjustment of methadone with health care provider.
warfarin	Somatropin induces metabolism of warfarin	Monitor PT/INR. Monitor for signs of thromboembolism. Discuss adjustment of warfarin with health care provider.

Observe patients with diabetes or glucose intolerance closely during somatropin therapy. Evaluate individuals with GH deficiency secondary to an intracranial lesion regularly for progression or recurrence of the underlying disease process. Assess individuals routinely for any malignant transformation of skin lesions. Monitor those with growth failure secondary to chronic renal insufficiency regularly for progression of renal osteodystrophy progression, because slipped capital femoral epiphysis or avascular necrosis of the femoral head may be seen in children with advanced renal osteodystrophy. Whether these problems are affected by GH therapy is uncertain. Examine the injection site for pain and swelling.

Life Span and Gender

It is important to assess whether the patient is pregnant or breast-feeding. Somatropin is classified in pregnancy category C and should be given to a pregnant or lactating woman only if use is clearly indicated. It is not known whether somatropin is excreted in breast milk. Available data suggest that rGH clearances are similar in adults and children. Treatment with GH requires a long-term regimen. Children receiving this drug need continual monitoring, and once therapy has begun, measure and record the patient's height and weight at regular intervals. Question pediatric patients about hip or knee pain at each visit.

Lifestyle, Diet, and Habits

Adherence to the drug regimen is imperative; therefore, evaluating the patient's ability and willingness to adhere is important. Actual somatropin dosage is individualized to each patient. SC injections each evening are most effective because nightly injections mimic the natural hormone surge that occurs after sleep. Stimulation of growth is most effective when treatment begins early and injections are continued until the epiphyses close. Response to treatment tends to decrease with time.

Environment

Assess the setting in which somatropin will be administered, the ability of the patient or caregiver to administer the drug properly, and the patient's and family's financial situation. Most often, it is necessary to instruct the patient or caregiver in the proper way to reconstitute and administer the medication according to the manufacturer's instructions because it is frequently given in the home. Also, tell the patient to refrigerate the drug following reconstitution. The drug is very expensive, and some insurance companies resist covering the cost of treatment. In such cases, sources of financial support may have to be solicited. Health care visits are decreased if parents or caregivers administer the injections, but regular visits to the physician must still occur to monitor blood and urine samples, make bone age determinations, and track growth rate. Regular follow-up health care is necessary.

Nursing Diagnoses and Outcomes

- Delayed Growth and Development related to deficiency of GH secretion
  Desired outcome: *The patient will demonstrate an increase in linear growth.*
- Imbalanced Nutrition: More (or Less) than Body Requirements, related to endocrine changes and rapid changes in height and weight
  Desired outcome: *The patient will receive adequate nutrition for growth appropriate to age and need.*
- Impaired Tissue Integrity related to pain and swelling at injection site
  Desired outcome: *The patient will not experience pain and swelling at the injection site.*
- Altered Comfort related to headache, joint, and muscle discomfort secondary to somatropin effects
  Desired outcome: *The patient will describe measures to improve comfort.*

Planning and Intervention

Maximizing Therapeutic Effects

Hypothyroidism may develop during somatropin therapy and, if untreated, may prevent an optimal response. For this reason, it is essential to perform periodic thyroid function tests and initiate thyroid hormone replacement therapy if indicated. Glucocorticoid replacement dosage must be carefully adjusted in patients with coexisting ACTH deficiency to avoid an inhibitory effect on growth. Inform patients who require dialysis in a daytime ambulatory setting of the need to take their doses before bedtime. Patients who require chronic cycling peritoneal dialysis should receive their doses of somatropin in the morning, after the dialysis is completed.

Minimizing Adverse Effects

GH therapy may induce insulin resistance; thus, it is important to monitor the patient closely for glucose intolerance. Children being treated with rGH for growth failure secondary to chronic renal insufficiency may develop problems of renal osteodystrophy (generalized bone changes resembling osteomalacia and rickets). Slipped capital femoral epiphyses or avascular necrosis of the femoral head can also occur in these patients. Although it is uncertain whether these problems are a direct result of GH therapy, x-rays of the hip should be obtained before initiating GH therapy. Be alert for the development of a limp or complaints of hip or knee pain, and tell parents to do the same. Slipped capital femoral epiphysis may occur more frequently in patients with endocrine disorders or in patients undergoing rapid growth. Pain and discomfort related to headache, bone, and muscle discomfort can be treated with appropriate analgesics and environmental controls.

Sudden growth spurts and changes in growth and development, coupled with potential thyroid changes and insulin resistance, may cause nutritional imbalance that can complicate the desired effect of the GH. Consider nutritional assessment and appropriate replacement of necessary nutrients.

Providing Patient and Family Education

- Explain that this drug is replacing an important hormone (GH) that is necessary for normal growth and development.
- Explain to patients and their families that the drug can be given only by injection. Teach patients, family members, or caregivers how to reconstitute and administer the drug. Review injection site rotation to maximize therapeutic effect and avoid problems of lipodystrophy. Periodic review of injection technique is important to ensure effectiveness and decrease adverse effects.
- Instruct patients to refrigerate the reconstituted solution. Vials are stable for up to 14 days if reconstituted with diluent or bacteriostatic water for injection. If sterile water is used, only one dose of somatropin can be used, and the unused portion must be discarded.

- Alert patients with diabetes to the fact that insulin resistance may develop. Instruct these patients to monitor blood sugar closely and to report variations to their health care team.
- Instruct patients or their families to report any adverse drug effects and emphasize the importance of reporting a limp or any hip or knee pain as soon as possible. Slipped capital femoral epiphysis may occur more frequently in patients with endocrine disorders or in patients undergoing rapid growth.

Ongoing Assessment and Evaluation

In patients taking somatropin, evaluate thyroid function at regular intervals because hypothyroidism compromises rGH drug effects. Additionally, it is important to be alert for signs of glucose intolerance because insulin resistance may develop and disrupt diabetes control. As with all protein pharmaceuticals, a small percentage of patients may develop antibodies to the protein. Evaluate adherence to the prescribed treatment program, assess thyroid status, and test for GH antibodies in any patient who fails to respond to therapy. Stress the importance of follow-up appointments and periodic analysis of thyroid function, glucose tolerance, and GH levels to evaluate the effectiveness of the drug and possible development of adverse effects. Therapy is considered effective when anticipated growth occurs. The patient and family should demonstrate appropriate drug administration technique, acknowledge the importance of monitoring for adverse effects, and show understanding of when to report findings to the health care team (Box 50.2).

BOX 50.2 COMMUNITY BASED CONCERNS

Children Receiving Growth Hormone (somatropin)

As a nurse educating patients and families about the use of growth hormone (GH) therapy, you should include the following information:

- GH is indicated for children with inadequate endogenous GH secretion and for those with short stature caused by Turner syndrome.
- GH is not clearly indicated for children who are born to a short family but whose parents want them to be taller.
- GH is not indicated for children with closed epiphyses.
- GH therapy requires long-term commitment from the patient; treatment generally lasts 3 to 9 years.
- Although GH may be covered in part by insurance, the cost of treatment can be as much as $50,000 annually.
- GH is given as a daily SC injection, usually in the evening, because this timing mimics the natural hormone surge that occurs after sleep.
- Parents or other caregivers are taught how to administer the injections, but regular physician visits are mandatory during treatment to monitor bone age determinations, growth rate, and blood and urine samples.
- Insulin resistance may develop in a diabetic patient taking GH; therefore, blood sugar in these patients must be closely monitored.

Drugs Closely Related to P Somatropin

Other Somatropin Preparations

Commercially available drug preparations of somatropin include Genotropin, Genotropin MiniQuick, Norditropin, Nutropin, Omnitrope, Saizen, Serostim, Tev-Tropin, and Zorbtive. Most are powders that need reconstitution. They differ in the amounts of rGH international units contained in the vial, whether vials are single or multiple dose, what diluents are used (some diluents are preservative free), and FDA-approved indications.

Genotropin is approved for use in both children and adults with GH deficiency. It is also approved for long-term management of growth failure in pediatric patients born small for gestational age who fail to complete "catch-up growth" by 2 years of age, and those with growth failure due to Prader-Willi syndrome. This syndrome is a complex genetic disorder that includes short stature, incomplete sexual development, mental retardation or learning disabilities, behavior problems, low muscle tone, and an involuntary urge to eat constantly, which leads to obesity.

Nutropin is indicated for long-term treatment of growth failure stemming from inadequate endogenous GH secretion, for growth failure associated with chronic renal insufficiency (until renal transplant), idiopathic short stature and for short stature related to the chromosomal disorder, Turner syndrome. Turner syndrome exclusively affects females and is characterized in part by short stature and incomplete sexual development. Nutropin is also indicated for adults with growth hormone deficiency who developed GH deficiency as a result of pituitary disease, hypothalamic disease, surgery, radiation, or trauma.

Serostim is indicated for concomitant use with antiviral therapy for HIV-associated cachexia (wasting syndrome) to increase lean muscle mass and body weight. Serostim is in pregnancy category B.

MEMORY CHIP

P Somatropin

- Genetically engineered (recombinant DNA) human growth hormone used for long-term treatment of children with deficient endogenous growth hormone
- Major contraindications: closed epiphyses and cranial lesions
- Most common adverse effects: joint and muscle pain
- Most serious adverse effects: development of antibodies to growth hormone, hypothyroidism, and insulin resistance
- Maximizing therapeutic effects: Reconstitute drug according to manufacturer's directions.
- Minimizing adverse effects: periodic testing of glucose tolerance, thyroid function, and presence of growth hormone antibodies
- Most important patient education: proper preparation and storage of medication; proper SC or IM injection technique

Zorbtive is approved for use in patients with short-bowel syndrome receiving specialized nutritional support.

Norditropin, Tev-Tropin, and Saizen are used for the long-term treatment of children with inadequate endogenous GH secretion. Omnitrope is used in both children and adults with GH deficiency.

Sermorelin Acetate

Sermorelin acetate (Geref) is another drug used in the diagnosis and management of GH deficiency. It is also known as growth-releasing hormone and GHRH. Sermorelin directly stimulates the pituitary gland to release GH. It is given cautiously in patients with growth deficiency due to intracranial lesions and those older than 65 years of age. Adverse effects to sermorelin include injection site reactions, flushing, and antibody development. Sermorelin is a pregnancy category C drug and is not recommended for women who breast-feed.

Drugs Significantly Different From Somatropin

GH antagonists decrease GH secretion. Almost all conditions of GH hypersecretion are caused by pituitary tumors and are usually treated by radiation therapy or surgery. Pharmacotherapy for GH excess includes two groups of drugs: the somatostatin analogues (octreotide acetate) and the dopamine agonists (bromocriptine) (see Table 50.5). Hypothalamic somatostatin (from the hypothalamus) is an effective GH inhibitor, but it is rarely used because of its short initial half-life (1 to 3 minutes) and its multiple effects on many secretory systems (e.g., it inhibits the release of gastrin, glucagon, insulin).

Octreotide Acetate

Octreotide acetate (Sandostatin) is a more potent inhibitor than somatostatin of growth hormone, insulin, and glucagon. It also suppresses LH response to GnRH (gonadotropin-releasing factor), inhibits the release of serotonin, gastrin, and pancreatic polypeptide, and decreases visceral blood flow and the secretion of TSH. Octreotide is highly effective in treating both children and adults with excess GH, and it has replaced bromocriptine as the most commonly used agent for acromegaly. It is indicated to reduce GH blood levels and IGF-1 (somatomedin C) levels in patients with acromegaly, who either cannot be treated surgically or have an inadequate response to surgery or irradiation of the pituitary. The goal of treatment is to reduce blood levels of GH and IGF-1. GH is reduced to normal ranges in 50% of patients treated with octreotide acetate; IGF-1 is reduced to normal ranges in 50% to -60% of patients. Adjunctive therapy with octreotide acetate is beneficial for patients who have been treated with pituitary irradiation, as it takes several years for the maximal benefit of this treatment to be realized.

Other indications for octreotide include treating diarrhea and flushing symptoms associated with metastatic carcinoid tumors and profuse and watery diarrhea that can occur with vasoactive intestinal peptide tumors (VIPomas) as well as esophageal varices. In single doses, the drug has been shown to decrease bile secretion and to inhibit gallbladder contractility in normal volunteers. Those with acromegaly have an increased incidence of biliary tract abnormalities if this medication is used for extended periods of time (one year or longer). Off-label uses include AIDS-associated diarrhea, breast cancer, insulinomas, small bowel fistulas, Cushing syndrome, dumping syndrome after gastrectomy, and graft-versus-host disease–induced diarrhea.

The elimination half-life of octreotide from the plasma is 1.7 hours, with approximately 32% of the dose excreted unchanged in the urine. During clinical trials in elderly patients there was a significant increase in the half-life of the drug (46%) and a significant decrease in clearance (26%); therefore, dose adjustment may be necessary in these patients. In patients with severe renal failure requiring dialysis, octreotide half-life is increased, which also necessitates adjusting the maintenance dose.

Individuals with acromegaly may experience either hypoglycemia (3%) or hyperglycemia (16%) during octreotide therapy. This effect may result in overt diabetes mellitus or require dosage changes for insulin or other hypoglycemic agents.

Adverse effects of octreotide include GI discomfort (diarrhea, loose stools, abdominal discomfort, and nausea), headache, and sinus bradycardia or other cardiac arrhythmias. Decreased glucose tolerance may also occur. Octreotide therapy may cause acute cholecystitis, cholestatic jaundice, biliary tract obstruction, or pancreatitis. More frequently, it causes cholelithiasis in patients requiring therapy for 12 months or more. Dietary fat absorption may be altered in some patients. Periodic fecal fat and serum carotene determinations should be performed to help assess possible drug-induced fat malabsorption. It is vital to stress the importance of reporting icterus (jaundice), dark urine, or clay-colored stools to the health care team immediately, as well as any abdominal pain, edema, chest pain, shortness of breath, or fainting.

When octreotide is administered concomitantly with cyclosporine, it may decrease blood levels of cyclosporine and cause rejection of transplanted organs. Octreotide is associated with alterations in nutrient absorption and may have an effect on oral medications. Drug and food interactions include altered absorption of dietary fats, decreased vitamin B_{12} levels, and abnormal Schilling test results. (The Schilling test is done to diagnose pernicious anemia.)

For prolonged storage, unused octreotide should be protected from light and stored in the refrigerator. If refrigerated, the solution should be allowed to warm to room temperature before administration. At room temperature, octreotide is stable for 14 days if protected from light. Octreotide is usually administered subcutaneously but can also be delivered through a continuous subcutaneous infusion. Because it is most often given subcutaneously, the patient and family should be taught details of sterile technique, injection-site

rotation, and signs of infection for which to watch. The patient receiving octreotide therapy requires long-term follow-up and regular evaluation for signs of acromegaly and other endocrine dysfunction (e.g., thyroid or insulin resistance), which may require dosage adjustment. The importance of regular follow-up visits with the health care provider should be emphasized. Responsiveness to octreotide therapy may be evaluated by assessing GH and IGF-1 serum levels.

Bromocriptine Mesylate

Bromocriptine mesylate (Parlodel) is a semisynthetic ergot alkaloid that inhibits prolactin secretion. In the majority of patients with acromegaly, it also lowers elevated blood levels of GH. It can be used alone or as an adjunct to irradiation. In some children, bromocriptine and octreotide used in combination have proved successful. Bromocriptine, a dopamine receptor agonist, is also used to treat Parkinson disease, prolactin-secreting adenomas and dysfunctions associated with hyperprolactinemia including infertility, amenorrhea, and hypogonadism. Dopamine agonists inhibit GH secretion in some patients with acromegaly, although the opposite effect occurs in healthy individuals. Dopamine increases somatostatin release from the hypothalamus. This effect may explain the GH-inhibiting properties of bromocriptine. Off-label uses for bromocriptine include treating neuroleptic malignant syndrome, cocaine addiction, and cyclical mastalgia (pain in the breast). Bromocriptine is administered orally. It has a substantial hepatic first-pass effect; 28% of an oral dose is absorbed from the GI tract. Bromocriptine undergoes first-pass metabolism, and only a small percentage (6%) of the absorbed dose reaches the systemic circulation unchanged. Plasma half-life is 6 to 8 hours. Bromocriptine is highly bound (90% to 96%) to serum albumin and is metabolized in the liver before being excreted in the feces and urine. The most common adverse reactions include nausea, headache, dizziness, drowsiness, and fatigue, but serious reactions including seizures, stroke, hallucination, and syncope have also been reported. Contraindications include sensitivity to ergot alkaloids, severe ischemic heart disease, or peripheral vascular disease. This medication is pregnancy category B.

Pegvisomant

Pegvisomant (Somavert) is a genetically engineered GH receptor antagonist that has selective affinity for the GH receptor. It reduces IGF-1 levels and improves the clinical symptoms of GH excess. Pegvisomant is considered second-line treatment. It is given as a subcutaneous injection once a day. Pegvisomant is given cautiously to patients with pre-existing hepatic dysfunction, diabetes mellitus, and those over the age of 65 (clinical studies did not include enough subjects over 65 to determine whether they react differently to this medication than younger subjects). It is a pregnancy category B drug and is not approved for use in children. Patients receiving pegvisomant need baseline hepatic function tests prior to initiation of therapy and periodically thereafter because it may cause hepatotoxicity. Patients with a history of diabetes mellitus require determination of the baseline hemoglobin A_{1C} level and close monitoring of blood glucose levels. Adverse effects include injection site reactions, chest pain, hypertension, and peripheral edema.

• C Posterior Pituitary Hormone Regulators

The posterior pituitary stores two hormones that are produced in the hypothalamus: vasopressin (also known as ADH), which controls the concentration of body fluids; and oxytocin, which stimulates uterine contractions and causes the milk let-down reflex.

Desmopressin and vasopressin are synthetic analogues of the naturally occurring posterior pituitary hormone, vasopressin, that are used to treat DI. In pharmacologic doses, oxytocin can be used to induce or improve uterine contractions during labor. Oxytocin is discussed in depth in Chapter 52. The prototype posterior pituitary hormone is desmopressin acetate (see Table 50.5). It is the preferred treatment for most individuals with chronic DI because it has a longer duration of action, a more specific antidiuretic action, and an antidiuretic-to-pressor ratio significantly greater than that of vasopressin.

Nursing Management of the Patient Receiving P Desmopressin

Core Drug Knowledge

Pharmacotherapeutics

Desmopressin (DDAVP, Stimate, Minirin) may be administered intranasally, orally, or parenterally (IV or SC route) to manage central DI and for temporary polyuria and polydipsia following surgery in the pituitary region or head trauma. Primary nocturnal enuresis and episodes of spontaneous or trauma-induced bleeding are also effectively managed with intranasal desmopressin. Parenteral desmopressin maintains homeostasis in hemophilia A and von Willebrand disease (type I). It is ineffective for treating nephrogenic DI.

An off-label use for intranasal desmopressin is treating chronic autonomic failure characterized by nocturnal polyuria, morning postural hypotension, and overnight weight loss. Individualized dosage is necessary to maintain normal urine volume.

Pharmacokinetics

Desmopressin provides prompt onset of antidiuretic action with a long duration after administration because it has biphasic half-lives of 7.8 and 75.5 minutes for the fast and slow phases, respectively. The injectable form has an antidiuretic effect 10 times that of an equivalent dose of intranasal desmopressin. The half-life of the nasal spray is approximately 3.5 hours. Plasma concentrations of the nasal spray are highest 40 to 45 minutes after dosing. Desmopressin is metabolized rapidly by the liver and excreted by the kidneys.

Pharmacodynamics

The naturally occurring posterior pituitary hormone, vasopressin (ADH), and its synthetic analogue (desmopressin) interact with V1 and V2 receptors. V1 receptors have a pressor response, whereas V2 receptors have both an antidiuretic and hemostatic response. General vasoconstriction by smooth muscle contraction of most blood vessels occurs with the binding of the V1 receptors. At higher concentrations, ADH interacts with these receptors. This vasoconstriction is marked in the portal vessels, somewhat less in cerebral, coronary, peripheral, and pulmonary vessels, and slightly in intrahepatic vessels. GI motility and tone are also enhanced. V2 receptors are found on renal tubule cells. They mediate antidiuresis by stimulating the increase of water permeability and resorption in the renal collecting tubules. Release of and increase in circulating levels of factor VIII and von Willebrand factor occur with the binding of the V2 receptors. These proteins are involved in blood coagulation.

Contraindications and Precautions

The only contraindication to desmopressin use is hypersensitivity. Intranasal delivery may be inappropriate if the patient has an impaired level of consciousness. Use with caution in patients with coronary artery insufficiency or those who are hypertensive because high intranasal doses of desmopressin may elevate the blood pressure slightly. Caution should also be used in patients who are predisposed to thrombus formation, because of reports of thrombotic events, such as thrombosis, acute cerebrovascular thrombosis, or myocardial infarction (MI), although such reports are rare. Use with caution in patients with conditions associated with fluid and electrolyte imbalance, such as cystic fibrosis or renal or cardiovascular diseases, because these patients are especially prone to hyponatremia. When administered to either pediatric or geriatric individuals, fluid intake should be adjusted downward to limit the risk of hyponatremia and water intoxication.

Desmopressin is in pregnancy category B.

Adverse Effects

Most adverse effects of desmopressin are mediated through the V1 receptor acting on vascular and GI smooth muscle. Adverse reactions are mild and infrequent and are often resolved with dosage reduction. Possible reactions for intranasal or parenteral administration include mild abdominal pain and cramps, transient headache, nasal congestion, nausea, rhinitis, and facial flushing. Injection of desmopressin is associated with local erythema, burning, pain, or swelling. Changes in blood pressure (either a slight elevation or a transient fall) with a compensatory heart rate increase have also been reported infrequently. Oral administration of tablets for 12 to 44 months has shown a transient increase in aspartate aminotransferase (AST); however, the elevated AST returned to normal range despite continued use of the medication. The major V2 receptor–mediated adverse effect is water intoxication. Rare severe allergic reactions have been reported with desmopressin.

Drug Interactions

Although desmopressin pressor activity is very low, large intranasal or parenteral doses (greater than 0.3 mcg/kg) should be used cautiously with other pressor agents because of the potential for additive or synergistic effects. Carbamazepine, chlorpromazine, and nonsteroidal anti-inflammatory drugs (NSAIDs) enhance the antidiuretic response to vasopressin; thus, these drugs may potentiate the effects of desmopressin.

Assessment of Relevant Core Patient Variables

Health Status

Assess for pre-existing health conditions that require cautious use of desmopressin. Perform a baseline assessment, including measurements of weight, serum and urine osmolality, and serum sodium to allow determination of the effectiveness of the drug. Careful monitoring for cardiac reactions during desmopressin treatment is also important. Posterior pituitary agonists should be used with caution in patients with vascular disease, especially coronary artery disease, because changes in blood pressure can occur. Desmopressin should also be used cautiously in patients with conditions associated with fluid and electrolyte imbalances, such as cystic fibrosis, because these patients are prone to hyponatremia and water intoxication while taking this drug. Early signs include confusion, drowsiness, listlessness, and headache.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding. Desmopressin is a pregnancy category B medication. Although there are several publications describing the use of desmopressin to manage diabetes insipidus during pregnancy, no adequate and well-controlled studies have determined its safety and efficacy for use during pregnancy and lactation. It is unknown whether this drug is excreted in human milk. Thus, use in pregnancy and lactation should occur only when the potential benefits outweigh the potential hazards to the fetus or infant.

Clinical trials have demonstrated that desmopressin is an effective agent in both adults and children and has few side effects. Safety and efficacy of parenteral desmopressin in children (less than 12 years of age) or intranasal desmopressin in infants (less than 3 months of age) have not been established. Infants and children require careful fluid intake restriction to prevent possible hyponatremia and water intoxication, which can cause seizures.

Lifestyle, Diet, and Habits and Environment

Assess the patient's lifestyle in terms of work, rest patterns, leisure activities, and use of social or recreational drugs. Decreased plasma volume, pain, stress, sleep, exercise, and use of certain drugs (e.g., barbiturates, nicotine, morphine, and vincristine) are all factors that stimulate the secretion of ADH.

Nursing Diagnoses and Outcomes

- Risk for Fluid Volume Excess related to administration of desmopressin, secondary to diabetes insipidus
  Desired outcome: *The patient will not demonstrate signs and symptoms of water intoxication and will maintain urine specific gravity within a normal range.*
- Risk for Ineffective Therapeutic Regimen Management related to lack of knowledge of diabetes insipidus, disease management, and signs and symptoms of complications
  Desired outcome: *The patient will describe the disease process, causes, and factors contributing to symptoms and the regimen for disease or symptom control, relate intent to practice health behaviors needed or desired to control disease and prevent complications, and report less anxiety from fear of the unknown and loss of control.*

Planning and Intervention

Maximizing Therapeutic Effects

Establish baseline values for weight, blood pressure, electrolytes, and urine specific gravity. Individualize the dosage of desmopressin according to the diurnal pattern of water elimination, control of nocturia, and adequate duration of sleep. During long-term therapy, periodically assess the condition of nasal passages. Inappropriate administration may lead to nasal ulceration and, as a consequence, subsequent administered doses may be inadequate.

Protect ADH solutions from agitation and temperature extremes (excessive heat or freezing). To maintain potency, it is important to refrigerate nasal and parenteral solutions of desmopressin.

Minimizing Adverse Effects

Assess the patient for pre-existing cardiovascular or renal disorders and monitor patients carefully for cardiac reactions from desmopressin. The very young and elderly require careful fluid intake restriction to prevent possible water intoxication and hyponatremia. Limit fluid intake 1 hour before and 8 hours after the dose. Desmopressin therapy should be temporarily interrupted during acute illness, febrile episodes, hot days and other conditions that require increased water intake.

When administering the drug by IV infusion, ensure patency of venous access, preferably in a large vein, and use an infusion-control device. This precaution decreases the chance of extravasation.

Providing Patient and Family Education

- Provide information about antidiuretic drugs, including action, use, adverse effects, and drug interactions that may occur. Emphasize to patients and families that sudden changes in weight, pulse rate, and blood pressure may indicate serious fluid imbalance.
- Alcohol can alter the therapeutic response to desmopressin. Caution patients against consuming alcohol during therapy. Many over-the-counter (OTC) products contain alcohol, so it is important to discuss the need to read drug labels before taking any OTC medications. Also, advise patients to carry appropriate medical identification to alert medical personnel in case of an emergency.
- Review with patients and families or caregivers the proper administration technique for nasally administered dosage forms. Intranasal preparations are administered through a flexible nasal catheter that measures the appropriate dose. After the drug is drawn into the catheter, one end is placed in the mouth and the other end in the nose. Patients should then blow into the catheter to deposit the drug into the nasal passageways. Proper technique lessens nasal irritation that may occur. Nasal congestion may impair absorption when desmopressin is administered intranasally.
- Stress the importance of taking desmopressin as directed and to consult the health care provider before discontinuing its use.

Ongoing Assessment and Evaluation

Instruct patients taking desmopressin to monitor urine specific gravity and intake and output as well as to weigh themselves daily to determine drug efficacy. Decreased urine output and thirst are signs of therapeutic drug response. If desmopressin is being used for abdominal distention, it is important to assess bowel sounds and the presence or absence of flatus. During prolonged therapy, electrocardiographic (ECG) studies should be monitored as well as fluid and electrolyte status.

MEMORY CHIP

P Desmopressin

- Synthetic analogue of human ADH; for treatment of neurogenic diabetes insipidus
- Major contraindication: presence of hemophilia A with factor VIII levels 5% or less
- Most common adverse effects: localized erythema with intranasal administration; burning pain with parenteral injection
- **Life span alert: Infants, children, and the elderly require careful fluid intake restriction to prevent possible hypo-natremia and water intoxication.**
- Maximizing therapeutic effects: Keep solutions (nasal, parenteral) refrigerated.
- Minimizing adverse effects: Monitor urine volume/osmolality, plasma osmolality; patients with conditions associated with fluid/electrolyte imbalances are prone to hyponatremia.
- Most important patient education: Inform patients that medication bottle accurately delivers 25 to 50 doses and any solution remaining after 25 to 50 doses should be discarded because the amount delivered thereafter may be substantially less than prescribed. The remaining solution should not be transferred to another bottle.

Drug Closely Related to P Desmopressin

Vasopressin

Synthetic vasopressin (Pitressin) is effective for treating DI resulting from a partial or complete deficiency in production and secretion of posterior pituitary ADH. It also may be used to prevent or treat postoperative abdominal distention and to facilitate abdominal radiography. According to the American Heart Association Advanced Cardiac Life Support Guidelines (AHA, 2005) a single dose of vasopressin (40 units IV) may be used to replace the first or second dose of epinephrine in the management of pulseless ventricular tachycardia or ventricular fibrillation.

An off-label use of vasopressin is managing bleeding esophageal varices. Following SC, IM, or IV injection, synthetic vasopressin aqueous solution has a plasma half-life of 10 to 20 minutes. The duration of antidiuretic activity is 2 to 8 hours. Vasopressin is metabolized rapidly by the liver and is excreted by the kidneys.

Use of vasopressin is contraindicated in patients with hypersensitivity or chronic nephritis with increased levels of blood urea nitrogen (BUN). Vasopressin is in pregnancy category C. Its effect on lactation is unknown. The literature reports that vasopressin, when used during pregnancy in doses sufficient for an antidiuretic effect, is not likely to produce tonic uterine contractions that could be harmful to the fetus or threaten the continuation of the pregnancy.

THYROID DRUGS

Thyroid hormones influence essentially every organ system in the body. They have numerous biological effects, including stimulation of the basal metabolic rate, which affects protein, carbohydrate, and lipid metabolism. Thyroid hormones are essential for normal growth and development throughout the entire life cycle. Like most endocrine glands, the thyroid glands can secrete too much hormone (hyperthyroidism) or too little hormone (hypothyroidism).

Thyroid disorders involve an alteration in the quantity of thyroid hormone secretion, enlargement of the thyroid gland (goiter), or both and are classified as either hyperthyroidism or hypothyroidism.

The prevalences of hyperthyroidism (thyrotoxicosis) and hypothyroidism are similar—approximately 2% of women and 0.2% of men are affected. Increasing age is associated with an increase in the incidence of hypothyroidism. Six percent of women and 2.5% of men older than 60 years have TSH levels greater than twice the upper limit of normal. Hypothyroidism may be mistaken for the normal aging process.

• C Thyroid Hormones

The only treatment for hypothyroidism is lifelong replacement of thyroid hormones that are adequate to meet the individual's metabolic needs. A number of pharmacologic preparations of endogenous thyroid hormone, including levothyroxine, desiccated thyroid, liothyronine sodium, and liotrix can completely correct hypothyroidism. The preferred treatment, and prototype drug, for hypothyroidism is levothyroxine (T_4; Levothroid, Synthroid), and it is used almost universally. Table 50.7 presents a summary of selected thyroid hormones.

Nursing Management of the Patient Receiving P Levothyroxine

Core Drug Knowledge

Pharmacotherapeutics

Levothyroxine is used as replacement therapy in hypothyroidism of any etiology, except transient hypothyroidism during

TABLE 50.7 Summary of Selected C Thyroid Hormones

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P levothyroxine (T_4 L-thyroxine; Synthroid, Levothroid)	Replacement therapy for hypothyroidism, including cretinism	*Adult:* PO, 50–200 mcg/d *Child:* PO, 0–6 mo, 8–10 mcg/kg/d; 6–12 mo, 6–8 mcg/ kg/d; 1–5 y, 5–6 mcg/kg/d; 6–12 y, 4–5 mcg/kg/d; >12 y, 2–3 mcg/kg/d	*Onset:* Slow *Duration:* 3 wk $t_{1/2}$: 2–7 d
	Emergency treatment of myxedema coma	*Adult:* IV, 400 mcg initially	
liothyronine (T3; Cytomel, Triostat)	Same as above	*Adult*: PO, 25 mcg/d; increase q1–2wk by 12.5–25 mcg; maintenance, 25–75 mcg/d *Child (and elderly adult)*: PO, 5–50 mcg/d	*Onset*: Varies *Duration*: 3–4 d $t_{1/2}$: 1–2 d
liotrix (T4 and T3; Thyrolar)	Same as above	*Adult*: PO, 15–30 mg/d; increase q2wk to maximum of 60–120 mg/d	*Onset*: Slow *Duration*: 3 wk $t_{1/2}$: 2–7 d
thyroid desiccated (T3 and T4; Armour Thyroid)	Same as above	*Adult*: PO, 300 mg/d initially; increase by 15 mg q2–3wk; maintenance, 60–120 mg/d *Child*: PO, 1.2–6 mg/kg/d, depending on age	*Onset*: Slow *Duration*: 3 wk $t_{1/2}$: 2–7 d

the acute phase of subacute thyroiditis. It also can be used for pituitary suppression of TSH in treating and preventing euthyroid goiter, in managing hypothyroidism secondary to thyroid cancer, and in treating **myxedema coma.** Levothyroxine also may be used in conjunction with antithyroid drugs to treat thyrotoxicosis and to prevent goiter formation, hypothyroidism, and thyrotoxicosis during pregnancy.

Pharmacokinetics

The absorption of levothyroxine from the GI tract varies from 48% to 79% of the administered dose. Absorption is increased during fasting states. Excessive fecal loss has been found with malabsorption syndromes. Levothyroxine must be converted to T_3 for its clinical effects. When the drug is taken orally, the onset of effect occurs very slowly, with the peak effect occurring in 1 to 3 weeks. When the drug is administered intravenously to treat myxedema, the onset of effect is 6 to 8 hours, with a peak effect in 24 to 48 hours. Levothyroxine has a half-life of 6 to 7 days. Levothyroxine is metabolized in the liver and excreted in the bile. It crosses the placenta and enters breast milk.

Pharmacodynamics

Levothyroxine acts as a replacement for natural thyroid hormone. Increased oxygen consumption, respiration, heart rate, growth and maturation, and speed of fat, protein, and carbohydrate metabolism occur secondary to increases in the basal metabolic rate.

Contraindications and Precautions

Contraindications include hypersensitivity, thyrotoxicosis uncomplicated by hypothyroidism, acute MI complicated by hypothyroidism or in patients with uncorrected adrenal insufficiency. The metabolic stimulating effects of levothyroxine could worsen the MI, cause arrhythmias, and lead to further complications and thyroid hormones may precipitate an acute adrenal crisis.

Levothyroxine is a pregnancy category A drug. It is safe for maintaining and regulating thyroid function during pregnancy but should be used with caution in lactating women because it crosses into breast milk and can affect the infant's thyroid-pituitary balance. Levothyroxine should also be used with caution in patients with coronary artery disease or coronary insufficiency because the resulting increase in basal metabolic rate may aggravate angina pectoris caused by the increased myocardial oxygen demand. Use of levothyroxine in cardiovascular disease should be initiated at a low dosage and titrated upward gradually. Its use in patients with concomitant DI, diabetes mellitus, or adrenal insufficiency (Addison disease) exacerbates the intensity of their symptoms. An appropriate adjustment in therapy for these concomitant diseases is necessary. For individuals with myxedema, it is necessary to begin treatment at low doses with gradual increases, because they are particularly sensitive to thyroid preparations.

Adverse Effects

Adverse effects observed with the use of levothyroxine are related to therapeutic overdosage. These include hypertension, tachycardia, arrhythmias, anxiety, headache, nervousness, GI irritation, sweating, and heat intolerance. Long-term use in women has been shown to lead to increased bone resorption and decreased bone density. Patients with sensitivity to lactose may show intolerance because lactose is used in the manufacture of this product. There is no well-documented evidence of allergic reactions to thyroid hormones. In children, partial hair loss may occur in the first few months of therapy. There is a black box warning that levothyroxine is not appropriate for obesity or weight loss. Large doses may cause serious or life-threatening toxicity especially when given concurrently with sympathomimetic or anorectic drugs.

Drug Interactions

Levothyroxine interacts with many drugs. Many drugs interfere with its absorption, resulting in decreased serum concentration. Coadministration with levothyroxine should be separated by several hours. In addition, many drugs increase the metabolism of levothyroxine, decreasing the efficacy of levothyroxine. It is necessary to assess the patient for signs of hypothyroidism and discuss potential dosage adjustments with the health care provider. Table 50.8 lists the drugs that interact with levothyroxine.

Assessment of Relevant Core Patient Variables

Health Status

Before administering levothyroxine, review the patient's record to determine whether the drug can be administered safely. Perform a baseline physical examination to monitor the effects of the drug. Skin color, temperature, texture, and presence of any lesions should be noted to monitor for any reactions and to assess thyroid hormone effectiveness. Note muscle tone, weight, temperature, blood pressure, pulse, and respirations to assess for the desired therapeutic effects of levothyroxine and to monitor for toxic or adverse effects. Thyroid function tests, ECGs, and serum laboratory analyses must be completed to monitor appropriate dosage and response to the drug.

Individuals with known cardiac problems should begin drug therapy with smaller doses of thyroid hormone replacement, because of the cardiac stimulant effect of levothyroxine. Carefully monitor the individual for angina and cardiac arrhythmias.

Life Span and Gender

Determine the patient's age before administering levothyroxine. Geriatric patients should start with a low dosage of thyroid hormone replacement. Gradual increases prevent serious cardiovascular and neurologic adverse effects. If the pulse rate is greater than 100 bpm, withhold the levothyroxine dose. Closely monitor elderly patients who are also receiving beta blockers or digitalis glycosides, because of the increased risk of toxic effects. In both premenopausal and postmenopausal women, long-term levothyroxine therapy has been associated with decreased

TABLE 50.8 Agents That Interact with P Levothyroxine

Interactants	Effect and Significance	Nursing Management
beta-adrenergic blockers	Actions of beta blockers possibly blocked as patient returns to euthyroid state	Assess for decreased beta-blocking action. Discuss dosage alteration of beta blockers with health care provider.
cholestyramine	Cholestyramine binds with thyroid hormones in gut, decreasing its absorption.	Administer 4–6 h apart. Monitor TSH when patients start or stop cholestyramine therapy.
conjugated estrogens	Serum-free thyroxine concentration may be decreased, increasing serum thyrotropin concentration and need for levothyroxine.	Obtain serum thyrotropin concentrations ~12 wk after starting estrogen.
digitalis glycosides	Reduced serum levels of digitalis and decreased therapeutic effects	Evaluate serum digoxin levels. Discuss dosage alteration of digoxin with health care provider.
HMG-CoA reductase inhibitors	HMG-CoA reductase inhibitors may increase or decrease efficacy of thyroid hormones.	Monitor TSH. Monitor for signs of hypo- or hyperthyroidism. Discuss dosage alteration of thyroid hormones with health care provider.
Imatinib	Imatinib may increase metabolism of thyroid hormones.	Monitor TSH. Monitor for signs of hypothyroidism. Discuss dosage alteration of thyroid hormones with health care provider.
iron salts	Iron salts may decrease the absorption of thyroid hormones.	Administer 12 h apart. Monitor TSH. Monitor for signs of hypothyroidism.
protease inhibitors	Protease inhibitors decrease glucuronosyl transferase activity of levothyroxine, resulting in increased T_3/T_4 levels.	Monitor patients with PI therapy for signs of hyperthyroidism. Discuss dosage alteration of thyroid hormones with health care provider.
raloxifene	Raloxifene may decrease absorption of thyroid hormones.	Monitor TSH. Monitor for signs of hypothyroidism. Discuss dosage alteration of thyroid hormones with health care provider.
rifamycins	Rifamycins may increase thyroid metabolism, resulting in a hypothyroid state.	Monitor TSH when patients start or stop rifamycin therapy. Discuss dosage alteration of thyroid hormones with health care provider.
sucralfate	Sucralfate decreases the absorption of levothyroxine.	Administer at least 8 h apart. Monitor TSH. Monitor for signs of hypothyroidism.
theophylline	Hypothyroid states induce decreased theophylline clearance, and hyperthyroid states induce decreased theophylline clearance.	Monitor TSH. Euthyroid does not affect theophylline clearance. Discuss dosage alteration of theophylline with health care provider.
warfarin	Thyroid hormones increase anticoagulant effect of warfarin. The mechanism is unknown.	Monitor PT/INR closely. Monitor for bruising or bleeding. Discuss dosage alteration of warfarin with health care provider.

bone density in the spine and hip. A basal bone density measurement and monitoring for osteoporosis would be beneficial.

Monitor children maintained on levothyroxine for growth and development and for toxic effects. Additionally, adjust the dosage as the child grows.

Because pregnant patients who are receiving thyroid hormone replacement may require a dosage increase during pregnancy, assess the patient for pregnancy. Thyroid hormone deficiency may have an adverse effect on fetal nervous system development and on the outcome of the pregnancy. Levothyroxine is in pregnancy category A.

Lifestyle, Diet, and Habits

Assess the patient's ability to adapt to a long-term drug regimen. Patients maintained on levothyroxine most often take the drug for life. Levothyroxine is best taken as a single

CRITICAL THINKING SCENARIO

LEVOTHYROXINE AND WEIGHT CONTROL

A woman comes to the clinic and asks for a prescription for thyroid hormone. She has tried multiple diets without success and is convinced that she must have a "glandular" problem. She tells you that she read that thyroid hormone is an effective way to lose weight because it increases your metabolism, and she wants to try it. After obtaining thyroid function tests, it is determined that this patient has normal thyroid function.

1. Think about the problems that could occur if thyroid replacement hormone is given to a euthyroid patient. Outline the normal controls of thyroid activity, and predict what could happen.
2. Develop a patient education tool to explain this situation to the patient, and propose other ways of dealing with her weight problem.

daily dose before breakfast. Assist the patient to establish a routine for taking the medication.

Assess the patient's intake of grapefruit juice. Excessive grapefruit juice may delay the absorption of levothyroxine.

Caution the patient to avoid changing from one brand of this drug to another without first consulting the pharmacist or prescriber. Products manufactured by different companies may not be equally effective, and bioavailability differences have occurred with different preparations of levothyroxine.

Environment

Know the environment where the drug will be administered. Most often, levothyroxine is taken at home as an oral drug. IV levothyroxine is administered only for myxedema coma. It is used for short-term therapy until the patient is able to take the oral drug.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: More than Body Requirements, related to dietary intake in excess of metabolic demands secondary to hypothyroidism
  Desired outcome: *The patient will maintain normal body weight, describe reasons why weight gain may occur, discuss nutritional needs related to age, lifestyle, and diagnosis, and discuss the effects of exercise and diet on weight control.*
- Risk for Injury related to adverse drug reactions
  Desired outcome: *The patient will not experience adverse reactions to thyroid hormone replacement.*
- Risk for Injury related to pre-existing health status that requires cautious use of a thyroid agent
  Desired outcome: *The patient will not experience complications of pre-existing health conditions linked to the prescribed thyroid hormone replacement therapy. Such complications include coronary artery disease, angina, myocardial infarction, and hypertension secondary to increased metabolic demands on the heart, and acute adrenal crisis secondary to increased tissue demand for adrenal hormones.*
- Knowledge Deficit related to thyroid dysfunction and the necessity for thyroid hormone replacement
  Desired outcome: *The patient and family will express an accurate understanding of the teaching regarding the disease process and the prescribed thyroid hormone replacement therapy. An example includes avoidance of myxedema coma from interrupted drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Replacement therapy is a lifelong occurrence. Levothyroxine is absorbed best when taken once a day on an empty stomach, preferably before breakfast. During drug therapy, monitor cardiovascular response and serum thyroid function to determine the appropriate dosage and response to levothyroxine. Monitor children regularly to assess the need to change dosage to allow for appropriate growth and development. If the patient is on other medications, it is important to monitor the response to these drugs and to levothyroxine, especially as the patient achieves a euthyroid state. Offer support and encouragement to deal with the need for lifelong therapy.

Minimizing Adverse Effects

Young adults without evidence of coronary artery disease can begin a full replacement dose of levothyroxine. Older individuals and those with (or at risk for) coronary artery disease, atrial arrhythmias, or both should begin with a low dose (e.g., 25 to 50 mcg/d), which can be slowly titrated to the target dosage.

Check adrenal function in hypothyroid patients because some of these individuals also have adrenal insufficiency. Without appropriate glucocorticoid replacement, thyroid administration in these individuals can precipitate an acute adrenal crisis because thyroid agents increase tissue demand for adrenal hormones.

Thyroid agents may potentiate the hypo-prothrombinemic effect of oral anticoagulants by increasing the catabolism of vitamin K. Administering thyroid agents to diabetic patients may increase the dosage requirement of insulin or oral agent.

Providing Patient and Family Education

- Explain to patients and their families that this drug is a hormone that is being used to replace the thyroid hormone that their body is not able to produce. Tell them that this hormone is responsible for regulating the body's metabolism. Explain to patients that they will most likely need to take levothyroxine for life and that it should be taken every day, preferably in the morning before breakfast.
- Explain that although this drug causes few adverse effects, patients should report any increase in the symptoms of thyroid dysfunction, such as weight changes,

nervousness, skin changes, lethargy, and sleeplessness, or any skin rash or lesions.
- Advise patients to avoid OTC drugs and to check with the prescriber if they feel that an OTC medication is needed. Many OTC drugs contain ingredients that interfere with thyroid function, and patients may want to obtain a medical identification tag or card so that people taking care of them in an emergency are aware that they are taking a thyroid replacement drug.
- Educate patients to keep this drug out of the reach of children.
- Stress the importance of notifying the health care provider if manifestations of hyperthyroidism (e.g., headache, nervousness, chest pain, palpitations, increased pulse rate, diarrhea, diaphoresis, or heat intolerance) occur.

Ongoing Assessment and Evaluation

In patients taking levothyroxine, monitor serum thyroid hormone levels periodically. As a patient reaches a euthyroid state, reassess the potential for drug interactions and the need to adjust the dosage of other drugs appropriately. It is important to monitor pulse rate and rhythm as well as respiratory rate to assess the effect of the thyroid hormone on these systems and the possible need for dosage adjustment. Medications are administered to the patient with hypothyroidism very cautiously because of altered metabolism and excretion and depressed metabolic rate and respiratory status.

Long-term use of levothyroxine may decrease hip and spine bone density in women. Measure bone density before beginning levothyroxine therapy to establish a baseline and then monitor it routinely.

Thyroid hormones may increase blood glucose levels, necessitating adjustment in doses of insulin or oral hypoglycemic agents for patients with diabetes. Patients with hypothyroidism have an increased susceptibility to all hypnotic and sedative agents, analgesics, and anesthetics. These drugs, even in small doses, may induce profound somnolence lasting far longer than anticipated. Respiratory depression is likely as a result of the decreased respiratory reserve and alveolar hypoventilation that occur with hypothyroidism.

As the patient moves from a hypothyroid to a euthyroid state, the body's response to many drugs may be altered. Closely monitor patients taking multiple drugs as they return to a euthyroid state and adjust dosages of the other drugs as needed. For example, the actions of some beta-adrenergic blockers may be impaired. Serum digitalis levels may be reduced, reducing the therapeutic effect of digitalis glycosides. Theophylline clearance is altered. Nursing management of drug therapy is considered effective if the patient adheres successfully to drug therapy, can recognize various signs and symptoms of hypothyroidism, and seeks appropriate attention from the health care team.

MEMORY CHIP

P Levothyroxine

- Synthetic thyroid hormone replacement
- Major contraindications: acute myocardial infarction, thyrotoxicosis; use cautiously in hypoadrenalism
- Most common adverse effects: symptoms of hyperthyroidism, alopecia with initial therapy (particularly in children)
- Maximizing therapeutic effects: Monitor drug response carefully at the start of therapy; administer oral drug as a single daily dose before breakfast.
- Minimizing adverse effects: Monitor cardiac response, as increased basal metabolic rate may exacerbate angina pectoris.
- Most important patient education: Have patient wear medical ID (tag or bracelet) to alert emergency medical personnel of drug therapy.
- **Black box warning: Not for use for obesity or weight loss.**

Drugs Closely Related to P Levothyroxine

Desiccated Thyroid

Desiccated thyroid (Armour Thyroid) is composed of desiccated (dried) animal thyroid glands. It is much less pure, stable, and predictable than synthetic preparations of thyroid hormone. The active thyroid hormones (T_4 and T_3) are available in their natural states and at their natural ratios. Although these preparations are the least expensive, their standardization by iodine content or bioassay is inexact. Optimal dosage is determined by the patient's clinical response and laboratory findings. Therapy is instituted using low doses, with increments that depend on cardiovascular status. The usual starting dose is 30 mg, with increments of 15 mg every 2 to 3 weeks. Patients with long-standing myxedema are started at a lower dose (15 mg/d), particularly if cardiovascular impairment is suspected. The drug dosage should be reduced if angina occurs.

Liothyronine Sodium

Liothyronine sodium (Cytomel [oral form]; Triostat [parenteral form]) is a synthetic form of the natural thyroid hormone T_3. It has the pharmacologic activities of the natural hormone. Its short duration of activity enables quick dosage adjustment and facilitates control of overdosage. Patients who are allergic to thyroid extract derived from pork or beef can be safely treated with this medication. Liothyronine injection is for IV use only and should be stored between 2°C and 8°C (36°F to 46°F).

Liotrix

Liotrix (Thyrolar) is a uniform mixture of synthetic T_4 and T_3 in a 4:1 ratio by weight. Optimal dosage is determined by patient's clinical response and laboratory findings.

• C Antithyroid Compunds

Hyperthyroidism is treated with thyroid-hormone antagonist drugs, surgery, or radioactive iodine. The purpose of treatment is to reduce the amount of functional thyroid tissue. The antithyroid agents used clinically to manage hyperthyroidism include methimazole, propylthiouracil, iodide or iodine solutions (Lugol solution), radioactive iodine (I-131), and propranolol. Methimazole (MMI) is the prototype antithyroid compound. Table 50.9 presents a summary of selected antithyroid agents.

Nursing Management of the Patient Receiving P Methimazole (MMI)

Core Drug Knowledge

Pharmacotherapeutics

MMI is used for palliative treatment of hyperthyroidism, as an adjunct in preparation for surgery (thyroidectomy) or radioactive iodine therapy, or to manage thyrotoxic crises. Additionally, if thyroidectomy is contraindicated or otherwise not advised, MMI is the drug of choice.

Pharmacokinetics

MMI is readily absorbed from the GI tract. Onset of action is slow, and it requires an average of 5.8 weeks to lower T_4 levels to normal. The half-life of MMI is 5 to 13 hours. It is metabolized in the liver and excreted in the urine. MMI is usually preferred over propylthiouracil (PTU), another thionamide, because it reverses hyperthyroidism more quickly and has fewer adverse effects. MMI can be administered in single or divided doses, whereas PTU must be given in three equal doses at approximately 8-hour intervals.

Pharmacodynamics

MMI inhibits the synthesis of thyroid hormones (T_4 and T_3); hence, new T_3 and T_4 are not produced. It neither inactivates existing thyroxine and triiodothyronine that are stored in the thyroid nor interferes with the effectiveness of thyroid hormones given as tablets or by injection. Some clinical evidence suggests that the thionamide drugs have immunosuppressant effects. Thus, they are beneficial for suppressing the immune-mediated hyperthyroidism of Graves disease.

Contraindications and Precautions

MMI is contraindicated with any known hypersensitivity to antithyroid drugs. The drug is in pregnancy category D. It is contraindicated during pregnancy and nursing because the drug crosses the placenta and is excreted in breast milk.

Adverse Effects

Most adverse effects are minor, but some major ones can occur. Up to 15% of people taking an antithyroid drug experience minor adverse effects. Both MMI and PTU can cause hives, itching, rash, fever, arthralgia, joint swelling, vertigo, drowsiness, nausea and vomiting, and altered taste sensation. The nausea and vomiting may depend on the amount of the drug ingested with each dose. For this reason, spreading large total daily doses out over the day may reduce these side effects. If adverse effects occur with one drug, frequently the same effects will occur if the patient switches to the other drug.

Major adverse effects include agranulocytosis, which affects only 0.2% to 0.5% of all people taking antithyroid medication. If this adverse effect occurs, it usually does so within the first 3 months of treatment. Agranulocytosis resolves within a few days when treatment is discontinued. Hepatotoxicity, aplastic anemia, and vasculitis are other rare complications. Most people recover fully when the drug is stopped.

Drug Interactions

A hyperthyroid state *increases* the pharmacologic effects of beta-blocking agents and theophylline. As MMI becomes

TABLE 50.9 Summary of Selected C Antithyroid Drugse

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P methimazole (Tapazole)	Treatment of hyperthyroidism Amelioration of hyperthyroidism before thyroidectomy, radioactive iodine	*Adult:* PO, 15 mg/d for mild hyperthyroidism; 30–40 mg/d for moderate hyperthyroidism; 60 mg/d for severe hypothyroidism *Child:* PO, 0.4 mg/kg/d; maintenance, 1/2 initial dose	*Onset:* 1 wk *Duration:* Weeks $t_{1/2}$: 5–13 h
propylthiouracil (PTU)	Treatment of hyperthyroidism Attain euthyroid state before thyroidectomy, radioactive iodine therapy	*Adult*: Initial dose, PO, 300–900 mg/d; maintenance, PO, 100–150 mg/d *Child*: PO, 6–10 y, 50–150 mg/d; ≥10 y, 150–300 mg/d; maintenance, based on response	*Onset*: 10–21 d *Duration*: Weeks $t_{1/2}$: 1–2 h
sodium iodide I-131 (Iodotope, Sodium iodide I-131 [therapeutic])	Treatment of hyperthyroidism, thyroid cancer	*Adult*: PO, hyperthyroidism, 4–10 mCi; thyroid cancer, 50 mCi; then 100–150 mCi as needed	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 7.61 d
strong iodine solution (Lugol solution, Thyro-Block)	Treatment of hyperthyroidism	*Adult*: PO, 2–6 drops tid for 10 d before surgery	*Onset*: 24–48 h *Duration*: 6 wk $t_{1/2}$: Unknown

effective and the patient becomes more euthyroid, these drugs have a greater effect on the body, necessitating a decrease in their dosage. A hyperthyroid state *decreases* the vitamin K–dependent clotting factors. As the patient becomes more euthyroid, the clotting factors increase and the dose of warfarin is less effective. In rare circumstances, the efficacy of warfarin is increased by an unknown mechanism and the patient has an increased risk of bleeding. It is necessary to monitor prothrombin time/international normalized ratio (PT/INR) levels closely whenever MMI is administered to a patient taking warfarin. Conversely, a hypothyroid state *increases* serum digoxin levels. As the patient becomes more euthyroid, the risk of digoxin toxicity increases.

Assessment of Relevant Core Patient Variables

Health Status

Before administering MMI, review the patient's record to determine whether the drug can be administered safely. Perform a physical examination before starting drug therapy to establish a baseline for monitoring the drug's effects. Note skin color, temperature, texture, and presence of any lesions to assess for allergic reactions and thyroid hormone effectiveness. It also is important to review liver and kidney function tests, because MMI is metabolized in the liver and excreted in the urine. Perform a complete blood count (CBC) with differential as a baseline for potential hematologic changes that can occur during therapy. In addition, perform baseline thyroid function tests to monitor the effect of the drug on thyroid function.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding. Antithyroid agents are in pregnancy category D. They readily cross the placenta and can induce goiter and cretinism in the developing fetus. Fortunately, in many pregnant women, thyroid dysfunction decreases as the pregnancy proceeds. This decrease enables reduction of the thionamide dose. If thionamide therapy is necessary during pregnancy, PTU is preferred because it crosses the placenta to a lesser extent than MMI. Patients receiving antithyroid preparations during the postpartum period should use formula preparations to feed their infants.

Note the patient's age before administering MMI. Hepatotoxicity has occurred in some pediatric patients. Monitor children closely to ensure that thyroid function is maintained and that growth and development proceed normally. Dosage adjustment may be required with prolonged use.

Lifestyle, Diet, and Habits

Assess the patient's ability to adapt to a long-term drug regimen because patients taking MMI may require prolonged therapy to achieve the full effect. The drug can be taken once daily or in divided doses every 8 hours around the clock. Help the patient establish a schedule that causes the least interference with the patient's sleep pattern. Drowsiness and vertigo are potential adverse effects of this drug. Therefore, caution the patient to avoid driving or performing tasks that require precision and alertness if these effects occur.

Environment

Know the environment where MMI will be administered. It is usually given in the home. It is necessary to teach patients the importance of taking the drug as prescribed and the necessity of making special arrangements in their schedules and routines to facilitate this need.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to increased metabolic demands secondary to hypothyroidism
  Desired outcome: *The patient will describe reasons why weight loss may occur and discuss nutritional needs related to age, lifestyle, and diagnosis.*
- Risk for Injury related to blood dyscrasias (e.g., granulocytosis) or to drowsiness and vertigo secondary to adverse reactions of PTU
  Desired outcome: *The patient will demonstrate no adverse hematologic reactions to thyroid therapy (e.g., hypoprothrombinemia or bleeding), identify factors that increase the risk from injury (e.g., from CNS side effects), and relate intentions to practice and use safety measures to prevent injury.*
- Nonadherence related to long-term use of the antithyroid agent and need to take the prescribed medication frequently
  Desired outcome: *The patient will describe the reasons for the therapeutic regimen, identify barriers to adherence, and identify the behaviors that must change to facilitate adherence.*

Planning and Intervention

Maximizing Therapeutic Effects

If the patient is unable to take MMI once daily, ensure that the drug is being administered appropriately (three equal doses at 8-hour intervals) to maintain serum concentration. Encourage fluid intake of 3 to 4 L/day unless contraindicated. MMI can be given with meals to minimize GI irritation.

Minimizing Adverse Effects

During drug therapy, arrange for periodic blood tests to monitor for hematologic and thyroid functions. Also, encourage frequent, small meals to alleviate GI symptoms and to help maintain nutrition while the patient is taking MMI. Encourage the patient to avoid driving or performing hazardous tasks if drowsiness or vertigo occurs. Monitor the patient's bone marrow function. It is important to obtain a baseline assessment of the CBC with a differential. Emphasize the importance of regular follow-up care and monitoring of bone marrow, CBC, and thyroid functions at intervals determined by the physician.

Providing Patient and Family Education

- Explain to patients and their families that this agent is an antithyroid drug that blocks the production and activity of the thyroid hormone responsible for regulating the body's metabolism, that is, the speed with which the body's cells burn energy. This drug will most likely have to be taken for a prolonged time to achieve the desired effect.
- If the drug is taken in divided doses, instruct patients to take them every 8 hours around the clock. Work with patients and families to establish a schedule that causes the least interference with sleep.
- Adverse effects of this drug include vertigo and drowsiness. Advise patients to avoid driving or performing hazardous tasks while taking this drug and to take extra precautions to prevent falls and injuries.
- Other adverse effects include nausea, vomiting, and epigastric distress. Encourage patients to eat small, frequent meals to maintain nutrition and alleviate some of the discomfort associated with these adverse effects.
- Advise patients that they will have periodic blood tests while taking this drug to monitor its effectiveness and possible adverse effects. Stress the need to report fever, sore throat, unusual bleeding or bruising, and headache to the health care team.
- Review the signs and symptoms of hepatotoxicity with patients. Assure them this adverse effect is rare but needs to be reported if any symptoms occur.
- Instruct patients to keep this drug, and all other medications, out of the reach of children.

Ongoing Assessment and Evaluation

Monitor serum thyroid hormone levels periodically to evaluate the effectiveness of MMI and to assess the need for replacement thyroid hormone because the thyroid gland is suppressed. With continued antithyroid therapy, an insidious goitrogenic hypothyroidism may appear. Alert the patient to watch for signs of this adverse effect, such as decreased cardiac rate, intolerance to cold, and weight gain. Thyroid function tests, used to evaluate drug therapy, should be measured routinely (every 4 to 6 weeks). Periodically review the signs of hypothyroidism and hyperthyroidism with the patient and significant others. Review the signs and symptoms of hepatotoxicity and the importance of contacting the health care provider if any symptoms occur. As the patient reaches a euthyroid state, assess the need for dosage adjustment with drugs affected by metabolic rate and activity. Therapy is considered successful when normal thyroid status is maintained, and the patient can explain and demonstrate self-monitoring techniques.

Drug Closely Related to P Methimazole

Propylthiouracil (PTU) is a thionamide with characteristics similar to those of MMI. Adverse effects are also similar and include pruritus, rash, urticaria, arthritis, fever, abnormal taste, nausea, and vomiting. Serious complications, such as agranulocytosis, are dose dependent. Serum aminotransferase concentrations increase transiently in up to one third of patients taking PTU. Well-documented hepatotoxicity is equally divided between PTU and MMI.

MEMORY CHIP

P Methimazole (MMI)

- Inhibits the synthesis of thyroid hormones; antithyroid agent
- Major contraindications: sensitivity to the drug; breast-feeding, because the drug is excreted in breast milk
- Most common adverse effects: GI (nausea, vomiting, epigastric pain), itching, rash, hives, and arthralgia
- Most serious adverse effects: agranulocytosis, liver damage, aplastic anemia, and vasculitis. Most adverse effects resolve spontaneously with discontinuation of the drug.
- Maximizing therapeutic effects: Administer drug around the clock at 8-hour intervals, although it can be given in a single daily dose.
- Minimizing adverse effects: periodic blood tests to assess bone marrow function and bleeding tendencies
- Most important patient education: Drug must be taken for a prolonged period (months) to achieve the desired effects; report fever, sore throat, unusual bleeding or bruising, and malaise.

Drugs Significantly Different From P Methimazole

Iodide or Iodine Solutions (Lugol Solution, Thyro-Block (tablets))

Iodine is the oldest of the antithyroid drugs. Low doses of iodine are needed in the body to form thyroid hormone. However, high doses tend to inhibit thyroid function. A hyperfunctioning thyroid gland responds to iodine by promptly inhibiting the release of hormone. Iodine helps firm the thyroid gland by reducing its size and vascularity. This effect helps prevent postoperative hemorrhage and the surgical complication of thyroid storm.

Potassium iodide, or occasionally strong iodine solution, is used preoperatively to reduce the vascularity of the gland before thyroidectomy and, alone or in combination with the beta blocker, propranolol, to manage thyrotoxic crisis (thyroid storm), usually in conjunction with other antithyroid agents (e.g., MMI). When used preoperatively, potassium iodide is administered 10 to 14 days before surgery.

Chronic toxicity may occur when potassium iodide is given in large doses or over a long duration. Chronic toxicity is usually dose dependent and is manifested as a metallic taste, burning in the mouth and throat, sore teeth and gums, increased salivation, and eye irritation with swollen eyelids. Gastric irritation is common, and diarrhea may occur. When the drug is discontinued, the clinical manifestations of toxicity generally subside spontaneously within a few days.

Hypersensitivity reactions to iodides may cause angioedema, cutaneous and mucosal hemorrhage, and clinical signs (e.g., fever, arthralgia, lymphadenopathy, and eosinophilia) resembling serum sickness.

Prolonged use or excessive doses of iodides may result in thyroid gland hyperplasia, thyroid adenoma, goiter, and severe hypothyroidism.

Concomitant use of lithium salts, other iodides, or antithyroid agents and potassium iodide may result in an additive or synergistic hypothyroid effect. If these drugs are used together, the patient should be monitored closely for signs and symptoms of hypothyroidism. Simultaneous use of potassium iodide and potassium-containing drugs or potassium-sparing diuretics may result in hyperkalemia.

Cautious initial administration of potassium iodide is recommended because some individuals are markedly sensitive to iodides. Persons at highest risk are those with goiter or autoimmune thyroid disease (Hashimoto thyroiditis). Some commercially available formulations of potassium iodide contain sodium bisulfite, a sulfite that may cause allergic-type reactions, including anaphylaxis and life-threatening asthmatic episodes, in susceptible individuals. It is necessary to question the patient carefully about the presence of goiter, autoimmune thyroid disease, or asthma, because this sensitivity occurs more frequently in asthmatic individuals.

Iodine-131

I-131 (radioactive iodine) is used to treat hyperthyroidism and well-differentiated thyroid carcinoma. While destroying thyroid tissue, it exposes only the thyroid tissue to the altering radiation, eliminates the problems of surgery, and enables outpatient treatment. Most patients treated with radioactive iodine become euthyroid and then require lifelong replacement therapy with thyroid hormones.

The total amount of I-131 needed to achieve clinical remission of hyperthyroidism without destroying the entire gland varies widely. The usual dosage range to treat hyperthyroidism is 4 to 10 millicuries (mCi). The usual dosage for ablation of normal thyroid tissue (in thyroid carcinoma) is 50 mCi, with subsequent therapeutic doses of 100 to 150 mCi.

The exposure level around a patient treated with I-131 depends on the administered dose, the time elapsed following treatment, and the amount absorbed by thyroid tissue. Hospital radiation-safety protocols (based on the U.S. Nuclear Regulatory Commission [NRC] regulations for radiopharmaceutical therapy) must be strictly followed during the hospitalization. Radioactive iodine therapy is considered safe. Some individuals, particularly the elderly, may be treated with antithyroid drugs before I-131 therapy to minimize the risk of exacerbating the hyperthyroidism.

I-131 has orphan-drug status for detection of hepatocellular carcinoma, hepatoblastoma, and alpha-fetoprotein–producing germ-cell tumors; detection of tumors that produce human chorionic gonadotropin; adrenal cortical imaging; and B-cell lymphomas and leukemias. It also has orphan-drug status as a diagnostic adjunct in pheochromocytoma.

I-131 is absorbed readily from the GI tract and distributed primarily within the extracellular fluid of the body. It is trapped and rapidly converted by the thyroid to protein-bound iodine. It is then concentrated by the stomach and salivary glands and excreted within several days by the kidney. The physical half-life of I-131 is 8.04 days.

I-131 is in pregnancy category X. It is contraindicated for women who are or may become pregnant because it crosses the placenta and can cause permanent damage to the fetus' thyroid gland. It is also contraindicated for lactating women because iodine is excreted in breast milk. Another contraindication to therapy is pre-existing vomiting because if the patient vomits during the first few hours after therapy, the vomitus will be highly radioactive. I-131 is seldom used in patients younger than 30 years of age unless circumstances preclude other treatment.

The immediate adverse reactions following I-131 treatment for hyperthyroidism are usually mild. More severe reactions occur following larger doses, such as those used in thyroid carcinoma. Severe reactions include depression of the hematopoietic system (acute leukemia, depressed bone marrow function, anemia, leukopenia, and thrombocytopenia). Signs of radiation sickness may also occur. Manifestations may include nausea and vomiting, tachycardia, chest pain, itching skin, hives, rash, chromosomal abnormalities, acute thyroid crisis, and death. Tenderness and swelling around the neck area, pain on swallowing, sore throat, and cough may occur 72 hours after treatment. These manifestations usually respond to treatment with analgesics.

The uptake of I-131 is affected by recent intake of iodine in any form and by thyroid and antithyroid agents. Antithyroid therapy (e.g., methimazole) of a severely hyperthyroid patient is usually discontinued 3 to 4 days before I-131 is administered.

Fears of radiation-induced genetic damage, leukemia, and neoplasia have shaped this practice, although these fears have not been realized during several decades of clinical experience. Studies indicate that the risk for infertility and birth defects following I-131 treatment is not increased if pregnancy is avoided for at least 1 year following treatment.

Patients with Graves disease may be given an antithyroid drug, such as MMI, for several months preceding radiotherapy in order to establish a euthyroid state. I-131 dosing is then based on the ability of the abnormal thyroid tissue to absorb and eliminate I-131.

Patients should be questioned regarding previous medication and procedures involving radiographic contrast media because the uptake of I-131 is affected by recent intake of these agents. Patients should be reassured that they will not be isolated from other household members. Instead, they should be cautioned to avoid prolonged, close contact with others, particularly children and pregnant women, for about 1 week following therapy with I-131.

Household contamination is not a great risk, but saliva and urine may be contaminated for several days following treatment. Patients and families should be provided with both verbal and written instructions specific to their living

situations. Patients should be instructed to sleep alone, to avoid close personal contact with family members, and to drink liberal amounts of fluids for 2 days after treatment. Eating utensils should be washed thoroughly with soap and water after every meal. The importance of handwashing should be emphasized. Typically, the toilet is the most contaminated item because most of the I-131 dosage is excreted in the urine. The NRC recommends an annual radiation dose limit of 100 mrem for the general public. This limit excludes exposure to family members of outpatients receiving radiation, however. Hyperthyroid patients treated with I-131 typically emit only low levels of radiation beyond a 1-meter distance (approximately 3.3 ft). It is necessary to make certain that household members understand they can minimize their exposure by staying 1 meter or more away from the patient for the first few days. Anxious household members should understand that exposure from diagnostic x-rays (typically, 10–2,000 mrem) is considerably greater than exposure that results from minimal contact with the patient.

Patients should be advised that temporary thinning of the hair may occur 2 to 3 months after treatment. Patients and families should be educated about the signs and symptoms of hypothyroidism, which may occur following I-131 therapy.

Propranolol

Propranolol (Inderal), a beta-adrenergic blocker, is commonly used intravenously in treating thyroid storm to minimize the excessive cardiac stimulation that results from the catecholamine activity. Therefore, it controls the symptoms but does not alter the disease. Propranolol is discussed in depth in Chapter 13.

PARATHYROID DRUGS

• C Antihypercalcemic, Calcium-Regulator Drugs

Antihypercalcemic drugs do not directly affect the parathyroid gland or PTH but rather inhibit bone resorption of calcium. These agents are frequently used in the treatment of **Paget disease,** which is an idiopathic disease characterized by chronic bone inflammation that results in thickening, softening, and bowing of the affected bones. Many people with Paget disease are not symptomatic because only small areas of the bones are involved. However, individuals with symptomatic disease experience bone pain and deformity, fractures, spinal cord compression, or cranial and spinal cord entrapment. Because vascularity of the bone is increased, high-output chronic heart failure may be evident. When a large mass of bone is involved, urinary hydroxyproline excretion may increase secondary to the breakdown of the collagen-containing bone matrix. Serum alkaline phosphatase also increases, secondary to increased bone formation. Antihypercalcemic drugs decrease the rate of bone turnover, with a resultant decrease in both urinary hydroxyproline excretion and serum alkaline phosphatase.

Calcitonin is a polypeptide hormone secreted by the thyroid gland. Commercially available calcitonin drugs are calcitonin, salmon and calcitonin, human. Both are derived synthetically and are used when the hypercalcemia is related to hyperparathyroidism. The prototype calcium-regulator drug is calcitonin, salmon. Table 50.10 presents a summary of selected antihypercalcemic drugs.

Nursing Management of the Patient Receiving P Calcitonin, Salmon

Core Drug Knowledge

Pharmacotherapeutics

Calcitonin, salmon (Miacalcin) is indicated for treatment of symptomatic Paget disease of the bone (osteitis deformans), postmenopausal osteoporosis, and hypercalcemia. The actions of this synthetic polypeptide of 32 amino acids are very similar to those of the hormone secreted by the parafollicular cells of the thyroid gland but with a greater potency per milligram and longer duration of action. It inhibits **bone resorption** (pathologic or physiologic loss or destruction of bone tissue, which can occur as a result of neoplasm, hyperparathyroidism, osteoporosis, or prolonged immobility). Calcitonin also increases the excretion of calcium, sodium, and phosphorus by the kidney, thereby lowering serum calcium levels. Intranasal calcitonin increases spinal bone mass in postmenopausal women with established osteoporosis, but has not been shown to be effective early in menopause.

Calcitonin, human (Cibacalcin) is a synthetic form of the hormone produced by the human thyroid gland. Calcitonin, human is also used to treat Paget disease. It must be administered subcutaneously up to three times a week. It should be discontinued once symptoms are relieved.

Pharmacokinetics

Calcitonin can be administered subcutaneously, intramuscularly (for Paget disease, postmenopausal osteoporosis, and hypercalcemia), or intranasally (for postmenopausal osteoporosis). It is rapidly metabolized, primarily in the kidneys, by conversion to smaller inactivated fragments. A small amount of unchanged hormone and its inactive metabolites are excreted in the urine. Half-life is 1.2 hours. Calcitonin does not cross the placenta. Whether it passes to breast milk and cerebrospinal fluid has not been determined.

Pharmacodynamics

In mammals, calcitonin is a polypeptide hormone that is secreted by the parafollicular cells of the thyroid gland. Calcitonin, salmon is a synthetic polypeptide with essentially the same actions as calcitonin. It plays a role in the regulation of calcium and bone metabolism and has direct renal effects and actions on the GI tract. Single injections of calcitonin cause a transient but marked inhibition of bone resorption. With prolonged use, a persistent, smaller decrease occurs in the rate of bone resorption. This decrease is associated with a decreased number of osteoclasts and a

TABLE 50.10 Summary of Selected Antihypercalcemic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P calcitonin, salmon (Calcimar, Miacalcin Nasal Spray, Miacalcin)	Treatment of Paget disease Postmenopausal osteoporosis with calcium and vitamin D Emergency treatment of hypercalcemia	*Adult:* Paget disease, initial dose, SC or IM, 100 IU/d; maintenance, 50 IU/d or qod; postmenopausal osteoporosis, SC or IM, 100 IU/d; hypercalcemia, SC or IM, 4 IU/kg q12h, may increase to 8 IU/kg q6h *Child:* Safety and efficacy not established	*Onset:* 15 min *Duration:* 8–24 h $t_{1/2}$: 1.2 h
cinacalcet (Sensipar)	Secondary hypertension in patients on renal dialysis Parathyroid cancer	*Adult*: PO, 30 mg/d, increase gradually to maximum 180 mg/d *Adult*: PO, 30 mg bid up to 90 mg qid	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: 30–40 h
alendronate (Fosamax)	Treatment of Paget disease in patients at risk for complications	*Adult*: Osteoporosis, PO, 70 mg/wk or 10 mg/d; Paget disease, PO, 40 mg/d for 6 mo *Child*: Safety and efficacy not established	*Onset*: Slow *Duration*: Days $t_{1/2}$: Unknown
etidronate (Didronel)	Treatment of Paget disease Heterotropic ossification Hypercalcemia resulting from malignancy	*Adult*: Paget disease, PO, 5–10 mg/kg/d up to 6 mo or 11–20 mg/kg/d not to exceed 3 mo; Heterotropic ossification, PO, 20 mg/kg/d, total; treatment not to exceed 4 mo; Hypercalcemia, IV, 7.5 mg/kg/d × 3 d. May repeat with at least 7-d interval between courses of tx. Follow with oral dose of 20 mg/kg/d not to exceed 3 mo.	*Onset*: Slow *Duration*: 6 h; 6 h (serum) $t_{1/2}$: 90 d
furosemide (Lasix)	Promotes renal excretion of calcium	*Up to 100 mg IV*	*Onset*: 5 min *Duration*: 2 h $t_{1/2}$: 2 h
gallium nitrate (Ganite)	Treatment of malignancy-related hypercalcemia	*Adult*: IV, 200 mg/m2/d for 5 consecutive d *Child*: Safety and efficacy not established	*Onset*: Slow *Duration*: 3–4 d $t_{1/2}$: Unknown
pamidronate (Aredia)	Treatment of hypercalcemia resulting from malignancy Paget disease Osteolytic bone lesions Postmenopausal osteoporosis	*Adult*: Hypercalcemia, IV, 60–90 mg over 24 h; Paget disease, IV, 30 mg/d over 4 h for 3 d; osteolytic bone lesions, IV, 90 mg over 4 h each mo *Child*: Safety and efficacy not established	*Onset*: Rapid *Duration*: 72 h $t_{1/2}$: 1.6 h, then 27.3 h
plicamycin (Mithracin)	Hypercalcemia and hypercalciuria in symptomatic patients associated with advanced neoplasms	Base dose on body weight. Use ideal weight if patient has abnormal fluid retention. 25 mcg/kg/d for 3 or 4 d; may repeat at intervals of ≥1 wk to maintain serum and urinary calcium excretion at normal levels.	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: Unknown
risedronate (Actonel)	Treatment of Paget disease Prevention of bone loss in postmenopausal women	*Adult*: PO, 30 mg/d for 2 mo *Adult*: PO, 5 mg/d or 35 mg/wk	*Onset*: Rapid *Duration*: Unknown $t_{1/2}$: 480 h
tiludronate (Skelid)	Treatment of Paget disease	*Adult*: PO, 400 mg/d for 3 mo *Child*: Safety and efficacy not established	*Onset*: 2 h *Duration*: Days $t_{1/2}$: 150 h

reduction in their resorptive activity. Endogenous calcitonin, in conjunction with PTH, has been shown to regulate blood calcium in animal studies. High blood calcium levels increase secretion of calcitonin, which inhibits bone resorption. This effect returns the blood calcium to normal.

Contraindications and Precautions

In calcitonin, salmon, there is a risk for allergic reaction to the salmon antigens. For this reason, if a person is suspected to have sensitivity to calcitonin or has multiple allergies, skin testing is recommended. The skin test consists of administering 0.1 mL of a 10-IU/mL solution subcutaneously on the inner aspect of the forearm. The appearance of a wheal or mild erythema, usually within 15 minutes, indicates a positive reaction. No serious allergic-type reactions have been reported with the nasal spray. Use caution when administering calcitriol to patients with renal dysfunction or upper GI disease.

Calcitonin is in pregnancy category C.

Adverse Effects

Adverse effects are generally infrequent and mild. GI disturbances are most evident at the start of treatment and tend to decrease with continued use. Other adverse effects include injection site reactions, dermatologic effects of skin rash and flushing of the face and hands, and nasal irritation or rhinitis (if using the nasal spray).

Rare but serious allergic-type reactions, such as anaphylaxis, have been reported with injectable calcitonin, salmon. People who are allergic to fish products are at a greater risk for anaphylaxis.

Drug Interactions

If calcitonin, salmon is taken with calcium supplements, antacids, or vitamin D, there is a risk of hypercalcemia, and therapeutic effect is decreased. Advise patients against using OTC vitamin and mineral preparations and antacids, because many of these products contain calcium. Concurrent administration of theophylline may increase bone resorption. Formal studies to evaluate drug interactions with the nasal spray have not been done.

Assessment of Relevant Core Patient Variables

Health Status

Before administering calcitonin, review the patient's record to determine whether calcitonin can be administered safely. Perform a physical examination to establish a baseline from which to monitor the drug's effects. It is important to evaluate bone pain, muscle tone, bowel sounds, renal function tests, and serum calcium levels. While collecting a thorough health history, ask about bone disease, endocrine disorders, kidney stones, or ulcer diseases. Also, obtain a complete drug history, including use of prescription and OTC drugs. Thiazide diuretics and excessive ingestion of vitamin D can cause hypercalcemia.

Include the family history because primary hyperparathyroidism occurs in a number of familial syndromes. Perform a nasal examination before nasal calcitonin administration and repeat it if the patient experiences nasal complaints.

Life Span and Gender

Calcitonin is in pregnancy category C. Assess for pregnancy and lactation. Whether calcitonin is excreted in human milk is unknown. For this reason, nursing is not recommended while the patient is on this drug. No studies have been conducted with pregnant women, but in animal studies, decreased fetal birth weights have been shown. In one large study utilizing the nasal spray, subjects greater than 65 years of age had a higher incidence of rhinitis, erythema, excoriation, and irritation. Most were mild, however greater sensitivity of the older population must be considered.

Lifestyle, Diet, and Habits and Environment

Long-term treatment with calcitonin occurs in the home or community. Monitor the patient's responses to detect adverse effects or previously unrecognized effects of the drug. Abnormal serum calcium levels and signs of allergy may occur.

Take a thorough health history to identify factors relating to the cause of hyperparathyroidism, such as vitamin D intoxication, hyperphosphatemia, and osteolytic bone metastases. Obtain a broad database about the patient for comparison during therapy; for example, record dietary practices, visible bone deformities that may interfere with activities, allergic tendencies, emotional lability, and lethargy.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to GI effects of drug therapy
  Desired outcome: *The patient will relate the importance of good nutrition and ingest daily nutritional requirements in accordance with activity level and metabolic needs.*
- Pain, Acute or Chronic related to complications of calcium or phosphate imbalances (e.g., renal stones, pathologic fractures, and osteoporosis)
  Desired outcome: *The patient will practice pain relief measures to avoid or manage the pain.*

Planning and Intervention

Maximizing Therapeutic Effects

Be aware of the proper dosages of calcitonin, salmon. For postmenopausal osteoporosis, the recommended intranasal dose of calcitonin is 200 international units, in alternating nostrils each day. This practice decreases nasal irritation. An adequate diet and supplemental calcium carbonate (1.5 g daily), plus vitamin D intake (400 U daily), is essential. SC and IM injections of 100 international units per day are also available.

For Paget disease, it is necessary to give the drug by injection. The recommended starting dose is 100 international units per day SC (preferred for outpatient administration) or IM. Arrange for periodic measurement of serum alkaline phosphatase and 24-hour urinary hydroxyproline in order to measure drug effect. Decrease in bone pain and normalization of biochemical abnormalities usually occur within the first few months of treatment, if they are going to occur. When normalization does occur, 50 international units per day or every other day is often sufficient to maintain clinical and biochemical improvement.

For hypercalcemia, the recommended starting dose is SC or IM injection of 4 international units per kilogram every 12 hours. If adequate response does not occur within 2 days, an increase to 8 international units per kilogram every 12 hours is expected. If this dosage is inadequate, it can be further increased to 8 international units per kilogram every 6 hours. If the volume is greater than 2 mL, IM injection is preferred.

Minimizing Adverse Effects

Watch for nausea, which is the most common adverse effect with SC or IM administration. It is most evident at the initiation of treatment and tends to decrease or disappear with continued administration. Rotate injection sites to minimize

local inflammatory reactions from SC and IM injections. Rhinitis, nasal crusts, and dryness are the most common adverse effects of nasal calcitonin. Alternating nostrils daily is recommended. Nasal symptoms, including rhinitis, crusting, dryness, and erythema were reported less frequently with the nasal spray than with the placebo.

Providing Patient and Family Education

- Instruct patients or family members in sterile SC and IM injection technique.
- For nasal forms of the drug, teach patients how to activate the pump and instruct them to evaluate the mucous membranes daily.
- This drug is designed to decrease the level of calcium in the blood. Calcium is needed for many of the body's activities, and it is important to keep the blood calcium levels in an effective range.
- Explain that adverse effects are usually mild but may include GI upset with nausea, vomiting, and epigastric discomfort or local inflammation. The drug should be taken once a day at the same time each day. If GI upset occurs, suggest small, frequent meals to maintain nutrition and decrease the unpleasant effects of the drug. Explaining that these adverse effects usually decrease with continued use may promote adherence.
- Starting therapy may exacerbate Paget disease–associated bone pain. It is important to assure patients that such exacerbation is usually transient. Teach patients the following ways to manage bone pain associated with Paget disease:
  - Nonnarcotic analgesics (e.g., NSAIDs, cytochrome-C-oxidase-2 [COX-2] inhibitors)
  - Applications of heat
  - Massage
  - Bracing
  - Guided imagery
  - Relaxation techniques
  - Biofeedback
  - Meditation
- Instruct patients to report twitching, muscle pain, severe diarrhea, or dark urine.
- Instruct patients to keep this drug, and all other medications, out of the reach of children.
- Alert patients and family members that skeletal deformities (e.g., bowed tibia or femur, kyphosis, or barrel-shaped chest) are not corrected by treatment. You can teach patients to camouflage deformities using clothing (e.g., slacks for women, tunic-style tops, and loosely fitted apparel).

Ongoing Assessment and Evaluation

Calcitonin can cause the serum calcium level to drop, resulting in tetany and cardiac arrhythmias. In addition, antibodies may form after several months of therapy, causing resistance to the drug and decreased therapeutic effects. Monitor the calcium level and clinical response in those receiving long-term therapy.

Nursing management of drug therapy is judged effective when calcium levels are maintained within a normal range. The patient should express the importance of self-monitoring for adverse effects and of reporting significant effects to the prescriber.

Drugs Closely Related to P Calcitonin, Salmon

Bisphosphonates

The bisphosphonates are calcium-regulator drugs closely related to calcitonin. The major pharmacologic action of this class of drugs is to inhibit normal and abnormal bone resorption. Reduction of abnormal bone resorption is responsible for therapeutic benefit in hypercalcemia. Bisphosphonate drugs are recommended for long-term management of hypercalcemia to increase bone resorption of calcium, in treating and preventing osteoporosis in postmenopausal women, and in managing Paget disease.

Patients taking bisphosphonates should be cautioned that the expected benefits of the drug are obtained only when each tablet is taken upon arising in the morning with a full glass of plain water (6 to 8 oz) and at least 30 minutes before ingesting any other medications, food, or beverages. Taking bisphosphonates with juice or coffee markedly reduces absorption (especially of alendronate). After taking the drug, the patient must stay in an upright position for 30 minutes to facilitate drug delivery to the stomach and prevent esophageal irritations. Patients must be instructed not to take this medication at bedtime or before arising for the day. Sucking on or chewing these medications can cause oropharyngeal ulceration. Supplemental calcium and vitamin D must also be administered for the bisphosphonates to be effective. Weight-bearing exercise and modifying certain behavioral factors (e.g., cigarette smoking and alcohol consumption)

MEMORY CHIP

P Calcitonin, Salmon

- Calcium regulator used to treat postmenopausal osteoporosis, Paget disease, hypercalcemia
- Major contraindication: hypersensitivity to fish products
- Most common adverse effects: nausea, vomiting, and diarrhea
- **Life span alert:** Children—**safety and efficacy not established.**
- Maximizing therapeutic effects: Store unopened bottle (nasal drug formulation) in the refrigerator between 36° and 43°F; once the pump has been activated, store at room temperature.
- Minimizing adverse effects: Periodically examine urine sediments of patients on chronic therapy; coarse granular casts and renal tubular epithelial cell casts result from therapy and may cause renal calculi.
- Most important patient education: With intranasal dosing, alternate nostrils daily; notify health care provider if significant nasal irritation occurs.

may aid in diminishing bone resorption. Bisphosphonates are very effective when given as a once-a-week medication. If a dose is missed, the patient should be instructed to take the missed dose on the morning after it is remembered and then resume taking the medication on the regularly chosen day. Chapter 52 discusses bisphosphonates in detail.

Drugs Significantly Different From P Calcitonin, Salmon

Cinacalcet

Cinacalcet (Sensipar) an oral calcimimetic agent, is the first approved agent in this drug class. It is indicated to treat patients with secondary hyperparathyroidism caused by chronic kidney disease and patients with hypercalcemia associated with parathyroid carcinoma. Cinacalcet directly reduces PTH levels while lowering calcium and phosphorus levels. This action is consistent with the National Kidney Foundation Disease Outcomes Quality Initiative clinical practice guidelines for bone metabolism and disease in chronic kidney disease. In a clinical trial reported by the manufacturer, cinacalcet was shown to reduce high serum calcium levels in patients with parathyroid carcinoma. Nearly 500 patients develop this rare condition annually, and the FDA designated cinacalcet as an orphan drug.

Furosemide

Furosemide (Lasix) is a loop diuretic that promotes renal excretion of calcium. Dosage of up to 100 mg may be given intravenously. Adverse effects include dehydration, hypokalemia, hyperuricemia, hypomagnesemia, and hypochloremic alkalosis. Fluid balance, blood pressure, pulse, and serum electrolytes must be carefully monitored when furosemide is administered. Furosemide is discussed in depth in Chapter 27.

Gallium

Gallium (Ganite) inhibits calcium resorption from bone and reduces bone turnover, effects that result in a lowered serum calcium level. Gallium is indicated for treating cancer-related hypercalcemia. It is administered intravenously over a 5-day period to patients who are symptomatic and do not respond to conventional treatment. This drug carries a substantial risk of severe renal insufficiency, especially if it is administered concomitantly with other nephrotoxic agents (e.g., amphotericin B or aminoglycosides). Renal function tests must be monitored closely for any sign of renal toxicity. It is crucial to maintain adequate hydration in patients receiving gallium and to monitor serum electrolytes closely.

Plicamycin

Plicamycin (Mithracin) is an antineoplastic, antihypercalcemic agent that is indicated for hypercalcemia secondary to neoplasms. It has been reported to be effective in treating Paget disease; however, it has not been approved by the FDA for this use. This medication is for IV administration only, and it is highly recommended that it be given only under the supervision of a qualified physician experienced in the use of chemotherapeutic agents. The patient must be hospitalized during administration because of the possibility of severe reactions.

When plicamycin is used for Paget disease, the dose should be about 10% of that used for cancer treatment. Adverse effects are much less common with this use, because of the lower dose. The dosage is based on body weight; ideal body weight should be used if the individual has abnormal fluid retention. Extravasation may cause local irritation and cellulitis at injection sites. Plicamycin blocks the hypercalcemic action of pharmacologic doses of vitamin D, acts on osteoclasts, and blocks the action of PTH. Plicamycin inhibition of DNA-dependent RNA synthesis renders osteoclasts unable to respond fully to PTH with the biosynthesis necessary for osteolysis. Decreases in serum phosphate levels and urinary calcium excretion accompany the lowering of serum calcium concentrations. The drug is cleared rapidly from blood within the first 2 hours; excretion also is rapid (90% in the first 24 hours after injection). Contraindications to plicamycin use are thrombocytopenia, coagulation disorders, impaired bone marrow function, and pregnancy. The drug is in pregnancy category X. The most common adverse effects include GI symptoms (anorexia, nausea, vomiting, diarrhea, and stomatitis). Electrolyte disturbances and depression of serum calcium, phosphorus, and potassium levels may occur. Calcium supplements are sometimes needed during plicamycin therapy.

• C Antihypocalcemic Drugs

Vitamin D compounds regulate absorption of calcium and phosphate from the small intestine, reabsorption of phosphate from the renal tubules, and mineral resorption in bone. Vitamin D is considered a hormone, although it is not a natural human hormone. The commonly used term "vitamin D" refers to both ergocalciferol (D_2) and cholecalciferol (D_3). Vitamin D_2, a plant vitamin, is predominantly used to fortify milk and cereals, and it can substitute for D_3.

Vitamin D metabolites control intestinal absorption of dietary calcium, tubular reabsorption of calcium by the kidney, and mobilization of calcium from the skeleton, in conjunction with PTH. They act directly on bone cells (osteoblasts) to stimulate skeletal growth and on the parathyroid glands to suppress PTH synthesis and secretion. Vitamin D is also involved in magnesium metabolism.

Vitamin D works together with PTH and calcitonin to regulate calcium homeostasis. It functions as a hormone. Hypoparathyroidism is treated primarily with vitamin D. If necessary, dietary supplements of calcium are also given. Patients with hypoparathyroidism have deficient levels of PTH, which result in hypocalcemia. Vitamin D stimulates calcium absorption from the intestine and restores the serum calcium to a normal level. It is a fat-soluble vitamin derived from natural sources (fish liver oils) or from conversion of provitamins. In humans, natural supplies of vitamin D depend on ultraviolet (UV) light for conversion to vitamin D_3 or vitamin D_2. Following exposure to UV light, vitamin D_3 must then be

TABLE 50.11 Summary of Selected C Antihypocalcemic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P calcitriol (Calcijex, Rocaltrol)	Management of hypocalcemia in chronic renal dialysis Hypoparathyroidism Predialysis	*Adult:* 0.25 mcg/d; may increase by 0.25 mcg/d at 4–8-wk intervals *Hypoparathyroidism:* 0.25 mcg/d. *Adult and child ≥6 y:* usually respond to 0.5–2 mcg/d. *<6 y:* 0.25–0.75 mcg	*Onset:* 2–6 h *Duration:* 3–5 d $t_{1/2}$: 3–6 h
dihydrotachysterol (DHT, Hytakerol)	Treatment of hypoparathyroidism; postoperative or idiopathic tetany	*Adult and child >3 y:* 0.25 mcg/d *Adult:* PO, 0.75–2.5 mg/d initially; maintenance, PO, 0.2–1.75 mg/d to maintain serum calcium levels	*Onset:* 10–24 h *Duration:* 3–5 d $t_{1/2}$: 16 d
doxercalciferol (Hectorol)	Reduction of elevated parathyroid hormone levels in the management of secondary hyperparathyroidism in patients undergoing chronic renal dialysis	10 mcg administered three times a week at dialysis; initial dose adjusted as needed to lower blood PTH to 15- to 300-pg/mL range. Increase dosage at 8-wk intervals by 2.5 mcg, to maximum recommended dose of 20 mcg 3×/wk at dialysis, for a total of 60 mcg/wk.	*Onset:* 10–24 h *Duration:* 3–5 d $t_{1/2}$: 32–37 h
paricalcitol (Zemplar)	Prevention and treatment of secondary hyperparathyroidism associated with chronic renal failure	Initially, 0.04–0.1 mcg/kg (2.8 to 7 mcg); dose may be increased by 2–4 mcg at 2–4-wk intervals, to maximum of 0.24 mcg/kg (16.8 mcg), administered as a bolus every other day during dialysis.	*Onset:* 10–24 h *Duration:* 16 d $t_{1/2}$: 15 h

converted to its active forms by the liver and kidneys. Vitamin D is hydroxylated by the hepatic microsomal enzymes to calcifediol. It is further hydroxylated in the kidney to calcitriol and doxercalciferol. Calcitriol (1,25-dihydroxyvitamin D_3, Rocaltrol [capsules, solution], Calcijex [parenteral]) is believed to be the most active form of vitamin D in stimulating intestinal calcium and phosphate transport, and it is the prototype antihypocalcemic drug. Table 50.11 presents a summary of selected antihypocalcemic drugs.

Nursing Management of the Patient Receiving P Calcitriol

Core Drug Knowledge

Pharmacotherapeutics

Clinical indications for calcitriol include management of hypocalcemia and resulting bone disease in patients on chronic renal dialysis; management of secondary hyperparathyroidism and metabolic bone disease in predialysis patients with moderate to severe chronic renal failure (creatinine clearance, 15 to 55 mL/min); and management of hypocalcemia and its clinical manifestations in patients with hypoparathyroidism (postsurgical, idiopathic, or pseudohypoparathyroidism). Off-label uses for calcitriol (oral) include increasing bone mass and preventing fractures in patients with osteoporosis, and (topical) decreasing severity of psoriatic lesions.

Pharmacokinetics

Calcitriol can be administered orally or intravenously. It is rapidly absorbed from the small intestine, with a peak effect occurring in 3 to 6 hours. Absorption is reduced with liver or biliary disease because bile is essential for adequate absorption. Vitamin D is chiefly stored in the liver but is also found in fat, muscle, skin, and bones. Calcitriol is 99% bound in blood. It is transported in blood by an alpha-globulin vitamin D–binding protein. Vitamin D is converted to calcifediol in the liver and then to doxercalciferol in the kidney. The half-life of calcitriol is 5 to 8 hours. Its pharmacologic activity persists for 3 to 5 days. The half-life increases at least twofold in patients with chronic renal failure and in hemodialysis patients. The primary route of vitamin D excretion is in the bile, but a small percentage is found in the urine.

Pharmacodynamics

Vitamin D is a fat-soluble vitamin derived from natural sources (fish liver oils) or from conversion of provitamins, 7-dehydrocholesterol, and ergosterol. In humans, natural supplies of vitamin D depend on UV light for conversion of 7-dehydrocholesterol to vitamin D_3 or ergosterol to vitamin D_2. Following exposure to UV light, vitamin D_3 is converted to the active form of vitamin D, calcitriol, in the liver and kidneys. Calcitriol is believed to be the most active form of vitamin D_3. It stimulates intestinal calcium and phosphate transport. Calcitriol is a fat-soluble vitamin that helps to regulate calcium homeostasis, bone growth, and maintenance. It increases calcium absorption from the intestine, thereby increasing serum calcium levels. It decreases alkaline phosphatase and possible PTH levels.

Biologically active vitamin D metabolites control the intestinal absorption of dietary calcium, the tubular reabsorption of calcium by the kidney, and, in conjunction with

PTH, the mobilization of calcium from the skeleton. They act directly on bone cells (osteoblasts) to stimulate skeletal growth and on the parathyroid glands to suppress PTH synthesis and secretion. Vitamin D also is involved in magnesium metabolism.

Contraindications and Precautions

Excessive doses of calcitriol can cause hypercalcemia and hypercalciuria. For these reasons, it is important to monitor serum calcium twice a week during initial dosing. In dialysis patients, decreased serum alkaline phosphatase levels often precede hypercalcemia. An abrupt increase in calcium intake, usually from dietary sources, may trigger hypercalcemia. If hypercalcemia develops, it is necessary to discontinue calcitriol immediately. During periods of hypercalcemia, daily serum calcium and phosphate levels must be determined. When calcium levels return to normal, calcitriol can be readministered at a daily dose 0.25 mcg lower than initially used. Patients on digitalis therapy are at an increased risk for cardiac arrhythmias; thus, calcitriol must be given cautiously. Chronic hypercalcemia can lead to generalized vascular calcification, nephrocalcinosis, and other soft-tissue calcifications. Chronic hypercalcemia may be associated with a transient increase in serum creatinine levels in patients with normal renal function. It is important for these patients to pay careful attention to factors that may lead to hypercalcemia. Patients with end-stage renal disease are unable to adequately synthesize calcitriol, the active hormone formed from the precursor vitamin D. Resultant hypocalcemia and secondary hyperparathyroidism are major causes of the metabolic bone disease of renal failure.

Some vitamin D products contain tartrazine, which may cause allergic-type reactions (including bronchial asthma) in susceptible individuals. Although the incidence of this sensitivity is low, it is frequently seen in patients with aspirin hypersensitivity. Products containing tartrazine are identified in product listings on the label.

Calcitriol therapy should always be started at the lowest possible dose and increased only with careful monitoring of serum calcium levels. During periods when the medication is adjusted, serum calcium levels should be monitored twice a week. Once the optimal dose is determined, serum calcium levels require monthly monitoring.

Calcitriol is in pregnancy category C.

Adverse Effects

Adverse effects are similar to those encountered with vitamin D excess. Early signs include weakness, headache, nausea and vomiting, dry mouth, constipation, and bone pain. Late signs include polyuria, polydipsia, and weight loss; elevated BUN, AST, and alanine aminotransferase (ALT); and cardiac arrhythmias, hypertension, and dehydration.

Drug Interactions

There are very few significant drug–drug interactions with calcitriol. Hypermagnesemia is a risk if calcitriol is taken with magnesium-containing antacids. If both drugs must be taken, they should be spaced 2 to 4 hours apart. Patients on chronic renal dialysis should not take both types of medications. Calcitriol may decrease the efficacy of verapamil. Monitor the cardiovascular status of the patient if the drugs are given concurrently. A possible risk of hypercalcemia occurs in some patients when thiazide diuretics and calcitriol are combined. Table 50.12 lists drugs that interact with calcitriol.

TABLE 50.12 Agents That Interact with P Calcitriol

Interactants	Effect and Significance	Nursing Management
Cholestyramine, ketoconazole, mineral oil, phenytoin, pheno-barbital, thiazide diuretics	Decreased pharmacologic effects of vitamin D Intestinal absorption of vitamin D may be reduced. Ketoconazole may inhibit both synthetic and catabolic enzymes of calcitriol. Absorption of vitamin D is reduced with prolonged use of mineral oil. Hypoparathyroid patients on vitamin D may develop hypercalcemia due to thiazide diuretics. Endogenous synthesis of calcitriol will be inhibited; higher doses of calcitriol may be necessary with concurrent administration of phenytoin and phenobarbital.	Assess the patient for management of concurrent disease states. Assess the patient for evidence of therapeutic effects of interacting drugs. Check for therapeutic serum levels (if applicable) of interacting drugs.
Mg^{++}-containing antacids, digitalis glycosides, verapamil	Increased pharmacologic effects from interaction with vitamin D Hypermagnesemia may develop in patients on chronic renal dialysis. Hypercalcemia in patients on digitalis may precipitate cardiac arrhythmias.	Assess the patient for control of concurrent disease states. Evaluate patient for evidence of therapeutic effects of interacting drugs. Measure therapeutic serum levels (if applicable) of interacting drugs. Monitor cardiac rhythm and function.

Assessment of Relevant Core Patient Variables

Health Status

A thorough health history is necessary to identify any factors that relate to the cause of hypoparathyroidism. Before administering calcitriol, review the patient's record to determine whether calcitriol can be safely administered. Caution should be used when administering the drug to patients with renal stones.

Before beginning drug therapy, perform a physical examination including skin color, temperature, orientation, and status of mucous membranes to establish a baseline from which to monitor the effects of the drug. Determine serum levels of calcium, phosphorus, magnesium, alkaline phosphatase, and renal and liver function to establish a baseline from which to measure drug activity and adverse effects.

Life Span and Gender

Assess the patient for pregnancy or breast-feeding. Calcitriol is in pregnancy category C. No adequate, well-controlled studies have been performed in pregnant women. The drug should be used during pregnancy only if the potential benefits outweigh the potential hazards to the fetus. Vitamin D may be excreted in breast milk; therefore, breast-feeding should be avoided when taking calcitriol. Safety of vitamin D in amounts greater than 400 international units per day is not established.

The safety and efficacy of calcitriol given to pediatric patients undergoing dialysis have not been studied but are based on adult patients. Dosing guidelines have not been established for patients with hypoparathyroidism who are younger than 1 year of age or for those younger than 6 years of age with pseudohypoparathyroidism. Long-term calcitriol therapy is well tolerated by pediatric patients who are not undergoing dialysis. Pediatric doses should be individualized and monitored closely.

Calcitriol should be used with caution in elderly patients, especially those with coronary disease, renal function impairment, and arteriosclerosis. Dosage for elderly patients should start at the low end of the dosing range, because they have a greater risk of decreased renal, hepatic, or cardiac function.

Lifestyle, Diet, and Habits

Calcitriol is generally given in the home setting. IV doses can be given following dialysis to increase calcium levels. Evaluate vitamin D ingested in fortified foods, dietary supplements, and other concomitantly administered drugs. It may be necessary to limit dietary vitamin D and its derivatives during treatment.

Patients receiving calcitriol are likely to experience multiple GI effects. Small, frequent meals may help alleviate some of these symptoms. A bowel-training program may be needed if constipation is a problem. Closely monitor nutritional status.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements related to reduced absorption of fat-soluble vitamins, including calcitriol, in the presence of a very low-fat diet
  Desired outcome: *The patient will ingest a nutritionally balanced diet to allow for normal absorption of fat-soluble vitamins.*
- Imbalanced Nutrition: More than Body Requirements, related to drug–vitamin interaction of vitamin D and calcium supplements
  Desired outcome: *The patient will identify sources of dietary vitamin D and calcium, consume these foods in moderation, and refrain from consuming vitamin or dietary supplements containing vitamin D and calcium.*
- Acute Pain related to headache and general discomfort secondary to drug effects
  Desired outcome: *The patient will not experience undue pain and discomfort as a result of drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Calcitriol capsules should be swallowed whole, rather than crushed or chewed. Eating a balanced diet and getting exposure to sunlight usually satisfies normal vitamin D requirements. Caution the patient and family to avoid using vitamin supplements as a substitute for a balanced diet. Monitor serum calcium levels before and during drug therapy because adequate dietary calcium is necessary for a clinical response to vitamin D therapy. Begin therapy at the lowest possible dose, with dosage increases made only after careful analysis of the serum calcium. Adjust the dosage as soon as clinical improvement is seen. It is essential to estimate the daily dietary calcium intake and adjust that intake as indicated. Patients with normal renal function taking calcitriol should maintain an adequate fluid intake to avoid dehydration because the range between therapeutic and toxic doses is narrow. When high therapeutic doses are used, frequent serum and urinary calcium, phosphate, and BUN determinations are necessary.

The recommended initial IV dose of calcitriol injection (Calcijex) is 1 to 2 mcg administered every other day (approximately three times/week). Doses may be increased slowly at 2 to 4 week intervals if a satisfactory response is not detected. While titrating the medication, serum calcium and phosphorous levels should be monitored twice weekly. If hypercalcemia occurs, Calcijex should be discontinued immediately until levels return to the appropriate range, then a lower dose should be administered.

Serum calcium levels should be maintained between 9 and 10 mg/dL.

Minimizing Adverse Effects

Chronic dialysis patients should avoid magnesium-containing antacids while taking these drugs. Arrange for small, frequent meals to alleviate GI discomfort and to provide adequate

nutrition. Monitor bowel function and begin a bowel-training program as appropriate. Provide analgesics as appropriate to decrease discomfort and pain related to drug effects.

Providing Patient and Family Education

- Explain to patients and their families that this drug is a form of vitamin D and that it is being used to increase the patient's low calcium levels. Calcium is needed for many of the body's activities, and it is important to keep calcium levels in the blood in an effective range.
- Discuss the possible adverse effects of the drug, including GI upset with nausea, vomiting, and epigastric upset. Advise patients to eat small, frequent meals to maintain nutrition and decrease some of the unpleasant side effects of the drug.
- Advise patients to monitor noise, temperature, and light and to take prescribed analgesics as needed to decrease discomfort of the headache, muscle ache, and irritability that are common adverse effects of the drug.
- Instruct patients to report lethargy, weight loss, severe bone pain, excessive urine output, or constipation.
- Instruct patients to keep this drug, and all other medications, out of the reach of children.

Ongoing Assessment and Evaluation

Dosage adjustment is required for patients taking calcitriol as soon as clinical improvement occurs. Therapy should be started at the lowest possible dose, with increases made after careful monitoring of the serum calcium. It is important to estimate daily dietary calcium intake and adjust the intake when indicated. Patients with normal renal function taking calcitriol should avoid dehydration by maintaining adequate fluid intake. The range between therapeutic and toxic doses is narrow. When high therapeutic doses are used, it is especially important to chart the progress with frequent determinations of urinary calcium, phosphate, and BUN and to chart serum calcium, phosphate, magnesium, and alkaline phosphatase levels. Monitor 24-hour urinary calcium and phosphate levels. These laboratory determinations are especially important in hypoparathyroid and dialysis patients. Serum calcium levels should be maintained between 9 and 10 mg/dL.

Nursing management in drug therapy is considered effective when calcium levels are maintained within a normal range and when the patient recognizes and expresses the importance of self-monitoring for adverse effects and takes responsibility for reporting significant adverse effects to the health care provider.

Drugs Closely Related to P Calcitriol

Dihydrotachysterol

Dihydrotachysterol (DHT) is a vitamin D derivative that is indicated for treating postoperative tetany (acute, chronic, and latent), idiopathic tetany, and hypothyroidism. Off-label, it is used for familial hypophosphatemia and renal osteodystrophy. DHT mobilizes bone calcium and stimulates intestinal calcium absorption in the absence of PTH. It also increases the excretion of phosphate from the kidneys. It exerts a slow but persistent effect and can be used for long periods. The beginning dose is 0.8 to 2.4 mg/d for several days, followed by a maintenance dose of 0.2 to 1.0 mg/d to maintain normal serum calcium levels. It can be supplemented with 10 to 15 mg of oral calcium gluconate or calcium lactate daily if needed. Toxicity is manifested by symptoms of hypercalcemia. It is important to monitor standard hypercalcemia-related metabolic parameters (e.g., serum levels of calcium, phosphate, magnesium, and potassium) carefully.

MEMORY CHIP

P Calcitriol

- Vitamin D; management of hypocalcemia and resultant bone disease in patients undergoing chronic renal dialysis
- Major contraindications: hypercalcemia, hypervitaminosis D, malabsorption syndrome, and decreased renal function
- Most common adverse effects: weakness, headache, somnolence, nausea, vomiting, dry mouth, constipation, muscle or bone pain, and metallic taste
- Most serious adverse effect: chronic hypercalcemia can lead to generalized vascular calcification, nephrocalcinosis, and other soft tissue calcifications
- **Life span alert: Use caution in elderly patients, especially those with coronary disease, renal function impairment, and arteriosclerosis.**
- Maximizing therapeutic effects: Patients with normal renal function taking calcitriol should maintain adequate fluid intake and avoid dehydration; periodically monitor serum calcium, phosphate, magnesium, alkaline phosphatase, and 24-hour urinary calcium and phosphate, especially in hypoparathyroid and dialysis patients.
- Minimizing adverse effects: Maintain serum calcium levels between 9 and 10 mg/dL.
- Most important patient education: Adequate dietary calcium is necessary for a clinical response to vitamin D therapy; compliance with dosage instructions, diet, phosphate-binder use, and calcium supplementation is essential; avoid use of nonprescription drugs, including magnesium-containing antacids.

Doxercalciferol

Doxercalciferol (Hectorol), a vitamin D analogue, is indicated to treat hyperparathyroidism secondary to renal failure. It can be administered intravenously or orally and has a mean half-life of 32 to 37 hours. Doxercalciferol is a prohormone of vitamin D that undergoes hepatic conversion to active vitamin D. Hyperphosphatemia lessens its effectiveness. Decreased absorption may occur when it is combined with agents known to interfere with the absorption of fat-soluble vitamins (e.g., cholestyramine and mineral oil). Adverse effects include edema, headache, dizziness, malaise, nausea, and vomiting.

Paricalcitol

Paricalcitol (Zemplar) is a parenterally administered synthetic vitamin D analogue used for hyperparathyroidism secondary to renal failure. It has a mean half-life of 15 hours. Paricalcitol suppresses PTH levels in patients with chronic renal failure. It may also reduce serum total alkaline phosphatase levels. Effective therapy with paricalcitol requires a dietary regimen of calcium supplementation and phosphorus restriction. Phosphate-binding compounds may be needed. Excessive use of aluminum-containing compounds should be avoided.

CHAPTER SUMMARY

- A combination of neural and endocrine systems, originating in the hypothalamus, regulates CNS, autonomic nervous system, and endocrine functions.
- The hypothalamus produces two hormones—oxytocin and vasopressin—that are stored in and released from the posterior lobe of the pituitary gland. The hypothalamus releases a series of stimulating and inhibiting factors to promote the release of stimulating hormones from the anterior pituitary gland. These stimulating hormones affect several other endocrine glands.
- The anterior lobe of the pituitary gland produces growth hormone (GH), a hormone important for the regulation of growth and development. Release of GH is determined by inhibiting and releasing factors and by chemical signals for growing tissue.
- The thyroid gland is a bilobar gland located in the neck around the trachea. This vascular gland uses dietary iodine to produce two thyroid hormones (T_3 and T_4). These hormones affect the way many body cells utilize energy and maintain metabolism. These hormones are regulated by a balance between TRH, TSH, and the thyroid hormone levels.
- The parathyroid glands are four very small groups of tissue located on the back of the thyroid gland. These cells produce parathyroid hormone (PTH), the most important regulator of serum calcium levels in the body. PTH stimulates osteoclasts to release calcium from the bone, increases intestinal absorption of calcium, and increases calcium resorption from the kidneys. It also stimulates cells in the kidney to produce calcitriol, the active form of vitamin D, which stimulates intestinal transport of calcium into the blood. Calcium is a vital anion that is used in many of the body's metabolic processes, including membrane transport processes, conduction of nerve impulses, muscle contraction, and blood clotting. To be effective, the serum levels of calcium must be maintained between 9 and 11 mg/dL.
- The GH somatropin is an example of a drug used to replace a pituitary hormone. It is given by injection to children with GH deficiency, to some adults with GH deficiency, and to girls with Turner syndrome.
- Release of GH is blocked by octreotide, bromocriptine, and GH-inhibiting factor (somatostatin). These drugs can be used to treat acromegaly and must be given by injection.
- Vasopressin (or ADH) is administered by injection or intranasally in order to regulate water loss when levels of ADH are low or absent. Vasopressin blocks the release of water in the nephron and increases vascular volume while decreasing osmolarity. The dosage of this drug is determined by patient response and water balance.
- Thyroid hormone is given to replace low levels of thyroid hormone resulting from surgery, radiation, autoimmune disorders, inadequate iodine in the diet, malignancies, or pituitary-hypothalamic disorders. Levothyroxine (T_4) is the most commonly used thyroid hormone because of its predictability and reliability.
- Patients treated with thyroid hormone need lifelong therapy. They should be monitored for nutritional balance related to changes in metabolism and should be evaluated periodically for the effectiveness of other maintenance drugs as the patient reaches normal thyroid function and metabolism changes.
- Drugs used to block thyroid function include the thionamides—methimazole (MMI) and propylthiouracil (PTU)—and iodine preparations. The thionamides block the coupling of iodine to the thyroid hormone, whereas the iodine preparations prevent formation of thyroid hormone by blocking iodine uptake. I-131 is used in diagnostic imaging to isolate areas of increased thyroid gland activity or in one large dose to cause thyroid gland destruction by beta ray emission. Patients effectively treated with antithyroid drugs will need to be monitored for hypothyroidism and the need for thyroid hormone replacement.
- Hypercalcemia is treated with calcitonin (a thyroid hormone that counters the action of PTH), the bisphosphonates, and gallium. These drugs are used to treat any condition characterized by increased calcium levels or bone resorption, such as postmenopausal osteoporosis, Paget disease, and hypercalcemia associated with malignancy.
- Hypocalcemia is treated with vitamin D derivatives. Vitamin D compounds regulate the following processes: absorption of calcium and phosphate from the small intestine, mineral resorption in bone, and reabsorption of phosphate from the renal tubules. Working with PTH and calcitonin to regulate calcium homeostasis, vitamin D actually functions as a hormone. Patients receiving vitamin D products need to be cautioned about using OTC multiple-vitamin preparations and should be encouraged to increase dietary intake of calcium.

QUESTIONS FOR STUDY AND REVIEW

1. What is the importance of calcium balance, and how is it maintained in the body?
2. How do the hypothalamus and pituitary glands interact to help maintain homeostasis in the body?
3. What are the special educational needs of the patient and family when somatropin is used to replace deficient GH?
4. List the signs and symptoms of hypothyroidism.

5. A patient with malignancy-induced severe hypercalcemia is admitted with a serum calcium level of 18 mg/dL. The patient is given IV gallium as an emergency treatment. What special precautions need to be observed with the use of this drug?
6. An order is written for calcitonin, salmon to treat hypercalcemia. Before administering the drug, the patient assessment reveals a history of allergy to animal products. What steps should you take before administering the drug?

Drugs Affecting Men's Health and Sexuality

Learning Objectives

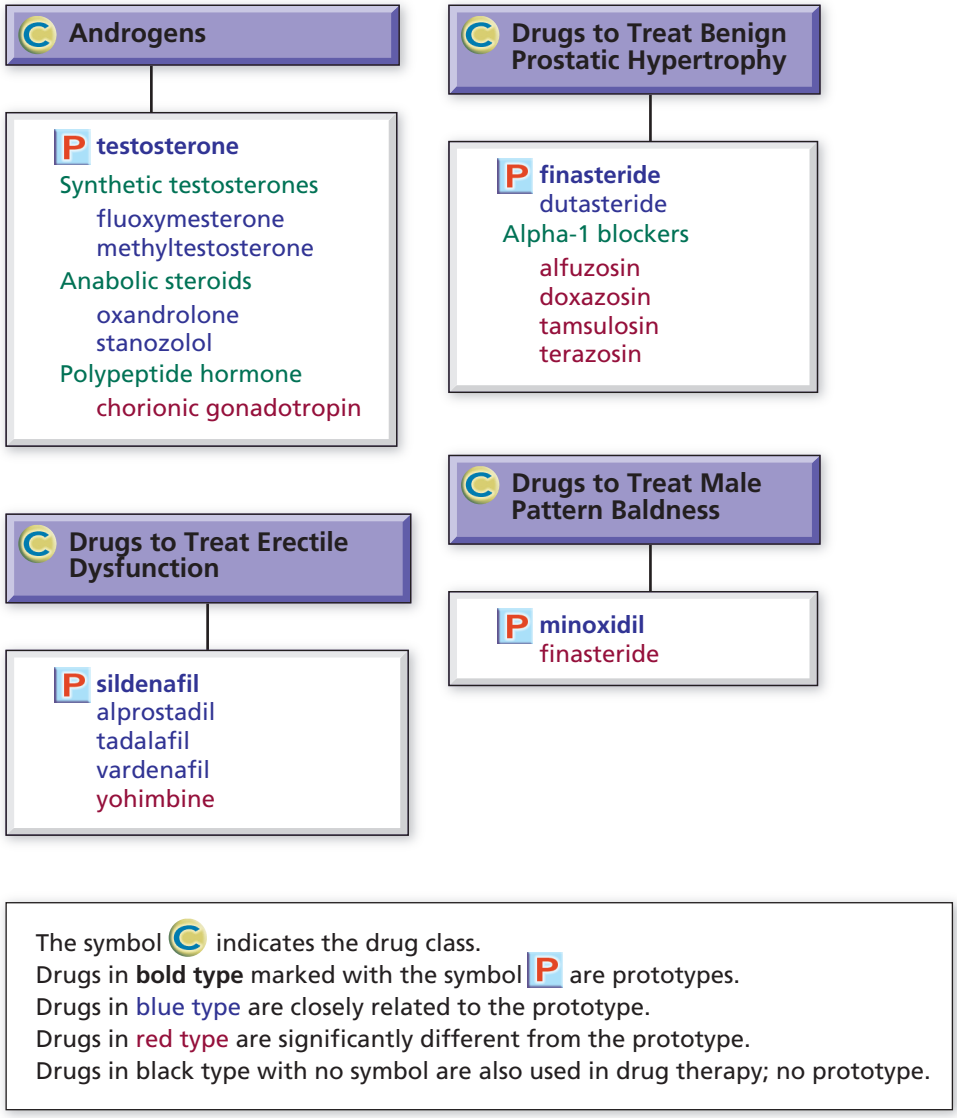
At the completion of this chapter the student will:

1. Identify common health problems of men that are treated with drug therapy.
2. Identify core drug knowledge about drugs that affect men's health and sexuality.
3. Identify core patient variables relevant to drugs that affect men's health and sexuality.
4. Relate the interaction of core drug knowledge and core patient variables for drugs that affect men's health and sexuality.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect men's health and sexuality.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects of drugs that affect men's health and sexuality.
7. Determine key points for patient and family education related to drugs that affect men's health and sexuality.

Key Terms

androgens
benign prostatic hypertrophy
erectile dysfunction
follicle-stimulating hormone
luteinizing hormone
male pattern baldness

Drugs Affecting Men's Health and Sexuality



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Men's health and sexuality differ from women's. Men, over their lifetime, experience unique health problems. Some of these may be directly related to deficiencies of the male sex hormone testosterone; others may be indirectly related to changing hormone levels. Additionally, cardiovascular (e.g., peripheral vascular disease, ischemic heart disease), neurologic (e.g., neuropathies), and endocrine (e.g., diabetes mellitus) system changes are responsible for other health problems in men.

This chapter discusses drug therapy used to treat problems specific to men, including: insufficient testosterone, erectile dysfunction (ED), benign prostatic hypertrophy (BPH), and male pattern baldness, with emphasis on prototype drugs such as sildenafil for treating ED; finasteride for treating BPH; and minoxidil for treating male pattern baldness. The prototype male sex hormone, testosterone, will also be discussed.In addition, this chapter briefly discusses prostatic cancer. Chapters 56 and 57 present a fuller discussion of the drugs used to treat prostate cancer.

PHYSIOLOGY

Hormones

Androgens are naturally occurring or synthetic steroidal compounds that produce the masculinizing and tissue-building properties of testosterone, the main male sex hormone. Other androgens include dihydrotestosterone, androstenedione, and dehydroepiandrosterone. During puberty, the pituitary gland secretes large volumes of **follicle-stimulating hormone** (FSH) and **luteinizing hormone** (LH). The predominant effect of FSH is forming sperm cells. LH in males stimulates the interstitial cells of the testes, which produce approximately 95% of the body's testosterone. Interstitial cell development is also influenced by interstitial cell-stimulating hormone (ICSH). Therefore, increased production of ICSH stimulates production of testosterone.

Testosterone is responsible for the normal growth and development of the male sex organs. Testosterone is also responsible for development and maintenance of the male secondary sexual characteristics: hair distribution (beard, pubic area, chest, and axillae); all hair related to secondary sex characteristics; hair texture and color (more deeply pigmented, heavier, and sometimes more curly); laryngeal enlargement and vocal cord thickening (resulting in voice deepening); and alterations in body musculature and fat distribution.

Testosterone causes retention of sodium, potassium, and phosphorus as well as decreased urinary excretion of calcium. Sodium retention may lead to fluid retention. Testosterone also has multiple effects on bone. It stimulates the growth of skeletal muscle tissue and enhances the growth of long bones in prepubescent boys—the growth spurt of adolescence. The ossification (hardening) of the epiphyseal growth plates, which stops the growth of the long bones, occurs with prolonged elevation of testosterone levels. Testosterone also is reported to stimulate the production of red blood cells by enhancing the production of erythropoietin-stimulating factor.

The adult male produces approximately 7 to 8 mg of testosterone daily. In women, the adrenal cortex and the ovaries secrete androgens, including testosterone, although in much smaller amounts than are found in men.

Penis

The male penis has a dermal layer of smooth muscle, under which is loose connective tissue. This pliable connective tissue allows the skin of the penis to move without distorting the underlying structures. This important characteristic enables the penis to become erect. Beneath the connective tissue is a dense network of elastic fibers that encircle the internal structures of the penis. Most of the shaft of the penis is composed of three cylindrical columns of erectile tissue, each of which consists of a maze of vascular channels incompletely separated by partitions of elastic connective tissue and smooth muscle fibers. In the non-aroused state, the arterial branches are constricted, and the muscular partitions are tense, so that blood flow into the erectile tissue is restricted.

The parasympathetic system innervates the penile arteries. Normal erection involves the release of nitric oxide, secondary to sexual stimulation, in the erectile tissue of the penis. The nitric oxide activates an intermediary enzyme that boosts cyclic guanosine monophosphate (cGMP), a substance that mediates the action of certain hormones. By some unknown mechanism, cGMP stimulates smooth muscle, producing relaxation and an inflow of blood into the erectile tissue.

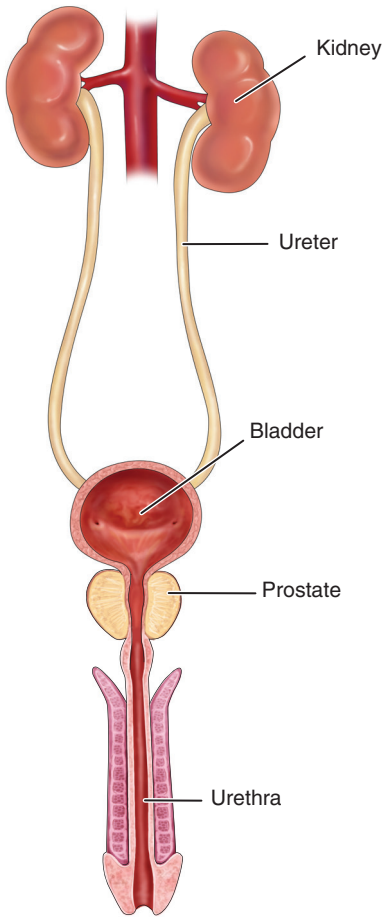
Urethra and Prostate

Passing through the penis is the urethra, which in men transports both urine and semen. The prostate gland is a small, muscular, rounded organ that encircles the proximal portion of the urethra as it leaves the urinary bladder (Figure 51.1). The ejaculatory duct joins the urethra in the prostate. The prostate gland is very small until puberty, when it begins to grow as a result of hormonal changes. The growth of the prostate gland slows after age 20 years but continues throughout the rest of a man's life. The primary hormone in prostate cells that affects growth of the prostate is dihydrotestosterone. A special enzyme, 5-alpha reductase, converts testosterone to dihydrotestosterone.

PATHOPHYSIOLOGY

Hormonal Problems

If a male is deficient in endogenous sex hormones, he does not experience normal sexual development. The primary sex organs do not mature, secondary sexual characteristics do not develop, reproduction is not possible, and the normal growth spurt of adolescence does not happen. If the level of endogenous hormones drops after puberty has occurred and the sexual organs and reproductive system have matured, secondary sexual characteristics may diminish. Ability to reproduce, despite developed organs, is diminished, and the man may not create enough sperm to impregnate a woman.



• FIGURE 51.1 Normal urine flow.

Erectile Dysfunction

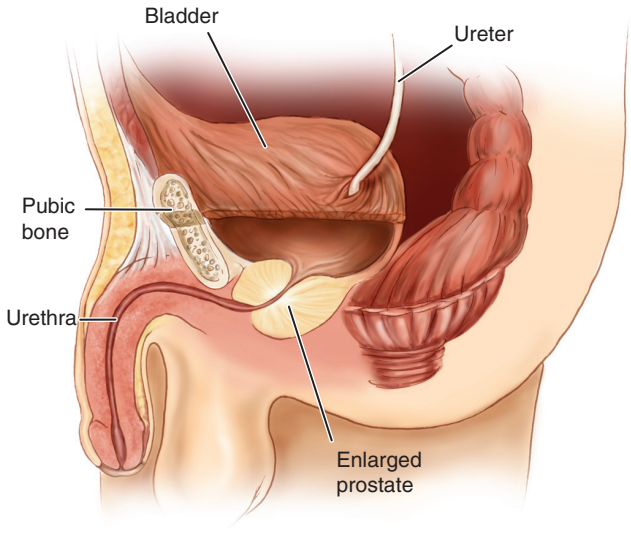
Erectile dysfunction (ED), a subjective complaint of being unable to attain or sustain an erection to satisfactorily complete sexual activity, is highly prevalent, affecting more than 18 million men in the United States. However, in spite of increased awareness and effective drug therapies, ED continues to be under-diagnosed, under-treated, and can have an adverse affect on an individual's self-esteem (Ellsworth & Kirshenbaum, 2008). As men become older they are more likely to have erectile dysfunction The problem may be temporary or chronic, and may be caused by certain drug therapies, alcohol use, trauma, or illness that affects either the autonomic nervous system or the central nervous system (CNS). Physiologic causes such as cardiovascular disease and diabetes are highly correlated with erectile dysfunction. Risk factors for heart disease such as hypertension, smoking, inactivity, and high cholesterol levels are also closely related to erectile dysfunction (Selvin, Burnett, & Platz, 2007;). Severe stress, emotional problems, depression, anxiety, or fear of impaired performance may all result in sexual dysfunction. In almost 90% of men older than 50 years of age, the cause of erectile dysfunction is organic; in most younger men, the cause is psychogenic.

Benign Prostatic Hypertrophy

Prostatic enlargement that is not caused by cancer is called **benign prostatic hypertrophy or hyperplasia** (BPH). BPH occurs spontaneously in men as they age, and the incidence rises after age 40 years. By age 80, approximately 90% of men have BPH (Rosenberg, Miner, Riley & Staskin, 2010).

The exact cause of BPH is not well understood; however, as a man ages, the prostate increases in size via cellular proliferation and expansion. Because of its location, the increase in size of the prostate causes constriction of the urethra and impairs the flow of urine (Figure 51.2). This mechanical component of BPH is the basis for therapies aimed at reducing the volume of the prostate in an attempt to decrease symptoms directly related to this obstruction. An additional component of BPH relates to insufficient relaxation of smooth muscle near the prostate and neck of the bladder during urination. Activation of alpha-adrenergic receptors leads to contraction of this smooth muscle. Blocking or inhibiting this response is the goal of alpha-adrenergic blockers which enhance relaxation of the bladder neck (Rosenberg, Miner, Riley, & Staskin, 2010). Although testosterone levels fall with aging, levels of DHT (the primary hormone in the prostate) remain fairly constant. DHT is the hormone primarily responsible for prostate growth. Additionally, the small amount of estrogen in the man may also affect prostate growth because decreasing testosterone levels no longer offset the effects of estrogen.

BPH first affects the urethra as the enlarged prostate tightens around it. The pressure of the gland against the urethra is like a clamp on a garden hose, making passage of fluid more difficult (see Figure 51.2). The man has difficulty initiating a stream or stopping the flow of urine (dribbling). Over time, this pressure on the urethra from the prostate causes the man's bladder to thicken. Initially, the bladder is irritable and



• FIGURE 51.2 Urine flow with benign prostatic hypertrophy.

contracts even when it contains only a small amount of urine, resulting in frequent urination and nocturia. As the prostate continues to place pressure on the bladder, the bladder weakens, resulting in poor contraction during urination. Eventually, the bladder can no longer empty completely, causing urinary retention. Urinary tract infections may result. Complete inability to void may also occur.

Male Pattern Baldness

The adult has two major types of hair: vellus hair and terminal hair. *Vellus hair* is the fine "peach fuzz" located over much of the body surface. *Terminal hair* is heavy, more deeply pigmented, and sometimes curly. It is located mostly on the head. Hair follicles may alter the structure of the hair on the body in response to circulating hormones. In men, decreasing levels of sex hormones can affect the scalp, causing a shift from terminal hair to vellus hair production beginning at the temples and the crown of the head. Changes in the receptors for testosterone and other male sex hormones may also induce hair loss.

Male pattern baldness, also called androgenetic alopecia, is baldness of the vertex of the scalp. Women may also have hair loss related to decreased sex hormone levels, but it differs from hair loss in men in that the loss is diffuse or may involve thinning of the frontoparietal areas.

Prostate Cancer

Prostate cancer is a malignant metastasizing cancer and the second most common cause of cancer death in men. One in 6 men in the United States will develop prostate cancer, and 1 in 33 will die from it. As men become older, their risk of developing prostate cancer increases. Compared with white men, the incidence of prostatic cancer is more common in African American men and less common in Hispanic, Asian, Pacific Islander, and Native American men. Until recently, there was no scientific consensus on effective strategies to reduce the risk of prostate cancer; however, a combined panel of experts from the American Society of Clinical Oncology and the American Urological Association, after reviewing multiple studies, developed evidence-based recommendations for prostate cancer chemoprevention. These guidelines suggest that men who have regular PSA screenings and are asymptomatic may benefit from 7 years of 5-alpha-reductase inhibitors for the prevention of prostate cancer and are encouraged to discuss this option with their healthcare provider (Kramer, Hagerty, Justman, et al., 2009).

Prostate cancer is not caused by BPH. It usually originates in one of the secretory glands. As the cancer grows, it produces a nodular lump on the surface of the prostate. During a digital rectal examination, this lump can be palpated through the rectal wall. If diagnosis is not made until after the cancer has metastasized, the prognosis for survival decreases because metastasis can rapidly involve the lymphatic system, lungs, bone marrow, liver, or adrenal glands.

Treatment of prostate cancer varies for each affected man. Treatment options include the following:

- Watchful waiting—monitoring the prostate cancer by performing a prostate-specific antigen (PSA) test and digital rectal exam regularly, and treating the cancer only if and when it causes symptoms or shows signs of growing
- Surgical intervention—radical prostatectomy (removal of the prostate)
- Internal radiation therapy—brachytherapy (surgical placement of small radioactive pellets inside or near the cancer to destroy cancer cells)
- External radiation therapy—destruction of cancer cells by directing radiation at the prostate
- Cryotherapy—placement of a special probe inside or near the prostate cancer to freeze and destroy the cancer cells
- Hormonal therapy—using antiandrogen antineoplastics and gonadotropin-releasing hormone analogues, which keep prostate cancer cells from growing. (Drugs used to treat prostate cancer are discussed in Chapters 56 and 57.)

C ANDROGENS

The prototype male sex hormone is testosterone. When testosterone is administered exogenously as a drug, it may be given in different forms. These differences may relate to the onset or duration of action or to the route of administration (oral, buccal, parenteral, topical, transdermal, and subdermal implants).

Table 54.1 provides a summary of selected drugs used to treat men's health problems.

Nursing Management of the Patient Receiving P Testosterone

Core Drug Knowledge

Pharmacotherapeutics

In males, testosterone is used as replacement therapy for hypogonadism associated with low or no endogenous testosterone (see Table 51.1). Boys with low or no testosterone before puberty need testosterone treatment to develop secondary sexual characteristics and must continue it after puberty to maintain them. Men who develop a deficiency of testosterone after puberty require testosterone to maintain sexual characteristics. Testosterone may also be given to males with delayed puberty (puberty that is expected to occur but much later than normal) to stimulate the onset of puberty. These patients must be carefully selected and have a clear familial pattern of delayed puberty that is not secondary to a pathologic disorder. Brief treatment with conservative doses may be justified if these patients are having serious emotional problems as a result of delayed puberty. Testosterone is also used in treating erectile dysfunction and male climacteric symptoms when these conditions are secondary to androgen deficiency.

In women 1 to 5 years after menopause, testosterone may be used as secondary treatment to slow the growth of advanced, inoperable metastatic breast cancer.

TABLE 51.1 Summary of Selected Drugs Used to Treat Men's Health Problems

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Androgens			
P Testosterone			
testosterone (short-acting; Histerone)	*Males:* replacement therapy in hypogonadism, delayed puberty, impotence secondary to androgen deficiency	*Male:* hypogonadism (initiation of puberty), IM, 40–50 mg/m^2/dose/mo or 50–400 mg/dose q2–4wk; androgen replacement, IM, 25–50 mg 2–3×/wk	*Onset:* Slow *Duration:* 1–3 d $t_{1/2}$: 10–100 min
testosterone (long-acting; Delatestryl)	*Males:* replacement therapy in hypogonadism, delayed puberty *Females:* palliation of inoperable breast cancer	*Adult:* hypogonadism (initiation of puberty), IM, 50–200 mg q2–4wk; androgen replacement, IM, 50–400 mg q2–4wk *Female:* IM, 200–400 mg q2–4wk	*Onset:* Slow *Duration:* 2–4 wk $t_{1/2}$: Up to 8 d
testosterone, transdermal (Androderm, Testim)	*Males:* primary hypogonadism, hypogonadotropic hypogonadism	*Adult:* Patch, 4–6 mg/d applied to scrotal skin (Testoderm); 5 mg/d applied to nonscrotal skin (Androderm)	*Onset:* Rapid *Duration:* 24 h $t_{1/2}$: 10–100 min
Drugs to Treat Erectile Dysfunction			
P sildenafil (Viagra)	Erectile dysfunction	PO: usual dose, 50 mg once daily; may use 25–100 mg, based on effectiveness and tolerance	*Onset:* <30 min *Duration:* up to 4 h $t_{1/2}$: 4 h
sildenafil (Revatio)	Pulmonary hypertension	PO: 20 mg 3×/d, with or without food	Same as above
tadalafil (Cialis)	Erectile dysfunction	PO, 10 mg or 20 mg once daily	*Onset:* <30 min *Duration:* Up to 36 h
vardenafil (Levitra)	Erectile dysfunction	PO, 2.5–20 mg once daily, with recommended starting dose of 10 mg	*Onset:* 15–30 min *Duration:* Up to 4 h
alprostadil (Caverject, Edex, Muse)	Erectile dysfunction	Intracavernosal injection: initial dose, 2.5 mcg; titrate upward, first by another 2.5 mcg, then by 5–10 mcg, until desired effect achieved; give no more than 3×/wk. Intraurethral: 125–1,000 mcg; use smallest effective dose (no more than 2 doses in 24 h)	*Onset:* 5–20 min *Duration:* 1 h $t_{1/2}$: 40–60 min *Onset:* 30–60 min *Duration:* Unknown $t_{1/2}$: Unknown
Drugs to Treat Benign Prostatic Hypertrophy (BPH)			
P finasteride (Proscar, Propecia)	BPH Male pattern baldness	PO: 5 mg/d PO: 1 mg/d	*Onset:* <2 h *Duration:* 24 h $t_{1/2}$: 6 h
C Alpha-1 Blockers tamsulosin (Flomax)	BPH	PO: 0.4 mg/d about 30 min after the same meal daily	*Onset*: Varies *Duration*: 24 h $t_{1/2}$: 9–13 h
Drugs to Treat Male Pattern Baldness			
P minoxidil (Rogaine, Minoxidil for Men)	Male pattern baldness	Topically: to affected area of scalp, 1 mL bid	*Onset:* ≥4 mo *Duration:* 3–4 mo after discontinuing effective dosing $t_{1/2}$: Unknown

Testosterone is available as an oral drug (Android, methyltestosterone, Testred); as a buccal extended-release tablet (Striant); as a parenteral drug (Delatestryl, Depo-Testadiol, Depo-Testosterone); as a topical drug (AndroGel); as a transdermal (Androderm, Testim), and as an implantable pellet (Testopel).

Pharmacokinetics

Natural testosterone undergoes a high first-pass effect and is not used orally. The form of testosterone that is used orally is a synthetic androgen that is less extensively metabolized and has a longer half-life than natural testosterones. The synthetic androgens are also available

as buccal tablets. They are absorbed directly into the bloodstream, bypassing the gastrointestinal (GI) tract and the first-pass effect. These buccal androgens have approximately twice the potency of oral androgens. Peak serum level from buccal administration occurs in 1 hour, compared with 2 hours for oral administration. Testosterone esters are less polar than free testosterone. Testosterone esters in oil are given intramuscularly. These testosterone esters are slowly absorbed, allowing for dosing intervals of 2 to 4 weeks.

In the plasma, testosterone is about 98% bound to a specific testosterone-estradiol–binding globulin. The amount of binding globulin in the plasma determines the relative percentages of free and bound testosterone. The concentration of free testosterone determines half-life. Inactivation of testosterone occurs mostly in the liver. The conjugates and metabolites of testosterone are eliminated in the urine and feces. Testosterone crosses the placenta and enters the breast milk.

Pharmacodynamics

The effects of exogenous testosterone on males are the same as the effects of endogenous testosterone. In females, the drug causes masculinization. In addition, increased testosterone levels in women slow the growth of advanced breast cancers, which are estrogen dependent.

Contraindications and Precautions

Testosterone is contraindicated for patients with serious cardiac, hepatic, or renal disease because edema with or without chronic heart failure (CHF) may be a complication in these patients. It is also contraindicated in those people hypersensitive to the drug and in men with carcinomas of the breast or prostate. Testosterone is not normally used in premenopausal women, but it is nonetheless designated as a pregnancy category X drug because it causes masculinization of the genitalia in the female fetus.

Caution must be used when administering testosterone to the following patients:

- Young males with delayed puberty, because of testosterone's adverse effect on bone maturation
- Males with pre-existing gynecomastia (breast enlargement) because testosterone may compound the problem
- Elderly men because they may be at increased risk for BPH and prostate cancer
- Patients with BPH because they may develop acute urethral obstruction
- Patients with acute intermittent porphyria (a group of disorders that result from a disturbance in the metabolism of porphyrins, nitrogen-containing organic compounds in protoplasm) because androgens have precipitated attacks of this condition
- Patients with a history of myocardial infarction (MI) or coronary artery disease (CAD) because testosterone may promote hypercholesterolemia

Adverse Effects

Most adverse effects are related to high doses of the drug. In males, the most common adverse effects include gynecomastia, excessive frequency and duration of penile erections, decreased ejaculatory volumes, and oligospermia (low sperm count).

In females, the most common adverse effects are androgenic and include amenorrhea and other menstrual irregularities (if given before menopause), inhibition of gonadotropin secretion, and virilization, including deepening of the voice and clitoral enlargement. Clitoral enlargement is not reversible after therapy ends.

Other effects related to the actions of testosterone on the body may occur. They include hypercalcemia, particularly in immobile patients and patients with metastatic breast cancer; retention of sodium, chloride, water, potassium, calcium, and inorganic phosphates; hypercholesterolemia; and edema. In addition, rash, acne, seborrhea, and hirsutism may occur. Prostatic hypertrophy, prostatic cancer, and urethral obstruction are also possibilities. Other potential adverse effects include hepatitis (which can be life threatening), hepatocellular carcinoma (with prolonged use of high doses), premature closing of the long bones, dizziness, headache, sleep disorders, fatigue, changes in libido, and polycythemia (excess of red blood cells).

Drug Interactions

No important drug interactions are associated with natural testosterone. With the synthetic forms, anticoagulation effect is increased if anticoagulants are given with either fluoxymesterone or methyltestosterone. Coadministering methyltestosterone and imipramine may result in paranoia-like symptoms.

Assessment of Relevant Core Patient Variables

Health Status

Assess for existing serious heart, kidney, or liver disease, which are contraindications for therapy, and screen for established hypersensitivity to testosterone. Determine whether male patients have carcinoma of the breast or prostate, which is a contraindication, or whether they have gynecomastia or BPH, because these conditions require precautions. Assessing for a history of MI, CAD, or acute intermittent porphyria is important because all these factors require caution in use of testosterone. Because of testosterone's effects on bone growth, only people with expert training and knowledge of the drug and its effects on bone growth should prescribe it.

Life Span and Gender

Carefully consider age-related assessment data for problems possibly related to the use of testosterone. When testosterone is used in prepubescent boys to treat hypogonadism or delayed onset of puberty, premature closure of the long bones may lead to stunted growth. Caution also is necessary when testosterone is used in elderly men. Testosterone is not normally used in

BOX 51.1 COMMUNITY BASED CONCERNS

Athletes and Testosterone

Nurses perform a significant service when they teach patients or community groups about pitfalls of unorthodox drug use:

- Athletes have used and abused testosterone and anabolic steroids in an effort to increase muscle mass. These drugs have not been shown to be effective for this purpose.
- Serious potential adverse effects include early closure of epiphyseal growth plates, which stunts normal growth; edema (with or without CHF); and male gynecomastia.
- Increase in weight and muscle size is partially the result of water retention.

premenopausal females because it is likely to produce masculinization. If a woman is prescribed testosterone, assess the patient for pregnancy. Testosterone is a pregnancy category X; it causes masculinization of the female fetus, as characterized by clitoromegaly, abnormal vaginal development, and fusion of the genital folds to form a scrotum-like structure. These effects are most likely to occur if testosterone is given during the first trimester. If large amounts of the drug are given to a male fetus, adverse effects also are possible. It is not known whether testosterone crosses into breast milk, but testosterone is rarely used in young women.

Lifestyle, Diet, and Habits

Although anabolic steroids are abused more frequently to enhance athletic performance, testosterone has also been abused for this purpose. This use is not a safe and effective one for this drug. Verify that the patient is not abusing testosterone (Box 51.1).

Environment

Testosterone may be administered in any setting.

Nursing Diagnoses and Outcomes

- Delayed Growth and Development related to potential for early epiphyseal closure secondary to drug therapy
  Desired outcome: *The patient will attain normal height while receiving drug therapy.*
- Ineffective Sexuality Patterns related to effect of drug therapy
  Desired outcome: *The male patient will develop normal male sexual organs and characteristics. The female patient will not experience excessive masculinization during therapy.*
- Excess Fluid Volume related to potential effects of drug therapy
  Desired outcome: *The patient will not experience enough increase in fluid volume to become edematous during drug therapy.*
- Potential Complication: Hypercalcemia related to drug therapy, immobility, breast cancer
  Desired outcome: *The patient will not develop hypercalcemia.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer the drug at regular intervals to maintain therapeutic testosterone levels. Adjust the dose upward per order when giving testosterone to treat hypogonadism and induce puberty. At the end of the growth spurt, the patient should remain on a maintenance dose.

Some nursing actions specific to the route of administration can maximize the therapeutic effect of testosterone. Do not place transdermal patches on the scrotum. Rather, place them on clean, dry skin on the arm, back, or upper buttocks. The skin area should not be oily, damaged, or irritated. The patient wears these patches for 24 hours and then replaces them. Apply topical preparations to clean, dry, intact skin of the shoulder, upper arm, or abdomen, *not* to the genitals.

Either the nurse or the patient places buccal tablets between the gum and the cheek. The tablets should be allowed to dissolve; they should never be swallowed.

For suspensions, agitate the vial to mix the drug thoroughly before drawing it into a syringe and administering it intramuscularly.

Minimizing Adverse Effects

When prepubescent boys undergo testosterone therapy, radiographs should be taken every 6 months to assess bone age. Radiographs help document bone maturation and the effect of testosterone on the epiphyseal centers.

Some nursing actions can minimize the adverse effects of testosterone. Monitor serum cholesterol levels and liver function periodically. Check hemoglobin and hematocrit levels periodically for polycythemia during treatment with high doses. Monitor serum and urine calcium levels in women receiving testosterone for disseminated breast cancer. In women receiving testosterone for palliative treatment of metastasized breast cancer, monitor the disease progression closely because occasionally the drug may accelerate the disease process.

When administering testosterone by intramuscular injection, inject deep into the gluteal muscle to prevent inflammation and pain at the administration site. Never administer the drug intravenously.

When administering transdermal testosterone, rotate sites of application, with at least 1 week between applications to the same area to minimize localized reactions. Discard used transdermal patches by folding them and putting them into trash in an appropriate manner or flush them down the toilet. Active drug remains after use, so accidental application or ingestion of patches by children would be dangerous.

Assess for signs of adverse effects and contact the prescriber if adverse effects are noted, especially severe masculinization in women or edema or jaundice in either sex. Dosage adjustments or cessation of therapy may be indicated.

Providing Patient and Family Education

- Teach patients and families the rationale for use of the drug, including therapeutic effects and potential adverse effects.

- Instruct patients and families about proper administration technique. If drug administration is intramuscular, teach patients how to safely dispose of needles and syringes. If administration is transdermal, teach patients how to dispose of used patches. If administration is buccal, teach patients to place the tablet between gum and cheek and not to swallow it. Remind these patients not to eat, drink, or smoke while the tablet is in place, because doing so will alter absorption of the drug.
- Review the importance of scheduling and keeping follow-up appointments for radiographs and blood tests.
- Alert patients to notify the prescriber if swelling of the extremities (edema), jaundice, or prolonged painful erection develops. Women should notify the prescriber if they develop hoarseness, deepening of the voice, menstrual irregularities, acne, or facial hair growth.

Ongoing Assessment and Evaluation

Throughout testosterone therapy monitor for adverse effects as well as blood test results. Assess bone growth regularly, as noted previously. In men, therapy is considered effective if development of male sex organs and male sexual characteristics occurs normally, or if patients maintain secondary male sexual characteristics without adverse effects. In women with breast cancer, testosterone therapy is considered effective if discomfort from the malignant tumor is minimized and the disease advances no further.

Drugs Closely Related to P Testosterone

Synthetic Testosterones

Fluoxymesterone (Halotestin) is a synthetic testosterone derivative with significant androgen activity. Synthetic fluoxymesterone is similar to the endogenous form; it suppresses testosterone release and spermatogenesis. It also inhibits the secretion of luteinizing hormone and follicle-stimulating hormone through a negative feedback mechanism. Fluoxymesterone is approved for use as an adjunct treatment for breast cancer in women who are more than 1 year but less than 5 years postmenopausal. It has palliative (not curative) effects in tumors that are androgen hormone responsive but recurrent and metastasized. Fluoxymesterone is also approved for use in adults and children with delayed puberty and hypogonadotropic hypogonadism.

Methyltestosterone (Android) is a synthetic derivative of testosterone. Its uses include delay in male sexual development and/or puberty, hypogonadotropic hypogonadism, primary hypogonadism, and metastasis from inoperable metastatic (to the skeletal system) breast cancer in women who are 1 to 5 years postmenopausal.

Anabolic Steroids

The anabolic steroids are derived from testosterone and, like testosterone, have both anabolic and androgenic effects. Unlike testosterone, these drugs have anabolic effects that are much stronger than their androgenic effects. In fact, their two major actions are to promote body tissue-building processes and reverse catabolic or tissue-depleting processes. Anabolic steroids are also used to control metastatic breast cancer in women.

Oxandrolone (Oxandrin), given orally, is an adjunct for weight gain in adults and children who have lost weight as a result of chronic infection, surgery, or severe trauma as well as in patients who fail to gain or maintain weight without definite pathophysiologic reasons. The drug is also used to offset protein catabolism after prolonged corticosteroid use. Its anabolic activity is approximately six times that of methyltestosterone in human subjects following oral administration. Oxandrolone stimulates protein synthesis in skeletal muscle without affecting protein breakdown, resulting in net anabolism. The increase in protein synthesis is accomplished by increased intracellular reutilization of amino acids.

Oxandrolone is effective in increasing weight gain in HIV-associated weight loss (AIDS-related wasting syndrome) but is associated with significant increases in transaminases and low-density lipoproteins (LDLs) as well as decreases in high-density lipoproteins (HDLs). This remains an off-label use of the drug.

Stanozolol (Winstrol), another anabolic steroid, is used prophylactically to decrease the frequency and severity of attacks of hereditary angioedema (characterized by episodic edema of the abdominal viscera, extremities, face, and airway). It also has the ability to decrease HDL and increase LDL cholesterols, sometimes markedly. Stanozolol carries a Black Box warning concerning its ability to increase cholesterol levels.

MEMORY CHIP

P Testosterone

- Used as hormone replacement therapy in male hypogonadism that is associated with low or absent endogenous testosterone
- Major contraindication: serious cardiac, hepatic, or renal disease, because edema with or without CHF may be a complication
- Most common adverse effects: gynecomastia, excessive frequency and duration of penile erections, decreased ejaculatory volumes, and oligospermia; masculinization in females
- Most serious adverse effect: life-threatening hepatitis
- **Life span alert: Pregnancy category X drug; prepubescent boys may have premature closing of long bones.**
- Maximizing therapeutic effects: Administer at regular intervals; place transdermal patches appropriately on skin.
- Minimizing adverse effects: radiographs every 6 months to determine bone maturation and the effect on the epiphyseal growth centers when treating prepubescent boys; safe disposal of used transdermal patches
- Most important patient education: Notify health care provider if swelling of the extremities (edema), jaundice, or painful, continued erection develops.

Serious adverse effects common to both oxandrolone and stanozolol include peliosis hepatitis (in which blood-filled cysts replace normal liver cells and sometimes spleen cells, a condition that can be associated with liver failure), liver tumors (possibly malignant), and blood lipid changes associated with an increased risk of atherosclerosis (resulting from the previously mentioned decreased HDLs and sometimes increased LDLs). Stanozolol and oxandrolone carry Black Box warnings for these adverse effects. In females, masculinization effects similar to those effects produced by (short-acting) testosterone occur with use of anabolic steroids. Like testosterone, anabolic steroids are in pregnancy category X because of the possibility of fetal masculinization.

An abuse or addiction syndrome has been recognized with the chronic use of anabolic steroids to improve athletic performance (see Box 51.1). The use of these drugs to improve athletic performance is questionable because of the possibility of serious adverse effects, which may be irreversible.

Drug Significantly Different From Testosterone

Chorionic gonadotropin is virtually identical to luteinizing hormone, which is produced in the pituitary gland. However, this drug has a small amount of follicle-stimulating hormone activity as well. Chorionic gonadotropin exerts its actions primarily on the ovaries and testes. In the ovaries, it works with follicle-stimulating hormone to produce a mature ovum, and it stimulates the corpus luteum to produce progesterone. In the testicles, it stimulates the production of androgen, leading to the development of male secondary sex characteristics, and it may stimulate testicular descent if there are no anatomic abnormalities preventing descent. Chorionic gonadotropin is used in the treatment of cryptorchidism (undescended testes in boys), in the treatment of hypogonadotropic hypogonadism in men, and to induce ovulation in women with fertility problems. It is discussed further in the chapter on women's health and sexuality (Chapter 52).

Drugs Used To Treat Erectile Dysfunction

Agents to treat erectile dysfunction work to mimic the body's natural methods of achieving an erection. Sildenafil (Viagra)is a cGMP-specific phosphodiesterase type 5 (PDE5) inhibitor. This drug class is considered the standard first-line therapy for erectile dysfunction (Ellsworth & Kirshenbaum, 2008).

Nursing Management of the Patient Receiving P Sildenafil

Core Drug Knowledge

Pharmacotherapeutics

Sildenafil is used to treat erectile dysfunction. It is administered orally, usually 1 hour before sexual activity. Sildenafil is effective only with accompanying sexual stimulation. A large percentage of men with diabetes and cardiovascular risk factors also have erectile dysfunction. The drug has been shown to be effective and well tolerated in men with erectile dysfunction, diabetes, and at least one other cardiovascular risk factor. In controlled studies, men with known heart disease who were taking sildenafil or one of the other PDE5 inhibitors, did not experience increased cardiac discomfort or increased ischemia during stress testing (Ellsworth & Kirshenbaum, 2008). Sildenafil is effective in erectile dysfunction after a radical prostatectomy, but only if either a bilateral or unilateral nerve-sparing procedure has been performed. It may be effective in men younger than 55 years of age if one nerve is not cut (unilateral sparing).

Sildenafil, sold under the trade name of Revatio, is also used as treatment for pulmonary arterial hypertension (PH) (Box 51.2). When given for PH, sildenafil is dosed differently; it is administered three times a day, with or without food. The RELAX trial, funded by the National Institutes of Health, is currently studying the potential for the use of sildenafil for the treatment of diastolic heart failure (Desai, 2009).

BOX 51.2 FOCUS ON RESEARCH

New Indications for Sildenafil

Blanco, I., Gimeno, E., Munoz, P. A., et al. (2010). Hemodynamic and gas exchange effects of sildenafil in patients with chronic obstructive pulmonary disease and pulmonary hypertension. *American Journal of Respiratory and Critical Care Medicine,* 181(3):270–278.

The Study

The researchers studied the hemodynamic and gas exchange effects of sildenafil in patients with COPD-associated pulmonary hypertension (PH). Eleven patients were randomly assigned to 20 mg, and nine patients to 40 mg, of sildenafil. Pulmonary hemodynamics and gas exchange, including ventilation-perfusion (V(A)/Q) relationships, were assessed at rest and during exercise, before and 1 hour after sildenafil administration. Both doses of sildenafil equally decreased the mean pulmonary arterial pressure (PAP) at rest and during exercise (–6 mm Hg at rest; –11 mm Hg during exercise). In addition, during rest, PaO_2 decreased –6 mm Hg because of increased perfusion in units with low V/Q ratios. PaO2 and V/Q relationships remained stable during exercise. The researchers concluded sildenafil improves pulmonary hemodynamics at rest and during exercise in patients with COPD-associated PH. Sildenafil also inhibited hypoxic vasoconstriction, which impairs arterial oxygenation at rest.

Nursing Implications

There are few effective drugs for the management of pulmonary hypertension (PH) and most have significant contraindications and precautions that preclude their use. Sildenafil (Revatio) is a new dosage formulation made specifically for the management of PH. Studies are now being conducted that will assess its use in COPD and heart failure patients. It is important for the nurse to remain updated on the off-label use of drugs and how to manage the patient appropriately.

Pharmacokinetics

Sildenafil is rapidly absorbed. Maximum plasma concentrations are reached within 30 to 120 minutes of oral dosing when taken on an empty stomach (the most frequent peak time is 60 minutes). When taken with a high-fat meal, absorption is delayed, so that approximately 60 extra minutes are needed to reach peak plasma levels. A high-fat meal also reduces peak serum concentrations by 29%.

Sildenafil is metabolized by two hepatic microsomal isoenzymes. The primary isoenzyme involved in metabolism is CYP3A4. A second isoenzyme, with a more minor effect on metabolism, is CYP2C9. Through these pathways, sildenafil is converted into an active metabolite that is further metabolized. The metabolite has pharmacologic properties similar to the parent drug and accounts for about 20% of sildenafil's pharmacologic effect. The metabolite of sildenafil is excreted primarily in the stool and to a small extent in the urine. Men older than 65 years have a reduced sildenafil clearance and elevated free plasma concentrations that are about 40% greater than in younger men.

Pharmacodynamics

Sildenafil inhibits PDE type 5, the isoenzyme that metabolizes cGMP. The decreased metabolism of cGMP allows it to remain active longer, increasing smooth muscle relaxation and inflow of blood. These circumstances allow for an improved and more sustained erection. Because sildenafil works at the end of a cascade of events that produce erection, starting with sexual stimulation releasing nitric oxide, in normal doses sildenafil is not effective without sexual stimulation. Men must continue sildenafil treatment to maintain improvement in erectile function. Use of sildenafil improves erectile function and also self-esteem, confidence, and satisfaction in a man's personal relationship. Studies suggest improved erectile quality leading to more satisfying sexual experiences can have a positive impact on psychosocial quality of life (Ellsworth & Kirshenbaum, 2008).

When sildenafil is used to treat pulmonary arterial hypertension, it stabilizes patients clinically, as well as improving their exercise capacity and the function of the right ventricle (Ramani & Park, 2010). The drug causes vasodilation of the pulmonary vascular bed, and to a lesser degree, vasodilation in the systemic circulation.

Contraindications and Precautions

Sildenafil is contraindicated if the patient is currently using nitrates because its vasodilating effects potentiate the hypotensive effects of nitrates. Sildenafil is also contraindicated if the patient has hypersensitivity to any component of the tablet.

The American College of Cardiology and the American Heart Association recommend caution when sildenafil is prescribed to patients who have coronary ischemia, CHF, or hypotension, or to those patients with a history of MI, cerebrovascular accident (stroke), or life-threatening arrhythmias within the past 6 months. These professional groups also recommend that any patients with strong cardiac risk factors or known cardiac disease should undergo an exercise stress test before beginning any treatment for erectile dysfunction.

Adverse Effects

Adverse effects from sildenafil are generally transient and mild to moderate in nature. The most common adverse effects are facial flushing, headache, nasal congestion, and heartburn. Other adverse effects are diarrhea, urinary tract infections, blue-tinged vision and light sensitivity, blurred vision, dizziness, and rash.

A rare adverse effect of sildenafil has been reported: nonarteritic anterior ischemic optic neuropathy, in which the patient has a sudden loss of vision in one or both eyes that is occasionally permanent. It is believed that other comorbidities, considered risk factors for nonarteritic anterior ischemic optic neuropathy, are the underlying cause of this problem, but this has not been determined conclusively. In the few post-marketing reports, most of the patients who developed this adverse effect had underlying anatomic or vascular risk factors (low cup-to-disc ratio, age older than 50 years, diabetes, hypertension, coronary artery disease, hyperlipidemia, and smoking).

Although some cardiovascular system–related deaths of patients taking sildenafil have been reported since the drug has been on the market, research and statistical analysis have found that sildenafil is not responsible for causing an excessive number of cardiovascular deaths. The anecdotal reports of deaths are believed to be caused by pre-existing cardiac risk factors (e.g., hypertension, diabetes mellitus, smoking, and depression) and the cardiovascular "work" or effort involved in sexual intercourse. However, based on these incidents, precautions must be used with patients who have known cardiovascular problems because they may have greater risk for cardiovascular adverse effects from sildenafil (see Contraindications and Precautions, above).

Overdosing produces adverse effects similar to those effects associated with normal dosing but at an increased rate of incidence. Standard supportive measures for drug overdose should be used. Renal dialysis is not helpful because little of the drug is excreted renally.

Drug Interactions

The CYP3A4 isoenzyme and, to a lesser degree, the CYP2C9 isoenzyme mediate sildenafil metabolism. Any drug that inhibits these systems may produce a drug interaction with sildenafil and decrease its clearance, raising plasma levels as a result. Strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, erythromycin, and cimetidine) have been shown to increase the plasma levels of sildenafil as much as 200%. Any drug that induces CYP3A4, such as rifampin, will therefore probably increase the metabolism of sildenafil and subsequently decrease plasma levels of sildenafil. However, this association has not been definitively proved. As previously discussed, nitrates interact with sildenafil, increasing both vasodilation and hypotension. Table 51.2 lists drugs that interact with sildenafil.

TABLE 51.2 Drugs That Interact with P Sildenafil

Interactants	Effect and Significance	Nursing Management
Nitrates	Sildenafil potentiates the vasodilating effect of nitric oxide from nitrates, resulting in a significant and potentially fatal decrease in blood pressure (BP).	Teach patient that he should not use any nitrate while taking sildenafil.
Azole antifungal agents	Azole antifungal agents inhibit the metabolism of sildenafil. Elevated plasma levels of sildenafil may increase risk for adverse effects	Monitor for adverse effects; a decreased dose may be indicated; consider starting dose of 25 mg.
macrolides	Macrolide antibiotics inhibit the metabolism of sildenafil. Elevated plasma levels of sildenafil may increase risk for adverse effects	Monitor for adverse effects; a decreased dose may be indicated; consider starting dose of 25 mg.
Protease Inhibitors	Protease inhibitors inhibit the metabolism of sildenafil. Elevated plasma levels of sildenafil may result in severe and potentially fatal hypotension.	Advise the patient of the risk for hypotension. Encourage the patient to refrain from use.
Serotonin Reuptake Inhibitors	SSRIs inhibit the metabolism of sildenafil. Elevated plasma levels of sildenafil may increase risk for adverse effects	Monitor for adverse effects; a decreased dose may be indicated; consider starting dose of 25 mg.

A drug–food interaction occurs when a patient takes sildenafil with a high-fat meal, delaying the rate of absorption and reducing peak serum levels.

Assessment of Relevant Core Patient Variables

Health Status

Review the patient's medication history to determine whether the patient is taking nitrates, because nitrate use is a contraindication for use of sildenafil. Assess for any of the cardiovascular problems that require cautious use of sildenafil: coronary ischemia, CHF, or hypotension; or a history of MI, cerebrovascular accident, or life-threatening arrhythmias within the past 6 months. Verify that the patient is not allergic to any component of sildenafil. Assess also for hepatic cirrhosis, which decreases metabolism of sildenafil and increases blood level of active sildenafil. Such patients may need a decreased dose. Although only a small portion of sildenafil is excreted renally, severe renal impairment does increase the maximum blood concentration of the drug. A decreased dose may also be indicated in this situation. Finally, assess for a history of nonarteritic anterior ischemic optic neuropathy, because this may increase the patient's risk of developing this adverse effect from sildenafil.

Life Span and Gender

Inquire about the patient's age. Men aged 65 years or older show increased circulating levels of sildenafil, which is most likely the result of decreased metabolism from normal age-related changes in the liver. These patients may require a decreased dose. Sildenafil is not approved for use in women.

Lifestyle, Diet, and Habits

A high-fat meal eaten before the use of sildenafil decreases the rate of absorption and reduces the maximum blood level achieved by drug therapy by about 29%. If the patient states that the drug is not always effective, assess his dietary intake. Decreasing dietary fat may increase the effectiveness of the drug therapy without a need for an increased dose.

Environment

Sildenafil is self-administered in the home.

Culture and Inherited Traits

Although most research on sildenafil has been performed on white men, the drug has also been studied in Asian men and found to be effective and well tolerated in this population.

Nursing Diagnoses and Outcomes

- Sexual Dysfunction related to erection dysfunction
  Desired outcome: *Use of sildenafil will allow the patient to experience normal expression of sexuality.*
- Risk for Injury related to adverse effects of drug therapy
  Desired outcome: *The patient will not experience adverse effects from sildenafil, or effects will be mild, transient, and well tolerated.*

Planning and Intervention

Maximizing Therapeutic Effects and Minimizing Adverse Effects

Nursing strategies to maximize the therapeutic effects and minimize the adverse effects of sildenafil are related to the patient education that is provided.

Providing Patient and Family Education

- Tell patients that sildenafil is not effective without sexual stimulation and arousal.
- Teach patients to take sildenafil about 1 hour before sexual activity.
- Instruct patients not to take nitrates (e.g., nitroglycerin, isosorbide) while taking sildenafil.
- Inform patients that sexual activity increases the risk of cardiovascular problems, including MI, for people with known cardiovascular risks. If patients experience any

CRITICAL THINKING SCENARIO

EFFECTIVENESS OF SILDENAFIL

Joe Rosenbaum is 64 years old and takes sildenafil for erectile dysfunction. He returns to the clinic for follow-up. On assessment, you learn that the drug therapy appears to be effective and that Mr. Rosenbaum is tolerating it well without apparent adverse effects. You ask whether he has any other concerns or questions. He hesitates, and then laughingly says, "The only thing is, this pill doesn't seem to be as helpful if we've gone out to a restaurant for dinner. I guess it likes my wife's cooking better." What questions might you ask Mr. Rosenbaum to help determine a possible cause of this variation in sildenafil's effectiveness?

symptoms of cardiovascular problems during sexual intercourse (e.g., angina, dizziness, nausea), they must stop the sexual activity. They should discuss any such problems with the prescriber.
- Tell patients to avoid high-fat meals before using sildenafil.
- Instruct patients that if vision loss occurs, they should discontinue the drug and notify the physician or nurse practitioner as soon as possible.

Ongoing Assessment and Evaluation

Sildenafil therapy is considered if the patient reports decreased problems with erectile dysfunction, or if the pulmonary arterial hypertension is controlled.

Drugs Closely Related to P Sildenafil

Two Food and Drug Administration (FDA)–approved drugs closely related to the prototype sildenafil are vardenafil and tadalafil, which are also PDE5 inhibitors. All three of these PDE5 inhibitors have a similar action and efficacy; however, slight differences exist—primarily related to their duration of action. Sildenafil should be taken approximately one hour before anticipated sexual activity, while tadalafil has a much longer duration and can be taken if sexual activity is anticipated within 36 hours. Another drug closely related to sildenafil is the injectable drug alprostadil.

MEMORY CHIP

P Sildenafil

- Used to treat erectile dysfunction in men
- Major contraindication: current use of nitrates
- Most common adverse effects: facial flushing, headache, nasal congestion, and heartburn
- Most serious adverse effect: may increase risk of cardiovascular death in patients with current cardiovascular problems
- Most important patient education: Sexual stimulation and arousal are needed for drug effectiveness; take 1 hour before engaging in sexual activity.

Vardenafil

Vardenafil (Levitra) treats erectile dysfunction similarly to sildenafil, as another PDE5 inhibitor. Like sildenafil, it is taken orally 1 hour before intercourse for best results. Vardenafil is metabolized by the P-450 system, primarily CYP3A4 and CYP2C isoforms. Patients who take other drugs that inhibit CYP3A4, such as ritonavir, may have elevated blood levels of vardenafil, although no specific recommendations to decrease the dose of vardenafil exist. Coadministering vardenafil with alpha blockers can produce severe hypotension and is contraindicated. Nitrate use is also contraindicated for vardenafil, as it is for sildenafil. The contraindications and adverse effects of vardenafil are similar to those of sildenafil. The incidence of visual disturbances is somewhat less with vardenafil than with sildenafil.

Tadalafil

The third cGMP drug for treating erectile dysfunction is tadalafil (Cialis). Like the other two drugs in this class, sildenafil and vardenafil, tadalafil works by blocking the degradation of cyclic guanosine monophosphate. Like the other drugs, tadalafil should not be taken within 48 hours of taking nitrates, such as nitroglycerine, because substantially lower blood pressure and possibly death may result. Nitroglycerine use is a contraindication for taking tadalafil, as it is for all drugs in this class. Additionally, tadalafil should not be taken with alpha blockers, other than tamsulosin (given for BPH), because the same drug interaction may occur. Adverse effects are similar to the other drugs in the class.

The major advantage of tadalafil is that it has a longer duration of action than the other two drugs used to treat erectile dysfunction. Improved ability to achieve and sustain an erection can occur as soon as 30 minutes after taking tadalafil and as long as 36 hours after taking the drug.. This longer duration may be an advantage for those patients who feel that the need to take the drug within 60 minutes of desired sexual activity produces emotional anxiety.

Alprostadil

A drug closely related to sildenafil is alprostadil (Caverject, Edex, Muse), which is also used to treat erectile dysfunction. It is used in men who have failed to respond to sildenafil or for whom sildenafil is contraindicated. Unlike sildenafil, which is administered orally, alprostadil is administered by injection into the dorsal lateral aspect of the proximal third of the penis, or by intraurethral pellets. Alprostadil produces various pharmacologic effects; the most important are relaxation of smooth muscle, vasodilation of the arteries in the erectile tissue, and inhibition of platelet aggregation. Erection is achieved by the combination of relaxation of smooth muscles in the penis and vasodilation. An erection should occur within 5 to 20 minutes after administration. Unlike sildenafil, sexual arousal is not a prerequisite to the effectiveness of alprostadil.

Alprostadil is also given intravenously as palliative treatment for infants with patent ductus arteriosus until surgery can be performed. Off-label uses of alprostadil include

pulmonary hypertension, Raynaud disease, peripheral vascular disease, and fulminant hepatic failure due to viral hepatitis.

Absorption of alprostadil occurs from the urethra with both forms of administration. With the intraurethral technique, urination should precede drug administration. The residual urine then disperses the medicated pellet, allowing absorption through the urethral mucosa. Little alprostadil enters the general circulation. Alprostadil is rapidly converted to compounds that are further metabolized before excretion. Metabolism occurs in the first pass through the lung by way of enzymatic oxidation, and almost all the drug is metabolized. This finding accounts for the very low systemic concentration of alprostadil. Excretion of the metabolites occurs primarily through the kidneys.

Contraindications to alprostadil use are those conditions that might predispose the patient to priapism (erection lasting more than 6 hours), including sickle cell anemia or trait, multiple myeloma, and leukemia. Alprostadil is also contraindicated in patients with anatomic deformations of the penis (e.g., angulation, cavernosal fibrosis) or penile implants (intracavernosal placement), if sexual activity is inadvisable or contraindicated for the man, and for sexual intercourse with a pregnant woman unless a condom is used, because vasodilation from the drug's action may be harmful to the fetus. The most common adverse effect for both routes of administration is penile pain, which is usually mild or moderate. The most common adverse effects that are solely related to intraurethral administration are urethral pain and burning. Vaginal burning, itching, or both can occur in the female partner of the man using intraurethral alprostadil. Other adverse effects that may occur with intracavernosal administration are penile fibrosis, hematoma at the injection site, prolonged erection, and penile rash or edema. Priapism may occur, although it is not common. The pharmacodynamics of alprostadil may lead to hemodynamic changes, such as decreased blood pressure and increased heart rate, although these changes are not clinically important.

Patient education on the administration technique is important. Assess the patient's technique before the patient uses the drug on his own at home.

Drug Significantly Different From P Sildenafil

Yohimbine

Yohimbine (Aphrodyne, Dayto Himbin, Yocon, Yohimex), although recognized as a drug by the FDA, has no FDA-approved indications. It is actually an herbal preparation. It is the principal alkaloid of the bark of the *Corynanthe yohimbe* tree. Clinical trials show that it has a modest benefit in treating erectile dysfunction, particularly in psychogenic erectile dysfunction, but results of the trials are not always statistically significant. Since the development of sildenafil and the other PDE5 inhibitors, its use is not generally recommended (American Urological Association, 2005/2006).

Yohimbine is taken orally, three times a day. It is an alkaloid with chemical similarities to the drug reserpine. Yohimbine is believed to have properties similar to *Rauwolfia* alkaloids. It is primarily an alpha-2 adrenergic blocker of presynaptic alpha-2 receptors, which causes release of norepinephrine. It affects the peripheral autonomic nervous system by increasing parasympathetic (cholinergic) activity and by decreasing sympathetic (adrenergic) activity, thus producing erection. Yohimbine has a stimulating effect on mood and may increase anxiety, although mostly at high doses. Yohimbine is contraindicated in renal disease. All major adverse effects occur in the CNS (e.g., nervousness, irritability, tremor, dizziness, headache, and skin flushing). Reportedly, the drug exerts no appreciable influence on cardiac stimulation. Its exact effect on blood pressure is not known.

Drugs To Treat Benign Prostatic Hypertrophy

As discussed earlier, 5-alpha reductase (specifically type II) converts testosterone into the androgen 5-alpha dihydrotestosterone (DHT). Alpha-1 blockers are also used in treating BPH, either alone or as combination therapy with a 5-alpha reductase; the combination therapy has been found to be more effective than alpha blockers alone (American Urological Association, 2003). Because the prostate gland depends on DHT for growth, interference with this process is helpful in treating BPH. Surgical intervention is another option. Transurethral resection of the prostate is the most common surgical intervention, although a prostatectomy or radical prostatectomy may be performed.

The prototype drug for treating BPH is finasteride (Proscar). Alpha-blockers are discussed briefly in this chapter related to their use in BPH; additional information about these drugs can be found in Chapters 13 and 26.

Nursing Management of the Patient Receiving P Finasteride

Core Drug Knowledge

Pharmacotherapeutics

Finasteride is used to treat BPH and androgenetic alopecia (male pattern baldness); the dose used for male hair loss is much smaller than that used for BPH (see Table 51.1). Two separate trade names are used to differentiate these preparations. Proscar is the trade name of finasteride used in BPH. Propecia is the trade name of finasteride used for male pattern baldness. The therapeutic effect for BPH is seen within 6 to 12 months of treatment, although it sometimes occurs earlier. Daily usage for more than 3 months is needed to see therapeutic effects when treating baldness. The therapeutic effects are reversed for both BPH and hair loss if the patient stops drug therapy.

Pharmacokinetics

Finasteride is well absorbed after oral administration. Food does not affect its absorption. Finasteride is highly protein bound, at a rate of about 90%. It is extensively metabolized

in the liver through oxidative pathways. The inactive metabolites are excreted in the bile and feces.

Pharmacodynamics

Finasteride specifically inhibits the steroid 5-alpha reductase and consequently blocks the peripheral conversion of testosterone to DHT. Increased DHT contributes to increased size of the prostate and subsequently, to the symptoms associated with urethral obstruction. Finasteride leads to lowered serum and tissue DHT concentrations, reducing prostatic DHT by as much as 90% and circulating levels of DHT by between 60% and 80%. Finasteride also decreases DHT prostate-specific antigen levels by between 41% and 71%. As noted earlier, by blocking the conversion of testosterone to DHT, the goal of finasteride therapy is to reduce the volume of the prostate in an attempt to decrease symptoms directly related to this obstruction. These changes improve BPH-related symptoms, increase maximum urinary flow rates, and decrease prostate size.In men with male pattern hair loss, DHT is found in increased amounts in the scalp. Finasteride decreases scalp and serum DHT concentrations in these men. Finasteride does not appear to affect body hair.

Contraindications and Precautions

Finasteride is contraindicated in women and children. It is a pregnancy category X drug because it causes abnormalities of the external genitalia in the male fetus. Because of these risks, pregnant women or women who may become pregnant should not handle crushed or broken finasteride tablets. Finasteride is also contraindicated if hypersensitivity to the drug or any of its components exists. Caution should be used if the patient has impaired liver function, because finasteride is metabolized extensively in the liver.

Adverse Effects

Finasteride is generally well tolerated; adverse effects are usually mild and transient. Adverse effects, which occur in less than 4% of patients taking finasteride, include erectile dysfunction, decreased libido, and decreased volume of ejaculate. Sexual adverse effects resolved with continued treatment in more than 60% of patients who reported these effects. Overdose of finasteride has not been associated with adverse effects.

Drug Interactions

Finasteride decreases PSA levels by about 50%. A decrease in PSA level occurs even if the patient has prostate cancer. This reduction does not suggest a beneficial effect of finasteride on prostate cancer but rather an effect of the drug.

Assessment of Relevant Core Patient Variables

Health Status

Before administering the drug, verify that the patient has the clinical indications for receiving finasteride. Assess patients with BPH for prostate cancer before beginning therapy and periodically throughout therapy.

Life Span and Gender

Finasteride is not given to women or children.

Lifestyle, Diet, and Habits

Assess the patient for use of alternative medications, such as herbs.

Environment

Be aware of the environment in which the medication will be administered. Finasteride may be administered in any environment but is most frequently self-administered in the home.

Nursing Diagnoses and Outcomes

- Risk for Sexual Dysfunction related to drug therapy
  Desired outcome: *If the patient experiences sexual dysfunction, it will resolve with continued drug therapy.*
- Impaired Urinary Elimination related to BPH
  Desired outcome: *Following drug therapy with finasteride, the patient will have no or fewer lower urinary tract symptoms from BPH.*

Planning and Intervention

Maximizing Therapeutic Effects

No specific actions maximize the therapeutic effects of finasteride.

Minimizing Adverse Effects

Adverse effects are a concern for the female nurse as well as the patient. The drug is in pregnancy category X. If you are pregnant or a female and in your childbearing years do not handle crushed or broken finasteride tablets, because absorption is more likely to occur in these circumstances.

When the drug is given at home, teach the patient and family how to handle the drug to minimize risks.

Providing Patient and Family Education

- Teach patients about the rationale for drug use.
- Teach patients about possible adverse effects of the drug (impotence and decreased libido), and inform patients that these effects are usually transient.
- Tell patients that the volume of ejaculate may decrease with the use of finasteride but that this effect does not interfere with normal sexual function.
- Teach patients and their families that female family members who are pregnant or capable of having children must not handle broken or crushed finasteride.

Ongoing Assessment and Evaluation

Monitor the patient for improvement in BPH-related symptoms and increased ease of urination. If finasteride is used for male pattern baldness, increased hair growth and decreased hair loss indicate effectiveness. Throughout therapy, monitor men with BPH for prostate cancer and check PSA levels. Carefully evaluate any man on finasteride whose PSA levels increase; this development may be related to nonadherence to the drug regimen or to prostate cancer.

MEMORY CHIP

P Finasteride

- Used to treat BPH and male pattern baldness
- Major contraindication: use in women and children
- Most common adverse effects: altered sexual function (effects are mild and transient)
- **Life span alert: pregnancy category X**
- Most important patient education: Women who are or may become pregnant should not handle crushed or broken tablets.

Drug Closely Related To C Finasteride

Dutasteride (Avodart) is a 5-alpha reductase inhibitor like finasteride. Preliminary data from a 2-year study comparing dutasteride and finasteride indicated greater decreases in serum dihydrotestosterone with dutasteride after 24 weeks of treatment (at least 95% versus 70%). Compared with finasteride, dutasteride has a much longer systemic half-life (5 weeks versus 6 to 8 hours). It is metabolized through the P-450 isoenzyme 3A4 pathway, so it is likely to cause drug interactions with drugs also metabolized through this pathway. Otherwise, dutasteride is similar to finasteride.

Drugs Significantly Different From P Finasteride

Drugs significantly different from finasteride are the alpha-1 blockers, which include terazosin (Hytrin), doxazosin (Cardura), tamsulosin (Flomax), and alfuzosin (Uroxatral). As mentioned earlier, an additional component of BPH relates to insufficient relaxation of smooth muscle near the prostate and neck of the bladder during urination. Activation of alpha-adrenergic receptors leads to contraction of this smooth muscle. Blocking or inhibiting this response is the goal of these alpha-adrenergic blockers which enhance relaxation of the bladder neck (Rosenberg, Miner, Riley, & Staskin, 2010).

Each of the alpha-adrenergic blockers has been found to be equally effective in treating BPH. Larger doses generally provide additional therapeutic effects. All alpha-adrenergic receptor antagonists may work similarly, but the FDA has approved only terazosin, doxazosin, tamsulosin, and alfuzosin for this use. Alpha-1 blockers have a rapid onset of action, producing a therapeutic response within weeks (regardless of the presence of prostatic enlargement or bladder outlet obstruction). In contrast, finasteride takes longer to achieve therapeutic effects and alleviates only those symptoms associated with a large prostate.

Terazosin and doxazosin are alpha-1 blockers that are also used to treat hypertension (see Chapter 26 for more information). Alfuzosin and tamsulosin are used only to treat BPH.

Terazosin is a little more likely to cause cardiovascular adverse effects than doxazosin. Terazosin has the least hepatic metabolism of any of these drugs.

Tamsulosin is similar to finasteride in that neither drug lowers blood pressure and therefore neither is associated with the cardiovascular adverse effects (e.g., dizziness, postural hypotension) that are linked with the other alpha blockers. However, both are associated with an increased risk of sexual dysfunction; tamsulosin is associated with ejaculatory dysfunction, and finasteride is associated with decreased libido and erectile dysfunction. Alfuzosin hydrochloride (Uroxatral) is known outside of the United States as Oxatral OD. Compared with terazosin and doxazosin, it has a low incidence of possible adverse effects such as postural hypotension, syncope, and sexual side effects. This medication is dosed as a once-daily extended-release formula. It is metabolized through the P-450 3A5 pathway and so has many potential drug interactions. Alfuzosin is a pregnancy category B drug, whereas the others are in pregnancy category C.

DRUGS TO TREAT MALE PATTERN BALDNESS

At present, the FDA has only approved two drugs to treat male pattern baldness: the prototype drug, minoxidil (Rogaine, Minoxidil for Men) (see Table 51.1) and finasteride (Propecia), which is significantly different from minoxidil, as previously noted.

Nursing Management of the Patient Receiving P Minoxidil

Core Drug Knowledge

Pharmacotherapeutics

Minoxidil is used topically to treat androgenetic alopecia. Although men primarily use minoxidil, women also may use it. Minoxidil is effective in male pattern baldness of the vertex and in women with diffuse hair loss or thinning of the frontoparietal areas. It is not effective in patients who have predominantly frontal hair loss. Topical minoxidil is available as an over-the-counter (OTC) medication.

Pharmacokinetics

Topical minoxidil is poorly absorbed from normal intact scalp. Decreased integrity of the epidermal barrier from conditions such as inflammation, excoriations of the scalp, scalp psoriasis, or severe sunburn may increase systemic absorption. These abnormal scalp conditions may increase absorption enough to pose a risk for increased adverse effects.

Pharmacodynamics

The exact mode of action for topical minoxidil is unknown; however, it seems to increase the length of the anagen phase and possibly has a positive effect on the blood supply to the hair follicle (Feinstein, 2010). Oral minoxidil was originally developed as a peripheral vasodilator used in treating hypertension, and hair growth was considered an adverse effect of the drug (see Chapter 26 for more information on peripheral vasodilators used in hypertension). Topical applications require at least 4 months of twice-daily application before the patient can expect evidence of hair growth. About 60% of patients who use minoxidil experience hair growth.

Patients who respond to drug therapy need to continue the drug to maintain therapeutic effects. Reports indicate that the balding process resumes fairly soon after drug therapy is stopped.

Contraindications and Precautions

The only contraindication to topical minoxidil is hypersensitivity to any component of the drug. Topical minoxidil is classified as a pregnancy category C drug because no adequate and well-controlled studies in pregnant women have been conducted. Thus, women must avoid using it during pregnancy. Safety and efficacy in children younger than 18 years have not been established.

Adverse Effects

The most common adverse effects of topical minoxidil are irritant dermatitis and allergic contact dermatitis. Other dermatologic effects are eczema, local erythema, pruritus, dry skin and scalp flaking, and exacerbated hair loss. Systemic absorption can cause the adverse effects associated with orally administered minoxidil, including edema, chest pain, increased or decreased blood pressure, and increased or decreased pulse. Oral minoxidil carries a Black Box warning for its appropriate use and its potential for serious cardiac events in patients with preexisting cardiovascular disorders.

Topical minoxidil contains alcohol. Burning or irritation may develop if the drug gets into the eyes, mouth, or mucous membranes or onto sensitive skin. Overdose has not been reported with topical applications of minoxidil.

Drug Interactions

Topical minoxidil should not be used with other topical agents (e.g., corticosteroids, retinoids, petrolatum) known to enhance cutaneous drug absorption.

Assessment of Relevant Core Patient Variables

Health Status

Verify that the patient has male pattern baldness and does not have predominantly frontal hair loss, because topical minoxidil is not effective for frontal hair loss. If the drug is given to women, the hair loss must be diffuse or identified as thinning of the frontoparietal area for therapy to be effective. Ensure that the patient has a normal, healthy scalp before and throughout therapy. A non-intact scalp promotes systemic absorption, and adverse effects may be more prominent, especially in patients with a history of heart disease. Monitor these patients closely for any problems with tachycardia or fluid retention.

Life Span and Gender

Topical minoxidil is used primarily in men, although it may be used in women. In female patients, assess for pregnancy and intention to become pregnant because use of minoxidil in pregnancy is to be avoided. Minoxidil is a pregnancy category C drug. Ensure that the patient is older than 18 years of age because the drug's safety in children has not been established.

Environment

Be aware of the environment in which minoxidil will be administered. Topical minoxidil is self-administered in the patient's home.

Nursing Diagnoses and Outcomes

- Situational Low Self-Esteem related to hair loss
  Desired outcome: *The patient's self-esteem will improve, related to hair growth from drug therapy.*
- Risk for Injury related to adverse effects of drug therapy
  Desired outcome: *The patient will not experience adverse effects of drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Nursing actions to maximize the therapeutic effect are related to patient education.

Minimizing Adverse Effects

Nursing actions to minimize the adverse effects are related to patient education.

Providing Patient and Family Education

- Teach patients receiving topical minoxidil the purpose and possible adverse effects of the drug.
- Teach patients to administer the drug using this technique:
  1. Dry the hair and scalp before application.
  2. Apply 1 mL to the total affected area of the scalp twice daily, once in the morning and once at night.
  3. Wash hands after applying the drug.
- Advise patients not to use minoxidil with other topical medications on the scalp.
- Caution patients not to apply minoxidil if the scalp is irritated or sunburned, because these conditions may increase the risk of adverse effects.
- Advise patients not to try to make up for any missed doses but to simply resume the normal administration schedule instead.
- Teach patients not to use more than the prescribed amount twice a day.

MEMORY CHIP

P Minoxidil (topical)

- Used topically to promote growth of hair in male pattern baldness
- Use for 4 months or more required to see effect
- Is an over-the-counter drug
- Most common adverse effects: irritation and dermatitis at application site
- Most serious adverse effects: edema and tachycardia
- Most important patient education: Use bid; do not increase dosage or frequency; do not use if scalp is irritated or sunburned.

- Advise patients that twice-daily use for 4 months or longer may be needed to see results. Fine, soft, colorless hair that is barely visible may be the first hair to grow. Over time, the new hair will become the same color and thickness as the other hair on the scalp.
- Keep medication out of the eyes and mouth; avoid applying it to sensitive skin on the face. If accidental exposure occurs, flush the area with large amounts of cool tap water. Consult with the prescriber if irritation continues.
- If no response to treatment occurs in 4 months or more, consult with the physician about the appropriateness of continuing therapy.

Ongoing Assessment and Evaluation

Assess the patient's scalp periodically to determine whether irritation has developed. The patient usually checks his own scalp during therapy. Topical minoxidil treatment is effective when hair growth has occurred with no adverse effects.

CHAPTER SUMMARY

- Testosterone is the main male sex hormone. Insufficient testosterone prevents the growth spurt of adolescence and the development of secondary male sex characteristics. Lack of testosterone after development of secondary sex characteristics causes those characteristics to diminish.
- Exogenous testosterone is used when endogenous levels are low. Exogenous testosterone causes the same effects on the body as endogenous testosterone.
- One problem affecting male sexuality is erectile dysfunction. This problem may result from multiple factors, such as stress, adverse effects of drug therapy, and cardiovascular or neurologic impairments.
- When erectile dysfunction is a recurring problem, drug therapy may be used. Sildenafil and the other PDE5 inhibitors have the advantage of being very effective oral drugs. However, they are effective only in conjunction with sexual stimulation; they are not aphrodisiacs.
- PDE5 inhibitor drugs are the first-line drug treatment for erectile dysfunction. Because they cause vasodilation, significant hypotension can occur if they are taken with nitrates or alpha-1 blockers, which also cause vasodilation and hypotension.
- Sildenafil is also used in the treatment of pulmonary arterial hypertension and under study for the management of diastolic heart failure.
- A common problem of the older man is BPH. The exact cause of BPH is unknown, although excessive growth of the prostate is believed to be caused primarily by elevated levels of DHT (the primary hormone in the prostate cells). Overgrowth of the prostate places pressure on the urethra and the bladder, resulting in lower-urinary-tract symptoms.
- Drug therapy is one type of treatment for BPH. Drug therapy for BPH includes finasteride or dutasteride, which decreases the size of the prostate over time, and alpha-1 blockers, which relax the smooth muscle of the bladder and decrease difficulties in voiding.
- Male pattern baldness is another men's health issue. This problem may be related to changing testosterone levels or alterations in the male sex hormone receptors.
- Topical minoxidil can be effective in promoting hair growth for male pattern baldness. This drug is available OTC. Women may also use minoxidil.

QUESTIONS FOR STUDY AND REVIEW

1. What effects does testosterone have on the male?
2. What is the main risk when administering testosterone to induce the growth spurt of puberty?
3. How does sildenafil act to help the man achieve an erection?
4. Why should women not handle broken or crushed finasteride?
5. Topical minoxidil is poorly absorbed into the systemic circulation. What is the advantage of this factor?

Drugs Affecting Women's Health and Sexuality

Learning Objectives

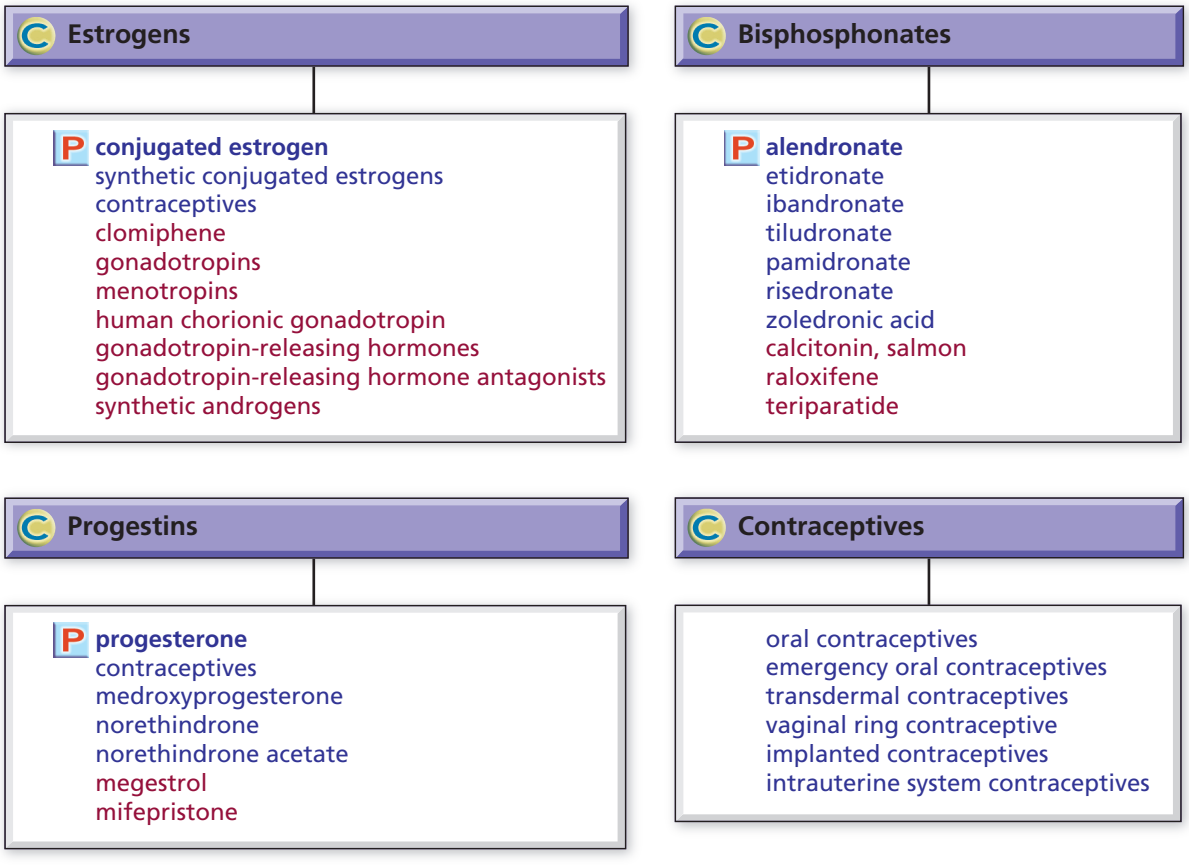
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect women's health and sexuality.
2. Identify core patient variables relevant to drugs that affect women's health and sexuality.
3. Relate the interaction of core drug knowledge to core patient variables for drugs that affect women's health and sexuality.
4. Compare the risks and benefits of hormone replacement therapy in postmenopausal women.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect women's health and sexuality.
6. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects of drugs that affect women's health and sexuality.
7. Determine key points for patient and family education for drugs that affect women's health and sexuality.

Key Terms

estrogen
follicle-stimulating hormone
gonadotropin-releasing hormone
luteinizing hormone
menopause
osteoporosis
Paget disease
progestin
proliferative phase
secretory phase

Drugs Affecting Women's Health and Sexuality



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

The female sex hormones are responsible for the normal development and maintenance of adult female sexual characteristics. If endogenous hormone levels are insufficient, sexual characteristics fail to develop. If endogenous levels are low after female sexual characteristics develop, the woman may be unable to become pregnant or maintain a pregnancy. If levels of sex hormones become low enough, masculinization may occur. Additionally, research has shown that low levels of female sex hormones contribute to some common women's health problems. This chapter presents the use of female sex hormones as replacement drug therapy when endogenous levels are absent or insufficient. It discusses two classes of female sex hormones: estrogens and progestins. The prototype estrogen is conjugated estrogen (Premarin), and the prototype progestin is progesterone (Prometrium, Progesterone).

This chapter also discusses bisphosphonates, the drugs used in treating osteoporosis, a common health problem in postmenopausal women. The prototype bisphosphonate is alendronate (Fosamax).

PHYSIOLOGY

The female sex hormones are responsible for producing female sexual characteristics, developing the female reproductive system, and maintaining pregnancy. The two types of female sex hormones are **estrogen** and **progestin.** Both are steroidal compounds that the ovaries begin to secrete at puberty and that the placenta secretes during pregnancy. The adrenal cortex also secretes estrogen and progestin, but in much smaller amounts.

Estrogen

The female body produces six different estrogens but only three in substantial amounts: estradiol, estrone, and estriol. Estradiol is the most potent and the major estrogen secreted by the ovaries. In addition to promoting and maintaining female organs and secondary sexual characteristics (e.g., distribution of body hair, high-pitched voice), estrogen affects the release of pituitary gonadotropins, causes capillary dilation, and promotes fluid retention. It also enhances protein anabolism, promotes thinning of cervical mucus, inhibits or facilitates ovulation, and prevents postpartum breast pain. Estrogen also maintains the tone and elasticity of the urogenital structures and stimulates growth of axillary and pubic hair and pigmentation of the nipples and genitals.

Estrogen promotes growth during the adolescent growth spurt; continued elevated levels of estrogen terminate growth by stimulating closure of the epiphyses of the long bones. Closure occurs because estrogen stimulates the osteoblasts in the bone to produce bone faster than the epiphyseal cartilage can expand. Because estrogens cause a faster epiphyseal closure than androgens, women are generally shorter than men by adulthood. Estrogen indirectly contributes to strengthening the skeleton by conserving calcium and phosphorus and encouraging bone formation. After puberty, estrogen is important in maintaining normal bone density and composition. The organic and mineral components of bone are continuously being recycled and renewed throughout life; this process is called bone remodeling.

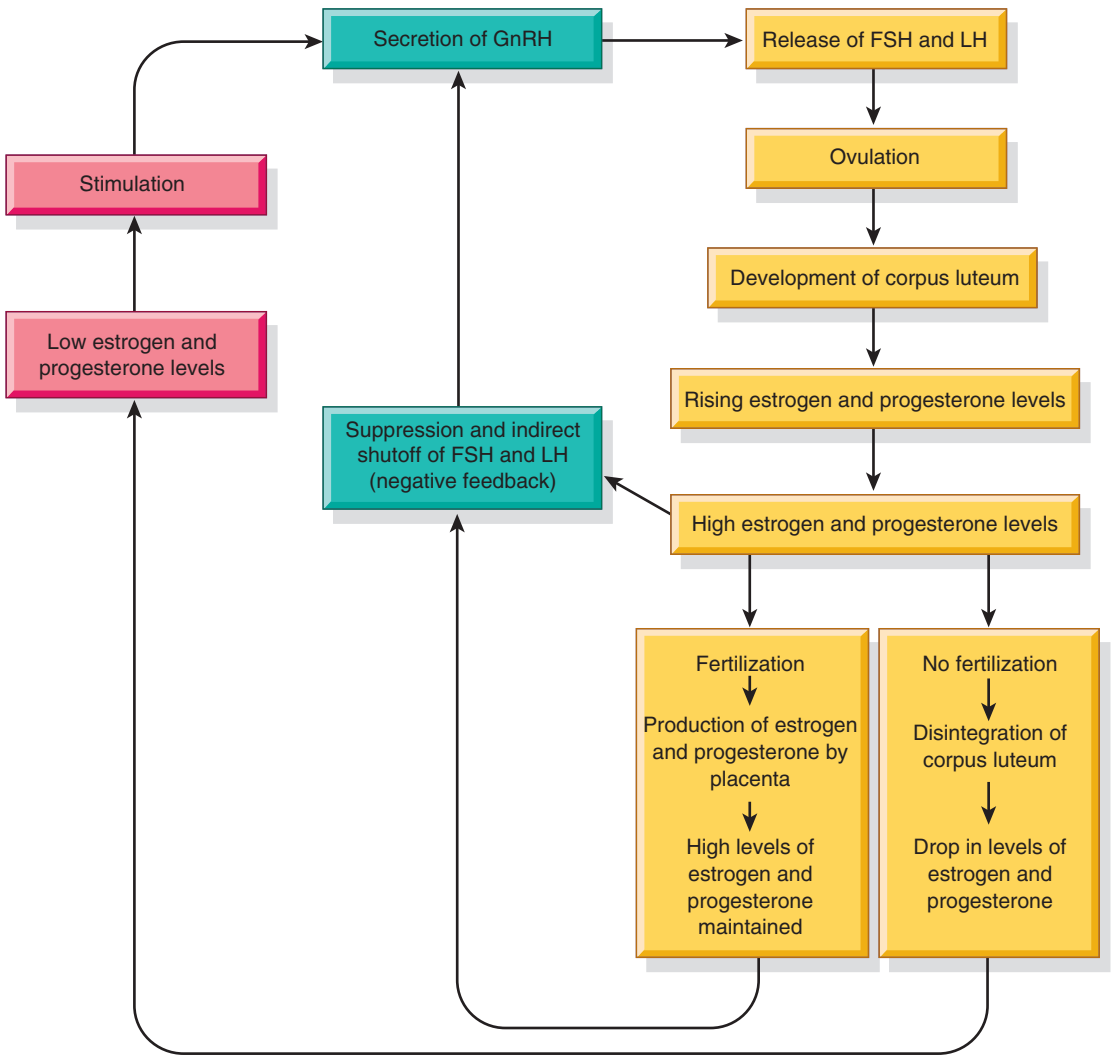
Progestin

Progestins, which include progesterone and its derivatives, are the other female sex hormones. Progesterone is the primary endogenous progestin. The progestins change the proliferative endometrium into a secretory endometrium. Through positive feedback, they also inhibit or facilitate secretion of pituitary gonadotropins. Doing so either prevents follicular maturation and ovulation or promotes maturation for the primed follicle. Progestins also inhibit spontaneous uterine contractions and contractions of other smooth muscles throughout the body. They may also demonstrate some anabolic or androgenic activity.

Menstrual Cycle

Much secretion of the female sex hormones is cyclic, and these cyclic changes constitute the menstrual cycle. **Gonadotropin-releasing hormone** (GnRH), which is secreted by the hypothalamus and then perfused throughout the anterior pituitary, stimulates the release of **follicle-stimulating hormone** (FSH) and **luteinizing hormone** (LH). During puberty, the pituitary gland secretes large volumes of FSH and LH to initiate and establish the menstrual cycle. These hormones stimulate the development of the ovarian follicles and the release of the ovum from the mature follicle (Figure 52.1). As the follicles grow, they produce estrogen. Estrogen increases the vascularity of the uterine lining, preparing it for implantation of a fertilized egg. This phase of the menstrual cycle is termed the **proliferative phase.** The rapidly rising estrogen levels further stimulate GnRH, encouraging further release of LH. The high levels of LH trigger the rupture of the mature follicle, and ovulation occurs.

After ovulation, the follicle is transformed into the corpus luteum, which secretes progesterone and estrogen. This phase is known as the **secretory phase** of the menstrual cycle. In response to the rising levels of estrogen and progesterone, the endometrial glands continue to grow, the arteries of the endometrium become spiraled, and the endometrium prepares for implantation of a fertilized egg. When estrogen and progesterone have reached critical levels, they create negative feedback, directly preventing further release of GnRH and indirectly preventing the release of FSH and LH. If fertilization does not occur, the corpus luteum disintegrates, estrogen and progesterone levels fall, and the endometrial tissue sloughs off in the menses. As the levels of estrogen and progesterone continue to decline, GnRH is again secreted, reinitiating the process. If fertilization occurs, the corpus luteum remains and continues to secrete estrogen and progesterone until the placenta takes over at approximately 10 weeks



• FIGURE 52.1 Menstrual cycle and fertility. In the *proliferative phase* of the menstrual cycle, gonadotropin-releasing hormone (GnRH) is secreted by the hypothalamus and perfused through the anterior pituitary, which stimulates release of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH). In response, estrogen production is stimulated in preparation for implantation of a fertilized egg. Then the *secretory phase* of the menstrual cycle begins, during which rising estrogen levels stimulate GnRH, which stimulates release of more LH, which in turn prompts ovulation and the formation of the corpus luteum. Estrogen and progesterone levels continue to rise in preparation for implantation of a fertilized egg. When estrogen and progesterone levels peak, they halt additional release of GnRH and, indirectly, FSH and LH. When fertilization does not occur, the corpus luteum is sloughed off, and estrogen and progesterone levels fall. GnRH is again secreted to continue the cycle. When fertilization occurs, the corpus luteum remains to provide estrogen and progesterone until the second month of pregnancy, when the placenta is developed and becomes the major source of estrogen and progesterone to maintain the pregnancy.

gestation and becomes the major source of estrogen and progesterone to maintain the pregnancy.

PATHOPHYSIOLOGY

If a woman is deficient in endogenous sex hormones, she does not experience normal sexual development. The primary sex organs do not mature, secondary sexual characteristics do not develop, reproduction is not possible, and the normal growth spurt of adolescence does not happen. If levels of endogenous hormones drop after puberty has occurred and the sexual organs and reproductive system have matured, secondary sexual characteristics may diminish. The ability to reproduce is diminished, despite the presence of developed organs, and the woman may be unable to carry a pregnancy to term.

Menopause is defined as the last menstrual period and is confirmed after the cessation of menstrual cycles for 1 year, in the absence of other obvious causes (i.e., lactation amenorrhea). The average age of menopause occurs at age 51. Menopause is considered to occur prematurely prior to age 40 years. There is a transitional phase spanning several years and marked by variations in menstrual cycle length before the final menstrual cycle. A decline in the number of ovarian follicles to a critically low level (approximately 100 per ovary) is considered to be the major contributing factor to the onset of menopause. With the decline in follicle numbers, inhibin B secretion from the follicles decreases, FSH levels rise and estradiol levels fall. These hormonal changes during the menopause transition are complex and demonstrate a large degree of variability. Measurement of FSH or estradiol is not reliable for determining menopausal status (Burger, 2008). Multiple symptoms accompany the fluctuations in hormonal levels during the menopausal transition. One of the first signs of fluctuating estrogen levels are vasomotor symptoms (VMS), including hot flushes and profuse night sweats. VMS often precede the last menstrual cycle and may be more severe in women with surgical menopause (surgical oophrectomy) than women with natural ovarian decline. It is theorized that VMS are related to a disturbance in the temperature-regulating circuit in the CNS, body core, and peripheral vascular system. In addition to VMS, there is a complex of menopausal symptoms related to unstable estrogen levels. These symptoms are multifaceted and include physical (sleep disturbances, urogenital symptoms—vaginal thinning, dryness, and painful intercourse), psychological (irritability, depression, anxiety, loss of libido), and somatic (pain, fatigue) symptoms. While menopause is a natural, normal, healthy phase of the life cycle, most women experience some degree of recurrent symptoms, with nearly 20% seeking treatment for relief and improved quality of life (Rossmanith & Ruebberdt, 2009).

Although a normal part of the life cycle, menopause is associated with several negative health sequelae. Menopause is a well recognized risk factor for cardiovascular disease (CVD), which is the leading cause of morbidity and mortality in women over age 50 years. The complex relationship of menopause to CVD risk is due to the effect of estrogen withdrawal on cardiovascular function and metabolism. There are changes in body weight as well as body fat distribution to a more android pattern. Changes in body weight are associated with insulin resistance, sodium and fluid retention, abnormal plasma lipid levels, increased blood pressure, and vascular inflammation (Rosano, Vitale, Maazzi, & Volterrani, 2007). This combination of risk factors (abdominal obesity, dyslipidemia, glucose intolerance, and hypertension), known as metabolic syndrome, is common in postmenopausal women, with estimates that nearly 40% of postmenopausal women meet criteria for the disorder. Metabolic syndrome may be an important link to postmenopausal cardiovascular disease (Kaaja, 2008).

In postmenopausal women, the loss of estrogen and its positive effects on bone remodeling contribute to the development of osteoporosis. **Osteoporosis,** a metabolic disease characterized by low bone mineral mass and increased bone fragility, is a major public health problem. Osteoporosis occurs when the body fails to form enough new bone, reabsorbs too much of the old bone, or both. Approximately 13% to 18% of women over 50 years of age in the United States have osteoporosis, and 37% to 50% have osteopenia—low bone density that may deteriorate into osteoporosis. Nearly 50% of women over age 50 years will have an osteoporosis—related fracture in their lifetime, with the most common sites being the hip, spine, and wrist. In fact, a woman's risk of hip fracture is equal to her risk of breast, uterine, and ovarian cancer combined. Hip and vertebral fractures are linked to an increased mortality risk, with nearly one-fourth of patients over age 50 dying in the year following the fracture (Lim, Hoeksema, Sherin, et al., 2009; National Osteoporosis Foundation, 2009).

In postmenopausal women, deficiency of sex hormones is the leading cause of osteoporosis. Approximately 80% of people with osteoporosis are women because decreases in estrogen levels occur sooner and are more substantial in women than decreases of testosterone in men. Other causes of osteoporosis include corticosteroid excess (e.g., in Cushing disease), hyperthyroidism, hyperparathyroidism, immobilization, bone malignancies, genetic disorders, HIV/AIDS, eating disorders, and type 1 diabetes. Medications that may be associated with an increased risk of osteoporosis include antiepileptics (e.g., phenytoin), cytotoxic drugs, lithium, and heparin used long-term.

Major risk factors for osteoporosis include Asian or white race, history of fracture as an adult, history of fragility fracture in a first-degree relative, low body weight (less than about 127 lb), family history of osteoporosis, smoking, and use of oral steroid medications for more than 3 months. Additional risk factors include impaired vision, estrogen deficiency at an early age (less than 45 years), dementia, poor health or frailty, recent falls, low calcium intake (lifelong), low physical activity, and alcohol in amounts of more than 2 drinks per day (National Osteoporosis Foundation, 2009).

Osteoporosis produces weak bones and leads to an increased risk of fractures. Fractures can lead to serious complications, including pain, loss of mobility, complications related to immobility, and death. Bone changes in postmenopausal women may also be related to decreased physical activity. Heavily stressed bones, such as those used in regular weight-bearing exercise (e.g., walking, running), are stronger and thicker than bones not subjected to these ordinary stresses, which become thin and brittle. Moderate physical activity and weight bearing are essential for bone remodeling.

Nonpharmacologic interventions to reduce fracture risk from osteoporosis can be recommended to the general population. These include an adequate intake of calcium and vitamin D, lifelong participation in regular weight-bearing and

muscle-strengthening exercise, avoidance of tobacco use, identification and treatment of alcoholism, and treatment of other risk factors for fracture. A recent analysis of data from the Framingham Osteoporosis Study found that 41.1% of women and 17% of men 50 years of age and older met the 2008 National Osteoporosis Foundation Guidelines recommending pharmacologic treatment of osteoporosis (Berry, Kiel, Donaldson, et al., 2010).

C ESTROGENS

Estrogens are available in many chemical formulations, including conjugated estrogens, synthetic conjugated estrogens, esterified estrogens, estradiol, estropipate, ethinyl estradiol, and estradiol acetate. The many different types of exogenous estrogen differ somewhat in terms of indications, route of administration, and pharmacokinetics. Routes of administration may be oral, intramuscular (IM), transdermal, or topical (as vaginal creams). Most of these estrogens are used for correction of low endogenous estrogen or in birth control products combined with progestins. The prototype estrogen is conjugated estrogen (Premarin). Table 52.1 provides a summary of selected estrogens.

Nursing Management of the Patient Receiving P Conjugated Estrogen

Core Drug Knowledge

Pharmacotherapeutics

Conjugated estrogen is used primarily in hormone replacement therapy (HRT) in female hypogonadism, female castration, and primary ovarian failure. Estrogen replacement therapy is also used in menopausal women to treat moderate to severe vasomotor responses (hot flashes). Other uses in menopause include treating atrophic vaginitis, vaginal dryness, painful intercourse, mood swings, and loss of tone in genitourinary muscles. *Menopausal symptoms should be treated with as small a dose as possible for as short a time as possible*. It should not be considered life-long therapy. Although estrogen is approved for use in postmenopausal women who have evidence of bone loss (osteoporosis) and has been shown to reduce further bone loss and to improve bone density, it is *not* currently recommended as a first-line treatment for this condition because of complications arising from estrogen use. Other drugs to help promote bone density are safer and should be used first (Mitchner & Harris, 2009). (See the discussion of alendronate later in this chapter; also

TABLE 52.1 Summary of Selected C Estrogens

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P conjugated estrogen (Premarin)	Hormone replacement therapy	*Adult:* PO, 0.3–0.625 mg/d cyclically (3 wk on, 1 wk off)	*Onset:* Slow *Duration:* 24 h $t_{1/2}$: Unknown
estradiol, transdermal (Vivelle, Estraderm, Climara)	Female hypogonadism Vasomotor symptoms associated with menopause Hormone replacement therapy	*Adult:* 0.025–0.05 mg applied to skin once or twice weekly (brand dependent)	*Onset:* Slow *Duration:* 3–7 d $t_{1/2}$: Unknown
estradiol, oral (Estrace)	Hormone replacement therapy Inoperable breast cancer Prostatic cancer	*Adult:* PO, 1–2 mg/d *Adult:* PO, 10 mg tid *Adult:* PO, 1–2 mg tid	*Onset:* Slow *Duration:* Unknown $t_{1/2}$: Unknown
estradiol valerate in oil (Delestrogen)	Hormone replacement therapy Prostate cancer	*Adult:* IM, 10–20 mg q4wk *Adult:* IM, 30 mg q1–2wk	*Onset:* Slow *Duration:* 4 wk $t_{1/2}$: Unknown
Selected Nonestrogens			
clomiphene (Clomid, Milophene)	Ovulatory failure	*Adult:* PO, 50–100 mg/d for 5 d	*Onset:* 5–8 d *Duration:* 6 wk $t_{1/2}$: 5 d
menotropins (Pergonal, Humegon)	Ovulation stimulation Spermatogenesis stimulation	*Adult:* IM, 75 IU/d for 7–12 d; follow with HCG *Adult:* IM, 75–150 IU 3∞/wk; pretreat and cotreat with HCG	*Onset:* Slow $t_{1/2}$: Unknown *Duration:* Months
chorionic gonadotropins (Choron, Pregnyl)	Hypogonadotropic hypogonadism (males) Ovulation stimulation Spermatogenesis stimulation	*Adult:* 500–4,000 USP 3∞/wk *Adult:* 5,000–10,000 USP 1 d after last menotropin dose *Adult:* Pretreatment, IM, 5,000 IU 3∞/wk for 4–6 mo; cotreatment, 2,000 IU 2∞/wk with menotropins	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown after pretreatment with menotropins

see Table 52.3). Conjugated estrogen is also used to treat abnormal uterine bleeding resulting from hormonal imbalance with no organic pathology. Additionally, conjugated estrogen is used as palliative therapy in advanced prostatic cancer, in men with metastatic breast cancer, and in selected women with breast cancer who do not have an estrogen-dependent tumor. General consensus holds that estrogen replacement therapy should *not* be used in postmenopausal women in an attempt to prevent cardiovascular disease or complications. Recent research however suggests that the timing of estrogen treatment may be a factor. There may be potential cardiovascular benefits with earlier initiation of therapy after menopause, specifically in women between 50 and 59 years. Continued research is needed to address this issue (Gungor, Kalelioglu, & Turfanda, 2009; Palacios, 2008).

Pharmacokinetics

Absorption from the gastrointestinal (GI) tract is complete. Estrogen binds to specific receptor proteins in tissues that are responsive to estrogen (female genital organs, breasts, hypothalamus, pituitary). Metabolism occurs primarily in the liver. While circulating through the liver, estrogen is degraded to less active estrogenic compounds. Some estrogens are excreted into the bile and then reabsorbed from the intestines and returned to the liver. The estrogen conjugates are water soluble and are excreted through the kidneys, with minimal resorption. Conjugated estrogen crosses the placenta and enters breast milk.

Pharmacodynamics

Estrogen given to females with insufficient endogenous estrogen (hypogonadism) stimulates the development of the female sex organs and secondary female sexual characteristics. Estrogen also stimulates the long-bone growth spurt of adolescence; when circulating estrogen reaches a certain level, it triggers closure of the epiphyseal plates to stop growth. Other actions of estrogen include facilitating or inhibiting ovulation (depending on dose), increasing fluid retention, facilitating protein anabolism, conserving calcium and phosphorus, stimulating bone formation, and maintaining tone and elasticity of urogenital structures.

The use of hormonal replacement therapy (HRT) for postmenopausal symptoms is controversial. Some symptoms occur due to declining ovarian function, while other may be related to more complex life changes and aging. In 2005, the National Institute of Health published a Consensus and State-of-the-Science statement evaluating the current evidence on HRT. Evidence was supportive for relieve of vasomotor symptoms (hot flashes and night sweats) as well as for vaginal dryness and painful intercourse. There was insufficient support for the role of HRT in mood symptoms, cognitive disturbances, somatic symptoms, urinary incontinence, sexual dysfunction, or quality of life. Recently, additional research has focused new light on the role of HRT demonstrating that it may alleviate some postmenopausal symptoms, improve quality of life, and provide chemoprevention of some co-morbid conditions when used within the first 5 years of cessation of menses. A recent systematic review by Canerelli and colleagues (2007) found beneficial effects for type II diabetes, cardiovascular disease, osteoporosis, and colorectal cancer when used within a therapeutic window early in menopause and for a limited time. The protective effect for colon cancer is not demonstrated with estrogen therapy alone (Boursi & Arber, 2007; Schindler, 2007).

Contraindications and Precautions

There are also substantial risks associated with HRT. The Women's Health initiative (WHI), a randomized controlled clinical trial of over 16,000 postmenopausal women, was stopped early when the risks exceeded the benefits of treatment. Specifically, women assigned to the HRT arm of the trial had significantly higher risk of cardiovascular disease, stroke, venous thromboembolism, and breast cancer than those assigned to the placebo group (Rossouw, Anderson, Prentice, et al., 2002). In 2003, based on the findings of the WHI, the FDA issued a black box warning to be included on the labeling of HRT products stating the medication increases the risk of cardiovascular events, including stroke, memory loss, and dementia. Additionally, therapy should only be prescribed for the shortest duration possible consistent with treatment goals.

Estrogen is contraindicated in patients with breast cancer because it stimulates the growth of breast cancer cells. However, it may be used in appropriately selected patients receiving treatment for metastatic disease. For a discussion of the role of hormones in cancer, see Chapter 37. Estrogen is also contraindicated in the following conditions:

- Estrogen-dependent neoplastic diseases
- Undiagnosed abnormal genital bleeding
- Active thrombophlebitis or thromboembolic disorders
- History of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treating breast or prostatic malignancy)
- Known or suspected pregnancy (estrogen is a pregnancy category X drug because of known adverse effects on the developing fetus)

Conjugated estrogen should be administered with caution to breast-feeding women because estrogen has been shown to decrease the quantity and quality of breast milk and may be excreted into it. Its safety and efficacy in children have not been established. Cautious use must be observed in patients with incomplete bone growth because of the epiphyseal closure that accompanies estrogen use. Caution also is necessary in patients for whom some degree of fluid retention may cause complications, such as those with epilepsy, migraine headaches, cardiac dysfunction, or renal dysfunction. Caution should also be used in patients with renal insufficiency or metabolic bone diseases associated with hypercalcemia.

Adverse Effects

Postmenopausal estrogen use has been associated with some serious and important adverse effects, and estrogen now carries several Black Box warnings related to these adverse effects. Although postmenopausal women are more at risk for cardiovascular disease and MI than premenopausal women, recent landmark research from the WHI trial indicates that estrogen given to postmenopausal women in combination with progestin significantly increases the risk of stroke and coronary heart disease (CHD) in all subgroups examined (Focus on Research Box 52.1); when used without progestin, estrogen was found to also increase the risk of stroke, but had no major effect on CHD (Hsia, Langer, Manson, et al., for the Women's Health Initiative Investigators, 2006). A recent review of the women involved in this study found that prehypertension was present in more than one third of participants and that prehypertension was associated with more cardiovascular complications (MI, stroke, heart failure, and cardiovascular death), regardless of race (Hsia, Margolis, Eaton, et al., 2007).

Findings from the WHI also indicate that estrogen-progestin combinations increase the incidence of breast cancers, and that when cancer is detected, it is at a more advanced stage than if the woman were not taking HRT. Additionally, it is more likely that a woman receiving estrogen-progestin will have an abnormal mammogram. Estrogen with progestin, therefore, may stimulate breast cancer growth and hinder breast cancer diagnosis (Chlebowski, Hendrix, Langer, et al., 2003). However, a Black Box warning on the estrogen labeling now states that it may increase the risk of invasive breast cancer in postmenopausal women. Findings from the WHI study also indicate that estrogen with progestin appears to increase the risk of ovarian cancer, although it does not have this effect on endometrial cancer (Anderson, Judd, Kaunitz, et al., 2003). Estrogen given alone is known to increase the risk of endometrial cancer and carries a Black Box warning to this effect. The progestin in combination therapy has a positive effect on the endometrium, offsetting any increase in risk for endometrial cancer from estrogen.

The branch of the WHI study that examined the use of estrogen alone continued until March 2004, when it was stopped a year early. Final data analysis shows that, like combination HRT, estrogen replacement appears to increase the risk of stroke and probably for dementia or mild cognitive impairment but decreases the risk of hip fracture. Estrogen, alone or in combination with a progesterone, carries a Black Box warning not to use it to prevent dementia. Unlike combination HRT, estrogen alone did not appear to have any effect (positive or negative) on heart disease and did not increase the risk of breast cancer (Stefanick, Anderson, Margolis, et al., Women's Health Initiative Investigators, 2006).

The adverse effects that have been found in postmenopausal women treated with HRT cannot be generalized to premenopausal women, because premenopausal women were not included in the clinical trials. However, it has been concluded that hormones found in birth control pills do not increase cardiovascular risk unless the dose of estrogen is high. Most forms of oral contraceptives now have low doses of estrogen.

Most other adverse effects of estrogen therapy are related to the effect of estrogen on the body and may be dose related. Common adverse effects include breakthrough bleeding, changes in menstrual flow, dysmenorrhea, premenstrual-like syndrome, headache, nausea, vomiting, bloating, abdominal cramps, chloasma (dark, patchy pigmentation to skin), and photosensitivity. Less common adverse effects include cholestatic jaundice, colitis, acute pancreatitis, steepened corneal curvature, intolerance to contact lenses, migraine headaches, dizziness, mental depression, pain at injection site, edema, changes in libido, and breast tenderness, enlargement, or secretion.

The use of estrogen during early pregnancy may have teratogenic effects on the fetus. Use of conjugated estrogen in patients with breast cancer and bone metastases may cause severe hypercalcemia. Estrogen use increases the risk of thrombosis formation (thrombophlebitis and thromboembolism) in all women receiving the drug, regardless of age.

Drug Interactions

No important drug interactions are associated with conjugated estrogen.

Assessment of Relevant Core Patient Variables

Health Status

Before the patient begins estrogen therapy, assess her blood pressure (for hypertension) and breasts (for masses). If the patient is prehypertensive, this may increase the risk of cardiovascular complications (Hsia, Margolis, Eaton, et al., Women's Health Initiative Investigators, 2007). The patient should also undergo a pelvic examination and a Papanicolaou test to rule out cervical cancer. It is important to determine whether the patient has breast cancer, undiagnosed genital bleeding, active thrombophlebitis or thromboembolic disorders, or a history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except in the palliative treatment of breast or prostate cancer). These conditions are contraindications to use of conjugated estrogen.

Assess whether the patient has a personal or family history of breast cancer, a history of benign breast tumors, early menarche, a first pregnancy late in life, or never having been pregnant. These factors are thought to increase the risk of breast cancer with estrogen replacement therapy.

It is also important to determine whether the patient has a metabolic bone disease associated with hypercalcemia or renal insufficiency, because these conditions mandate cautious use of estrogen. Determine whether the patient has a condition that might be adversely affected by fluid retention, such as epilepsy, migraine headaches, cardiac dysfunction, or renal insufficiency.

The Study

The Women's Health Initiative (WHI) was a large, multicenter, randomized clinical trial of almost 27,000 postmenopausal women between the ages of 50 and 79 years. The women were divided into two groups: those without a uterus who received just estrogen (10,739), and those with a uterus who received estrogen with progestin (16,608). The primary goal of the trial was to determine whether estrogen or estrogen-progestin hormone replacement therapy (HRT) was cardioprotective for postmenopausal women. The chief outcome criterion was the incidence of CHD (nonfatal MI or death caused by CHD). The study was designed to follow the women for up to 13 years. However, both arms of the study were prematurely stopped because the data indicated that the overall risks of continuing the study exceeded any benefits that could be obtained.

When estrogen was administered alone, the researchers concluded that the women had:

- Increased risk of stroke
- Increased risk of deep venous thrombosis, especially within the first two years of use, but this risk elevation was less than that for women taking estrogen plus progestin.
- No overall protection from MI or coronary death. Although there was a slight trend of lower CHD in this group, in general it did not have any effect (positive or negative) on the overall risk of CHD.
- No increase in incidence of breast cancer, but abnormal or suspicious mammograms were more prevalent, increasing the need for short-term follow-up.
- No difference in colorectal cancer
- Decreased risk of hip fractures

When estrogen was administered with progestin, the researchers concluded that the women had:

- Increased risk of stroke
- Increased risk of CHD within the first year of hormone therapy use, including the risk of MI
- Increased (double) risk of venous thrombosis. Venous thrombosis is more likely if risk factors for venous thrombosis (older age, overweight or obese, and genetic variations of factor V Leiden) were present
- Neither increased nor decreased risk of pulmonary artery disease
- Increased risk of breast cancer. When breast cancer was determined, the stage at which breast cancer was diagnosed was more advanced if the woman had been on HRT. This finding suggests that HRT not only stimulates breast cancer growth but also may make its diagnosis more difficult.
- Increased risk of ovarian cancer but not endometrial cancer.
- Decreased risk of colorectal cancer
- Decreased risk of hip fractures

From the main study, 4,532 of the women were also recruited to participate in a study (WHI Memory Study) to evaluate the effect of HRT on memory and cognitive processes. The findings from these women showed that, contrary to previous thinking, HRT increased the risk of dementia, including Alzheimer disease, and did not prevent mild cognitive impairment.

All of these findings caused the researchers to conclude that postmenopausal estrogen alone or plus progestin conferred greater risks than benefits and that this therapy should generally be avoided.

Nursing Implications

The results of the WHI study dramatically changed the thinking in the medical community about the use of HRT in postmenopausal women. Although postmenopausal women are known to be at a substantially higher risk for coronary heart disease, and estrogen is known to reduce low-density lipoprotein (LDL) cholesterol, a cardiovascular risk factor, exogenous hormone therapy with estrogen or estrogen and progestin is obviously not the answer, as was previously thought. Couple this information with the knowledge that HRT increases the risk of Alzheimer disease, breast cancer (in combination), and ovarian cancer (in combination), and the therapy now appears to pose too great a risk compared to its known benefits (e.g., increasing postmenopausal bone density and slightly improving sleep). How is it possible that the scientific thinking could switch from encouraging women to use HRT to avoiding its use as much as possible?

First, understand that science and the state of knowledge on any topic are constantly evolving. As more is learned through research, different recommendations about therapy may be indicated. Second, the WHI was an exceedingly large study, much larger than any previous studies, some of which had a few thousand participants. The larger the number of participants in a clinical drug study, the more likely adverse effects of drug therapy will be identified. Similarly, the larger the trial, the more likely that findings regarding drug efficacy (whether the drug is found effective or not) are valid and can be applied to a larger population. Here, although the study was initially intended to prove a positive effect, the data pool was large enough to show there was too much risk for any small benefit that could be achieved.

It is important to understand how clinical trials are conducted and how their results modify practice. Patients often hear of an outcome from a trial reported in the general media. The report may not accurately or completely represent the facts from the clinical trial. Patients can become fearful, angry, or confused as to why medical advice regarding a particular drug therapy may change. Nurses should be able to discuss the facts of these studies with patients to help them sort out and understand the findings in relation to their own health.

Life Span and Gender

Check the patient's age. The use of parenteral conjugated estrogen in premature infants has been associated with the development of a fatal "gasping syndrome" because of the benzyl alcohol in the preparation. Assess whether long-bone growth has been completed. If the patient is prepubescent, monitor growth throughout therapy to prevent premature closing of the epiphyses.

Assess for pregnancy, which is a contraindication for therapy (estrogen is pregnancy category X). Use of conjugated estrogen during pregnancy may promote congenital defects, including heart and limb-reduction defects. Male fetuses exposed to conjugated estrogen through maternal use may develop genitourinary structural problems and, later, abnormal semen. Use of estrogen to treat threatened or habitual miscarriage has not been proved effective. Also, assess the patient's menopausal or postmenopausal status. If the patient is menopausal, assess for severity of symptoms.

Environment

Conjugated estrogen may produce photosensitivity. Patients who are outdoors frequently need to take precautions against the sun's ultraviolet rays until tolerance to the drug is determined. Be aware of the environment in which estrogen will be administered. Oral conjugated estrogen may be administered in any setting, including in the home by the patient. Parenteral conjugated estrogen (IM or intravenous [IV]) is administered in a hospital setting.

Nursing Diagnoses and Outcomes

- Ineffective Sexuality Patterns related to therapy for female hypogonadism or lack of intrinsic estrogen
  Desired outcome: *The patient will develop normal sex organs and secondary sexual characteristics while using estrogen drug therapy.*
- Risk for Delayed Growth and Development related to intrinsic estrogen deficiency and early hypophysis closing from estrogen replacement therapy
  Desired outcome: *The patient will achieve normal growth and development while using drug therapy.*
- Decisional Conflict related to comparison of risks and benefits of postmenopausal estrogen replacement therapy
  Desired outcome: *The patient will make an informed decision about estrogen replacement therapy after comparing personal risks and benefits.*

Planning and Intervention

Maximizing Therapeutic Effects

Several nursing actions are geared toward maximizing the therapeutic effects of estrogen. Administer conjugated estrogen cyclically (3 weeks of daily administration followed by 1 week off) to simulate the normal cycling of endogenous estrogen when given due to low intrinsic levels of the hormone. Give it on a daily basis for carcinomas, postpartum breast engorgement, and treatment of severe menopausal symptoms. Refrigerate the drug before reconstitution (IV or IM use); after reconstitution, the solution can remain refrigerated for up to 60 days. Do not use the solution if it darkens or if precipitation occurs.

Minimizing Adverse Effects

To minimize adverse effects of estrogen therapy, monitor for signs of thrombophlebitis and thromboembolus. In women with a uterus, the combination of estrogen and progestin should always be used to minimize the risk of endometrial cancer. The estrogen dosage should remain as low as possible to minimize the chances for development of ovarian cancer or breast cancer, but still achieve the desired therapeutic effects. HRT should be limited to treating only those menopausal women who have substantial menopausal symptoms. The dose and the duration of therapy should be minimized in menopausal women to decrease the risk of cancer, stroke, and CHD. Applying estrogen topically to urogenital structures may decrease the risk of systemic adverse effects, compared with risk of oral preparations, when it is used to treat the symptoms of menopause. Do not administer IV conjugated estrogen with other agents. (An exception is in emergencies in which a separate drug infusion has already been started. In such cases, inject the drug into the IV tubing as close to the angiocatheter insertion site as possible.) Protect the patient from ultraviolet light until it is determined whether the patient experiences photosensitivity.

Providing Patient and Family Education

- Teach patients and their families about the therapeutic purpose of estrogen. Provide and clarify information on risks and benefits of postmenopausal therapy, so that patients can make an informed choice regarding drug therapy.
- Provide instruction on how to take the estrogen, either cyclically or daily, depending on the clinical indication for the drug.
- Instruct patients about the signs and symptoms of thrombophlebitis and thromboembolism (pain in groin or calves, sharp chest pain or sudden shortness of breath, sudden severe headache, dizziness or fainting, vision or speech disturbance, weakness or numbness in arm or leg). Urge patients to notify the physician or nurse practitioner at once if these signs or symptoms occur.
- Teach patients to notify the physician or nurse practitioner if any of the following signs or symptoms occurs: abnormal vaginal bleeding, missed menstrual period or suspected pregnancy, lumps in the breast, severe abdominal pain, yellowing of the skin or eyes, or severe depression.
- Teach patients to avoid prolonged exposure to the sun and to use sunblock and appropriate clothing in the sun, because photosensitivity may occur.
- In addition, emphasize to patients the importance of returning for follow-up care and physical examinations while receiving estrogen therapy.

CRITICAL THINKING SCENARIO

INDIVIDUAL DECISIONS ABOUT HORMONE REPLACEMENT THERAPY

Sue Rosario is 46 years old and is undergoing menopause. She reports that she hasn't slept well in the past 3 months because she awakens two or three times a night with such severe episodes of sweating that she has to get up and change her night clothes because they are soaked in perspiration. She states she is having trouble focusing at work, where she is a computer software engineer, because she is fatigued. Additionally, she often has severe hot flashes and episodes of sweating at work, which further impair her ability to be productive. Her physician has ordered her a course of HRT to treat the menopausal symptoms. She discusses with you her concerns about taking HRT. She says, "I heard these drugs cause you to have a heart attack. Isn't this drug too dangerous to take?"

1. How will HRT be helpful to Sue at this time?
2. What points will you include in your patient education to help Sue understand the risks and benefits of HRT in her situation? Include what precautions should be used to minimize any risk she might incur.

Ongoing Assessment and Evaluation

If the patient is a prepubescent girl, evaluate for normal sexual development with estrogen therapy and monitor the patient's growth as appropriate. It is essential to check for evidence of early epiphyseal closure. Monitor the postmenopausal woman for development of endometrial cancer (when estrogen is used alone) and ovarian or breast cancer (when estrogen is used in combination with progestin), as well as for cardiovascular complications. Therapy is considered effective when normal growth and sexual development occur, the symptoms of menopause are controlled, and the patient does not show any serious adverse effects from the drug therapy.

Drugs Closely Related to P Conjugated Estrogen

Contraceptives are combinations of estrogen and progesterone and are discussed later in the chapter. Synthetic conjugated estrogens, such as Cenestin, are very similar to conjugated estrogen. The major difference is that Cenestin is made of nine synthetic estrogen components obtained from plant material, whereas conjugated estrogen is derived from the urine of a pregnant mare. Cenestin is approved only for short-term use in treating vasomotor symptoms of menopause. It is administered orally.

Drugs Significantly Different From P Conjugated Estrogen

Clomiphene

Clomiphene (Clomid, Milophene, Serophene) is an ovulation stimulant. This nonsteroidal agent promotes ovulation by indirectly increasing the output of the pituitary gonadotropins. Clomiphene binds to estrogenic receptors, preventing estrogen from binding. The hypothalamus and pituitary gland interpret this development as indicative of low estrogen levels and respond by increasing secretion of LH, FSH, and gonadotropins, thus stimulating ovulation. Clomiphene is used in treating ovulatory failure in patients who want to become pregnant and have a fertile partner. Use of clomiphene increases the chance of multiple pregnancies, although most births are single births. Clomiphene therapy is not effective in primary pituitary or ovarian failure. Clomiphene is administered orally. Hot flashes are the most common adverse effect; they are usually not severe and disappear after treatment stops.

Gonadotropins and Menotropins

The gonadotropins are preparations of FSH and include follitropin alpha, follitropin beta, and urofollitropin. Follitropin alpha and follitropin beta are human FSH preparations made using recombinant DNA technology. Urofollitropin is an FSH preparation extracted from the urine of postmenopausal women. Menotropins (Humegon, Menopur, Pergonal), purified

MEMORY CHIP

P Conjugated Estrogen

- Used as hormone replacement when premenopausal endogenous levels of estrogen are low
- Used in combination with progesterone in contraceptives
- Used to treat moderate to severe symptoms of menopause (small dose, short duration of therapy)
- Major contraindications: most breast cancers, estrogen-dependent cancers, thrombophlebitis or thromboembolic disorders (active or history of), undiagnosed abnormal genital bleeding; do **not** use to prevent cardiovascular events or to prevent dementia
- Most common adverse effects: menstrual cycle problems (breakthrough bleeding, changes in menstrual flow, dysmenorrheal, premenstrual-like syndrome, headache, nausea, vomiting, bloating, abdominal cramps, chloasma, and photosensitivity)
- Most serious adverse effects (when used alone): thromboembolic events, increased risk for stroke, increased risk for dementia or mild cognitive impairment, increased risk for endometrial cancer
- Most serious adverse effects (when used with progestin): increased risk for stroke, increased risk for coronary heart disease, increased risk for breast and ovarian cancers
- **Life span alert: pregnancy category X drug**
- Maximizing therapeutic effects: Administer cyclically or daily, depending on clinical indication.
- Minimizing adverse effects: Administer with progestin if the woman has a uterus, to reduce risk of endometrial cancer; monitor for thrombophlebitis or thromboembolism; minimize dose and duration of therapy (in postmenopausal women); monitor bone growth for early epiphyseal growth plate closure (in prepubescent girls).
- Most important patient education: benefits and risks of postmenopausal HRT; report signs and symptoms of thrombophlebitis or thromboembolism at once.

preparations also made from the urine of postmenopausal women, are biologically standardized for FSH and LH activity. All of these drugs stimulate ovarian follicular growth in women who do not have primary ovarian failure yet do not experience an endogenous surge in LH level. They must be administered in conjunction with, but slightly before, human chorionic gonadotropin (HCG) to induce ovulation (see below for discussion of HCG). HCG is administered after it has been determined by laboratory analysis that sufficient follicular development has occurred. The gonadotropins are also used in follicle stimulation for women being treated with assisted reproduction technologies, such as in vitro fertilization. Urofollitropin is used to induce ovulation in women with polycystic ovary disease who are unresponsive to clomiphene therapy. Menotropins with HCG are also given to men with primary or secondary hypogonadism to stimulate spermatogenesis.

Overstimulation of the ovary occurs in approximately 20% of women receiving therapy with gonadotropins, resulting in mild to moderate uncomplicated ovarian enlargement with or without abdominal distention or pain. A more severe condition, ovarian hyperstimulation syndrome, may occur and result in severe ovarian enlargement, abdominal pain and distention, nausea, vomiting, diarrhea, dyspnea, and oliguria. Ascites, pleural effusion, hypovolemia, electrolyte imbalance, hemoperitoneum, and thromboembolic events may also occur.

Use of follitropins is associated with multiple births, including triplets, quadruplets, and quintuplets. The incidence of multiple births is about 12% with follitropin alpha, 8% with follitropin beta, and 21% with urofollitropin. Singleton births still outnumber multiple births, however. Follitropin alpha and urofollitropin are administered by subcutaneous (SC) injection, follitropin beta is administered by SC or IM injection, and menotropins are administered by IM injection. All gonadotropins are in pregnancy category X. Adverse effects include vascular and pulmonary complications, ovarian enlargement, ovarian cysts, nausea, headaches, and sensitivity reactions.

Human Chorionic Gonadotropin

HCG (A.P.L., Follutein, Gonic, Pregnyl) is a polypeptide hormone that stimulates the interstitial cells to produce androgens in male patients. In women, it can substitute for LH to trigger ovulation. It is used to induce ovulation in females after pretreatment with follitropins or menotropins. It is also used to treat prepubertal cryptorchidism not resulting from anatomic obstruction and to treat hypogonadism in males. HCG is administered by IM injection. It is a pregnancy category X drug. Adverse effects include headache, irritability, edema, precocious puberty, and ovarian hyperstimulation syndrome. Choriogonadotropin alfa is a DNA derived form of human chorionic gonadotropin and acts as endogenous HCG acts.

Gonadotropin-Releasing Hormones

Gonadorelin acetate (Lutrepulse, Canadian only) is a synthetic GnRH used to induce ovulation in women with primary hypothalamic amenorrhea. The hypothalamus releases endogenous GnRH in a pulsating manner. As discussed in the Physiology section of this chapter, GnRH also helps synthesize and promote the release of FSH and LH. FSH and LH stimulate the gonads to produce steroids necessary for reproductive processes. Gonadorelin acetate works similarly. It is administered by a special pump, a Lutrepulse pump, through an IV line. Gonadorelin acetate may cause multiple pregnancies, ovarian hyperstimulation syndrome, and anaphylaxis.

Nafarelin acetate (Synarel) is a potent agonistic analogue of GnRH and stimulates the release of FSH and LH from the pituitary. Repeated dosing abolishes the stimulatory effect on the pituitary gland and leads to decreased secretion of FSH and LH. Therefore, tissues and body functions that depend on gonadal steroids for their maintenance become inactive. Nafarelin acetate is used to treat endometriosis and central precocious puberty of children of both sexes. When used in children with precocious puberty, nafarelin causes the LH and sex steroid hormone levels to remain at prepubertal levels. This effect arrests development of secondary sexual characteristics and slows linear growth and skeletal maturation. Nafarelin acetate is a pregnancy category X drug. It is administered as a nasal spray. Adverse effects are hypoestrogenic (hot flashes, decreased libido, vaginal dryness) and androgenic (acne, myalgia, reduced breast size, edema) effects. An additional adverse effect is nasal irritation.

Gonadotropin-Releasing Hormone Antagonist

Ganirelix inhibits the premature LH surges in women undergoing controlled ovarian hyperstimulation as part of treatment for infertility. It suppresses natural gonadotropin secretion. When gonadotropin is suppressed, LH and FSH secretion by the pituitary are suppressed—LH more so than FSH. After starting FSH therapy on day 2 or 3 of the menstrual cycle, begin daily SC injections of ganirelix. Continue with therapy until the day that HCG is to be administered, as determined by follicular development. Ganirelix is packaged in a container with a natural rubber stopper and should not be given to patients with latex allergies. It is a pregnancy category X drug and causes resorption of fetal contents if administered to a pregnant woman. Confirm that the patient is not pregnant before administering this drug.

Synthetic Androgens

Androgen-estrogen combination drugs are indicated for treating moderate to severe vasomotor symptoms associated with menopause (e.g., hot flashes) if estrogen use alone has been ineffective. Effects are similar to those of each hormone individually. See Chapter 54 for a discussion of the effects of testosterone.

Danazol (Danocrine) is a synthetic androgen with weak, dose-related androgenic effects. Its similarities to testosterone are limited. Danazol suppresses pituitary ovarian response by inhibiting pituitary gonadotropins. It is used to treat endometriosis because it inactivates and atrophies the normal and ectopic endometrial tissue. It is also used in

treating fibrocystic breast disease when pain and tenderness are severe enough to warrant suppression of ovarian function. Danazol is also used prophylactically for hereditary angioedema. Three off-label uses include treatment of precocious puberty, gynecomastia, and menorrhagia.

Adverse effects are mostly androgenic and hypoestrogenic (flushing, sweating, vaginitis, nervousness, emotional lability); they also include hepatic dysfunction. Like testosterone, danazol can cause masculinization in the female fetus.

C PROGESTINS

Progestins consist of progesterone and its derivatives. Through stimulation or inhibition, they regulate secretion of pituitary gonadotropins, which in turn regulate development of the ovarian follicle. Progestins also inhibit spontaneous uterine contractions. The prototype progestin is progesterone (Prometrium, Crinone). Table 52.2 provides a summary of selected progestins.

Nursing Management of the Patient Receiving P Progesterone

Core Drug Knowledge

Pharmacotherapeutics

Progesterone helps produce normal menstrual cycles in patients with amenorrhea and stops dysfunctional uterine bleeding. These seemingly opposite uses are possible because of the timing of drug administration and the drug's pharmacodynamics (see Table 52.2). Progesterone is also added to postmenopausal HRT to decrease the risk of endometrial cancer from estrogen therapy. It may be added cyclically (i.e., for so many days in every cycle) or daily. The exact dose and the preferred number of days the drug is given in a month (if dosing is cyclic) are still unknown, and research continues in this area. Progesterone may be administered intramuscularly (for dysfunctional uterine bleeding and for amenorrhea), orally (for endometrial hyperplasia or amenorrhea), or by vaginal gel (for amenorrhea). One form of progesterone can be administered by the intrauterine route for contraception (see Drugs Closely Related to Progesterone, later in chapter).

Pharmacokinetics

Progesterone is absorbed rapidly, whether administration is oral or by IM injection. Hepatic transformation is rapid; metabolites are present in the bloodstream for several days. Nonmetabolized progesterone and the metabolites of progesterone are excreted in the urine. Progesterone crosses the placenta and enters breast milk.

Pharmacodynamics

Exogenous progesterone affects the body in ways similar to endogenous progesterone. When the ovarian follicle creates the corpus luteum, progesterone is produced. Progesterone changes the endometrium from its proliferative phase into its secretory stage. When levels of progesterone (in combination with estrogen) are high enough, a signal is sent to the pituitary gonadotropins to stop producing FSH and LH, thus preventing further ovulation. Progesterone is necessary to increase endometrial receptivity for implantation of an embryo. Once the embryo is implanted, progesterone helps maintain the pregnancy. If pregnancy does not occur, the corpus luteum disintegrates, progesterone levels fall, the pituitary gonadotropins are stimulated, and more FSH and LH are produced, causing ovulation again. Progesterone also inhibits spontaneous uterine contractions and contractions of other smooth muscles in the body, but because of its potential teratogenic effects, its use to prevent spontaneous abortion (miscarriage) is not recommended. Progesterone

TABLE 52.2 Summary of Selected C Progestins

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P progesterone (Prometrium)	Endometrial hyperplasia, prophylaxis Amenorrhea	*Adult:* 200 mg/d for 12 d *Adult:* PO, 400 mg/d for 10 d	*Onset:* Within 1 h *Duration:* Unknown $t_{1/2}$: About 16 h
medroxyprogesterone (Provera, Depo-Provera [IM])	Amenorrhea Abnormal uterine bleeding Contraception Inoperable recurrent endometrial or renal cell cancer	*Adult:* PO, 5–10 mg/d for 5–10 d *Adult:* IM, 150 mg q3mo *Adult:* IM, 400 mg–1g every week	*Onset:* <2 h *Duration:* Unknown $t_{1/2}$: 50 d
megestrol (Megace)	Breast cancer, palliative Endometrial cancer, palliative Appetite enhancement in AIDS patients	*Adult:* PO, 400–800 mg/d	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown
Letonogestrel implants (Implanon)	Prevention of pregnancy	*Adult:* Insertion of a single sterile rod containing 68 mg of etonogestrel	*Onset:* Slow *Duration:* Up to 3 y $t_{1/2}$: Unknown

has demonstrated beneficial effects in the prevention of preterm birth prior to 32 weeks gestation in women with singleton pregnancies who have a history of preterm delivery. Additionally, a systematic review identified decreased perinatal death, respiratory distress syndrome, and necrotizing enterocolitis in the neonate (Rode, Langhoff-Roos, Andersson, et al., 2009).

Progesterone decreases the risk of endometrial cancer in postmenopausal women receiving estrogen. Progesterone, when combined with estrogen, increases bone mineral density and reduces the risk of fracture (Cauley, Robbins, Chen, et al., 2003). However, the risks of therapy outweigh these benefits in treating osteoporosis.

Contraindications and Precautions

Progesterone is contraindicated in patients with hypersensitivity to progestins. It should not be prescribed to prevent cardiovascular disease (a Black Box warning). Progesterone is also contraindicated for patients with thrombophlebitis, thromboembolic disorder, cerebral hemorrhage, or a history of any of these conditions. Further contraindications include impaired liver function or disease, carcinoma of the breast or genital organs, undiagnosed vaginal bleeding, or missed abortion. Progesterone is a pregnancy category B drug. However, there have been case reports of fetal abnormalities in male and female infants, including masculinization of the female fetus during the first four months of pregnancy. Additionally, because progesterone causes uterine relaxation, if the pregnancy is due to a fertilized defective ovum, the body takes longer to respond with a spontaneous abortion; this can increase the risk of complications to the mother. For these reasons, progesterone should be avoided during the first four months of pregnancy. It passes into breast milk, but the concentration is believed to be too low to affect the nursing infant. The American Academy of Pediatrics has determined that progesterone is usually compatible with breast feeding.

Caution should be used in patients with pathologies that may be adversely affected by fluid retention (epilepsy, migraine headaches, asthma, cardiac dysfunction, or renal dysfunction). Patients who have a history of depression should be observed carefully for signs of this disorder while taking progesterone. Photosensitivity may occur with use of this drug. As mentioned with regard to conjugated estrogen, the benzyl alcohol that some progesterone products contain may produce a fatal gasping syndrome if given to premature infants.

Adverse Effects

Research from the WHI indicates that progesterone may increase the risk of breast and ovarian cancer when given in combination with estrogen to postmenopausal women (Chlebowski, Hendrix, Langer, et al., 2003; Anderson, Judd, Kaunitz, et al., 2003). All estrogens and progesterones now carry a Black Box warning related to this adverse effect. The WHI also found that postmenopausal women who received these hormones had an increased risk of MI, stroke, pulmonary embolus, and deep vein thrombosis; progesterone carries a Black Box warning for these effects also. A post-hoc analysis of the WHI study recently demonstrated an increased rate of death from lung cancer in the combined HRT group, although incidence rates for lung cancer were similar in both the HRT and placebo groups (Chlebowski, Schwartz, Wakalee, et al., 2009).

When it is used alone, common adverse effects of progesterone include menstrual disorders (breakthrough bleeding, spotting, change in flow, amenorrhea, changes in cervical secretions), breast tenderness, changes in weight, and nausea, mental depression, and changes in mood. Uncommon but serious adverse effects include MI, thromboembolic disorders, sudden partial or complete loss of eyesight, and cholestatic jaundice. Progesterone is irritating at the injection site; the aqueous form is especially painful.

Drug Interactions

No known drug interactions are associated with progesterone. However, progesterone may affect results of the following laboratory tests: hepatic function, coagulation (decrease in prothrombin and factors VII, VIII, IX, and X), thyroid, metyrapone, and endocrine function.

Assessment of Relevant Core Patient Variables

Health Status

Assess for conditions that contraindicate use of progesterone: a history of or current thrombophlebitis, thromboembolic disorder, and cerebral hemorrhage; impaired liver function or disease; depression; and undiagnosed vaginal bleeding. Before progesterone treatment, a complete physical examination is required, including assessment of the breasts and pelvic organs. A Papanicolaou test should be performed. Assess the patient's menstrual cycles for irregularities. All vaginal bleeding should be diagnosed carefully before therapy starts.

Life Span and Gender

Assess the patient for pregnancy or intention to become pregnant because progesterone, which is in pregnancy category B, is associated with genital and congenital abnormalities when exposure occurs in the first four gestational months. Genital abnormalities include masculinization of the genital organs in the female fetus and hypospadias in the male fetus. Congenital abnormalities include congenital heart defects and limb-reduction defects. If the patient is in the later stages of pregnancy, progesterone might be used to halt premature labor. Assess whether the patient is breast-feeding, because progesterone's effects on the infant are unknown. Progesterone may be added to postmenopausal HRT.

Environment

Caution patients about exposure to ultraviolet light. Be aware of the environment in which progesterone will be

administered. Progesterone may be administered in any environment, including the home, if the patient or family member has learned to administer an IM injection correctly.

Nursing Diagnoses and Outcomes

- Disturbed Body Image related to potential breakthrough bleeding, spotting, changes in menstrual flow, weight gain, or breast tenderness secondary to adverse effects of drug therapy
  Desired outcome: *The patient will not experience substantial adverse effects from drug therapy to alter body image.*
- Risk for Injury related to loss of vision, onset of thrombotic disorders, and depression secondary to adverse effects of drug therapy
  Desired outcome: *The patient will not suffer an injury related to adverse effects of drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

The dosing schedule varies, depending on the clinical indication for using progesterone. In treating amenorrhea, the drug should be administered for 6 to 8 consecutive days. For treating dysfunctional uterine bleeding, the drug should be administered daily for 6 days. The best dosing schedule when progesterone is used in HRT is currently unknown.

Minimizing Adverse Effects

Take steps to minimize the adverse effects of progesterone therapy. To avoid risk for injury to the fetus, do not administer the drug to any woman who is in the first 4 months of pregnancy. In postmenopausal women, use the minimum effective dose to decrease risk of endometrial cancer while limiting any increased risk of breast or ovarian cancer. It is essential to assess throughout therapy for signs and symptoms of breast or ovarian cancer. Do not give progesterone to patients with a history of or active thrombophlebitis, thromboembolic disorders, breast cancer, ovarian cancer, or cerebral hemorrhage because these conditions are possible adverse effects of therapy. Discontinue therapy at the first sign of any of these conditions. Carefully monitor patients who may be adversely affected by fluid retention; therapy also must be discontinued if excessive fluid retention places patients at risk for their primary disease or disorder.

Providing Patient and Family Education

- Instruct patients and their families on the therapeutic and adverse effects of progesterone.
- Teach patients how to perform breast self-examination.
- Teach patients to notify the prescriber if they suspect that they are pregnant or if sudden loss of vision, severe headache, or numbness in an arm or leg occurs.
- Inform patients who are using the vaginal gel form of progesterone that it is the only intravaginal therapy they should be using. If they require other intravaginal therapy, administration should be at least 6 hours before or after progesterone gel. If indicated, discuss with patients how to time self-administration of intravaginal therapies.

Ongoing Assessment and Evaluation

Monitor premenopausal women taking progesterone for return of normal menstrual flow and cessation of abnormal bleeding. If amenorrhea or dysfunctional uterine bleeding is corrected without adverse effects, the drug therapy has been effective. Assess postmenopausal women throughout progesterone therapy for signs or symptoms of breast or ovarian cancer. Combination therapies of estrogen and a progestin (e.g., progesterone) are effective in the postmenopausal woman if they relieve symptoms while avoiding serious adverse effects.

Drugs Closely Related to P Progesterone

Medroxyprogesterone, Norethindrone, and Norethindrone Acetate

Other progestins are medroxyprogesterone (Depo-Provera, Provera), norethindrone (Ortho Micronor, Nor-QD), and norethindrone acetate (Aygestin).

Medroxyprogesterone, a derivative of progesterone, has androgenic and anabolic effects. Medroxyprogesterone is used to treat abnormal uterine bleeding, endometrial

MEMORY CHIP

P Progesterone

- Used to treat amenorrhea to help produce normal menstrual cycles, to stop dysfunctional uterine bleeding, or as part of postmenopausal HRT to decrease risk of endometrial cancer
- Used alone or in combination with estrogen in contraceptives
- Major contraindications: thrombophlebitis, thromboembolic disorder, cerebral hemorrhage (current or history of), breast or genital organ cancer, undiagnosed vaginal bleeding, and missed abortion
- Most common adverse effects: menstrual irregularities (breakthrough bleeding, spotting, change in menstrual flow, amenorrhea, changes in cervical secretions), breast tenderness, changes in weight, and nausea
- Most serious adverse effects (when used alone): MI, thromboembolic disorders, sudden loss of sight, gallbladder disorders
- Most serious adverse effects (when used with estrogen): increased risk for stroke, increased risk of coronary heart disease, increased risk of breast and ovarian cancers
- **Life span alert: pregnancy category B drug**
- Maximizing therapeutic effects: Dosing schedule will vary based on clinical indication for drug.
- Minimizing adverse effects: Minimize dose and duration of therapy in postmenopausal women.
- Most important patient education: Premenopausal women should report serious adverse effects at once; postmenopausal women should perform breast self-examination.

hyperplasia prophylaxis, pain from endometriosis, and amenorrhea and is a progestin-only contraceptive. Off-label uses include treatment of breast cancer, endometrial cancer, and renal cell cancer. Medroxyprogesterone can be administered orally, intramuscularly, and subcutaneously. Long-term use may increase bone loss. If the drug is used in adolescence or early adulthood, when bone mass is being stored for adult use, it may increase the risk of osteoporosis and osteoporotic fractures later in life.

Norethindrone, a synthetic progestin, is used as a progestin-only contraceptive. Norethindrone acetate (Aygestin), the acetic acid ester of norethindrone, is not used as a contraceptive but as treatment for abnormal uterine bleeding, amenorrhea, and endometriosis. These two drugs differ in terms of potency; norethindrone acetate is approximately twice as potent as the parent drug (norethindrone).

Other Forms of Progesterone

Other closely related drugs are forms of progesterone used alone or in combination with estrogens as contraceptives. These are described below under the section titled Contraceptives.

Drugs Significantly Different From Progesterone

Megestrol

Megestrol (Megace) is a progestin-like progesterone and shares many of progesterone's qualities and characteristics. The two drugs differ mostly in their pharmacotherapeutic effects. Unlike progesterone, megestrol is used as palliative treatment for patients with advanced breast or endometrial cancer (tablet form) or to increase appetite in patients with AIDS (suspension form), cancer–related anorexia-cachexia syndrome, and severe malnutrition. Exactly how megestrol increases appetite in patients with AIDS who have anorexia and cachexia is unknown. The resulting weight gain is not related to water retention. Megestrol is not used as part of HRT in postmenopausal women. Its contraindications are similar to those of progesterone. Safety and efficacy of megestrol acetate therapy in children have not been established.

Mifepristone

Mifepristone (Mifeprex) is used to end an early pregnancy (defined as 49 days or less from the start of the last menstrual period). It competes with progesterone for binding at the progesterone-receptor sites and is a progesterone antagonist. Mifepristone inhibits the activity of endogenous and exogenous progesterone, resulting in termination of pregnancy. Mifepristone also has antiglucocorticoid and weak antiandrogenic effects. Compensatory elevation of adrenocorticotropic hormone and cortisol levels have been observed in some patients. Animal studies have indicated some antiandrogenic effects with large doses, but no studies have been done on this effect in humans. Mifepristone is rapidly absorbed. It is highly protein bound and is metabolized by the CYP3A4 pathway in the liver. Most mifepristone is excreted in the feces.

Mifepristone, although effective for most women who use it, may result in an incomplete medical abortion, necessitating surgical intervention. Mifepristone may also fail to initiate an abortion or produce substantial vaginal bleeding; either of these events may also require a surgical procedure. Between 1% and 5% of women require a surgical procedure related to one of these problems. For this reason, the FDA has established very specific and unique requirements in the United States for the use of mifepristone. Although it is a prescription drug, mifepristone is not available in pharmacies. Instead, it is distributed directly to physicians, who can determine the duration of a patient's pregnancy through menstrual history and clinical examination and are able to detect an ectopic pregnancy. Ultrasonographic scanning should be used if the duration of pregnancy is uncertain or if ectopic pregnancy is suspected. Physicians must be able to provide surgical intervention in cases of incomplete abortion or severe bleeding, or they must have pre-established plans for providing such care through others. Some states allow nurse practitioners or nurse midwives who work closely with physicians to be authorized prescribers of mifepristone.

Drug therapy with mifepristone should not be used if the patient cannot return or is unwilling to return to the physician's office for two follow-up visits. It also should not be administered to patients who do not have adequate access in the following 2 weeks to medical facilities equipped for emergency treatment of incomplete abortion, blood transfusion, and emergency resuscitation. The prescriber must give the patient the FDA-written Medication Guide for mifepristone and discuss the information thoroughly. The Medication Guide contains FDA-approved information written especially for patients. Medication Guides accompany drugs that the FDA has determined to pose a serious risk; appropriate patient education reduces the risk. The patient should be instructed to bring the Medication Guide with them if they need to go to an emergency department so that other providers realize that they have received mifepristone for an abortion. The patient must sign an agreement before receiving treatment.

After the patient meets all the baseline requirements, she swallows three tablets of mifepristone in the physician's or other provider's office. This visit is considered day 1. At day 3, the woman returns to the provider's office to determine whether she is still pregnant. If medical abortion is incomplete, the woman takes two tablets of misoprostol. (Misoprostol is a different drug, a synthetic prostaglandin E_1 analogue. Although it is used to prevent gastric ulcers resulting from the use of nonsteroidal anti-inflammatory drugs [NSAIDs], it also is known to have abortifacient properties, by producing uterine contractions. See Chapter 50 for more information on the antiulcer properties of misoprostol.) It is recommended that the labeled routes and timing of administration of the misoprostol tablets be followed exactly; off-label uses (including intravaginal placement of the misoprostol tablets) have been associated with sepsis (see below).

In clinical trials, about 44% of women who took misoprostol following mifepristone expelled the products of conception within 4 hours; approximately 63% expelled them within 24 hours after the misoprostol dose. The patient returns to the provider's office at day 14 to verify complete ending of the pregnancy. Although bleeding itself is not proof that the pregnancy has been terminated, lack of bleeding indicates that the therapy was ineffective in causing a medical abortion. If the pregnancy has not been completely terminated, surgical intervention to end the pregnancy is recommended. Pregnancies that are carried to term after use of mifepristone may result in fetal deformities.

Contraindications for using mifepristone are a pregnancy that has lasted longer than 49 days since the start of the last menstrual period; confirmed or suspected ectopic pregnancy; intrauterine device in place (which must be removed before drug therapy begins); chronic adrenal failure; concurrent long-term corticosteroid therapy; bleeding disorders or use of anticoagulant drugs; allergy to mifepristone, misoprostol, or other prostaglandins; and inherited porphyrias (rare inherited disturbances in porphyrin metabolism that may cause hemolytic anemia and splenomegaly).

The most common adverse effects of mifepristone are heavy vaginal bleeding, abdominal pain, and uterine cramping. Most women have vaginal bleeding or spotting for 9 to 16 days after ending the pregnancy; some women bleed for 30 days or more. Prolonged heavy bleeding may indicate an incomplete abortion. Vaginal bleeding may be severe enough to warrant blood transfusion, treatment with vasoconstrictor or uterotonic drugs, surgical intervention, or IV fluids.

Case reports of deaths from sepsis have been reported and are highlighted in a Black Box warning for mifepristone. The patients who have died have all had the same unusual but very serious bacterial infections (e.g., *Clostridium sordellii*). Patients with sepsis may present with atypical findings: without fever, with or without abdominal pain, and without other signs of infection. However, what is present is an elevated white blood cell count with a marked shift to the left, tachycardia, hemoconcentration, and general malaise. The FDA recommends that all providers of medical abortion and emergency department health care providers should investigate the possibility of sepsis in patients who are undergoing medical abortion and present with nausea, vomiting, or diarrhea and weakness with or without abdominal pain, and without fever or other signs of infection *more than 24 hours after taking misoprostol*. To help identify those patients with a hidden infection, obtain a complete blood count. If infection is suspected it is recommended that immediate treatment with an antibiotic that will treat anaerobic bacteria, such as *Clostridium sordellii,* be started (FDA Public Health Advisory, 2006). Nausea, vomiting, and diarrhea may occur initially after taking the mifepristone; this should not be confused with their occurrence 24 hours later after drug administration, which can indicate sepsis.

Specific drug or food interactions with mifepristone have not been studied; however, because the CYP3A4 pathway metabolizes this drug, other drugs that are metabolized by or inhibit metabolism from this pathway may produce a drug interaction.

Mifepristone does not prevent subsequent pregnancies. The patient should resume contraception after verifying that the pregnancy has been completely eliminated or before resuming sexual activity.

CONTRACEPTIVES

Contraceptives are forms of estrogen and progesterone, usually in combination. They are administered orally and by a number of other routes (Box 52.2).

• Oral Contraceptives

The oral contraceptives are closely related to both estrogen and progestin because they contain varying amounts of these drugs in combination. A very few oral contraceptives contain progestins only. Oral contraceptives are given to prevent pregnancy; the patient's cultural beliefs may affect their use because some cultures and religions do not support interference with reproduction. Combination oral contraceptives inhibit ovulation by suppressing the gonadotropins FSH and LH. In addition, oral contraceptives alter the quality of cervical and other mucus in the female genital tract (inhibiting sperm penetration) and change the characteristics of the endometrium (reducing the likelihood of implantation). These drug effects may also assist in preventing pregnancy.

Oral contraceptives differ in the type and relative strength (potency) of their components and the relative dominance of estrogen or progesterone activity. Their ultimate effect is related to combined activity. Progestin-only oral contraceptives prevent pregnancy in a way that is not clearly understood. They are known to alter the cervical mucus and exert a progestational effect on the endometrium, which apparently produces cellular changes that render the endometrium hostile to implantation of a fertilized egg. In some patients, the effects of progestin also prevent ovulation.

BOX 52.2 COMMUNITY BASED CONCERNS

Contraceptives and Sexually Transmitted Diseases

Women who use any of the hormonal contraceptives are protected against pregnancy. Pregnancy can also be prevented with over-the-counter preparations that are spermicides, although they are not as effective in preventing pregnancy as the hormonal contraceptives are. None of these contraceptives protect women from sexually transmitted diseases, such as syphilis, gonorrhea, chlamydia, or HIV. Barrier protection from a condom is needed to prevent the transmission of the bacteria or viruses that cause these diseases. Condoms may be used with any of the other contraceptives. After ejaculation, care must be taken not to allow the semen to spill out of the condom during withdrawal of the penis from the vagina.

The three types of combination oral contraceptives are as follows:

- Monophasic: the dose of estrogen and progestin remains the same throughout the entire cycle.
- Biphasic: the amount of estrogen remains the same, but the amount of progestin rises in the second half of the cycle.
- Triphasic: estrogen amounts remain the same or may vary throughout the cycle, whereas progestin varies throughout the cycle.

Some serious adverse effects may occur with oral contraceptive use. These effects are usually related to high doses of estrogen in the drug. Oral contraceptives should be prescribed with the smallest effective dose of estrogen possible; thus, high-dose estrogen formulations are prescribed infrequently, usually only when a lower dose has been ineffective. Dose-related serious adverse effects include thromboembolism, stroke, MI, hepatic lesions, and gallbladder disease. The risk of cardiovascular and cerebrovascular effects is substantially increased in women age 35 years or older with other risk factors (e.g., smoking, uncontrolled hypertension, hypercholesterolemia, elevated low-density lipoprotein [LDL] cholesterol, obesity, and diabetes). Mortality rates associated with circulatory disease have been shown to increase substantially in smokers older than 35 years and in nonsmokers older than 40 years.

In addition, a decrease in glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combination drugs; the mechanism appears to be related to estrogen dose. Elevated blood pressure may be related to the use of oral contraceptives and is believed to result from estrogen and progesterone effects. Other adverse effects are related to the dosage of estrogen and progestin and reflect the individual adverse effects of these drugs. Lower doses minimize these effects, which include breakthrough bleeding (transitory), spotting, amenorrhea during and after treatment, breast tenderness, nausea and vomiting (usually transitory), steepening of the corneal curvature, contact lens intolerance, weight gain or loss, edema, migraine, elevated triglyceride levels, and depression.

An important nursing intervention is teaching about signs and symptoms of potential complications of estrogen and progestin contraceptives. The nurse can use the acronym ACHES to guide patient instruction: A (abdominal pain—severe: may be related to hepatic problems or gallbladder disease), C (chest pain—severe: may be due to cardiovascular event, MI, pulmonary embolism), H (headache—severe: may be due to hypertension or CVA), E (eye problems—visual loss or blurring: may be related to CVA or hypertension), and S (severe pain in calf or thigh: may be DVT).

Oral contraceptives are known to interact with the penicillins and the tetracyclines (both classes of antimicrobials). This drug interaction decreases the level of circulating hormones, and contraceptive failure may result. Although the interaction is well documented with these classes of antimicrobials, it can potentially occur with other antimicrobials as well. Women should be cautioned about this potential lack of effectiveness and encouraged to use another form of birth control while they are taking a penicillin or a tetracycline. There is a drug interaction between oral contraceptives and St. John's wort, an over-the-counter (OTC) herb used as an antidepressant, which induces the P-450 system, specifically the CYP3A isoenzymes. Although studies on this subject are small and may be considered inconclusive, St. John's wort appears to increase the metabolism of the oral contraceptives, allowing breakthrough bleeding, follicle growth, and ovulation with unplanned pregnancies (Hu, Yang, Ho, et al., 2005; Murphy, Kern, Stanczyk, et al., 2005). Patients should be cautioned that they may experience some breakthrough bleeding if they use this combination. They should also be counseled to use a second form of birth control if they use St. John's wort while taking oral contraceptives. Patients may not always receive accurate information about the risk of a drug interaction between oral contraceptives and St. John's wort. They may purchase St. John's wort OTC (perhaps in a health food store), or their health care providers may not know of the interaction (Sarino, Dang, Dianat, et al., 2007).

For greatest effectiveness, the woman should take the oral contraceptive every day at the same time, such as with a particular meal or at bedtime. Packets have either 21 or 28 pills. The last 7 pills in the 28-day pack are inert and do not contain hormones; they are a different color from the active pills. If the woman is using a 21-pill pack, she takes one pill daily for 21 days and then no pill for 7 days. If she is using the 28-day pack, she takes one pill every day. The advantage of this regimen is that the risk of forgetting to take an active pill is minimized if taking a pill every day is routine. Patients may follow one of several regimens for beginning a cycle. The patient should refer to the package insert with each preparation.

Another form of oral combination contraceptive is now available for women. Femcon Fe (Ovcon 35) is the first chewable oral contraceptive tablet. It is spearmint flavored. To guarantee that the entire dose reaches the stomach, the woman should drink a glass of water after chewing and swallowing the tablet. The contraceptive tablet can also be swallowed whole. Ovcon comes in 28-day packs, with 21 active pills and 7 inert pills.

The newest combination oral contraceptives (termed extended-cycle contraception) contain both the progesterone levonorgestrel and an estrogen. Two of these drugs (Seasonale and Seasonique) are taken daily for 84 days, followed by either 7 days of inert pills or 7 days of a pill that has only a low-dose estrogen, depending on the brand. The menstrual period occurs only once every 3 months. Another of these drugs, Lybrel is taken continuously with no breaks for a menstrual cycle. Initial breakthrough bleeding or spotting may occur more often with these extended-cycle contraceptives than with normal monthly cycling versions.

If the woman misses one dose of an oral contraceptive, she should take the next dose as soon thereafter as possible; a woman may take two tablets on the same day. If a woman

misses two doses of active pills, she should make up two missed pills over 2 days. If she misses three consecutive pills, she may not have adequate birth control protection, and she should also use a nonhormonal backup contraceptive. At that point, if she is receiving monthly cycle packs, she has two choices for how to proceed. She can either begin a new cycle pack as soon as she realizes that she has missed 3 days' worth of pills, or she can wait until it has been 7 days since she last took a pill and then begin a new cycle pack. She should use another form of birth control as a backup for at least the first 7 consecutive days after starting a new cycle pack and preferably for the entire new cycle. If she is using one of the extended-cycle contraceptives and misses three pills, she should not attempt to make up the pills but should finish the pack on the normal daily schedule. She should use backup contraception at this time. If she misses one of the inert pills in the monthly or Seasonale pack, or one of the low-estrogen (last 7) pills in a Seasonique pack, she does not have to make up these pills.

If a woman misses a menstrual period while on any form of oral contraceptive, she should be evaluated for pregnancy. Oral contraceptives should be withheld until pregnancy is ruled out because of possible damage to the fetus if the woman takes the drug during early pregnancy. Because there is no regular menstrual period with Lybrel, it may be difficult to determine whether unintended pregnancy has occurred. To prevent this, Lybrel is started during the first 24 hours of a menstrual period.

Mothers who do not breast-feed may begin use of oral contraceptives 4 to 6 weeks after delivery even if they have not resumed spontaneous menstrual periods. Oral contraceptives are not recommended in breast-feeding women, although they may be used carefully if absolutely necessary.

Emergency Oral Contraceptives

Emergency oral contraceptives are used to prevent pregnancy after unprotected sexual intercourse or a known or suspected contraceptive failure (such as a condom breaking). Currently, the only available emergency oral contraceptive is a progestin-only product (levonorgestrel) known by its trade name of Plan B. In Plan B, levonorgestrel prevents pregnancy in the same manner as when it is taken as a daily oral contraceptive, that is, *by preventing ovulation*. If the woman is already pregnant when she takes Plan B, the drug does *not* cause a spontaneous abortion. The first dose should be taken as soon as possible after intercourse; the drug is most effective if taken within 24 hours of unprotected sex but may be taken up to 72 hours after the event. The second dose is taken 12 hours after the first. Plan B One Step has the advantage of only requiring one pill. Both forms of emergency contraception are effective in preventing pregnancy when taken as directed. Emergency contraceptive pills are not used for routine contraception.

Plan B and Plan B One Step are unique in that the same formula is available as an over-the-counter (OTC) drug for women 18 years of age and older and as a prescription drug for those younger than 18 years of age. (The FDA recently approved sale without a prescription to young women 17 years of age, but it will take some time before this takes effect.) Because of its dual status, there are some unique limitations regarding how it can be sold. Plan B is sold only behind a pharmacy counter, unlike other OTC drugs, such as aspirin, which are offered for sale not only in the aisles of a pharmacy, but in convenience stores and gas stations, among other places. Proof of age is required to buy the drug OTC. Pharmacists in some states (Alaska, California, Hawaii, Maine, Massachusetts, New Hampshire, New Mexico, Vermont, and Washington) can provide emergency contraception to women younger than 17 without a prescription.

Nurses providing contraceptive counseling to patients should include information about how to access emergency contraception if it is needed and that the effectiveness of the drug is improved the sooner it is taken after unprotected sex. Keeping an emergency dose of the drug allows the drug to be taken as quickly as possible after unprotected sex. Information related to how it works and its general safety should be emphasized. After taking Plan B (or Plan B One Step), the woman should experience a menstrual period at the normal expected time (Aschenbrenner, 2006).

• Other Combination Contraceptives

Transdermal Contraceptives

The norelgestromin/ethinyl estradiol transdermal system (Ortho Evra) is similar to oral contraceptives in that it is a combination of a progestin and an estrogen. Unlike oral contraceptives, the combination of hormones is administered topically from a patch that releases the drugs. Its efficacy in preventing pregnancy and adverse effects are similar to those of oral contraceptives. Like 21-day cycle packs of oral contraceptives, the transdermal system is designed to be used for 3 weeks and then not used for 1 week, creating a 4-week cycle. A new patch is applied weekly on the same day of the week for three consecutive weeks. During the fourth week, no patch is applied. Menstruation begins during this week, when the woman is not wearing a patch.

The first time a woman uses the norelgestromin/ethinyl estradiol transdermal system, she should start it after her menstrual period begins. She can choose to apply the first patch either the day her period starts or the following Sunday. If she chooses the Sunday after the start of her period, she needs to use backup contraception for the first week of her first cycle (unless there is no delay in starting the method because the start of the menstrual period is on a Sunday). Directions for applying the patch are as follows:

- Choose a site to apply the patch on clean, dry, intact, healthy skin on the buttocks, abdomen, upper outer arm, or upper torso. Do not place on the breasts. The patch should be placed so that it will not be rubbed by tight clothing.
- Avoid using makeup, creams, lotions, powders, or other topical products on the site where the patch will be placed.

- Peel apart the foil pouch that contains the patch and open flat. Grasp a corner of the patch and gently remove it from the pouch.
- Using a fingernail, lift one corner of the patch, removing both the patch and the plastic liner from the foil liner.
- Peel away half of the clear plastic protective liner. Care should be taken to avoid touching the sticky surface of the patch.
- Apply the sticky surface of the patch to the skin and then remove the other half of the backing.
- Press down on the patch with the palm for 10 seconds to guarantee that the edges stick well to the skin.
- Change the patch weekly, using a new location for each patch. Before discarding the used patch, fold it in half so that it sticks to itself and seals in any active hormone remaining in the patch.

If the patch comes off and remains off for less than 24 hours, it can be reapplied if still sticky, or it can be replaced with a new patch. If the patch has been off for more than 24 hours, a new 4-week cycle must be started immediately and the "Day 1" patch from a new packet applied. Backup contraception should be used for the first week of the new cycle. If a woman forgets to replace a patch at the start of a new cycle (the end of week 4), she should apply the new week "Day 1" patch as soon as she remembers and use backup contraception for the first week. Birth control is not guaranteed if more than 7 days elapse without wearing a patch. In that case, backup birth control is needed.

If the woman forgets to change the patch for up to 48 hours at the end of week 1 or 2, she should change the patch as soon as she remembers. No backup contraception is needed in this situation. If more than 48 hours have elapsed, she should stop the current cycle and start a new 4-week cycle. Backup contraception should be used for the first week. If she forgets to remove the patch at the end of the third week, she should remove it as soon as possible. The first patch of the next cycle should be applied on the usual patch-change day.

Vaginal Ring Contraceptive

The etonogestrel/ethinyl estradiol vaginal ring (NuvaRing) is another combination of progestin and estrogen used for contraception. It has actions and adverse effects similar to those of the norelgestromin/ethinyl estradiol transdermal system. It is inserted into the vagina by the woman, left in place for 3 weeks, and then removed for 1 week. The drug is absorbed through the mucous membranes of the vagina and into the vascular system. Exact placement of the ring inside the vagina is not critical for effective birth control. The ring is removed by hooking the index finger under the forward rim of the ring or by grasping the rim between the index and middle fingers and pulling it out. Removed rings should be wrapped in the foil pouch and discarded in the trash; they should not be flushed down the toilet. Menstruation follows after the ring is removed, usually 2 or 3 days later.

Implanted Contraceptives

Implanon, an implantable contraceptive containing the progestin etonogestrel, was approved in the United States in 2006. It consists of a single, flexible plastic rod, about the size of a matchstick, implanted under the skin on the arm. It is effective for up to 3 years. Implanon prevents pregnancy by inhibiting ovulation through suppression of the lutenizing hormone surge, thickening the cervical mucus, and thinning the endometrium. It is more than 99% effective in preventing pregnancy. Prior to insertion, a negative pregnancy test must be documented. Insertion should be done within the first few days of the menstrual cycle and a backup form of contraception, such as condoms, should be used for the first 7 days. Irregular bleeding is the most common side effect, especially during the first 3 months of use. Implanon must be removed at the end of 3 years, at which time a new rod can be inserted if desired. Contraindications to use include current pregnancy, undiagnosed vaginal bleeding, history of or current breast cancer, liver tumors, active liver disease, thromboembolic disorders, chronic use of cytochrome P-450 3A4 inducing medications, or sensitivity to etonogestrel. Two small studies of lactating women suggest that use of Implanon does not interfere with breastfeeding and has no untoward effects on the infant. It is recommended that Implanon not be inserted until 6 weeks postpartum in women who are breastfeeding (Adams & Beal, 2009).

Intrauterine System Contraceptive

Intrauterine progesterone inserts (Levonorgestrel-releasing intrauterine system: LNG-IUS) are T-shaped units filled with 52 mg of levonorgestrel, with low doses administered directly into the uterine cavity. This form of contraception is recommended for women who have already had a child and are in a monogamous relationship. The insert is positioned in the uterine cavity by a health care provider and remains in place for up to 5 years; after 5 years it must be replaced. The mechanism of action is localized to the uterine cavity, resulting in glandular atrophy, leucocyte infiltration, and marked thinning of the endometrium. The progesterone also may thicken cervical mucus and inhibit ovulation. The LNG-IUS is highly effective and its contraceptive effect is immediately reversible after removal (Fantasia, 2008).

The LNG-IUS has additional non-contraceptive benefits due to decreased menstrual blood loss, and has been used as a treatment for menorrhagia due to fibroids. Adverse effects of the intrauterine progesterone inserts include some that are similar to all progesterone products and some that are unique to the route of administration; the latter may be severe. They include increased risk of pelvic inflammatory disease, increased risk of ectopic pregnancy (if there was a previous history of this condition), and enlarged ovarian follicles. Bleeding changes are likely, with most women having lighter menstrual periods after their uterus has adjusted to having the device. IUDs are contraindicated in pregnancy, active pelvic inflammatory

disease, recent history of postpartum endometritis or septic abortion, uterine abnormalities, or a history of sexually transmitted diseases.

C BISPHOSPHONATES

The bisphosphonate drug class affects normal and abnormal bone resorption. The prototype is alendronate (Fosamax). The other bisphosphonates are closely related to alendronate. Table 52.3 provides a summary of selected drugs used to treat bone resorption.

Nursing Management of the Patient Receiving P Alendronate

Core Drug Knowledge

Pharmacotherapeutics

Alendronate is used to treat and prevent osteoporosis in postmenopausal women. Alendronate is also approved to treat men who have osteoporosis. Other uses are treating glucocorticoid-induced osteoporosis (in men and women) and treating patients with **Paget disease.** Paget disease is an idiopathic bone disease characterized by chronic, focal areas of bone destruction complicated by concurrent excessive bone repair. The result is thick but weak bones that may fracture or bend under stress. Off-label uses include treating osteoporosis from Crohn disease and treating hypercalcemia of malignancy. Alendronate is given orally, except for hypercalcemia of malignancy, for which it is administered as an intravenous infusion.

Alendronate is also available in a combination tablet containing cholecalciferol, a vitamin D preparation. It is sold under the trade name Fosamax Plus D.

Pharmacokinetics

Alendronate is absorbed orally. Food and beverages other than plain water can decrease its absorption and bioavailability by about 40%. After absorption, alendronate is stored in the skeleton and does not appear to be metabolized. It is excreted in the urine as it is slowly released from the skeleton.

Pharmacodynamics

The major action of alendronate is to inhibit both normal and abnormal bone resorption. Alendronate is a highly selective and potent inhibitor of bone resorption, which occurs following recruitment, activation, and polarization of osteoclasts. The exact mechanism of antiresorptive action is not fully understood but may be related to the inhibition of hydroxyapatite crystal dissolution or the drug's action on bone-resorbing cells. Reduction of abnormal bone resorption is responsible for reductions in serum calcium and phosphate concentrations. Alendronate greatly increases bone-mineral density in patients with osteoporosis. Evidence of increased bone-mineral density is seen after 3 months of use and continues throughout therapy. Alendronate thus appears to reverse the progression of osteoporosis.

TABLE 52.3 Summary of Selected C Drugs Used to Treat Bone Resorption

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P alendronate (Fosamax)	Treat/prevent postmenopausal osteoporosis Paget disease	PO, 10 mg/d PO, 40 mg/d for 6 mo	*Onset:* Slow *Duration:* Days $t_{1/2}$: Unknown
etidronate (Didronel)	Paget disease Hypercalcemia of malignancy	PO, 5–10 mg/kg/d not to exceed 6 months IV, 7.5 mg/kg/d for 3 successive d diluted in at least 250 mL sterile normal saline	*Onset:* Slow for PO, rapid for IV *Duration:* Days $t_{1/2}$: 6 h in plasma; >90 d in bone
pamidronate (Aredia)	Paget disease Hypercalcemia of malignancy Breast cancer with bone metastases	IV, 30 mg diluted in 500 mL normal saline or 0.45% saline, infuse over 4 h for 3 consecutive d IV, 60–90 mg as a single-dose infusion diluted in 1 L normal saline, 0.45% saline, or 5% dextrose. Infuse 60 mg over 4 h, 90 mg over 24 h IV, 90 mg over 4 h every 3–4 wk in at least 500 mL	*Onset:* Rapid *Duration:* Days $t_{1/2}$: 28 h ± 7 h Terminal elimination from bone up to 300 d (in animal studies)
risedronate (Actonel)	Paget disease	PO, 30 mg/d for 2 mo	*Onset:* Rapid *Duration:* Days $t_{1/2}$: Multiphasic, 1.5 to 220 h
tiludronate (Skelid)	Paget disease	PO: 400 mg active tiludronate/d (comes in 240 mg tablets each with 200 mg active drug) for 2 mo	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown

Contraindications and Precautions

Alendronate is contraindicated if the patient is hypocalcemic or hypersensitive to the drug or any of its components. It is also contraindicated if the patient has any abnormalities of the esophagus that delay esophageal emptying, such as stricture or inability of the esophagus to relax. Alendronate should not be used if the patient is unable to stand or sit upright for at least 30 minutes. The drug is not recommended for patients with severe renal insufficiency, which can cause increased accumulation of alendronate in the bone. Alendronate is a pregnancy category C drug. Animal studies show increases in maternal and fetal hypocalcemia and deaths; no studies have been done on pregnant women. Alendronate is used in pregnancy only if benefits outweigh risks. Although it is unknown whether alendronate enters breast milk, based on the fetal risks determined from results of animal studies, the drug should not be given to breast-feeding mothers. Its safety and efficacy in children have not been established.

Spontaneous osteonecrosis of the jaw has been reported primarily in cancer patients who have received bisphosphonates as a component of their therapy, but it has also occurred in postmenopausal women with other types of diagnoses. Symptoms include nonhealing extraction socket or an exposed jawbone. A dental examination with appropriate preventive dentistry should be considered before treatment with bisphosphonates. Invasive dental procedures should be avoided during treatment.

Adverse Effects

When given to treat osteoporosis, the most common adverse effect of alendronate is abdominal pain; musculoskeletal pain is also fairly common. Other adverse effects are flatulence, acid regurgitation, esophageal ulcer, abdominal distention, gastritis, headache, rash, and erythema (rare). GI irritation is more likely to occur if the patient does not take the drug with a full glass of water, or if the patient lies down after taking the drug. When given to treat Paget disease, alendronate increases the risk for upper GI symptoms; otherwise, the adverse effects are similar to those for osteoporosis.

Overdose of alendronate produces hypocalcemia, hypophosphatemia, and upper GI adverse effects. Administering milk or antacids to bind with the alendronate may be helpful in counteracting the effects of overdose, but dialysis is not beneficial. Otherwise, care is directed at treating the symptoms of overdosage.

Drug Interactions

Drug interactions are known to occur between alendronate and some other drugs. Because of potential interactions, the patient is advised to wait at least 30 minutes after taking alendronate before taking any other drug. Table 52.4 lists drugs that interact with alendronate. All food and beverages interfere with the absorption of alendronate, by as much as 60%. For this reason the drug must be taken at least 30 minutes before any other food or beverage.

Assessment of Relevant Core Patient Variables

Health Status

Assess whether the patient has hypocalcemia or other disturbances in mineral metabolism, such as phosphate or vitamin D deficiency. These imbalances must be corrected before starting drug therapy with alendronate, because alendronate may cause additional slight decreases in serum calcium and phosphate levels. Verify that the patient has a clinical indication for use of alendronate (e.g., treating or preventing osteoporosis or Paget disease) before beginning therapy. Also, assess for a family history of osteoporosis, which increases a woman's risk of developing osteoporosis. Assess for severe renal insufficiency as well because this condition may necessitate a dose reduction.

Life Span and Gender

Alendronate is used in postmenopausal women to treat or prevent osteoporosis; it may be used as treatment for all patients with Paget disease. Assess the patient for pregnancy or intention to become pregnant, because alendronate is a pregnancy category C drug. Also, assess the patient's lactation status, because administration to breast-feeding mothers must be avoided. Use of this drug in children requires caution because its safety and efficacy for this age group have not been established. Older adults require no precautions or dosage adjustments.

TABLE 52.4 Agents That Interact with Alendronate

Interactants	Effect and Significance	Nursing Management
ranitidine	IV ranitidine doubles alendronate's bioavailability. Clinical significance is unknown.	Monitor for therapeutic and adverse effects.
calcium supplements, antacids	Products with calcium and other multivalent ions interfere with absorption of alendronate.	Separate doses of alendronate and calcium or antacids by 2 h.
aspirin	Coadministration increases risk of adverse effects in upper gastrointestinal system.	Monitor for adverse effects. If severe adverse effects develop, discontinue aspirin.

Lifestyle, Diet, and Habits

Review the patient's normal eating habits, because all food and beverages (e.g., coffee, orange juice, and mineral water) will decrease absorption of alendronate. Verify that the patient's diet contains adequate intake of calcium and vitamin D. Patients who have a history of eating disorders, such as excessive dieting, have an increased risk of osteoporosis. Assess for normal weight-bearing exercise, which helps prevent osteoporosis. Also, ask the patient about smoking and alcohol consumption because these factors increase the risk of osteoporosis.

Environment

Be aware of the setting in which alendronate will be administered. Alendronate is normally self-administered in the home, although it could be given in any setting.

Culture and Inherited Traits

Asian and white women are at increased risk of osteoporosis.

Nursing Diagnoses and Outcomes

- Risk for Injury related to fractures from osteoporosis or Paget disease
  Desired outcome: *The patient using drug therapy will have no fractures.*
- Potential Complication: Electrolyte Imbalance related to drug therapy with alendronate
  Desired outcome: *The patient will not experience electrolyte imbalance.*
- Potential Complication: Altered GI Function related to adverse effects of drug therapy with alendronate
  Desired outcome: *The patient will experience either no or minimal adverse effects.*

Planning and Intervention

Maximizing Therapeutic Effects

Nursing actions to maximize therapeutic effects are related to patient education. Assist patients in identifying a time in their normal routine when it will be appropriate to take alendronate.

Minimizing Adverse Effects

To minimize adverse effects from hypocalcemia, take measures to correct pre-existing hypocalcemia before treatment. Monitor electrolyte levels throughout therapy as indicated. Other actions to minimize adverse effects are related to patient education.

Providing Patient and Family Education

- Teach patients to take alendronate at least 30 minutes before eating, drinking any beverage other than plain water, or taking any other medication. Patients should swallow the medicine with 6 to 8 oz (180 to 240 mL) of plain water, which improves absorption of the drug.
- Instruct patients not to lie down for at least 30 minutes after swallowing alendronate, to decrease adverse GI effects.
- Encourage patients to take supplemental calcium and vitamin D if dietary intake is inadequate to meet the needs of the bones. However, calcium or vitamin D decreases absorption of alendronate if either is taken at the same time as alendronate. Instruct patients to take alendronate at least 1 hour before taking calcium or vitamin D.
- Encourage patients to make lifestyle changes that benefit bone health, such as engaging in weight-bearing exercise (including walking as tolerated and permitted by the patient's physical condition), limiting or stopping cigarette smoking, and limiting or stopping alcohol use.

Ongoing Assessment and Evaluation

Verify throughout therapy that the patient is not experiencing hypocalcemia or other adverse effects from alendronate therapy. Therapy is effective when adverse effects are absent or minimal, bone mass density increases, and bone resorption and bone formation decrease.

Drugs Closely Related to P Alendronate

Ibandronate

Ibandronate (Boniva) is another bisphosphonate that is approved for use in treating postmenopausal osteoporosis. It is administered orally once monthly or intravenously as an IV push over 15 to 30 seconds once every 3 months. Its pharmacologic characteristics are similar to those of the prototype. A large, randomized controlled, 12-month trial comparing ibandronate to alendronate—the MOTION (Monthly Oral Therapy with Ibandronate for Osteoporosis Intervention) study—found that 150-mg ibandronate is clinically comparable to 70-mg alendronate for bone mineral density response, reduction of bone turnover, and GI tolerability (Emkey, Delmas, Bolognese, et al., 2009). A recent meta-analysis found that adherence to bisphosphonate therapy was better with weekly rather than daily regimens, and this improved compliance with therapy results in a reduction of fracture risk (Cramer, Gold, Silverman, & Lewiecki, 2007).

MEMORY CHIP

P Alendronate

- Used to treat or prevent osteoporosis in postmenopausal women, and other sources of osteoporosis; also used to treat Paget disease
- Prevents bone resorption
- Major contraindication: hypocalcemia
- Most common adverse effects: GI problems
- Most serious adverse effect: hypocalcemia (uncommon)
- **Life span alert: used in postmenopausal women**
- Most important patient education: Take medication at least 30 minutes before eating, drinking, or taking other medication; take with plain water only. Do not lie down after taking the medication.

Risedronate

Risedronate (Actonel), a bisphosphonate, is approved for used in postmenopausal osteoporosis (treatment or prevention) as well as osteoporosis in men, osteoporosis from corticosteroids, and Paget disease. For postmenopausal osteoporosis, it is given orally once weekly. In some regimens it is prescribed in combination with oral calcium carbonate tablets; the risedronate is given one day per week and the calcium carbonate is given the other 6 days of the week.

Etidronate, Tiludronate, Pamidronate, and Zoledronic Acid

The other bisphosphonates are etidronate (Didronel), tiludronate (Skelid), pamidronate (Aredia), and zoledronic acid (Zometa). They all act primarily on bone to prevent bone resorption. Unlike alendronate, they are not used to treat or prevent osteoporosis; their therapeutic indication is for treatment of Paget disease. Additional indications are as follows:

- Etidronate—(1) treatment or prevention of heterotropic ossification (formation of bone in an abnormal location) after total hip replacement or spine injury; (2) hypercalcemia of malignancy
- Pamidronate—(1) hypercalcemia of malignancy; (2) breast cancer or multiple myeloma in conjunction with standard chemotherapy
- Zoledronic acid—(1) bone metastasis; (2) hypercalcemia of malignancy; (3) multiple myeloma; (4) prophylaxis of osteopenia secondary to androgen-deprivation therapy in prostate cancer. The FDA recently approved IV administration of zoledronic acid as a once-a-year treatment for postmenopausal osteoporosis and every 2 years to prevent osteoporosis in postmenopausal women with osteopenia (In Brief, 2010).

Pharmacokinetics, pharmacodynamics, and adverse effects of all of these drugs are similar to those of alendronate.

Drugs Significantly Different From P Alendronate

Raloxifene

Like alendronate, raloxifene (Evista) is prescribed to prevent osteoporosis in postmenopausal women. It reduces resorption of bone and decreases overall bone turnover. Unlike alendronate, however, raloxifene works as a selective estrogen-receptor modulator. Raloxifene is actually an estrogen antagonist at some sites because it blocks estrogen from attaching itself to the estrogen-receptor sites. At other estrogen-receptor sites, it produces estrogen-like effects. These effects include increasing bone-mass density and decreasing levels of total and LDL cholesterol. Raloxifene does not share estrogen's effects on the uterus or the breasts because it is an antagonist at these receptor sites.

Raloxifene is rapidly absorbed after oral dosing and can be administered any time of the day without regard to meals. It has extensive first-pass metabolism, although the P-450 pathways do not appear to metabolize it. The metabolites that are formed have a long half-life. The drug is highly protein bound. Raloxifene is excreted in the feces. It may cause fetal harm if given to pregnant women. It is a pregnancy category X drug, and its use is therefore contraindicated in pregnant women. Raloxifene is also contraindicated if the woman has a history of or active venous thromboembolic events (deep vein thrombosis, pulmonary embolism, retinal vein thrombosis). Caution should be used if raloxifene is coadministered with other highly protein-bound drugs, such as lidocaine, diazoxide, or diazepam. Raloxifene may decrease the binding of these drugs, which results in more free and active drug. When coadministered with warfarin, the anticoagulant, a 10% decrease in the prothrombin time (PT) may occur. If patients are receiving oral anticoagulation with warfarin, the prothrombin time or international normalized ratio should be closely monitored with the addition and withdrawal of treatment with raloxifene. Coagulation parameters should also be reassessed periodically during concurrent therapy. Adjustments of the warfarin dose may be necessary in order to maintain the desired level of anticoagulation. Cholestyramine greatly decreases the absorption of raloxifene (by about 60%); cholestyramine and raloxifene should not be administered concurrently. If both therapies are necessary, administration of the drugs should be spread out as much as possible.

Common adverse effects of raloxifene are hot flashes and leg cramps. Raloxifene increases the risk of venous thromboembolic events, especially during the first 4 months of treatment. To minimize this risk, patients should discontinue use of raloxifene at least 72 hours before an expected prolonged immobilization (e.g., a planned surgical event requiring immobilization or bed rest). Raloxifene also should be discontinued throughout periods of prolonged immobilization and bed rest. Patients should resume raloxifene therapy only when fully ambulatory. If patients are traveling, advise them to avoid prolonged sitting in the same position.

Teach patients to take supplemental calcium and vitamin D if their dietary intake is inadequate. As with alendronate, the patient should be encouraged to do weight-bearing exercises and to decrease alcohol consumption and cigarette smoking to promote bone density.

Calcitonin, Salmon

Calcitonin, salmon (Fortical) is a calcium regulator. It is a potent synthetic polypeptide hormone that has effects similar to those of calcitonins of mammalian origin. It reduces the number of osteoclasts and prevents resorptive activity of the bone, resulting in a reduced bone turnover rate. It also temporarily improves bone formation by increasing osteoblastic activity. Calcitonin, salmon is used in the treatment of hypercalcemia and Paget disease as well as in postmenopausal osteoporosis. It does not appear to be as effective as alendronate for treating osteoporosis. See Chapter 53 for further information.

Teriparatide

Teriparatide (Forteo) is a recombinant human parathyroid hormone. Like alendronate, it is approved for use in postmenopausal osteoporosis. When administered once daily, teriparatide stimulates new bone; however, it has been found to increase the bone mass density at the spine, but not at the hip or femoral neck, unless given in combination with alendronate. Teriparatide needs to be administered subcutaneously. See Chapter 53, which discusses parathyroid hormones.

CHAPTER SUMMARY

- Women need adequate levels of sex hormones to develop and maintain the sexual and reproductive organs, create and maintain the secondary sexual characteristics, induce and stop the growth spurt of adolescence, and achieve and maintain pregnancy.
- Estrogen and progestin are the primary female sex hormones.
- Estrogen causes capillary dilation, promotes fluid retention, enhances protein anabolism, contributes to strengthening the skeleton, and maintains normal bone density and composition.
- Progestins are composed of progesterone and its derivatives. They regulate, through stimulation or inhibition, the secretion of pituitary gonadotropins. This secretion, in turn, regulates the development of the ovarian follicle. Progestins also inhibit spontaneous uterine contractions.
- Decreased levels of female sex hormones (primarily estrogen) that result from menopause increase the risk for cardiovascular disease and osteoporosis. Cardiovascular disease is the primary cause of death in postmenopausal women. Osteoporosis affects women more than men because male sex hormones (testosterone) decline more gradually and at a later age than estrogen in women.
- Postmenopausal hormone replacement therapy (HRT) carries substantial risks. Research has found that the risk of coronary artery disease and stroke increases substantially with the use of postmenopausal hormones. An adverse effect on cognition and a greater risk of Alzheimer disease also exist.
- Use of HRT should be limited to menopausal women who have considerable vasomotor symptoms. The dose and the length of time therapy is administered should be kept to a minimum. Postmenopausal HRT should never be administered to prevent cardiovascular events.
- Most contraceptives are combinations of estrogen and progestin, although some contain progestin only. They prevent pregnancy. They may have serious adverse effects, but these effects are usually related to higher doses of estrogen in the drugs. Contraceptives should be prescribed with the smallest effective dose of estrogen possible. Contraceptives are available in various forms and routes of administration: oral tablets, transdermal patches, vaginal inserts, uterine inserts, and subcutaneous implants.
- The bisphosphonates, like alendronate, are used to treat or prevent osteoporosis by increasing bone mineral density and decreasing the risk of fractures. These drugs are preferred to estrogen therapy for treatment or prevention of postmenopausal osteoporosis because, unlike estrogens, they do not have negative effects on the cardiovascular system or on cognition. Because these drugs have interactions with food, beverages, and other drugs that impair their absorption, and because a flat position after taking the drug significantly increases the risk of GI irritation, patient education about the timing of the drug dosage is extremely important.

QUESTIONS FOR STUDY AND REVIEW

1. Explain why progesterone can be used to treat amenorrhea and abnormal uterine bleeding.
2. What are the serious adverse effects that may result from estrogen therapy?
3. What is the benefit of using the selective estrogen receptor modulator raloxifene instead of conjugated estrogen to treat postmenopausal osteoporosis?
4. What teaching points regarding missed pills would you review with a patient who is starting oral contraceptives?
5. What unique instructions about drug administration do you need to give to a patient who is to receive alendronate for osteoporosis?

Drugs Affecting Uterine Motility

Learning Objectives

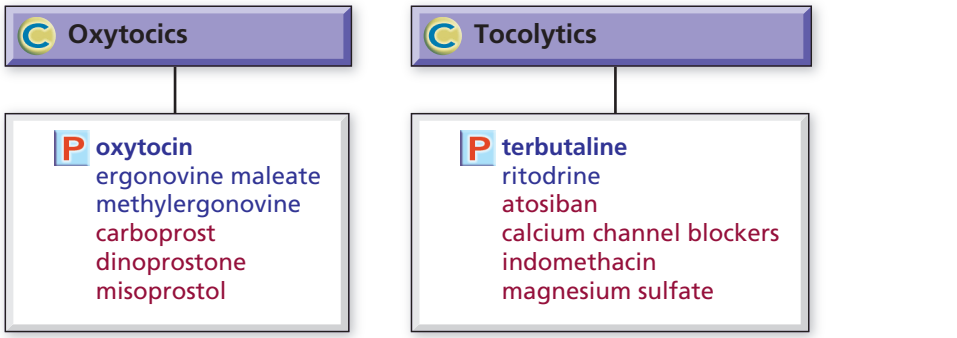
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect uterine motility.
2. Identify core patient variables relevant to drugs that affect uterine motility.
3. Relate the interaction of core drug knowledge to core patient variables for drugs that affect uterine contraction.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect uterine motility.
5. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect uterine motility.
6. Determine key points for patient and family education for drugs that affect uterine motility.

Key Terms

antepartum
intrapartum
oxytocics
postpartum
tachysystole
tocolytics

Drugs Affecting Uterine Motility



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

For labor and delivery of the fetus, normal uterine function is necessary. Normal uterine function consists of labor contractions beginning between 38 and 42 weeks of gestation. The contractions must be regular and strong enough to facilitate delivery of the fetus. At times, labor occurs prematurely, and stopping the uterine contractions is desirable. This chapter examines two classes of drugs that are used when the uterus does not function normally:

- **Oxytocics:** uterine stimulants used to initiate or augment a contractile pattern of labor
- **Tocolytics:** uterine relaxants used to stop labor contractions that occur before completion of the 37th week of gestation

The prototype oxytocic drug is oxytocin. The prototype tocolytic drug is terbutaline.

PHYSIOLOGY

Contractions and Related Changes

Most women progress through pregnancy, with contractions beginning between 38 and 42 gestational weeks. The onset of labor begins the **intrapartum** period of pregnancy, which concludes with delivery. Although the mechanisms of labor initiation are unclear, there is increasing evidence supporting the role of an inflammatory response pathway via a complex interplay of fetal and maternal signals. Pro-inflammatory cytokines released from the myometrium, cervix, and fetal membranes increase the expression of cyclooxygenase-2 (COX2) and prostaglandins, which stimulate uterine contractility. Prostaglandins also interact with oxytocin. Endogenous oxytocin stimulates the release of prostaglandins and prostaglandins increase the number of oxytocin receptors. Oxytocin does not initiate labor, but it is important in maintaining labor (Jabbour, Sales, Catalano, & Norman, 2009; Vidaeff & Ramin, 2008). Oxytocin is a hormone that is produced in the hypothalamus, stored in the posterior pituitary, and released into the circulatory system. Once the pituitary releases oxytocin, oxytocin binds to cell membrane receptors on target tissues, primarily the uterine myometrium (muscle cells), the decidua (lining of the gravid uterus), and the mammary epithelium. Although circulating oxytocin levels are unchanged before labor, there may be an increase in myometrial sensitivity to oxytocin prior to labor. Recent research suggests that this increased sensitivity may be related to a functional progesterone withdrawal and estrogen activation (Vidaeff & Raamin, 2008). If the number of oxytocin receptors is limited, the response of the uterus to oxytocin will be diminished. Pretreatment with prostaglandins, which increase the number of oxytocin receptors, results in an increased uterine response to exogenous oxytocin in labor. Oxytocinase, produced by the placenta, rapidly degrades oxytocin, which allows circulating oxytocin to restimulate the oxytocin receptors.

Endogenous oxytocin also has some vasopressive effects (causing vascular constriction) and antidiuretic effects (causing increased water resorption from the glomerular filtrate). Oxytocin is also necessary for the let-down of breast milk. Additionally, oxytocin is believed to have an intricate role in the creation and maintenance of maternal behavior (e.g., bonding with and caring for the infant).

Systemic Changes in Labor

Systemic changes initiated in the **antepartum** period (pregnancy before labor starts) continue into the intrapartum period. When labor contractions begin, the childbearing woman and her fetus exhibit additional physiologic alterations. The stress produced by uterine contractions affects many maternal systemic responses.

The woman experiences cardiovascular system changes. Blood pressure remains close to the antepartal baseline, except during uterine contractions. With contractions during the first stage of labor, the systolic pressure may increase by 35 mm Hg, whereas the diastolic pressure may increase by 25 mm Hg. During the second stage of labor, blood pressure increases even more with efforts to bear down. Pulse rate may increase because of the pain of labor contractions but should return to antepartal baselines. Use of the Valsalva maneuver (pushing against a closed glottis) is discouraged during the second stage of labor because of untoward alterations in maternal and fetal hemodynamics. Sustained bearing-down efforts longer than 5 to 6 seconds result in increased intrathoracic pressure, decreased blood flow from the lower extremities, decreased maternal cardiac output and blood pressure, decreased placental blood flow, fetal acidosis, non-reassuring fetal heart patterns, neonatal academia, and lower APGAR scores. Evidence-based practice recommendations support the use of open-glottis pushing to avoid these physiologic alterations in second stage (Roberts & Hansen, 2007). Immediately after birth, cardiac output increases to 80% above prelabor values; within the first hour after delivery, cardiac output slowly returns to normal. Most childbearing women adapt to these cardiovascular changes successfully.

During the intrapartum period, the woman experiences respiratory system changes because oxygen demand and consumption increase. Uterine contractions cause the respiratory rate to increase above pregnancy rates. This hyperventilation causes the level of $PaCO_2$ to fall; consequently, respiratory alkalosis develops.

As labor progresses, the contracting uterus increases muscular activity and oxygen requirements, which produces a mild metabolic acidosis. This mild metabolic acidosis continues, so that during the second stage of labor and by the time of birth, the acid-base imbalance remains because metabolic acidosis is uncompensated by respiratory alkalosis. The acid-base imbalances created by labor are quickly reversed after delivery because respiratory rates return to prepregnancy values and lactic acid production decreases. By 24 hours after birth, acid-base status is similar to prepregnancy levels.

The major labor adaptation in the hemopoietic system is the development of leukocytosis above pregnancy levels. The childbearing patient's white blood cell count may be between 25,000 and 30,000 mm^3. Although an elevated white

blood cell count is normally considered a sign of infection, laboratory assessment that shows an elevation of the white blood cells in the woman who has just delivered must not routinely be considered a sign of infection. This leukocytosis most likely results from labor stress, heavy exertion, and healing of the opened placental site.

Profuse perspiration and hyperventilation alter fluid and electrolyte balance during labor. Generally, healthy women having uncomplicated vaginal deliveries do not require intravenous (IV) fluids during labor. Clear liquid intake during labor does not increase maternal complications and modest amounts should be encouraged, according to a recent ACOG committee opinion (ACOG, 2009). IV fluids, including a preload bolus, are needed prior to regional analgesia (i.e., epidural) to mitigate the resulting maternal hypotension and subsequent insufficient placental perfusion and non-reassuring fetal heart tracings.

The renal system compensates for this decreased oral intake and increased water loss in part by excreting urine that is more concentrated. Also, the increasing uterine muscular activity leads to a breakdown of proteins and the presence of a trace of protein in the urine. As the fetal head descends in the pelvis, it extends pressure against the bladder walls and the urethra. The woman may not be sensitive to bladder filling. Regional anesthesia also alters bladder sensation and results in an inability to void. Overfilling of the bladder results in loss of uterine tone and ineffective labor contractions.

The gastrointestinal (GI) system experiences a reduction of gastric motility and absorption of solid foods during labor. Gastric emptying time is prolonged, and more than 25 mL of gastric contents remain in the stomach regardless of when the woman consumed her last meal. Narcotic analgesia or the use of epidural opioids further delays gastric emptying. Gastric acidity increases, and more than 50% of laboring women have a gastric pH below 2.5. This may be related to fasting in labor, which increases the concentration of hydrochorlic acid. Most circulating blood shifts away from the GI system to more vital maternal organs during labor.

The healthy fetus can progress through a normal labor and delivery with no adverse effects. The labor process produces a stressful physiologic state in the fetus with each contraction, but fetal compensatory mechanisms generally allow the fetus to respond successfully to those events.

Fetal acid-base status in labor depends on the maternal contractile pattern and the fetus's ability to compensate for contraction-produced decreases in oxygen. Oxygen/carbon dioxide exchange between the mother and the fetus occurs primarily between contractions, when the blood flow is not impeded. In women who are laboring efficiently, the contractions occur at intervals that allow the intervillous spaces in the placenta to refill with oxygenated blood between contractions; this refilling maintains an adequate oxygen supply to the fetus. The healthy fetus thus maintains a pH above 7.25. The indicators of fetal well-being and adequate fetal compensation during labor are a Category I tracing consisting of (1) a baseline rate of 110 bpm to– 160 bpm, (2) moderate variability, (3) absence of late or variable declerations. Accelerations and early decelerations may be absent or present (Macone, Hankins, Spong, Hauth, & Moore, 2008).

PATHOPHYSIOLOGY

Occasionally, uterine function proceeds abnormally, causing failure of labor to occur or failure of labor to progress. The two main categories of obstetric situations that require drug administration to initiate the onset of contractions include labor that does not begin at term and a pregnancy that is detrimental to the patient or her fetus.

Stimulation of uterine contractions using drugs before spontaneous labor has started is called induction of labor. Elective inductions for non-medical reasons should not be performed prior to 39 weeks gestation, to minimize complications from prematurity. Specific maternal and fetal conditions that may require induction of labor include the following:

- Gestational or chronic hypertension
- Post-term gestation
- Pre-eclampsia or eclampsia
- PROM at term
- PPROM near term with pulmonary maturity
- Severe intrauterine growth restriction

Before induction is initiated, the patient's cervix is assessed using the Bishop scoring system, and the fetus is assessed for evidence of maturity. The Bishop scale is a prelabor scoring system used to assist in predicting patient success if labor is induced. The system consists of five assessment parameters:

1. Cervical dilation
2. Cervical effacement
3. Fetal station
4. Cervical consistency
5. Cervical position

Each parameter is scored on a scale of 0 to 3. The higher the score, the greater is the likelihood that induction will lead to a vaginal delivery. The favorable cervix is described as one that is anterior, soft, at least 50% effaced, and 2 cm dilated, with the fetal station at +1 or lower. Induction is more likely to be successful if the score is 9 or greater in nulliparas or 5 or greater in multiparas.

Drugs may be administered to increase uterine contractions if labor is spontaneous but its patterns are dysfunctional, particularly when labor patterns are not strong or rhythmic enough to effect delivery. This type of labor needs augmentation with drug therapy that increases uterine contractions.

Another obstetric event usually requiring drug therapy is premature labor. The parturitional (child-birthing) process is now known to begin long before clinically detected preterm labor. If labor begins before completion of the 37th gestational week, drug therapy may be used to stop the uterine contractions and prolong the pregnancy. None of the currently used drug therapies, including IV fluid hydration, appears to alter the fundamental process of preterm parturition. The goal of

tocolytic drug therapy, covered later in this chapter, is to secure some additional time before delivery to administer drugs to the mother. Delaying delivery allows other drugs, which help to promote fetal respiratory function, to be administered and allows time to transfer the mother, if necessary, to a hospital capable of providing acute medical care to the mother and neonatal intensive care to the newborn. During this short but crucial interval, corticosteroids are administered to improve neonatal outcomes. Corticosteroid administration significantly reduces the risk for neonatal death, respiratory distress syndrome, and intraventricular hemorrhage, a risk factor for cerebral palsy. These effects of corticosteroids are greatest if the pregnancy is prolonged for at least 24 hours; the benefits continue for at least 7 days. (See Chapter 48 for a complete discussion of corticosteroids.)

C OXYTOCICS

Oxytocic drugs are synthetic forms of the endogenous posterior pituitary hormone oxytocin. They produce uterine contractions and milk ejection for breast-feeding. The prototype oxytocic drug is oxytocin (Pitocin). Table 53.1 provides a summary of selected uterine motility drugs.

Nursing Management of the Patient Receiving P Oxytocin

Core Drug Knowledge

Pharmacotherapeutics

Oxytocin is given by IV drip infusion to initiate or augment (improve) labor contractions when important fetal or maternal reasons to do so exist. Indications for labor induction were previously listed. Augmentation of labor with oxytocin is done when hypotonic uterine dysfunction exists, resulting in a protracted labor. IV oxytocin may also be used to treat incomplete or inevitable spontaneous abortion during the second trimester Evidence-based practice calls for the administration of oxytocin by IV drip infusion or intramuscularly (IM) in the third stage of labor to decrease the risk of postpartum hemorrhage.

Oxytocin is considered a high-alert medication that has substantial implications for patient safety. Labor nurses are primarily responsible for management of oxytocin administration. Evidence -based strategies to prevent errors and harms must be in place. Based on recommendations by Simpson & Knox (2009), these processes include the following:

- Standardized order sets and protocols which start induction or augmentation at 1 mU/min and increase by 1– to 2 mU/min every 30 to 60 min based on maternal-fetal response;
- Standard concentrations prepared by the pharmacy
- Standard definition of uterine tachysystole as a contraction frequency of more than 5 in 10 minutes or a series of single contractions lasting 2 minutes or more.
- Standard treatment of oxytocin-induced uterine tachysystole.

The desired contractile pattern consists of one contraction every 2 to 3 minutes, with durations of 40 to 90 seconds per contraction and, an intensity of 40 to 90 mm Hg for internal uterine monitoring, or strong to palpation for external monitoring. Conservative, specific protocols are currently recommended to improve maternal and neonatal outcomes. High-dose regimens for pitocin administration are not supported due to increased adverse events and a lack of improved perinatal outcomes (Clark, Simpson, Knox, & Garite, 2009).

Currently, research is ongoing about an unusual, off-label use of oxytocin: the infusion of oxytocin as a treatment for autism or Asperger syndrome. No labeled use of oxytocin exists for children or men.

Pharmacokinetics

Onset of action occurs almost immediately after IV administration. It is distributed throughout the extracellular fluid and has a plasma half-life of 1 to 6 minutes. Steady-state plasma levels are reached in approximately 40 minutes with continuous IV infusion, during which maximum uterine contraction occurs (see Table 53.1). Physiologic steady state is achieved when no further uterine response to increased oxytocin infusion occurs because the receptor sites are already bound with oxytocin and are temporarily unavailable. Elimination is through the liver, kidneys, and mammary glands and by the enzyme oxytocinase.

Pharmacodynamics

Synthetic, exogenous oxytocin has the same effects on the body as natural, endogenous oxytocin. It stimulates uterine contractions and milk let-down for breast-feeding. Although the endogenous hormone has a known effect on milk production, exogenous oxytocin is not administered for this purpose.

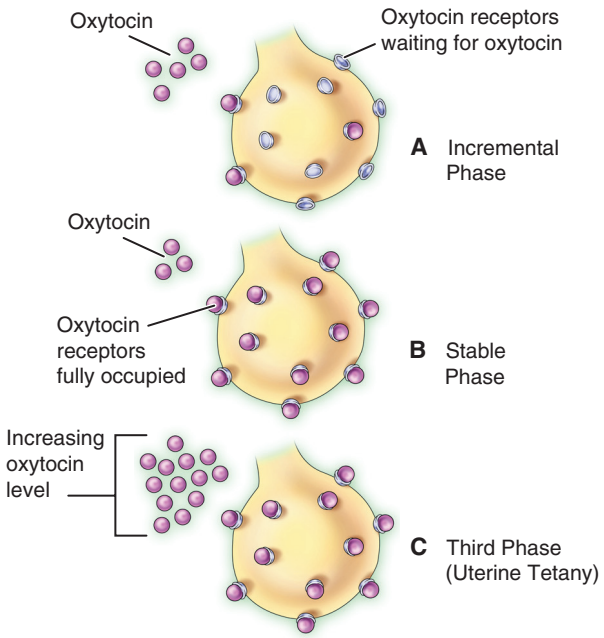
Response to oxytocin therapy has three phases (see Figure 53.1):

1. Incremental phase: uterine activity increases evenly as the dose of oxytocin increases.
2. Stable phase: uterine activity remains constant even if the oxytocin dose increases, because the myometrial receptor sites are already fully bound with oxytocin. Because the sites are full, they cannot be receptive to more effects from the oxytocin. As half-life and elimination of oxytocin occur, the uterus again has open receptors and is responsive to increases in oxytocin levels. The uterus shifts periodically between the incremental and stable phases.
3. Tachysystole: if this third phase of uterine response to oxytocin occurs, it indicates adverse effects from the drug. If the dose continually increases, the frequency of contractions will increase, but the uterine pressure will decrease so that the contractions are less effective. The result is tachysystole, with uterine fibrillation and prolonged contraction. Tachysystole is a pattern of more than 5 contractions in 10 minutes, averaged over

TABLE 53.1 Summary of Selected C Uterine Motility Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Oxytocics			
P oxytocin (Pitocin)	Antepartum: to induce or augment uterine contractions Postpartum: to control postpartum bleeding or hemorrhage (parenteral)	*Adult:* IV (induction or augmentation of labor), 1 mU/min via infusion pump; increase by this amount every 30–60 min; do not exceed 20 mU/min; IV (treatment of incomplete or spontaneous abortion), infusion of 30 U oxytocin with 500 mL Lactated Ringers solution, (concentration: 1 mL/h = 1 milliunit/min.); IV drip (control of postpartum uterine bleeding), add 10–40 U to 1,000 mL Lactated Ringers solution and run at a rate to control uterine atony; IM, 10 U after delivery of placenta as evidence-based practice to reduce risk of postpartum hemorrhage.	*Onset:* IV, immediate; IM, 3–5 min *Duration:* IV, 60 min; IM, 2–3 h $t_{1/2}$: 1–6 min
ergonovine maleate (Ergotrate Maleate)	Prevention and treatment of postpartum and postabortal hemorrhage due to uterine atony	*Adult:* IM, 0.2 mg (severe bleeding may require repeat dosing q2–4h); IV, 0.2 mg in emergency situations	*Onset:* IM, 7–8 min; IV, immediate *Duration:* IM, 3 h; IV, 45 min $t_{1/2}$: 0.5–2 h
methylergonovine (Methergine)	Routine management after delivery of the placenta Treatment of postpartum atony and hemorrhage; subinvolution of the uterus	*Adult:* IM, 0.2 mg after delivery of the placenta, after delivery of the anterior shoulder, or during puerperium; may be repeated q2–4h; IV, same dosage as IM, infused slowly over at least 60 sec (monitor BP very carefully because severe hypertensive reaction can occur); oral, 0.2 mg tid or qid daily in the puerperium for up to 1 wk. Typically administered every 6 hours for 24 h for uterine atony not responsive to oxytocin.	*Onset:* IM, 2–5 min; IV, immediate; oral, 5–10 min *Duration:* IM, 3 h; IV, 1–3 h; oral, 3 h $t_{1/2}$: 30 min
C Tocolytics			
P terbutaline sulfate (Brethine)	Unlabeled use: inhibition of premature labor	*Adult:* IV, initially 10 mg/min; titrate upward to a maximum of 80 mg/min; maintain at minimum effective dosage for 4 h Use is restricted to 48–72 h maximum	*Onset:* IV, unknown *Duration:* IV, unknown; $t_{1/2}$: Unknown
ritodrine	Management of preterm labor in selected patients at ≥20 wk gestation	*Adult:* IV, 0.05 mg/min initially; gradually increase by 0.05 mg/min q10min until desired result is attained; usual effective dosage between 0.15 and 0.35 mg/min, continued for at least 12 h after uterine contractions cease	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 1.7–2.6 h
C Others			
carboprost (Hemabate)	Termination of pregnancy at 13–20 wk Evacuation of the uterus in instance of missed abortion or intrauterine fetal death in the second trimester Postpartum hemorrhage due to uterine atony that does not re-spond to conventional methods	*Adult:* IM (abortion), 250 mcg at 1.5–3.5-h intervals; may be increased to 500 mcg; do not exceed 12-mg total dose or continuous administration over 2 d; IM (postpartum hemorrhage), 250 mcg as one dose; multiple doses at 15–90-min intervals may be used; do not exceed a total dose of 2 mg	*Onset:* 15 min *Duration:* Unknown $t_{1/2}$: 8 h
dinoprostone (Prostaglandin E_2)	Termination of pregnancy at 12–20 wk Evacuation of the uterus in missed abortion or intrauterine fetal death up to 28 wk gestational age Management of nonmetastatic gestational trophoblastic disease (benign hydatidiform mole) Initiation of cervical ripening before induction of labor	*Adult:* Intravaginally (abortion), one suppository (10 mg); additional suppositories may be given at 3–5-h intervals; intravaginal gel (cervical ripening), 0.5 mg, repeated if no response in 6 h	*Onset:* 10 min *Duration:* 2–3 h $t_{1/2}$: 2.5–5 min
magnesium sulfate	Unlabeled use: inhibition of premature labor; seizure prevention and control in preeclampsia and eclampsia	*Adult:* IM, 4–5 g of a 50% solution q4h as necessary; IV, 4 g of a 10%–20% solution; do not exceed 1.5 mL/min of a 10% solution; IV infusion, 4–5 g in 250 mL 5% dextrose; do not exceed 3 mL/min	*Onset:* IV, immediate; IM, 60 min *Duration:* IV, 30 min; IM, 3–4 h $t_{1/2}$: Unknown

PHYSIOLOGY



• FIGURE 53.1 Phases of oxytocin activity. Oxytocic drug therapy is usually initiated to mimic the role of natural oxytocin in prompting or augmenting labor. Oxytocin undergoes three phases of activity. (**A**) In the incremental phase, oxytocin levels rise, and oxytocin receptors are stimulated, producing increased intensity and frequency of uterine contractions. (**B**) In the stable phase, receptor sites are occupied with oxytocin, so no further oxytocin effects occur until a receptor site opens again. (**C**) In the third phase—uterine tetany tachysystole —oxytocin levels continually rise. Uterine contractions increase in number while the force of the contractions decreases. In such instances, the uterus experiences hyperstimulation tachysystole.

a 30-minute window, or a series of single contractions lasting 2 minutes or more.

Oxytocin therapy also has vasopressive and antidiuretic effects. Oxytocin affects the cardiovascular system by initially decreasing blood pressure. With prolonged oxytocin administration, baseline blood pressure may increase by 30%. Cardiac output and stroke volume also increase. Oxytocin doses of 15 milliunits/min or above have antidiuretic effects when administered over a prolonged period; the antidiuretic effect seems to reach its maximal effect at 45 milliunits/min. Antidiuresis appears to be initiated by the direct action of oxytocin on the kidney and not as a result of any stimulation of the release of antidiuretic hormone (i.e., syndrome of inappropriate secretion of antidiuretic hormone). Fatal water intoxication has occurred with the use of oxytocin, although the antidiuretic effects are weak. Additionally, oxytocin increases the water permeability of the nephron, which causes more water retention than sodium reabsorption and in turn leads to water intoxication and dilutional hyponatremia. Symptoms of water intoxication affect primarily the central nervous system (CNS) and musculoskeletal systems. CNS effects range from headache, fatigue, nausea, and anorexia to lethargy, confusion, disorientation, agitation, vomiting, seizures, and coma. Musculoskeletal symptoms may include cramps and weakness. Cardiovascular effects, such as tachycardia and hypotension, can also occur.

Oxytocin and vasopressin are known to play a role in social and repetitive behaviors. A small study of adults with autism or Asperger disorder who were administered oxytocin infusions showed a significant reduction in repetitive behaviors after the infusion, compared with placebo (Hollander, Novotny, Hanratty, et al., 2003). Oxytocin has also been linked to social recognition; the administration of oxytocin to individuals with autism appears to facilitate comprehension of the emotions behind speech (Hollander, Novotny, Hanratty, et al., 2003; Hollander, Bartz, Chaplin, et al., 2007).

Contraindications and Precautions

Oxytocin is contraindicated in cephalopelvic disproportion (fetal head relative to maternal pelvis) and with unfavorable fetal positions or presentations that must be converted before delivery (such as transverse lie). It is also contraindicated in the following conditions:

- Obstetric emergencies in which the benefit-to-risk ratio for either mother or fetus favors cesarean section
- Fetal distress without signs of imminent delivery
- Prolonged use in uterine inertia or severe preeclampsia
- Tachysystolic uterine patterns
- Failure of uterine activity to achieve satisfactory progress
- Contraindication to vaginal delivery (e.g., invasive cervical carcinoma, active genital herpes, cord presentation or prolapse, total placenta previa, vas previa)
- Hypersensitivity to the drug

Oxytocin must be administered very cautiously if cyclopropane anesthesia is used, because maternal sinus bradycardia with abnormal atrioventricular rhythms and hypotension may result. Water intoxication is possible with oxytocin use and should be considered if oral fluids or large doses of IV fluids are given in addition to oxytocin infusion. Overstimulation of the uterus, which may be hazardous to the mother or fetus, can occur with oxytocin administration, even with proper administration and supervision.

Adverse Effects

Adverse effects of oxytocin are dose related and take two forms: maternal and fetal. The most common maternal adverse effects are nausea, vomiting, uterine tachysystole and cardiac arrhythmias. Less common but potentially fatal are severe water intoxication and hyponatremia. Other maternal adverse effects are spasm and rupture of the uterus (usually from excessive doses or hypersensitivity to the drug), postpartum hemorrhage, subarachnoid hemorrhage, and pelvic hematoma. The most common fetal adverse effect is bradycardia. Other adverse fetal effects are premature ventricular contractions and other arrhythmias,

impaired fetal oxygenation, permanent brain or CNS damage and death (from excessive uterine motility), low Apgar scores 5 minutes after birth, neonatal jaundice, and retinal hemorrhage.

When administered intrapartally for induction or augmentation of labor, oxytocin does not cause fetal structural defects or congenital anomalies but may be responsible for fetal CNS depression. Such CNS depression severely compromises the neonate's ability to successfully adapt to the extrauterine environment.

Overdosage depends on uterine hyperactivity. Uterine tachysystole (greater than 5 contractions within 10 minutes or a series of single contractions lasting 2 minutes or more) or a resting tone of 15 to 20 mm Hg or more between contractions can cause tumultuous labor, uterine rupture, cervical and vaginal lacerations, postpartum hemorrhage, uteroplacental hypoperfusion, deceleration of FHR, fetal hypoxia, fetal hypercapnia, or fetal demise. These fetal effects occur as a result of uteroplacental hypoperfusion, a state in which the placenta does not have time to recover and be refilled with oxygenated blood. The lack of oxygenated blood creates a state of fetal hypoxia. The greatest drop in fetal oxygen saturation occurs 90 seconds after a contraction, and the fetus needs an additional 90 seconds to recover. In women who are laboring efficiently, intervals occur between the contractions that allow the fetus to be reoxygenated. In tachysystole from oxytocin therapy, no insufficient rest occurs between contractions. Fetal oxygen desaturation begins within 5 minutes of excess uterine contractions. With continued insult, anaerobic glycolysis, metabolic acidosis, and direct fetal myocardial depression results. The fetal heart rate tracing will demonstrate late decelerations with absent or minimal variability; a pattern associated with abnormal fetal acid-base balance (Simpson & Knox, 2009). Recovery of the fetus from oxytocin-induced hypoxia therefore requires cessation of oxytocin administration.

Water intoxication with convulsions may occur if large doses of oxytocin (40 to 50 milliunits/min) are given for a long time. Treatment consists of discontinuing the drug, restricting fluid intake, initiating diuresis, administering IV hypertonic saline solutions, correcting electrolyte imbalance, controlling convulsions cautiously with barbiturates, and following general nursing measures to care for an unconscious patient.

Drug Interactions

If oxytocin is given at the same time as sympathomimetic drugs (those drugs that stimulate the sympathetic nervous system), the vasopressor effect may be increased. A possible consequence is postpartum hypertension.

Assessment of Relevant Core Patient Variables

Health Status

Assess, or verify that the physician or nurse midwife has assessed, the patient's pelvic adequacy before beginning oxytocin therapy. Determine or confirm with the physician or nurse midwife that the fetal position is favorable for vaginal delivery. Assess for fetal distress and for conditions that would contraindicate vaginal delivery (e.g., invasive cervical carcinoma, active genital herpes, cord presentation or prolapse, total placenta previa, vas previa). Assess contractions for tachysystolic patterns or for contractions that should be successful in advancing labor but are not.

Assess whether the patient's cervix is favorable for induction (Bishop score of 5 or greater in multiparas and 9 or greater in primiparas). Before and throughout therapy, assess maternal vital signs, length of contractions, time between contractions, FHR, fetal movement, and fluid status. Assessment of FHR patterns and uterine activity is documented every 15 minutes in the active phase of the first stage of labor and every 5 minutes in the pushing phase of the second stage of labor. This assessment is performed by an RN providing care to not more than two induction patients (AWHONN, 2008).

Life Span and Gender

Before oxytocin is administered, assess the duration of the pregnancy. Oxytocin is not used during the first trimester except in cases of spontaneous or induced abortion.

Lifestyle, Diet, and Habits

Consider the patient's risk of water intoxication if the patient is receiving large amounts of fluids by either intravenous or oral route, or in the patient with impaired renal excretion (i.e., severe preeclampsia).

Environment

Be aware of the environment in which oxytocin will be administered. Oxytocin is administered only in a hospital labor and delivery suite where the patient and fetus can be continually monitored.

Nursing Diagnoses and Outcomes

- Risk for Fetal or Maternal Injury related to uterine hypertonicity secondary to oxytocin therapy
  Desired outcome: *The mother and fetus will progress through labor and delivery without injury during oxytocin therapy.*
- Excess Fluid Volume related to drug-induced water intoxication and altered electrolyte levels
  Desired outcome: *The patient's fluid status will remain normal during oxytocin therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Assess cervical ripening using the Bishop scoring system before oxytocin therapy starts. If the cervix is not ripe, PGE_2 gel may need to be instilled or vaginal doses of misoprostol given at least 4 hours before administering oxytocin. (For further discussion of these drugs, see the section on Drugs Significantly Different From Oxytocin.) Specific orders from the prescriber are required for administering either of these drugs. A protocol may also be required.

Standard concentrations of oxytocin in lactated Ringers IV solution should be prepared by the pharmacy to decrease risk of errors. Simpson (2009) recommends a pharmacy preparation of 30 U in 500 mL of LR yielding 1 mL/h = 1 mU/min. Use an infusion pump for precise administration of oxytocin.

Start the infusion at 0.5 to 1 milliunits/min and increase the dose by 1 to 2 milliunits/min every 30 to 60 minutes based on the maternal-fetal response until the desired contractile pattern is achieved. If labor is progressing at 1 cm/hour, oxytocin dosage does not need to be increased (Simpson & Knox, 2009). One research study found that once the patient achieves cervical dilation of 5 cm or more (active labor), there is no advantage in continuing oxytocin infusion at all; discontinuing the infusion did not result in significantly longer duration of the second phase of labor (Daniel-Spiegel, Weiner, Ben-Shlomo, et al., 2004).

If oxytocin is being used to control postpartum hemorrhage, the timing of the dose may be important. One small study found that if oxytocin was injected immediately after birth of the infant, there was less postpartum hemorrhage than if the drug was administered after the placenta had been delivered (Huh, Chelmow, & Malone, 2004).

Minimizing Adverse Effects

Piggyback the diluted oxytocin solution into a primary IV line, which also supplies a physiologic electrolyte solution. Doing so makes it possible to discontinue the solution immediately if adverse maternal or fetal effects occur. An infusion pump is continuously used throughout therapy to prevent overdosage.

Use of drugs that stimulate uterine activity requires close monitoring of the patient and fetus throughout administration of the oxytocin. Assess maternal vital signs, FHR, and contractile pattern before each increase in the infusion rate. If maternal vital signs show hypertension or substantial changes, if the FHR decreases, or if fetal movement stops, notify the prescriber immediately. Once the dose is stabilized during induction, check maternal vital signs at least every 4 hours.

The FHR monitor continuously records the patient's uterine contraction pattern. If the dose of oxytocin remains unchanged, assess FHR and uterine activity every 15 minutes during the active phase of stage one labor and every 5 minutes during the second stage of labor (Simpson & Knox, 2009).

Assess for evidence of tachysystole. Tachysystole occurs when there are 5 or more contractions within 10 minutes or contractions lasting 2 minutes or longer. Labor and delivery units should have a standardized procedure if a tachysystolic labor pattern develops from the oxytocin infusion. Simpson and Knox (2009) recommend a standard course of action based on fetal response. If there is a reassuring FHR: (1) place the mother in a lateral position, (2) provide an IV fluid bolus of 500 mL lactated Ringers, (3) if uterine activity has not returned to normal after 10 minutes, decrease oxytocin rate by half, and (4) if uterine activity has not returned to normal after 10 minutes more, discontinue oxytocin until normal uterine activity resumes and notify the provider. If there is a nonreassuring (Category II or III) FHR: (1) discontinue the oxytocin, (2) reposition the mother into a lateral position, (3) provide an IV fluid bolus of 500 mL lactated Ringers, (4) provide oxygen at 10 L/min via non-rebreather facemask, (5) give 0.25 mg terbutaline subcutaneously, and (6) notify the provider

The appropriate dose for restarting oxytocin after hyperstimulation is unknown. Simpson and Knox (2009) delineate a standardized protocol to decrease errors. Based on the physiology of contractions and the pharmacokinetics of oxytocin, it has been suggested that if the oxytocin has been discontinued for less than 20- to 30 minutes, if the fetal status is reassuring and the contractions no longer meet the definition of tachysystole, the oxytocin may be restarted at no more than half the previous rate. If the oxytocin was discontinued for more than 30- to 40 minutes, essentially all the circulating exogenous oxytocin has been metabolized. Restart at the initial rate.

Making these assessments in the intrapartum period is challenging and raises issues of nursing conduct and patient safety. If you have a professional difference of opinion with the physician or nurse midwife about whether the patient is experiencing tachysystole or whether the oxytocin should be slowed or stopped, use the appropriate chain of command in the institution to seek appropriate assistance for the patient. Failure to continue to seek care for a patient when necessary may legally be considered negligence on your part if the patient or fetus has an adverse outcome from oxytocin therapy (Simpson & Knox, 2009). A review of malpractice claims showed that the best ways to avoid litigation regarding oxytocin use include the following: accurate interpretation of FHR tracings, adoption and following of well-designed policies for the administration of oxytocin, using the chain of command, and comprehensive and objective documentation of the patient's response to oxytocin (Greenwald & Mondor, 2003).

Assess the patient's fluid intake and urinary output and urge the patient to urinate at least every 2 hours throughout oxytocin therapy. Assess for signs of water intoxication, including anorexia, nausea, vomiting, headache, confusion, muscle cramps, hypotension, and tachycardia.

Providing Patient and Family Education

- Educate the patient and family about the rationale for oxytocin use, the desired effects, and the potential adverse effects of oxytocin therapy (important).
- Explain that the patient and fetus will be monitored closely to determine the effectiveness of the therapy and to detect any early signs of adverse effects.

MEMORY CHIP

P Oxytocin

- Used to induce labor or to augment labor
- Works similarly to endogenous oxytocin by attaching to oxytocin receptors and stimulating them
- Major contraindications: conditions that require cesarean section; hypermotility of the uterus
- Most common adverse effects: maternal—nausea, vomiting, uterine hypertonicity, and cardiac arrhythmias; fetal—bradycardia
- Most serious adverse effects: maternal—uterine rupture, water intoxication (uncommon); fetal—demise, hypoxia, permanent brain damage, death
- **Life span alert: used in third trimester of pregnancy**
- **Patient safety alert: Oxytocin can cause maternal and fetal death, most commonly associated with overdosage of the drug.**
- Maximizing therapeutic effects: Administer when the cervix has ripened; titrate the dose upward slowly, based on the frequency of contractions and uterine response.
- Minimizing adverse effects: Assess mother and fetus carefully throughout therapy for adverse effects and poor fetal tolerance; stop the infusion if hypertonicity or fetal compromise occurs.
- Most important patient education: purpose of drug; rationale for frequent assessment

Ongoing Assessment and Evaluation

Throughout induction, monitor continually for evidence of adverse maternal or fetal effects. Oxytocin drug therapy is considered effective when labor progresses predictably, no maternal or fetal adverse effects occur, vaginal delivery happens without complications, and the postpartum period is uneventful.

Drugs Closely Related to P Oxytocin

Ergonovine maleate and methylergonovine, ergot derivatives, are two additional oxytocic drugs. Unlike oxytocin, they are primarily used to prevent postpartum or postabortal hemorrhage.

Ergonovine Maleate

Ergonovine maleate (Ergotrate), when used after placental delivery, increases the strength, duration, and frequency of uterine contractions and decreases uterine bleeding. Ergonovine maleate exerts its effects by acting as a partial agonist or antagonist at the alpha-adrenergic, dopaminergic, and tryptaminergic receptors. Ergonovine maleate may also be used to treat migraine headache (an off-label use of this drug), although it is less effective for this condition than the drug ergotamine.

Onset of action is rapid, although it varies by route of administration. IM injection is the preferred method. IV injection is confined to emergencies, such as excessive uterine bleeding, because of the higher incidence of adverse effects that accompany IV administration. Uterine contractions continue for 3 or more hours after IM injection. Ergonovine maleate promotes a higher uterine tone than oxytocin and therefore is not recommended for routine use before the delivery of the placenta. As with oxytocin, hypertension and headache may occur with use of ergonovine maleate. The principal manifestations of serious overdosage of ergonovine maleate are convulsions (acute overdosage) and gangrene of the fingers and toes (chronic overdosage). Other symptoms of overdosage include nausea, vomiting, diarrhea, hypertension or hypotension, weak pulse, dyspnea, loss of consciousness, numbness and coldness of extremities, tingling, chest pain, hypercoagulability, confusion, excitement, delirium, hallucinations, and coma.

Methylergonovine

Methylergonovine (Methergine) also has substantial effects on uterine tone. It acts directly on the smooth muscle of the uterus and induces a rapid and sustained tetanic uterotonic effect, which shortens the third stage of labor and reduces blood loss. Excretion is rapid and appears to be both renal and hepatic. IM use of methylergonovine is considered routine management after delivery of the placenta, although it may also be administered after the delivery of the anterior shoulder if full obstetric supervision is available. It is given orally three or four times a day immediately postpartum for a maximum of 1 week. Hypertension, sometimes with seizures or headache, is the most common adverse effect. Other adverse effects are hypotension, nausea, vomiting, dizziness, tinnitus, transient chest pain, hematuria, thrombophlebitis, water intoxication, hallucinations, leg cramps, nasal congestion, diarrhea, diaphoresis, palpitations, and dyspnea. Signs of acute overdosage include nausea, vomiting, abdominal pain, numbness, tingling of the extremities, and increase in blood pressure.

Drugs Significantly Different From P Oxytocin

Carboprost

Carboprost (Hemabate) is a prostaglandin used to induce abortion in pregnancies of 13 to 20 weeks' duration. Prostaglandins stimulate the myometrium of the pregnant uterus to contract in a manner similar to that of labor. The exact mechanisms of action of carboprost are unknown. Carboprost may also be used to control postpartum hemorrhage resulting from uterine atony that has not responded to oxytocin and IM ergot preparations. Carboprost is contraindicated in the following conditions: acute pelvic inflammatory disease; active cardiac, pulmonary, renal, or hepatic disease; and hypersensitivity to the agents. Carboprost is administered intramuscularly.

Carboprost also stimulates the smooth muscle of the GI tract, which may be responsible for the nausea, vomiting, and diarrhea that sometimes accompany its use. Nausea is the most common adverse effect. Other possible adverse effects are cardiovascular (arrhythmia, chest pain), CNS related (headache,

flushing, anxiety, hot flashes, paresthesia, dizziness, weakness), genitourinary (endometritis, uterine rupture, uterine or vaginal pain), and respiratory (coughing, dyspnea). Other miscellaneous adverse effects include chills and shivering, backache, blurred vision, breast tenderness, diaphoresis, eye pain, muscle cramps, fever, rash, and leg cramps.

Dinoprostone

Dinoprostone (Prepidil, Cervidil) has two major uses. Dinoprostone given as a vaginal suppository (Prostin E2) is used to terminate pregnancies of 12 to 20 weeks. It is usually reserved for evacuating the uterus in managing incomplete spontaneous abortion or intrauterine fetal death up to 28 weeks. It is also used in managing nonmetastatic gestational trophoblastic disease (benign hydatidiform mole).

Dinoprostone in a gel form (PGE_2 gel; Prepidil) or a vaginal insert (Cervidil) is used as an agent for cervical ripening at term when induction of labor is indicated. In most patients, treatment with dinoprostone changes the consistency, dilation, and effacement of the cervix.

The liver appears to be the primary site of metabolism for dinoprostone. Metabolites are excreted renally.

Misoprostol

Misoprostol (Cytotec) is a synthetic PGE_1 analogue. It produces uterine contractions. It also has antisecretory and mucosal protective properties. Although the only approved uses of misoprostol are to prevent gastric ulcers induced by therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) and after mifepristone use in medical abortion (see Chapter 52), many research studies have demonstrated that misoprostol is safe and effective in producing cervical ripening and initiating labor. Although still an off- label use, the FDA removed pregnancy as an absolute contraindication to misoprostol use in 2002.

Multiple studies have indicated that misoprostol is more effective than PGE_2 in achieving vaginal deliveries within 24 hours of administration with no difference in serious maternal or neonatal outcomes. There is conflicting data about cesarean delivery rates, with a trend toward fewer C-sections for failure to progress, but more C-sections for non-reassuring fetal heart tracings in the misoprostol group (Allen & O'Brien, 2009).

The best dose for induction of labor in pregnant women at term is still debatable; some studies support low oral doses (25 to 50 mcg), and others find no difference between low-dose and high-dose vaginal protocols (up to 200 mcg) (Ewert, Powers, Robertson, et al., 2006). Recent research studies found the drug to be effective in inducing labor in women at term who experienced prelabor rupture of their amniotic membranes, although not all studies concurred (Lin, Nuthalapaty, Carver, et al., 2005; Wing, Guberman, & Fassett, 2005). One study has shown that misoprostol has similar risks compared with oxytocin for causing contraction abnormalities (hypertonus, hyperstimulation) and maternal and neonatal complications (when used to induce labor in women at term with premature rupture of membranes) (Lin, Nuthalapaty, Carver, et al., 2005). When used to induce labor in midterm pregnancies (weeks 14 to 24), high-dose vaginal misoprostol shortens the labor induction compared with a low-dose regimen of vaginal misoprostol with oxytocin infusion (Nuthalapaty, Ramsey, Biggio, et al., 2005).

Misoprostol should not be used in patients with a previous cesarean delivery or prior major uterine surgery, to prevent uterine rupture. There is insufficient data to support the use of miesoprostol in the active management of third stage of labor to prevent postpartum hemorrhage or in the treatment of postpartum hemorrhage (Allen & O'Brien, 2009).

TOCOLYTICS

Drugs that inhibit uterine activity are classified as tocolytics. Preterm labor is the medical complication requiring the administration of tocolytics. Tocolytics are used when true labor begins after 20 weeks' gestation and usually before completion of the 34th gestational week. While late preterm neonates (34 –to 37 weeks gestation) have significantly more medical problems than full term infants, the major morbidities—respiratory distress, intraventricular hemorrhage, and necrotizing enterocolitis—are rare by 34 weeks gestation. Although the use of tocolytic drugs can stop preterm labor, they have not been found to have an effect on perinatal or neonatal outcomes. The use of tocolytics stops labor for 24 to 48 hours (and occasionally for up to 7 days), which affords additional time before delivery for the mother to receive corticosteroids. During that interval, the corticosteroids can exert a therapeutic effect on the fetal lungs so that they are prepared for life outside the uterus. If necessary, the mother can also be transferred to another facility during that time.

Currently, several drugs are used for their tocolytic properties, including beta agonists, such as terbutaline and ritodrine, and in the United States, magnesium sulfate. A new drug class, the oxytocin antagonists, works directly on the uterine receptors in treating preterm labor. Calcium channel blockers, especially nifedipine, have also been found to be effective in treating preterm labor. Prostaglandin inhibitors, such as indomethacin, have been used as tocolytic agents, but their use is limited to pregnancies less than 32 weeks gestation due to concern about premature closure of the fetal ductus arteriosis and effects on amniotic fluid volume (i.e., oligohydramnios) (Haas, et al., 2009). Thus far, the FDA has approved only ritodrine for use as a tocolytic. However, despite its approval and proven short-term effectiveness, this drug is seldom used to treat preterm labor. Discontinuation rates because of reported maternal adverse effects may be as high as 38%, contributing to the obstetric community's lack of confidence in ritodrine and a general view that ritodrine therapy is unsafe. However, clinical trials have shown that adverse effect profiles are actually very similar among beta agonists, and there may be no sufficient rationale for choosing one over another (Chan, Cabrol, Ingemarsson, et al., 2006). Terbutaline is a drug that acts similarly to ritodrine.

Although using terbutaline to control preterm labor is an off-label use, the drug has been widely used for this purpose. Because of its use, the prototype tocolytic for this chapter is terbutaline (Brethine).

Research on tocolytics has produced mixed results, with some studies showing that all of the tocolytics are equally effective in stopping preterm labor, some showing that a particular drug is better than other drugs, and some indicating that none of the drugs are very effective (Tan, Devendra, Tan, et al., 2006). Although tocolytics are accepted as effective over the short term (delaying delivery by 24 hours up to 7 days), research has not found them to be effective in delaying delivery over the long term. A recent meta-analysis of 58 studies including women between 28 and 32 weeks gestation, demonstrated that tocolytics are superior to placebo at delaying delivery for 48 hours and for 7 days, but not at delaying delivery until 37 weeks (Haas, Imperiale, Kirkpatrick, et al., 2009). Thus, the efficacy of all tocolytic drugs remains unclear, which is one reason for the continued controversy surrounding their use.

Nursing Management of the Patient Receiving P Terbutaline

Core Drug Knowledge

Pharmacotherapeutics

The labeled uses of terbutaline include treatment of asthma and bronchospasm, although it is rarely used in the treatment of asthma (see Chapter 35 Table 35.3, for more information on this use). Although the drug label for terbutaline specifically states that the drug should not be used to control preterm labor, terbutaline has been used off-label to control preterm labor in pregnancies of 20 weeks to 34 weeks. Some disagreement exists as to what the earliest gestational age to use terbutaline should be, and some authorities believe drug therapy should be started later than 20 weeks, if used at all. Recent Food and Drug (FDA) label changes for terbutaline (FDA, 2011) restrict the use of terbutaline to a maximum 48 to 72 hours given either by cutaneous subinjection or intravenous infusion. The drug must be administered in an inpatient setting.Using terbutaline to control preterm labor, although widespread, is still considered controversial by many experts, who believe that the effectiveness of the drug for this use has never been clearly demonstrated by positive perinatal or neonatal outcomes. Perscribing practices for terbutaline are likely to change based on the recent revised labeling of the drug from the FDA.

When terbutaline is administered to control preterm labor it should be used concomitantly with corticosteroids, which are effective in preventing respiratory complications in the premature newborns. Terbutaline prolongs delivery long enough for the corticosteroids to take effect. Like other tocolytic therapy, terbutaline therapy has not been found to be effective long term when used on a maintenance basis to prevent premature labor and its use in this manner is now contraindicated on the label (FDA, 2011) (Box 53.1).

BOX 53.1 FOCUS ON RESEARCH

Tocolytic Therapy: A meta-analysis and decision analysis.

Haas, D. M., Imperiale, T. F., Kirkpatrick, P. R., Klein, R. W., Zollinger, T. W., & Golichowski, A. M. (2009). Tocolytic therapy: A meta-analysis and decision analysis. *Obstetrics & Gynecology,* 113(3):585–594.

The Study

A meta-analysis of 58 randomized controlled trials of tocolysis was conducted to determine the optimal first-line tocolytic agent for treatment of preterm labor. Results demonstrated that all tocolytic agents were superior to placebo or control groups for delaying delivery for at least 48 hours and 7 days. Calcium-channel blockers were superior for delaying delivery to 37 weeks gestation. No statistically significant differences were found for neonatal outcomes, including respiratory distress syndrome or neonatal survival. A decision analysis found that prostaglandin inhibitors yielded the best tolerance and delayed delivery. Extrapolating to clinical implications, if 1,000 women were treated for preterm labor, 80 of those treated with prostaglandin inhibitors would deliver within 48 hours compared to 182 to 416 for other tocolytic treatments. The authors concluded that prostaglandin inhibitors may be the best first-line tocolytic agent before 32 weeks gestation to delay delivery for 48 hours and 7 days; calcium-channel blockers may be superior for delaying delivery until 37 weeks gestation.

Nursing Implications

Preterm birth, defined as a delivery prior to 37 completed weeks gestation, is a significant cause of neonatal morbidity and mortality in the United States. Current practice involves interventions to delay birth as long as possible to mitigate neonatal risk. Decisions about which treatments to use for prevention of preterm labor are made by the provider and are based on multiple fetal and maternal factors. Risks and benefits of therapy for both mother and fetus must be carefully considered in this decision process. Nurses are often faced with the task of explaining and clarifying these issues for patients and families. This can pose a dilemma when treatments have been shown to be ineffective or dangerous in achieving outcomes (i.e., bedrest for preterm labor). Patients may also have questions about which medication is the best to use. A meta-analysis of many trials is helpful because the sample size can be larger when several studies are considered as one and this yields the highest level of evidence for practice. Nurses can work with interdisciplinary evidence-based practice teams to bring the latest evidence to the bedside to achieve the best possible outcomes.

Intervention should begin as soon as a diagnosis of preterm labor is established and contraindications are ruled out. Conservative therapy (e.g., bed rest and lying on the left side), although lacking evidence to support its effectiveness, may be tried first and may also be used simultaneously with drug therapy. If terbutaline therapy is necessary, the drug is administered subcutaneously, or intravenously.

Some research, although quite limited, supports treating uterine tachysystole with tocolytics as a means of intrauterine resuscitation. A critical review of the literature by de Heus and colleagues (2008) found that the best available evidence supports the use of beta-adrenergic agonists such as terbutaline or ritodrine, although the dosage remains unclear.

Pharmacokinetics

Aspects of its pharmacokinetics are not well known.

Pharmacodynamics

Terbutaline is a beta-receptor agonist (stimulant) that selectively prefers the beta-2 receptors over beta-1 receptors. Stimulation of these receptors inhibits contractility of uterine smooth muscle and provides bronchial dilation, vasodilation, and hepatic glycogenolysis and gluconeogenesis, among other effects (for a full discussion of the effects from beta-2 receptor stimulation, see Chapter 13). Although terbutaline prolongs pregnancy, it has not been found to decrease the incidence of premature births or have any effect on perinatal or neonatal outcomes.

Contraindications and Precautions

Terbutaline now carries a black box warning that it should not be used for longer than 48–72 hours as it increases the risk of serious maternal cardiovascular events (including increased heart rate, cardiac arrhythmias, pulmonary edema, and myocardial ischemia), transient hyperglycemia, hypokalemia, and maternal death. Use of terbutaline in outpatient settings (such as via infusion pumps) is now contraindicated. Oral use of terbutaline is also now contraindicated as it has not been found to be effective in preventing or treating preterm labor and it has the same safety concerns.

Terbutaline is contraindicated before the 20th week of pregnancy because the impetus for a spontaneous abortion may be related to genetic fetal defects.

Terbutaline is also contraindicated in the following conditions, in which continuing the pregnancy is hazardous to the mother or fetus:

- Antepartum hemorrhage that requires immediate delivery
- Eclampsia and severe preeclampsia
- Intrauterine fetal death
- Chorioamnionitis (inflammation of the amniotic membranes)
- Maternal cardiac disease
- Pulmonary hypertension
- Maternal hyperthyroidism
- Uncontrolled maternal diabetes mellitus

Additional contraindications include pre-existing maternal medical conditions that would be seriously affected by the pharmacologic properties of a beta agonist such as terbutaline. Examples include hypovolemia, cardiac arrhythmias associated with tachycardia or digitalis toxicity, uncontrolled hypertension, and pheochromocytoma (a hypertension-producing tumor of the adrenal glands). Hypersensitivity to any component of the drug is also a contraindication. Precautions that apply to the use of terbutaline include controlled diabetes, controlled hypertension, and bronchial asthma already being treated with beta agonists. Terbutaline is a pregnancy category C drug.

Adverse Effects

Terbutaline is a potent drug that may produce serious, even fatal, adverse effects in the woman and the fetus. The adverse effects are related to the other effects of beta stimulants on the body, including beta-1 stimulation effects, because although terbutaline is relatively selective for beta-2 receptors, some stimulation of beta-1 receptors still occurs. These maternal adverse effects include tachycardia, palpitations, hypotension, cardiac arrhythmias, electrocardiographic changes, dyspnea, nervousness, tremor, transient hyperglycemia, hypokalemia (occurring possibly through intracellular shunting), pulmonary edema, cerebral and myocardial ischemia, nausea, and vomiting. Maternal deaths have occurred. Fetal and neonatal effects include increased FHR and neonatal hypoglycemia. Of these adverse effects, tachycardia (maternal and fetal), cardiac arrhythmias, palpitations, and tremor (maternal) are probably the most common, and pulmonary edema and cerebral and myocardial ischemia are the most serious. Cardiac arrhythmias are also potentially serious.

In instances of overdose, the drug should be discontinued, and an appropriate beta blocker, such as propranolol, should be given as an antidote.

Drug Interactions

Additive effects may occur if terbutaline is administered with other beta stimulants. Coadministration of terbutaline and beta blockers decreases the effectiveness of terbutaline. Table 53.2 lists drugs that interact with terbutaline.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient has any conditions that contraindicate therapy or require cautious use of terbutaline. These conditions may include cardiac arrhythmias

TABLE 53.2 Agents That Interact with P Terbutaline

Interactants	Effect and Significance	Nursing Management
Beta blockers	Will compete with terbutaline for the same receptors, thereby preventing terbutaline from having its effect	Give as antidote if overdosage of terbutaline; otherwise, not recommended to be coadministered.
Beta-2 agonists; other sympathomimetic drugs	Increased effects at other beta receptors; may significantly increase blood pressure	Avoid coadministration if possible; monitor patient's BP carefully if coadministration is essential.
Halothane, cyclopropane (halogenated hydrocarbon anesthetics)	Increases the risk for cardiac arrhythmias	Monitor patient carefully if this combination must be used.

associated with tachycardia, uncontrolled hypertension, pheochromocytoma, diabetes, or bronchial asthma already being treated with beta agonists. Assess the patient's pulse rate and blood pressure. A baseline electrocardiogram (ECG) should be performed to rule out undiagnosed maternal heart disease before beginning terbutaline infusion. Determine whether the patient is taking beta blockers.

Life Span and Gender

Ask whether the woman's pregnancy is 20 weeks' gestation or more, because pregnancy of less than 20 weeks is a contraindication. Terbutaline is a pregnancy category C drug.

Environment

Be aware of the environment required to administer terbutaline. Terbutaline given to control a current episode of preterm labor must be given in a hospital labor and delivery suite where the mother and fetus can be monitored while the IV solution or the continuous SC solution is infused. Terbutaline is contraindicated in the outpatient setting.

Nursing Diagnoses and Outcomes

- Risk for Injury to mother from adverse effects of drug therapy
  Desired outcome: *No adverse effects will occur from drug therapy.*
- Risk for Injury to infant stemming from premature delivery or adverse effects from drug therapy
  Desired outcome: *Drug therapy will prevent premature delivery of infant and will not cause adverse effects to the newborn.*
- Excess Fluid Volume, pulmonary edema, related to potential adverse effects of drug therapy
  Desired outcome: *The patient's fluid volume will remain within normal limits.*

Planning and Intervention

Maximizing Therapeutic Effects

Begin drug therapy as soon as possible after preterm labor is diagnosed and the order to start therapy has been received. Terbutaline therapy is usually given by the IV route. Administer the prescribed glucocorticoid steroids with the terbutaline to promote fetal lung development.

Minimizing Adverse Effects

Monitor the patient's pulse rate and blood pressure closely throughout therapy. Have the patient lie on her left side during infusion to help minimize the risk of hypotension and promote circulation to the fetus. Closely monitor the patient's fluid status and avoid fluid overload. Related measures include monitoring intake and output of fluids, assessing peripheries for edema, and auscultating breath sounds for rales and rhonchi every hour. If pulmonary edema develops, discontinue drug administration and notify the prescriber or nurse midwife immediately. Seek orders to manage the edema by diuretic therapy.

BOX 53.2 COMMUNITY BASED CONCERNS

Teaching About Drugs That Affect Uterine Function

Prenatal teaching should include the following:

- Signs of preterm labor
- Rationale for not giving tocolytics to stop preterm labor before 20 weeks' gestation (spontaneous abortion may be related to fetal defects)
- Rationale regarding use of oxytocin (these should focus on medical indications, not convenience of delivery)

If the patient demonstrates signs of adverse effects, such as palpitations, tachycardia, hypotension, or nervousness, the dosage of terbutaline should be decreased. Ensure that a beta blocker such as propranolol is available as an antidote in case of overdosage. If the patient is diabetic or receives potassium-depleting diuretics, monitor the serum glucose and potassium levels carefully. Administer terbutaline infusions through an IV infusion controller or pump to keep the dosage rate accurate. Because of the risk of pulmonary edema, avoid diluting terbutaline with saline (0.9% sodium chloride solution or lactated Ringer's solution) and Hartmann's solution; use a dextrose solution instead.

Providing Patient and Family Education

- Educate the patient and family about the therapeutic and adverse effects of the drug.
- Explain to the patient the rationale for lying on her left side.
- Instruct the patient to notify you or another health care provider immediately if she experiences swelling in her hands or feet, shortness of breath, palpitations, or chest pain.

For more on patient and family education, see Box 53.2.

Ongoing Assessment and Evaluation

Monitor the maternal heart rate, FHR, and maternal blood pressure and fluid status throughout terbutaline therapy. Drug therapy is considered effective when the premature contractions decrease in intensity and frequency, the woman and fetus do not experience adverse effects, and premature birth is avoided for at least 24 hours so that administered corticosteroids can exert their beneficial effects.

CRITICAL THINKING SCENARIO

MATERNAL MONITORING AND TERBUTALINE

Susan Hartmann, who is 30 weeks pregnant, has diabetes that is well controlled with glyburide, an oral antidiabetic agent. She begins preterm labor, and terbutaline is ordered for her.

1. Discuss which laboratory values you would monitor most closely if you were her nurse.
2. Explain the rationale for your choices.

MEMORY CHIP

P Terbutaline

- Used off-label to control preterm labor after 20 weeks' and up to 34 weeks' gestation; allows time for administered corticosteroids to be effective in newborn
- Beta-2 receptor agonist (stimulant); antidote: beta blockers
- Major contraindications: oral use for prevention or treatment;use in outpatient settings via infusion pumps;before the 20th week of pregnancy; when continuing the pregnancy is hazardous to the woman or fetus; pre-existing maternal medical conditions that would be seriously affected by the pharmacologic properties of a beta agonist
- Most common adverse effects: maternal and fetal tachycardia; maternal palpitations, cardiac arrhythmias, tremor
- Most serious adverse effects: maternal—multiple serious cardiovascular problems;death
- Maximizing therapeutic effects: Administer as soon as preterm labor is diagnosed and order is written for drug therapy.
- Minimizing adverse effects: Monitor maternal pulse rate, blood pressure, fluid status, and fetal heart rate; decrease infusion rate if adverse effects (excessive beta stimulation) are present.
- Most important patient education: Drugs to control preterm labor help buy time for other drug therapy to have an effect in preventing complications in the newborn.
- **Black box warning: IV and injectable use is limited to 48 to 72 hours in a hospital setting; oral doses should not be used at all**

Drug Closely Related to P Terbutaline

Ritodrine is a beta agonist, like terbutaline. Unlike terbutaline, it is labeled to treat preterm labor. Frequently perceived by clinicians to cause more adverse effects than terbutaline, ritodrine appears to have a similar (and potentially serious) adverse effect profile to other beta agonists and similar (although limited) efficacy (Chan, Cabrol, Ingemarsson, et al., 2006; Tan, Devendra, Tan, et al., 2006). Ritodrine's, as well as other beta agonists', place in therapy is still debatable in the literature. It is infrequently used.

Drugs Significantly Different From P Terbutaline

Magnesium Sulfate

Magnesium is a trace mineral involved in many chemical reactions in the body. Therefore, the pharmacotherapeutics of magnesium sulfate are diverse, and more potential therapeutic uses are under consideration. Oral magnesium sulfate preparations are used in laxatives and antacids (see Chapters 50 and 51). Oral and IV forms of magnesium sulfate are often given to correct electrolyte imbalances (hypomagnesemia). IV magnesium effectively suppresses ventricular ectopy and is a first-line therapy for torsades de pointes, a variation on ventricular tachycardia that can progress to fibrillation and be fatal. It may also be useful in treating patients with chronic heart failure or acute myocardial infarction. Magnesium sulfate is used to control hypertension, encephalopathy, and convulsions in children with acute nephritis. IV magnesium may be useful in treating asthma and chronic lung disease that have been unresponsive to conventional therapy with beta agonists.

Magnesium sulfate is used frequently for treating or preventing seizures associated with preeclampsia, eclampsia, and pregnancy-induced hypertension. Its effectiveness in preventing seizures in eclampsia is well accepted and documented. The onset of eclamptic seizures can be antepartum, intrapartum, or postpartum. Magnesium sulfate is the drug of choice for intrapartum or postpartum eclampsia, and it prevents furthers convulsions (Sibai, 2005). It is more controversial when used in women with preeclampsia or hypertension to prevent progression to eclampsia and seizures. Some research supports the use of magnesium sulfate in mild preeclampsia 12 hours postpartum (Ehrenberg & Mercer, 2006), but other clinical trials indicate that although the drug is effective, it has an adverse effect profile (respiratory difficulties and postpartum hemorrhage) and should probably be avoided in mild preeclampsia (Duley, Henderson-Smart, & Meher, 2006). One very large clinical trial (Magpie Trial) found no long-term differences among children at age 18 months who were exposed to maternal magnesium sulfate for preeclampsia before birth, compared with children who were not exposed to maternal magnesium sulfate before birth (i.e., their mothers had preeclampsia but they received a placebo). This study also found no difference in long-term complications for women treated with magnesium sulfate (Magpie Trial Follow-Up Study Collaborative Group, 2007a, 2007b).

Magnesium sulfate has been used as a tocolytic, although North American use of the drug in this manner is considered an anomaly, as other countries do not use magnesium sulfate as a tocolytic (Grimes & Nanda, 2006). As with terbutaline, use as a tocolytic is off-label. The effectiveness of magnesium sulfate as a tocolytic remains controversial, although it is widely used in the United States for this purpose. Some practitioners believe that magnesium sulfate appears to inhibit myometrial contractility but does not prolong pregnancy significantly. It can help prevent labor long enough to allow corticosteroids to be administered to the mother to protect the infant's lungs. But reviews of current research do not support this belief; instead, these findings state that magnesium sulfate is not effective in delaying birth or preventing preterm birth. In addition, magnesium sulfate carries a serious risk of adverse effects to the infant, including an increased risk of fetal death. For these reasons, some experts have begun to call for abandoning the use of magnesium sulfate as a tocolytic (Crowther, Hiller, & Doyle, 2002; Pryde, Janeczek, & Mittendorf, 2004; Grimes & Nanda, 2006). However, a recent Cochrane Review by Doyle and colleagues (2009) clearly supports the use of antenatal magnesium sulfate for neuroprotection of the fetus and significantly reduces the risk of cerebral palsy.

The mechanism of action of magnesium sulfate makes it particularly suitable for use in complications of pregnancy. Magnesium sulfate acts as a CNS and muscular depressant, producing peripheral neuromuscular blockade. It prevents or controls convulsions by blocking neuromuscular transmission and by decreasing the amount of acetylcholine freed at the end plate by the motor nerve impulse. Secondarily, magnesium sulfate relaxes smooth muscle and decreases blood pressure. This effect may be related to its antagonistic effect on calcium, which prevents calcium influx into the cells for cellular contraction.

Although magnesium sulfate is a pregnancy category A drug (which means that it does not cause fetal structural defects), its use still carries some risk to the fetus because the drug may cause other adverse effects. Magnesium sulfate may also cause adverse effects in the mother. Adverse effects are related to how the drug works and are usually associated with elevated serum levels or magnesium intoxication (Table 53.3). A serum level of 10 to 12 mg/dL is associated with toxicity (normal levels without any infusion of magnesium sulfate are 1.8 to 3 mg/dL). The most common maternal adverse effects are:

- Headache
- Hyporeflexia
- Weakness
- Thirst
- Flushing
- Burning at infusion site

The most life-threatening maternal adverse effects are:

- Circulatory collapse
- Respiratory depression
- Pulmonary edema

The most common fetal and neonatal adverse effects are:

- Heart rate changes
- Neonatal hypotonia
- Neonatal respiratory depression (possibly serious)

Other maternal adverse effects from magnesium toxicity are sweating, hypotension, flaccid paralysis, hypothermia, and cardiac depression. IV infusion, especially for prolonged periods (more than 24 hours), may produce hypermagnesemia in the newborn, including neuromuscular or respiratory depression. Overdosage produces a sharp drop in the blood pressure, respiratory paralysis, and ECG changes (increased PR interval, increased QRS complex, and prolonged QT interval). Heart block and asystole may also occur. Serum levels need to be monitored closely when the patient is receiving magnesium sulfate to prevent overdosage and adverse effects from therapy. Calcium gluconate antagonizes the effects of magnesium toxicity and is the antidote for overdose.

TABLE 53.3 Correlation of Serum Levels and Effects of Magnesium Sulfate

Serum Level (mEq/L)	Effect
1.5–3	Normal level
4–7	Therapeutic level for preeclampsia/eclampsia/convulsions
7–10	Loss of deep tendon reflexes, hypotension, loss of consciousness
13–15	Respiratory paralysis
16–25	Cardiac conduction altered (lengthened PR interval, QRS widening, prolonged QT interval, arrhythmias)
25	Cardiac arrest

Magnesium sulfate may be administered by the IM or IV route or by IV infusion (see Table 53.1). An IV pump should be used to regulate the flow of magnesium sulfate infusion. Dosing is accomplished with a loading dose followed by a maintenance dose. The IV route is preferred for initial stabilization; after that, an oral dose may be used for maintenance. The goal is to maintain a therapeutic serum level without causing adverse effects. The therapeutic level varies, depending on the clinical indication for the therapy. It is 5 to 8 mg/dL in preterm labor and 4 to 8 mg/dL in pregnancy-induced hypertension. These levels are higher than would normally be found in the serum but are the elevations required to produce a therapeutic effect.

In addition to using an IV pump, several other nursing actions can minimize adverse effects. It is necessary to assess for signs of magnesium toxicity by monitoring the serum magnesium levels and the patient's clinical response to drug administration. Continuous maternal cardiac monitoring and continuous fetal monitoring should be used while the patient is receiving IV magnesium sulfate. The patient should be placed on bed rest in the left lateral recumbent position to prevent hypotension and to maximize blood flow to the fetus. The patient must receive nothing orally to eat or drink (i.e., remain NPO) during stabilization to help prevent nausea and vomiting. With each change in dose, it is necessary to document uterine activity, cervical changes, and maternal-fetal responses. Safety measures or seizure precautions should be implemented if the drug is used to prevent or treat seizures associated with pregnancy-induced hypertension. Finally, calcium gluconate should always be kept at the bedside to use as an antidote if magnesium toxicity occurs.

Calcium Channel Blockers

Because calcium channel blockers prevent muscle contractility, they have been studied for their possible use as tocolytics. The calcium channel blocker that is used most often as a tocolytic is nifedipine. Research has shown that calcium channel blockers, like nifedipine, are as effective, if not more effective, in preventing preterm labor as the more traditionally used beta agonists, like terbutaline. Calcium channel blockers may be the best first-line tocolytic for delaying birth until 37 weeks gestation (Haas, et al., 2009). Calcium channel blockers do not induce the same adverse effects in the mother or infant as the beta agonists (Pryde, Janeczek, & Mittendorf, 2004), and they are effective in reducing blood pressure and

preventing recurrent elevations when used to treat hypertension in pregnancy (Duley, Henderson-Smart, & Meher, 2006). Long-term follow-up of children exposed to either the beta agonist ritodrine or the calcium channel blocker nifedipine showed no postnatal differences in terms of psychosocial and motor functioning (Houtzager, Hogendoorn, Papatsonis, et al., 2006). Calcium channel blockers are discussed in depth in Chapter 31 as well as in Chapter 28.

Atosiban

A new drug class, the oxytocin antagonists, works directly on the uterine receptors in treating preterm labor. These drugs do not seem to cause the maternal and fetal adverse effects seen with the beta agonists and are equally effective as, but not more effective than, the beta agonists. A recent Cochrane Review (Papatosonis, Flenady, & Liley, 2009) concluded that there was insufficient evidence to support the use of this class of drugs for preterm birth prevention.

Indomethacin

Indomethacin is an NSAID that suppresses uterine activity by inhibiting prostaglandin synthesis. It is effective in stopping premature labor for 48 hours and up to 7 days (Haas, et al., 2009). This may be related to a decreased adverse side-effect proficle when compared to beta-memetics and magnesium sulfate. Typically used prior to 32 weeks gestation, newer evidence suggests that indomethacin may be used safely up to 34 weeks gestation (Blumenfield & Lyell, 2009). For information about the other uses of indomethacin, see Chapter 25.

CHAPTER SUMMARY

- Drug therapy may be used when labor does not occur at term, does not bring about delivery effectively, or begins preterm.
- Oxytocin is given by IV drip infusion to initiate or augment (improve) labor contractions when important fetal or maternal reasons to do so exist. It is also used to control postpartum bleeding or hemorrhage.
- Response to oxytocin therapy has three phases: the incremental phase, the stable phase, and hyperstimulation. The hyperstimulation phase is undesirable and indicates that administration of oxytocin has been excessive.
- Adverse effects of oxytocin are dose related.
- You need an accurate understanding of the physiology involved in producing contractions, the core drug knowledge (most specifically the pharmacokinetics, pharmacodynamics, and adverse effects of oxytocin), and the relevant core patient variables to be able to make sound professional judgments in managing patients receiving oxytocin therapy.
- You are responsible for determining the maternal and fetal response to oxytocin therapy (frequency of contractions, progress of labor, and fetal tolerance) and for titrating the dose, per the physician's or nurse midwife's orders, based on this assessment.
- You must stop the infusion of oxytocin if tachysystole occurs.
- Tocolytic drugs are used to stop preterm labor. Although they are effective for short-term use, they have not decreased the number of preterm births, neonatal morbidity, or neonatal mortality. Tocolytic drugs do help prolong labor long enough to allow administration of corticosteroids and to transfer the mother (if necessary) to an institution that has facilities for premature infants.
- Terbutaline is a beta-receptor agonist (stimulant) that attaches to receptors in the uterine smooth muscle. Stimulation of these receptors inhibits contractility of uterine smooth muscle. Terbutaline decreases the intensity and frequency of uterine contractions and is used off-label to control premature labor. Its use is limited to 48 to 72 hours via injection or infusion in an inpatient setting due to the risk of serious maternal cardiovascular events and deaths. Oral terbutaline should not be used to treat or prevent preterm labor.
- Dose-related maternal and fetal tachycardia and changes in maternal blood pressure can occur in patients receiving terbutaline. Adverse effects reflect stimulation of the beta receptors.
- Magnesium sulfate infusions depress the CNS and cause muscle relaxation. Magnesium sulfate is the drug of choice to treat preeclampsia and seizures in eclampsia and is used off-label to stop preterm labor. Adverse effects, particularly respiratory depression, are related to high levels of the drug in the blood. Recent research demonstrates a neuroprotective effect of magnesium sulfate for the fetus.
- Drugs that alter uterine motility are potentially dangerous to the woman and fetus. Infusions of these drugs should be regulated with IV controllers or pumps. These patients need close monitoring for signs of adverse effects throughout therapy.

QUESTIONS FOR STUDY AND REVIEW

1. Why should you titrate oxytocin slowly upward, with dosage adjustments every 40 to 60 minutes?
2. Define the three phases of oxytocin response.
3. Which adverse effect of oxytocin is most dangerous to the pregnant woman?
4. What nursing assessments should be made to minimize adverse effects from oxytocin?
5. How does terbutaline stop preterm labor?
6. If the patient develops tachycardia, palpitations, and nervousness while on terbutaline infusion, what action should you take?
7. List the reasons that magnesium sulfate may be prescribed during pregnancy.
8. State the antidote to magnesium sulfate overdosage.
9. What are the most common maternal, fetal, and neonatal adverse effects from infusion of magnesium sulfate?

UNIT 12

Immune System and Cancer Chemotherapy Drugs

54

Drugs Affecting the Immune Response

Learning Objectives

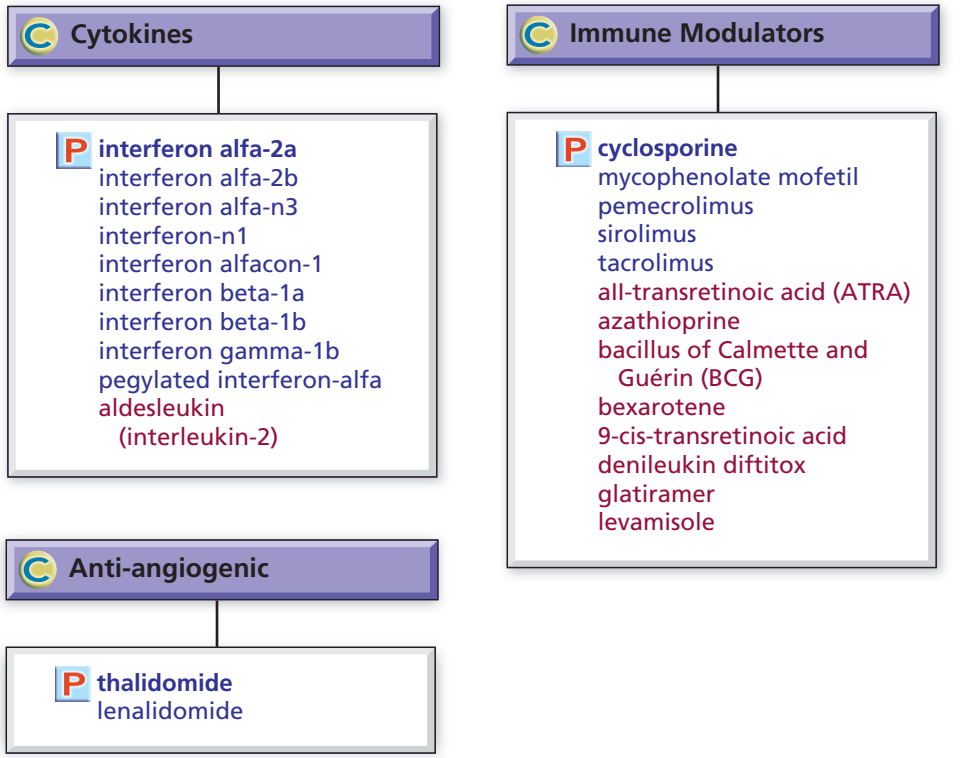
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect the biologic responses.
2. Relate the interaction of core drug knowledge to core patient variables for drugs that affect biologic responses.
3. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect biologic responses.
4. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect the immunologic system.
5. Determine key points for patient and family education for drugs that affect the immune system.

Key Terms

angiogenesis, anti-angiogenesis
autoimmune disease
biologic modulator
cellular immune response
chemotaxis
complement
cytokines
interleukins
immune modulators
immunotoxins
lymphokines
retinoids
rexanoids
vascular endothelial growth factor (VEGF)

Drugs Affecting the Immune Response



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Biologic modulators, or biologic modifiers, are a group of biopharmaceuticals that are naturally occurring proteins used to alter the body's immunologic responses (Polovich, Whiteford, and Olsen, 2009). The use of biologic modulators is also called biologic therapy. The rapid growth of these therapies has been attributed to two major biologic advances. In the 1970s, refinement of recombinant DNA technology enabled researchers to produce large quantities of active biologic molecules outside the body and then administer them systemically. More recently, advancements in defining tumor-specific molecular targets have enhanced development of targeted cytotoxic agents (Beijnen & Schellens, 2010). Agents are classified by their specific biologic mechanism of activity and by whether they stimulate or suppress immune processes. Some stimulate specific immunologic activity to combat unique antigens (substances that induce formation of antibodies). Moreover, some agents may at once stimulate some parts of the immune system and depress other parts of the immune system.

This chapter discusses three classifications of agents used to alter biologic responses: cytokines, immune modulators, and anti-angiogenic agents. Active and passive antibody-conferred vaccinations are addressed in Appendix E rather than in this chapter (appendices are located online at thePoint).

Cytokines are immunologic toxins produced by white blood cells (WBCs, also called leukocytes) in response to foreign antigens such as microorganisms, transplanted tissue, or malignant cells. The prototype cytokine is interferon alfa-2a (Roferon-A).

The **immune modulators** are a group of several agents with distinctly different structures that alter T-cell or B-cell activity. The prototype is cyclosporine (Sandimmune, Neoral, SangCya). As this area of pharmacology develops and broadens in scope, more specific types of agents are appearing. For the purposes of this text, polypeptide antibiotics also known as calcineurins used as immunosuppressives, immunoconjugates, retinoid-like agents, bacillus calmette Guerin (BCG), and miscellaneous immune modulators such as levamisole are grouped together; however, it is conceivable that in the future, they will be separated into discrete groups. Research is now being conducted to determine whether other essential cell proteins, nutrients, and growth factors (e.g., dendritic cells, enzyme or proteosome inhibitors) can be manipulated to provide a clinical benefit (Buchsel & DeMeyer, 2006; Wu & Lanier, 2003; Cho & Bhardwaj, 2003; Luo & Prestwich, 2002; Polovich et al., 2009). **Anti-angiogenesis** drugs are a new form of biologic therapy that block blood vessel development. Recent knowledge of the molecular process of carcinogenesis has led to recognition of the importance of vascularity to the growth and metastasis of some tumors (Cook & Figg, 2010). Anti-angiogenetic agents target VEGF and other secondary angiogenesis mechanisms. Small molecules that inhibit angiogenesis via tyrosine kinase pathways such as sunitinib, sorafenib, and the monoclonal antibody bevacizumab are included in Chapter 55. The most representative example of a general anti-angiogenic biologic agent is thalidomide Another agent similar to thalidomide is lenalidomide. Pamalidomide is another agent in this class that is still underinvestigation (Lacy, & Rajkumar, 2010).

The body of knowledge about the components and actions of the immune system is developing daily. As researchers make new discoveries and better understand biologic interactions, they will find more ways to modify immune systems and treat a variety of viral, autoimmune, hematologic, and neoplastic disorders.

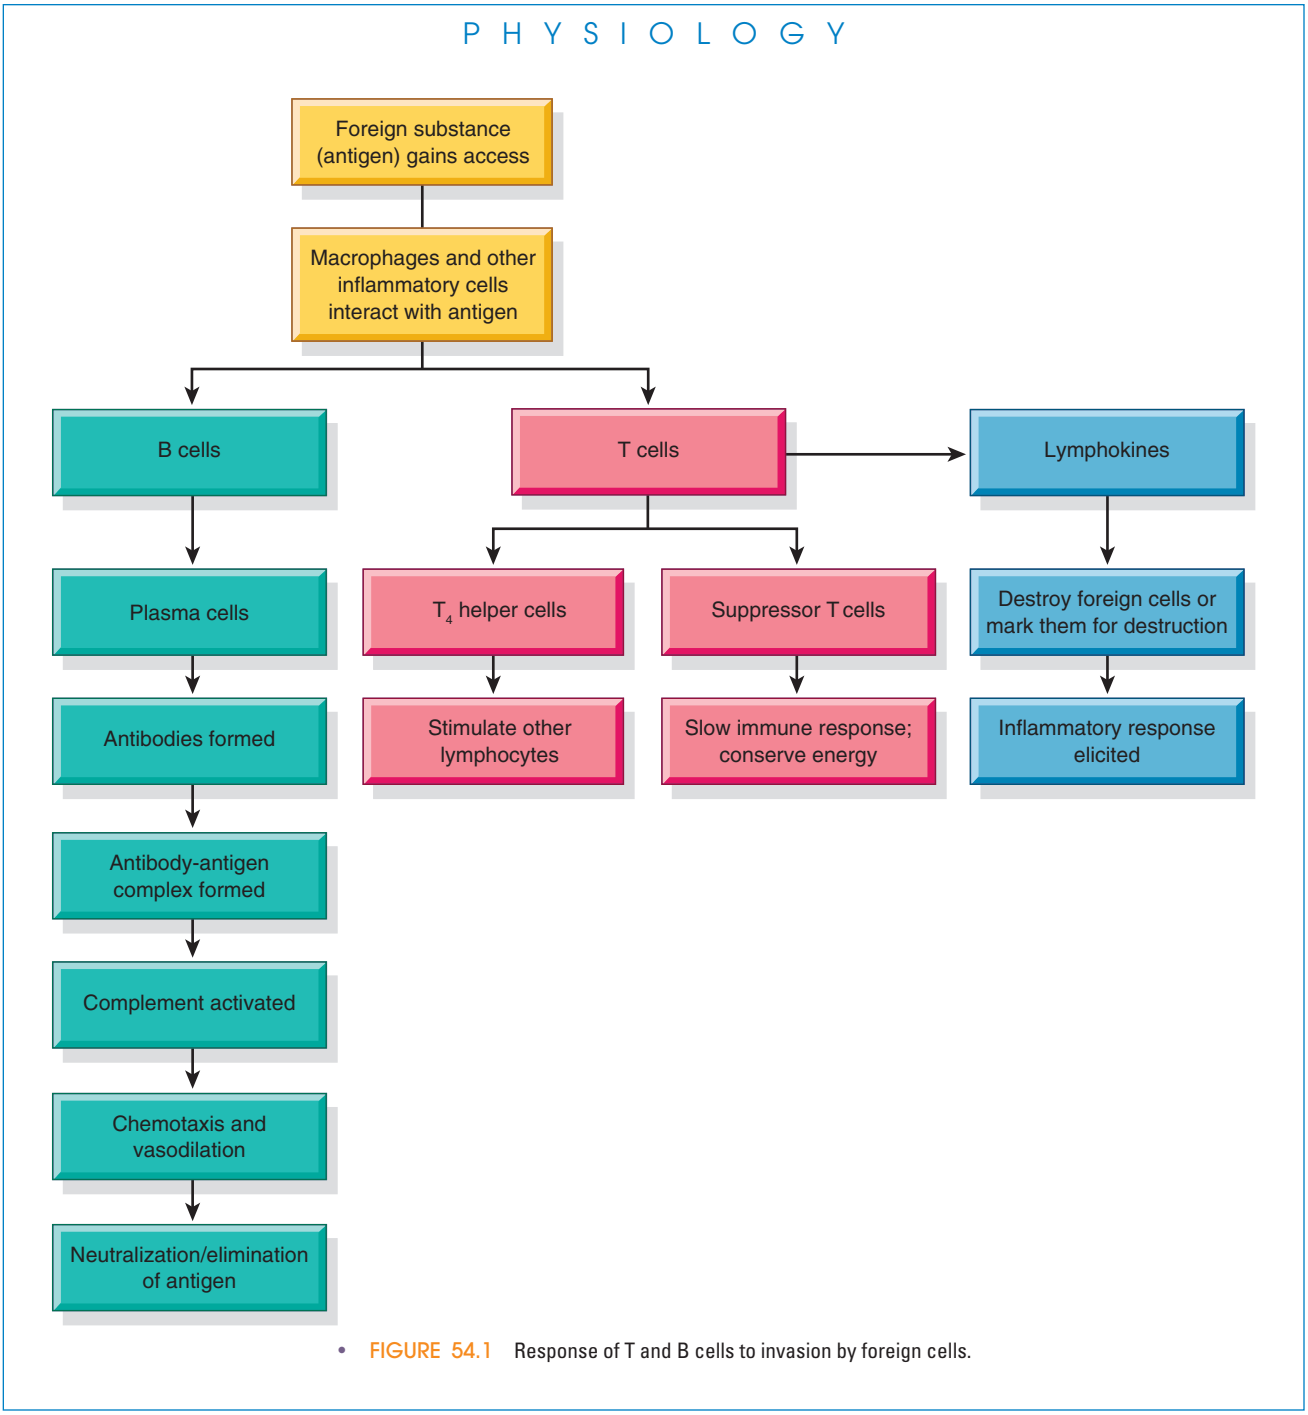
PHYSIOLOGY

The immune system is composed of hematopoietic cells and multiple hematologic-immunologic production and storage sites. Hematopoietic physiology and pharmacologic agents are described in greater detail in Chapter 33. The reticuloendothelial system includes immunologically active tissue and cells found in the lymph system, spleen, liver, lungs, gastrointestinal (GI) tract, and brain. An integrated immune response involving hematopoietic cells and immune tissues provides the body's nonspecific and specific response to invasion by antigens identified as nonself. The essential components of the immune system are hematopoietic cells, barrier defenses, the nonspecific immune response, the specific immune response, and immunity. Leukocytes (or WBCs) are key components of all immune system responses. (See Chapter 33 for an overview of hematopoiesis and a discussion of leukocytes' primary actions relating to combating invasion by microbes and establishing an initial barrier and inflammatory response.) This chapter will focus on pharmacologic agents that affect other aspects of the immune response.

Specific Immune Responses

If an invader gets past the barrier and nonspecific immune systems and enters the tissues or bloodstream, a specific immune response involving lymphocytes is initiated (Figure 54.1). Bone marrow stem cells develop into two types of lymphocytes: T lymphocytes, or T cells, and B lymphocytes, or B cells. These T and B lymphocytes may also differentiate into specialized cells, such as natural killer cells and lymphokine-activated killer cells, which have been identified as the cells that aggressively attack and destroy neoplastic cells. Because research in the area of lymphocyte identification is relatively new, other lymphocytes not yet identified may also take part in the immune response.

T cells are "programmed" in the thymus gland to develop into at least three different cell types. Effector or cytotoxic T cells are found in various areas of the body and aggressively attack nonself cells by releasing chemicals called **lymphokines.** These chemicals either directly destroy a foreign cell or mark it for destruction by phagocytes and elicit an inflammatory response. This effect is termed the **cellular immune response.** Foreign or nonself cells have different membrane-identifying antigens called histocompatibility



• FIGURE 54.1 Response of T and B cells to invasion by foreign cells.

leukocyte antigens (HLAs). Helper T cells respond to the chemical indicators of immune activity and stimulate other lymphocytes to be more aggressive and responsive. Suppressor T cells respond to rising levels of chemicals associated with an immune response and suppress or slow the reaction. The balance between these two systems permits a rapid response that destroys invaders immediately, followed by a slowing reaction if the invasion continues. This slowing conserves energy and the components of the immune and inflammatory reaction.

B lymphocytes are found in reticuloendothelial tissue throughout the body and responsible for develop of antigen-specific antibodies to target foreign cells. The antibody response system and agents that target antigen-antibody receptors are included in the Targeted Therapies Chapter 55.

Chemical factors also play an important role in the specific immune reaction, acting as communicators within the immune system to coordinate the immune response. For example, interferons are chemicals secreted by cells that have been invaded by viruses and possibly other stimuli.

They prevent viral replication and suppress malignant cell replication and tumor growth. **Interleukins** are chemicals secreted by active WBCs to influence other WBCs. Interleukin-1 (lymphocyte-activating factor) stimulates T cells to initiate an immune response. Interleukin-2 (T-cell growth factor) is released from active T cells to stimulate the production of more T cells and to increase the activity of B cells, cytotoxic cells, and natural killer cells. Interleukin-2 also causes fever, arthralgia, myalgia, and slow-wave sleep-energy-conserving measures that help the body fight off invaders.

Several other factors released by lymphocytes and basophils have been identified. These include B-cell growth factor, macrophage-activating factor, macrophage-inhibiting factor, platelet-activating factor, eosinophil-chemotactic factor, and neutrophil-chemotactic factor. The presence or absence of these factors can influence the immune response.

The thymus gland, located in the mediastinal cavity, also releases a number of types of hormones that circulate in the body to stimulate and communicate with T cells. Thymosin, a thymus hormone, is important in the maturation of T cells and cell-mediated immunity. Research is currently under way to evaluate the use of exogenous thymosin in treating certain leukemias and melanomas.

Immunity

Immunity to a pathogen is achieved when the body has formed antibodies, which protect the body from developing an illness. Vaccines are used to stimulate an active immunity to commonly encountered antigens that could cause serious illness with first exposure. These vaccines are discussed in Appendix E. Sera are used to provide preformed antibodies, or passive immunity, in situations of acute exposure that could prove serious. In other words, giving an antibody permits an immediate immune response, whereas giving an antigen would require time to produce antibodies and a later response against illness. Several drugs discussed in this chapter are used to affect immune system recognition or reaction to nonself proteins.

PATHOPHYSIOLOGY

Pathophysiologic conditions requiring drug therapy with immune modulators are varied and are related to a dysfunction in any part of the immune response. Four abnormal conditions can weaken the immune system and stimulate the immune response: neoplasms, viral invasion, autoimmune disease, and transplant rejection (Dillman, 2011). Neoplasms result from the growth of mutant cells that escape the normal surveillance of the immune system. Viral invasion of a cell changes the cell's membrane and antigenic presentation. In autoimmune disease, the body responds to specific self-antigens by producing antibodies against self-cells (autoantibodies). Organ transplantation weakens the immune system as the body reacts to the introduction of foreign cells. Three types of biotherapy agents are used to combat immune dysfunction: cytokines, immune modulators, and anti-angiogenesis agents. Table 54.1 provides a summary of selected biotherapy agents that affect the biologic response to immune dysfunction.

CYTOKINES

Cytokines are chemical mediators released by WBCs in response to antigenic invasion of the blood or tissues. Cytokines serve to enhance and accelerate the inflammatory and specific responses that will destroy the invading antigen. Cytokines are generally proinflammatory, but many also have antiviral, antiproliferative, and antineoplastic properties. Interferons and interleukins are cytokines produced by activated lymphocytes. The prototype is interferon alfa-2a (Roferon-A). Drugs in the same class as interferon alfa-2a include interferon alfa-2b, interferon alfa-n3, interferon-n1, interferon alfacon-1, interferon beta-1a, and interferon beta-1b. Interferon alpha is also available in a pegylated form (Pegasys, Peg-Intron). A drug that is significantly different from interferon alfa-2a is aldesleukin (also known as IL-2). One must recognize that these cytokines have considerable differences from the prototype in both actions and adverse effects.

The interferons available for pharmacologic use are produced by recombinant DNA technology from harvested human or animal WBCs. As stated, the prototype is interferon alfa-2a, produced by recombinant DNA technology using *Escherichia coli* bacteria.

Core Drug Knowledge

Pharmacotherapeutics

Interferon alfa-2a is licensed to treat hairy cell leukemia in selected patients 18 years and older, AIDS-related Kaposi sarcoma in selected patients 18 years and older, chronic myelogenous leukemia in chronic-phase Philadelphia chromosome–positive patients, chronic hepatitis, and metastatic renal cell carcinoma, and it is used as adjuvant therapy after resection of high-risk malignant melanoma or in patients with metastatic malignant melanoma. Substantial antineoplastic activity has been noted when this agent has been used to treat superficial bladder cancer, carcinoid tumors, cutaneous T-cell lymphoma, and low-grade non-Hodgkin's lymphoma (see Table 54.1). It has also been widely used to treat select viral diseases such as hepatitis C, condylomata acuminata, cutaneous warts, and cytomegalovirus. It is normally given by subcutaneous (SC) or intramuscular (IM) administration, although intravenous (IV) administration is preferred in some regimens.

Pharmacokinetics

Interferon alfa-2a must be given by injection. If given intramuscularly, it is absorbed rapidly with peak effects in 3.8 hours; if given subcutaneously, absorption is slower, with peak effects in 7.3 hours. IV infusion may be intermittent or continuous. The drug is metabolized in the liver and kidneys

TABLE 54.1 Summary of Selected Biotherapy Agents

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Cytokines			
P interferon alfa-2a (Roferon-A)	Hairy cell leukemia in patients >18 years, AIDS-related Kaposi sarcoma (KS), chronic myelogenous leukemia (CML)	Hairy cell leukemia: *Adult:* IM/SC, 3 million IU/d for 16–24 wk, then 3 million IU 3×/wk AIDS-related KS: IM/SC, 36 million IU/d for 10–12 wk, then 36 million IU 3×/wk CML: IM/SC, 1 million IU/d Chronic hepatitis C: 3–9 million units IM or SC 3×/wk for 3–12 mo *Child for any disorder:* safety and efficacy not established	*Onset:* IM, rapid; PO, slow *Duration:* Unknown $t_{1/2}$: 3.7–8.5 h
interferon alfa-2b (Intron A)	Hairy cell leukemia, intra-lesional treatment of condylomata acuminata, AIDS-related KS, malignant melanoma (adjuvant therapy with interleukin-2, or alone for localized disease), chronic hepatitis (non A/ non B/C)	Hairy cell leukemia: IM/SC, 2 million units/m^2 3×/wk Condylomata acuminata: intralesionally, 1 million IU/lesion 3×/wk AIDS-related KS: IM/SC, 30 million IU/m^2 3×/wk Malignant melanoma: IV, 20 million IU/m^2 for 4 wk, maintenance 10 million IU/m^2 3×/wk for 48 wk Chronic hepatitis: IM/SC, 3 million IU/m^2 3×/wk Pegylated interferon used for treatment of hepatitis is usually administered as a weekly IM injection of 180 mcg. *Child, for any disorder:* Safety and efficacy not established	*Onset:* IM/SC/IV, rapid *Duration:* IM/SC, 3–12 h; IV, end of infusion $t_{1/2}$: 2–3 h
interferon beta-1b (Betaseron)	Decrease exacerbations in relapsing or remitting multiple sclerosis (MS)	*Adult:* SC, 0.25 mg qod, discontinue if disease is unremitting longer than 6 mo *Child, for any disorder:* Safety and efficacy not established	*Onset:* Slow *Duration:* Hours $t_{1/2}$: 8 min–4.3 h
IL-2	Metastatic renal cell carcinoma or malignant melanoma; adjuvant therapy with IFN alfa-2a for high risk of recurrence of malignant melanoma	Metastatic renal cell and malignant melanoma: *Adult:* IV, short infusion, 600,000 IU/kg every 8 h for a total of 14 doses, separated into two 5-d cycles with 9-d rest between *Child:* Safety and efficacy not established	*Onset:* 5 min *Duration:* 180–240 min $t_{1/2}$: 85 min
C Immune Modulators			
P cyclosporine (Sandimmune IV and oral Neoral oral)	Prophylaxis of organ rejection in kidney, liver, heart, and bone marrow transplantation; solid organ transplantation regimen is concomitant with that of corticosteroids	*Adult and child:* PO, 15 mg/kg/d initially within 4–12 wk of transplantation, continued for 1–2 wk, then tapered by 5%/wk to maintenance level of 5–10 mg/kg/d; IV, 1/3 of PO dose, given 4–12 h before transplantation and infused over 2–6 h; switch to PO form as soon as possible	*Onset:* PO, varies; IV, rapid *Duration:* 24–36 h $t_{1/2}$: 17.9 h
all-transretinoic acid (ATRA, Tretinoin, Vesanoid)	Induction therapy for acute promyelocytic leukemia; topical therapy for acne vulgaris, used investigationally for other skin disorders	Promyelocytic leukemia: *Adult:* PO, 45–60 mg/m^2/d in evenly divided doses bid, to be continued for 30–90 d until complete remission is achieved Acne vulgaris: Topical cream (0.1%, 0.05%, 0.025%), gel (0.025%, 0.01%), or liquid (0.05%), applied once daily at bedtime to areas of skin where acneiform lesions appear	*Onset:* 1–2 h *Duration:* Approximately 2–3 wk $t_{1/2}$: 0.5–2 h
levamisole (Ergamisol)	Adjunct to fluorouracil for adjuvant postoperative treatment in surgically resected colorectal carcinoma, or with metastatic disease	*Adult:* PO, 50 mg q8 h for 3 d in conjunction with fluorouracil 450 mg/m^2/d for 5 d starting 7–30 d after surgery, or when presenting for treatment; maintenance dose is the same, but given every 2 wk during 1×/wk FU therapy	*Onset:* Varies *Duration:* Unknown $t_{1/2}$: 3–4 h
azathioprine (Imuran)	Adjunct therapy with corticosteroids or cyclosporine for prevention of allograft rejection in renal, heart, and lung transplantation	Transplantation: *Adult and child:* PO/IV, 3–5 mg/kg as a single dose on the day of organ transplantation; PO maintenance, 1–2 mg/kg/d Rheumatoid arthritis: *Adult:* PO, 1 mg/kg/d as a single or double dose; may be increased to 2.5 mg/kg/d	*Onset:* PO, varies; IV, immediate *Duration:* 6–8 h $t_{1/2}$: 5 h
C Anti-angiogenic Agents			
P thalidomide (Thalomid)	Used with dexamethasone for primary or secondary multiple myeloma; or used with bortezimid or prednisone or melphalan and prednisone for multiple myeloma	*Adult:* PO, 200 mg daily with other identified antineoplastic agents on days 1–4, 9–12, and 7–20 every 28 d. Most patients receive four of these 28 d cycles.	*Onset:* Unknown *Duration:* Unknown *$t_{1/2}$: 5–7 h*
	Treatment of erythema nodosum leprosy	*Adult:* PO, 100–300 mg/d	

with a half-life of 3.7 hours to 8.5 hours. Direct lesional injection or instillation (as in the bladder) is indicated for some disorders. Interferon alfa-2a crosses the placenta and may be secreted in breast milk. It is excreted in the urine.

Pharmacodynamics

Interferon alfa-2a inhibits the growth of tumor cells, prevents these cells from multiplying, and modulates the host immune response to help protect the body from tumor cells. It blocks specific viral infection by preventing viral replication in the body.

Contraindications and Precautions

Caution should be used when administering interferon alfa-2a to patients with pancreatitis, hepatic or renal disease, depressed bone marrow function, cardiac disease or a history of cardiac disease, or compromised central nervous system (CNS) function.

In addition, interferon alfa-2a is a pregnancy category C drug, so its use during pregnancy may be risky to the fetus. It should also be avoided during lactation and in patients with known allergies to interferon or its components.

Adverse Effects

The most common adverse effects of interferon alfa-2a are dizziness, confusion, lethargy, flu-like symptoms, anorexia, nausea, and changes in taste. Depression, anxiety, and suicidal ideation have been reported in a substantial number of cases. Disease processes that exacerbate these symptoms warrant careful monitoring. Hypothyroidism may occur in up to 10% of the patients treated with interferon alfa-2a. Long-term therapy increases the risk of this complication. Other adverse effects include hypotension or hypertension, edema, arrhythmias, depression of bone marrow function, increased liver enzymes, rash, dry skin, partial alopecia, and glucose intolerance.

Drug Interactions

An increased risk of theophylline toxicity occurs when theophylline is administered concomitantly with interferon alfa-2a. This effect is caused by a decrease in theophylline clearance through the liver. Monitor patients to evaluate theophylline levels and adjust their theophylline dosages appropriately. Interferon alfa-2a can also cause increased effects and toxicity when combined with other neurotoxic, hematotoxic, and cardiotoxic drugs. Neurologic and hematologic toxicity has been particularly problematic for patients with HIV who receive concomitant antiretroviral therapy. Renal toxicity is more likely if interferon alfa-2a is given with IL-2 than if either is given alone. Anyone receiving drugs with overlapping toxicities must be carefully monitored. Table 54.2 lists drugs that interact with interferon alfa-2a.

Assessment of Relevant Core Patient Variables

Health Status

Before administering interferon alfa-2a, review the patient's record to see whether the drug is contraindicated. Cardiovascular, pulmonary, and neurologic disorders may escalate the adverse effects of this agent. Patients with depression are at particular risk of suicidal ideation and should be screened prior to initiation of therapy. Glucose intolerance is a common effect of interferon alfa therapies, and patients with diabetes mellitus are at particular risk of hyperglycemic crises. Assess and monitor patients with borderline thyroid function carefully for potential hypothyroidism. Perform a complete physical examination to establish a baseline for monitoring therapy. Next, record the patient's weight, temperature, skin condition, orientation, reflexes, pulse, and blood pressure. Because bone marrow depression and liver damage can be very serious, obtain a complete blood count (CBC) and hepatic profile at least monthly during therapy (Rieger & Khari, 2001).

Life Span and Gender

Determine whether the patient is pregnant or lactating, because interferon alfa-2a is a pregnancy category C drug, and the drug enters breast milk. Assess the age of the patient because the drug is not approved for patients who are younger than 18 years.

Lifestyle, Diet, and Habits

Assess whether the patient consumes alcohol or other nonprescribed mood-altering drugs that might increase the neurotoxicities of this agent.

Environment

Be aware of the environment in which the drug will be administered. Interferon alfa-2a may be given at home or in a clinic. If it is given at home, the patient needs a refrigerator so that the reconstituted drug can be stored. Explore with the patient any factors in the home setting that may affect adherence to drug therapy.

TABLE 54.2 Agents That Interact with P Interferon Alfa-2a

Interactants	Effect and Significance	Nursing Management
theophylline/aminophylline	Decreased theophylline clearance in patients with hepatitis. This may raise theophylline levels.	Monitor theophylline levels. If they increase significantly, dosage adjustments may be required.
cimetidine	May amplify the effects of interferon when used in treating melanoma; significance unknown	Monitor effects of interferon.
vinblastine	Enhances interferon toxicity in some patients	Monitor for adverse effects of interferon.

Nursing Diagnoses and Outcomes

- Risk for Infection related to possible suppression of bone marrow function, injections
  Desired outcome: *The patient will be protected from exposure to infection and will remain infection free.*
- Altered Nutrition: Less than Body Requirements, related to GI effects and flu-like symptoms
  Desired outcome: *The patient will maintain nutritional status.*
- Risk for Injury related to CNS changes from drug therapy
  Desired outcome: *The patient will not sustain injury while on drug therapy.*
- Potential for Maladaptive Coping related to fatigue, mental status changes from medication
  Desired outcome: *Patient shows effective coping strategies and acceptance of therapy independently or with the assistance of mental health professionals.*
- Activity Intolerance attributed to treatment-related fatigue, flu-like syndrome
  Desired outcome: *Activity intolerance is mediated, and no therapy break is required.*

Planning and Intervention

Maximizing Therapeutic Effects

Following the manufacturer's guidelines for reconstitution and storage increases the therapeutic effectiveness of the drug. Obtaining baseline blood counts and chemistries before therapy and at least monthly during therapy helps direct therapy and ensures accurate dosage and treatment guidelines. Other nonpharmacologic strategies, such as adequate sleep and proper nutrition, may assist patients in coping with therapy and enhance their immunologic function.

Minimizing Adverse Effects

Most clinical experts recommend premedicating patients with drugs such as acetaminophen or diphenhydramine to reduce the flu-like adverse effects and administering interferon injections in the late evening to allow patients to sleep through most of the adverse effects. Encourage the patient to rest if he or she is experiencing fatigue with drug therapy. Observe how the patient and family members use sterile technique, perform the injection, and rotate injection sites. Advise the patient to avoid crowds and people with known infections and to wash and treat injuries immediately to prevent infection. Warn the patient that interferon alfa-2a can cause confusion and dizziness, making falls and injury a risk. Consequently, stress the need for adequate lighting, bedside rails, assistance with walking, and avoidance of dangerous activities and driving. Severe GI effects may warrant a nutritional consultation, and small, frequent meals or nutritional supplements may be prescribed. Unusual, but potentially life-threatening autoimmune disorders, infectious disease, ischemic organ failure, and neuropsychiatric conditions may occur and should become part of routine assessment of patients receiving treatment.

Providing Patient and Family Education

- Explain that interferon alfa-2a inhibits the growth of tumor cells.
- Teach patients or family members how to reconstitute the powder into a solution and to date and refrigerate the reconstituted solution.
- For maximum therapeutic effects, advise patients to use reconstituted solution within 30 days and to mark drug days on the calendar so that the drug is taken when prescribed.
- Teach patients and families to administer the drug, use sterile technique, and rotate injection sites. Review injection technique periodically to ensure effectiveness and decrease adverse effects.
- Advise any women of childbearing age to whom this drug is prescribed to use barrier contraception to avoid pregnancy.
- If patients have pre-existing infectious or autoimmune diseases, they may be exacerbated and life-threatening in the context of interferon therapy. Advise patients to report these symptoms immediately.
- Because hypotension can occur for several days after drug administration, advise patients to slowly move from a sitting to standing position and to avoid operating machinery or driving while adjusting to the therapy's adverse effects.
- Tell patients of the Black Box warning of potential neuropsychiatric effects, and advise them to contact their health care provider if they experience severe emotional distress, extreme sadness, or depression, or if they or family perceive that they are confused.
- Teach patients to avoid infection and injury, maintain good nutrition, get regular blood tests and medical follow-up care, and watch for adverse effects.
- Emphasize the importance of calling the prescriber if fever, chills, sore throat, unusual bleeding or bruising, chest pain, palpitations, or changes in mental status occur.

Ongoing Assessment and Evaluation

Monitor the patient's CBC and white cell differential and liver and renal function before interferon alfa-2a therapy and at least monthly during therapy to gauge the drug's effectiveness and to check for adverse effects.

Drugs Closely Related to P Interferon Alfa-2a

Drugs in the same class as interferon alfa-2a are interferon alfa-2b (Intron-A), interferon alfa-n3 (Alferon N), interferon-n1 (Wellferon), interferon alfacon-1 (Infergen), interferon beta-1a (Avonex), interferon beta-1b (Betaseron), and interferon gamma-1b (Actimmune). These agents differ from the prototype in terms of their specific cellular actions and therefore indications but are similar in molecular structure, mechanism of action, and adverse effects. Pegylated interferon-alfa is also available (Pegasys, Peg-Intron). With its longer half-life of approximately 72 hours, only one injection per week

MEMORY CHIP

P Interferon Alfa-2a

- Inhibits growth of tumor cells, prevents their multiplication, and heightens the host immune response to help protect the body from tumor cells. Blocks specifically viral infection by preventing viral replication
- Used to treat some types of leukemia, AIDS-related Kaposi sarcoma, and various cancers
- Most common adverse effects: dizziness, confusion, lethargy, flu-like symptoms, anorexia, nausea, and altered taste
- Most serious adverse effects: depression and suicidal ideation
- **Life span alert: Generally, avoid during pregnancy and breast-feeding.**
- Maximizing therapeutic effects: Reconstitute and store following manufacturers' instructions.
- Minimizing adverse effects: Premedicate patient with other drugs to reduce the flu-like adverse effects.
- Most important patient education: Teach patients about the importance of avoiding infection.
- **Black box warning: Interferon-alfa-2a has been associated with serious or fatal neuropsychiatric, autoimmune, ischemia and infectious disorders. Patients must be closely monitored and withdrawal of medication is indicated with persistently severe or worsening signs and symptoms. Symptom resolution will occur in many, but not all cases of toxicity.**

is necessary, rather than three. The pegylated form has a limited adverse-effect profile; however, myelosuppression and thrombocytopenia have been reported more frequently in patients receiving the pegylated form than the prototype interferon. Enveloping interferon in a liposomal molecule prolongs its clinical effects and slows its clearance.

Drug Significantly Different From P Interferon Alfa-2a

Interleukins are cytokines produced by T cells to communicate between WBCs. Aldesleukin (Proleukin) is approved for treating metastatic renal cell carcinoma and metastatic malignant melanoma, although many additional indications are emerging. The agent's immunostimulatory effects have been useful to stabilize helper T-cell counts in HIV disease and for bone marrow engraftment protection after bone marrow transplantation, and its antiviral effects have been promising in treating hepatitis.

Aldesleukin has been administered subcutaneously, intravenously, and intralesionally. It is paradoxically more potent when given by continuous infusion than by bolus injections, and the adverse effect profile is widely variable because of dose ranges from 20,000 IU daily after bone marrow transplantation to 72,000,000 IU daily for treating metastatic renal cell carcinoma or melanoma. The drug may be contraindicated in lactating patients or those with known allergies to aldesleukin. A Black Box warning cautions against its use in patients with abnormal thallium stress tests or abnormal pulmonary function tests and in those with organ homografts. In the Black Box warning is a statement that mild lethargy during administration can rapidly progress to coma, even after discontinuation of the agent. Coadministration of radiographic iodinated IV contrast material has been associated with atypical hypersensitivity reactions. The drug should be used cautiously in patients with renal, liver, or CNS impairment.

Aldesleukin has an adverse effect profile very similar to that of high-dose interferon, but effects are potentially more acute in onset and severe in intensity. Even severe adverse effects resolve when the agent is discontinued, although hepatic, endocrine, and neurologic effects can persist for months after the conclusion of therapy. Concomitant administration of corticosteroids is not recommended, based on preclinical data suggesting that steroids may nullify the immunostimulatory effects of this agent (Cuaron & Thompson, 2001).

C IMMUNE MODULATORS

Immune modulators appear to act directly on the function of T cells and B cells, stimulating or suppressing the immune response. Lymphocytic modulators are divided into subcategories according to their primary chemical structure and pharmacologic properties. Immune modulators may suppress or stimulate immune function. Some of these agents stimulate certain functions of the cell response and suppress others.

In this text, the prototype immune modulator is the immune suppressant cyclosporine (Sandimmune, Neoral). Cyclosporine is in the subclass of polypeptide antibiotics, although they are currently known as calcineurin inhibitors. This classification recognizes the precise mechanism of action that is inhibition of calcineurin, an essential nuclear substance responsible for T-lymphocytic activity (van Rossum et al., 2010). Drugs that are also immune modulators and calcineurin inhibitors and are represented by the prototype include tacrolimus, sirolimus, pimecrolimus, and mycophenolate mofetil. Drugs that are also immune modulators but are significantly different from cyclosporine are the retinoids (all-transretinoic acid [ATRA], 9-cis-transretinoic acid, acitretin, alitretinoin, bexarotene, and isotretinoin); levamisole; azathioprine; glatiramer; BCG; and denileukin diftitox. These drugs have a variety of immunologic actions and targets, making many of them more a group of miscellaneous agents rather than members of the same category.

The calcineurin inhibitors are a group of agents that were developed as antibiotics but were determined to be too toxic to hematopoietic cells for that use. What has evolved is a group of agents that destroy cells in the G_0 or G_1 phase of cell cycling, a long phase that is common for all lymphocytes. This is achieved by blocking nucleic mechanisms of T cell receptor activation and calcineurin activity that normally upregulates IL-2. The first drug of this class to be licensed for use was cyclosporine. Immune modulators that act as immune suppressants block the normal effects of the immune system in the body. This action is beneficial in organ transplantation, in which the body destroys foreign tissue, and in autoimmune diseases, in which the body destroys its own cells.

Nursing Management of the Patient Receiving P Cyclosporine

Core Drug Knowledge

Pharmacotherapeutics

Cyclosporine is used as an adjunct treatment to prevent rejection in solid organ transplantation and to prevent graft-versus-host disease in allogeneic bone marrow or stem cell transplants. Adjunct therapy with corticosteroids is recommended. Cyclosporine is also used as second line treatment of rheumatoid arthritis and various other blistering disorders or connective tissue diseases (Amor, Ryan, & Mentor, 2010). The two brands of the drug are different, and dosage adjustment may be required for patients who switch. Other labeled uses (for the Neoral form only) include severe rheumatoid arthritis and extensive, refractory psoriasis. Topical cyclosporine is commonly used for treatment of severe eczema, erythematosis nodosum, and atopic dermatitis (Gallini et al., 2011). Opthmalmic solution of cyclosporine (Restasis) is used for chronic dry eyes. Unlabeled uses include treating alopecia areata, biliary cirrhosis, Crohn's disease, ulcerative colitis, dermatomyositis, Graves disease, lupus nephritis, multiple sclerosis, myasthenia gravis, nephrotic syndrome, pemphigus, polymyositis, and pulmonary sarcoidosis. It is used with corticosteroids to prevent rejection in kidney, liver, and heart transplantation and to treat chronic rejection in patients previously taking other immunosuppressants. The drug is being studied for use in pancreas, liver, kidney, bone marrow, and heart and lung transplantation. Sandimmune formulations are available as soft gelatin capsules, an oral solution, and as an IV solution. The IV form should be administered at one third of the oral dose. Neoral formulations are available as soft gelatin capsules and as an oral solution.

Pharmacokinetics

The absorption of cyclosporine from the GI tract is incomplete and variable; the lipid formulation has improved absorption characteristics. The absolute bioavailability of oral cyclosporine varies widely among patients. Factors that affect bioavailability include food, enterohepatic recirculation, and the type of assay used to measure levels. Ingesting conventional cyclosporine (Neoral) with food high in fat may increase bioavailability. Sandimmune and Neoral are not bioequivalent and cannot be exchanged one for another without dose adjustments. Sandimmune capsules and oral solution have decreased bioavailability compared with Neoral. Cyclosporine is extensively metabolized by the cytochrome P-450 enzyme system in the liver, and to a lesser degree in the GI tract and the kidneys. Many metabolites have been identified in the bile, feces, blood, and urine. Fortunately, these metabolites contribute little to drug toxicity. Excretion is primarily biliary, with less than 6% excreted in the urine. Neither dialysis nor renal failure substantially alters cyclosporine clearance. Children often need a larger oral dose, probably because of the limited absorptive area of their intestines. Patients with malabsorption may have difficulty achieving therapeutic levels with oral use. The IV dose is not significantly related to age, body surface area, or bowel length.

Pharmacodynamics

Cyclosporine is a potent immunosuppressant that is produced as a metabolite by the fungus *Beauveria nivea*. It suppresses some humoral immunity, but to a greater extent, it suppresses cell-mediated immune reactions. The exact mechanism of action is not known, but experimental evidence suggests that cyclosporine acts by specific, reversible inhibition of immunocompetent T lymphocytes that target their cytotoxic effects to lymphocytes in the G_0 and G_1 phases of the cell cycle. The helper T cell is the main target, but the suppressor T cell may also be suppressed. It also inhibits lymphokine production and release, including IL-2 or T-cell growth factor. Cyclosporine does not suppress bone marrow function.

Contraindications and Precautions

Cyclosporine that is injected (Sandimmune) is contraindicated in patients with hypersensitivity to polyoxyethylated castor oil. Oral cyclosporine (Neoral) should not be used concomitantly with psoralen UV A range or UV B light therapy in patients with psoriasis. It is assigned to pregnancy category C and is used during pregnancy only if the potential benefit justifies the possible risk to the fetus. It readily crosses the placenta and is secreted in breast milk.

Adverse Effects

Cyclosporine is associated with a substantial risk of nephrotoxicity. A form of chronic, progressive cyclosporine-associated nephrotoxicity is characterized by deterioration in renal function and morphologic changes in the kidney, which may persist even if the drug is discontinued. Additional manifestations of drug-related renal dysfunction include: hyperkalemia, hypercalciuria, or hypomagnesemia. Oversuppression of the immune system can increase susceptibility to infection, and in the Black Box warning; it is recommended that the drug be administered only under the direction of a prescriber with specialized knowledge of immunosuppressive therapy. Hepatotoxicity is also possible. Liver and renal function tests should be monitored closely. If a severe reaction occurs, dosage should be decreased, or the drug should be discontinued.

The most common adverse effects of cyclosporine are renal dysfunction, tremor, hirsutism, hypertension, and gum hyperplasia. The risk of malignancy in recipients of cyclosporine is higher than in the healthy population but similar to that of patients receiving immunosuppressive therapies. Lymphoproliferative and skin malignancies are most commonly reported. Other, less common adverse effects primarily involve the CNS and include confusion, lethargy, headache, ataxia, blurred vision, depression, encephalopathy, and convulsions. Studies have associated these symptoms with low cholesterol, low magnesium, aluminum overload, high-dose methylprednisolone, nephrotoxicity, and hypertension. Miscellaneous adverse effects include brittle nails, pruritus, anorexia, gastritis, hiccups, mouth

sores, swallowing difficulty, pancreatitis, constipation, hypomagnesemia, anemia, conjunctivitis, hearing loss, edema, tinnitus, thrombocytopenia, joint pain, night sweats, hyperkalemia, and hyperuricemia. An uncommon, but serious and potentially life-threatening adverse effect associated with cvclosporine and other similar drugs is posterior reversible encephalopathy syndrome (PRES) that occurs in the vertebral basilar circulatory system. The disorder is associated with hypertension, but is unclear if the hypertension precipitates the ischemic brain injury, or if it is a protective reflection of compensation by the brain for the physiologic process of injury (Kim et al., 2011; Zhang, 2010).

Drug Interactions

Concomitant use of medications that affect the hepatic microsomal enzymes (P-450 system) requires monitoring and dose adjustment of cyclosporine. Drugs that can produce nephrotoxicity have an increased risk for producing renal dysfunction when used concomitantly with cyclosporine. Administering oral cyclosporine (Neoral) within 30 minutes of consuming food, particularly a high-fat meal, may decrease levels. Patients should not take cyclosporine with grapefruit juice unless instructed to do so; trough concentrations may be increased. Table 54.3 lists drugs that interact with cyclosporine.

Assessment of Relevant Core Patient Variables

Health Status

Before administering cyclosporine, review the patient's record to see whether the drug is contraindicated. If it can be administered safely, perform a physical examination to establish a baseline for monitoring therapy. Assess the patient's skin color, temperature, and texture, and note the appearance of any lesions to monitor for allergic reactions and signs of rejection. Assess vital signs, because hypertension is the most common adverse effect associated with cyclosporine administration. The associated hypertension is believed to be vasospastic in nature; therefore, calcium channel blockers are the antihypertensive treatment of choice. Hepatic function should be reviewed because the drug is metabolized primarily by the liver. Renal function should be evaluated because nephrotoxicity is a fairly common and irreversible adverse effect of the drug. Many now advocate changing to another immunosuppressive agent as soon as possible after engraftment or symptom resolution to minimize the risk of chronic renal insufficiency or loss of graft (Chapman, 2011). A CBC and differential should be done as a baseline for potential hematologic changes that might occur during therapy. Acute tremors, seizures, mental status changes, or visual disturbances are indicative of neurologic toxicities. These toxicities usually are related to high serum blood cyclosporine levels and are an indication to discontinue the medication.

Life Span and Gender

Assess whether female patients are of childbearing age, because the drug is in pregnancy category C. Children may require higher doses of medications because of decreased drug absorption.

Lifestyle, Diet, and Habits

Determine whether the patient is frequently in crowds, where he or she could be exposed to infection. Assess whether the patient has a lifestyle that involves frequent sun exposure. Determine whether the patient eats a high-fat diet because doing so increases the bioavailability of one form of the drug (Sandimmune) but decreases the bioavailability of another form (Neoral).

TABLE 54.3 Agents That Interact with P Cyclosporine

Interactants	Effect and Significance	Nursing Management
rifampin, phenytoin, phenobarbital	Decrease plasma concentrations of cyclosporine; may decrease therapeutic effectiveness of cyclosporine	Monitor for effectiveness of cyclosporine.
azithromycin, clarithromycin, diltiazem, erythromycin, fluconazole, itraconazole, ketoconazole, nicardipine, verapamil, and grapefruit juice	Increases the concentrations of cyclosporine through altering metabolism; may increase risk of adverse effects	Monitor for adverse effects of cyclosporine.
aminoglycosides, amphotericin B acyclovir, SMZ-TMP, melphalan, ketoconazole, diclofenac, naproxen, sulindac, cimetidine, ranitidine, tacrolimus	These nephrotoxic drugs may increase cyclosporine nephrotoxicity.	Monitor for signs of nephrotoxicity; dosage adjustment may be required.
HMG-CoA reductase inhibitors (atorvastatin, cerivastatin, fluvastatin, lovastatin, simvastatin)	Increased risk of myositis, rhabdomyolysis, and acute renal failure from cyclosporine	Monitor for adverse effects carefully. The HMG-CoA reductase inhibitor may need to be stopped if serious adverse effects occur.
nifedipine	Increased risk of gingival hyperplasia.	Provide good oral hygiene to minimize risk of gingival hyperplasia.

Environment

Be aware of the environment in which cyclosporine will be given. Cyclosporine is usually started in the hospital after solid organ or bone marrow transplantation and then continued at home. Explore with the patient any factors in the home setting that might affect adherence to drug therapy. For special teaching when the drug is used at home, see Box 54.1.

Nursing Diagnoses and Outcomes

- Risk for Infection related to suppression of the immune system
  Desired outcome: *The patient will be protected from exposure to infection, and infections will be prevented or decreased.*
- Altered Perfusion related to hypertension caused by the medication
  Desired outcome: *Blood pressure will remain within normal limits or be controlled to normal limits with antihypertensive medications.*
- Altered Renal Function related to nephrotoxic and hypertensive effects of the medication
  Desired outcome: *The patient will be monitored closely for deterioration in renal function, and permanent renal damage will be prevented.*
- Altered Mental Status related to neurotoxic effects of cyclosporine (tremors, seizures, mental status changes, visual defects)
  Desired outcome: *The patient will maintain normal orientation, reasoning ability, and motor activity.*
- Deficient Knowledge related to multiple drug interactions and adverse effects
  Desired outcome: *The patient will be instructed in potential drug interactions, including both prescription and over-the-counter medications. The patient will be instructed in potential adverse effects of medications and the need for close monitoring after discharge.*

BOX 54.1 COMMUNITY BASED CONCERNS

Cyclosporine at Home

Patients who receive cyclosporine at home need to have the following points emphasized in their teaching:

- Take this drug at the same time every day and consistently in relation to meals to maximize the immunosuppressive activity of the drug.
- Do not substitute an oral preparation of one form of cyclosporine for another without making dosage adjustments. Be familiar with the form you take and check each prescription refill to make sure you have the same product.
- Measure oral solutions using the dosing syringe provided with the medication, not a household teaspoon or tablespoon. Do not rinse the syringe with water either before or after measuring a dose because any water that is accidentally mixed into the drug will cause a variation in the dose provided.
- To improve the flavor, mix the cyclosporine with orange or apple juice (preferably at room temperature). Avoid using grapefruit juice because it interacts with the P-450 system and changes drug metabolism. (Sandimmune can be mixed with milk or chocolate milk, but the combination of Neoral and milk is unpalatable.)
- Use a glass container, not plastic, to prevent possible chemical interactions.
- Stir the oral solution into the diluent and drink immediately, all at once. Do not allow the drug to sit in the diluent.
- After drinking the medication and diluent, pour more of the same type of diluent into the glass to rinse it. Drink this glass also to ensure that you have received the entire dose.
- Inform your health care provider if you are taking any of the following medications, which may interfere with cyclosporine absorption or blood levels: drugs for irregular heart rhythms, medications to prevent or treat fungal infection, antibiotics, seizure medications, medications to treat tuberculosis, agents to treat HIV infection, lipid-lowering medications, or heart disease–related platelet-blocking agents.

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that cyclosporine therapy is started soon after transplantation. Medication should be administered as prescribed and according to recommendations to ensure therapeutic drug levels. Although cyclosporine can be given intravenously, the oral form should be used as soon as possible. It can be mixed with juice (other than grapefruit juice) to increase palatability but should not be refrigerated. Drug levels should be appropriately monitored to ensure adequate dosing. The metabolism of this agent is significantly variable, particularly in the oral form, and it warrants a warning in the prescriber's information suggesting the need for specialized laboratory support and drug level monitoring (Box 54.2). Cyclosporine should not be taken with foods, particularly those that are high in fat.

Minimizing Adverse Effects

Arrange for periodic blood tests to monitor for renal, hepatic, and hematologic effects of the medication. The drug should be held, and the physician should be notified, if signs of toxicity occur. Avoid mixing the drug with grapefruit juice. The patient should be protected from exposure to infection; immediate action must be taken at the first sign of infection. Assess patients for adverse CNS effects, and monitor vital signs, watching for hypertension.

Providing Patient and Family Education

- Teach patients how to take the oral form of this agent to maximize absorption and maintain stable blood levels.
- Caution patients not to discontinue taking this drug without consulting with their prescribers.
- Discuss with women of childbearing age the potential adverse effects on the fetus (most commonly, premature birth).
- Teach patients receiving cyclosporine to avoid exposure to infection by avoiding crowds and to promptly report injuries or signs of infection.
- Advise patients to avoid sun exposure to decrease the risk of skin malignancies.
- Ensure patients have blood drawn for medication levels and electrolyte panels to detect potential sub or supra

BOX 54.2 FOCUS ON RESEARCH

Blood Levels of Cyclosporine Drawn Peripherally or From a Central Access Device

Senner, A. M., Johnston, K., & McLachlan, A. J. (2005). A comparison of peripheral and centrally collected cyclosporine A blood levels in pediatric patients undergoing stem cell transplant. *Oncology Nursing Forum,* 32(1):73–77.

The Study

This prospective, comparative study of 14 pediatric patients in a university hospital in Australia was designed to compare trough serum blood levels of cyclosporine. The researchers compared 71 paired blood samples drawn from a peripheral line and from a central venous catheter.

The study found that when blood levels were drawn from a central venous catheter lumen not used for cyclosporine administration, they correlated well with peripherally drawn levels. All patients in the study were receiving intermittent infusion cyclosporine, and it is advisable to generalize these findings to a similar clinical situation.

Nursing Implications

Cyclosporine doses are based on trough blood levels. Pediatric patients have variable rates of metabolism and clearance of medications, making it exceptionally challenging to ensure reliable laboratory test results. The accuracy of these levels is essential to ensure protection from rejection with minimal toxicities. Inaccurate blood levels may lead either to underdosing of cyclosporine, which is associated with an increased risk of rejection, or overdosing of cyclosporine, which may cause hypertension, nephrotoxicity, or thromboembolic events.

therapeutic drugs levels, hyperkalemia, or hypomagnesemia that may require dose adjustment or supportive measures.

Ongoing Assessment and Evaluation

Cyclosporine is an agent with many drug interactions, issues of bioavailability, and considerable adverse effects. It is important to follow cyclosporine serum drug levels and have the dose adjusted appropriately to achieve maximal immune suppression without excess adverse effects. There is some debate whether trough, two-hour post dose or four-hour post dose levels are most accurate, so clinicians should establish institutional standards and perform levels in a consistent manner (Einollahi & Teimoori, 2011).

MEMORY CHIP

P Cyclosporine

- Immunosuppressant that inhibits T-lymphocytes by causing cytotoxicity during the G_0 and G_1 phase.
- Used as an adjunct treatment to prevent rejection in solid organ transplantation and to prevent graft-versus-host disease in allogeneic bone marrow or stem cell transplant recipients.
- Major contraindication: hypersensitivity to polyoxyethylated castor oil
- Most common adverse effects: renal dysfunction, tremor, hirsutism, hypertension, and gum hyperplasia.
- Most serious adverse effects: renal toxicity and hepatic toxicity
- **Life span alert: Children may need higher doses; therapy usually avoided during pregnancy.**
- Maximizing therapeutic effects: Start as soon after transplantation as possible.
- Minimizing adverse effects: Monitor blood work.
- Most important patient education: Teach patients about the importance of preventing infection.
- **Black box warning: This medication produces extreme immune suppression and only prescribers experienced in management of patient who have medical conditions requiring therapeutic immune suppression and in facilities which are equipped to evaluate and treat serious life-threatening infections if they should occur. Monitoring for secondary malignancies should also be incorporated into the patient's plan of care.**

Drugs Closely Related to P Cyclosporine

Tacrolimus

Tacrolimus (Prograf) is a calcineurin inhibitor more similar to cyclosporine than any other agent. It is administered both orally and intravenously, and more recently a topical form of the medication is available for serious dermatologic disorders. It causes potent T-lymphocytic destruction. The variability of absorption and clearance necessitates serum blood level monitoring with dosage adjustment. Like cyclosporine, the most common adverse reactions are nephrotoxicity, neurotoxicity, and a risk of developing diabetes. Hypertension is also common and may be dose-related. The incidence of dysrhythmias and left ventricular hypertrophy with heart failure, microangiopathic anemia, and pulmonary fibrosis are higher with tacrolimus than with cyclosporine. Tacrolimus is rarely used as initial therapy because of its potency of immunosuppression and additional myelosuppressive properties that affect granulocytes and platelets. Interactions with antiretroviral protease inhibitors and phenobarbital are common, and the assistance of pharmacists familiar with the interactions can reduce the potential for serious toxicities.

Sirolimus

Sirolimus (Rapamycin, Rapamune) is a macrolide antibiotic much like cyclosporine and tacrolimus in terms of its structure and function, but it works later in the immune activation pathway, directly blocking the effects of interleukin-2. This agent is rarely used as rejection prevention therapy for this reason but may be used to treat acute or chronic rejection. Sirolimus has less nephrotoxicity and neurotoxicity than either cyclosporine or tacrolimus, but is noted for its propensity for hepatotoxicity and arthralgias. Hyperlipidemia and hypercholesterolemia occur with this agent but not with cyclosporine or tacrolimus.

Pemecrolimus

A topical immune suppressive used for treatment of dermatologic conditions such as atopic dermatitis, eczema, or psoriasis, this agent is only known for its added risk for infection (Sehgal & Pahwa, 2007).

Mycophenolate Mofetil

Mycophenolate mofetil (CellCept), a semisynthetic ester created from a mold, is a prodrug for mycophenolic acid. It has direct and selective destruction of actively replicating lymphocytes. This selectivity means that mycophenolate is usually given in combination with at least one other immunosuppressive agent. This agent is available in only an oral form, and patients must be advised of food and drug interactions. They should take it on an empty stomach and avoid antacids within one hour of consuming the drug. Patients receiving around the clock proton pump inhibitors may have erratic absorption and inconsistent drug levels. The most common adverse effect is GI toxicity in the form of nausea, vomiting, and diarrhea. Bone marrow suppression is also common. However, unlike many other immunosuppressives, mycophenolate is not mutagenic and is not associated with secondary malignancies.

Drugs Significantly Different From P Cyclosporine

Retinoids

The **retinoids** are a group of naturally occurring compounds that are derivatives of preformed (dietary) vitamin A or provitamin A carotenoid. Preformed vitamin A is primarily found in food substances, and the provitamin A group involves precursors of retinol. Retinol has long been recognized for its importance in vision, growth, reproduction, and epithelial cell differentiation. We now know that retinoids exert most of their effects through their influence on gene expression (Rieger, 2001; Yousefi & Azizzadeh, 2010). They are essential for controlling growth and differentiation of normal cells during embryonic development. Because of their ability to influence differentiation of some cells while arresting development of others, they have become an important part of chemoprevention protocols aimed at preventing cancer in high-risk individuals (Tang & Gudas, 2011). Retinoids are known to enhance humoral and cell-mediated immune responses as well. Bexarotene is used to treat cutaneous lymphoma such as mycosis fungoides (Abbott et al., 2009). There are two major families of nuclear retinoid receptors: the RAR receptors and the RXR receptors. Because the RAR receptors must first bind with RXR receptors before activating gene expression, it is thought that agents targeting RXR receptors may have greater immunologic antitumor activity (Tang & Gudas, 2011). The agent that has been used the longest and most extensively is all-transretinoic acid (ATRA). Other similar retinoids include 9-cis-transretinoic acid (panretinide) and bexarotene. Retinoids used for severe dermatologic conditions include acitretin, alitretinoin, and isotretinoin (Gallini et al., 2011). Some are only available in topical form, but alitretinoin may also be administered systemically by the oral route. These agents capitalize upon the epidermal effects, producing skin sloughing without other systemic effects or mutagenicity. Promising **rexanoids** (synthetic retinoids) still in investigational trials include 13-cisretinoic acid, tazarotene, and TAC-101 (Tang & Gudas, 2011).

All-Transretinoic Acid

This natural retinol metabolite is licensed for treating acute progranulocytic leukemia refractory to or relapsed from anthracycline chemotherapy; some unlabeled uses include treating myelodysplasia and providing chemoprevention against cervical dysplasia and precancerous skin lesions. The pharmacokinetics of ATRA (Tretinoin, Vesanoid) are poorly defined. For its licensed use, ATRA is given intravenously as an infusion. Chemoprevention protocols use oral formulations, and some research protocols use a topical formulation (Tang & Gudas, 2011).

Like all retinoids, ATRA is teratogenic and in pregnancy category D; this classification precludes pregnancy during therapy and for an undefined period afterward. Egg or sperm banking before therapy is recommended for patients of childbearing age.

Acute hypervitaminosis A toxicity is a commonly described phenomenon with treatment doses of this agent. CNS symptoms prevail and include drowsiness, irritability, headache, and vomiting. More common are the dermatologic symptoms that include alopecia, dry desquamation, pruritus, and increased pigmentation. Constitutional symptoms are arthralgia, hepatosplenomegaly, and eye irritation. Symptoms are not usually life threatening and resolve 1 to 4 weeks after the conclusion of therapy. Other major toxicities of retinoids are hypercholesterolemia, hypothyroidism, teratogenesis, visual disturbances, and hyperleukocytosis (Abbott et al., 2009).

Hyperleukocytosis with fever, respiratory distress, pulmonary infiltrates, and fluid retention are the characteristics of a syndrome called retinoic acid syndrome, which occurs in 20% to 30% of patients receiving therapy for progranulocytic leukemia (Rogers & Yang, 2011). It so closely mimics infection and sepsis that it may be difficult to differentiate from them. High-dose steroids and leukapheresis have been used to supplement supportive care, to help resolve the symptoms without discontinuing therapy. ATRA has no known drug interactions.

9-Cis-Transretinoic Acid

Like ATRA, 9-cis-transretinoic acid (Panretinide, isomer ATRA) is a naturally occurring retinol derivative that acts on several sites. It is licensed for topical treatment of Kaposi sarcoma lesions. Administration guidelines and adverse effects are similar to those of ATRA except for the absence of retinoic acid syndrome, which is unique to ATRA. This retinoid is taken with food to enhance its bioavailability (Schmitt-Hoffmann et al., 2011).

Bexarotene

Bexarotene (Targretin gel), a naturally occurring retinol derivative, is available in both a systemic and topical form to treat cutaneous T-cell lymphoma (mycosis fungoides) (Abbott et al., 2009). This agent is also used to treat acne (Accutane).

Levamisole

Levamisole (Ergamisol) is used as an adjunctive therapy in patients being treated with fluorouracil (Adrucil) after surgical resection of colon cancer. It may also be included in

the regimen to manage early stage disease. The exact mechanism of synergy is unclear, but therapy responses are nearly doubled when the two agents are administered concomitantly (Bese et al., 2005). Levamisole restores depressed immune function, stimulating antibody formation, enhancing T-cell response, and potentiating monocyte and macrophage activity. Levamisole is readily absorbed when given orally. An interesting phenomenon has emerged in recent years since illicit cocaine has become commonly contaminated with levamisole. Patients using large amounts of contaminated cocaine develop neutropenia or thrombocytopenia thought to be related to the effects of levamisole (ref). This is termed levamicoke syndrome (Van Wieren et al., 2010).

Levamisole is assigned to pregnancy category C and should also be avoided with lactation. Common adverse effects include dizziness, headache, depression, paresthesias, changes in taste, nausea, stomatitis, diarrhea, dermatitis, alopecia, fatigue, fever, arthralgia, myalgia, and infection. Depression of bone marrow function is a potentially serious but infrequent complication.

Increased phenytoin (Dilantin) levels and phenytoin toxicity can occur if this drug is combined with levamisole. Patients on this combination should be monitored closely and have their phenytoin levels checked regularly, with changes in dosage made as appropriate. Because disulfiram (Antabuse)–like reactions can occur if levamisole is combined with alcohol, patients should be warned not to drink alcohol.

Azathioprine

Azathioprine (Imuran) is an intravenously infused antimetabolite that splits into a precursor, mercaptopurine. It is a unique antimetabolite agent because it is exclusively an immunosuppressant and not an antineoplastic. Because of its action, it is highly mutagenic and has been associated with the development of secondary malignancies, resulting in reduced use as safer and equally effective immunosuppressive regimens have been identified. It is indicated as part of a multidrug regimen to prevent rejection in renal transplantation and to treat rheumatoid arthritis not responsive to conventional management. Unlabeled uses include treating Crohn's disease and myasthenia gravis and preventing rejection after cardiac transplantation. Notable drug interactions occur with allopurinol, angiotensin-converting enzyme inhibitors, and anticoagulants. The most common and severe adverse event is infection, although GI distress may be great enough to warrant limiting the dose. Azathioprine is given cautiously with other immunosuppressants because of increased risk of infection, and dose reduction is necessary in hepatic dysfunction.

Glatiramer

Glatiramer acetate (Copaxone) is a synthetic copolymer of essential amino acids. It suppresses the specific immune processes involved in the pathogenesis of multiple sclerosis and reduces the frequency of relapses. Although the exact mechanism of action is unknown, it is thought to act by modulating T-cell autoimmune responses to myelin. The drug is given by daily SC injections and must be reconstituted and used immediately. A set of postinjection reactions—including chest pain, palpitations, anxiety, dyspnea, and urticaria—occurs in about 10% of patients with injection and is usually transient. Transient chest pain separate from the postinjection reaction has also been reported by about 20% of patients, but the symptom is self-limiting and not associated with other life-threatening symptoms. This drug may interfere with normal immune function while blocking the mechanism that causes multiple sclerosis; therefore, the patient should be protected from infection and injury. Photosensitivity is also common, necessitating use of sunscreen and protective clothing when outdoors.

Bacillus of Calmette and Guérin (BCG)

BCG in the form of ImmuCyst is a suspension of an attenuated strain of *Mycobacterium bovis* that has been used as immunoadjuvant since the 1960s. TheraCys is live BCG. This agent in either of its forms is currently licensed to treat carcinoma in situ of the urinary bladder with or without papillary tumors (Uchida, Yonou, Hayashi, et al., 2007; Babjuk et al., 2011), although its unlabeled uses also include hematologic malignancies and non-pulmonary tuberculosis (Triccas, 2010). It has been given intradermally, although it is more frequently administered intravenously or instilled into the bladder. Acting as a nonspecific immunomodulatory agent, it stimulates both nonspecific and specific immune responses, although the precise mechanism of action is not known (Shintani et al., 2007).

Denileukin Diftitox

Denileukin diftitox (Ontak) (diphtheria toxin and IL-2) is an **immunotoxin** that combines an inactivated microbe (diphtheria toxin) and a cytokine (IL-2); it is licensed for treating persistent or relapsed cutaneous T-cell lymphoma whose malignant cells express the CD25 component of the IL-2 receptor (Manoukian & Hagemeister, 2011). It is administered at either 9 mg/kg/day or 18 mg/kg/day for a 5-day course every 21 days (Lansigan, Stearns, & Foss, 2010). Denileukin diftitox is administered over at least 15 minutes while observing the patient for infusion-related reactions such as fever, chills, urticaria, or respiratory distress. Although no clear guidelines exist regarding the length of treatment, most individuals receive approximately four cycles of therapy. Two acute reactions have been reported with this agent: acute hypersensitivity and a flu-like syndrome complex (Lansigan, Stearns, & Foss, 2010). Acute hypersensitivity reactions within hours of infusion are common (67%) (Lansigan, Stearns, & Foss, 2010). These reactions may be prevented by administering acetaminophen or diphenhydramine, although many clinicians also administer nonsteroidal anti-inflammatory agents or corticosteroids to these patients. A more delayed flu-like syndrome often has the typical fever and chills, but also GI distress, myalgias, and asthenia. In addition to these hypersensitivity toxicities, vascular leak syndrome with weight gain, edema, hypoalbuminemia, and hypotension occurs in up to 27% of patients. This agent has

not been studied and established safe for administration to children or to women who are lactating or pregnant.

Nursing Management of the Patient Receiving P Thalidomide

Core Drug Knowledge

Pharmacotherapeutics

Thalidomide (Thalomid), used for many years for various purposes, has immunomodulatory, anti-inflammatory, and anti-angiogenic properties. It is believed that thalidomide's most promising features for treating malignancy lie in its "anti-angiogenesis" properties, yet its actions on autoantibodies have also made it a useful agent for treating autoimmune diseases and organ transplant rejection. Some of its immunomodulatory activities include antiproliferative and pro-apoptosis functions (Prommer, 2010). Immune suppression properties vary considerably between individuals and seem to be based on suppression of tumor necrosis factor-alpha production and macrophage function, and down-regulation of tumor cell-surface adhesion molecules responsible for leukocyte migration.

Licensed uses for thalidomide include treating cutaneous manifestations of erythema nodosum leprosum (a complication of leprosy treatment), rheumatoid arthritis, multiple myeloma, bone marrow transplantation, and chronic graft-versus-host disease refractory to standard therapy. There are several reports of its effective use for severe aphthous ulcers of the oropharynx, esophagus and stomach, myelodysplastic syndrome, follicular non-Hodgkin's lymphoma, diffuse large cell lymphoma, and refractory psoriasis (Eichholz, Merchant, & Gaya, 2010; Li, Gill, & Lentzsch, 2010).

Pharmacokinetics

Thalidomide has immunomodulatory, anti-inflammatory, and anti-angiogenic properties. Its mechanism of action is not fully understood. It is not hepatically metabolized to a large extent and appears to undergo nonenzymatic hydrolysis in plasma into multiple metabolites.

Pharmacodynamics

This is an oral agent available in 50, 100, 150, and 200 mg capsules. Bioavailability is poorly defined due to poor aqueous solubility; however, once in solution, reportedly 90% is bioavailable. The mean time to peak blood concentrations is 2.9 to 5.7 hours, indicating that thalidomide is slowly absorbed in the gastrointestinal tract. This feature makes it difficult to plan a time of administration that will not be impaired by food or antacids. Administering thalidomide with a high-fat meal does not seem to alter the onset of absorption, but does prolong the time to peak serum concentration.

Thalidomide's mean protein binding capacity is 55% to 66%, and it is found well distributed throughout the body, inclusive of excrement such as semen.The exact metabolic route for thalidomide distribution and excretion is not well understood but it is thought to be hydrolyzed without significant secondary metabolites. The mean half-life is 5 to 7 hours, and all drug is absent from the urine at the end of 48 hours. The effects of renal impairment have not been well studied, but appear to not influence excretion, so thalidomide is not dose adjusted for renal insufficiency. The same is true for hepatic impairment.

Contraindications and Precautions

The most significant contraindication for use of thalidomide is the unwillingness or inability to ensure that the individual receiving the drug will not get pregnant or impregnate another person. This agent is highly teratogenic and informed consent and signed agreement to avoid pregancny is required before prescription of the drug.

Absolute contraindications include only pregnancy, based on the fetal risk for birth defects or death. Relative contraindications considered based on a therapeutic risk-benefit ratio include the presence of pre-existing peripheral neuropathy or venous thromboembolism. These serious and common adverse effects may become life-threatening or highly morbid when combined with other pre-existing risks.

Precaution is advised before prescribing thalidomide in patient with pre-existing seizure disorders or bradycardia as these are significant medical problems of themselves, and the addition of thalidomide has been noted to increase their incidence. The prescribing information also suggests that during ongoing therapy, the medication should be withheld if the absolute neutrophil count falls below 750 mg/dL.

During therapy, close monitoring for neurologic changes and skin reactions is advised with prompt discontinuation when present. These symptoms can progress to severe and irreversible complications, which may be abrogated by immediate discontinuation of the drug.

Adverse effects

Common adverse effects include thrombotic problems, drowsiness, photosensitivity, and peripheral neuropathies (Prommer, 2010). The incidence of VTE is as high as 22.7% in patients with multiple myeloma receiving thalidomide in conjunction with dexamethasone, while the same population receiving only dexamethasone had an incidence of only 4.9% with VTE (Celgene Corporation, 2010). Skin disorders, GI distress, secretory disorders (e.g., decreased lacrimation, dry mouth), and fluid retention have also been reported with some frequency. Dose-related tremors occur in about 35% of patients (Prommer, 2010). Patients taking thalidomide are advised to immediately report neurologic symptoms because toxicity may be reversible only if the agent is promptly stopped.

Drug Interactions

High-fat meals or snacks taken with thalidomide may prolong the time to peak drug concentrations, so this medication should be taken orally with water, preferably at bedtime and at least two hours after the evening meal. Table 54.4 presents a summary of agents that interact with thalidomide.

TABLE 54.4 Agents That Interact with P Thalidomide

Interactant	Effect and Significance	Nursing Management
docetaxel	Concurrent use of docetaxel and thalidomide may result in an increased risk of venous thromboembolism	Assess for co-administration; discuss with prescriber to determine necessity if ordered; assess for thromboembolism if co-administered; use appropriate nursing interventions and seek orders for thromboembolism prophylaxis
dexamethasone acefurate	Concurrent use may result in increased risk of developing toxic epidermal necrolysis	Assess for co-administration; discuss with prescriber to determine necessity if ordered; assess for trashes and skin alterations
darbepoetin alfa	When used in patients who have myelodysplastic syndromes the likelihood of blood clots may increase	Assess closely for indication of blood clots; notify prescriber if symptoms present
midazolam	Concurrent use may result in increased midazolam metabolism and clearance	Assess for potential decreased effectiveness of midazolam
cyclosporine	Concurrent use may result in increased cyclosporine A metabolism and clearance	Assess for potential decreased effectiveness of cyclosporine

Assessment of Relevent Core Patient Variables

Health Status

Limited data are available to inform the use of thalidomide in patients with comorbid health conditions, but information suggests that no dosage adjustment is required for patients with renal or hepatic impairment.

Life Span and Gender

As a result of its early use in pregnant women and the resulting severe birth defects, it is classified as a pregnancy category X drug. It is possible that severe birth defects can occur with only one dose. In the United States, it is marketed under a special distribution program called "System for Thalidomide Education and Prescribing Safety," which means that it is a restricted drug that may be prescribed only by registered individuals. Male and female patients who are prescribed thalidomide must receive oral and written instructions about the need to use two methods of contraception; they must use the contraception for 1 month before starting thalidomide, during treatment, and for 1 month after stopping thalidomide. Periodic pregnancy testing is required while receiving thalidomide. Breast-feeding must also be avoided.

The safety of this drug in children has not been established and is therefore considered unsafe in children below the age of 18 years. No special precautions have been identified for the elderly. No gender or race-based differences in bioavailability or metabolism have been identified.

Lifestyle, Diet and Habits

Patients receiving thalidomide must be aware of the significant influence that adverse effects may have on their personal and private life. The physical effects may influence their energy level, ability to eat foods they like, and safety to independently perform activities of daily living. Drowsiness may interfere with their ability to work, operate machinery, or drive a vehicle. When taking thalidomide, the patient must time their medication to be between meals despite their sensations of nausea, and refrain from taking antacids. More personally, since thalidomide is teratogenic, patients are advised to implement stringent birth control measures that may influence their intimate relationships.

Environment

Thalidomide should be stored at room temperature and protected from light. These capsules may be administered in the hospital, clinic or home care setting. Assurance that the patient is competent to remember when and how to take the medication is essential. It is important for healthcare providers to offer information and supplies to implement chemotherapy safety precautions for family at home.

Nursing Diagnosis and Outcomes

- Altered nutrition due to persistent nausea or vomiting.
  Desired outcome: Absence of nausea or vomiting.
- Altered sensory perception related to peripheral neuropathy
  Desired outcome: Absence of fall or injury due to altered perception
- Altered elimination related to constipation
  Desired outcome: Normal bowel habits maintained.
- Altered mental status due to severe drowsiness
  Desired outcome: Patient verbalizes no distress related to drowsiness and able to maintain desired level of ADLs.
- Potential altered circulation due to risk for venous thromboembolism
  Desired outcome: Absence of venous thromboembolism or other hypercoagulability syndromes.
- Potential risk for infection due to immunosuppressive effects
  Desired outcome: Absence of infection.

Planning and Intervention

Maximizing Therapeutic Effects

Patients receiving thalidomide will achieve the greatest benefit from therapy when they have a complete understanding of when is best to take their medication for best absorption. This may be challenging and require review of their other medications and meal planning. Thalidomide is such a dangerous drug if not taken properly, that a pillbox and system for pill counting to ensure proper administration is usually implemented. Most patients find that taking their thalidomide at night-time is the most effective way to ensure there is no interruption of absorption and to compensate for the drowsiness that is often encountered. If this is the plan, ensure measures are taken to reduce the patient's fall risk due to orthostasis. Thalidomide is prescribed in conjunction with other medications for treatment of multiple myeloma, and administration of the thalidomide should follow the prescribed combination therapy plan as closely as possible to ensure optimum tumor response. Some new data also suggests that some of the disorders that are treated may benefit from a lower dose maintenance therapy, but these are still under investigation except with erythema nodosum leprosum.

Minimizing Adverse Effects

Ensuring that preventive measures for the most common and severe adverse effects will enhance the ability to continue therapy without dose-limiting toxicities. Compression stockings, and planned exercise can reduce the risk of VTE, although many patients will also receive prophylactic anticoagulation. Blood counts are monitored carefully and infection prevention precautions are implemented even with limited neutropenia. Proper health maintenance to boost the immune system includes adequate rest, nutritional meal planning, and maintaining activities of daily living. Infection prevention strategies such as avoiding crowds, careful food selection, avoidance of soil exposure and excellent personal hygiene are employed even before neutropenia occurs. Neutropenia lower than 750 cells/mm^3 is an indication for holding the medication. Precautions to prevent pregnancy are essential and must be followed, and constantly evaluated by the healthcare team to reduce the risk of injury to the fetus. Precautions are recommended for a month prior to starting treatment until one month after the conclusion of therapy. During therapy, healtyhcare providers should frequently interview patients about the sexual practices and reinforce the need for contraception. Patients are usually placed on a "bowel regimen" of stool softeners (docusate [Colace]) with mild laxatives (Senna) unless constipation occurs despite this regimen. The next progression is to Miralax, and anticholinergic medications such as lomotil or irritants such as magnesium citrate are reserved for refractory constipation. It is unclear whether peripheral neuropathies from thalidomide can be prevented, but frequent assessment for hand and feet sensory changes may provide early detection. There is some evidence that supplemental Vitamin E may reduce this adverse effect, but it has not been tested in patients

CRITICAL THINKING SCENARIO

Mrs. Jones is a 45 year old moderately obese (Height 64 inches, weight 200 pounds, BMI 34) woman who recently presented to the primary care provider with hip and back pain, fatigue, and persistent nausea. Upon physical exam and diagnostic evaluation she was found to have multiple myeloma, stage III, IgG subtype.

She works as a hygienist at a pediatric dentist's office, is married, and has two teen-age boys aged 14 years and 15 years. Denies smoking and rare alcohol intake.

Physical Exam Findings:
- Neurologically intact and excellent cognition
- No tenderness in spine or joints
- Heart rate 110/min and regular, lungs clear
- Pulses normal bilaterally in upper and lower extremities
- 1+ edema bilateral lower extremities
- Conjunctiva and mucous membranes pale

Past Medical History:
- Hypertension for 2 years
- Life-long severe upper respiratory allergies to grasses and trees
- Intermittent irritable bowel syndrome

Medications:
- Lisinopril (ACE inhibitor) once daily
- HCTZ (thiazide diuretic) twice daily
- Omeprezole (proton pump inhibitor) twice daily
- Laxatives and immodium as needed for gastrointestinal distress

CBC: Hgb 7.9 g/dL (baseline 12.7 g/dL)

Metabolic Panel:
- BUN 22 mg/dL; creatinine 2.4 mg/dL (baseline 1.3 mg/dL); calcium 10.5 mg/dl; albumin 3.5 g/dL
- CrCl 42 mL/min
- Total protein 12.6 g/dL (baseline 8.0 g/dL)

B2M: 8.0 g/mL

Urinalysis:
- 2+ proteinuria
- Glucose >1,000 mg/dL
- No increased leukocytes, no casts

Skeletal x-ray: Acute fracture of I,2 and three skeletal lytic lesions
Bone marrow biopsy: 30% plasma cells

Impressions:
Treatment plan: Bortezomib, thalidomide and dexamethasone for four months to be followed by hematopoietic stem cell transplant

1. Before starting therapy, what mandated patient counseling and consent must occur?
2. Mrs. Jones has compromised renal function, with a creatinine clearance of <50mL/min. Do we need to alter the dose or administration procedures for thalidomide?
3. Based upon her occupation, what adverse effect(s) would we want to alter her to based upon her specific risks?
4. Based upon her past medical history and current medications, what unique concerns may be present related to initiation of thalidomide?

receiving thalidomide. Patients should consult their healthcare provider for taking any of the available recommended complementary therapies to abrogate any symptom. Other symptoms are managed supportively as they arise.

Providing Patient and Family Education

This drug's administration is only permitted in circumstances in which there is not a viable alternative therapy and the patient or health care proxy can be educated about its teratogenic risks. Females must receive both oral and written warning about the risks of thalidomide to fetuses and the importance of using two simultaneous forms of birth control and acknowledge in writing her understanding and agreement to these precautions. Males must acknowledge in writing a similar understanding and agreement to perform contraceptive measures appropriate to men. These measures are in place from one month prior to starting therapy until one month after conclusion of treatment.

From the onset of therapy, safety measures are reinforced and patients are advised to implement preventive measures for thromboemboembolic events and monitor for their occurrence. They are advised to remain as active as possible, consume one quart or more of water daily and if advised by their healthcare provider implement mechanical prophylaxis measues such as compression stockings or sequential compression devices. Many of these patients have additional thromboembolic risks and may be prescribed prophylactic anticoagulation. This may involve education regarding self-administration techniques, food monitoring, frequent blood assessment, and bleeding precautions. Due to the complexities of their risks and the prophylactic regime, these patients are often referred to an anticoagulation clinic for management of their anticoagulation and ongoing education.

Safety measures also extend to protection from injury related to altered sensation if peripheral neuropathies occur. Patients should be taught to protect their hands and feet from excessive temperatures and other trauma. They should reduce the temperature of their home water heater, wear gloves and socks when appropriate, spend more time in supportive footwear and remove injury risks such as loose rugs or low-standing tables from their home, keeping clear walking pathways.

Ongoing Assessment and Evaluation

Patients receiving thalidomide will be monitored closely by health care providers who are "certified" by the S.T.E.P.S. program to prescribe and counsel patients receiving thalidomide. During visits, serum laboratory tests for toxicity (e.g., neutropenia) are drawn, and medication validation is performed and include pill counts and assessment for medications or over the counter products that may interfere with contraception. Healthcare providers will also assess the patient's risk for venous thromboembolism and institute prophylactic measures if additional risk factors occur. The patient must be interviewed for resolvable adverse effects such as constipation, or signs and symptoms of dose-limiting toxicities such as neuropathies.

MEMORY CHIP

P Thalidomide

- Anti-angiogenic agent that has immunomodulatory, anti-inflammatory, and anti-angiogenic properties thought to be related to suppression of tumor necrosis factor alpha production and down-regulation of surface adhesion molecules involved in leukocyte migration.
- Used as primary therapy for newly diagnosed or relapsed multiple myeloma, myelodysplastic syndrome, follicular and diffuse large cell lymphoma, erythema nodosum leprosy, and refractory rheumatoid arthritis.
- Major contraindications: it is essential for patients receiving thalidomide to avoid becoming pregnant or impregnating another for four weeks prior to and after concluding therapy due to the certain teratogenic effects of the medication.
- Most common adverse effects: drowsiness, neutropenia, constipation, peripheral neuropathies and venous thromboembolism.
- Most serious adverse effects: human teratogenecity
- **Life span alert: Teratogenecity is of such high risk that and male or female of childbearing age must be enrolled in the S.T.E.P.S. counseling always use contraception with a latex condom while on therapy and for four weeks after treatment conclusion. Additionally, consult the prescriber who is counseling the patient on the S.T.E.P.S. program for any medication changes that may influence the efficacy of contraception.**
- Maximizing therapeutic effects: High fat meals or snacks taken with thalidomide may prolong the time to peak drug concentrations, so this medication should be taken orally with water, preferably at bedtime and at least two hours after the evening meal.
- Minimizing adverse effects: Use cautiously with medications that also cause somnolence, peripheral neuropathies or neutropenia, as these effects will be enhanced by combination agents with these adverse effects.
- Most important patient education: The most important patient educations with thalidomide is the importance of effective contraception and prevention of pregnancy. The teratogenic effects are well-documented and consistent. Patients are also advised to monitor for the presence of drowsiness or sedation and modify their activities accordingly, and drink plenty of fluids or take mild laxatives to reduce the incidence or severity of constipation. Since many patients experience a safety risk due to drowsiness, peripheral neuropathies or neutropenia, precautions to prevent injury are emphasized.
- **Black box warning: This medication is teratogenic and should never be administered to an individual who is or could become pregnant. Black box warning provide extensive advisement to prevent infection and avoid medications that could interfere with contraception. The risk for venous thromboembolism is as high as 22.7% and also outlines in the black box warning. Clinicians should be observant for signs and symptoms of venous thromboembolism and provide concurrent prophylactic anticoagulation.**

Drugs Closely Related to Thalidomide

Lenalidomide

Lenalidomide is a thalidomide analogue with similar pharmacokinetic properties to the native drug thalidomide. It is licensed with dexamethasone for second-line treatment of multiple myeloma, but has been administered concurrently with bortezimib, prednisone, melphalan, and cyclophosphamide (Zeldis et al., 2010). Lenalidomide is also licensed for treatment of transfusion dependent, low-to-intermediate risk myelodysplastic syndrome (MDS) with a deletion of 5 g abnormality. Like thalidomide, this agent also has a black box warning related to its teratogenic effects and requires patient counseling, consent, and agreement to not become pregnant or impregnate another. It is also associated with neutropenia and venous thromboembolism when administered concomitantly with dexamethasone. Other notable unique adverse effects include fatigue, gastrointestinal distress, peripheral edema and thrombocytopenia. Patients with MDS also experiences pruritis, nasopharyngitis, and arthralgias. This medication is oral, and administered 25 mg daily days 1–21 every 28 days for multiple myeloma and 10 mg once daily for MDS. The starting dose of lenalidomide is reduced by 50% for patients with renal insufficiency or on dialysis. The only significant interaction is with digoxin, where digoxin levels may increase while receiving lenalidomide. Patients receiving lenalidomide are carefully monitored and taught similar key points as with thalidomide.

CHAPTER SUMMARY

- The immune system is a complex system of cells and chemical mediators that prevents foreign pathogens or cells from invading the body.
- WBCs are active in the surveillance and initiation of inflammatory reactions to specific stimuli. WBCs include neutrophils, which digest foreign material; basophils, which release chemicals to initiate the immune response; mast cells, which are located in the skin and the respiratory and GI tracts; macrophages, which release chemicals to initiate the immune response; and eosinophils, which seem to be active in allergic reactions.
- Lymphocytes include T cells, which are important in modifying the immune response and in protecting the body from nonself cells, and B cells, which produce antibodies to specific antigens. The antibodies stimulate an immune and inflammatory reaction to the antigen and cause its destruction.
- Interferons are produced by WBCs in response to viral invasion and other stimuli. They block viral replication and inhibit tumor cell growth. Interferons are used to treat various malignant and viral diseases.
- Interleukins are chemicals secreted by active WBCs to influence other WBCs.
- Immune modulators may restore depressed immune function, stimulate immune function, stimulate antibody formation, or enhance T-cell response.
- Drugs that suppress the immune system are used to block T-cell activity in organ transplant patients when the immune system tries to destroy the foreign cells, and to treat autoimmune diseases when the immune system is mistakenly trying to destroy self cells.
- The most significant adverse effects of calcineurin inhibitors are hypertension, nephrotoxicity, and neurotoxicity.
- Retinoids alter cell proliferation and differentiation and are used in treatment of leukemia, but resistance is common.
- Patients taking drugs that modify the immune system need protection against infection, injury, and neoplasms because their susceptibility is increased.
- These drugs often cause adverse GI effects; therefore, efforts must be made to maintain nutritional status. A nutritional consultation, supplemental feedings, and small, frequent meals are often necessary.
- Anti-angiogenic agents act by interfering with tumor necrosis factor and development of new blood vessels, and are among the most teratogenic and mutagenic agents used as therapeutic medications.
- Anti-angiogenic require patient monitoring for dose-limiting somnolence, peripheral neuropathy, venous thromboembolism, or neutropenia.

QUESTIONS FOR STUDY AND REVIEW

1. What effects do cytokines have on the immune response?
2. What are interferons and interleukins?
3. Why are interferons used against malignant cells?
4. How do the adverse effects of IL-2 differ from those of interferons?
5. What are the labeled indications for cyclosporine?
6. What are the dose-limiting toxicities of cyclosporine?
7. What are the most common toxicities of the family of retimoid agents?
8. Name two clinical indications for administrations of bacillus calmette Guerin (BCG).
9. What is the most common toxicity limiting clinical use of thalidomide?
10. What special precautions and consenting procedures are required prior to administration of thalidomide?

Targeted Therapies

Learning Objectives

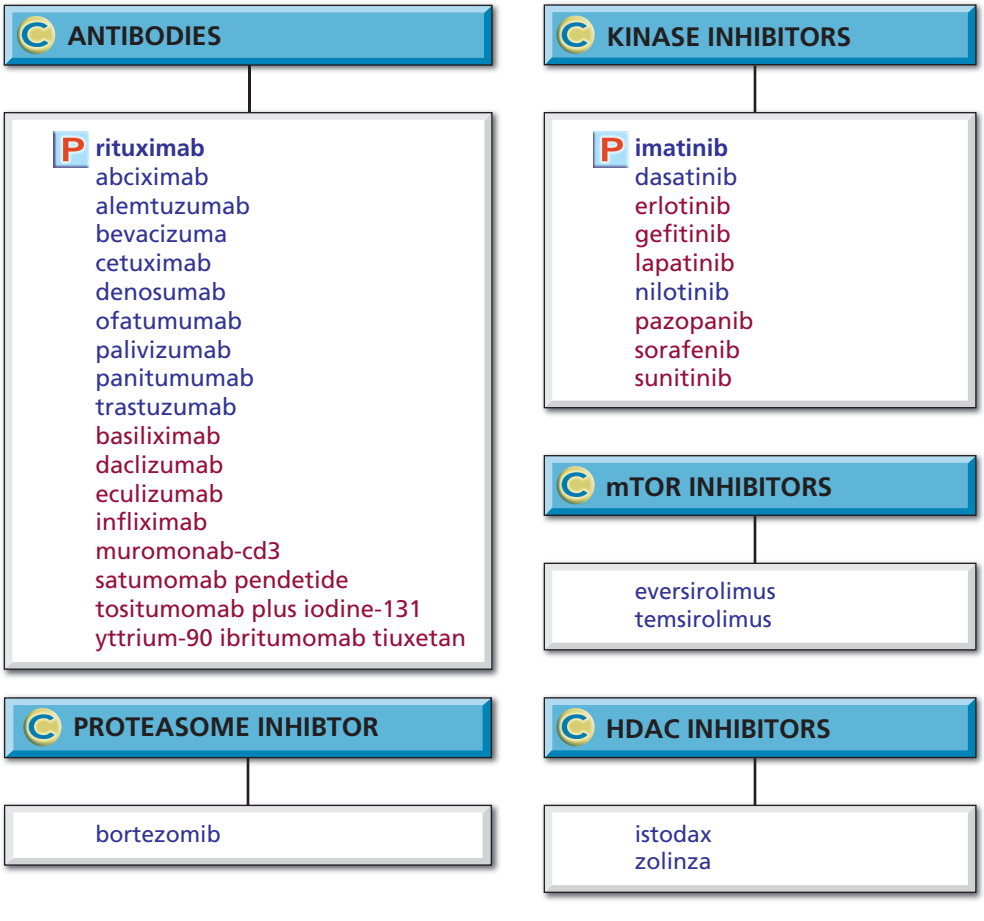
At the completion of this chapter the student will:

1. Understand the goals of treatment and the strategies used in targeted therapy.
2. Identify the internal and external molecular targets which are inhibited by drugs in this category.
3. Differentiate mechanisms of action and adverse effects between targeted therapies and traditional chemotherapy drugs.
4. Explain the differences in classifications of monoclonal antibodies: conjugated and nonconjugated, murine derived and human derived.
5. Identify the different routes of administration for the various targeted therapies.
6. Identify core drug knowledge about targeted drugs.
7. Identify core patient variables relevant to targeted drugs.
8. Relate the interaction of core drug knowledge to core patient variables for targeted drugs.
9. Generate a nursing plan of care from the interactions between the core drug knowledge and core patient variables for targeted drugs.
10. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects targeted drugs.
11. Determine key points for patient and family education for targeted drugs.

Key Terms

Epidermal growth factor receptor (EGFR, also known as HER1)
HER2/neu receptor
Monoclonal antibodies
Polyclonal antibodies
Small molecule inhibitors
Tyrosine kinase
Mammalian target of rapamycin (mTOR) inhibitor
Vascular endothelial growth factor (VEGF)

Targeted Therapies



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Targeted cancer therapies are new types of drugs used to treat cancer. Targeted cancer therapies interfere with specific extracellular and intracellular molecules and receptor sites involved in carcinogenesis (the process by which normal cells become cancer cells) and tumor growth or proliferation. These molecules are sometimes referred to as molecular targets or molecular receptors; therefore, targeted therapies that deactivate or destroy the receptors are sometimes called "molecular-targeted drugs," "molecularly targeted therapies," or other similar names. Targeted cancer therapies interfere with cancer cell growth and division in different ways and at various points during the development, growth, and spread of cancer. These molecules are present in normal tissues but are often overexpressed or dysfunctional in cancerous tissue. Many of these therapies focus on proteins that are involved in the signaling process. By blocking the signals that tell cancer cells to grow and divide uncontrollably, targeted cancer therapies can help stop the growth and division of cancer cells. By focusing on molecular and cellular changes that are specific to cancer, targeted cancer therapies may be more effective than current treatments and less harmful to normal cells so that they may produce fewer adverse effects. Proteins on the membrane of tumor cells are responsible for a host of events contributing to carcinogenesis. Proteins located in the cytoplasm of tumor cells are also involved in carcinogenesis and are being identified as targets for new cancer therapies.

Many targeted cancer therapies are still being studied in clinical trials; however, a number of these drugs are now approved for use in various cancers. Whether these drug therapies are best if used alone, in combination with each other, or in combination with other treatment modalities, such as chemotherapy, is still to be determined. Targets for various solid tumors and hematologic malignancies include; epidermal growth factor receptors (EGFR), vascular endothelial growth factors (VEGF), Her2 Neu, BCR-Abl, C-Kit, and platelet derived growth factor receptor (PDGFR). Many more targets exist and new targets are constantly being identified.

Targeted therapies are generally considered to be less toxic than traditional chemotherapy drugs however, adverse reactions to targeted therapies can occur such as severe skin reactions, GI toxicities, skin reactions, and thrombosis. Class specific effects may include hypersensitivity reactions (Monoclonal antibodies), cardiotoxicities (kinase inhibitors), and vasculitis (kinase inhibitors). Drugs considered targeted therapies are often metabolized by cytochrome P-450 enzymes. This may increase the risk of drug interactions and patients should be carefully evaluated and monitored to avoid problems.

Two other important considerations with targeted therapies include cost and patientadherance. These therapies tend to be costly and careful analysis of cost benefit ratio must be considered. Patient adherance with the oral targeted therapy regimens is an important area of interest. Tumor resistance to targeted therapies has occurred in select tumor types and is an area of concern and investigation, with particular attention to resistance emergence related to consistent regimen adherence. Traditional treatments for cancer in particular have been administered by the health care provider intravenously in a hospital or clinic setting making it easier to ensure correct dosing and timing of therapy is followed.

A number of targeted therapies have been approved by the FDA for the treatment of cancer. These therapies include polyclonal and monoclonal antibodies and kinase inhibitors. Targeted therapies are also licensed by the FDA for nonmalignant diseases such as Crohn disease and rheumatoid arthritis. A number of clinical trials with use of targeted therapies in autoimmune diseases are currently in progress (REF). Additionally, some monoclonal antibodies are used for cancer diagnostic purposes.

As research identifies more cancer targets, it is likely that many more drugs will be licensed for use within this category. Emergence of new target and effective disruption in tumorogenesis are likely to drastically alter the future of cancer treatment.

The prototype for monoclonal antibodies is rituximab. The prototype for the kinase inhibitors is imatinib. These two prototyoes represent the initial discovery of this exciting new class of drugs used to treat malignancy known as targeted therapy. Knowledge gained from these two prototypes opened the door for many similar drugs used in a variety of malignancies.

PHYSIOLOGY

B cells are found throughout the reticuloendothelial system in like groups called clones. These cells are "programmed" to identify specific antigens and are discussed in greater detail within Chapter XX. When a B cell reacts with its specific antigen, it changes into a plasma cell. Plasma cells produce antibodies, or immunoglobulins, that circulate in the body and react with their specific "destiny" antigen when encountered. This effect is called a receptor–receptor site reaction and constitutes the humoral immune response. When the antigen and antibody react, they form an antigen–antibody complex, which reveals a new receptor site on the antibody that activates a series of plasma proteins in the body called **complement.** Complement proteins can destroy the antigen by altering the membrane and allowing osmotic inflow of fluid that bursts the cell. These proteins can also induce **chemotaxis** (attraction of phagocytic cells to the area) and increase the activity of phagocytes. In addition, they can release histamine, which causes vasodilation, increases blood flow to the area, and brings together all the components of the inflammatory reaction to destroy the antigen. Direct cytotoxicity may also occur when a receptor site is occupied by a ligand other than the normal one. This mechanism is capitalized upon by monoclonal antibody therapy that is intended to disrupt that cell's normal function, growth and replication.

The initial formation of antibodies, called the primary response, takes several days. However, once the response is activated, the B cells form memory cells that, in turn, produce

antibodies that are released immediately whenever the antigen is encountered. This process is a lifelong reaction called active immunity. B cells cluster in areas where they are most likely to encounter their specific antigen. For example, airborne antigens meet B cells in the tonsils and upper respiratory tract. Experts believe that most B cells are programmed genetically and are formed before birth. The introduction of a new and unusual antigen can result in widespread disease because the body is unable to recognize the foreign protein and mount an immune response.

PATHOPHYSIOLOGY

Pathophysiologic conditions requiring drug therapy with targeted agents are usually related to abnormal cell surface markers or molecular pathways. The molecular activities governing differentiation, proliferation, and cell death are often impaired in the cells of patients with disease. When the specific surface marker or molecular pathway of fault in a disease is known, it has become possible to administer targeted agents to disrupt or modify that process, redirecting cell activity. In some therapies such as the antineoplastic agents, the goal is to induce cell death, or apoptosis. For others, it may be to redirect the signal transduction or recreate messenger RNA in order to alter the final cell activity. This chapter discussed the monoclonal antibodies that target surface markers and the tyrosine kinase inhibitors that affect internal cell processes for treatment of malignancies, autoimmune disease, transplanted tissue, and other specific pathophysiologic disorders. Table 55.1 provides a summary of selected targeted agents that affect the external and internal molecular signals.

ANTIBODIES

The earliest antibody preparations were general agents directed toward destruction of lymphoid cells (antilymphocyte globulins). They were derived from animals (horses and rabbits) that were injected with human thymocytes (the thymus gland is the source of T cells in humans) and RBCs; the injections stimulated the animal to produce nonspecific immunoglobulin G (IgG) antibodies. The most common preparations were equine antithymocyte globulin (ATG, Atgam), antilymphocyte globulin (ALG), and antilymphocyte serum (ALS). These polyclonal antibodies are so named because they react to more than one antigen. The term *antilymphocyte immunoglobulin* (ALG; lymphocyte immune globulin) implies a product raised against all lymphocytes, and antithymocyte immunoglobulin (antithymocyte gammaglobulin; antithymocyte globulin; ATG) implies specificity for T cells. Despite what appear to be substantial differences in levels of immune suppression, in clinical practice, these agents show few differences in action and only ATG is currently available. These agents have historically been administered to graft recipients, so that the foreign antibodies directly attack the host's T cells and reduce their circulating number.

Because these agents are derived from nonhuman sources, they have caused the production of atypical antibodies, and individuals easily become resistant to their beneficial effects. Because of production shortages, difficulties in purification, and scientific advances in specific antibody development, these agents are now rarely used and not discussed in detail within this chapter. Instead, targeted antibodies called monoclonal antibodies are used, which suppress one cell subtype or receptor site. Monoclonal antibodies can react with specific tumor receptor sites for diagnosis or treatment of malignancy. As the body of knowledge regarding specific cellular defects with particular diseases grows, so does our ability to develop cell-targeted antibody therapy for abnormal cells, genes, or receptor sites.

Antibody therapy has rapidly progressed in recent years, with increasingly greater specificity of the newly developed agents. Monoclonal antibodies target specific receptor sites of cells, causing varied immunologic effects depending on the cell to which they attach themselves. Each monoclonal antibody has a defined "destiny" target that is expressed on cells and predict the clinical indication. Abiximab (ReoPro) targets the platelet, interfering with platelet aggregation and used extensively in cardiology to reduce coronary thrombus after interventional procedures; whereas trastuzumab is attracted to the her-2-neu receptor that is overexpressed in certain patients with breast cancer. Clinical indications are based upon which diseases are characterized by the presence of unique antigens. Monoclonal antibodies may be created from animal antibodies (almost always murine fused), animal-human antibodies (chimeric), mostly human (humanized), or totally human antibodies. Monoclonal antibodies are named based upon their origin; murine are –momab, chimeric antibodies end in-iximab, humanized are –zumab, and fully human antibodies end with –tumumab (Polovich et al., 2009). The nonhuman antibodies produce more allergic and rejection reactions, caused by human antimurine antibodies (HAMA), which can contraindicate future therapy with a specific monoclonal antibody or any other with a murine component. These antibody responses manifest as allergic or anaphylactic reactions in patients receiving the antibody product. Monoclonal antibodies also may directly target a cell receptor, paralyzing the usual actions by that receptor and its ligands. Alternatively, they can be conjugated, meaning combined with another substance such as radiation or toxic drug that then produces indirect cell destruction as the conjugate infiltrates the cell (Polovich et al., 2009). Because of the rapidly developing practice of using antibodies to target tumor cell receptor sites, the antibody prototype is the monoclonal antitumor antibody called rituximab (Rituxan). Monoclonal antibodies available for use as immunosuppressants are considered significantly different from the prototype, as are the monoclonal antibodies fused to radioactive substances, or those used to highlight a cell for diagnostic purposes. All antibodies can produce allergic reactions, and most administration guidelines suggest premedicating the patient with acetominophen and diphenhydramine and

TABLE 55.1 Summary of Selected Targeted Agents

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Monoclonal Antibodies			
P rituximab (Rituxan)	Relapsed or refactory low-grade or follicular CD20-positive B-cell non-Hodgkin's lymphoma, or multiple myeloma, refractory rheumatoid arthritis	*Adult:* IV, 375 mg/m2 once weekly for four doses *Child:* Safety and efficacy not established	*Onset:* Unknown *Duration:* 3–6 mo after completion of treatment $t_{1/2}$: 59.8 h after first dose, and 174 h after fourth dose
muromonab CD (Orthoclone OKT3)	Acute allograft rejection in renal transplantation, steroid-resistant acute allograft rejection in liver, lung, cardiac, and bone marrow transplantation	*Adult:* IV (bolus only: <1 min), 5 mg/d with diagnosed rejection *Child:* Safety and efficacy not established	*Onset:* Minutes *Duration:* 7 d $t_{1/2}$: 47–100 h
trastuzumab (Herceptin)	All women with breast cancer that overexpresses the her2 neu receptor. It may also be administered with adjuvant chemotherapy in women without active disease, but who are at risk of relapse.		*Onset:* Slow *Duration:* Days $t_{1/2}$: 2–9 d
bevacizumab (Avastin)	In combination for initial treatment of colorectal cancer; in combination with chemotherapy for management of metastatic or relapsed colorectal cancer, metastatic non-small-cell lung cancer, metastatic breast cancer, metastatic renal cell carcinoma. Given as a single agent for refractory ovarin cancer or glioblastoma multiforme.	*Always administered as IV infusion over 90 min first week, then if tolerated, over 60 min in subsequent dose.* *For initial treatment of colorectal cancer:* 5 mg/kg or 10 mg/kg with irinotecan, fluorouracil, and leukovorin. *For metastatic colorectal cancer:* 10 mg/kg with oxaliplatin, flourouracil and folinic acid. *Non-small-cell lung cancer:* IV infusion 15 mg/kg every 3 wk. *Breast cancer:* 10 mg/kg every 14 d in conjunction with paclitaxel. *Ovarian cancer:* 15 mg/kg every 3 wk. *Renal cell carcinoma:* 10 mg/kg every 2 wk in conjunction with interferon alia. *Glioblastoma multiforme:* 10 mg/kg every 3 wk *Pediatric solid tumors:* 10 mg/kg in combination with chemotherapy or 15 mg/kg every 28 d.	*Onset:* Slow *Duration:* 100 d $t_{1/2}$: 20 d
cetuximab (Erbitux)	As a single agent or in combination with irinotecan for treatment of metastatic colorectal cancer where KRAS wild-type cytogenetics are verified; as a single agent or in combination with radiation therapy for locally invasive squamous cell carcinoma of the head and neck	Initial loading IV dose of 400 mg/kg over 120 min (not exceeding 5 mL/min), followed by IV weekly 250 mg/kg administered over 60 min. In all circumstances, patients are observed for an additional 60 min for infusion reactions.	*Onset:* 3–12 h *Duration:* 24 h to 3 wk $t_{1/2}$: 75–188 h
C Kinase Inhibitors			
P imatinib (Gleevec)	Philadelphia positive (PH+) CML: gastrointestinal stromal tumor	PO 400–800 mg daily	*Onset:* Unknown *Peak:*2–4 h *Duration:* Unknown
dasatinib (Sprycel)	PH+ CML	PO 140 mg daily	*Onset:* Unknown *Peak:* Unknown *Duration:* Unknown
nilotinib (Tasigna)	PH+ CML	PO 300–400 mg BID	*Onset:* Unknown *Peak:* 3 h *Duration:* Unknown
erlotinib (Tarceva)	Non-small cell lung cancer and pancreatic cancer	PO 100–150 mg daily	*Onset:* Unknown *Peak:* 4 h *Duration:* Unknown

TABLE 55.1 **Summary of Selected Targeted Agents** *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
gefitinib (Iressa)	Non-small cell lung cancer	PO 200 mg daily	*Onset:* Unknown *Peak:* 3–7 h *Duration:* Unknown
lapatinib (Tykerb)	Breast cancer	PO 1250–1500 mg daily	*Onset:* Unknown *Peak:* 4 h *Duration:* Unknown
sorafenib (Nexavar)	Hepatocellular and renal carcinoma	PO 400 mg BID	*Onset:* Unknown *Peak:* 3 h *Duration:* Unknown
sunitinib (Sutent)	GIST, renal carcinoma, pancreatic neuroendocrine tumors	PO 37.5–50 mg daily	*Onset:* Unknown *Peak:* Unknown *Duration:* Unknown
pazopanib (Votrient)	Renal carcinoma, pancreatic neuroendocrine tumors, subependymal giant cell astrocytoma associated with tubous sclerosis		*Onset:* Unknown *Peak:* Unknown *Duration:* Unknown
temsirolimus (Torisel)	Renal cell carcinoma	IV 25 mg once weekly	*Onset:* Unknown *Peak:* Unknown *Duration:* Unknown

having emergency equipment, corticosteroids, and adrenaline (epinephrine) readily available. All antibody products also carry the risk of cross-reactivity with other vaccine products, necessitating careful consideration before administering any other antibody or vaccine to these patients after monoclonal antibody therapy.

Nursing Management of the Patient Receiving P Rituximab

Core Drug Knowledge

Pharmacotherapeutics

Rituximab has historically been used to treat CD20-positive B-cell malignancies such as B-cell leukemias, chronic lymphocytic leukemia, non-Hodgkin's lymphoma, and some multiple myeloma. Since the recognition of CD20 positivity among all B-cell malignancies, the application of rituximab exceeds the specific licensed indications. Recent research advances have demonstrated the activity of CD20 positive cells in autoimmune diseases, reflected in new licensed indication for treatment of rheumatoid arthritis, and use with other therapy-refractory autoimmune disorders (Perosa et al., 2010).

Pharmacokinetics

Rituximab binds to the B-lymphocytes which are expressing CD20 surface marker, and because of individual tumor variability, the blood concentrations and duration of action will vary as well. Our greatest experience with this agent is with non-Hodgkin's lymphoma, and pharmacologic information is based upon these patients. Rituximab is given as a slow IV infusion at 375 mg/m^2 weekly for 4 to 8 weeks, with a possible additional 4 weeks for responsive patients. Although initially used as a single agent therapy, Rituximab is now usually given in conjunction with standard chemotherapy regimens. The serum half-life is 59.8 hours after the first infusion (375 mg/m^2) and 174 hours after the fourth infusion, although the drug is detectable for 3 to 6 months after treatment is completed. The actual drug infusion is calculated based on the total dose the patient is to receive,

not exceeding 50 mg/h for the first half-hour of the initial infusion. If no reactions are apparent after 30 minutes, the dose may be escalated every 30 minutes by 50 mg/h until a maximum infusion rate of 400 mg/h is reached. All subsequent infusions begin at 100 mg/h and can be escalated by 100-mg/h increments every 30 minutes until the maximum infusion rate of 400 mg/h is reached. The average infusion time for routine periodic rituximab when the patient has no history of reactions is about 90 minutes. Patients with large cell lymphoma receive this agent concomitant with chemotherapy, but with nonprogressing low grade lymphoma, it is given at the conclusion of chemotherapy cycles. Prolonged maintenance therapy for patients with responding tumors is currently under investigation (Vidal et al., 2009).

- In chronic lymphocytic leukemia, rituximab is administered as a loading dose of 375 mg/m^2 prior to fludarabine and cyclophosphamide on the same day, then 500 mg/m^2 at the beginning of cycles 2 to 6 (Biogen Idec, Inc and Genentech, Inc, 2010).
- Recently, rituximab has been licensed in combination with methotrexate for treatment of rheumatoid arthritis. It is administered as two- 1,000 mg IV infusions separated by two week, given every 24 weeks or based upon clinical evaluation. In this setting, the prescribed premedications are only methylprednisilone 100 mg or equivalent corticosteroid given 30 minutes prior to rituximab infusion.

See also Table 55.1, summary of selected targeted agents.

Pharmacodynamics

Rituximab is a type of monoclonal antibody that binds specifically to the CD20 antigen found on the surface of normal and malignant B lymphocytes and causes cell lysis. The CD20 antigen is expressed in more than 90% of B-cell non-Hodgkin's lymphoma cells but not on normal bone marrow cells, pre-B cells, or other normal tissues. The CD20 antigen is also expressed excessively in patients with specific autoimmune disorders. One section of the drug binds to CD20 antigen and another section of the drug calls other immune activators to assist in cell lysis. Cell lysis is possibly caused by complement-dependent cytotoxicity or antibody-dependent cytotoxicity (Biogen Idec, Inc. & Genentech, Inc., 2010). Decreased IgG and IgM serum levels are evident for 5 to 11 months after the last infusion. This direct cytotoxicity is believed to be the mechanism of acute tumor lysis syndrome that may occur 24–72 hours after administration. It is viewed as a positive clinical sign of antitumor activity but can cause fatal electrolyte disturbances and renal failure if not closely monitored and treated. The significance of this complication has resulted in a special warning label on the product prescribing information (see below).

Contraindications and Precautions

The only contraindication to rituximab therapy is type 1 hypersensitivity or anaphylaxis to murine proteins or any components of the product. Severe and fatal reactions within 24 hours of rituximab infusion have been reported, most often with the first infusion. A Black Box warning to observe for reactions is included in the prescribing information. Safety in children or in pregnant or lactating women has not been tested. Experience with older adults has developed considerably since the initial licensing and thought to produce good clinical effects without excessive toxicity (Barni et al., 2008).

Adverse Effects

Infusion-related effects reportedly occur in 80% of patients within 30 minutes to 2 hours after beginning the first rituximab infusion, although only 7% have severe reactions (Biogen-Idec, Inc and Genentech, Inc, 2010). Although reactions are less common with subsequent infusions (40%), its severity is unchanged. With several years experience in administration of this agent and perfection of pre-medication regimens, recent reaction rates may be less frequent, but literature updating these data were not available. Reactions may be related to dose because most of the reaction dissipates when the infusion rate is slowed or interrupted. The most common infusion-related reactions include fever, flushing, chills, and rigors. Other reported symptoms include nausea, urticaria, fatigue, headache, pruritus, bronchospasm, dyspnea, hypotension, angioedema, dyspnea, rhinitis, vomiting, flushing, pain at disease sites, and throat swelling (Castells, 2008). Mucocutaneous reactions associated with the allergic response can be severe. Respiratory distress and hypotension are reportedly more common when tumors are larger than 10 cm. As many as 16% of patients experience asthenia on retreatment. Other possible effects include tachycardia, arrhythmias, anorexia, peripheral edema, dizziness, and depression. Bone marrow effects such as leukopenia, thrombocytopenia, and anemia can be present for up to 30 days after the last dose. A rare but potentially fatal neurologic adverse effect called progressive multifocal leukoencephalopathy that can cause seizures, coma, or death is associated with rituximab infusion (Ram et al., 2009). Initially it was thought to occur only in conjunction with JC virus (a type of human polyomavirus); but now it has been reported in a greater variety of patients without this risk factor (Perosa, 2010).

About 1% of patients develop antibodies to human antimurine or chimeric antibodies, producing severe allergic reactions and limiting their future treatment with any antibody (Biogen Idec, Inc and Genentech, Inc, 2010).

Drug Interactions

Concomitant vaccines of any type are not recommended because of theorized potential interactions; no research has been done on these potential interactions (Biogen Idec, Inc and Genentech, Inc, 2010).

Assessment of Relevant Core Patient Variables

Health Status

Assess for pre-existing cardiac and respiratory problems. Rituximab should be used cautiously in patients with

CRITICAL THINKING SCENARIO

RITUXIMAB FOR TREATMENT OF NON-HODGKIN'S LYMPHOMA

James Miller is a 54-year-old man recently diagnosed with low-grade follicular lymphoma. Physicians consider his tumor pathology and decide that the best therapy is an outpatient biochemotherapy regimen of rituximab with cyclophosphamide, doxorubicin, Oncovin, and prednisone (R-CHOP). He has been instructed to make certain he has a driver to take him home the day he receives the biochemotherapy. Before starting chemotherapy, extensive laboratory tests (CBC, serum metabolic panel with magnesium, phosphate, uric acid) and diagnostic tests (chest and abdomen computed tomography, bone marrow aspiration, and MUGA scan of the heart) are performed to assess baseline organ function. Adequate renal function is confirmed. You obtain the necessary premedications: diphenhydramine and a 5-HT_3 blocker antiemetic. The dexamethasone that is usually administered with chemotherapy can be omitted, because the patient is receiving corticosteroids with his regimen. However, you know that additional follow-up doses of corticosteroids should be prescribed.

1. When starting the rituximab infusion, what rate is set, and how quickly and in what increments is the rate titrated?
2. What are symptoms of rituximab-related infusion reaction?
3. How is an infusion reaction managed?
4. How long after infusion of rituximab is it possible for a reaction to occur?
5. Will this patient be able to receive future doses of rituximab if he has an infusion reaction?

pre-existing cardiac conditions such as arrhythmias or coronary artery disease because ventricular tachycardia, supraventricular tachycardia, angina, hypotension, and hypertension are potential adverse effects, which are all most often associated with infusion reaction syndrome. Interstitial pneumonitis and alveolar hemorrhage have been reported infrequently, but require careful monitoring in high risk patients with pre-existing pulmonary disease or tumors larger than 10 cm in size (Heresi et al., 2008).

Assess for other concurrent drug therapy use before giving rituximab. Rituximab has such potential for infusion reactions that concomitantly administering other agents that may cause severe allergic or anaphylactic reactions should be avoided during infusion and within 2 hours before or after infusion. Agents to avoid include amphotericin, blood products, or first doses of antibiotics.

Consider the serum lactate dehydrogenase (LDH) level, which often reflects the severity and extensiveness of tumor burden. Patients with high LDH values are at highest risk for developing tumor lysis syndrome.

Life Span and Gender

Consider the patient's age. Rituximab is not recommended for use in children or in pregnant or lactating women. Experience with elderly patients is limited; thus, careful evaluation for contraindications is strongly recommended before starting therapy with this agent.

Environment

Be aware of the environment in which rituximab will be administered. Rituximab is usually given in the ambulatory care oncology clinic, although patients with specific risk factors for cardiac or pulmonary adverse effects may be admitted to the hospital for the first dose.

Nursing Diagnoses and Outcomes

- Altered Comfort related to fever, chills, or headache
  Desired outcome: *Symptoms will be abrogated with premedications or relieved with mild analgesics or antipyretics.*
- Potential Altered Cardiac Output related to drug infusion
  Desired outcome: *Cardiac symptoms will not occur.*
- Potential Alteration in Nutrition (fluids and electrolytes) because of cytotoxicity and tumor lysis syndrome
  Desired outcome: *Normal fluid and electrolyte balance will be maintained throughout the treatment period.*
- Potential Impaired Oxygenation caused by infusion-related adverse effects
  Desired outcome: *The patient will maintain a normal breathing pattern, oxygen saturation will be adequate, and adventitious breath sounds will be absent.*

Planning and Intervention

Maximizing Therapeutic Effects

Mix rituximab in normal saline or dextrose solutions in a plastic bag, not in a glass container. The antibody sticks to glass, diminishing the amount of drug administered.

Minimizing Adverse Effects

Because infusion-related adverse effects are common, many clinicians administer premedications to reduce their severity. Premedications often include antipyretics (e.g., acetaminophen) and antihistamines (e.g., diphenhydramine and ranitidine). If patients experience infusion-related adverse effects, stop rituximab until symptoms resolve, then restart it at half the dose that produced adverse effects. Subsequent infusions should begin slowly and can be escalated in the same manner, with temporary discontinuation if infusion effects recur. Patients are usually observed in the ambulatory area for several hours after the initial dose (Chung, 2008).

For patients with hypertension, all antihypertensive agents are usually held for 12 hours before rituximab administration and for 12 to 24 hours afterward. Patients with cardiac or pulmonary risk factors should have continuous cardiac monitoring and frequent vital sign assessment. Stop the infusion at the first sign of adverse effects, which may worsen before resolving. To reduce the risk of recurrence, medications such as nitrates or magnesium can be administered. After symptoms have resolved, resume the infusion at a slower infusion rate, with continuous monitoring.

Providing Patient and Family Education

- Teach patients and families about the purpose of the drug and common adverse effects. Instruct patients to notify the prescriber if they begin to experience adverse effects.
- Assure patients that they will be closely monitored while receiving rituximab. Doing so may require prolonged visits in the clinic, even after the infusion is complete, or frequent follow-up visits after initial therapy to permit monitoring clinical and laboratory parameters for tumor lysis syndrome.
- Ambulatory patients returning home after therapy including rituximab are advised to consume large amounts of water to enhance renal excretion of tumor lysis products as well as to report any unusual symptoms or decreased voiding.
- Because immunologic effects persist for many weeks or months, instruct patients to use birth control for 12 months after completing treatment and to avoid breast-feeding for the same amount of time.

MEMORY CHIP

P Rituximab

- Binds specifically to CD20 antigen on the surface of malignant B lymphocytes and causes cell lysis.
- Used in non-Hodgkin's lymphoma
- Major contraindication: Patients with hepatitis C, major infection, JC virus, renal dysfunction, or cardiac dysrhythmias, may experience worsening of their condition while receiving rituximab. It is administered cautiously to these patients. Live vaccines are contraindicated for patients receiving rituximab.
- Most common adverse effects: infusion-related effects (fever, flushing, chills, and rigors)
- Most serious adverse effects: respiratory distress and hypotension (more common when tumors are larger than 10 cm)
- **Life span alert: Use birth control during therapy and for 1 year afterward and avoid breast-feeding during this time; use with caution in older adults.**
- Maximizing therapeutic effects: Administer in saline or dextrose stored in plastic bags, not glass.
- Minimizing adverse effects: Premedicate patient with other drug therapies.
- Most important patient education: Instruct patient to notify nurse of adverse effects.
- **Black box warning: Fatal infusion reactions have been reported and it is unclear if this relates to hypersensitivity or acute tumor lysis. When acute reactions including angioedema, hypotension, bronchospasm, or respiratory distress occur, the infusion should be immediately stopped and supportive measures instituted. In some cases, rituximab may be resumed after additional premedications and slowed infusion rate. Severe mucocutaneous reactions such as Stevens-Johnson syndrome have been reported. Severe skin reactions warrant immediate discontinuation of the drug. Progressive multifocal leukoencephalopathy (PML) is a rare but potentially fatal neurologic infiltration with lymphocytes. Neurologic symptoms indicate the need to discontinue the drug until diagnostic tests can validate PML.**

Ongoing Assessment and Evaluation

Given the high rate of infusion reactions after the first dose, patients require premedication and close monitoring of vital signs for all rituximab infusions, unless no reactions have occurred.

Drugs Closely Related to P Rituximab

Monoclonal antibodies that are considered closely related to rituximab are those that target a specific receptor site overexpressed by tumors. These agents vary widely in their clinical effects and adverse effects and trastuzumab, bevacizumab,cetuximab, panitumumab, alemtuzumab, and ofatumumab.

Trastuzumab

Trastuzumab (Herceptin) is a humanized monoclonal antibody that targets cells overexpressing the HER2 protein. This protein is overexpressed in as many as 25% to 30% of breast cancers (Murphy & Fornier, 2010). Patients are tested at the time of diagnosis or disease recurrence for amplification of HER2/neu or p185-HER2 protein. Trastuzumab is indicated in all patients with HER2-expressing tumors, even after total tumor resection, who are receiving adjuvant therapy. Patients whose breast cancer cells overexpress this protein then are clinically evaluated for eligibility based on their ability to tolerate the expected adverse effects. A focused cardiopulmonary physical examination, in addition to a test of cardiac function (echocardiogram or MUGA scan), screens patients for adequate cardiovascular reserve or for lung diseases that predispose the patient to adverse effects that have been defined as potentially life threatening in the Black Box warning in the prescribing information. Patients treated previously or concurrently with anthracyclines (e.g., doxorubicin, epirubicin), cyclophosphamide, or radiation to the chest have enhanced risk for the most common cardiac toxicity—chronic heart failure (CHF). CHF with or without persistent cardiomyopathy occurs most commonly as reversible CHF that occurs hours to days after a dose of trastuzumab. Although usually self-limiting, it is a relative indication for discontinuing trastuzumab therapy, especially if independent risk factors such as older age, heavy pretreatment with anthracyclines, or chest irradiation are present (Fiuza, 2009). Pulmonary toxicity may overlap with cardiac symptoms, making it difficult to tell which is which. Infusion-related allergic reactions and cases of acute lung injury have been known to occur. Taxanes have also been reported to increase serum blood levels of trastuzumab that may enhance toxicities. Other clinical effects include suppression of bone marrow function (especially anemia and leukopenia), diarrhea, and rare nephrotic syndrome or acute pneumonitis/respiratory distress syndrome.

Trastuzumab is administered as an initial loading dose of 4 mg/kg over 90 minutes, with subsequent weekly doses of 2 mg/kg over 30 minutes. The clinical benefit of prolonged therapy (beyond planned chemotherapy dosing) is currently being studied to ascertain whether disease-free survival can

be extended, because patients who overexpress the HER2 protein have a high risk of relapse (Iwata, 2009).

Bevacizumab

Early in 2004, the Food and Drug Administration (FDA) approved licensing of bevacizumab (Avastin), the first monoclonal antibody to target the natural protein VEGF that is responsible for stimulation of new blood vessel formation. Although new blood vessels are important for all cell growth, malignant cells are notoriously more dependent on a large blood supply for their survival. Technically a monoclonal antibody, bevacizumab was the first agent licensed specifically for its antiangiogenesis properties. It is a humanized monoclonal antibody that binds to VEGF so that it is unable to attach to its receptor site on cells. Bevacizumab is licensed for use as a single agent or in combination with chemotherapy for refractory or metastatic tumors of the colon/rectum, kidney, nonsmall cell lung, and glioblastoma. Intravitreal bevacizumab application for treatment of chronic progressive macular degeneration has shown promise in improving vision, but is not yet commercially available for this use (Schmucker et al, 2010).

Bevacizumab is administered at a dosage of 5 mg/kg over 90 minutes for two weeks in initial treatment of metastatic colorectal cancer. It may also be administered as 10 mg/kg every two weeks or 15 mg/kg every three weeks. Dosages in other solid tumor malignancies range from 10 mg/kg every two weeks inc onjunction with chemotherapy to 15 mg/kg every three weeks for refractory glioblastoma. The drug is light sensitive and should be covered during administration. As with all monoclonal antibodies, allergic reactions have been reported, and careful monitoring during the initial minutes of the infusion is recommended.

The most common adverse effects of bevacizumab have been asthenia, headache, hypertension, anorexia, mouth sores, diarrhea, minor bleeding, leukopenia, and proteinuria. Hypertensive crises and thromboembolic events have occurred with a frequency rate of 2% to 18%, so this agent is rarely used in patients with a previous history of uncontrolled hypertension, or central nervous system metastases that may bleed (Mir, Mouthon, Alexandre, et al., 2007; Zangari et al, 2009). In patients with non-small-cell lung cancer, life-threatening hemoptysis has occurred, warranting a special warning to prescribers. Bevacizumab may also be contraindicated for use in other patients at high risk for life-threatening hemorrhage. A few isolated reports have also described the occurrence of nasal septal perforation with bevacizumab, although the incidence is less than 1%. Serious but infrequent complications described in a Black Box warning in the prescribing information include intestinal perforation and wound dehiscence. Patients with a higher risk of this complication or those with abdominal pain should not receive bevacizumab. Wound dehiscence has also occurred, even outside the context of leukopenia, so the agent is not recommended for use within 28 days before or after a surgical procedure (Hapani, et al., 2009).

Cetuximab

Cetuximab (Erbitux) is a chimeric monoclonal antibody, licensed early in 2004, that targets the EGRF site of both malignant and normal tissues. Competitive binding of this site with this monoclonal antibody can deprive cells of cytokines and ligands that are necessary for cellular growth and metabolism. Certain tumor cells overexpress EGFR, often connoting a poorer prognosis, and are more reliant on activation of this receptor, thus making them prone to apoptosis when the receptor is blocked. The downstream effects of EGFR competitive binding include inhibition of cell differentiation and proliferation, inhibitions of endothelial growth factors such as VEGF, inhibition of matrix metalloproteinases (MMPs), and induction of apoptosis that enhances mutant cell death (Lurje & Lenz, 2009; Martinelli et al., 2009). As our understanding of the biology of this drug has advanced, we have recognized that there are two different presentations of the k-ras gene- kras- wild-type and k-ras mutant. Patients with k-ras wild-type gene have a significantly higher clinical response rate to EGFR inhibition, and the drug labeling now reflects that patients with metastatic colorectal cancer should have k-ras tumor testing, and only be offered therapy with cetuximab if their tumor is k-ras wild-type (Fakih, 2010).

The FDA has licensed cetuximab for use (1) as a single agent, (2) in combination with irinotecan to treat colorectal cancer previously refractory or intolerant to irinotecan, and (3) as either a single agent or in combination with radiation therapy in patients with locoregional squamous cell carcinoma of the head and neck (Imclone, Inc & Bristol-Myers Squibb, 2010). Antitumor response rates in heavily pretreated patients with colorectal cancer approximate 20%. EGRF is also overexpressed in multiple other solid tumor malignancies, but studies to date have not shown adequate clinical response to warrant new indications for this agent. Although the colorectal cancer indication stipulates that patients must overexpress EGRF receptor tumors, immunohistochemistry testing in these patients is no longer required because response rates have not been associated with receptor status. Patients with squamous cell head and neck cancer have demonstrated a 10% to 15% response to cetuximab as a single agent, and significantly enduring (30-month) responses of 30% to a cetuximab–radiation combination.

Cetuximab is administered as a 2-hour loading dose of 400 mg/m^2, followed by a 1-hour weekly infusion of 250 mg/m^2, and is well tolerated by most recipients. When given with radiation therapy, the first dose is administered a week before the start of radiotherapy. The most common adverse effect, occurring in 85%–90% of patients, is an acne-like rash with dry or cracking skin that can be a dose-limiting toxicity if it becomes infected (Tan & Chan, 2009). A severe infusion-related reaction with bronchospasm, stridor, urticaria, and hypotension has been reported in 3% of patients except in specific geographic regions where the severe reaction rate may be as high as 25% (Chung, 2008). Potentially fatal interstitial lung disease has been reported, but occurrence is extremely infrequent (Peerzada et al, 2010; Hoag et al, 2009). Significant

hypomagnesemia that begins within two weeks of starting treatment and may persist for up to 8 weeks after treatment conclusion has been recognized as a manifestation of renal tubular injury (Imclone, Inc & Bristol-Myers Squibb, 2010). Safety of this agent in children, pregnant or lactating women, and the elderly has not been established. An in-line filter is used for administration.

Panitumumab

Panitumumab (Vectibix) is a fully human monoclonal antibody that binds to the ligand-binding site of the extracellular domain of the EGFR, causing effects similar to cetuximab (Martinelli et al., 2009). This agent has been licensed for use in patients with metastatic colorectal cancer that has progressed on or following fluoropyrimidine-, oxaliplatin-, and irinotecan-containing regimens. This agent is administered as 6 mg/kg diluted in 100 mL and given intravenously over sixty minutes every two weeks. Infusional reactions are rare because of the human origin of this antibody, although other adverse effects of EGFR inhibition such as rash, hypomagnesemia, and interstitial pneumonitis are similar to those seen with other EGFR antagonists.

Alemtuzumab

Alemtuzumab (Campath 1-H) is humanized monoclonal antibody directed against the CD52 cell surface antigen of the lymphocytic cells of patients with B- and T-cell chronic lymphocytic leukemia (CLL). This medication is indicated as single-agent first-line therapy all patients with CLL having 17p deletion in at least 20% of the malignant cell line, or for patients over 70 years of age even without 17p deletion. It is also acceptable second-line therapy in alkylating-agent or fludarabine-refractory chronic leukemias or low-grade lymphoma because many of these diseases are histopathologically difficult to differentiate from one another (Hallek et al, 2008). It is administered as a daily 2-hour infusion with dose escalation until toxicity is reached; then therapy is begun three times weekly on alternate days. The first dose is 3 mg, and when this dose is tolerated with minimal toxicity, the dose is increased to 10 mg daily, until tolerated. Once 10 mg per day is tolerable, the patient is given the planned maintenance dose of 30 mg three times a week for a 12-week course (Bayer Healthcare Pharmaceuticals, 2009). More recent studies with a broader range of hematologic malignancies, including the peripheral T-cell lymphomas and adult T-cell leukemia, have shown equivalent efficacy with reduced adverse effects when this agent is administered subcutaneously in the same dose and frequency of administration (Moccia & Ghielmini, 2008). The most common adverse effects are related to lymphopenia and infections associated with suppressed lymphocytes (e.g., *Pneumocystis jerivichi* or *cytomegalovirus*). Prophylactic trimethoprim-sulfamethoxazole DS twice daily three times per week is used to protect against *pneumocystis jirovechi*, and famciclovir 250 mg twice daily is taken as herpes virus prophylaxis. Patients are at risk for cytomegalovirus (CMV), but the approach to prophylaxis varies with the patient's past history of CMV, and their total lymphocyte count. Other bone marrow components may also be suppressed, and infusion-related allergic reactions may also occur, although they are less frequent with SC administration. Injection site erythema and edema are transient, becoming less severe after a few weeks. Lymphocyte counts can be monitored weekly to determine the need to discontinue therapy early, and many patients receive antimicrobial prophylaxis against viruses (acyclovir) or *Pneumocystis* species (e.g., sulfamethoxazole-trimethoprim) (Morrison, 2009).

Ofatumumab

Ofatumumab (Arzerra™) is a fully human monoclonal antibody licensed by the FDA in 2009, and indicated for fludarabine-resistant CD20 positive chronic lymphocytic leukemia. Its use in rituximab-refractory non-hodgkins lymphoma has also shown considerable promise (Zhang, 2009). It binds to a variable epitope of the CD20 molecule, creates direct antibody cytotoxicity through complement activation, and disassociates more slowly, perhaps conferring benefit even rituximab does not control CD20 growth. It appears to even have affinity for cells that have low CD20 expression (Ostenborg, 2010). Like other monoclonal antibodies causing infusional reactions and antibody-induced cytotoxicity, patients receive premedication with acetaminophen, diphenhydramine, and corticosteroids 30 minutes prior to administration, and gradual infusion rate escalation as tolerated. It is administered as progressive dose escalation starting at 300 mg for the initial dose, followed one week later at 2000 mg weekly for seven doses, then 2000 mg every four weeks for four doses (GlaxoSmithKline, 2010). The most common adverse effects are related to leukocyte suppression, with fever, and infectious complications leading the list. Other reported adverse effects include: rash, nausea, and diarrhea.

Abciximab

Abciximab (ReoPro) is a monoclonal antibody and is actually a fragment called the Fab fragment. Unlike the prototype, rituximab, it does not have an antitumor function. It binds to a glycoprotein receptor on human platelets and inhibits their aggregation, leading to reduced hemostasis. The circulating half-life after IV bolus injection is 30 minutes, although clinical effects are evident for about 48 hours. In some patients, antiplatelet activity persists for up to 10 days. Many patients receive a 6- to 12-hour continuous IV infusion after the initial bolus to maintain optimal antiplatelet activity. Abciximab is used with a number of cardiovascular conditions, such as ischemic heart disease, or after percutaneous coronary interventions in which antiplatelet activity is desired. It is administered as an IV infusion before planned procedures or at the onset of unstable angina. It may be contraindicated in patients with a recent history of stroke, major surgery or trauma, GI or genitourinary bleeding, vascular deformities, or uncontrolled hypertension. The primary adverse effect associated with abciximab is increased risk of bleeding.

Palivizumab

Palivizumab (Synagis) is a monoclonal antibody like rituximab; unlike rituximab, it has a unique function. This monoclonal antibody has been developed by recombinant DNA technology to be directly cytotoxic to the respiratory syncytial virus (RSV), reducing the number of viral organisms in the lower respiratory tract. It is administered as prophylaxis in neonates at high risk for developing life-threatening pulmonary disease if infected with RSV (e.g., premature infants, children with cystic fibrosis). Its use in treating confirmed RSV infection has not been established. It is contraindicated in adults in whom serious illness with RSV infection has not been documented. It is administered as a monthly IM injection given fall through spring and has a half-life of 18 to 20 days. The reconstituted drug does not contain a preservative and should be administered within 6 hours of reconstitution. Common adverse effects include infection with other organisms, worsening respiratory symptoms, GI upset, hepatic dysfunction, injection site erythema, and flu-like syndrome. The serum blood levels of alanine aminotransferase and aspartate transaminase may be elevated as a consequence of treatment with this agent.

Denosumab

Denosumab (Xgeva) is a new monoclonal antibody licensed late in 2010 that binds to the RANK ligand that is a transmembrane protein essential to formation and function of the osteoclasts. Its similarity to rituximab is in its affinity for a specific transmembrane receptor, but it produces a very different clinical effect. Osteoclasts are known for their activity in dermineralizing and weakening bone. This process is upregulated in patients with solid tumors and bone metastases and multiple mveloma with bone involvement. Administration of denosumab as a 120 mg subcutaneous injection monthly has been shown to reduce the time to skeletal related events such as pathologic fractures. This agent is a pregnancy category C and has not been tested in children. The most common adverse effects are fatigue, nausea, hypophosphatemia and hypocalcemia. Uncommonly osteonecrosis of the jaw and immunogenicity due to antibodies against this protein have occurred (Henry et al., 2011).

Drugs Significantly Different From P Rituximab

Monoclonal antibodies significantly different from rituximab include muromonab-CD3, infliximab, basiliximab, and daclizumab. These drugs are significantly different because unlike the prototype rituximab, which targets the B lymphocytes, they target T lymphocytes to produce therapeutic immune suppression or have attached molecules such as radioactive substances, chemotherapy agents, or toxins.

Muromonab-CD3

Muromonab-CD3 (Orthoclone OKT3) is used to prevent allograft rejection in patients who have undergone renal transplantation and to treat steroid-resistant acute allograft rejection in heart and liver transplants. Muromonab-CD3 is a murine monoclonal antibody to the T3 complex of T cells. It acts on the T cell as an antigen and disables it. Muromonab-CD3 is available only for IV use.

Muromonab-CD3 is assigned to pregnancy category C. It is contraindicated in patients with known allergies to the drug or any murine product and in cases of fluid overload. It should be used cautiously in patients with fever (give antipyretics before drug administration) and in those previously on muromonab-CD3, because serious reactions can occur.

The most common adverse effects of muromonab-CD3 are nausea, vomiting, diarrhea, tremor, fever, chills, dyspnea, and chest pain. Potentially serious adverse effects include acute pulmonary edema and cytokine-release syndrome (flu-like symptoms progressing to shock).

Muromonab-CD3 combined with other immunosuppressants poses a serious risk of infection and lymphoma. To decrease this risk, the dosage of other immune suppressants should be reduced and then returned to previous levels 3 days before muromonab-CD3 treatment is finished. Encephalopathy and CNS effects are risks when muromonab-CD3 is combined with indomethacin (Indometh); therefore, this combination should be avoided.

Daclizumab

Daclizumab (Zenapax) saturates a subunit of the IL-2 receptor (Tac subunit), thus inhibiting IL-2–mediated cellular responses known to be important in allograft rejection. It is indicated as part of a three- or four-drug regimen for prophylaxis of acute organ rejection in adults receiving their first cadaveric kidney transplant. It is currently undergoing human trials for prevention and treatment of allograft rejection with other solid-organ and bone marrow transplants. It is dosed at 1 mg/kg and administered within 24 hours before transplantation, then every 14 days for a total of 5 doses. It effectively binds at the Tac subunit for as much as 120 days when the serum levels are 5 to 10 mg/mL. It has the same precautions and gender and age recommendations as basiliximab. Immunosuppression is the most important adverse effect; however, as with other immunosuppressive monoclonal antibodies, GI distress is common. Hypertension is agent specific and reported in both children and adults.

Basiliximab

Basiliximab (Simulect) is a monoclonal antibody that is an IL-2 receptor antagonist. It acts by binding to and blocking the CD25 antigen receptor site; this site is active in the cellular immune response involved in allograft rejection. Basiliximab is licensed as part of an immunosuppressive regimen that includes cyclosporine with or without corticosteroids for preventing organ transplantation rejection in patients undergoing renal transplantation. More effective immunosuppression without significant rejection or need for prolonged immunosuppressive therapy has led to increased use of this agent in these patients (McKeage & McCormack, 2010). It is administered as an IV infusion over 20 to 30 minutes, 2 hours before

transplantation surgery and 4 days after surgery. The average duration of immunosuppressive IL-2 receptor blockade activity is 36 days. Readministration after initial therapy with basiliximab has not been studied, but excess immunosuppression or hypersensitivity reactions are projected. Pediatric patients in whom it has been used have demonstrated slower renal clearance, although no appreciable differences have been noted between adults and the elderly. This agent has not been tested with pregnant or lactating women, because IL-2 is known to cross the placenta, and great risk to the fetus has been suspected. The most common adverse effects relate to the infection risk associated with the immunosuppressive regimen; however, GI symptoms such as nausea, vomiting, and diarrhea have also commonly occurred (McKeage & McCormack, 2010). Occasional reports of headache, tremors, insomnia, and electrolyte disorders warrant careful assessment within 48 hours of therapy.

The following three agents are monoclonal antibodies attached to radioactive substances that attach to tumor cells and either target them for recognition on scan or enhance tumor-specific cell lysis. All agents require special handling procedures appropriate to radiopharmaceutical use by professionals. Reasonable limitations on exposure of bodily fluids with others are advised, although all radiolabeled monoclonal antibodies emit beta rather than gamma emissions; hence, fewer precautions are necessary. Patients may be advised to wash their dishes or clothes separately, or to flush the toilet two times after use, or to use condoms for sexual relations (Hendrix, 2004). These measures are suggested to avoid exposing family members to the small amount of radioactive substance that may be emitted.

Infliximab

Infliximab (Remicade) is a monoclonal antibody, a chimeric human-murine IgG antibody that acts by blocking tumor necrosis factor (TNF). It is licensed for treating moderate to severe Crohn's disease. Its safety and efficacy have not been established in children or in pregnant or lactating women, or beyond three doses. It is also licensed for use with methotrexate to treat rheumatoid arthritis in patients who do not respond to methotrexate alone. In studies with this disease, more than 50% of patients achieved clinical remission, with a tolerable toxicity profile. Infliximab is administered once as a short IV infusion; in severe Crohn's disease, it is readministered on a monthly basis for a total of three doses. Because of its low toxicity profile, many allogeneic bone marrow transplantation protocols have been established to evaluate the efficacy of this agent in this population. The most common adverse effect is an infusion-related allergic-type reaction that includes fever, chills, pruritus, dyspnea, chest pain, and hypotension. Skin reactions such as rash, eczema, dry skin, acne, sweating, and flushing are also common. Autoimmune antibodies that produce a lupus-like syndrome have been reported and warrant discontinuing the drug. Infliximab is incompatible with polyvinyl chloride tubing and should be mixed in glass bottles and administered through polyethylene line infusion sets.

Eculizumab

Eculizumab (Solirus) is a chimeric monoclonal antibody that binds to the complement protein C5, inhibiting cleavage of the a and b components, preventing formation of C5b-9 that causes the hemolysis of paroxysmal nocturnal hemoglobinemia (PNH). Eculizumab is indicated for patients with PNH and refractory, persistent hemolysis (Alexion Pharmaceuticals, 2009). It is administered as a 600 mg 35 minute infusion weekly for the first 4 weeks, followed by 900 mg every 2 weeks until disease exacerbation or unacceptable toxicity is reached. The most serious adverse effect of therapy is meningococcal infection, so patients are advised to receive meningococcal vaccination at least two weeks prior to starting therapy. Other adverse effects include headache, nasopharyngitis, back pain, fatigue and nausea. Adverse effects are well tolerated. Since it is unclear that ecuclizumab therapy alters thrombotic risk, anticoagulation therapy should be continued as prior to treatment.

Satumomab Pendetide

Indium-111 (^{111}In) satumomab pendetide (OncoScint CR/OV) is a murine monoclonal antibody that is unlike the prototype because it is bound to indium and targets tumor-associated glycoprotein but does not have properties that initiate cell lysis. This agent is used during lymphoscintigraphy to detect microscopic extrahepatic colorectal or ovarian cancer, although tumor types (e.g., breast, non–small cell lung, esophageal, gastric, pancreatic cancers) have also shown some sensitivity to its actions. It is not indicated as a screening tool for any of these diseases. After IV injection, serial nuclear scans detect the distribution of this radiolabeled monoclonal antibody. It is eliminated by natural metabolic pathways, with about 10% cleared through the kidneys over approximately 56 hours, but in some cases, it can be detectable for up to 120 hours. This agent has not been studied in children or in pregnant or lactating women, and it is therefore not recommended for use in these groups. Data are limited, but no clear contraindication exists for using this agent in the elderly. Preparation to administer this agent includes a laxative or enema to prevent nuclear localization in stool within the colon that could interfere with interpretation of the scans performed after injection of the antibody. Common adverse effects are similar to those for other monoclonal antibodies, but because satumomab pendetide is a murine-based product, allergic and late antibody reactions may also occur.

Tositumomab Plus Iodine-131

Tositumomab plus ^{131}I (Bexxar) is a murine antibody directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes. It is indicated to treat CD20-positive follicular non-Hodgkin lymphoma that has relapsed after chemotherapy and has been refractory to rituximab. Because most of the tositumomab plus ^{131}I is renally cleared, serum blood urea nitrogen (BUN) and creatinine levels are checked before administration, and creatinine clearance is calculated if renal function is potentially impaired. Treatment

with this radiolabeled monoclonal antibody involves a two-step plan involving a dosimetric step, in which a priming dose of 450 mg tositumomab is administered intravenously over 1 hour, followed by administration of ^{131}I tositumomab (5 millicurie [mCi] ^{131}I combined with 35 mg tositumomab) intravenously over 20 minutes. Whole-body scans for biodistribution must be obtained within 1 hour of the end of infusion of ^{131}I tositumomab and before the patient voids. This process is repeated once between days 2 and 4, with scans after the patient voids, and again on day 6 to 7. These serial scans verify biodistribution of the monoclonal antibody carrier before a therapeutic dose of radiation is administered. At about the seventh day, tositumomab is again administered as a 450-mg dose, followed this time by ^{131}I and tositumomab, 35 mg, designed to deliver 75 cGy of whole-body radiation.

Because hypothyroidism is a common clinical effect with tositumomab plus ^{131}I, all eligible patients must receive thyroid-blocking agents from 24 hours before the dosimetric dose until 14 days after the therapeutic dose, to protect against permanent thyroid destruction (Estes & Clapp, 2004). Prolonged myelosuppression has been reported, particularly if the patient's disease involves the bone marrow. Consequently, baseline and weekly CBCs are monitored for bone marrow tolerance. As with other murine proteins, severe or persistent hypersensitivity reactions may occur. The safety of future vaccines and antibody therapy may be compromised in the patient who receives this drug, because of the creation of antimurine antibodies (Estes & Clapp, 2004). This therapy is not recommended for children and pregnant or lactating women.

Yttrium-90 Ibritumomab Tiuxetan

^{90}Y ibritumomab tiuxetan (Zevalin) is licensed as a two-step therapy similar to tositumomab, but rituximab is used as the monoclonal antibody carrier. In the dosimetric phase, rituximab is administered as a 250-mg/m^2 dose by IV infusion with a graduated infusion rate, as is done routinely with this agent. Four hours after the administration of rituximab, ^{111}In ibritumomab tiuxetan is administered intravenously over 10 minutes (dose of 5 mCi [1.6 mg total antibody dose]). Imaging for biodistribution is performed within the first 2 to 24 hours, between 48 and 72 hours, and optionally between 90 and 120 hours after the infusion. Initially, it was recommended that if biodistribution is acceptable, a therapeutic infusion should be administered between days 7 and 9, with the rituximab dose unchanged, but the ^{111}In ibritumomab tiuxetan administered as 0.4 mCi/kg (14.8 megabecquerels/kg [actual body weight of ^{90}Y ibritumomab tiuxetan; maximum dose is 32 mCi, or 1184 MBq]). More recent studies have shown that the dosimetry step is unnecessary in heavily pretreated patients, and patients may safely move straight to therapeutic doses. Infusion-related reactions are prevented by administering premedications. The most common adverse reactions involve suppression of bone marrow function and its clinical effects. Infection and bleeding caused by leukopenia or thrombocytopenia are more common when the patient's disease involves the bone marrow. Patients are cautioned to implement radiation precautions for 3 days after tositumomab is administered.

KINASE INHIBITORS

Kinase inhibitors include tyrosine kinase inhibitors, mTOR inhibitors proteasome inhibitors, and histone deacetylase inhibitors. They work on a specific type of cell involved in cancer reproduction. Extracellular tumor targets include: epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF-1, 2 and 3), platelet-derived growth factor beta (PDGF-beta), and transforming growth factor alfa (TGF-alfa). Intracellular tumor targets that have been identified include: platelet-derived growth factor (PDGF-alfa), hypoxia-inducible factor (HIF), c-Raf, b-Raf, and transforming growth factor (TGF).

Tyrosine kinase inhibitors are small molecules that prevent signal transduction, usually by interfering with binding of ATP. They vary in their affinity for various receptors and consequently have differing spectra of activity and adverse effects. Intracellular tyrosine kinase pathways branching from the RTK receptor include the RAS and RAF pathways and the P13K-Akt pathway. The P13K-Akt pathway is commonly mutated in malignancy (Ciuffreda et al., 2010). The prototype kinase inhibitor is imatinib (Gleevec).

Agents that can be inhibit multiple growth pathways are thought to have multiple anti-tumor effects, and may not only destroy tumor cells through their extracellular targets, but also target activities known to give rise to malignant transformation (Wood & Manchen, 2007). These agents are classified as multikinase inhibitors. The two multikinase inhibitors currently FDA licensed are sorafenib and sunitinib, both for primary or secondary treatment of metastatic renal cell carcinoma. They are discussed as drugs significantly different from the prototype.

Drug–drug interactions can be unpredictable and complicated with these drugs. Health care professionals need to be knowledgeable about the clinical pharmacokinetics of these drugs when prescribing and administering to minimize complications. More detailed information is described with each individual drug in this chapter.

Nursing Management of the Patient Receiving P Imatinib

Core Drug Knowledge

Pharmacotherapeutics

Imatinib is a "small molecule" tyrosine kinase inhibitor. "Small-molecule" drugs block specific enzymes and growth factor receptors involved in cancer cell growth. These drugs are also called signal-transduction inhibitors. Imatinib mesylate is an oral drug licensed by the FDA to treat GI stromal tumor (a rare cancer of the GI tract), Philadelphia chromosome positive chronic myeloid leukemia (CML) and acute lymphoblastic leukemia (ALL).

Pharmacokinetics

Imatinib is well absorbed and has a mean absolute bioavailability of 98% after oral administration with an elimination half life of about 18 hours. Imatinib is primarily eliminated in the feces as metabolites. Dose adjustments may be necessary for hepatic impairement, renal impairment, neutropenia, thrombocytopenia, and severe fluid retention.

Pharmacodynamics

Imatinib mesylate inhibits bcr-abl tyrosine kinase which is created by the Philadelphia chromosome abnormality. This drug induces apoptosis in bcr-abl positive cell lines as well as fresh leukemic cells from Philadelphia chromosome positive CML. It is also an inhibitor of platelet-derived growth factor, c-kit, and stem cell factor (SCF).

Contraindications and Precautions

Imatinib may be associated with edema. Patients should be weighed regularly and assessed for signs of fluid retention that could be severe (e.g. pleural or pericardial effusions or ascitis). The risk of edema increases with higher doses of Imatinib and age greater than 65 years. Imatinib is associated with myelosuppression and a complete blood count should be used to monitor patients on a regular basis. Combining Imatinib with chemotherapy can result in an increase in these toxicities. Gastric irritation can occur with Imatinib. The drug should be taken with food and water to minimize this problem. Imatinib is a pregnancy category D drug. Caution should be taken when Imatinib is administed with strong CYP3A4 inhibitors. CYP3A4 inhibitors may decrease metabolism and increase concentrations of imatinib. Concomitant warfarin administration should be avoided in patients receiving this drug. Grapefruit juice should also be avoided as it may increase concentrations of imatinib.

Adverse Effects

As previously mentioned the most common toxicities associated with Imatinib are fluid retention which is treated by holding (or discontinuing if severe) the drug or administering diuretics. Another significant toxicity is myelosuppression. The severity of myelosuppression is related to the stage of the patient's disease in chronic myelogenous leukemia patients and usually occurs in the first few months of therapy. Severe congestive heart failure and left ventricular dysfunction have been reported most commonly in patients with comorbid conditions or risk factors. Hypothyroidism can be exacerbated in patients who are on levothyroxine replacement or those who have had a thyroidectomy. TSH levels should be closely monitored in these cases. Gastrointestinal bleeding can occur and is associated with gastric intestinal stromal tumor (GIST) sites that become friable and necrotic as they are destroyed. Patients taking imatinib may also experience muscle cramps, rashes and fatigue while on this therapy.

Drug Interactions

CYP3A4 inhibitors may decrease metabolism and increase concentrations of imatinib. CYP3A4 inducers may decrease concentrations of imatinib. Enzyme-inducing anti-epileptic drugs such as carbamazepine, phenytoin, fosphenytoin and Phenobarbital can reduce the AUC of imatinib. Acetaminiphen levels may be increased if taken concurrently with imatinib. See also Table 55.2.

Assessment of Relevant Core Patient Variables

Health Status

A thorough history and physical exam should be conducted to monitor for fluid retention, myelosuppression and cardiac toxicities during treatment. Patient's home medications, including any over the counter or complimentary therapies, should be screened on an ongoing basis to avoid drug interactions.

Life Span and Gender

Imatinib can cause fetal harm when administered to women who are pregnant. Imatinib is introduced into breast milk as an active metabolite. Breast feeding while on imatinib is not recommended. The safety of imatinib has been established in children over the age of 2 years. Patients over the age of 65 in clinical trials demonstrated similar toxicities with the exception of a higher incidence of edema.

Lifestyle, Diet, and Habits

Discuss the importance of monitoring for edema or other signs of severe fluid retention or cardiac abnormalities.

TABLE 55.2 Agents That Interact with P Imatinib

Interactants	Effect and Significance	Nursing Management
carbamazepine, phenytoin, fosphenytoin, phenobarbital	Reduces the AUC	
acetaminophen	Imatinib may increase acetaminophen levels	Monitor for increased liver toxicity. Ensure acetaminophen maximum dose allowed is not exceeded.
warfarin	Metabolized by CYP3A4	Avoid use in patients receiving imatinib. Utilize low molecular weight or standard heparin instead.

Note: CYP3A4 inducers decrease imatinib C_{max} and AUC. CYP3A4 inhibitors increase imatinib C_{max} and AUC.

Patients may need to modify their medication regimes to ensure optimal imatinib absorption or reduced interference of other drugs by imatinib.

Environment

Because imatinib is an oral drug patients can self administer this therapy as outpatients. Patient compliance should be monitored closely during treatment. Home safety to ensure other members of the family are not exposed to this hazardous agent may include instructions to not share eating utensils, store medications in a safe place, or double flush the toilet after use.

Nursing Diagnoses and Outcomes

- Risk for edema related to adverse effects of imatinib
  Desired outcome: *The patient will be absent of edema. The patient will state reportable signs and symptoms of edema or severe fluid retention.*
- Risk for Infection and Bleeding related to depression of bone marrow function
  Desired outcome: *Bone marrow recovery will be attained; rare and mild myelosuppression might occur. The patient will verbalize and also implement self-care measures to prevent infection.*

Planning and Intervention

Maximizing Therapeutic Effects

Imatinib should be taken orally with food and a large glass of water. Doses between 400 and 600 mg should be administered once daily. Doses of 800 mg should be administered in divided doses of 400 mg twice daily. This is important to decrease iron exposure as the tablet coating contains iron. For patients who cannot take oral tablets, the tablet(s) can be placed in 50 mL of juice or water and stirred until dissolved. The suspension must be taken orally immediately after tablet is disintegrated.

Minimizing Adverse Effects

Assess for signs of fluid overload and heart failure (e.g., weight gain, dyspnea, shortness of breath, edema, fatigue). Prevent exposure to people with infections. Evaluate for infection if a low grade fever (greater than 100.5°) develops. Assess complete blood count on a regular basis. Severe hepatic impairement requires dose reductions of imatinib by at least 25%. Renal impairment defined as CrCL 20 to 39 mL/min, should be dose reduced by 50%. Doses greater than 600mg are not recommended for mild renal impairment (CrCL 40 to 59 mL/min. Imatinib may be held or dose reduced for hematologic toxicities at the discretion of the provider consider disease state and goals of therapy.

Providing Patient and Family Education

- Discuss signs and symptoms of edema and severe fluid retention. Teach importance of routine weight assessment and reporting weight gain.
- Teach patients to report any rash or pruritis and how to implement supportive care measures for management.
- Stress the importance of regular laboratory tests to monitor for toxicities
- Teach patients measures to avoid infection resulting from myelosuppression and signs and symptoms to report that might indicated the presence of an infection (e.g., temperature greater than 100.5, redness, pain, drainage from any site, or chills.
- Instruct the patient to notify the provider for any gastrointestinal pain or bleeding.
- Discuss with patients and their significant others both reproductive goals and birth control.
- Discuss the importance of avoiding any new medications such as over the counter medications or complimentary therapies until discussing in detail with provider.

Ongoing Assessment and Evaluation

Patients should be closely monitored to ensure compliance with this oral therapy. Fluid retention should be assessed for at each visit and diuretics administered if necessary.

Drugs Closely Related to P Imatinib

Dasatinib (Sprycel)

Dasatinib is also approved for Philadelphia chromosome positive CML and for Philadelphia chromosome positive acute lymphocytic leukemia (ALL). Dasatinib works similarly to imatinib and is used for patients who are refractory to imatinib. Dasatinib should be used with caution in patients who have QT prolongation. The impact of this adverse effect can be reduced by providing electrolyte replacement to ensure the serum potassium level is greater than 4.0mEq/L and the magnesium is greater than 2.0 mEq/L. Antacids and H2 antagonists may decrease dasatinib concentrations.

MEMORY CHIP

P Imatinib

- A tyrosine kinase inhibitor that targets special mechanisms of cancer cell growth. Used in the treatment of GI stromal tumor, Philadelphia chromosome positive chronic myeloid leukemia, and acute lymphoblastic leukemia.
- Most common adverse effects: fluid retention and myelosuppression
- Most serious adverse effects: heart failure and left ventricular dysfunction
- Maximizing therapeutic effect: take orally with food and a large glass of water
- Minimizing adverse effects: assess for fluid overload and heart failure; monitor complete blood count regularly
- Most important patient education: teach to monitor for signs/symptoms of fluid overload (e.g., weight gain, dyspnea, shortness of breath, edema); teach to avoid infections and report any low grade fever (greater than 100.5°)

Nilotinib (Tasigna)

Nilotinib is indicated for newly diagnosed Ph+ CML. The mechanism of action is similar to other drugs in this category. Nilotinib and dasatinib are also used in patients who show resistance to one of the other drugs in this category. Nilotinib has a black box warning related to QT prolongation and sudden deaths. Hypokalemia and hypomagnesemia should be corrected prior to administering nilotinib. Drugs that prolong QT interval and CYP34A inhibitors should be avoided. Patients should avoid food 2 hours before and 1 hour after taking nilotinib. Nilotinib should be taken with water only, twice daily and capsules should not be opened.

Drugs Significantly Different from P Imatinib

Many of the other tyrosine kinase inhibitors primarily work by inhibiting the cellular action of growth factors. Other kinase inhibitors include drugs such as erlotinib (Tarceva), gefitinib (iressa), lapatinib (Tykerb), sunitinib (Sutent), sorafenib (Nexavar), pazopanib (Votrient). These drugs work in various solid tumors including; breast, lung and renal cancer.

Erlotinib (Tarceva)

Erlotinib is indicated for non-small cell lung cancer and advanced, unresectable, metastatic pancreatic cancer in combination with gemcitabine. Erlotinib inhibits EGFR. Erlotinib tablets should be taken on an empty stomach at least one hour before or two hours after food. The most common adverse effects include mild to moderate rashes, mucositis, fatigue, nausea, vomiting, infection, dyspnea and diarrhea. Cigarette smoking decreases erlotinib plasma concentrations and should be avoided. Corneal ulceration or perforations have been reported in patients receiving erlotinib. Abnormal eyelash growth and kerititis have been observed. A rare but potentially life threatening toxicity of erlotinib is interstitial lung disease and pneumonitis.

Gefitinib (Iressa)

Gefitinib is licensed by the FDA for the continued treatment in responding patients with locally advanced or metastatic non–small-cell lung cancer after failure of platinum and docetaxel failures. Currently the optimal use of gefitinib is under investigation. It appears that in non-small cell lung cancer patients that have EGFR mutations this drug may provide benefit, investigation is currently underway. Being a non-smoker, having a bronchioloalveolar carcinoma and being female has been found to be associated with EGFR mutations. (Marchetti, et al., 2005). Gefitinib is only available in the United States through a mail order pharmacy using an access program developed by the pharmaceutical company that makes the drug. This drug targets the epidermal growth factor receptor, which is overproduced by many types of cancer cells. The most significant toxicity with gefitinib is interstitial lung disease which can be fatal. Patients present with acute onset of dyspnea, which may be associated with cough, or low grade fever. If interstitial disease is diagnosed gefitinib should be discontinued. Gefitinib is administered once daily as a tablet with or without food. See Box 55.1.

Lapatinib (Tykerb)

Lapatinib has a unique dual action and blocks tyrosine kinase receptor for epidermal growth factor receptor and HER2 receptors. Lapatinib is approved for use in advanced or metastatic breast cancer whose tumor overexpress HER2 in combination with Xeloda (capecitabine). Lapatinib should be taken once daily at least one hour before or one hour after a meal. Capecitabine is to be taken with food or within 30 minutes of taking food. Adverse effects include decreases in left ventricular ejection fraction, hepatotoxicity, severe diarrhea, interstitial lung disease and pneumonitis. Other toxicities are similar to the prototype drug. A rare but potentially life threatening toxicity of erlotinib is interstitial lung disease and pneumonitis.

BOX 55.1 FOCUS ON RESEARCH

Gefitinib First Line for Patients with Advanced Non-Small-Cell Lung Cancer with Egfr Mutations Shows Improved Progression-Free Survival when Compared to Standard Chemotherapy.

Maemondo, M., Inoue, A., Kobayashi, K., et al. (2010). Gefitinib or Chemotherapy for Non-Small-Cell Lung Cancer with Mutated EGFR. *N Engl J Med,* 363:2380–2388.

The Study

230 patients with metastatic, non-small-cell lung cancer and EGFR mutations with no prior history of receiving chemotherapy were randomized to receive gefitinib or carboplatin-paclitaxel. The primary end point of this study was progression-free survival. Additionally they studied overall survival, response rate and toxicities. The interim analysis demonstrated that progression free survival was significantly longer in the group that received gefitinib compared to the group that received chemotherapy (10.8 months versus 5.4 months). The median overall survival was 30.5 months in the gefitinib group and 23.6 months in the chemotherapy group. The gefitinib study group experienced rash (71.1%) nad elevated aminotransferase levels (55.3%) and the chemotherapy group experienced neutropenia (77%), anorexia (56.6%), sensory neuropathy (54.9%), and anemia (64.6%). One patient who received gefitinib experienced fatal interstitial lung disease.

This study demonstrates the importance of identifying specific populations of patients who respond to therapies, determining factors that improve sensitivity and selecting those who are more likely to benefit from a drug therapy than others. This allows for a more focused approach while minimizing the risk of administering unnecessary treatments to nonresponders which increases the likelihood of toxicities.

Sorafenib (Nexavar)

Sorafenib is indicated for unresectable hapatocellular carcinoma and advanced renal cell carcinoma. Toxicities of sorafenib are similar to sunitinib. Sorafenib tablets are administered twice daily without food (1 hour before or 2 hours after a meal). Drug interactions with UGT1A1, UGT1A9, CYP2B6, CYP2C8 and CYP3A4 substrates can occur increasing the drug AUC. Other drugs that increase sorafenib AUC when administered concurrently include doxorubicin, docetaxel, and fluorouracil. Immunosuppression, hypertension, hand and foot syndrome, diarrhea and fatigue are also common toxicities. Rarely cardiac toxicity has been reported. Additional laboratory values that can be affected include amylase, lipase, (both increase) and phosphorous (decreases).

Sunitinib

Sunitinib (sutent) is licensed for GIST after disease progression or intolerance to imatinib and for patients with advanced renal cell cancer. Sunitinib is given orally in capsules. Sunitinib is primarily metabolized by the cytochrome P-450 enzyme, CYP3A4 and is eliminated via the feces and urine (60% and 16 % of the administered dose, respectively). The terminal half life of sunitinib is 40 hours. Sunitinib may be taken with or without food. Dosage forms are 12.5, 25, and 50 mg capsules. Sunitinib inhibits multiple tyrosine kinases including VEGF, SCF, PDGFR, FLT-3. This causes inhibition of the growth of tumor cells and pathologic angiogenisis. Sunitinib can cause prolonged QT intervals and hypokalemia and hypomagnesemia should be corrected. Electrocardiograms should be monitored before and during treatment. The most frequent adverse effects are fatigue, diarrhea, nausea, mucositis, dyspepsia, abdominal pain, constipation, hypertension, congestive heart failure, rash, hand-foot reaction, skin discoloration, taste changes and bleeding. Bleeding characterized by tumor related hemorrhage has been reported. Thrombolytic events may occur with sunitinib and patients should be thoroughly assessed for deep vein thrombosis/pulmonary embolism and be instructed on reportable signs and symptoms. Skin discoloration can occur secondary to the yellow coloring in the capsules. Depigmentation of the hair and skin can occur with sunitinib. Blood pressure should be measured prior to and weekly during Sunitinib therapy due to the risk of hypertension. Pre-existing hyprtension should be resolved prior to starting therapy to help ensure that the full treatment can be administered without dose-limiting hypertension. Baseline assessment of thyroid function should be performed and treatment initiated if necessary as sunitinib can cause thyroid dysfunction.

Pazopanib (Votrient)

Pazopanib is indicated for the treatment of renal cell carcinoma. Hepatic impairment can occur and pazopanib is not recommended in patients with severe hepatic impairement. Toxicities are similar to the prototype drug however; additional side effects include arterial thrombotic events and protenuria. Pazopanib is administered orally once daily with food (at least 1 hour prior or 2 hours after a meal). The dose should not exceed 800 mg. Tablets should not be crushed due to the potential for rapid systemic absorption. Doses should be reduced for hepatic impairment. Discontinue at least 7 days prior to surgery due to the potential for decreased wound healing. Safety of pazopanib in pediatric patients has not been established.

MTOR-I INHIBITORS

A significant receptor on the P13K-Akt arm of intracellular kinase leads to the mammalian target of rapamycin (mTOR) pathway that enhances cell division. When this agent binds with the KBP-12 protein, a complex is formed that inhibits mTOR signaling, and enzymes responsible for cell cycle regulation, cell motility and angiogenesis are impaired. Some early research suggests that inhibition of cell motility may reduce metastatic potential or rate (Zhou & Huang, 2010). The mTOR pathway is also essential for fat and lipid metabolism, influencing metabolic regulation of these essential nutrients. This target is also highly expressed in lymphocytes, and has been the focus of the transplant immunosuppressive rapamycin, hence serious immunosuppression is associated with medications in this class. Drugs in this class are noted for risk for opportunistic infections and idiopathic pneumonitis. There are currently two licensed agents classified as mTOR inhibitors. (Feldman & Shokat, 2010).

MTOR-I Inhibitors: Temsirolimus, Eversirolimus

Temsirolimus (Torisel)

Temsirolimus (Torisel™) was the first mTOR inhibitor to be licensed by the FDA in 2007 as treatment for advanced or metastatic renal cell carcinoma. In a comparison trial to standard therapy with interferon, it offered more than double the objective response rate and a longer duration of response. It is less clear where this agent is placed in therapy options for newly diagnosed disease due to availability of two multikinase inhibitors and another mTor inhibitor. It is administered as an initial dose of 25 mg infused over 30 to 60 minutes once a week until disease progression or unacceptable toxicity is experienced. Premedication 30 minutes prior to therapy with 25 to 50 mg diphenhydramine or its equivalent is recommended (Abraham, 2007). If infusion reaction occurs, corticosteroids with redosing of diphenhydramine may be administered and the infusion resumed at a slower rate (Wyeth Pharmaceuticals, 2010). Concomitant use of known inducers of the P-450 3A4 metabolic pathway should be avoided, or the dose of temsirolimus increased to 50 mg. If inhibitors of CYP 3A4 are administered, temsirolimus may be dose-reduced to 12.5 mg. Medication and over the counter remedies should be assessed frequently to quickly detect those that may interfere with temsirolimus blood levels. Like other anti-angiogenic agents, this medication should not be administered to patients during the perioperative period. Although

not specifically recommended in prescribing information, other agents' precautions suggest a 28 day period before or after surgical intervention. Common adverse effects include: infection, rash, fatigue, oral mucositis, edema, nausea, loss of appetite, and renal impairment. Because of its effects on metabolism, hyperglycemia and hyperlipidemia commonly occur during therapy and necessitate frequent ongoing laboratory monitoring of glucose and triglycerides. Although rare, interstitial lung disease and idiopathic bowel perforation can occur and require prompt assessment of distressing respiratory or gastrointestinal symptoms. Temsirolimus administered concomitantly with sunitinib demonstrated dose-limiting toxicities and is not recommended (Wyeth, Inc, 2010).

Eversirolimus (Afinitor)

Everolimus (Afinitor™) is the first oral mTor Inhibitor available and was licensed in 2009 for treatment of advanced renal cell carcinoma after treatment with sorafenib and sunitinib. Patients who have progressive disease while on or within 6 months of the multikinase inhibitors are eligible to receive everolimus (Coppin, 2010). This agent inhibits the mTOR pathway in two distinct locations producing reduced cell proliferation, cell division, metabolism and angiogenesis. It is similar to temsirolimus in both action and adverse effect provide. Administered as a once a day 10 mg oral agent, it is essential to provide thorough patient and family education regarding conscientious administration and follow-up with providers as well as home chemotherapy safety.

OTHER INHIBITORS

The discovery of additional mutagenesis pathways are contributing greatly to our knowledge of malignant disease and its therapeutic targets. Other licensed targeted therapies that inhibit cellular processes include proteasome inhibitors and histone deacetylase inhibitors. A proteasome inhibitor is bortezomib (velcade) and the histone deacetylase inhibitors include zolinza (vorinostat) and Istodax (Romidepsin). Each has unique targets and limited clinical indications at present, but it is anticipated that more will be licensed for use in the upcoming years.

PROTEASOME INHIBITORS

Bortezomib (Velcade)

The first apoptosis-inducing drug to be approved by the FDA was bortezomib (Velcade), which is indicated for treatment of multiple myeloma in both up-front and relapsed disease (Stadtmauer, 2010). It has also been licensed for treatment of refractory mantle cell lymphoma that have progressed after at least one other treatment. Apoptosis-inducing drugs cause cancer cells to undergo apoptosis (cell death) by interfering with proteins involved in the process. Bortezomib causes cancer cells to die by blocking enzymes called proteasomes, which help to regulate cell function and growth. Proteosomes in normal cells are also temporarily inhibited, but unlike malignant cells, they resume normal function within 72 hours. This medication should not be given to anyone who has a history of hypersensitivity to boron or mannitol. Bortezimib is administered 1.3 mg/m^2 as a 3 to 5 second IV push twice a week for two weeks in a row, followed by 10 days rest. It is important to space the twice weekly injections by at least 72 hours to allow for normal cell recovery. Each cycle comprises a total of 21 days, and up to eight cycles may be prescribed. This agent has been commonly associated with drowsiness, gastrointestinal distress, bone pain, peripheral neuropathy and bone marrow suppression. The platelet count nadirs around day 11, and the white blood cell count decreases shortly after. Anemia is a later and more chronic adverse effect. Less common but serious adverse events include hepatic dysfunction, hypotension, interstitial pneumonitis, and heart failure exacerbation. The most common causes of dose-reduction due to toxicity is due to bone marrow suppression, peripheral neuropathy, posterior reversible leukoencephalopathy (PRES), or hepatic failure. This medication interacts with the Cytochrome P-450 metabolic pathway, and all medications should be reviewed with each patient encounter (Millennium Pharmaceuticals, Inc, 2009).

HDAC INHIBITORS

Zolinza (Vorinostat)

Zolinza (vorinostat) is a drug in a new category of targeted drugs called histone deacetylase inhibitors (HDAC). Currently Zolinza is approved for refractory cutaneous T-cell lymphoma however, it is being studied in clinical trials for many different tumor types.

Zolinza is eliminated primarily through metabolism. Less than1 % of the drug was found excreted in the urine in clinical studies. The mean terminal half life was approximately 2 hours. Zolinza was not evaluated in patients with liver abnormalities. Furthermore Zolinza is not an inhibitor of CYP drug metabolizing enzymes making it less susceptible to drug interactions.

Zolinza works by inhibiting histone deacetylases. Vorinostat is thought to induce cell-cycle arrest and apoptosis and inhibit angiogenesis. It may also improve NK cell-mediated tumor immunity. The mechanism of action has not been fully characterized.

Zolinza is a category D drug and should not be given in women who are breast feeding. This drug has not been fully studied in patients with liver or renal impairment and thus should be used with caution in these populations. QT prolongation can occur and electrolytes should be monitored at baseline and ongoing. Gastrointestinal disturbances such as nausea, vomiting, anorexia, and diarrhea may occur and appropriate symptom management may be necessary. Pulmonary embolism or deep vein thrombosis were reported in clinical trials. Hyperglycemia was observed in patients receiving

Zolinza. Myelosuppression is an adverse effect with Zolinza. Thrombocytopenia and gastrointestinal bleeding can occur in patients who are on valproic acid concurrently. Prolongations of prothrombin time and international normalized ratio (INR) have been noted in patients receiving coumarin derivative anticoagulants in conjunction with Zolinza.

Baseline electrocardiogram should be evaluated prior to initiation of Zolina therapy. Contraception should be utilized to prevent fetal harm during treatment with Zolinza. Carefully assess a complete blood cell count, serum creatinine and electrolytes prior to and during treatment to monitor for toxicities. Zolinza is taken once daily with food. Capsules should not be opened or broken. Patients should be instructed to drink at least 2 liters of fluid per day to prevent dehydration. Assess patients for nausea and vomiting that may affect intake and increase the risk of dehydration. Before administering Zolinza ensure that electrolytes and complete blood counts are reviewed to ensure results do not preclude administration of the drug.

Assess QT interval and electrolytes prior to and during therapy. Hyperglycemia may occur in as many as 40% of patients. High risk patients include those with preexisting diabetes and treatment or modifications to existing diabetes treatment may be necessary. Antiemetics may be indicated for nausea and vomiting. Diarrhea should be treated after an infectious source is ruled out.

Istodax (Romidepsin)

Istodox is also approved for cutaneous T-cell lymphoma however, it is administered intravenously over 4 hours. The most common adverse reactions are nausea, fatigue, myelosuppression, vomiting, and anorexia, QT prolongation, and lymphopenia. Strong CYP3A4 inhibitors may increase concentrations of Istodax and should be avoided. Potent CYP3A4 inducers may decrease concentrations and should be avoided. Concurrent warfarin administration can prolong prothrombin time and INR.

CHAPTER SUMMARY

- The humoral immune system involves the interaction between cell surface antigens of B-lymphocytes and antibody formation. The antibodies stimulate an immune and inflammatory reaction to the antigen and cause its destruction.
- Antibodies can be used to target malignant cell clones, to modify T or B lymphocytes, or to alter normal cell effects. Antibodies are usually monoclonal, and attach to a specific destiny antigen to alter the normal actions of that cell.
- Current licensed monoclonal antibodies originate from murine antibodies, modified part-murine (chimeric) antibodies, or humanized antibodies.
- Hypersensitivity reactions are common with monoclonal antibody therapy. Antibodies without murine proteins produce fewer adverse effects and less risk for eliciting human antimurine antibodies (HAMAs) that preclude future therapy with other antibodies.
- Targeted therapies cause antineoplastic effects by selectively blocking a specific extracellular or intracellular receptor or metabolic pathway. Nurses administering these targeted antineoplastic agents understand how these targeted receptors and pathways cause tumor cell death.
- Subtypes of the targeted therapies have some common class effects based upon their similar targets.
- Several agents in the class of targeted therapies are oral. Patients should receive extensive education on taking oral therapy correctly and implementing chemotherapy protective strategies for their family and friends when at home.
- Many oral targeted therapies are metabolized by the CYP3A4 pathway and have a large number of drug-drug interactions to consider when planning nursing care.
- These drugs often cause adverse GI effects; therefore, efforts must be made to maintain nutritional status. A nutritional consultation, supplemental feedings, and small, frequent meals are often necessary.

QUESTIONS FOR STUDY AND REVIEW

1. What are the intracellular tumor targets for kinase inhibitors?
2. List two important considerations for patient taking kinase inhibitors.
3. How do targeted therapies differ from traditional chemotherapy treatments?
4. Why are drug interactions significant with many of the kinase inhibitors?

Drugs That Are Cell Cycle–Specific

Learning Objectives

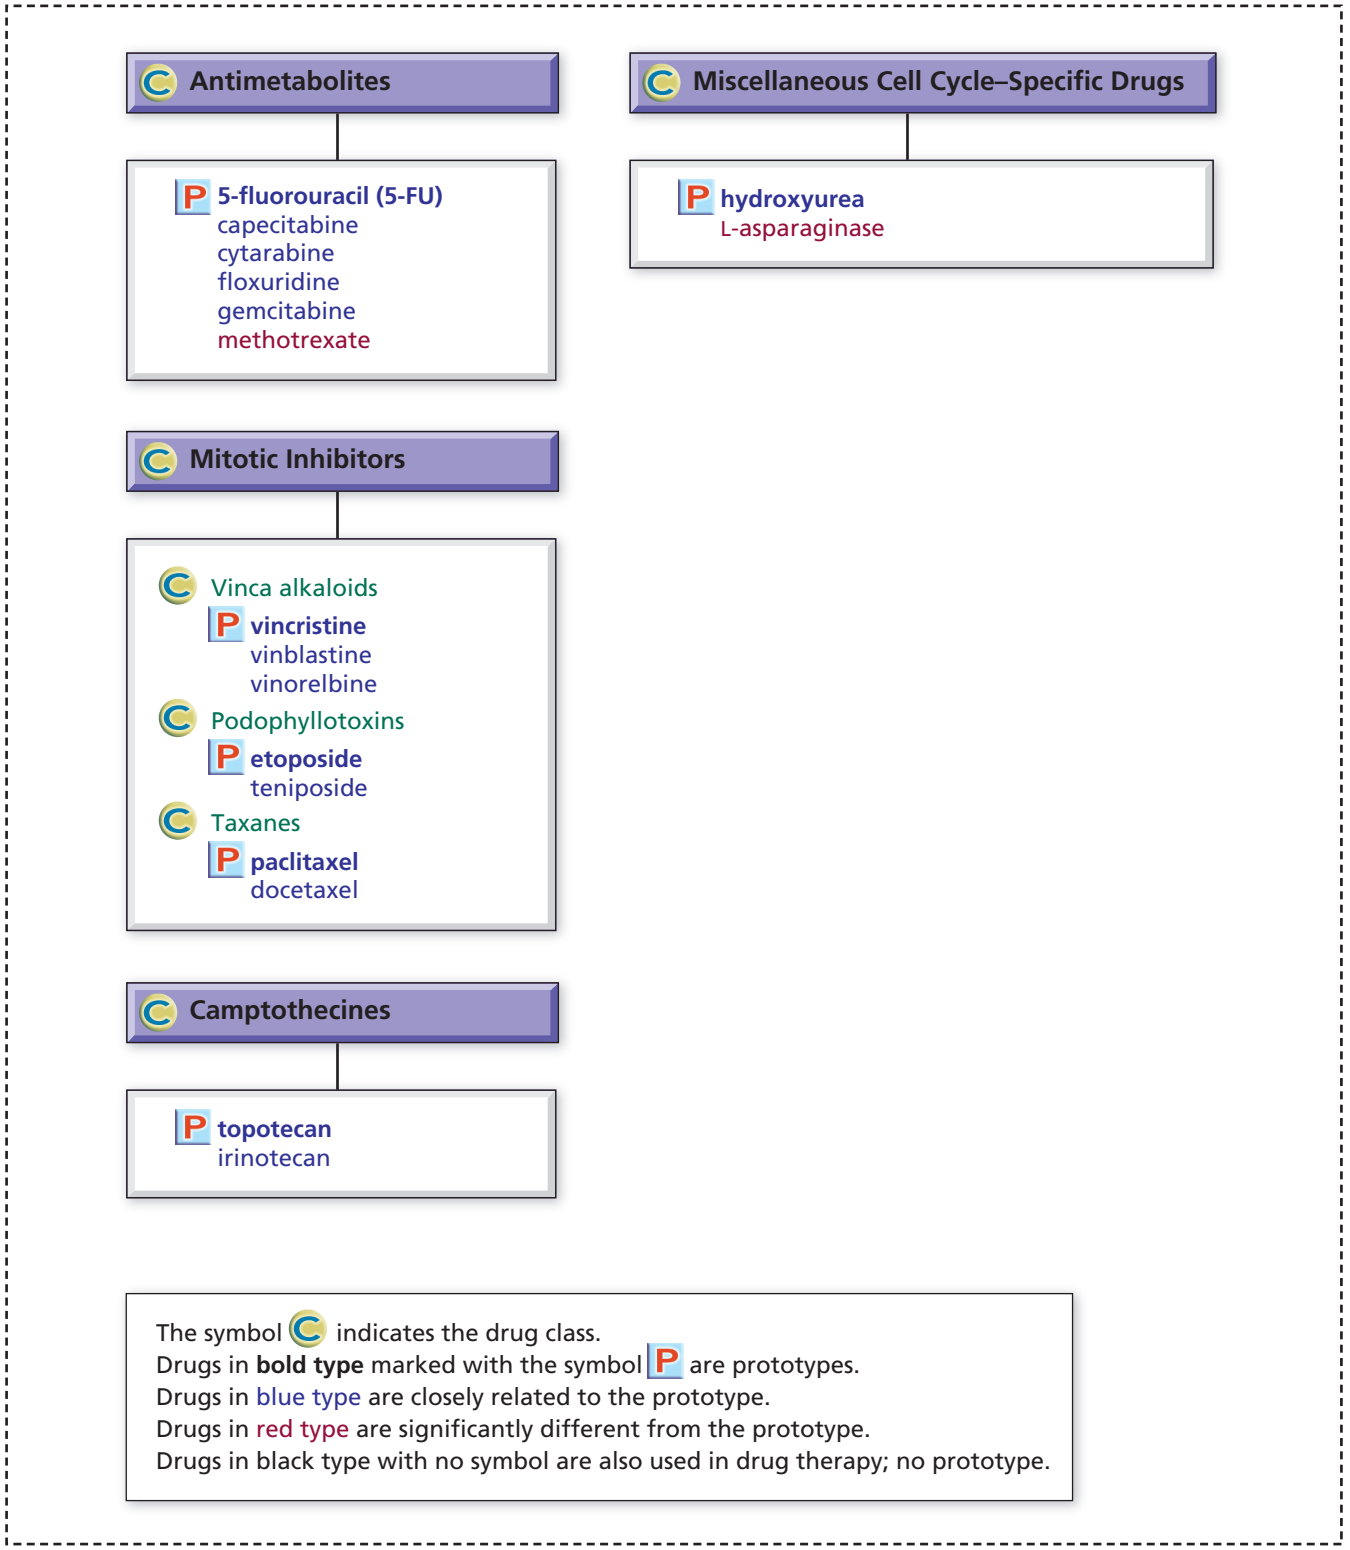
At the completion of this chapter the student will:

1. Understand the goals of treatment and the strategies used in chemotherapy.
2. Identify the phases of the cell life cycle and describe what happens at each phase.
3. Differentiate a normal from a malignant cell.
4. Explain the difference between a cell cycle–specific and a cell cycle–nonspecific chemotherapeutic agent.
5. Identify the different routes of administration for the various chemotherapeutic agents.
6. Describe precautions and practices to ensure safety, minimize exposure, and deal with untoward effects of chemotherapy to the patient, health care provider, and the environment.
7. Identify core drug knowledge about cell cycle–specific drugs.
8. Identify core patient variables relevant to cell cycle–specific drugs.
9. Relate the interaction of core drug knowledge to core patient variables for cell cycle–specific drugs.
10. Generate a nursing plan of care from the interactions between the core drug knowledge and core patient variables for cell cycle–specific drugs.
11. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for cell cycle–specific drugs.
12. Identify the potential effects of herbal medicine on chemotherapy.
13. Determine key points for patient and family education for cell cycle–specific drugs.

Key Terms

adjuvant therapy
cell cycle
cell cycle–nonspecific
cell cycle–specific
chemotherapy
consolidation therapy
cytokinesis
first-order kinetics
G_0 phase
G_1 phase
G_2 phase
generation time
growth fraction
induction therapy
intensification
irritant
maintenance
mitosis (M) phase
nadir
neoadjuvant therapy
palliative therapy
radiation recall
salvage therapy
synthesis (S) phase
vesicant

Drugs That Are Cell Cycle–Specific



Cancer remains the second leading cause of death in the U.S., behind heart disease, despite improvements in 5-year survival rates. Between 1984 and 1986, the five-year relative survival estimate was 53%. The latest estimates for the years between 1996 and 2002 showed improvement to 66%. According to estimates by the American Cancer Society, almost 1.5 million new cases of cancer will be diagnosed in the United States in 2009, and more than 500,000 people will die from the disease in that same year. This translates to almost 1,500 deaths each day from cancer.

Today, the treatment options for cancer include more choices than ever before. Novel agents that function differently from the familiar cancer regimens of radiation, chemotherapy, surgery, and biotherapy have generated a lot of research initiatives and hopes for cure. However, chemotherapy remains a vital part of the cancer armamentarium. **Chemotherapy** is the term that describes the use of cytotoxic agents (substances that are toxic to cells) that inhibit the growth, development, and proliferation of malignant cells. Sometimes the term *antineoplastic* is used instead of the term *chemotherapy*. Chemotherapy dates back to the 1500s, when heavy metals were used to treat cancers. Severe toxicities and few cures were reported. Since then, a vast spectrum of chemotherapeutic drugs has been discovered to achieve the goals of chemotherapy: cure, control, and palliation.

Unlike two other methods of treating cancer, surgery and radiation, chemotherapy produces a systemic effect. The chemotherapeutic drugs are transported by the bloodstream throughout the body, although most of these drugs do not cross the blood–brain barrier and therefore cannot reach the central nervous system (CNS).

Chemotherapy plays an important role in cancer therapy. It is the primary treatment for some cancers (Box 56.1) and serves as an adjunct to the other treatment methods. Chemotherapeutic agents may be administered as single agents or in combination regimens. They are used in the following treatment strategies:

- **Adjuvant therapy:** This therapy involves a short course of high-dose drug therapy (usually with a combination of drugs) administered after radiation or surgery to destroy residual tumor cells or micrometastases and prevent recurrence.
- **Induction therapy:** This term refers to the start of chemotherapy. As commonly used in treating hematologic cancers, induction consists of high-dose drug therapy (usually with a combination of drugs) given to induce a complete response when initiating a curative regimen.
- **Consolidation therapy:** This strategy consists of chemotherapy given after induction therapy has achieved a complete remission; the regimen is repeated to increase the probability of cure or to prolong patient survival.
- **Intensification:** After complete remission is achieved, the same agents used for induction therapy are given at higher (intensified) doses, or different drugs are given (also at high doses) to improve the chances of cure or longer remission.
- **Maintenance:** This therapy involves using low-dose cytotoxic drugs, singly or in combination, on a long-term basis in patients who are in complete remission, to delay regrowth of residual cancer cells.
- **Neoadjuvant therapy:** Chemotherapy is administered to reduce the tumor burden before surgery or radiation, to improve the outcomes of these methods by shrinking the tumor.
- **Palliative therapy:** This therapy involves the use of chemotherapeutic drugs to control symptoms, provide comfort, and improve the patient's quality of life if cure is not achievable.

Box56.1 ROLE OF CHEMOTHERAPY IN VARIOUS CANCERS

Primary Treatment

Chemotherapy is the primary treatment for the following localized cancerous neoplasms:

- Burkitt's lymphoma
- CNS lymphomas
- Hodgkin's disease (of childhood and some adult stages)
- Embryonal rhabdomyosarcoma
- Wilms' tumor
- Small-cell lung cancer
- Large-cell lymphomas

Future as a Primary Treatment

Chemotherapy holds promise as a future primary treatment for the following cancers:

- Breast cancer
- Esophageal cancer
- Non–small-cell lung cancer
- Nasopharyngeal cancer and other cancers of the head and neck
- Pancreatic cancer
- Prostate cancer
- Cervical carcinoma
- Gastric carcinoma

Treatment Before Surgery

Sometimes chemotherapy is the treatment used to shrink a tumor so that surgery can be less extensive and therefore less mutilating. Some cancers for which chemotherapy is used as a pretreatment include the following:

- Soft-tissue sarcomas
- Laryngeal cancer
- Anal carcinoma
- Bladder cancer
- Breast cancer
- Osteogenic sarcoma

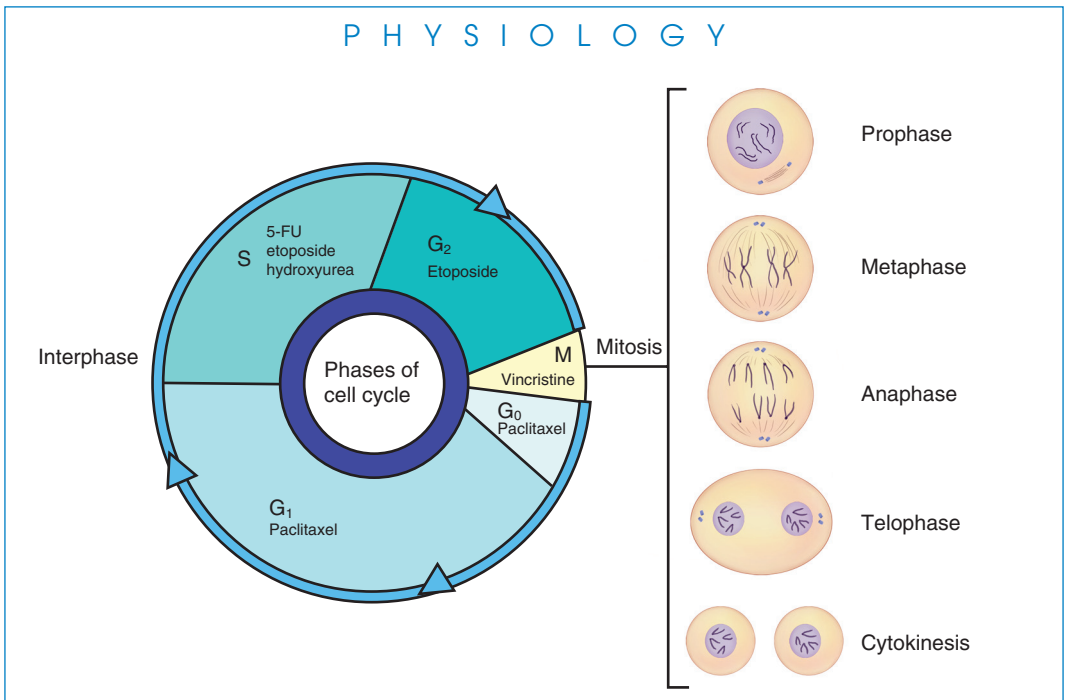
- **Salvage therapy:** This strategy involves the use of a potentially curative high-dose drug regimen given to a patient whose symptoms have recurred or whose treatment by another regimen has failed.

Nurses need to be equipped with a clear knowledge of cell physiology, cancer pathophysiology, routes of administration for chemotherapeutic drugs, safety guidelines for handling chemotherapeutic drugs, classifications of antineoplastic drugs, and the therapeutic and adverse effects (toxicities) of antineoplastic drugs so that patients' needs can be anticipated early. Armed with this knowledge and set of skills, the nurse will be able to assist the patient in navigating the often overwhelming challenges that the various treatment options offer. It is important to offer the best education for the patient and family so that the patient can be managed well within any clinical setting and be able to participate in his or her care and adhere to a treatment regimen with a clear understanding of the goals and expectations of treatment.

PHYSIOLOGY

Knowledge of cellular kinetics and the life span of the **cell cycle** is needed to understand how chemotherapy works. The cell is the basic structure of the human organism. Normally, cell growth is strictly regulated. The process by which a cell replicates itself, forming two identical daughter cells, is called cell division. Cell division, which is rare, occurs only to replace worn-out or dying cells and as part of the process of wound healing. Cell death is controlled, and when cells die, they are replaced in an orderly fashion. However, in cancer, the mechanisms for cell growth are disrupted, resulting in uncontrolled proliferation of cells. The time span over which a cell reproduces is called the cell cycle. The cell cycle has five phases: G_0, G_1, S, G_2, and M. All cells, whether normal or abnormal, progress through the different phases of the cell cycle. The complete cycle is illustrated in Figure 56.1.

The cell cycle is the cornerstone of cell cycle division and proliferation. Both normal and malignant cells undergo this process, which can last for approximately 25 to 30 hours. In the first phase, the **Gap 0 (G_0) phase** (also known as the resting phase), a cell can stay in a dormant or latent state for months or even years until stimulated to move forward in the cycle. Because certain cells divide more rapidly than others, some rest in the G_0 phase for a brief period, whereas others bypass the G_0 phase and directly enter the second phase, the **Gap 1 (G_1) phase,** if the body needs a certain cell immediately. During the G_1 phase, the cell increases in size and synthesizes ribonucleic acid (RNA) and the proteins needed for deoxyribonucleic



• FIGURE 56.1 Cell cycle. The cell cycle has five phases through which it passes in reproducing itself. The phases represented include G_0 (resting, nonreproductive phase), G_1 (waiting for reproductive stimulus), S (stimulus received; DNA and RNA assembled), G_2 (mitotic spindles constructed and RNA synthesized), and M (mitosis; cell division). Antineoplastic drugs with actions that occur in a particular phase of the cycle are known as cell cycle–specific drugs. Among these drugs are 5-fluorouracil, which affects the S phase of the cell cycle; vincristine, which affects the M phase (mitosis); etoposide, which affects the S and G_2 phases; paclitaxel, which affects the G_0 and possibly the G_1 phases; and hydroxyurea, which affects the S phase.

acid (DNA) synthesis. The time a cell spends in this phase varies and can last from hours to days, depending on the cell type.

After RNA and protein synthesis occur, the cell enters the third phase, the **synthesis (S) phase.** During the S phase, RNA, proteins, and enzymes necessary for DNA synthesis are formed. DNA contains the genetic code necessary for the growth and replication of the cell. DNA is an essential nucleic acid composed of deoxyribose, a phosphate, and four nitrogenous bases: adenine, guanine, cytosine, and thymine. Adenine and guanine are purines, and cytosine and thymine are pyrimidines. Chemical reactions occur between the two purines and between the two pyrimidines, leading to the formation of the double-stranded DNA helix, which serves as the genetic template of the cell. Generally, the synthesis phase lasts 8 to 12 hours.

The cell then enters the fourth phase, the **Gap 2 (G_2) phase,** during which more RNA and protein synthesis takes place in preparation for mitosis (cell division). In this phase, the cellular apparatus called the mitotic spindle is constructed. The G_2 phase lasts for approximately 2 hours. After the G_2 phase, the cell is ready to undergo cell division.

The fifth phase of the cell cycle is the **mitosis (M) phase,** which consists of the following orchestrated subphases: prophase, metaphase, anaphase, and telophase (see Figure 56.1). As the cell progresses through these subphases, the cytoplasm and nucleus divide, so that replication of the cell results in the birth of two daughter cells. When the nucleus divides, the cell's genetic material (chromosomes) is duplicated and distributed into the two daughter cells. The remainder of the cell (its cytoplasm) is also divided into the new daughter cells; this process is called **cytokinesis.** Each of these two new daughter cells will either pass through a new reproductive cycle or become arrested in G_0 and perform other cellular activities.

The time needed to complete the cell cycle, which varies with each type of cell, is called **generation time.** Tumors consisting of cells that have a short generation time or rapid mitotic rate are most sensitive to antineoplastic agents. Tumors that have cancer cells with a long generation time or slow mitotic rate are often resistant to chemotherapy.

Exactly how the body maintains normal cellular homeostasis is not clearly understood. The body is thought to possess a feedback system that signals a cell to enter the G_1 phase of the cell cycle in response to a neighboring cell's death. In individuals with cancer, this feedback system is dysfunctional, and the cancer cell enters the G_1 phase without prompting from the body's feedback system.

PATHOPHYSIOLOGY

Every cell in the body has a genetically programmed clock that directs the timing of its reproductive activity. Cancer is a disease in which the cells fail to respond to this clock, the homeostatic mechanism that controls the normal cellular birth and death processes.

Four basic features differentiate the cancer cell from the normal cell:

- Uncontrolled cell proliferation
- Decreased cellular differentiation
- Inappropriate ability to invade surrounding tissue
- Ability to establish new growth at ectopic sites

Although cancer cells have the same chemical structures as normal cells and undergo the same phases of the cell life cycle, the critical difference appears to be in their altered response to mechanisms that control growth and differentiation. Cell production in a cancer is not proportional to cell loss; production of new cells occurs at a faster rate than is needed to compensate for the loss of cells.

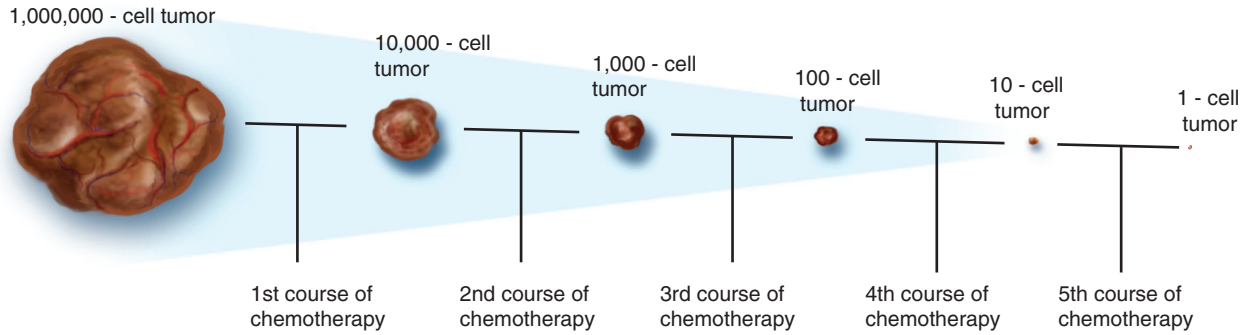
CELLULAR KINETICS OF CHEMOTHERAPY DRUGS

Most chemotherapy drugs exert cytotoxic activity primarily on macromolecular synthesis or function. In other words, they interfere with the synthesis of DNA, RNA, or proteins or with the appropriate functioning of the preformed molecule. When this interference happens, a proportion of the cells die. Chemotherapy works on the principle of **first-order kinetics:** the number of tumor cells killed by an antineoplastic drug is proportional to the dose used. The proportion of cells killed after chemotherapy administration is a constant percentage of the total number of malignant cells present. For example, if a tumor containing 1 million (1,000,000) cells is exposed to a chemotherapeutic drug that has a 90% cell kill rate, the first dose of chemotherapy destroys 90% (900,000) of the cancer cells, and 100,000 cells survive. The second dose kills another 90% of the remaining cells (90,000 cells), and 10,000 cells survive. Because only a portion of the cells die, doses of chemotherapy must be repeated to reduce the population of cancer cells until just one cell remains. The hope is that the body's immune response will kill the final cell. Figure 56.2 gives a visual explanation of the cell-kill theory.

ROUTES OF CHEMOTHERAPY ADMINISTRATION

As advances in chemotherapy occur, variations in the routes of administration continue to evolve. The choice of drug route depends on the therapeutic intent. Drug administration intravenously through peripheral or central lines (or both) is the method most commonly used for chemotherapy. Alternate routes of drug delivery to specific sites within the body, using devices or catheters, are becoming more popular in clinical practice. More oral formulations of cytotoxic agents are now available, in response to the changing nature of cancer to a chronic disease state; this makes it very convenient for patients to receive treatment at home less expensively, because less cost is incurred for health care personnel. This route presents different challenges for the clinician because adverse effects may be different or the ability of the patient

PHYSIOLOGY



• FIGURE 56.2 Cell kill theory. A set percentage of cells is killed after each dose of chemotherapy. The percentage killed is dependent upon the drug therapy. In this example, each course of chemotherapy kills 90% of cells in a cancerous tumor. After the fifth course of chemotherapy in this example, a 1-cell tumor remains; the patient's immune system would destroy this malignant cell.

to tolerate the therapy may vary. Table 56.1 lists the different methods of drug delivery, including traditional and alternate routes, and outlines the practice implications for nurses who participate in the care of patients using these various routes and treatment methods in cancer therapy.

HANDLING AND PROPER DISPOSAL OF CHEMOTHERAPY AGENTS

Over the past decade, more health care professionals than ever before have handled chemotherapy agents. The Oncology Nursing Society (2009) recognizes the potential hazard that chemotherapeutic drugs pose to nurses administering these drugs and has created recommendations to help protect nurses. The mutagenic and carcinogenic effects known to occur from repeated exposure have raised great concern regarding the potential long-term risks to health care professionals who are exposed to antineoplastic drugs. For health care professionals of childbearing age, potential teratogenic risks and fertility impairment are another concern. Genotoxicity involving chromosomal changes has been documented following exposure to chemotherapy agents. Some drugs are also known to cause organ damage to the skin, mucous membranes, and corneas. Accidental exposure in poorly ventilated areas has resulted in acute symptoms, including headache, nausea, dizziness, and skin, throat, or eye irritation.

Conflicting research findings regarding the suspected and unknown potential long-term effects of exposure to chemotherapeutic agents led to the establishment of advisory bodies that address exposure issues and recommend safe practice techniques for handling and disposing of these drugs. These advisory bodies are as follows:

- National Institute for Occupational Safety and Health (NIOSH)
- Occupational Safety and Health Administration (OSHA)
- American Society of Hospital Pharmacy (ASHP)
- Oncology Nursing Society (ONS)
- National Study Commission on Cytotoxic Exposure

The potential risk to health care professionals who handle chemotherapy agents and the body excreta of patients who have received these agents is unknown. Therefore, health care professionals must know the recommended precautions and implement them to minimize their potential exposure. According to the ONS guidelines, cancer chemotherapy should be administered by registered nurses who have successfully completed a course in chemotherapy administration. Exposure to chemotherapy can occur through the following routes: skin and mucous membrane absorption, inhalation, injection by needlestick, and ingestion.

Skin and mucous membrane absorption and inhalation can occur during the following activities:

- Opening a chemotherapy vial or ampule
- Eliminating air from a syringe filled with a chemotherapy agent
- Disposing of intravenous (IV) bags, bottles, syringes, and tubing used in administering these agents
- Disposing of the body excreta of patients who have received these drugs within the past 48 hours

Ingestion can occur through hand-to-mouth contact with the following items:

- Food (including such items as gum and mints)
- Cosmetics
- Cigarettes
- Equipment contaminated with chemotherapy agents

The recommendations made by these advisory bodies serve as guidelines, and therefore institutional policies for handling, administering, and disposing of chemotherapeutic agents may vary. Employees must be familiar with their own institution's policies and procedures and use them as precautionary measures to minimize their potential exposure.

TABLE 56.1 Administration Routes for Antineoplastic Drugs

Route	Advantages	Disadvantages	Potential Complications	Nursing Implications
Oral	Ease of administration	Inconsistency of absorption Redosing issues if the patient has emesis	Drug-specific complications (e.g., drug–herb–diet interactions)	Evaluate compliance with medication schedule. Teach patient handling techniques, drug-specific diet considerations.
Subcutaneous, intramuscular	Ease of administration Decreased side effects	Requires adequate muscle mass and tissue for absorption (may require more than 1 injection, based on the maximum recommended safe volumes for injections) Pain	Infection, bleeding	Evaluate platelet count Use smallest needle gauge possible. Prepare injection site with an antiseptic solution. Assess injection site for signs and symptoms of infection.
IV	Consistent absorption Required for vesicants	Sclerosing of veins over time	Infection, phlebitis, extravasation, tissue necrosis (vesicants)	Check for blood return before, during, and after administration of chemotherapy agentss Mandatory with vesicants..
Intra-arterial*	Increased dose directly to tumor with decreased systemic toxic effects	Requires surgical procedure or special radiography for device placement	Bleeding, embolism	Monitor for signs and symptoms of bleeding. Monitor partial thromboplastin time, prothrombin time.
Intrathecal,* intraventricular	More consistent drug levels in cerebrospinal fluid Bypass blood–brain barrier	Requires lumbar puncture or surgical placement of reservoir or implanted pump for drug delivery	Headaches, confusion, lethargy, nausea and vomiting, seizures (increased intracranial pressure)	Observe site for signs of infection. Monitor functioning of reservoir or pump. Assess patient for headache or signs of increased intracranial pressure.
Intraperitoneal*	Direct exposure of intra-abdominal metastases to drug	Requires placement of Tenckhoff catheter or intraperitoneal port	Abdominal pain, abdominal distention, bleeding, ileus, intestinal perforation, infection	Warm chemotherapy solution to body temperature. Check patency of catheter or port. Instill solution according to protocol—infuse, dwell, and drain or use continuous infusion.
Intrapleural	Sclerosing of pleural lining to prevent recurrence of effusions	Requires insertion of a thoracotomy tube	Pain, infection, fever	Monitor for complete drainage (or minimal drainage <100 mL/d optimal) from pleural cavity before instillation of drug. Following instillation, clamp tubing and reposition patient q10–15 min for 2 h (or as ordered). Attach tubing to suction for 18 h (or as ordered). Assess patient for pain, fever, or anxiety. Provide analgesic, antipyretic, and emotional support.
Intravesicular	Direct exposure of bladder surfaces to drug	Requires insertion of Foley catheter	Urinary tract infections, cystitis, bladder contracture, urinary urgency, allergic drug reactions	Maintain sterile technique when inserting Foley catheter. Instill solution, clamp catheter for 1 h, and unclamp to drain (or as ordered).

*Note: Specialized nursing education may be required for certain administration methods. Refer to individual state nurse practice acts and agency policies and procedures.

Recommendations to Minimize Exposure During Preparation, Transport, Disposal, and Storage of Chemotherapeutic Agents

To minimize exposure during preparation, transportation, disposal, and storage of chemotherapeutic agents, adhere to the following recommendations:

1. Prepare these in a primary engineering control (PEC), such as a biologic safety cabinet (BSC). These cabinets contain high-efficiency particulate air filters that pull and filter air away from the face of the person preparing the drug. It is recommended that these cabinets remain functioning 24 hours a day, 7 days a week, that they be vented to the outside, that they be cleaned daily with a 70% alcohol solution, and that they be serviced according to manufacturer's recommendations to ensure adequate performance.
2. During drug preparation, wear disposable, lint-free, long-sleeved, nonabsorbent gowns made with a low-permeability fabric. The gowns should have a solid front with tight-fitting elastic at the wrists and back closure to prevent skin exposure.
3. Use disposable, powder-free latex gloves that have been tested for use with hazardous drugs. Double gloving is recommended activities such as drug preparation, administration and handling of body excreta of patients who have received these drugs within a 48-hour period. Personnel who have latex allergy should use alternative products made with nitrile. Change gloves when soiled, torn, or punctured. Change gloves every 30 minutes when in continuous use.
4. Wear a mask with face shield whenever there is a possibility of splashing. Wear a NIOSH-approved mask when cleaning up spills.
5. Use a plastic absorbent pad to cover the work surface preparation area so that any droplet contamination is absorbed.
6. Prime IV lines for chemotherapy administration with a compatible non hazardous solution before the actual drug administration. Do not prime with the chemotherapy drug unless the infusion device has an in-line prime function to reduce the risk of aerosolization.
7. If more than a negligible amount of air exists in the syringe, return to the preparation area for removal of air using the BSC. Carefully connect and disconnect IV tubing containing antineoplastic drugs, and remove syringes from IV lines used for IV push administration. Remove empty chemotherapy bags or bottles when completed, leaving the spike intact, and dispose of in an approved hazardous waste container. Consider the use of a closed system transfer device when preparing and administering chemotherapy (e.g. Phaseal ®).
8. Use a needleless delivery system or Luer-Lok connection to prevent accidental disconnection.
9. Wash hands before and after handling antineoplastic agents to protect from exposure to hazardous drugs.
10. Never store food or beverages in a refrigerator used for chemotherapy storage, to reduce the risk of food contamination.
11. Avoid eating, drinking, applying cosmetics, or chewing gum in the vicinity of drug preparation/administration, to prevent ingestion of chemotherapy/hazardous materials.
12. Transport chemotherapeutic drugs in sealed bags to prevent spilling. Spill kits should be readily available to personnel who have been properly instructed in chemotherapy handling and exposure procedures.
13. Institute standard precautions when handling the blood, vomitus, stool, or bed linens of a patient who has received chemotherapy within the past 48 hours. Wear personal protective equipment, including mask with face shield if splashing may occur.
14. Flush the toilet with the lid down and flush twice after disposing of body fluids from patients who have received cytotoxic agents within the past 48 hours. Although this practice is not research based, this may be helpful for minimizing exposure of others from residual chemotherapy not effectively removed with low-flow toilets.
15. Cover the toilet with a waterproof shield or pad before flushing to reduce the risk of aerosolization of chemotherapeutic agents.
16. Dispose of all chemotherapy waste in impervious, leakproof containers dedicated for chemotherapy waste and not used for other hospital waste.
17. Instruct patients who receive chemotherapy at home to label drugs to indicate hazardous content and to store the drugs in areas where proper temperature will be maintained and where children cannot reach them.
18. All equipment contaminated with antineoplastic drugs must be disposed of in distinctly labeled hazardous waste receptacles or cleaned per institutional guidelines. These chemotherapy wastes should be disposed of in Environmental Protection Agency–approved landfill waste sites or incinerators.

Management of Chemotherapy Spills

To manage spills of chemotherapeutic agents, adhere to the following recommended sequence:

1. Post a sign immediately to warn people away from the exposed area.
2. Don two pairs of powder-free gloves, a disposable gown, and eye protection.
3. Wear a NIOSH-approved respirator.
4. Place an absorbent pad over the spill to contain it.
5. Pick up glass fragments with a scoop and dispose of them in a puncture-proof container.
6. Clean the area with a detergent three times, from the least contaminated to the most contaminated areas.
7. Rinse the absorbed spill area with clean water. Repeat the washing and rinsing.

8. Dispose of all cleanup equipment according to institutional policy for chemotherapeutic waste.
9. Document the spill according to institutional policy. The following data should be included in the documentation: name of chemotherapy agent and approximate volume spilled, how spill occurred, procedures followed to contain and clean up spill, and names of people who were exposed and of those who were notified of spill.

To expedite the handling of a spill and to minimize undue patient and employee exposure, well-equipped chemotherapy spill kits and staff trained in the proper procedure for cleaning spills should be readily available.

Measures for Accidental Exposure to Chemotherapy

To manage accidental exposure to chemotherapy, implement the following measures:

1. Eye contact: Immediately rinse the affected eye or eyes with copious amounts of water for no less than 15 minutes. Seek emergency treatment per institutional policy.
2. Skin contact: Immediately wash the area with soap and water. Refer to Material Safety Data Sheets (MSDS) for specific agents.
3. Clothing contact: Immediately remove the contaminated clothing; if skin contact occurred, wash all such areas with soap and water. Place soiled clothing in a plastic bag until it is laundered, and then wash it twice, separately from all other clothing. After laundering the clothing twice, put the machine through a separate wash-rinse cycle.
4. Bed linen contact: Immediately remove the linens and place them in a contaminated linen receptacle; then clean the mattress using a 70% alcohol solution. Once the alcohol dries, the bed may be remade with clean linens.
5. Complete institutional reporting and documentation requirements.

CLASSIFICATION OF ANTINEOPLASTIC DRUGS

Antineoplastic drugs are classified according to their mode of action and the phase of the cell cycle in which the drug is active. However, rapidly dividing cells are the most sensitive to these drugs. Chemotherapeutic drugs that are most effective during a particular phase of the cycle are known as **cell cycle–** (or cell phase) **specific,** whereas drugs that act independently of a specific cell cycle (or cell phase) are **cell cycle–nonspecific.** This classification is not absolute; the cytotoxic effects of the drugs likely involve more than one mechanism. Multiple intracellular sites might be affected, and the drugs' effects might not be confined to specific cycle events.

This chapter discusses the cell cycle–specific group of drugs (Table 56.2). Chapter 37 discusses the cell cycle–nonspecific group of drugs and targeted therapy. The cell cycle–specific drugs consist of the antimetabolites (prototype, 5-fluorouracil [5-FU]) and mitotic inhibitors. These drugs exert the greatest killing effect on tumors when given as a continuous infusion or in divided doses with a short cycle. The mitotic inhibitors are subdivided into the vinca alkaloids (prototype, vincristine), the podophyllotoxins (prototype, etoposide), and the taxanes (prototype, paclitaxel). Another category of cell cycle–specific drugs is called camptothecines (prototype, topotecan). A miscellaneous group of antineoplastic drugs, such as the prototype drug hydroxyurea and L-asparaginase, is also discussed in this chapter.

ANTIMETABOLITES

Antimetabolites are synthetic products that mimic the naturally produced metabolites, purines, pyrimidines, and folates that are essential for DNA and RNA synthesis. When the cell uses antimetabolites instead of the naturally occurring metabolites, cell death results. Because antimetabolites exert their cytotoxic activity during the S phase of the cell's life cycle, they are most effective against tumors that have a high **growth fraction.** The growth fraction of a tumor is the fraction of its cell population that is in any active phase of the cell cycle. Relatively quiescent tumors found in organs such as the pancreas and the uterus have low growth fractions, whereas rapidly proliferating tumors, such as those of the gastrointestinal (GI) mucosal epithelium and the hair follicles, have high growth fractions.

The prototype antimetabolite drug is 5-fluorouracil (5-FU, Adrucil), a pyrimidine antagonist that is a mainstay in chemotherapy.

Nursing Management of the Patient Receiving P 5-Fluorouracil

Core Drug Knowledge

Pharmacotherapeutics

The drug 5-FU interferes with DNA synthesis and, to a lesser extent, inhibits the formation of RNA. It has proved to be clinically effective against a wide spectrum of solid tumors, particularly malignant GI tumors. It is indicated for the palliative management of carcinoma of the colon, breast, liver, ovary, pancreas, rectum, head and neck, and stomach. It has been used in combination with cisplatin, irinotecan, oxaliplatin, bevacizumab and most often with leucovorin, which potentiates the action of 5-FU.

Dosage adjustments (see Table 56.2) are imperative for patients who develop severe toxicities. Patients must be monitored closely throughout therapy.

In addition to being administered intravenously (the most common route), 5-FU is given by intra-arterial infusion into the hepatic artery through a surgically implanted pump. The goal of this type of delivery is to supply a high concentration of the antineoplastic drug directly to the tumor and surrounding area while sparing the normal tissues from toxic effects. A topical form of 5-FU is also available and has been curative for basal cell carcinomas and other malignant skin cancers.

TABLE 56.2 Summary of Selected C Cell Cycle–Specific Antineoplastic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Antimetabolites			
P 5-fluorouracil (5-FU, Adrucil)	Carcinoma of colon, rectum, stomach, pancreas, breast, and ovary; hepatocellular carcinoma	*Adult:* IV, 12–15 mg/kg daily for 4 d/wk (maximum daily dose: 800 mg), then 6 mg/kg on days 6, 8, 10, and 12; maintenance, repeat first course q30 d Bolus, 400 mg/m^2 with irinotecan or oxaliplatin, followed by 2,400–3,000 mg/m^2 22-h infusion on days 1, 2, 15, and 16 *or* 2400 mg/m^2 46-h infusion on days 1 and 15	*Onset:* IV, immediate *Duration:* IV, 6 h $t_{1/2}$: IV, 18–20 min
	Skin cancer, superficial basal cell cancer	*Adult:* Topical, apply sufficient drug to cover affected area bid	*Onset:* Minimal absorption in topical use *Duration:* Unknown $t_{1/2}$: Unknown
capecitabine (Xeloda)	Metastatic colon cancer, breast cancer	*Adult:* PO, 1,250 mg/m^2 bid for 2 wk q21–28 d for 8 cycles or 1,000 mg/m^2 in combination with oxaliplatin for 2 wk q21–28 d. Lower doses may be used for esophagogastric or gastric cancers in combination with epirubicin, oxaliplatin or cisplatin.	*Onset:* Rapid (food decreases absorption) *Duration:* Unknown $t_{1/2}$: 30–60 min
cytarabine (Ara-C)	Acute myelocytic leukemia, acute lymphocytic leukemia (ALL), Hodgkin's and non-Hodgkin's lymphoma, CNS leukemia	*Adult:* IV, 100 mg/m^2/d by continuous infusion for 7 d; then 100 mg/m^2 q12h for 1–3 wk; high dose induction therapy, 3 g/m(2) IV infused over 1–3 hr every 12 hr for 2–6 d, intrathecal, 20–30 mg/m^2 (higher dose up to 75 mg/m^2 may be used to treat CNS disease). A liposomal cytarabine, DepoCyt can also be used at a dose of 50mg.	*Onset:* Rapid *Duration:* 12–18 h $t_{1/2}$: 1–3 h
floxuridine (FUDR)	Gastrointestinal (GI) adenocarcinoma with metastasis to liver, gallbladder, or bile ducts	*Adult:* Intra-arterial only, 0.1–0.6 mg/kg/d	*Onset:* Immediate *Duration:* 3 h $t_{1/2}$: 20 h
fludarabine (Fludara)	Chronic lymphocytic leukemia, non-Hodgkin's lymphoma (investigational)	*Adult:* IV, 25 mg/m^2/d for 5 d, q28d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 10 h
6-mercaptopurine (Purinethol)	Acute leukemia, chronic myelogenous leukemia (CML)	*Adult and child:* PO (induction and consolidation), 2.5 mg/kg/d; maintenance, 1.5–2.5 mg/kg/d	*Onset:* Varies *Duration:* Unknown $t_{1/2}$: 20–50 min
methotrexate (Mexate, Folex)	Hodgkin's lymphoma, non-Hodgkin's lymphomas; acute lymphoblastic and myelocytic leukemia; CNS metastasis; carcinoma of ovary, lung, cervix, testicle, breast; sarcomas; epidermoid carcinoma of head and neck	*Adult:* Trophoblastic neoplasms, PO/IM, 3–5 cycles of 15–30 mg/d for 5 d; leukemia maintenance, IV, 2.5 mg/kg q14 d or 15 mg/m^2 PO/IM 2×/wk; lymphoma, PO, 10–25 mg/d *High dose:* 8,000–12,000 mg/m^2 q2–4wk-only with urine alkalinization and leukovorin.	*Onset:* PO, varies; IV, rapid *Duration:* Unknown $t_{1/2}$: 2–4 h (high dose, 8–15 h)
6-thioguanine (Tabloid)	Acute myelocytic leukemia, chronic granulocytic leukemia	*Adult:* PO, 1–3 mg/kg/d	*Onset:* Slow *Duration:* 8 h $t_{1/2}$: 11 h
C Vinca Alkaloids			
P vincristine (Oncovin)	ALL, Hodgkin and non-Hodgkin lymphoma, CML, sarcomas, breast and small-cell lung cancers	*Adult:* IV, 1.4 mg/m^2/wk *Child:* 2.0 mg/m^2/wk; • Maximum single dose of 2 mg is seldom exceeded. INTRATHECAL ADMINISTRATION OF VINCRISTINE IS FATAL; vincristine is for intravenous use only	*Onset:* Varies *Duration:* Not available $t_{1/2}$: 5 min, then 2–3 h, then 85 h
vinblastine (Velban)	Hodgkin's disease, lymphocytic and histiocytic lymphomas, mycosis fungoides, advanced testicular cancer, breast cancer, squamous cell carcinoma of head and neck, Kaposi sarcoma	*Adult:* IV, 0.1 mg/kg to 6 mg/m^2 weekly; continuous infusion, 1.4–1.8 mg/d for 5 d • INTRATHECAL ADMINISTRATION OF VINCRISTINE IS FATAL; vincristine is for intravenous use only	*Onset:* Slow *Duration:* Unknown $t_{1/2}$: 3.7 min, then 16 h, then 24.8 h

TABLE 56.2 Summary of Selected C Cell Cycle–Specific Antineoplastic Drugs *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
vinorelbine (Navelbine)	Non–small-cell lung cancer, breast cancer combination with cisplatin	*Adult:* IV, 30 mg/m^2 weekly • INTRATHECAL ADMINISTRATION OF VINCRISTINE IS FATAL; vincristine is for intravenous use only	*Onset:* Slow *Duration:* Unknown $t_{1/2}$: 22–66 h
C Podophyllotoxins			
P etoposide (VePesid)	Refractory testicular tumors Small-cell lung cancer Other cancers	*Adult:* IV, testicular cancer, 50–100 mg/m^2/d for 5 d q3–4wk or 100 mg/m^2 on days 1, 3, and 5 *Adult:* IV, 35 or 50 mg/m^2/d for 5 d q3–4wk *Adult:* PO, twice the IV dose *Higher doses are used for acute leukemia treatment and as a preparatory regimen for stem cell transplantation.*	*Onset:* IV, 30 min; PO, 30–60 min *Duration:* IV/PO, 20–30 h $t_{1/2}$: 4–11 h
teniposide (VM-26, Vumon)	Childhood acute lymphoblastic leukemia	*Adult:* IV, 165 mg/m^2 with cytarabine 300 mg/m^2 2×/wk for 8 or 9 doses	*Onset:* 30 min *Duration:* Unknown $t_{1/2}$: 5 h
C Taxanes			
P paclitaxel (Taxol)	Metastatic carcinoma of the breast, ovary; small-cell lung cancer, Kaposi;s sarcoma	*Adult:* IV, 135–200 mg/m^2 over 3–24 h q3 wk *Low-dose:* 80 mg/m^2 over 1 h *Kaposi's sarcoma-* 135 mg/m(2) IV over 3 h every 3 wk; OR 100 mg/m(2) IV over 3 hr every 2 wk;	*Onset:* Rapid *Duration:* 6–12 h $t_{1/2}$: 5.3–17.4 h
docetaxel (Taxotere)	Breast, gastric, non-cmall cell lung cancer, head and neck cancer, metastatic prostate cancer	*Adult:* IV, 60–100 mg/m^2 q3 wk	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 11 h
C Camptothecines			
P topotecan (Hycamtin)	Metastatic carcinoma of the ovary, cervical cancer, non small cell lung cancer.	*Adult:* IV, 1.5 mg/m^2 for 5 d q3 wk	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 3 h
irinotecan (Camptosar, CPT-11)	Metastatic carcinoma of the colon or rectum in patients whose disease has progressed or recurred after 5-FU therapy. Also used investigationally in many other cancer types at lower doses.	*Adult:* IV, 125 mg/m^2/wk for 4 wk, then 2 wk rest. Dosage varies by protocol.	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 6 h
C Miscellaneous			
P hydroxyurea (Hydrea)	CML, malignant melanoma, inoperable carcinoma of ovary, squamous cell carcinoma of head and neck, sickle cell disease.	*Adult:* PO, for CML, 20–30 mg/kg as continuous therapy; for solid tumors, 80 mg/kg q3d or 20–30 mg/kg/d, 15 mg/kg daily for sickle cell disease- based on blood counts.	*Onset:* Varies *Duration:* 18–20 h $t_{1/2}$: 2–3 h
L-asparaginase (Elspar)	ALL, used investigationally for CLL, Hodgkin's lymphoma, lymphosarcoma	*Adult:* IV/IM, 200 IU/kg for 28 d; dosage varies with protocol	*Onset:* IM, varies; IV, 30–40 min *Duration:* Unknown $t_{1/2}$: 8–30 h

*Note: Antineoplastic drug dosages are calculated specifically for each patient based on his/her body surface area (BSA). The BSA is calculated from height and weight measurements and determined by using an institutionally approved BSA formula (e.g., Mosteller's formula = square root of [height in cm multiplied by weight in kg/3,600]) or an electronic conversion calculator. The Oncology Nursing Society does not recommend the use of a nomogram because of inaccuracy that can occur from distortion due to the copying of nomograms and difficulty of reading these charts. (need a disclaimer here about dosage ranges?)

Pharmacokinetics

After infusion, 5-FU distributes into tumors, intestinal mucosa, bone marrow, liver, and tissues throughout the body. It diffuses readily across the blood–brain barrier and distributes into cerebrospinal fluid (CSF) and brain tissue. The drug is extensively metabolized in the liver and excreted by the kidneys and lungs. The mean half-life of elimination from plasma is about 16 minutes, with a range of 8 to 20 minutes. The clearance of 5-FU is substantially lower in women than in men, whereas age has no appreciable effect on clearance in either gender. There is increased interest in pharmacokinetic dose adjustments when administering 5-FU due to the variability person to person when based soley on BSA. This approach used in the future may assist with minimizing toxicities while administering the maximum dose needed to reach therapeutic levels.

Pharmacodynamics

During the S phase, 5-FU exerts its maximum cytotoxic effects. It acts as a "false" antimetabolite, causing a thymine deficiency. This deficiency deprives the cell of DNA and RNA, which are essential for cell division and growth. The result is unbalanced growth and death of the cell. The deprivation of DNA and RNA is most marked in rapidly growing cells because these cells take up 5-FU at a faster rate.

Contraindications and Precautions

5-FU is a pregnancy category D drug. Whether it is excreted in human milk is not known, so caution should be exercised by women who are breast-feeding. The drug has demonstrated carcinogenic and mutagenic properties. The use of 5-FU is contraindicated in patients with poor nutritional status, depressed bone marrow function, and any known serious infection. The drug should not be administered to patients who have a known sensitivity to the drug. Patients with familial pyrimidinemia, an enzyme deficiency (dihydropyrimidine dehydrogenase enzyme deficiency), should not receive 5-FU because of the potential for severe neurotoxicity due to the inability to metabolize 5-FU.

Adverse Effects

Serious adverse effects of 5-FU include myelosuppression (evidenced by anemia, leukopenia, and thrombocytopenia), which is the dose-limiting side effect of 5-FU. The **nadir** is the period during which the maximum cytotoxic effect of the drug is exerted on the bone marrow, causing the lowest blood cell count. The white blood cell (WBC) nadir occurs within 10 to 14 days after the drug is given; recovery is within 21 days.

Cardiotoxicity is also an important rare but severe adverse effect of 5-FU. Cardiac events occur during the first 72 hours of the initial treatment cycle, manifested by angina, palpitations, sweating, and/or syncope. Electrocardiogram (ECG) changes, arrhythmias, pulmonary edema, myocardial infarction, (rarely) cardiac arrest, and severe but reversible cardiogenic shock have been noted with this drug.

Patients may also develop an acute cerebellar syndrome characterized by headache, disorientation, and nystagmus; this condition may persist after the drug is discontinued. Photophobia and ocular changes, such as increased lacrimation and blurred vision, may occur as well.

Other dose-dependent toxicities that can be mild to severe include nausea, vomiting, anorexia, diarrhea, and stomatitis. GI ulceration and hemorrhage can lead to death. Cutaneous changes can also occur: alopecia (hair loss; thinning of the hair); hyperpigmentation of the skin, hands, and vein along the site of infusion; brittle and cracking nails; maculopapular rash; and painful, erythematous desquamation and fissures of the palms and soles. Palmar–plantar erythrodysesthesia, also known as hand–foot syndrome, is also possible; symptoms include pain, swelling, numbness, tingling, and redness of the hands or feet.

Because 5-FU is known for its toxicity, patients who are at increased risk for these toxicities should be monitored vigilantly; for example, death from toxicity, anaphylaxis, angina, or thrombophlebitis can result even in patients who are relatively healthy. Patients with familial pyrimidinemia, an enzyme deficiency (dihydropyrimidine dehydrogenase enzyme deficiency), should not receive 5-FU because of the potential for severe neurotoxicity due to the inability to metabolize 5-FU.

Drug Interactions

A number of drug- drug interactions have been observed with 5-FU. A careful review of all of the patients medications should be done prior to starting 5-FU and periodically. Examples of drugs that cause interactions include; warfarin, phenytoin, and tamoxifen. 5-FU is incompatible with diazepam, droperidol, metoclopramide, ondansetron, and other chemotherapeutic drugs such as cytarabine, gallium nitrate, and vinorelbine. Leucovorin calcium may enhance the toxicity of 5-FU. Some drug–laboratory test interferences can occur with 5-FU administration, such as increased excretion of 5-hydroxyindoleacetic acid (5-HIAA); plasma albumin levels may decrease as a result of protein malabsorption. Table 56.3 lists drugs that interact with 5-FU.

Assessment of Relevant Core Patient Variables

Health Status

Before treatment begins, assess the patient's hematologic profile and document baseline neurologic status. Asses liver function prior to administration. Because GI alterations may occur with 5-FU dosing, check the patient's oral mucosa, bowel elimination patterns, and dietary habits. Review the patient's drug and hypersensitivity history, especially to 5-FU. Because of potential cutaneous changes, assess the condition of the patient's skin, nails, and hair. Monitor patients with a pre-existing cardiac disease closely.

Life Span and Gender

Explore the reproductive goals of the patient and assess women of childbearing age for pregnancy and lactation.

TABLE 56.3 Agents That Interact with P 5-Fluorouracil

Interactants	Effect and Significance	Nursing Management
thiazide diuretics: hydrochlorothiazide, chlorothiazide, chlorthalidone, benzthiazide, metolazone	Possible blood abnormalities	Notify physician for possible dose modification. Monitor hematopoietic status of patient.
cimetidine	Increased pharmacologic effect of 5-fluorouracil (5-FU)	Same as above.
leucovorin	Potentiates toxicity of 5-FU	Same as above.

Chemotherapy with 5-FU may cause fetal harm when administered to pregnant women. The drug has been found to be carcinogenic and mutagenic, and it can impair fertility. It is not known whether 5-FU is excreted in the breast milk; therefore, breast-feeding may be hazardous. Compare the benefits and risks to children. The safety and efficacy of 5-FU in children are not established.

Lifestyle, Diet, and Habits

One adverse effect of 5-FU is skin sensitivity to the sun. Ask the patient whether he or she engages in activities that cause undue exposure to the sun and what methods of sun protection are used. Assess the patient's feelings regarding hair loss—the major visible reminder that the patient is undergoing chemotherapy—and consider its effect on the patient's sexuality and body image. The possibility and actuality of hair loss can be very distressing, particularly if the patient has an active social and work life. Because of 5-FU's deleterious effects on the GI mucosa, obtain information on normal dietary intake and eating patterns, which might necessitate dietary modifications.

Environment

5-FU is given in both inpatient and ambulatory care settings. In some situations, 5-FU may be given as a continuous infusion through an ambulatory pump in the home setting. In these instances, explore whether the patient or significant other is ready to take on this responsibility and knows how to troubleshoot problems with the pump, should they arise.

Nursing Diagnoses and Outcomes

- Risk for Infection related to drug-induced suppression of bone marrow function
  Desired outcome: *The patient will be free from infection and exercise caution to avoid exposure to sources of infection.*
- Risk for Injury: Bleeding related to drug-induced suppression of bone marrow function
  Desired outcome: *The patient will recover adequate hematologic status and learn to recognize, monitor, and manage situations that might induce bleeding.*
- Imbalanced Nutrition: Less than Body Requirements, related to drug-induced nausea, vomiting, mucositis, and diarrhea
  Desired outcome: *The patient will maintain adequate nutrition with good emetic control and less frequent passage of stools. Patient will state proper oral mucosa care and self-care measures to manage pain or discomfort in the GI mucosa.*
- Disturbed Body Image related to loss of cutaneous integrity, as evidenced by alopecia and changes in skin and nails
  Desired outcome: *The patient will develop coping strategies (use of wigs, hair covering) to enhance appearance that may be distorted because of hair loss. In addition, cutaneous integrity will be sustained.*
- Disturbed Sensory Perception related to ocular changes, photophobia, and cerebellar ataxia
  Desired outcome: *The patient will be free from adverse effects resulting from oculomotor dysfunction.*

Planning and Intervention

Maximizing Therapeutic Effects

Do not exceed the 800-mg maximum daily dose of 5-FU. Reduce the dose if the patient has impaired liver function or poor nutritional status. Protect the drug from light and inspect it for precipitates before infusion. Make sure that the solution is stored at controlled temperature. If a precipitate caused by low-temperature storage occurs, restabilize the solution by heating it to 140°F, shaking it vigorously, and allowing it to cool down to body temperature before administration. A slight discoloration may occur during storage, which does not affect the potency and safety of 5-FU.

Minimizing Adverse Effects

Monitor the patient closely, hematologic and GI toxicities can be fatal despite dosage reductions. A WBC differential count should be obtained before each drug course. Treatment should be withheld if laboratory test values are below safe levels (e.g., absolute neutrophil count (ANC) less than 1,500 and platelets less than 100K). Carefully monitor patients with pre-existing cardiac conditions. Do not administer to patients with familial pyrimidinemia because of the risk of severe neurotoxicity.

If any of the following conditions occur, immediately notify the prescriber and consider discontinuing the drug:

- Mucositis (e.g., Stomatitis, esophagopharyngitis and perirectal cellulitis) (first visible sign)
- Leukopenia (WBC count less than 1,500 cells/mm^3)
- Thrombocytopenia (platelet count less than 100,000 cells/mm^3)

- Intractable vomiting
- Diarrhea
- GI ulceration and bleeding
- Bleeding from any site

Providing Patient and Family Education

Follow the guidelines described in Box 56.2.

- Explain that 5-FU requires special precautions to prevent chemotherapy from coming into accidental contact with patients or others.
- Give troubleshooting instructions if an alternative access device or an ambulatory infusion device is used at home.

BOX 56.2 COMMUNITY BASED CONCERNS

General Patient and Family Education for Chemotherapy

The nurse plays a pivotal role in providing adequate information to assist the patient/family with the new roles so that treatment outcomes will be achieved. After diagnosis, the treatment modality is discussed and chosen. For most cancers, chemotherapy is a significant benefit. The talking points for the nurse when called on to educate patients, irrespective of the type of chemotherapeutic agent used, include:

- Instruct patient about the significant side effects and reportable signs and symptoms of the chemotherapeutic agent(s).
- Emphasize self-management measures to be undertaken to prevent or decrease the side effects:
  - Practice good personal hygiene, wash hands frequently, and avoid sources of infection.
  - Maintain dietary intake of food and fluids. Refer to dietician for consultation.
  - Avoid trauma or injury and potential sources of bleeding by shaving with an electric razor, avoiding aspirin and other nonsteroidal anti-inflammatory drugs, and avoiding unnecessary injections, use of rectal thermometers, and venipunctures.
  - Check urine, stool, skin for signs of bleeding.
  - Practice good oral hygiene; use soft toothbrush, noncommercial (i.e., non-alcohol-based) mouthwashes, and lubricants.
  - Schedule appointments for blood tests and follow-up visits for chemotherapy and related medications.
- If the patient goes to other physicians, dentists, or another health care provider, patient should inform them of chemotherapy treatment.
- Teach patients the importance of relaxation techniques and other forms of complementary medicine from which they might benefit.
- Refer to other agencies and support groups as appropriate. Provide patient with a list of these resources.
- Instruct patients in the importance of maintaining a balance between rest and exercise to minimize fatigue.
- Explain to patient that some side effects of treatment are reversible and are thus not a sign of disease progression.
- If a patient is using chemotherapy drugs at home, teach the patient how to properly handle, store, and dispose of the agents and related materials.
- Encourage and support patient to accept a "new" baseline, especially in activities and responsibilities, imposed by demands of disease and treatment. Encourage patients to learn how to delegate and ask for assistance with activities of daily living.

Patients should also know whom to call and how to reach that person, in case of problems.

- Explain that nausea and vomiting may occur 3 to 6 hours after drug therapy is administered; provide an appropriate antiemetic regimen. The metallic taste of the drug may be minimized by sucking on hard candy.
- Instruct patients to observe the stools and notify the prescriber if stools are black or if blood is visible. Instruct the patient to notify the prescriber for loose stools including freqnecy and amount.
- Mouth sores may develop 5 to 8 days after drug administration. Offer helpful strategies such as practicing daily oral hygiene after meals and at bedtime, using a salt, baking soda and water rinse (1½ teaspoons of baking soda, 1 tsp salt to 1 quart of water), brushing with a soft toothbrush, avoiding alcohol containing mouthwashes, and gently flossing with unwaxed dental floss if the patient currently flosses. If bleeding occurs, flossing should be stopped until bleeding subsides.
- Caution patients not to use aspirin or any pain-relieving drugs containing aspirin without consulting the prescriber, to decrease the risk of bleeding following 5-FU therapy.
- Teach patients to self-assess for signs and symptoms of potential infection, check temperature, and report temperature spikes higher than 100.5°F.
- Suggest that patients apply moisturizer to the lips and to avoid irritating, very hot, cold, or spicy foods and beverages. Bland, cool, soft foods, such as yogurt, custards, gelatins, and puddings, may be less irritating.
- Help patients to understand that drug therapy produces photosensitivity. Instruct the patient to avoid the sun or protect the skin by applying a sunscreen (skin protection factor [SPF] = 15) and wearing protective clothing year round.
- Encourage patients to express their concerns about the effects of cutaneous changes on body image and assist in developing strategies to minimize the emotional impact. Offer cosmetic strategies, such as wearing nail polish to cover darkened, dry, brittle nails and using wigs, hats, and scarves to protect the scalp and prevent heat loss..
- Instruct patients to notify the physician if confusion or any visual disturbances occur.
- Advise women of childbearing potential about the possibility of harm to the fetus and about methods of contraception.

Ongoing Assessment and Evaluation

The main adverse effects of 5-FU therapy are alterations in the patient's hematopoietic system and GI functions. Therefore, monitor the patient's complete blood counts (CBCs) closely during each drug administration cycle to make sure that bone marrow recovery has occurred before another dose of the drug is given. Likewise, assess the patient's nutritional status. Stomatitis or other problems related to the gastric mucosa should be kept under control to avoid putting the patient at risk for poor nutrition.

MEMORY CHIP

P 5-Fluorouracil

- Indicated for treating carcinoma of the colon, rectum, breast, stomach, and pancreas
- Major contraindications: poor nutritional status, decreased bone marrow reserve, or a potentially serious infection
- Most common adverse effects: mucositis, diarrhea, alopecia and other cutaneous changes, such as photosensitivity and increased pigmentation of the skin
- Dose-limiting effects: mainly on the bone marrow, manifested by myelosuppression, and the gastrointestinal mucosa, causing nausea, vomiting, diarrhea, and stomatitis
- **Life span alert: Advise women of child-bearing age of the potential for harm to the fetus so that they practice contraception. It is not known whether the drug is excreted in breast milk; therefore, explain that breast-feeding is not advised.**
- Maximizing therapeutic effects: Potentiate antineoplastic activity of 5-FU by the addition of reduced folates, such as leucovorin calcium.
- Minimizing adverse effects: Monitor CBC and assess for signs and symptoms of myelosuppression, which include infection and bleeding.
- Most important patient education: Teach patient good oral care and to monitor for signs and symptoms of mucositis and infection. Advise patient of the possibility of transient alopecia, which will reverse after chemotherapy is finished.

Drugs Closely Related to P 5-Fluorouracil

The other drugs in the antimetabolite category are listed in Table 56.2, which includes specific disease indications and routes of administration.

Cytarabine

Cytarabine (Ara-C) is commonly used in hematologic malignancies. It is associated with a unique toxicity termed chemical keratitis, which is usually treated with dexamethasone eye drops. Ara-C given in high doses as a bolus infusion can cause cerebellar toxicitiess. Cerebellar checks must be completed at baseline and prior to each bolus dose of Ara-C so that changes can be detected early and the drug can be discontinued. Ara-C given in high doses as a continuous infusion is associated with pulmonary toxicity, and nurses must carefully monitor fluid status, weight, and lung sounds and administer diuretics to maintain patients at a specified goal weight.

Floxuridine

Floxuridine (FUDR) is an analogue of 5-FU. FUDR is most commonly administered directly into the liver through a hepatic arterial pump for patients with colorectal or GI cancer and liver metastasis. Special training is required prior to administering chemotherapy through a hepatic arterial pump.

Gemcitabine

Gemcitabine (Gemzar) causes myelosuppression, most notably thrombocytopenia. It is important to note that infusion times longer than 60 minutes can cause increased toxicities. In addition, Gemcitabine causes a skin rash in about 20% of patients. Gemcitabiner should be reconstituted with normal saline only.

Capecitabine

Capecitabine (Xeloda) is the oral prodrug of 5-FU, which means that when capecitabine is taken orally, it converts to 5-FU in the body. Despite its oral administration, capecitabine is as efficacious as 5-FU (Box 56.3). The most common dose-limiting adverse effect is hand-and-foot syndrome. Development of this syndrome requires stopping of the drug until resolution, with subsequent dose modifications.

BOX 56.3 FOCUS ON RESEARCH

Capecitabine Results in Superior Response Rate, Improved Safety Profile, and Improved Convenience

Van Cutsem, E., Hoff, P. M., Harper, P., Bukowski, R. M., Cunningham, D., Dufour, P., et al. (2004). Oral capecitabine vs intravenous 5-fluorouracil and leucovorin: Integrated efficiency data and novel analysis from two large randomized, phase III trials. *British Journal of Cancer,* 90: 1190–1197.

The Study

This trial involved a total of 1207 patients with metastatic colorectal cancer who were randomized to treatment with standard therapy of 5-fluorouracil (5-FU) and leucovorin (5-FU/LV) versus oral capecitabine (OX). Treatment involved either of the following:

1. Capecitabine, 1,250 mg/m^2 twice daily on days 1 to 14, every 21 days
2. Leucovorin, 20 mg/m^2, followed by 5-FU, 425-mg/m^2 IV bolus, on days 1 to 5 every 28 days.

OX showed a statistically significant superior response rate compared to 5-FU/LV ($p < 0.0002$). Even in patients with poor prognostic indicators, subgroup analysis showed that OX demonstrated superior effects. Patients were treated for up to 48 weeks or until disease progression. Capecitabine resulted in a superior response rate and equivalent time to progression and overall survival. In addition, this study demonstrated the improved safety profile of the drug. It had a significantly lower rate of diarrhea (47.7% versus 58.2%), stomatitis (24.3% versus 61.6%), nausea (37.9% versus 47.6%), and alopecia (6% versus 20.6%). The only adverse effect that occurred significantly more frequently was hand-and-foot syndrome (53.5% versus 6.2%).

The results of this study support the use of capecitabine as first-line monotherapy for advanced colorectal cancer. Capecitabine offers patients an effective oral treatment, which can be administered on an outpatient basis. This study also showed that fewer patients required hospitalization related to adverse effects (11.6% versus 18%; $p < 0.005$).

Drug Significantly Different From P 5-Fluorouracil

Methotrexate (MTX) is a folate antimetabolite that induces folate depletion, leading to the inhibition of purine synthesis and arrested DNA, RNA, and protein synthesis. MTX is indicated in managing Hodgkin's disease; trophoblastic neoplasm; acute leukemia; meningeal leukemia; breast carcinoma; head, neck, and lung neoplasms; Burkitt lymphoma; CNS lymphomas, osteosarcoma; lymphosarcoma; and mycosis fungoides. It may be given in a variety of doses and schedules through various routes of administration. A small portion is metabolized in the liver; the drug is excreted in the urine mostly as unchanged drug. Because MTX is secreted by the renal tubules, certain drugs that follow the same pathway, such as salicylates, sulfonamides, phenytoin, and penicillin, may compete with MTX excretion, resulting in accumulation and increased toxicity. Therefore, these drugs should be discontinued 2 days before and restarted 2 days after MTX therapy. Adverse effects are similar to 5-FU, with the exception of neurotoxicity (at high doses) and acute hepatotoxicity manifested by elevated liver enzyme levels. With high-dose regimens, the following important considerations should be undertaken:

- Emetogenic potential is moderate (30% to 90% frequency of emesis) with doses greater than 250 mg/m^2; make sure that an appropriate antiemetic regimen is initiated.
- Monitor urine specific gravity, urine output, and urinary pH. Administer sodium bicarbonate and hydrate the patient to maintain urinary alkalinization (pH >7) and urinary output of more than 100 mL/h.
- Obtain orders for leucovorin rescue. Leucovorin is given to bypass the inhibitor action of MTX and supplies the form of folic acid needed by the normal cells for DNA synthesis. Leucovorin is usually initiated 24 to 36 hours after MTX, according to a prescribed schedule based on serum MTX and creatinine levels. No doses of leucovorin should be missed, because missed doses may increase toxicity.
- Monitor MTX blood levels for at least 72 hours until the nontoxic level of less than 0.1 micromolar is reached.

Like 5-FU, MTX is a pregnancy category X drug. MTX is discussed in depth in Chapter 25.

C MITOTIC INHIBITORS

The mitotic inhibitors (also known as plant alkaloids) interfere with the formation of the mitotic spindle, causing metaphase arrest. They are primarily known as M-phase active drugs, but they may also have some activity in the G_2 and S phases. These drugs are the vinca alkaloids, the podophyllotoxins, and the taxanes.

• C Vinca Alkaloids

Vinca alkaloids are extracts of the periwinkle plant *Vinca rosea*. They bind to microtubular proteins, which are key to formation of the mitotic spindle in dividing cells. This binding arrests mitosis and eventually causes cell death. The vinca alkaloids act mainly in the M phase. However, high doses of the vinca alkaloids vincristine (Oncovin, Vincasar PFS) and vinblastine (Velban, VLB) can also disrupt RNA and protein synthesis. The prototype vinca alkaloid is vincristine.

Nursing Management of the Patient Receiving P Vincristine

Core Drug Knowledge

Pharmacotherapeutics

The major clinical use of vincristine is in the treatment of acute lymphoblastic leukemia. It is used in combination therapy for Hodgkin's and non-Hodgkin's lymphomas, sarcoma, breast cancer, small-cell lung cancer, rhabdomyosarcoma, neuroblastoma, and Wilms' tumor. The recommended dosage of vincristine for an adult is discussed in Table 56.2. For children weighing less than 10 kg or with body surface areas of less than 1 square meter, the dose is 0.05 mg/kg/wk.

Pharmacokinetics

Following IV administration, vincristine binds extensively to both the plasma proteins and the blood elements, particularly the platelets. Its penetration across the blood–brain barrier is poor. Vincristine is metabolized by the hepatic system, and 70% of the drug is excreted in the bile or feces. A small fraction is excreted in the urine.

Pharmacodynamics

The mechanism of action of vincristine is attributed to mitotic inhibition, which arrests cell division in the metaphase stage of mitosis. The drug interferes with a protein called tubulin, which is required for formation of microtubules and the mitotic spindle. The depolymerized tubulin proteins do not allow the spindle proteins to assemble, and cell division is halted in the metaphase.

Contraindications and Precautions

Neurotoxicity from vincristine may be more pronounced in patients with underlying neurologic problems. Vincristine is contraindicated in patients with the demyelinating form of Charcot-Marie-Tooth syndrome, a neurologic disease characterized by absence of deep tendon reflexes. Because liver disease may alter the elimination of vincristine, dosage modifications may be needed in patients with elevated bilirubin levels. Care must be taken to prevent accidental contamination of the eyes, especially when the drug is administered intravenously under severe pressure, because the drug can cause severe eye irritation, including corneal ulceration if it splashes into the eye. If eye contamination occurs, the eyes must be washed immediately and thoroughly.

Vincristine is administered by IV routes only. Given intrathecally, vincristine may be fatal. The drug can be delivered through a side port of a free-flowing IV line to allow dilution. It can also be given by continuous infusion, but only through a central venous access device with positive blood return. Vincristine is a **vesicant.** Vesicants are drugs that may cause substantial tissue damage, including tissue

Box56.4 MANAGING PERIPHERAL EXTRAVASATION

Extravasation is the inadvertent infiltration of the chemotherapeutic drug into the subcutaneous tissues surrounding the site of infusion. Vesicant drugs can cause severe damage depending on the tissue infiltrated, the amount of drug the tissue absorbed, and the length of the tissue's exposure to the infiltrated drug.

Extravasation over joint spaces, tendons, or neuromuscular bundles increases the risk of tissue damage and therefore should be avoided as areas for infusion of vesicants. When a drug extravasates, the patient typically complains of pain, burning, or discomfort and possible swelling at the injection site. There may be leaking around the injection site of the drug. Sometimes pain might be a delayed reaction with other signs, such as reddening of the skin and blistering, which may progress to severe tissue involvement. The best approach when dealing with vesicantsis prevention of extravasation.

The nurse should be familiar with the institutional policies for managing extravasation. Although specific protocols for managing extravasation may vary among health care settings, general guidelines for managing extravasation include the following:

- Stop the infusion immediately.
- Attempt to aspirate residual drug in the intravenous cannual and tissues.
- Apply warm or cold compresses as indicated to the extravasation site, and if prescribed, administer the appropriate antidote to minimize any tissue damage.
- Notify the health care provider.
- Rest and elevate the affected extremity for 48 hours.
- Apply a sterile dressing that allows the extravasation area to remain visible. Avoid any pressure to the site.
- Obtain a photograph of the site for baseline comparisons.
- Document the following in the patient's medical record per institutional guidelines: date and time of extravasation, name of drug, approximate volume of infiltrate, needle gauge, site of extravasation, symptoms reported by the patient and assessed by the nurse, nursing measures implemented, name of health care provider notified, patient education provided, and nurse's signature.
- Consult physician regarding need for referral to plastic surgeon, if appropriate.

Ensure patient has appropriate follow up to monitor site.

necrosis, when accidental infiltration occurs. Therefore, extravasation precautions should be exercised during their infusion (Box 56.4). Vincristine carries a Black Box warning related to the risk of extravasation.

Vincristine is a pregnancy category D drug.

Adverse Effects

The most common dose-limiting adverse effects with vincristine are neurologic, including motor, sensory, and autonomic neuropathies. Signs and symptoms of these neurologic deficits include loss of deep tendon reflexes, numbness and tingling of the hands and feet, foot drop, myalgias, weakness, and jaw pain. Constipation, which is a forerunner of paralytic ileus, can be serious and bothersome to the patient. The neurotoxic signs and symptoms appear weeks or months after drug administration and are long lasting and slow to resolve. The severity of the neurotoxicity is related to the cumulative dose of the drug.

Drug Interactions

The toxicity of vincristine may be potentiated by drugs that act on the peripheral nervous system. Vincristine has been reported to increase the uptake of high-dose MTX by cancer cells. When given concomitantly with digoxin, vincristine may decrease serum digoxin levels and, consequently, the effects of digoxin. Mitomycin used together with vincristine may cause acute pulmonary reactions. Table 56.4 presents drug interactions with vincristine.

Assessment of Relevant Core Patient Variables

Health Status

Give careful consideration to administering vincristine to patients with pre-existing neuromuscular disease or to those who are taking other neurotoxic drugs. Clinical evaluation, including a thorough history and physical examination, may be needed for dose adjustments. Also take into account concurrent use of drugs that cause constipation, such as narcotic analgesics and cholinergic drugs.

Life Span and Gender

Vincristine may affect sexual function. Explore the patient's sexual patterns. Assess women of childbearing age for pregnancy and lactation. Vincristine may cause fetal harm; therefore, pregnant patients should be apprised of this possibility if the drug is used in pregnancy. Whether vincristine is excreted in breast milk is unknown. Because of the potential for adverse effects in breast-feeding infants, the patient should decide either to stop breast-feeding or to stop drug therapy. Note the patient's age and developmental status. Vincristine therapy may cause azoospermia and amenorrhea in postpubertal patients, although recovery occurs after therapy is completed. Risk of potential motor and sensory dysfunction (peripheral neuropathies) associated with

TABLE 56.4 Agents That Interact with P Vincristine

Interactants	Effect and Significance	Nursing Management
digoxin	Decreased serum level and therapeutic effect	Monitor digoxin level.
methotrexate (MTX)	Increased cellular uptake of MTX when given sequentially	Notify physician for dosage modification. Monitor for signs and symptoms of neurotoxicity.

vincristine is greater in patients with liver dysfunction, with advanced age, and with cumulative doses of vincristine.

Lifestyle, Diet, and Habits

Before drug administration, determine the patient's sensory, motor, and perceptual functions, because of the potential dysfunctions associated with vincristine. Consider bowel elimination patterns and food and fluid intake.

Environment

Vincristine may be given in an inpatient or ambulatory care setting.

Nursing Diagnoses and Outcomes

- Disturbed Sensory Perception related to perceptual neuropathies, as evidenced by absent deep tendon reflexes, numbness, weakness, and myalgias
  Desired outcome: *The patient will be able to function safely without injury. Optimal sensory and perceptual function will be maintained.*
- Risk for Constipation related to adverse effects of vincristine
  Desired outcome: *The patient will have a regular bowel elimination pattern and will pass soft stools. The patient will state self-care measures if he or she is unable to pass stool.*
- Risk for Infection and Bleeding related to depression of bone marrow function
  Desired outcome: *Bone marrow recovery will be attained; rare and mild myelosuppression might occur. The patient will verbalize and also implement self-care measures to prevent infection.*
- Impaired Skin Integrity related to potential for vesicant extravasation
  Desired outcome: *The skin will remain intact, without cutaneous breakdown. The patient and health care provider will be able to recognize signs and symptoms of suspected extravasation and initiate prompt measures that will prevent further tissue damage.*
- Disturbed Body Image related to drug-induced hair loss
  Desired outcome: *The patient will develop strategies to cope with hair loss and changes in physical appearance.*
- Ineffective Sexuality Patterns: Impotence related to adverse effects of vincristine
  Desired outcome: *The patient will state understanding that this effect of the drug is reversible and will exhibit behavior changes that will result in more satisfying sexual functioning.*

Planning and Intervention

Maximizing Therapeutic Effects

The drug is light sensitive; therefore, protect it from light. Also, refrigerate it. Give an initial bolus through a new and patent free-flowing IV access, noting patient's response during and after drug instillation. If the drug is given as a continuous infusion, a central line should always be used.

Minimizing Adverse Effects

The occurrence of peripheral neuropathies is a major concern with vincristine therapy. Its toxicity to the nerve fibers can induce severe motor, sensory, and autonomic deficits. Conduct a neurologic evaluation of the patient before each cycle to assess for major changes. Report any changes in perceptual or sensory functioning and consult the oncologist immediately regarding dosage modifications or discontinuation of the drug.

Because vincristine has vesicant properties, careful attention should be given to prevent extravasation (see Box 56.4). Anyone administering vesicants must be thoroughly familiar with appropriate antidotes and protocols for the use of vesicants (Table 56.5).

Make sure that every patient is prescribed stool softeners to prevent constipation.

Providing Patient and Family Education

Follow the guidelines described in Box 56.2.

- Discuss and explain precautionary measures to the patient to lessen further insult to the cutaneous systems.
- Advise patients to promptly report problems resulting from the IV infusion—for example, pain, burning, redness, swelling, or blistering at the infusion site.
- Instruct patients and caregivers to observe and monitor the infusion site for early extravasation and cutaneous reactions.
- Teach patients and caregivers how to care for suspected extravasation at home until medical attention can be obtained, if needed.
- Discuss methods for coping with adverse effects, such as a metallic taste sensation during drug administration, nausea or appetite loss, or constipation accompanied by cramping.
- Encourage patients to maintain adequate nutrition. A high-fiber diet and plenty of fluids should be consumed to help relieve constipation. Stool softeners, laxatives, or both should be given for severe constipation. The usual constipation regimen consists of Colace, 100 mg once a day; and Senokot, two tablets at bedtime.
- Instruct patients to avoid injury related to altered sensory and perceptual changes manifested by muscle weakness and neuropathy, numbness of the fingers and toes, tingling sensation, or absence of deep tendon reflexes. These changes may be temporary or permanent.
- Review with patients strategies for taking care of hair and skin, because thinning or loss of hair may occur 2 or 3 weeks after treatment. Teach patients techniques to provide gentle care by avoiding heat or chemical irritants and wearing wigs or hair coverings. Educate patients that hair will regrow within a few months after therapy stops.
- Emphasize to patients and caregivers the importance of scheduling and keeping appointments for laboratory tests and medical checkups.
- Explore with patients and their significant others sexuality issues and discuss strategies for maintaining sexual

TABLE 56.5 Common Vesicants and Known Antidotes

Vesicant	Antidote	Nursing Management
vincristine (Oncovin, Vincasar PFS) vinblastine (Velban) Etoposide if in large volumes of concentrated solutions	Hyaluronidase	Stop infusion of drug. Inject antidote locally to extravasation site subcutaneously. Apply warm compress to extravasation site for 15–20 min at least 4 times a day for 24–48 h.
vinorelbine (Navelbine) mechlorethamine hydrochloride (nitrogen mustard)	Isotonic sodium thiosulfate	Stop infusion of drug. Rapid administration of antidote is crucial. Prepare antidote as prescribed. The solution should be 1/6 molar. 2 mL solution for each mL of vesicant extravasated. Give four 1-mL SC injections in a clockwise pattern around site using a new 25 guage needle at each site. Apply ice for 6–12 h following antidote injection.
Others: cisplatin (Platinol) (>20 mL of 0.5-mg/mL solution), dactinomycin (Actinomycin), daunorubicin (Cerubidine), doxorubicin (Adriamycin), epirubicin (Ellence), idarubicin (Idamycin), fluorouracil (5-FU, rare vesicant potential), mitomycin (Mitomycin-C), mitoxantrone (Novantrone)	Isotonic sodium thiosulfate Dimethyl sulfoxide (DMSO)	Rapid administration of antidote is crucial. Apply ice pack for 15–20 min at least four times a day for the first 24 h. Teach patient how to prevent infection. Protect from sunlight. For anthracylines: remove ice pack at least 15 minutes prior to administration of Totect ®. Administer Totect ® IV over 1–2 h in a large vein in an area other than the extravasated area, preferably the opposite arm. See Totect ® package insert for detailed administration guidelines.

health. Reassure patients that impotence, should it occur, is usually reversible after drug therapy is discontinued.

Ongoing Assessment and Evaluation

Acute elevation of uric acid may occur during induction of remission for patients with leukemia. Measure uric acid levels during the first week of treatment and undertake measures to prevent the occurrence of uric acid nephropathy. Assess the patient's bowel function and motor and sensory functions daily.

Drugs Closely Related to P Vincristine

Vinblastine

Vinblastine (Velban) is another vinca alkaloid derived from the periwinkle plant. Although its chemical structure, pharmacokinetics, and mechanism of action are similar to those of vincristine, this drug has markedly more clinical indications than vincristine does. Similar to vincristine in its efficacy in treating lymphomas, vinblastine is also used for chemotherapy in testicular carcinoma, Kaposi sarcoma, choriocarcinoma, squamous cell cancer of the head and neck, and breast cancer.

The toxicity profile of vinblastine differs from that of vincristine. The dose-limiting toxicity of vinblastine is myelosuppression, whereas that of vincristine is neurotoxicity. Neurotoxicity occurs less frequently with vinblastine; however, with high doses, this adverse effect can occur. The mildly myelosuppressive action of vincristine makes it more attractive than vinblastine for combination chemotherapy. Vinblastine is considered a vesicant.

MEMORY CHIP

P Vincristine

- Primarily indicated for acute leukemia and for other cancers such as Hodgkin's disease, breast cancer, neuroblastoma, and multiple myeloma
- Major contraindications: demyelinating form of Charcot-Marie-Tooth syndrome
- Most common adverse effect: tissue necrosis if the drug, which is a vesicant, accidentally extravasates
- Most serious adverse effects: neurotoxic deficits manifested by paresthesias, myalgias, loss of deep tendon reflexes, and jaw pain. Paralytic ileus as evidenced by constipation may also occur.
- **Life span alert: Caution elderly patients regarding the potential for motor and sensory deficits that may compromise their safety and sensory acuity. Vincristine may cause fetal harm or risk to mothers who are breast-feeding. Apprise patients of these side effects.**
- **Patient safety alert: Vincristine is fatal if given intrathecally.**
- Maximizing therapeutic effects: The drug is light sensitive; protect it from light. Infuse it slowly over approximately 1 minute.
- Minimizing adverse effects: Always assess bowel elimination pattern because of the danger of paralytic ileus.
- Ensure good vascular access and monitor for signs and symptoms of extravasation.
- Most important patient education: Instruct the patient to obtain a prescription for a prophylactic stool regimen.

Vinorelbine

Vinorelbine (Navelbine) is a semisynthetic vinca alkaloid active against breast, cervical, and non–small-cell lung cancer. This drug's toxicity profile is similar to that of vinblastine and vincristine and involves myelosuppression (WBCs) and neurotoxicity. In addition to its vesicant properties, vinorelbine is also considered an irritant that can cause aching, tightness, and phlebitis with or without inflammation. It is important to flush peripheral lines with at least 125 mL of normal saline following administration to reduce irritation to the vein.

• C Podophyllotoxins

The podophyllotoxins were isolated from the mandrake plant (May crab apple). Examples of drugs in this group are etoposide (VP-16) and teniposide (VM-26), both of which are semisynthetic derivatives extracted from the American mandrake, *Podophyllum peltatum*. They are also known as epipodophyllotoxins. They act in the premitotic, G_2, and S phases and interfere with the topoisomerase II enzyme reaction. The prototype podophyllotoxin is etoposide.

Nursing Management of the Patient Receiving P Etoposide

Core Drug Knowledge

Pharmacotherapeutics

Etoposide is used in combination therapy for refractory testicular tumors and small-cell lung cancer. It is also effective in treating Hodgkin's and non-Hodgkin's lymphomas, acute lymphocytic leukemia (ALL), breast cancer, and multiple myeloma. Etoposide is usually administered intravenously but is also available in an oral formulation (see Table 56.2). The recommended dose for oral use is twice the IV dose rounded to the nearest 50 mg.

Pharmacokinetics

Etoposide binds to serum albumin and becomes extensively bound to tissues. It is predominantly excreted in the urine and to a lesser extent in the bile. About 30% of the drug is excreted unchanged. The drug's half-life is 4 to 11 hours.

Pharmacodynamics

Etoposide acts by inhibiting a DNA enzyme called topoisomerase II, causing breaks in the double strands of protein-linked DNA. This action inhibits DNA synthesis in the S and G_2 phases so that cells do not enter mitosis and prophase.

Contraindications and Precautions

Etoposide should not be given to patients with a known hypersensitivity to the drug or teniposide, the other podophyllotoxin derivative. Etoposide should never be administered by IV push or rapid IV infusion because doing so can cause hypotension. It should be infused over 30 to 60 minutes or longer, depending on the volume of the infusion. If the patient is taking warfarin concomitantly with etoposide, the patient's prothrombin time should be monitored closely.

Etoposide is a pregnancy category D drug and should not be used in pregnant women.

Adverse Effects

Hypersensitivity or anaphylaxis-like reactions manifested by hypotension, chills, fever, facial flushing, bronchospasm, dyspnea, and tachycardia can occur during an etoposide infusion. However, these signs are not related to any cardiorespiratory pathology but rather to the rapid infusion of the drug itself. They can be ameliorated by stopping the infusion and giving the patient IV fluids, corticosteroids, antihistamines, and volume expanders as ordered.

The major dose-limiting effect of etoposide is myelosuppression, manifested primarily by granulocytopenia, which reaches a nadir in 7 to 14 days; the platelet nadir is 9 to 16 days after parenteral administration. Recovery is noted in 20 days. When etoposide is given orally, the nadir granulocyte counts occur between 21 and 28 days, with recovery in 35 days. Etoposide carries a Black Box warning relating to myelosuppression; resulting infection or bleeding may occur. The other adverse effects of note are mild to moderate nausea and vomiting, which can be controlled by antiemetics. GI toxicities are more pronounced with the oral form of the drug. Hepatic toxicity, shown by elevated liver enzyme levels, results from administering higher than recommended doses. Etoposide is also associated with the development of secondary malignancies.

Drug-induced alopecia is reversible when the drug is discontinued. Although rare, patients who have had radiation therapy may develop **radiation recall,** which is characterized by an erythematous rash in the irradiated area. This condition may progress to desquamation, vesicle formation, and permanent hyperpigmentation of the affected area.

Etoposide is classified as an **irritant.** As such, it may produce pain, aching, tightness, urticaria, or redness, with or without inflammation along the path of the vein (phlebitis) into which the drug is infusing. Apply warmth for local care. If a large amount of concentrated solution extravasates, treat as for a vincristine extravasation. Unlike vesicants, irritants do not generally cause tissue damage.

Drug Interactions

Etoposide has a synergistic effect with cisplatin. It is incompatible with gallium nitrate and MTX. Table 56.6 presents more information about these interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for prior extensive myelosuppressive chemotherapy or irradiation to marrow-bearing areas of the skeleton. Knowing such a history is important so that dose reduction can be considered, if indicated, to avoid the potential for more severe myelosuppression. Obtain the patient's CBC before and during etoposide therapy. Monitor the patient's renal and hepatic functions, so that dose adjustments may be made in case these systems malfunction.

TABLE 56.6 Agents That Interact with P Etoposide

Interactants	Effect and Significance	Nursing Management
warfarin	Increases prothrombin time (PT)	Monitor PT closely. Monitor for signs of increased bleeding.
gallium-nitrate and methotrexate	Incompatible combinations	Avoid combined therapy.

Life Span and Gender

Document the age and gender of the patient. The safety and efficacy of etoposide have not been established in children. Explore the patient's sexual patterns and reproductive goals. Assess women of childbearing age for pregnancy. This drug has mutagenic, carcinogenic, and teratogenic properties. Secondary malignancies have been reported with the use of this drug.

Lifestyle, Diet, and Habits

Alopecia affects 20% to 90% of patients who receive etoposide. Explore with the patient the likely effect of therapy on sexuality and body image. Hair loss could be complete and may be more distressing for socially active, working patients.

Environment

Etoposide can be given in an acute care or ambulatory setting where the necessary clinical support is available in case hypotension or an anaphylactic reaction develops.

Nursing Diagnoses and Outcomes

- Risk for Injury related to etoposide-induced hypotension or anaphylactic reaction
  Desired outcome: *The patient will not experience hypotension or anaphylactic reaction.*
- Risk for Infection related to bleeding resulting from suppression of bone marrow function
  Desired outcome: *The patient will recover adequate hematologic function. The patient will undertake self-care measures to prevent infection and bleeding.*
- Imbalanced Nutrition: Less than Body Requirements, related to nausea, vomiting, and anorexia from drug therapy
  Desired outcome: *The patient will maintain proper nutritional status and good emetic control.*
- Disturbed Body Image related to drug-induced alopecia
  Desired outcome: *The patient will implement coping strategies to alleviate feelings associated with loss of hair.*
- Sexual Dysfunction related to disease process and drug therapy
  Desired outcome: *The patient will increase knowledge about the effects of chemotherapy on sexual function and will continue functioning without interfering with sexual patterns and reproductive goals.*
- Impaired Skin Integrity resulting from irritation to infusion site and possible radiation recall
  Desired outcome: *The patient's skin will remain intact without breakdown from irritant chemotherapy. Patient will demonstrate competence in wound management if radiation recall occurs.*

Planning and Intervention

Maximizing Therapeutic Effects

The stability of etoposide depends on the concentration. At a concentration of 0.2 mg/mL, etoposide is stable in a glass container for 96 hours and in plastic for 48 hours. (To prevent crystallization, dilute it in 5% dextrose for injection or in 0.9% sodium chloride solution to reach a final concentration of 0.2 to 0.4 mg/mL.)

Minimizing Adverse Effects

Because of dose-limiting myelosuppression, monitor WBC counts before chemotherapy and at the expected WBC nadir. Observe the patient receiving etoposide therapy closely for hypotension or anaphylactic reactions. Give the drug by slow infusion, never by rapid infusion, over 30 to 60 minutes and possibly longer, depending on the volume of the infusion. Cardiopulmonary resuscitation equipment should be present at the patient's bedside. During drug administration, help allay the patient's fears about possible anaphylactic reactions by staying with the patient and infusing the solution slowly through a patent IV line to prevent hypotension and chemical phlebitis. Apply warm compresses to the affected site. Monitor the patient's hepatic and renal function before and during therapy. Assess for signs and symptoms of infection and teach the patient to monitor and self-report the same. If the oral formulation of etoposide is given, also give the patient adequate antiemetics.

Providing Patient and Family Education

Follow the guidelines described in Box 56.2.

- Focus education for patients receiving etoposide on the importance of minimizing risks related to infection and injury, which are major concerns of patients with cancer.
- Discuss what to expect during the infusion (e.g., metallic taste, which may last a while but can be relieved by sucking on hard candy). If the oral formulation is used, the drug should be taken on a full stomach.
- Explain to patients that an allergic reaction may occur during infusion or after it and that this reaction is signaled by facial flushing, shortness of breath, or feeling faint.
- Help patients explore ways to manage adverse effects of mild nausea, loss of appetite, and mouth sores, which may develop in 4 to 7 days.
- Offer helpful oral hygiene practices, such as brushing the teeth at least four times daily with a soft brush and avoiding commercial mouthwashes containing alcohol, which can be irritating to the mucous lining.

- Provide nutritional guidelines, such as taking antiemetics as prescribed, eating many small meals rather than a few full meals, and avoiding highly seasoned food.
- Explain the importance of regular laboratory examinations, such as blood tests at certain intervals, to detect any decreases in blood counts (usually within 1 to 2 weeks after treatment).
- Stress guidelines for avoiding infection resulting from suppressed bone marrow function.
- Demonstrate methods to cope with hair loss and tingling in the hands and feet.
- Teach patients how to avoid injury resulting from drug-related neuropathy.
- Instruct the patient to contact the prescriber about serious adverse effects, such as a temperature higher than 100.5°F, excessive vomiting, painful mouth sores with inability to eat or drink for 24 hours, black stools, or uncontrolled bleeding.
- Discuss with patients and their significant others both reproductive goals and birth control because of the possible mutagenic and teratogenic properties of the drug.

Ongoing Assessment and Evaluation

Before each dose of etoposide therapy, check the WBC and platelet counts; platelet levels less than 50,000 cells/mm^3 or an absolute neutrophil count less than 500 cells/mm^3 may necessitate withholding the drug until the bone marrow recovers sufficiently.

Drug Closely Related to P Etoposide

Teniposide (VM-26, Vumon) and etoposide possess basic similarities in their pharmacologic makeup, toxicities, and clinical applications. The chemical structures of etoposide and teniposide differ only by the substitution of a methyl group (etoposide) for the thenylidene (teniposide) on the glucopyranoside sugar.

For teniposide administration, only nondiethylhexylphthalate (non-DEHP) containers, such as glass or polyolefin plastic containers, can be used. This precaution prevents DEHP from leaching out of polyvinyl containers and into the solution. Administration with heparin is contraindicated because heparin causes a precipitate to form.

• C Taxanes

The taxanes arrest mitosis by promoting the formation of abnormal spindle fibers and mitotic asters. Paclitaxel (Taxol), the first drug in this category, was isolated from the bark of the Pacific yew, *Taxus brevifolia*. Because the demand for this drug exceeded the supply of bark available, a semisynthetic form was developed. Docetaxel (Taxotere) is the other taxane, a semisynthetic derivative of the European yew, *Taxus baccata*. Both taxanes have similar structures and pharmacologic properties: long half-lives, substantial hepatic metabolism, biliary excretion, and large volumes of distribution. These drugs are given intravenously. They differ somewhat in their toxicity profile, particularly in the nonhematologic adverse effects. The prototype taxane is paclitaxel. Paclitaxel protein-bound (Abraxane) is a newer drug in this category that is free of solvents. Premedication for hypersensitivity is not required. Side effects are similar to the other drugs in this category.

MEMORY CHIP

P Etoposide

- Indicated for the treatment of testicular carcinoma, small-cell and non–small-cell lung cancer
- Major contraindications: known hypersensitivity to etoposide or to any podophyllotoxin derivative
- **Patient safety alert: The most common adverse effect is hypersensitivity or anaphylaxis evidenced by orthostatic hypotension, chills, dyspnea, or bronchospasm (wheezing) when given rapidly.**
- Dose-limiting effect: myelosuppression
- **Life span alert: Radiation recall may occur. The safety and efficacy of VP-16 have not been established in children.**
- Maximizing therapeutic effects: Always infuse slowly (over 30 to 60 minutes or slower), never by IV push.
- Minimizing adverse effects: Monitor results of complete blood count before chemotherapy and at expected nadir, approximately 10 to 14 days after the drug dose. Monitor for signs and symptoms of myelosuppression, which include infection and bleeding.
- Most important patient education: Forewarn the patient that the infusion causes a metallic taste. Advise the patient that sucking on hard candy may alleviate the metallic taste.

Nursing Management of the Patient Receiving P Paclitaxel

Core Drug Knowledge

Pharmacotherapeutics

The most important cytotoxic activity of paclitaxel has been in treating ovarian and breast cancers. It is approved for use after failure of first-line or subsequent therapy in metastatic ovarian cancer. In breast cancer, it is given to patients who have metastatic breast cancer that has progressed or relapsed during anthracycline-based therapy. It is also used for adjuvant treatment of node-positive breast cancer, administered sequentially to standard doxorubicin-containing combination chemotherapy. Clinical studies have shown that it is effective against a diverse range of solid tumors that are refractory to conventional chemotherapy. It has recently been approved for second-line treatment of AIDS-related Kaposi sarcoma. Several administration regimens are used, such as 1-, 3-, 6-, and 24-hour infusions with varying doses.

Pharmacokinetics

Paclitaxel crosses the placenta and enters breast milk. The liver is the principal organ responsible for paclitaxel

metabolism. The drug is excreted into the bile; less than 10% of the intact drug is excreted in the urine.

Pharmacodynamics

Paclitaxel inhibits the normal dynamic reorganization of the microtubular network during interphase and mitosis. Microtubules are cellular elements that appear to play an important role in the initiation of DNA synthesis, mitosis, and other cellular functions. The interference with the microtubules prevents depolymerization, which triggers apoptosis, or cell death, in rapidly dividing cells. It also prevents transition from the G_0 phase to the S phase by blocking cellular response to protein growth factors.

Contraindications and Precautions

Patients who have a history of hypersensitivity to drugs formulated in Cremophor EL—an excipient used as a vehicle for paclitaxel because the drug is not water soluble—should not be challenged with paclitaxel because of the possibility of a hypersensitivity reaction, including anaphylaxis. Paclitaxel is a pregnancy category D drug. Taxanes are not used in children.

Adverse Effects

Paclitaxel carries a Black Box warning related to the risk of anaphylaxis and risk of severe hypersensitivity reaction. About 10% of patients experience a hypersensitivity reaction. In nearly 80% of patients, this reaction occurs during the first 20 minutes of the infusion and happens on the first or second exposure to the drug. Whether the hypersensitivity reaction is caused by the drug itself or by Cremophor EL is debated. The manifestations of this anaphylactoid reaction are dyspnea, hypotension, tachycardia, wheezing, and chest pain.

Myelosuppression, especially risk of severe neutropenia, is also included in the Black Box warning for paclitaxel. Neutrophils reach nadir at day 11, and platelets reach nadir by day 8. Fever is associated with low WBC counts. Neurotoxicity is another important problem, which generally begins 2 or 3 days after infusion. Patients complain of numbness, tingling, and pain in the hands and feet, which may progress to painful paresthesias, loss of deep tendon reflexes, arthralgia, and diffuse myalgia. The GI manifestations are mucositis, diarrhea, mild nausea and vomiting, and elevated liver enzyme levels. The cutaneous reactions are alopecia, facial flushing, and chemical phlebitis.

Paclitaxel has irritant properties. It also appears to be cardiotoxic: bradyarrhythmias, including heart block, have been reported. Severe conduction abnormalities have been observed in less than 1% of patients receiving paclitaxel, in some cases necessitating pacemaker insertion.

Drug Interactions

The most substantial drug interaction is between paclitaxel and cisplatin. When given in combination, they can cause synergistic myelosuppression and neurotoxicity. Table 56.7 presents other drugs that might have substantial interactions with paclitaxel. Additionally, paclitaxel infusion must be administered in glass, or in polyolefin or polypropylene containers with polyethylene-lined administration sets. Polyvinyl chloride containers and tubing cause the plasticizer DEHP to leach into the fluid and should not be used. An in-line filter of 0.22 microns should also be used because particulates can form.

Assessment of Relevant Core Patient Variables

Health Status

Before administering the first dose of paclitaxel, ensure that baseline CBC, ECG, and vital signs are recorded. Assess the patient's hepatobiliary function, particularly serum bilirubin levels. Patients with existing neuropathies resulting from diabetes mellitus or alcohol ingestion could experience potentiated neurotoxicity resulting from paclitaxel administration. Investigate hypersensitivity to other drugs with a Cremophor EL base.

Life Span and Gender

Assess women of childbearing age for pregnancy and lactation. This drug is believed to be embryotoxic; therefore, its use should be avoided in pregnancy. It may be excreted in milk; breast-feeding should be stopped during paclitaxel therapy. The clinical efficacy of the taxanes in children has not been evaluated.

Lifestyle, Diet, and Habits

Discuss the impact of alopecia and other adverse effects on the patient's sexuality, body image, and activities of daily living. Alopecia, which may include loss of eyebrow, eyelash, pubic, and axillary hair, may be devastating to a patient who leads an active social life. Similarly limiting are the neurotoxic effects of pain, burning, sensory loss,

TABLE 56.7 Agents That Interact with P Paclitaxel

Interactants	Effect and Significance	Nursing Management
quinidine, cyclosporine, quinine, verapamil	Reversal of multidrug resistance	Administer medications as ordered.
cisplatin (CDDP)	Myelosuppression more severe when CDDP is given before paclitaxel	Give paclitaxel first when these two drugs are ordered sequentially.
ketoconazole	Inhibits metabolism of paclitaxel	Monitor for paclitaxel toxicity.

paresthesia, and loss of deep tendon reflexes. These symptoms might be more pronounced in patients with a history of alcohol abuse.

Environment

Paclitaxel may be administered on either an inpatient or outpatient basis. Severe reactions—manifested by hypotension, bronchospasm, tachycardia, and chest pain—can occur and are most common with the first or second infusion. In any setting where the drug is given, stay with the patient for the first 20 minutes and continue to closely monitor throughout the infusion. Resuscitation equipment and adequate supportive drugs should always be present, so that prompt intervention can be implemented if necessary.

Nursing Diagnoses and Outcomes

- Risk for Injury related to hypersensitivity or anaphylactic reactions from paclitaxel
  Desired outcome: *The patient will not suffer any injury resulting from a hypersensitivity reaction to paclitaxel.*
- Risk for Infection and bleeding related to depressed bone marrow function
  Desired outcome: *The patient will be free from infection and bleeding, evidenced by normal vital signs and recovery from neutropenia and anemia, demonstrated by blood counts.*
- Disturbed Sensory Perception related to neuropathy
  Desired outcome: *The patient will be able to function safely within limitations of lessened perceptual and sensory acuity caused by paclitaxel.*
- Imbalanced Nutrition: Less than Body Requirements, related to drug-induced nausea, vomiting, and diarrhea
  Desired outcome: *The patient will maintain adequate nutritional intake and be able to gain adequate control over emesis and diarrhea.*
- Impaired Skin Integrity and Disturbed Body Image related to drug-induced alopecia
  Desired outcome: *The patient will state understanding that the loss of hair is reversible and will initiate strategies to minimize body image distortion stemming from alopecia.*

Planning and Intervention

Maximizing Therapeutic Effects

Store diluted paclitaxel in glass bottles or plastic bags and administer with polyethylene-lined administration sets using an in-line 0.22-micron filter. Do not allow the undiluted concentrate to come in contact with polyvinyl chloride equipment or devices. When paclitaxel is used to treat breast cancer, it should be part of a multidrug regimen that includes doxorubicin. Paclitaxel may be used as part of combination therapy with cisplatin to treat certain types of cancer, such as non–small-cell lung cancer. The cytotoxicity from these two drugs is sequence dependent; for optimal results, give paclitaxel first.

Minimizing Adverse Effects

Measure and closely monitor the patient's baseline vital signs during the first 20 minutes of the paclitaxel infusion, and continue monitoring the patient for the first hour. Stay with the patient because most hypersensitivity reactions occur within the first 20 minutes of the first and second infusions. If the reaction is mild, patients can be rechallenged after the clinical manifestations have subsided. To prevent severe reactions, premedication is mandatory. Give premedication consisting of corticosteroids (dexamethasone), diphenhydramine, and an H_2-antagonist (e.g., cimetidine) at least a half hour before the paclitaxel infusion. Current experience indicates that longer infusions and an adequate premedication regimen, such as the one mentioned previously, minimize the hypersensitivity effect. If a severe hypersensitivity reaction or anaphylaxis occurs, discontinue the drug immediately and institute supportive measures (Box 56.5). Under these circumstances, the patient should not be rechallenged.

Ensure that baseline neutrophil counts are checked prior to paclitaxel infusion. The use of growth factors are often used to accelerate bone marrow recovery and prevent severe WBC nadir from occurring. Give filgrastim subcutaneously

Box 56.5 MANAGING A GENERALIZED HYPERSENSITIVITY REACTION AND ANAPHYLAXIS

Hypersensitivity or anaphylactic-like reactions manifested by hypotension, chills, fever, facial flushing, bronchospasm, dyspnea, and tachycardia can occur during a chemotherapeutic infusion. Hypersensitivity reactions usually occur within the first 10 to 15 minutes of the first infusion, but they may also happen during a later cycle, even after an uneventful first infusion. Because hypersensitivity reactions can be life threatening, the nurse needs to know what to do should one occur:

1. Stop the infusion immediately.
2. Stay with the patient.
3. Call for medical support.
4. Maintain a good IV line with normal saline solution.
5. Administer emergency drugs as prescribed: Adults: 1:1,000 (1 mg/mL) 0.2 to 0.5 mL IM or subcutaneously every 5 minutes as needed to control symptoms and increase blood pressure
   Pediatrics: 0.01 mg/kg (maximum 0.3 mg) IM or subcutaneously every 5 minutes as needed to control symptoms and increase blood; diphenhydramine, 50 mg IV; hydrocortisone 50 mg IV.
6. Place the patient in a supine position.
7. Measure vital signs every 2 to 5 minutes until they stabilize.
8. Maintain a patent airway, and administer oxygen as needed.
9. Provide emotional support to the patient and family.
10. Document all nursing measures and patient responses.
11. Consult with the health care provider about a change in treatment plans or the need to rechallenge the patient. If the drug needs to be given, the following measures should be implemented: desensitization with the health care provider's support, a premedication regimen, prolongation of infusion time or an increase in the volume of diluent and, if appropriate, substitution of a similar drug.

at a dose of 5 mcg/kg every day for 10 days, starting 24 hours after the completion chemotherapy.

Providing Patient and Family Education

Follow the guidelines described in Box 56.2.

- The first treatment is usually stressful for patients and families because of the fear of the possible anaphylactic reaction. Reassure patients that the health care team will be present during the first 20 minutes of the infusion, when most of these reactions occur. Teach patients to report the first symptoms of hypersensitivity/anaphylaxis, so that supportive measures can be undertaken.
- Explain drug delivery methods; for example, say that an IV drug can be given as a continuous infusion or intra-abdominally by a catheter placed in the abdomen.
- Review premedication regimens for preventing allergic reactions, including regimens for dexamethasone (Decadron), diphenhydramine (Benadryl), and an H_2-antagonist.
- Discuss medications to relieve adverse effects (nausea, joint pain, body aches), such as acetaminophen (Tylenol) or ibuprofen (Motrin, Advil) for pain.
- Offer methods to enhance appearance when alopecia occurs, such as wearing wigs and hats.
- Explain signs and symptoms of peripheral neuropathy, such as numbness, tingling in the hands and feet, impairment of fine motor skills, and difficulty in ambulating, and explore their potential effects on the patient's activities of daily living; for example, suggest moving carefully to avoid injury.
- Discuss measures to alleviate fatigue by getting rest, sleep, and exercise; pacing activities; and obtaining help with activities and chores of daily living.
- Explain how to self-administer a prescribed drug (e.g., granulocyte colony-stimulating factor [G-CSF]) by subcutaneous (SC) injection to minimize a severe drop in WBC count.
- Review the danger signs of infection and blood abnormalities that should be reported, such as a temperature higher than 100.5°F.
- Explain the importance of oral hygiene and careful nutrition to relieve the discomfort of mouth sores.

Ongoing Assessment and Evaluation

Depression of bone marrow function, primarily neutropenia, is a dose-limiting toxicity of paclitaxel. Monitor the patient's CBCs frequently. Patients should not be given subsequent courses until the neutrophils reach a level exceeding approximately 1,500 cells/mm^3 and platelets recover to above 100,000 cells/mm^3. Perform cardiac monitoring during subsequent drug administration to ensure that patients do not develop severe cardiac abnormalities.

Drug Closely Related to P Paclitaxel

Docetaxel (Taxotere) is the only other drug in the taxane family. It is used in patients with locally advanced or metastatic breast carcinoma after disease progression with an anthracycline-based therapy or relapse during anthracycline-based adjuvant treatment. It is approved for the treatment of patients with head and neck malignancies, ovarian cancer, and non–small-cell lung cancer that is locally advanced or has metastasized and has not responded to cisplatin. The Food and Drug Administration has just approved docetaxel in combination with prednisone for patients with hormone-refractory prostate cancer. An adverse effect unique to docetaxel administration is fluid retention syndrome. This syndrome is manifested by edema, weight gain, and third-space fluid retention. The fluid retention is cumulative and is believed to be caused by increased capillary permeability and by the vehicle used to increase docetaxel's solubility, Tween 80. Prophylactic measures include the use of corticosteroids, such as dexamethasone, 8 mg orally twice daily for 5 days, before docetaxel, with or without H_1- and H_2-receptor antagonists given intravenously 30 minutes before the drug; these measures appear to be effective in reducing the fluid retention. Other measures include the use of diuretics, such as spironolactone or furosemide, if ordered by the prescriber.

MEMORY CHIP

P Paclitaxel

- Indicated for patients who breast and ovarian cancer, Kapos;s sarcoma, and non-small cell lung cancer.
- Major contraindications: hypersensitivity to Cremophor El, baseline neutropenia of less than 1,500/mm^3, pregnancy and lactation
- Most common adverse effects: nausea, vomiting, alopecia, and joint pains
- Dose-limiting effect: depression of bone marrow function, particularly neutropenia
- **Patient safety alert: Most serious adverse effects are severe hypersensitivity reactions (anaphylaxis), which occur during the first 10 to 15 minutes of drug infusion.**
- Maximizing therapeutic effects: Use glass or polyolefin containers, non-DEHP administration sets, and in-line filtration for drug administration.
- Minimizing adverse effects: Administer paclitaxel first when given in combination with cisplatin or carboplatin to prevent profound myelosuppression. Premedicate patients with a corticosteroid, diphenhydramine, and an H_2-antagonist IV 60 minutes before paclitaxel to avoid anaphylactic reactions.
- Most important patient education: If the physician prescribes the corticosteroid premedication regimen to be started at home, ensure that patient understands the importance of complying with the dosing schedule and will have enough medications (dexamethasone) at home.

C CAMPTOTHECINES (TOPOISOMERASE-I INHIBITORS)

Topoisomerase-I is a nuclear enzyme needed for maintaining DNA structure during replication, transcription, and translation of genetic materials. Inhibition of this enzyme causes

single-stranded DNA breaks and, subsequently, cell death. Topoisomerase-I inhibitors are the newest category of cell cycle–specific agents, semisynthetic agents derived from the Chinese tree *Camptotheca acuminata*. The parent compound, camptothecin, was isolated in 1966 and was found to have antitumor activity in animal models. However, further testing was not pursued because of unpredictable toxicities, such as hemorrhagic cystitis and myelosuppression. In the early 1980s, inhibition of topoisomerase-I activity was found to be an important anticancer strategy. The prototype is topotecan hydrochloride (Hycamtin).

Nursing Management of the Patient Receiving P Topotecan

Core Drug Knowledge

Pharmacotherapeutics

Topotecan HCl (Hycamtin), a semisynthetic derivative of camptothecin, was approved in 1996 to treat patients with metastatic ovarian cancer after failure of initial or subsequent chemotherapy. It has also demonstrated clinical efficacy in treating small-cell lung cancer and ALL. It is administered intravenously.

Pharmacokinetics

The half-life of topotecan is about 3 hours. The drug has minimal protein binding, which may contribute to its ability to cross the blood–brain barrier. Topotecan is metabolized in the liver. The drug is primarily excreted by the kidneys, with approximately 30% to 40% excreted unchanged. Renal clearance is an important determinant of topotecan elimination.

Pharmacodynamics

Topotecan inhibits the activity of topoisomerase-I, an enzyme involved in gene transcription and DNA replication. This enzyme causes nicks and breaks along DNA strands, relieving stresses that build up as the DNA molecule unwinds in preparation for cell division and protein synthesis. Normally, the nicks would then be repaired by topoisomerase-I. Topotecan, by attaching to the enzyme, prevents it from repairing the nicks in the DNA, and the cell is unable to repair them efficiently.

Contraindications and Precautions

Topotecan is myelosuppressive and is contraindicated in patients who have poor bone marrow reserves. It should only be administered when the baseline neutrophil count is at least 1,500 cells/mm^3 and the platelet count is at least 100,000 cells/mm^3. It is a pregnancy category D drug. Whether the drug is excreted in human milk is unknown. It should not be administered to patients who are pregnant or breast-feeding.

Adverse Effects

The dose-limiting toxicity of topotecan is myelosuppression, especially neutropenia (listed as a Black Box warning), with a median time to nadir of 11 days. Thrombocytopenia is also dose-limiting in some regimens; median time to nadir is 15 days, with resolution after 5 days. Growth factor support has not been necessary for most patients. The nonhematologic adverse effects are nausea and vomiting, which are usually relieved with the appropriate antiemetic regimen. Other GI adverse effects are diarrhea and abdominal pain, which are managed symptomatically. Headache is a common neurologic complaint. Alopecia, fever, and flu-like symptoms have also been reported.

Drug Interactions

No known interactions with other drugs occur that might affect the potency of topotecan. Concomitant use of topotecan and cisplatin or other cytotoxic drugs worsens myelosuppression; concomitant use of G-CSF can prolong neutropenia.

Assessment of Relevant Core Patient Variables

Health Status

Assess the adequacy of the patient's bone marrow reserve. Because severe neutropenia is most common with the first course of treatment, topotecan should be given only to patients who have a baseline neutrophil count of at least 1,500 cells/mm^3 and a platelet count of at least 100,000 cells/mm^3.

Life Span and Gender

Explore the patient's reproductive goals. Topotecan is in pregnancy category D. Assess women of childbearing age for pregnancy and lactation. Because it is not known whether the drug is excreted in human milk, this drug should not be administered to patients who are pregnant or breast-feeding. The safety and efficacy of topotecan have not been established in children.

Lifestyle, Diet, and Habits

Assess the patient's activities of daily living, including rest and exercise patterns. Fatigue is frequently reported. Obtain information on the patient's normal dietary intake to plan necessary antiemetic measures.

Environment

Topotecan is usually given in an ambulatory setting. There are no acute risks that necessitate inpatient hospitalization. Clinical trials are currently in progress with an oral form of the drug. Home therapy, an attractive alternative, will make drug administration convenient and cost effective for the patient.

Nursing Diagnoses and Outcomes

- Risk for Infection and Bleeding related to depression of bone marrow function
  Desired outcome: *The patient will be free from infection and bleeding evidenced by normal vital signs and recovery from neutropenia and anemia, as shown in the blood counts.*
- Imbalanced Nutrition: Less than Body Requirements, related to drug-induced nausea, vomiting, and stomatitis

Desired outcome: *The patient will maintain adequate nutritional intake and be able to gain adequate control of emesis and diarrhea.*

- Disturbed Body Image related to alopecia
  Desired outcome: *The patient will develop strategies to minimize body image distortion from loss of hair.*
- Altered Self-Image related to fatigue
  Desired outcome: *The patient will understand the etiology of fatigue and will implement fatigue management strategies that will minimize level of fatigue.*

Planning and Intervention

Maximizing Therapeutic Effects

A minimum of 4 courses (topotecan, 1.5 mg/m^2 intravenously for 5 days, given every 21 days) is recommended because the median time to response, as shown in three ovarian cancer clinical trials, was 9 to 12 weeks and median time to response in four small-cell lung cancer trials was 5 to 7 weeks. Protect unopened vials of the drug from light, and keep them at a controlled temperature of 68°F to 79°F. Use reconstituted solutions immediately.

Minimizing Adverse Effects

Because of dose-limiting myelosuppression, monitor WBC counts before chemotherapy and at the expected nadir. If the nadir is especially low, hematopoietic growth factors such as G-CSF may be given to decrease the depth and duration of the nadir. However, these substances should not be given concomitantly with topotecan, because doing so prolongs the duration of the neutropenia. Growth factors should be administered 24 hours after the last dose of topotecan.

Providing Patient and Family Education

Follow the guidelines described in Box 56.2.

- Advise patients of ways to lessen the fatigue level by conserving energy; engaging in moderate exercise and activity; observing good sleep hygiene; and talking to the physician about other possible underlying causes. Emphasize that fatigue is a side effect rather than a sign of disease progression or treatment failure.
- Teach patients to eat small and frequent meals and take antiemetics if needed. Emphasize good oral hygiene.
- Review the signs and symptoms of infection and bleeding and instruct patients about which ones should be reported to a prescriber.
- If G-CSF injections are necessary, ensure that patients or caregivers know how to administer the drug.
- Reassure patients that alopecia is a reversible process and teach them techniques for enhancing their appearance.

Ongoing Assessment and Evaluation

Undertake frequent monitoring of the patient's blood counts when subsequent topotecan therapy is planned. Neutrophil recovery to more than 1,000 cells/mm^3, platelet count to more than 100,000 cells/mm^3, and hemoglobin levels of 9.0 mg/dL are safe parameters to maintain for follow-up cycles.

MEMORY CHIP

P Topotecan

- Approved for use in patients with ovarian, small-cell lung, and cervical cancer
- Major contraindications: severe depression of bone marrow function, particularly when the neutrophil count is less than 1,500 cells/mm^3; known hypersensitivity to the drug or its components
- Most common adverse effects: nonhematologic adverse events including nausea and vomiting, diarrhea or constipation, alopecia, and fatigue
- Most serious adverse effect: depression of bone marrow function, particularly neutropenia
- Maximizing therapeutic effects: A minimum of four courses (1.5 mg/m^2 intravenously for 5 days given every 21 days) is recommended, because the median time to response as shown in three ovarian cancer clinical trials was 9 to 12 weeks, and median time to response in four small-cell lung cancer trials was 5 to 7 weeks.
- Minimizing adverse effects: To minimize severe neutropenia, reduce subsequent doses. Growth factor support may be necessary for neutrophil recovery.
- Most important patient education: Teach the patient the importance of careful monitoring of blood counts and the avoidance of risk factors that might expose patient to sources of bleeding and infection.

Drug Closely Related to P Topotecan

Irinotecan (CPT-11) is the second topoisomerase-I inhibitor. First synthesized in Japan in 1984, it was found to have activity against many tumor models, both in vitro and in animals. This drug is effective in treating metastatic carcinoma of the colon or rectum that has recurred or progressed following therapy with 5-FU; more recently, it has been useful as first-line therapy in combination with 5-FU and leucovorin in metastatic colon or rectal cancer. Irinotecan is also used in small-cell and non-small cell lung cancer and ovarian cancer.

The principal adverse effects associated with irinotecan are GI and hematologic. Diarrhea occurs early and late in treatment and can be dose limiting, depending on the time of onset. Early-onset diarrhea, which happens within 24 hours of drug administration, is thought to be caused by inhibition of anticholinesterase by irinotecan. It is characterized by sweating, flushing, abdominal cramping, hyperlacrimation, and sudden diarrhea. It responds to IV or SC injection of atropine, 0.25 to 1.0 mg. Late-onset diarrhea, which can be dose limiting, usually occurs between days 5 and 12 of the treatment cycle but can happen as early as day 2. Management of the diarrhea consists of giving loperamide, as a 4-mg first dose and then after each loose stool, up to 16 mg each day. Most patients also experience nausea and vomiting, which can be ameliorated with suitable antiemetic therapy. Other toxicities include leukopenia, anemia, and neutropenia, alopecia, and fatigue.

Irinotecan is usually given in an ambulatory setting, with follow-up telephone calls to patients to ensure proper

CRITICAL THINKING SCENARIO

IMPLEMENTING IRINOTECAN THERAPY

Mr. J is a 65-year-old patient with colon cancer whose disease has progressed after 5-FU therapy. He was started on irinotecan monotherapy at a starting dose of 125 mg/m^2 administered by IV. The patient will return each week for 4 consecutive weeks. He will have a 2-week rest period between cycles. Diarrhea is a principal adverse effect. What are the important nursing considerations to review regarding this problem?

control of side effects, particularly diarrhea, which can cause nutritional deficits. For colon cancer, the initial dose of irinotecan is 125 mg/m^2 given intravenously over 90 minutes every week for 4 consecutive weeks, followed by a 2-week rest period.

MISCELLANEOUS CELL CYCLE–SPECIFIC DRUGS

Several antineoplastic drugs, which are believed to be cell cycle–specific but have unclear modes of action, are classified in the miscellaneous group. Hydroxyurea and L-asparaginase are in this category. Hydroxyurea (Hydrea) is the prototype miscellaneous cell cycle–specific drug discussed in this chapter.

Nursing Management of the Patient Receiving P Hydroxyurea

Core Drug Knowledge

Pharmacotherapeutics

Hydroxyurea is used in managing hematologic cancers, such as acute myelogenous leukemia or chronic myelogenous leukemia particularly in the presence of hyperleukocytosis. It is also used in other hematologic conditions, such as essential thrombocytopenia, polycythemia vera, and sickle cell. It is used in combination chemotherapy or with radiation and has shown some clinical efficacy against renal cancer, malignant melanoma, ovarian cancer, head and neck tumors, and prostate cancer. It is given orally (see Table 56.2) until the WBC count falls to 50,000 cells/mm^3, after which dosage is reduced gradually or discontinued.

Pharmacokinetics

Hydroxyurea is well absorbed from the GI tract. It penetrates the blood–brain barrier, achieving peak levels in the CSF within 3 hours. About 50% of the drug is metabolized in the liver, excreted in the urine as urea, and eliminated in the respiratory tract as carbon dioxide. The remainder is excreted intact in the urine.

Pharmacodynamics

The exact mechanism of action of hydroxyurea remains unestablished. It is a potent inhibitor of the enzyme ribonucleotide reductase, and it causes inhibition of DNA without inhibiting RNA or protein synthesis. It is S-phase specific and may hold other cells in the G_1 phase of the cell cycle.

Contraindications and Precautions

Hydroxyurea is contraindicated in patients with severe anemia, severely depressed bone marrow function with WBC count of less than 1,500 cells/mm^3, or platelet count less than 100,000 cells/mm^3; an exception is patients being treated for blast crisis of acute leukemia. Megaloblastosis unrelated to vitamin B_{12} or folic acid deficiency is often seen during chronic hydroxyurea therapy. Because the drug is excreted in the urine, it should be used with caution in patients with marked renal problems. Renal function should be monitored carefully; reduced dosing may be necessary in patients with impaired renal function.

Adverse Effects

Hydroxyurea is a pregnancy category D drug. The major toxicity of hydroxyurea is dose-related myelosuppression. Leukopenia is common, with an onset of 10 days. Thrombocytopenia and anemia are less common and have a later onset. CNS effects, such as drowsiness, headache, dizziness, hallucinations, and disorientation, have been reported with high-dose therapy. GI problems, such as nausea, vomiting, diarrhea, and stomatitis, are less common. Combined therapy with radiation can increase the severity and incidence of side effects. If the reactions are severe, interruption of treatment might be indicated; this action is rarely necessary. Increases in serum uric acid, blood urea nitrogen (BUN), and creatinine levels have been noted.

A Black Box warning for cutaneous vasculitic toxicities (vasculitic ulcerations and gangrene) associated with the use of hydroxyurea has been issued. These toxicities have predominantly occurred in patients receiving hydroxyurea for myeloproliferative disorders who have a history of prior or concurrent therapy with interferon. Hydroxyurea also has a Black Box warning related to the risk of second malignancies, because it is a known mutagenic and possible carcinogenic drug.

Drug Interactions

No important drug interactions with hydroxyurea are known to exist.

Assessment of Relevant Core Patient Variables

Health Status

Before treatment, assess the patient's hematologic profile, including a CBC and, if indicated, a bone marrow biopsy, especially if the patient has previously received antineoplastic or radiation therapy. Ask the patient about adverse effects from these treatments. Order tests to determine adequate renal and hepatic function.

Life Span and Gender

Elderly patients may be more sensitive than young patients to the drug; dose reductions may be indicated. The dosage

regimens for children have not been established. Assess women of childbearing age for pregnancy and lactation. Hydroxyurea has shown teratogenic effects in animals and may be mutagenic. Therefore, women should be cautioned about possible fetal harm if they are or may become pregnant.

Lifestyle, Diet, and Habits

Because hydroxyurea is an oral formulation, ensure that the patient will adhere to the dosing schedule at home and will incorporate this schedule into his or her daily activities. No dietary restrictions apply to the ingestion of hydroxyurea.

Environment

Hydroxyurea is self-administered at home. No emergency adverse effects of the drug are known that might require hospitalization. Patients taking long-term hydroxyurea therapy should be monitored closely because of the possibility of severe depression of bone marrow function. If appropriate, assess the home for potential sources of infection and bleeding risk (Box 56.6).

BOX 56.6 COMMUNITY BASED CONCERNS

Home Therapy with Hydroxyurea

Some patients receive hydroxyurea (Hydrea) at home. They need to learn about safe, effective self-care. Some considerations to cover in patient education include the following:

- Because hydroxyurea is taken PO, problems with swallowing capsules can present difficulties. To counteract swallowing problems, hydroxyurea capsules can be mixed with applesauce, water, or juice and swallowed in liquid form.
- Taken in large doses, hydroxyurea may cause moderate drowsiness; patients should be cautioned to prevent injury.
- Early side effects of nausea, vomiting, diarrhea, and loss of appetite may interfere with drug effectiveness. Antiemetic medications should be taken as prescribed. In some cases, taking hydroxyurea before bedtime helps to decrease nausea.
- The health care provider should be notified if foods or liquids cannot be retained for more than 24 hours after taking hydroxyurea.
- If the physician recommends blood testing, appointments should be scheduled so that the blood count can be monitored closely. A temporary decrease may occur within 7 to 14 days after treatment, but the blood counts will recover. (blood counts will drop more significantly with higher dose therapy such as for acute leukemia),
- Ways to prevent infection include avoiding people who have colds or any infection during the drug therapy period and avoiding injury, such as cuts from razor blades or kitchen knives.
- The health care provider should be notified if a severe skin rash or facial redness develops, although a less severe rash may occur in 1 to 2 weeks after treatment.
- Because hydration is important for therapeutic effect, the patient should drink plenty of fluids to prevent any problems with kidney function.
- Proper handling of cytotoxic agents, particularly avoidance of contact with skin and crushing tablets, should be observed.

Nursing Diagnoses and Outcomes

- Risk for Infection and Bleeding related to suppressed bone marrow function
  Desired outcome: *The patient will recover adequate hematologic function. Patient will undertake self-care measures to prevent infection and bleeding.*
- Imbalanced Nutrition: Less than Body Requirements, related to nausea and vomiting, anorexia, stomatitis, and hepatic dysfunction
  Desired outcome: *The patient will maintain a proper nutritional state and good emetic control. The patient will maintain intact oral mucosa and practice a good oral hygiene regimen. The patient will have normal hepatic function.*
- Disturbed Sensory Perception: Drowsiness, disorientation, confusion, or headache related to adverse effects of drug therapy
  Desired outcome: *The patient will be free from injury. The patient will maintain sensory acuity and orientation to time and environment.*
- Ineffective Sexuality Patterns related to effects of hydroxyurea
  Desired outcome: *The patient will increase knowledge about the effects of chemotherapy on sexual function and will initiate behaviors that will not interfere with sexual patterns and reproductive goals.*

Planning and Intervention

Maximizing Therapeutic Effects

When hydroxyurea is given concomitantly with irradiation, give hydroxyurea 1 week before initiating radiation therapy. It can then be continued during radiotherapy and given indefinitely. The maximum therapeutic radiation dosage indicated for the clinical condition should be given. Modifying the radiation dosage is not usually necessary with concurrent hydroxyurea administration, as long as the patient is closely monitored and does not experience severe adverse effects.

Minimizing Adverse Effects

The dosage of hydroxyurea should be based on the patient's actual or ideal weight, whichever is less. Hydroxyurea therapy may be interrupted if the WBC count falls below 1,500 cells/mm^3 or the platelet count falls below 100,000 cells/mm^3, except in a patient with blast crisis of acute leukemia. Anemia does not necessitate interrupting hydroxyurea therapy because whole blood replacement can be given. Dose modifications may be indicated in patients who have received prior radiation therapy or other cytotoxic drugs. Assess the patient's renal function because hydroxyurea can impair renal tubular function, an event manifested by elevated uric acid, BUN, and creatinine levels. Because tumor lysis can occur, the patient may need to be pretreated to prevent this complication.

Providing Patient and Family Education

Follow the guidelines described in Box 56.2.

- Before initiating drug therapy, review the common side effects of hydroxyurea with the patient and caregiver.
- Emphasize the importance of monitoring blood counts, particularly the WBC and platelets, at the prescribed intervals.
- If patients will be managed from home, teach self-care measures to prevent risks of infection and bleeding. Also, instruct patients on which signs and symptoms to report when they become pronounced. For more information, see Box 56.6.
- Instruct patient not to crush hydroxyurea tablets due to hazardous exposure potential.
  Instruct patient to perform oral care as previously described to prevent oral mucositis.

Ongoing Assessment and Evaluation

Throughout therapy with hydroxyurea, assess the patient for signs of bleeding disorders and infection. Closely monitor CBCs to make sure that they are within safe treatment parameters. If the patient is receiving concomitant radiation therapy, check the oral mucosa to ensure that severe reactions, which can cause pain and difficulty with food intake, do not compromise the patient. Because radiation recall may occur with concomitant treatment, dermatologic changes should be reported to the prescriber and managed appropriately.

MEMORY CHIP

P Hydroxyurea

- Indicated for managing acute leukemia with blasts. Also indicated for Head and neck cancer, malignant melanoma, cervical cancer and sickle cell disease
- Major contraindication: depressed bone marrow reserve, except in blast crisis of acute leukemia
- Most common adverse effects: gastrointestinal effects manifested by anorexia, nausea and vomiting, stomatitis, and diarrhea or constipation
- Most serious adverse effects: depression of bone marrow function, including leukopenia, anemia, and thrombocytopenia. Rapid decrease in white blood cell counts may occur within a short period, which is the desired effect for leukemia patients.
- Minimizing adverse effects: Monitor the patient's blood count before, during, and after treatment. If anemia occurs, the patient may receive blood transfusion without interrupting treatment cycles. Premedicate the patient with the appropriate antiemetic regimen.
- Most important patient education: Hydroxyurea is administered orally, take with or without food. If unable to vomiting occurs after taking hydroxyurea notify prescriber immediately. Advise the patient on careful handling of a cytotoxic agent, particularly to avoid contact with the skin or mucous membrane.

Drug Significantly Different From P Hydroxyurea

L-Asparaginase (Elspar) belongs to the group of miscellaneous drugs that are cell cycle–specific. The inhibitory action of this drug occurs in the postmitotic (G_1) phase of the cell cycle. L-Asparaginase is indicated in patients with ALL. In this condition, the tumor cells depend on exogenous asparagine for survival. When L-asparaginase is administered to the leukemic patient, the serum asparagine is hydrolyzed to nonfunctional aspartic acid and ammonia, depriving malignant cells of the required amino acid. Absence of asparagine causes rapid inhibition of DNA and RNA synthesis. Normal cells are able to synthesize asparagines and therefore are less affected than tumor cells by depletion of this enzyme.

L-Asparaginase does not appear to cross the blood–brain barrier and is not excreted in the urine. It is administered by the intramuscular or IV routes. Patients receiving this drug should be treated in the hospital because anaphylactic reactions can occur. There is no predictable or reliable way to test for hypersensitivity; therefore, treat each dose as if it had the possibility of causing a serious reaction. Toxicity is more common in adults than in children. A modified version of L-asparaginase, PEG-L-asparaginase (Oncaspar), is given to patients who are hypersensitive to the native form. In addition to anaphylaxis, other common side effects are hepatotoxicity, which occurs in most patients, hyperglycemia, pancreatitis, and decreased clotting factors, which may lead to bleeding problems such as intracranial hemorrhage and fatal bleeding associated with low fibrinogen. Depression of bone marrow function is rare and transient. Mild to severe CNS effects, manifested by somnolence, lethargy, drowsiness, and malaise, have been noted. These effects are usually reversible with discontinuation of L-asparaginase.

CHAPTER SUMMARY

- All cells, normal and malignant, progress through the different phases of the cell life cycle.
- In general, antineoplastic drugs are most effective on cells in the proliferative phases.
- Cell cycle–specific drugs exert their cytotoxicity at a particular phase or phases of the cell cycle and cause no substantial harm during the remaining phases.
- The major toxicities of antineoplastic drugs act on rapidly dividing cells, such as the bone marrow, GI mucosa, hair follicles, and gonadal cells.
- Hypersensitivity, anaphylactic reactions, and extravasations are the most common immediate reactions associated with chemotherapy administration.
- Health care workers can be exposed to chemotherapy through the following routes: skin and mucus membrane absorption, inhalation, and ingestion.
- The major teaching points to emphasize with a patient receiving chemotherapy are to (1) practice good body and oral hygiene; (2) eat a nutritious diet and drink plenty of fluids; (3) avoid injury, especially cuts to the skin;

(4) avoid possible sources of infection, such as animal excrement or people with colds, chickenpox, and herpes; and (5) pace activities of daily living to provide adequate rest and exercise.

QUESTIONS FOR STUDY AND REVIEW

1. What are the goals of chemotherapy?
2. What are the different strategies undertaken in the use of chemotherapeutic agents?
3. What are the basic features of a malignant cell?
4. What is the procedure for cleaning up a chemotherapy spill?
5. How are health care workers exposed to chemotherapy?
6. What are the nursing measures to take when an extravasation occurs?
7. What causes hypotension during an etoposide infusion?
8. What are the signs and symptoms of a hypersensitivity reaction?
9. Before starting a paclitaxel infusion, what must the person administering the drug check for?

Drugs That Are Cell Cycle–Nonspecific

Learning Objectives

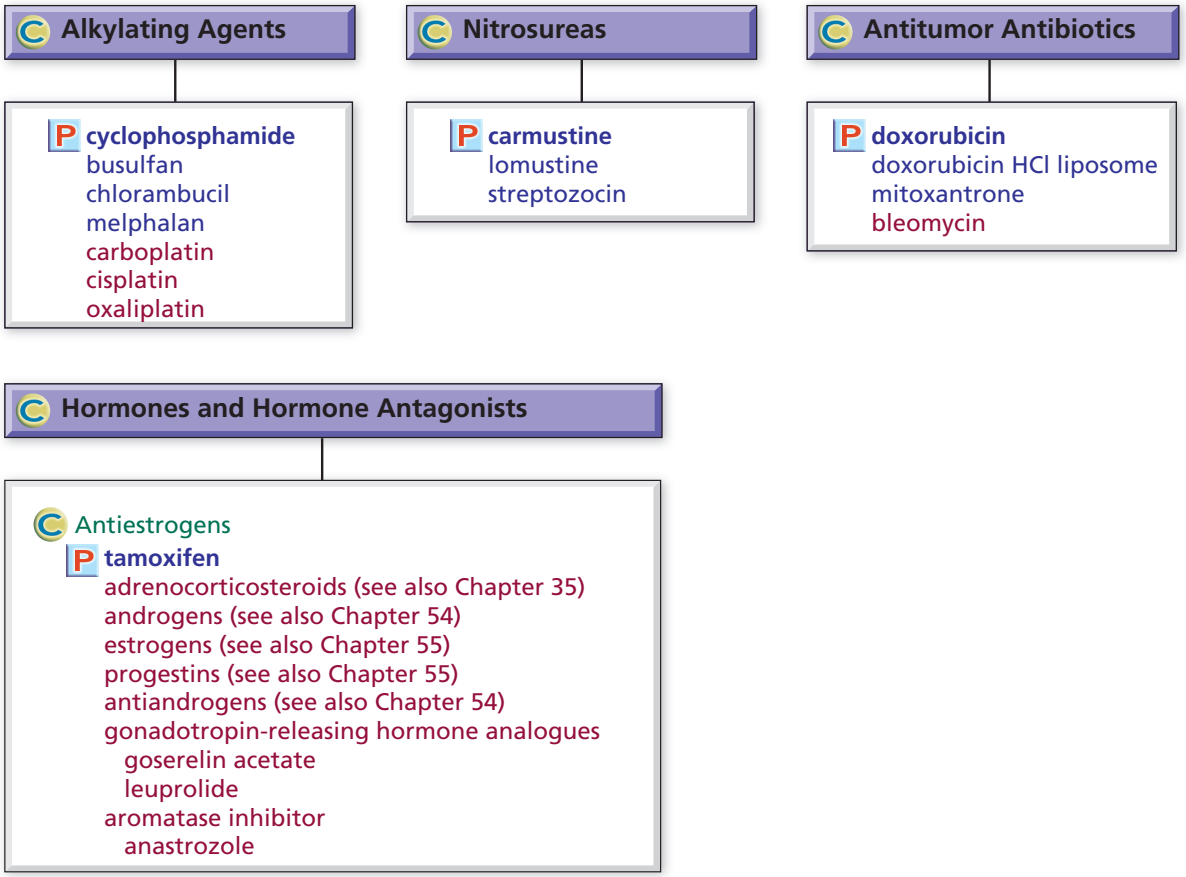
At the completion of this chapter the student will:

1. Differentiate a cell cycle–specific from a cell cycle–nonspecific agent.
2. Identify core drug knowledge about cell cycle–nonspecific drugs.
3. Identify core patient variables relevant to cell cycle–nonspecific drugs.
4. Relate the interaction of core drug knowledge to core patient variables for cell cycle–nonspecific drugs.
5. Generate a nursing plan of care based on the above interactions between core drug knowledge and core patient variables for cell cycle–nonspecific drugs.
6. Describe the nursing interventions to maximize therapeutic and minimize adverse effects of cell cycle–nonspecific drugs.
7. Determine key points for patient and family education for cell cycle–nonspecific drugs.
8. Discuss the treatment options for chemotherapy-induced nausea and vomiting.
9. State the rationale for using a combination of drugs in chemotherapy.
10. Identify the characteristics of drugs that are useful for combination chemotherapy.

Key Terms

acute emesis
alkylating agent
antitumor antibiotics
cell cycle–nonspecific
combination chemotherapy
delayed emesis
disease flare
emetogenics
hormones
hormone antagonists
liposomes
nitrosoureas
radiomimetic
tumor burden

Drugs That Are Cell Cycle–Nonspecific



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Cancer chemotherapy agents that are effective at specific phases in the cell's life cycle are classified as cell cycle–specific. Drugs that are effective through all phases of the cell cycle and are not limited to a specific phase are classified as **cell cycle–nonspecific.** This chapter focuses on the cell cycle– nonspecific antineoplastic drugs and the various management strategies used to ameliorate toxicities and maximize optimal therapeutic efficacy. Cell cycle–nonspecific drugs act on cells in both the proliferative and the nonproliferative phases of the cell cycle. They directly affect the deoxyribonucleic acid (DNA) molecule and do not display any specificity for cells that are dividing. They are considered more toxic than the cell cycle–specific drugs because their destructive action does not differentiate between normal and malignant cycling cells. Additionally, their toxicities occur throughout the cell cycle. This chapter also discusses the role of cytoprotectants and antiemetic agents, which have advanced the use of chemotherapeutic agents. Included in the cell cycle–nonspecific class of drugs are the alkylating agents, antitumor antibiotics, and hormonal drugs (hormones and hormone antagonists). Nonspecific agents are given in bolus doses because they cause cell death independently of the proliferative state of the cell. These agents also reduce the number of cells that make up a patient's tumor(s), which is known as the **tumor burden.**

This chapter also focuses on the important role of combination therapy: cell cycle–specific or cell cycle–nonspecific drugs, or both, used together to combat malignant neoplasms. The combination of a cell cycle–nonspecific and a cell cycle–specific drug can kill cells that are slowly dividing and those that are actively dividing. Cell cycle–nonspecific drugs also can help recruit cells into a more actively dividing state, which then makes them more sensitive to cell cycle–specific drugs. This chapter also discusses the rationale for implementing single-drug therapy and for designing effective combinations. Additionally, it includes some of the most common drug combinations in clinical use today. Finally, this chapter provides an overview of the newest type of chemotherapy, called targeted therapy.

The drug classes that are presented in this chapter include the alkylating agents, the antitumor antibiotics, and the hormone and hormone antagonists. Alkylating agents include nitrogen mustard and its derivatives, the nitrosoureas, and the platinum compounds. Prototypes for both the nitrogen mustard derivatives (cyclophosphamide [Cytoxan]) and the nitrosoureas (carmustine [BCNU]) are presented because they have significant differences. The prototype antitumor antibiotic is doxorubicin. The hormone and hormone antagonist group consists of adrenocorticosteroids, androgens, estrogens, progestins, antiestrogens, antiandrogens, gonadotropin inhibitors, and aromatase inhibitors. The prototype is the antiestrogen tamoxifen. Table 57.1 presents a summary of these antineoplastic drugs.

ALKYLATING AGENTS

The **alkylating agents** attack cells in any phase of the cell cycle, including (for some agents) the resting phase. They exert their toxic effects by transferring their alkyl groups to various intracellular components, including nuclear DNA. Once the nucleotides have been alkylated, abnormal base pairing may occur, leading to DNA breakage (scission) and cross-linking. The damaged DNA molecule cannot replicate itself, and cell death results. The alkylating drugs are described as **radiomimetic,** so named because they mimic the actions of radiation therapy on the cells.

The alkylating drugs, the first modern chemotherapeutic agents, are a product of the secret wartime gas programs in the first and second World Wars. The exposure of seamen to mustard gas in World War II led to the discovery that alkylating drugs cause marrow hypoplasia, which led to their use in treating hematopoietic neoplasms such as Hodgkin's and non-Hodgkin's lymphoma.

Cyclophosphamide (Cytoxan), a nitrogen mustard derivative, is the prototype alkylating drug discussed here. Drugs closely related to cyclophosphamide include busulfan, chlorambucil, and melphalan.

Nursing Management of the Patient Receiving P Cyclophosphamide

Core Drug Knowledge

Pharmacotherapeutics

Cyclophosphamide is the most widely used alkylating agent. It has a broad spectrum of antitumor activity and plays a major role in the treatment of hematologic malignancies such as Hodgkin's and non-Hodgkin's lymphoma and multiple myeloma. It is the only alkylating agent that is effective against acute as well as chronic leukemias. Cyclophosphamide is an important component of regimens used in stem cell transplantation. It is also effective against solid tumors, such as breast cancer, small-cell lung cancer, endometrial cancer, and ovarian cancer. Cyclophosphamide is given intravenously or orally.

Pharmacokinetics

Cyclophosphamide and its active and inactive metabolites are well distributed throughout the body, including the brain and cerebrospinal fluid. The drug also distributes into breast milk and saliva. Most of the drug is metabolized in the liver, and about 60% of some metabolites bind extensively to plasma protein. It is exclusively excreted by the kidneys, primarily as metabolites; however, because of avid tubular reabsorption, only about 5% to 25% of the drug is excreted unchanged in the urine.

Pharmacodynamics

Cyclophosphamide exerts its toxic effects by transferring alkyl groups to nuclear DNA, leading to abnormal base pairing, DNA breakage and cross-linking, and cell death. During extensive first-pass hepatic metabolism, cyclophosphamide

TABLE 57.1 Summary of Selected C Cell Cycle–Nonspecific Antineoplastic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Alkylating Agents			
P cyclophosphamide (Cytoxan)	Multiple approved indications: e.g. leukemia, lymphoma, **B**reast, genito-urinary, advanced ovarian, and cervical cancers	*Adult:* IV, single agent, 370 mg/m^2 on day 1, q4wk, depending on platelet count; in combination with cyclophosphamide, 300 mg/m^2 on day 1, q4wk. High dose therapy is used as a preparatory regimen for stem cell transplantation and for the decreasing tumor burden in patients with acute leukemia.	*Onset:* Rapid *Peak:* 1 h *Duration:* Unknown $t_{1/2}$: 4–6 h
cisplatin (Platinol, CDDP)	Testicular cancer and other genito-urinary tumors (bladder, prostate, metastatic ovarian, cervical, and endometrial)	*Adult:* IV, low level, 20–49 mg/mg^2; moderate level, 50–75 mg/m^2; and high level, 75–120 mg/m^2 or 3 mg/kg over 20–30 min or continuous 24-h infusion	*Onset:* 8–10 h *Peak:* 18–23 d *Duration:* 20–35 d $t_{1/2}$: 25–49 min; then 58–73 h
carboplatin (Paraplatin)	Ovarian cancer	*Adult:* IV, 300 mg/m^2 on day 1, q4wk, dose vary per protocol and AUC.	*Onset:* Rapid *Peak:* Unknown *Duration:* 48–96 h $t_{1/2}$: 1.1–2h, then 2.6–5.9 h
ifosfamide (Ifex)	Testicular cancer, sarcoma	*Adult:* 1–.2 g IV /day × 5 d repeat every 3 wk for testicular cancer. Dosing for other cancers such as sarcoma varies per protocol.	*Onset:* Rapid *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: 3–10 h for low dose; 13.8 h for high dose
busulfan (Myleran)	Chronic myelogenous leukemia, used as high dose therapy for the preparatory regimen for stem cell transplantation.	*Adult:* PO, 4–8 mg/d until WBC decreases by half, then maintenance doses up to 4 mg/d. High dose therapies differ per protocol.	*Onset:* 0.5–2 h *Peak:* 2–3 h *Duration:* 4 h $t_{1/2}$: Unknown
chlorambucil (Leukeran)	Hodgkin's lymphoma, chronic lymphocytic leukemia, non-Hodgkin's lymphoma, breast and ovarian cancer	*Adult:* 0.1–0.2 mg/kg for 3–6 wk, then a maintenance dose not to exceed 0.1 mg/kg/d	*Onset:* Varies *Peak:* 1 h *Duration:* 15–20 h $t_{1/2}$: 1 h
mechlorethamine (nitrogen mustard, Mustargen)	Lung cancer, chronic lymphocytic leukemia, chronic myelogenous leukemia, Hodgkin's disease, lymphosarcoma, malignant effusions	*Adult:* IV, 0.4 mg/kg/course; intracavitary, 0.2–0.4 mg/kg	*Onset:* Immediate *Peak:* Seconds *Duration:* Minutes $t_{1/2}$: Minutes
melphalan (Alkeran)	Multiple myeloma, ovarian cancer	*Adult:* PO, 0.25 mg/kg/d × 7 d, followed by 3 wk drug free, then maintenance dose of 2 mg/d; IV, 16 mg/m^2 q3wk × 4 doses, then q4wk	*Onset:* Varies (PO), Rapid (IV) *Peak:* 2 h (PO), 1 h (IV)
C Nitrosoureas			
P carmustine (BCNU)	Palliative therapy of brain tumors, multiple myeloma, Hodgkin's lymphoma, and non-Hodgkin's lymphoma as single-drug or combination therapy	*Adult:* IV, 150–200 mg/m^2 q6wk as a single dose or given over 2 d in divided doses as a slow infusion over 1–2 h, higher doses may be used in the setting of stem cell transplantation.	*Onset:* Immediate *Peak:* 15 min *Duration:* Unknown $t_{1/2}$: 15–30 min
streptozocin (Zanosar)	Pancreatic cancer, colon cancer, carcinoid tumors	*Adult:* IV, 500 mg/m^2 d for 5 d every 6 wk or 1 g/m^2/wk for 2 wk; dosages not to exceed 1.5 g/m^2/wk	*Onset:* Varies *Peak:* Unknown *Duration:* 24 h $t_{1/2}$: 35 min
lomustine (CCNU)	Hodgkin's disease, brain tumors	*Adult:* 130 mg/m^2 q6wk	*Onset:* 10 min *Peak:* 5 h *Duration:* 48 h $t_{1/2}$: 16–72 h

(*Continued*)

TABLE 57.1 Summary of Selected C Cell Cycle–Nonspecific Antineoplastic Drugs *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Antitumor Antibiotics			
P doxorubicin (Adriamycin)	Hematologic cancers (leukemias, Hodgkin's lymphoma, non-Hodgkin's lymphoma, multiple myeloma); solid tumors (breast, ovarian, prostate, stomach, thyroid, liver, small-cell lung, and head and neck cancers)	*Adult:* IV, 60–75 mg/m^2 as single injection every 21 d; alternate schedule, 30 mg/m^2 on each of 3 successive days for 4 wk; administered by slow IV push through a free-flowing IV line over 3–5 min or as a continuous 24 h infusion through a central venous access device	*Onset:* Rapid *Peak:* 2 h *Duration:* 24–37 h $t_{1/2}$: 12 min; then 3.3 h
doxorubicin HCl liposome (Doxil)	AIDS-related Kaposi sarcoma, ovarian cancer, multiple myeloma	*Adult:* IV, 20 mg/m^2 q3wk. doses up to 60 mg/m^2 is used in some indications.	*Onset:* Unknown *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: 55 h
bleomycin (Blenoxane)	Lymphomas, squamous cell carcinoma, and testicular cancers	*Adult:* IV/IM/SC, 10–20 units/m^2 weekly or twice a week. Cumulative doses should not exceed 400 units.	*Onset:* Immediate *Peak:* IV, 10–20 min; IM/SC, 30–60 min *Duration:* Unknown $t_{1/2}$: 2 h
daunorubicin hydrochloride (Cerubidine, DNR)	Acute myelogenous leukemia, acute lymphocytic leukemia	*Adult:* IV, 30–60 mg/m^2/d × 3d *Child:* IV, 25–45 mg/m^2	*Onset:* Slow *Peak:* Unknown *Duration:* 8 d $t_{1/2}$: 20 h
daunorubicin citrate liposome (DaunoXome)	Advanced AIDS-related Kaposi sarcoma	*Adult:* IV, 40 mg/m^2 q2wk	*Onset:* Unknown *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: 5.9–43.6 h
dactinomycin (Actinomycin, Cosmegen)	Testicular cancer, Ewing sarcoma, trophoblastic tumor, rhabdomyosarcoma, trophoblastic neoplasms	*Adult:* 500 mcg/d for a maximum 5 d *Child:* 15 mcg/d to a maximum of 500 mcg/d for 5 d	*Onset:* Rapid *Peak:* Unknown *Duration:* 9 d $t_{1/2}$: 37 h
idarubicin (Idamycin)	Acute myelogenous leukemia	*Adult:* 12 mcg/m^2/d × 3 d in combination with cytarabine	*Onset:* Rapid *Peak:* Minutes *Duration:* Unknown $t_{1/2}$: 6–9.4 h
mitoxantrone (Novantrone)	Acute myelogenous leukemia, prostate cancer, multiple sclerosis	*Adult:* 12 mg/m^2 d × 2–3 d (used in combination with cytosine arabinoside in AML). Do not exceed 140 mg/ m^2	*Onset:* Varies *Peak:* 10–14 d *Duration:* 28 d $t_{1/2}$: 5.8 d (median)
pentostatin (Nipent)	Alfa-interferon refractory hairy cell leukemia	*Adult:* IV, 4 mg/m^2 q other wk	*Onset:* Rapid *Peak:* 11 min *Duration:* Unknown $t_{1/2}$: 5.7 h
plicamycin (Mithramycin)	Testicular tumors, severe hypercalcemia	*Adult:* IV, 25–30 mcg/kg/d for 8–10 doses; severe hypercalcemia: 25 mcg/kg/d × 3–4 d	*Onset:* Rapid *Peak:* 4 h *Duration:* Unknown $t_{1/2}$: Unknown
C Hormones and Hormone Antagonists			
C Antiestrogens			
P tamoxifen (Nolvadex)	Breast cancers	*Adult:* PO, 20–40 mg/d	*Onset:* Varies *Peak:* 4–7 h *Duration:* Unknown $t_{1/2}$: 7–14 h

TABLE 57.1 Summary of Selected C Cell Cycle–Nonspecific Antineoplastic Drugs *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Androgens			
fluoxymesterone (Halotestin)	Advanced breast cancer in premenopausal women	*Adult:* PO, 10–40 mg/d in divided doses	*Onset:* Rapid *Peak:* 2 h *Duration:* Unknown $t_{1/2}$: 9.5 h
testolactone (Teslac)	Advanced breast cancer	*Adult:* PO, 250 mg qid	*Onset:* Rapid *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown
Estrogens			
estradiol (Estinyl)	Advanced breast cancer in postmenopausal women, prostate cancer	*Adult:* Breast cancer: PO, 0.5 mg/d initially, gradually increased to 3 mg/d in three divided doses; prostate cancer: PO, 0.15–2 mg/d. Also available as a vaginal cream and a transdermal patch.	*Onset:* Slow *Peak:* Days *Duration:* Unknown $t_{1/2}$: Unknown
Progestins			
medroxyprogesterone (Provera, Depo-Provera)	Advanced endometrial carcinoma	*Adult:* IM, 400–800 mg 2×/wk; PO, 200–300 mg/d	*Onset:* Slow, weeks *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown
megestrol acetate (Megace)	Advanced endometrial carcinoma, breast cancer	*Adult:* PO, 40–320 mg/d	*Onset:* Slow *Peak:* Weeks *Duration:* Unknown $t_{1/2}$: Unknown
Antiandrogens			
bicalutamide (Casodex)	Advanced prostate cancer	*Adult:* PO, 500 mg once daily	*Onset:* Slow *Peak:* 31.3 h *Duration:* Days $t_{1/2}$: 5.8 d
flutamide (Eulexin)	Advanced prostate cancer	*Adult:* PO, 250 mg q8 h	*Onset:* Varies *Peak:* 2 h *Duration:* 72 h $t_{1/2}$: 6 h
nilutamide (Nilandron)	Advanced breast cancer in postmenopausal women with disease progression after tamoxifen	*Adult:* PO, 300 mg/d × 30 d, then 150 mg/d	*Onset:* Varies *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown
Gonadotropin-Releasing Hormone (GnRH) Analogues			
goserelin (Zoladex)	Advanced prostatic cancer, advanced breast cancer, endometriosis	*Adult:* SC, 3.6 mg q28 d	*Onset:* Slow *Peak:* 12–15 d *Duration:* Unknown $t_{1/2}$: 4.2 h
leuprolide (Lupron, Lupron Depot)	Advanced prostatic cancer	*Adult:* SC, 1 mg/d *Depot:* IM, 7.5 mg monthly, q28–33 d	*Onset:* Slow *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown
Aromatase Inhibitors			
anastrozole (Arimidex) Aromasin (Exemestane) Femara (Letrozole)	Indicated in breast cancer for adjuvant, first line or second line therapy.	*Adult:* PO, 1 mg daily 25 mg once daily after a meal 2.5 mg PO daily	*Onset:* Rapid *Peak:* Unknown *Duration:* Unknown $t_{1/2}$: 7 d

undergoes hydroxylation and is converted into a cytotoxic agent with wide clinical utility in the treatment of various tumors. It is particularly effective with leukemias because the abnormal leukocytes are very sensitive to this drug's effects.

Contraindications and Precautions

Patients with severely compromised bone marrow function and with known hypersensitivity to cyclophosphamide should not be treated with the drug. The drug is in pregnancy category D.

Adverse Effects

The dose-limiting toxicity associated with cyclophosphamide (at high dosage) is leukopenia. Leukocytes reach nadir within 2 weeks, with recovery after 3 to 4 weeks. At very high doses, cyclophosphamide has a propensity for inducing sterile hemorrhagic cystitis. This problem is manifested by hematuria, pain, and burning on urination caused by the irritation of the bladder wall by acrolein, a metabolic by-product of cyclophosphamide. Other adverse effects of high-dose therapy (120 to 270 mg/kg) include syndrome of inappropriate antidiuretic hormone. High doses can also cause cardiomyopathy in the form of chronic heart failure (CHF) and hemopericardium secondary to hemorrhagic myocarditis and myocardial necrosis. In addition, high-dose cyclophosphamide is associated with high levels of acute and delayed nausea and vomiting.

Hypersensitivity to cyclophosphamide has been observed in both unpretreated and pretreated patients. Reproductive effects such as amenorrhea, gonadal suppression, sterility, and ovarian fibrosis can occur. Secondary malignancies have been reported. Other adverse effects include alopecia and transverse ridging and hyperpigmentation of the nails. Nausea, vomiting, and anorexia also occur. Dizziness, nasal stuffiness, and rhinorrhea are less common.

Drug Interactions

Table 57.2 notes the effects of cyclophosphamide on other drugs. It is compatible with other common antineoplastic agents such as melphalan, paclitaxel, vinorelbine, idarubicin, cisplatin, and bleomycin. Interaction with some herbal medicines has been noted. Patients should report all medications, whether over-the-counter or prescribed, to the health care team.

Assessment of Relevant Core Patient Variables

Health Status

Assess any organ system that could be potentially compromised by cyclophosphamide therapy. Before initiating treatment, baseline tests to determine sufficient hematopoietic and renal function should be performed. Carefully assess patients with impaired renal function, myelosuppression, or a known hypersensitivity to cyclophosphamide; these conditions may preclude administration of the drug. Patients who have had prior radiation to the pelvis or bladder are at increased risk for hemorrhagic cystitis. BK virus has also been associated with higher risk of hemorrhagic cystitis in stem cell transplant patients who receive cyclophosphamide.

Life Span and Gender

Document the age and developmental status of the patient. Cyclophosphamide can cause secondary malignancies such as bladder cancer, acute myeloid leukemia, and non-Hodgkin lymphoma, which can occur up to 20 years after treatment. Long-term and high-dose therapy increases the risk of secondary malignancies. Patients should be counseled about this serious risk. Patients who develop bladder cancer usually have a history of hemorrhagic cystitis. Adolescent patients who received cyclophosphamide for cancer treatment as children seem to be at higher risk than other populations for secondary cancers. Because of possible reproductive adverse effects, discuss reproductive goals with patients of childbearing potential who are considering high-dose therapy. Also, assess the woman of childbearing age for pregnancy and explore contraceptive methods because cyclophosphamide is a pregnancy category D drug.

Lifestyle, Diet, and Habits

Assess the daily dietary habits and elimination patterns of patients taking the oral formulation of the drug.

TABLE 57.2 Agents That Interact with P Cyclophosphamide

Interactants	Effect and Significance	Nursing Management
doxorubicin	Potentiates doxorubicin-induced cardiotoxicity	Dose modification is advised. Monitor cardiac function.
succinylcholine	Prolongs neuromuscular blocking activity	Administer with caution.
digoxin	Decreases pharmacologic effect	Digoxin dosage may need to be increased.
halothane and nitrous oxide	When used in conjunction, has produced mortality	Notify anesthesia department.
corticosteroids	Decreases conversion of cyclophosphamide to its active metabolites, decreasing activity	Notify health care provider for dose adjustment.

The metabolites of the drug should be excreted during the day. Instruct the patient to take all oral doses before 4 or 5 PM daily. If metabolite-rich urine stagnates, it can irritate and inflame the bladder wall. To promote diuresis and prevent this potential adverse effect of drug administration, the patient must drink at least 2 L of liquid a day. Assess activities of daily living, because the patient may have difficulty getting to the bathroom if he or she has impaired mobility.

Environment

Be aware of the environment in which the drug will be administered. High-dose intravenous (IV) cyclophosphamide therapy is usually given in an acute care facility, where patients can be adequately managed for potential major and acute toxicities, such as severe nausea and vomiting or hemorrhagic cystitis. For standard-dose IV and oral formulations, instruct the patient and caregiver about the necessity of retreatment hydration with vigorous oral intake, which can be accomplished in the home setting.

Nursing Diagnoses and Outcomes

- Risk for Infection related to suppression of bone marrow function
  Desired outcome: *The patient will be free from infection and exercise caution to avoid exposure to infection.*
- Risk for Injury associated with depression of bone marrow function and related bleeding and hypersensitivity reaction (anaphylaxis)
  Desired outcome: *The patient will attain pretreatment hematologic status, learn to monitor and prevent situations that may induce bleeding, and recognize and immediately report signs and symptoms associated with a hypersensitivity reaction.*
- Imbalanced Nutrition: Less than Body Requirements, related to nausea, vomiting, and taste alterations
  Desired outcome: *The patient will experience adequate emetic control, using pharmacologic and nonpharmacologic measures.*
- Impaired Urinary Elimination related to cyclophosphamide-induced urinary-bladder toxicity and nephrotoxicity.
  Desired outcome: *The patient will maintain fluid balance and be free from signs and symptoms of hemorrhagic cystitis as evidenced by adequate fluid intake and output with an absence of hematuria, pain, and dysuria. In addition, renal function will not be compromised, as shown by normal renal values.*
- Impaired Skin Integrity and Disturbed Body Image related to changes in skin pigmentation, nail conditions, and alopecia.
  Desired outcome: *The patient will be able to recognize and report any changes in the skin and integuments and will undertake measures to enhance appearance and body image.*

Planning and Intervention

Maximizing Therapeutic Effects

Before administering cyclophosphamide, ensure that the test results disclose adequate renal function and adequate hematopoietic reserves to achieve the intended therapeutic effects.

Minimizing Adverse Effects

The incidence of hemorrhagic cystitis can be reduced by a vigorous hydration regimen of at least 2 L of fluid a day and, in high-dose therapy, administering the uroprotectant agent mesna. Prehydrate the patient orally and intravenously with at least 2 L of normal saline solution. Potassium and magnesium additives may also be indicated. Monitor urine output vigilantly to ensure an output of at least half of the intake. Consider discontinuation of any medications that carry a high risk of renal toxicity to prevent compromising renal function. Assess for risk of nausea and vomiting and institute antiemetic therapy as appropriate.

Providing Patient and Family Education

- Emphasize methods of preventing the major toxicities of cyclophosphamide therapy.
- Encourage patients to drink large amounts of fluid, at least 2 L daily, to induce diuresis. Some of the pretreatment hydration can be accomplished at home; thus, if patients understand the reason for it, their adherence to the regimen the night before drug administration will be improved. Additional hydration will be given in the hospital to augment previous oral intake.
- Advise patients that temporary and reversible hair loss will occur. Refer patients to a wig specialist before treatment is initiated, and educate patients to refrain from using chemical treatments on the hair and from vigorous brushing. Teach patients to use mild shampoos and, if they have long hair, suggest that it be cut before

CRITICAL THINKING SCENARIO

DETERMINING THE MOST APPROPRIATE ANTIEMESIS REGIMEN TO PREVENT CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING

Mrs. H., a 50-year-old patient with acute myelogenous leukemia, is being admitted to receive high-dose cyclophosphamide to induce stem cell mobilization in preparation for an autologous stem cell transplantation. She has been properly hydrated, and she needs to receive her antiemetic regimen prior to starting cyclophosphamide.

1. To determine the appropriate antiemesis regimen, it is necessary to assess Mrs. H. for which risk factors?
2. Explain the types of nausea and vomiting that this patient may develop and the appropriate class of medications to treat each type.
3. Name additional nonpharmacologic interventions that could be utilized for this patient.

chemotherapy starts. Each patient will have individual preferences that should be explored. Reassure patients that hair regrowth will occur; however, advise them that new hair may be a different color or texture.
- Review signs and symptoms of a hypersensitivity reaction with patients to alleviate their anxiety. Ask patients about other known sensitivity to drugs and determine whether patients have asthma.
- Instruct patients to notify the prescriber about other serious adverse effects. Signs and symptoms to report include lower volume of urine or less frequent urination than usual; blood in the urine, dysuria, or burning with urination; a temperature of 100.5°F or higher; excessive vomiting, diarrhea, or inability to keep food and fluids down that persists for more than 24 hours; and the presence of black stools, red rash, or unusual bruising, which are signs of bleeding.
- Reassure patients that nausea and vomiting can be relieved with antiemetic drug therapy and emphasize that they should request these agents when needed. Teach nonpharmacologic measures such as relaxation and always ask patients to initiate practices that have helped alleviate these symptoms in the past. Good emesis management is important because both acute and delayed emesis have distressing effects on physical and psychological functioning (see discussion below on the types of chemotherapy-induced emesis).
- Counsel patients about the long-term risks of secondary malignancies (e.g., leukemia, lymphoma, bladder and skin cancers) associated with cyclophosphamide therapy.
- If patients are taking an oral formulation of the drug, instruct them to ingest the drug early in the morning on an empty stomach, to drink at least 10 to 12 glasses of water daily, and to empty the bladder frequently. These practices ensure that the metabolites of the drug are excreted during the day and do not stagnate to erode the bladder wall.
- Discuss the need for sperm and egg banking with patients who are on high-dose therapy and are considering having children in the future.

Ongoing Assessment and Evaluation

When patients undergo subsequent courses of chemotherapy with cyclophosphamide, assess renal function and hematopoietic reserve. Assess the patient's hematologic status every week during the first months of therapy and until maintenance therapy is set, and then at intervals of 2 to 3 weeks. For high-dose regimens, also monitor cardiac function. Dose modification may be considered in patients with impaired renal, hematologic, or hepatic function.

Drugs Closely Related to P Cyclophosphamide

Busulfan

Busulfan is used to treat chronic myelogenous leukemia. Both oral and IV formulations are also frequently used in high doses in the preparatory regimen for stem cell transplantations. The most notable toxicity of busulfan is myelosuppression, which can be severe and long lasting. Additionally, pulmonary fibrosis and seizures can occur with high-dose therapy. With high doses, prophylaxis with antiseizure medication is necessary. Prior to stem cell transplantation, hepatic venous occlusive disease is associated with doses greater than 16 mg/kg when combined with other chemotherapy agents.

MEMORY CHIP

P Cyclophosphamide

- Indicated for testicular, ovarian, and bladder cancers
- Major contraindications: severe depression of bone marrow function, serious infections, nursing mothers, and women and men with reproductive potential
- Most common adverse effect: hemorrhagic or nonhemorrhagic cystitis
- Dose-limiting effect: leukopenia
- **Life span alert: Patients on long-term therapy should be counseled about risks of secondary malignancy.**
- Maximizing therapeutic effects: Ensure that patient has adequate bone marrow reserve and good renal function.
- Minimizing adverse effects: Promote vigorous hydration and diuresis, and administer mesna, if indicated, to prevent hemorrhagic cystitis.
- Most important patient education: Instruct the patient to drink plenty of fluids and empty the bladder every 2 hours.
- **Patient safety alert: Obtain a current and accurate height and weight in order to calculate the body surface area. These numbers should be independently verified and not obtained from another provider's stated measurements to ensure that the proper dose of cyclophosphamide is administered. Death can result if inappropriate doses are administered.**

Chlorambucil

Chlorambucil is indicated in the treatment of chronic lymphocytic leukemia and lymphomas. Pulmonary fibrosis and seizures can occur, just as with busulfan. Barbiturates may increase the toxicity of chlorambucil and should be avoided, or patients should be carefully monitored. Chlorambucil should be avoided within 4 weeks of radiation or cytotoxic therapy.

Melphalan

Melphalan is a bifunctional alkylating agent active against both active and dividing cells in the cell cycle. This drug is commonly used to treat multiple myeloma and in the preparatory regimen for stem cell transplantation in myeloma. In high doses, melphalan is notable for severe oral mucositis. Oral and IV formulations are available; the oral formulation must be administered on an empty stomach. Finally, melphalan is associated with a delayed nadir, which can last 4 to 6 weeks.

Drugs Significantly Different From Cyclophosphamide

Cisplatin

Cisplatin (Cisplatinum, CDDP; Platinol-AQ) is a widely used heavy metal that acts as a bifunctional alkylating agent like cyclophosphamide. It also produces intrastrand and interstrand linking in DNA through covalent bonds with the platinum molecule, leading to breaking of DNA strands during cell replication. Cisplatin is clinically used to treat almost every solid tumor and lymphoma. The pharmacokinetics show rapid distribution of the drug to the tissues after IV infusion. Most cisplatin bonds to protein. It is believed to be metabolized in the liver and excreted in the urine.

Unlike cyclophosphamide, cisplatin has some unique features and adverse effects. Cisplatin belongs to a group of antineoplastic drugs called **emetogenics,** which have high potential for causing severe nausea and vomiting (Box 57.1). Approximately 75% of chemotherapy patients experience this distressing adverse effect, which can drastically affect physical functioning and quality of life. The risk factors that predispose the patient to this problem are listed in Box 57.2. The Black Box warning for cisplatin cites nausea and vomiting as dose-limiting effects.

Advances in understanding the pathophysiology of emesis have shifted attention from the roles of dopamine and serotonin in emesis to the potential role of substance P and the use of neurokinin-1 (NK-1) antagonists. The emetic center contains the chemoreceptor trigger zone and is stimulated through peripheral and central pathways. Peripheral stimulation occurs when chemotherapy causes damage to the gastrointestinal (GI) mucosa, activating afferent input through the vagus nerve. Serotonin is the neurotransmitter for peripheral stimulation. Substance P is found in vagal afferent neurons and binds to NK-1 receptors, causing vomiting. The study of this specific mechanism of vomiting has led to the development of a new class of antiemetics, NK-1 receptor antagonists.

Emesis associated with cytotoxic agents occurs in different patterns: acute, delayed, anticipatory, breakthrough, and refractory (Box 57.3). Cisplatin therapy can be associated with any of these patterns of nausea and vomiting, but it is primarily associated with **acute emesis** (vomiting within 24 hours after chemotherapy) and **delayed emesis** (nausea and vomiting 24 hours after chemotherapy). In cisplatin

Box 57.1 RANKING CHEMOTHERAPEUTIC DRUGS ACCORDING TO EMETOGENIC POTENTIAL

The following antineoplastic drugs are listed according to their emetogenic potential. Highly emetogenic drugs begin the list; mildly emetogenic drugs complete it.

Cisplatin*	Procarbazine
Dacarbazine	Taxanes
Streptozocin	Mitomycin-C
Nitrogen mustard	Etoposide
Hexamethylmelamine	Methotrexate
Actinomycin D	Irinotecan
Cyclophosphamide*	Topotecan
Carboplatin*	Gemcitabine
Lomustine	Bleomycin
Carmustine	Vinca alkaloids
Anthracyclines	5-Fluorouracil
Ifosfamide*	Hormones
Cytosine arabinoside	Chlorambucil

*Associated with acute and delayed nausea and vomiting.

Box 57.2 RISK FACTORS FOR NAUSEA AND VOMITING

Anxiety, expectations of severe side effects, and previous chemotherapy experience are predisposing factors to the adverse effects of nausea and vomiting. This type of nausea and vomiting is termed anticipatory. Certain patient characteristics and prognostic factors also affect the incidence of nausea and vomiting:

- Age: Younger patients experience nausea and vomiting more than older patients.
- Gender: A higher incidence of nausea and vomiting in women is thought to result from administration of more highly emetogenic drugs to women than to men and lower alcohol consumption among women.
- Alcohol and illicit drug intake: High alcohol consumption and use of illicit drugs are associated with a higher tolerance of nausea and vomiting.
- Performance status and motivation: Patients who have a better physical, emotional, and functional status have a better tolerance of emesis.
- History of motion sickness or severe emesis during pregnancy: These patients are more susceptible to chemotherapy-induced episodes of nausea and vomiting.

Box 57.3 TYPES OF EMESIS AND THEIR TREATMENTS

Acute: Occurs within 24 hours after chemotherapy

Delayed: Occurs more than 24 hours after chemotherapy; may severely affect a patient's food intake and prolong hospitalization. This type of nausea and vomiting is often underestimated by health care providers. Proactive treatment of delayed emesis is essential to decrease symptoms and increase quality of life in cancer patients receiving chemotherapy.

Anticipatory emesis: Learned response; occurs often if the patient has a negative experience with the first chemotherapy dose. Anticipatory nausea is difficult to treat; however, lorazepam and corticosteroids may be helpful. It can be minimized by effectively managing the first chemotherapy cycle and educating patients about adverse effects.

Breakthrough emesis: Occurs during a treatment cycle despite prophylaxis

Refractory emesis: Occurs after at least 1 cycle of chemotherapy; can persist despite attempts to prevent it

therapy, severe nausea and vomiting occur within 1 to 4 hours after treatment and usually last for 24 hours.

The drugs that are most effective in treating acute emesis from cisplatin therapy are the serotonin receptor antagonists. These first-line agents act by blocking serotonin from binding to receptors in the GI tract. The efficacy of these agents can be enhanced by using dexamethasone. For cisplatin-induced acute nausea, an NK-1 receptor antagonist is also indicated. Current clinical guidelines from the American Society of Clinical Oncology (Kris, Hesketh, Somerfield, et al., 2006) on antiemetics and the National Comprehensive Cancer Network guidelines (2009) recommend the use of all three drugs concurrently in managing the severe nausea that is related to cisplatin therapy. The National Comprehensive Cancer Network guidelines also state that lorazepam might also be added to this combination.

Delayed emesis from cisplatin therapy may persist for up to 5 days after treatment. The mechanism for delayed emesis is not as well understood. This type of emesis is usually treated with corticosteroids, NK-1 antagonists, lorazepam, and metoclopramide. Guidelines for treating various emetic patterns and adjunct nonpharmacologic treatments are found in Box 57.4 and Box 57.5. Antiemetics are discussed fully in Chapter 53; ondansetron is the prototype serotonin receptor antagonist drug presented.

The major dose-limiting adverse effect of cisplatin is nephrotoxicity, which is dose related and cumulative. Pretreatment hydration and forced diuresis are required to prevent nephrotoxicity. Cisplatin differs from the prototype cyclophosphamide in that it carries a Black Box warning related to its possible nephrotoxic adverse effects. Amifostine, a Food and Drug Administration (FDA)–approved cytoprotectant, is indicated for minimizing the nephrotoxic effects of cisplatin in advanced ovarian cancer or non–small cell lung cancer as well as the peripheral neurotoxicities. Neurotoxicity and ototoxicity may also limit the dose or the length of therapy of cisplatin, because these adverse effects more commonly occur with larger doses or after repeated use. Peripheral neuropathy is common and can be debilitating. Neurotoxicity may also occur or worsen after cisplatin therapy has been discontinued, and some forms are irreversible. Ototoxicity, which may be bilateral or unilateral and possibly permanent, is more severe in children treated with cisplatin. Cumulative ototoxicity is common, although deafness has occurred rarely after an initial dose. Patients should be assessed for pre-existing hearing loss; assessment should continue concurrently during cisplatin therapy. Coadministration of cisplatin with other drugs that produce ototoxicity, such as loop diuretics, may produce additive ototoxicity and should be avoided. In addition, cisplatin can cause another serious adverse effect—an anaphylaxis-like reaction. Black Box warnings for cisplatin include both ototoxicity and anaphylaxis, and these warnings are not given for the prototype cyclophosphamide. Epinephrine, corticosteroids, and antihistamines are used to alleviate anaphylactic reactions. Also, the Black Box warning describes a risk of myelosuppression as a dose-limiting adverse effect.

Other potential adverse effects of cisplatin are electrolyte imbalances. Cisplatin therapy can cause hypomagnesemia, hypocalcemia, hyponatremia, hypokalemia, and hypophosphatemia; these electrolyte imbalances are believed to be related to renal tubular damage that occurs with cisplatin therapy. Hypomagnesemia may be severe in high-dose cisplatin therapy, and this effect appears to contribute to some of the vascular toxicities caused by cisplatin, such as Raynaud phenomenon. Patients with low magnesium levels may need a diet high in magnesium to help offset losses from cisplatin therapy. Examples of these foods are nuts,

Box 57.4 GUIDELINES FOR MANAGING CHEMOTHERAPY-INDUCED EMESIS

1. Determine the emetogenic potential of the drug: high, intermediate, or low.
2. When combination agents are given, give the antiemetic appropriate for the chemotherapeutic agent with the highest risk.
3. For acute emesis, the agents with the highest therapeutic index are the serotonin antagonists. At equivalent doses, they have the same safety and efficacy profiles and can be used interchangeably.
4. The oral route is as effective and safe as the intravenous route.
5. For acute emesis with high-risk agents, the combination of a serotonin antagonist, an NK-1 antagonist, and a corticosteroid is recommended. A corticosteroid is suggested for patients treated with intermediate-risk agents, whereas for low-risk agents, no antiemetic is needed. Antiemetics should be given for each day of the chemotherapy. Lorazepam, a benzodiazepine, is sometimes added.
6. For delayed emesis, in patients receiving high-risk cisplatin, an NK-1 antagonist and a corticosteroid plus metoclopramide, lorazepam, or a serotonin antagonist is recommended. For intermediate- and low-risk agents, no preventive agent for delayed emesis is recommended.
7. Prevention of chemotherapy-induced emesis by using the most active antiemetic agents appropriate for the drug to prevent acute or delayed emesis is suggested. Such regimens should be used with all highly and moderately emetogenic chemotherapy treatment to avoid anticipatory nausea and vomiting with subsequent cycles. If anticipatory emesis occurs, behavioral therapy with systematic desensitization is effective and suggested.

Box 57.5 NONPHARMACOLOGIC TREATMENTS FOR CHEMOTHERAPY-INDUCED EMESIS

Nonpharmacologic methods for managing nausea and vomiting are adjuncts to antiemetic therapy, not substitutes for it. These include:

1. Music therapy
2. Moderate aerobic exercise
3. Acupressure wristbands
4. Behavioral interventions such as hypnosis, biofeedback, guided imagery, and cognitive distraction*

*Effectiveness believed to be from producing relaxation, giving the patient a sense of control, reducing feelings of helplessness, and diverting the patient's attention away from the acute situation to more neutral and relaxing images.

chocolate, whole-wheat breads and cereals, instant coffee and tea, oatmeal, beans, and peas. Calcium and magnesium compete to gain entrance into the intestines, so calcium-rich foods increase the body's requirements for magnesium. Calcium-rich foods, such as dairy products, should be limited when eating foods high in magnesium during cisplatin therapy.

When administering cisplatin, care should be taken not to use needles or administration sets containing aluminum because these devices result in precipitate formation or loss of drug potency; the drug reacts with aluminum.

Carboplatin

Carboplatin (Paraplatin; Paraplatin NovaPlus), another platinum compound, is very similar to cisplatin. It is used for a variety of malignancies, including many gynecologic cancers. Carboplatin exhibits less renal toxicity and neurotoxicity compared with cisplatin. However, the risk of myelosuppression appears greater, especially for anemia. Carboplatin carries a Black Box warning relating to anemia. Like cisplatin, carboplatin has a risk of anaphylaxis and nausea and vomiting. Unlike cisplatin, carboplatin causes thrombocytopenia, which can be dose limiting. Dosing is based on creatinine clearance, which seems to be the most reliable way of predicting toxicity and drug clearance. Health care providers must be knowledgeable in dose calculations and formulas that are unique to carboplatin to avoid accidental overdosing or underdosing.

Oxaliplatin

Oxaliplatin (Eloxatin) is another platinum compound similar to cisplatin. It is primarily used in combination with other chemotherapy agents for colorectal cancers. Oxaliplatin is well known for causing a rare but disturbing neuropathic side effect. The acute syndrome of pharyngolaryngeal dysesthesia, reported in 1% to 2% of patients, is exacerbated by cold. This neuropathic syndrome is characterized by feelings of dyspnea and/or difficulty swallowing without laryngospasm or bronchospasm. Although it can be frightening for patients, this condition is not life threatening. Proper instruction can prepare patients and help them avoid causative agents. They should be advised to avoid cold drinks, cold air, or cold food for up to one week after receiving the drug. Like cisplatin, oxaliplatin may cause anaphylaxis and carries a Black Box warning to that effect. Unlike cisplatin, oxaliplatin does not carry the risk of nephrotoxicity or ototoxicity.

NITROSOUREAS

The **nitrosoureas** are alkylating drugs that are frequently classified separately from the others because they also have additional mechanisms of cytotoxicity. Like the alkylating agents, they cause breaks and cross-linking in DNA strands. They also inhibit DNA repair. Nitrosoureas are highly lipid-soluble drugs. As such, they cross the blood–brain barrier. They have broad clinical activity in treating lymphomas and certain solid tumors. Unlike most other chemotherapy agents, nitrosoureas are associated with a delayed nadir. Myelosuppression caused by these drugs can be severe, and the neutrophils (one type of white blood cell) reach nadir 4 to 6 weeks after therapy starts, rather than the typical 7 to 10 days. Examples of frequently used nitrosoureas are carmustine and streptozocin, which are discussed in this chapter. The prototype nitrosourea is carmustine (BCNU). Drugs closely related to the prototype are lomustine and streptozocin.

Nursing Management of the Patient Receiving P Carmustine

Core Drug Knowledge

Pharmacotherapeutics

Carmustine is a nitrosourea used in the palliative therapy of brain tumors, multiple myeloma, Hodgkin's and non-Hodgkin's lymphoma. It is also frequently used in high doses during the preparative regimen for stem cell transplantations in lymphoma patients. It may be administered as a single drug or in combination with other antineoplastic agents. It is given as a slow infusion to prevent severe pain and burning at the IV site.

Pharmacokinetics

After IV administration, carmustine is rapidly degraded. Most of the drug is excreted by the renal system in 96 hours, and about 10% is excreted by the respiratory system as carbon dioxide. This drug crosses the blood–brain barrier because of its high lipid solubility.

Pharmacodynamics

The mechanism of action of carmustine is similar to that of an alkylating drug. It alkylates DNA and ribonucleic acid (RNA), thereby blocking synthesis and repair. It also inhibits essential enzymes by carbamylation of the amino acids.

Contraindications and Precautions

Carmustine is contraindicated in patients who are hypersensitive to it. It should be used cautiously in those with impaired respiratory or bone marrow function. Accidental skin contamination can cause hyperpigmentation and brown discoloration of the affected area. The drug should be dispensed in glass; plastic containers should be avoided. Carmustine is a pregnancy category D drug.

Adverse Effects

The major toxic effect of carmustine is suppression of bone marrow function, which generally occurs 6 weeks after drug administration. This delayed suppression is cumulative and is manifested as thrombocytopenia and leukopenia. Pulmonary toxicity in the form of pulmonary inflammation and/or fibrosis is associated with prolonged therapy and cumulative doses of more than 1,400 mg/m^2. Pulmonary fibrosis can be irreversible. A Black Box warning relates to the risk of myelosuppression and pulmonary toxicity. As with alkylating agents, carmustine and the other nitrosoureas are associated with the development of secondary malignancies.

TABLE 57.3 Agents That Interact with P Carmustine

Interactants	Effect and Significance	Nursing Management
cimetidine	Increased toxicity and myelosuppression	Monitor blood counts.
digoxin, phenytoin	Decreased serum level	Measure serum level. Consult health care provider about dose modification if needed.

Nausea and vomiting also occur frequently with carmustine. In addition, the patient may complain of local reactions, such as intense pain and discomfort in the vein used for drug administration, flushing of the skin, and suffusion of the conjunctiva within 2 hours that can last for 4 hours after administration of the drug.

Drug Interactions

When given concomitantly with other drugs, carmustine exhibits certain effects, as shown in Table 57.3.

Assessment of Relevant Core Patient Variables

Health Status

Because the major carmustine-induced toxicities are related to bone marrow and pulmonary functions, assess patients for adequate bone marrow reserve and pulmonary function. Patients at risk are those with a history of lung disease, patients receiving a greater cumulative dose than 1,400 mg/m^2 of carmustine, and children treated with cumulative doses of 770 mg/m^2 to 1,800 mg/m^2 and cranial irradiation.

Life Span and Gender

If the patient is on prolonged therapy, regularly perform pulmonary assessments to monitor for pulmonary dysfunction and disease. The onset of pulmonary problems is usually delayed, and disease is chronic. Pulmonary fibrosis has been reported to occur up to 15 years later in patients who received cumulative doses of as much as 1,800 mg/m^2, concomitantly with irradiation, as adolescents. Among adults, the same outcome has been noted with prolonged therapy and large cumulative doses. Assess women of childbearing age for pregnancy and lactation because carmustine is a pregnancy category D drug. It is not known whether carmustine is excreted in breast milk; hence, breast-feeding women should be cautioned.

Lifestyle, Diet, and Habits

Forewarn patients about the acute onset of nausea and vomiting associated with carmustine therapy. Assess the effect that nausea and vomiting will have on the patient's diet and activities of daily living. Nausea and vomiting usually occur 2 to 4 hours after drug administration. Because the signs and symptoms of myelosuppression are delayed, explore whether the patient's activities of daily living might expose him or her to risks for infection and bleeding.

Environment

Be aware of the environment in which carmustine will be administered. It is usually given in an acute care setting so that medical and nursing support are easily available should a hypersensitivity reaction or anaphylaxis occur.

Nursing Diagnoses and Outcomes

- Pain related to discomfort of drug administration
  Desired outcome: *The patient will be free from discomfort along the infusion route.*
- Risk for Infection and Injury, especially bleeding related to suppression of bone marrow function
  Desired outcome: *The patient will take steps to prevent exposure to potential sources of infection and bleeding, minimize risks for infection and bleeding, and comply with requirements for periodic blood counts.*
- Impaired Gas Exchange related to drug-related pulmonary fibrosis
  Desired outcome: *The patient will learn to recognize and report signs and symptoms of respiratory dysfunction. The patient will comply with the need to have pulmonary function tests during the course of treatment.*
- Imbalanced Nutrition: Less than Body Requirements, because of drug-induced nausea and vomiting
  Desired outcome: *The patient will expect emetic episodes and ask for antiemetics as needed. The patient will learn how to manage dietary intake and patterns to ensure adequate nutritional intake.*
- Reproductive and Sexual Dysfunction resulting from drug therapy.
  Desired outcome: *The patient will be aware of the physical changes in reproductive and sexual functions. The patient will accept these changes and explore ways to enhance sexual and reproductive health.*

Planning and Intervention

Maximizing Therapeutic Effects

Be aware that after reconstitution, the carmustine solution is stable in a glass container for 24 hours at 4°C or for 8 hours at 25°C when protected from light.

Minimizing Adverse Effects

In patients undergoing therapy with carmustine, monitor hematologic indices regularly, especially because myelotoxicity is delayed. Also, monitor renal, hepatic, and pulmonary function tests to forestall any impending problems that might compromise the patient. If long-term therapy is planned, the prescriber should discuss the possible use of a central venous access device (e.g., an implanted port through which to deliver the drug). During drug administration, the patient

may experience intense discomfort. Exercise care to use a large vein for infusion if a central venous access device is not used. To minimize the pain, slow the infusion, and prolong the duration of administration. To minimize inflammation, flush the vein postinfusion with 125 mL of normal saline. Treat nausea and vomiting, which may occur within 2 hours of the treatment, with an adequate antiemetic regimen. Assess the patient for concurrent medication use because drug interactions can occur with phenytoin (Dilantin) or cimetidine. If the patient cannot be switched from these drug therapies, additional monitoring may be warranted.

Providing Patient and Family Education

Once the patient can be treated safely in an outpatient setting, develop an education plan that includes both the patient and significant caregivers.

- Teach patients about general adverse effects and adverse signs and symptoms specific to carmustine therapy, including infection and bleeding (which might have delayed onset) and pulmonary fibrosis if the patient will receive high-dose or long-term therapy.
- Inform patients about IV drug delivery and describe reportable signs and symptoms that might signal possible phlebitis or extravasation.
- Discuss the potential for nausea and vomiting and provide the appropriate antiemetic regimen.
- Identify reportable problems, such as inability to eat or drink for more than 24 hours or respiratory problems.
- Explain the need for regular blood counts and pulmonary testing. Advise patients to report any shortness of breath, dry cough, or temperature greater than 100.5°F, which may indicate the development of pulmonary toxicity.
- Advise patients to avoid taking aspirin or drugs that contain aspirin unless ordered by the prescriber and to report signs of bleeding, such as black stools, bloody gums, bruises, and red rash.
- Discuss patients' concerns and the impact of the adverse effects regarding reproductive and sexual functions and quality of life.
- Teach patients which problems are most important to report to the health care team. Make sure patients have phone numbers or beeper numbers to use when appropriate.

Ongoing Assessment and Evaluation

In patients undergoing therapy with carmustine, closely monitor complete blood counts every week for 6 weeks to ensure that they are adequate before retreatment. Monitor pulmonary function tests before and during the course of therapy so that patients at risk for pulmonary toxicity can be managed appropriately.

Drugs Closely Related to P Carmustine

Streptozocin (Zanosar), another nitrosourea, is a product of the organism *Streptomyces achromogenes*. It is well known for its efficacy in treating malignant islet cell tumors of the pancreas. Streptozocin is given intravenously. Patients may complain of pain and burning during the infusion. This discomfort can be minimized by slowing the infusion, increasing the volume used for dilution, and increasing the total volume of the primary IV infusion.

The most frequently reported adverse effect of streptozocin is severe nausea and vomiting. Another GI reaction is hepatotoxicity, manifested by an increase in liver enzyme and bilirubin levels, hypoalbuminemia, and jaundice. Streptozocin is infamous for its renal toxicity, which is dose limiting and may be fatal. The mechanism of nephrotoxicity is unclear. Early manifestations include hypophosphatemia, glycosuria, proteinuria, azotemia, and renal tubular acidosis. Patients with pre-existing renal disease are at risk. Closely monitor renal, hematopoietic, and hepatic functions at baseline and periodically during therapy so that the patient's organ systems are not severely compromised. Additionally, streptozocin has shown diabetogenic activity evidenced by altered glucose metabolism, a decrease in insulin levels, and elevated fasting blood glucose levels. This activity is thought to result from an increased uptake of the drug into the islets, which may occur in some patients.

Lomustine, another nitrosourea, is most commonly used in brain tumors and Hodgkin's lymphoma. In addition to the mechanisms of action of other nitrosureas, lomustine creates a by-product that prevents normal DNA function. It is an oral chemotherapy agent and should be administered on an empty stomach. The capsules come in different dosages and colors, and patients should be carefully instructed on proper administration to ensure safety. Lomustine is toxic to the liver. In addition, like the other nitrosoureas, it is highly emetogenic. Acute nausea usually occurs 3 to 6 hours after an oral dose and usually lasts about 24 hours.

MEMORY CHIP

P Carmustine

- Indicated for treating brain tumors, multiple myelomas, Hodgkin's and non-Hodgkin's lymphomas, and malignant melanoma
- Major contraindications: poor pulmonary function, which places the patient at risk of developing pulmonary toxicity, and known hypersensitivity to the drug
- Most common adverse effects: acute nausea and emesis
- Dose-limiting effect: delayed myelosuppression
- Most serious adverse effects: pain and burning at the site during drug infusion
- Maximizing therapeutic effects: After reconstitution, solution is stable in a glass container for 24 hours at 4°C or for 8 hours at 25°C when protected from light.
- Minimizing adverse effects: To decrease pain and burning during drug administration, infuse the IV slowly over 1 to 2 hours, increase the primary IV volume, and then infuse 125 mL of normal saline.
- Most important patient education: Instruct patient to comply with the prescribed hematologic monitoring.

C ANTITUMOR ANTIBIOTICS

Most **antitumor antibiotics** are isolated from fermented broths of various *Streptomyces* bacteria. Antitumor antibiotics interfere with DNA-directed RNA synthesis by inserting between the base pairs of DNA, binding to DNA, and changing the normal structure of the DNA and RNA chains. This action prevents the normal duplication and separation of these chains and inhibits further synthesis. The antitumor antibiotics are dactinomycin, bleomycin, doxorubicin, daunorubicin, mitomycin, idarubicin, pentostatin, epirubicin, plicamycin, and mitoxantrone. Liposomal versions of doxorubicin and daunorubicin are available (see Table 57.1). Several of these antibiotics, because they also induce double-stranded DNA breaks, are considered topoisomerase II inhibitors. These drugs include doxorubicin, daunorubicin, and idarubicin, which are anthracycline based (i.e., red pigmented), as well as mitoxantrone, a synthetic anthracenedione that is structurally similar to the anthracyclines. (Anthracyclines are a group of antitumor antibiotics that work similarly.) Their major dose-limiting toxicity is cardiotoxicity. Doxorubicin (Adriamycin) is currently the most useful and popular antitumor antibiotic. Therefore, it is described here as the prototype drug for this class. Drugs closely related to the prototype are doxorubicin HCl liposome and mitoxantrone. A drug significantly different from the prototype is bleomycin.

Nursing Management of the Patient Receiving P Doxorubicin HCl

Core Drug Knowledge

Pharmacotherapeutics

Doxorubicin was isolated from the soil fungus *Streptomyces peucetius var caesius*. Although doxorubicin is the most recently discovered anthracycline, it has gained the distinction of being the most commonly prescribed. It has wide clinical activity, particularly against hematologic cancers, such as the leukemias, Hodgkin's and non-Hodgkin's lymphoma, multiple myeloma, and solid tumors, such as carcinoma of the breast, ovary, prostate, stomach, thyroid, liver, and small-cell lung and head and neck cancers.

Doxorubicin may be used as a single drug or in combination with other drugs, such as vinblastine, cyclophosphamide, and paclitaxel. It is administered intravenously. Dose adjustments are necessary for patients who have poor bone marrow reserve because of age, prior therapy, or neoplastic marrow infiltration. Dose reductions are also recommended for patients with impaired liver function, as evidenced by elevated serum bilirubin levels and transaminases.

Pharmacokinetics

Doxorubicin is rapidly distributed in body tissues. It is metabolized in the liver and is primarily excreted in the bile. A small percentage is excreted in the renal system and may produce reddish discoloration of the urine. The pharmacokinetic profile of doxorubicin appears in Table 57.1. Recent advances in pharmaceutical technology led to the approval by the FDA of two anthracycline antibiotics, daunorubicin and doxorubicin, in **liposomes.** Liposomes are microscopic spherical vesicles that encapsulate the drug molecules. This novel drug formulation enhances the therapeutic efficacy of the drug by increasing the concentration, delaying clearance, retarding metabolism, decreasing the volume of distribution of the drug, and shifting its distribution to the diseased tissues with increased capillary permeability.

Pharmacodynamics

Doxorubicin acts mainly by intercalation between specific base pairs within the cancer cell's DNA. This action results in blocking the synthesis of new RNA or DNA or preventing DNA strand scission. Normal proliferating cells are also affected by doxorubicin, which accounts for such adverse effects as myelosuppression, alopecia, and mucositis.

Contraindications and Precautions

Doxorubicin is contraindicated in severe CHF or any existing cardiomyopathy or marked myelosuppression from irradiation or chemotherapy. Precautions should be observed in patients with hepatic insufficiency because concentrations of active metabolites may be increased. A Black Box warning indicates that dosage should be reduced in patients with impaired hepatic function. Secondary acute myelogenous leukemia (AML) has been reported in patients treated with anthracyclines, including doxorubicin. The occurrence of refractory secondary leukemia is more common when such drugs are given in combination with DNA-damaging antineoplastic agents, when patients have been heavily pretreated with cytotoxic drugs, or when doses of anthracyclines have been escalated. A Black Box warning relates to this risk.

Doxorubicin is a pregnancy category D drug.

Adverse Effects

The adverse effects of doxorubicin may be grouped into acute, chronic, and local reactions. Acute toxicities include nausea, vomiting, suppression of bone marrow function, and mucositis. Alopecia is reversible; other cutaneous reactions are hyperpigmentation of the nail beds and dermal creases.

Cardiotoxicity is chronic and is the major toxicity that limits the use of doxorubicin; a Black Box warning relates to this severe adverse effect. This toxicity is cumulative and may manifest weeks or months after the initial treatment. Doxorubicin shows an affinity for myocytes, which are the cells of the heart muscle. The damaged myocytes are not easily replaced because they have a slow mitotic rate. The decreased number of myocytes and the ensuing interstitial edema weaken the pumping capacity of the heart muscle. Cardiac damage may range from insignificant electrocardiographic changes to more serious and potentially fatal complications, such as CHF.

Local adverse effects of doxorubicin include cutaneous effects, which can have devastating consequences for the patient. These include extravasation injury and radiation recall reaction. Anthracyclines such as doxorubicin

are the most toxic vesicants. Extravasation is especially problematic with these drugs because anthracyclines bind to nucleic acids, causing destructive and prolonged tissue injuries. They form free radicals that are toxic to the tissues and especially impede wound healing. The DNA–doxorubicin complex is retained and recirculates in the tissues, setting up a pattern for continuous tissue damage (refer to Chapter 36 for extravasation management). Doxorubicin carries a Black Box warning relating to the risk of severe local tissue necrosis if extravasation occurs during administration.

Radiation recall is exhibited with doxorubicin as erythematous changes, which appear at a previously irradiated site. The phenomenon can occur weeks or months—even years—after radiation, but happens more frequently with short intervals between sessions and high-dose chemotherapy. These reactions are manifested by erythema (redness), blisters, hyperpigmentation, edema (swelling), vesicle formation, exfoliation (skin loss), and sometimes ulcer formation, which all may occur in the skin, lung, heart, and GI tract.

Drug Interactions

Drug interactions with doxorubicin are summarized in Table 57.4. Doxorubicin should not be mixed with the following drugs in solution because of incompatibility: aminophylline, cephalothin sodium, dexamethasone sodium phosphate, diazepam, hydrocortisone, furosemide, heparin, and fluorouracil.

Assessment of Relevant Core Patient Variables

Health Status

The risk for cardiotoxicity in patients receiving doxorubicin can be potentiated by concurrent therapy with cyclophosphamide and mediastinal irradiation. Ensure that initial cardiac evaluations, which might include an electrocardiogram (ECG) and a multigated radionuclide angiogram (MUGA), are made to establish a safe baseline for treatment. Before initiating treatment, obtain a careful history to ascertain that the patient does not have existing cardiomyopathy or hepatic insufficiency that might put him or her at risk during treatment.

Life Span and Gender

Document the age and gender of the patient. The risk of cardiac damage increases with age. Age influences cardiac tolerance to anthracycline therapy. Children and the elderly are more susceptible than young adults to adverse cardiac effects at low cumulative doses. Children especially suffer more from the synergistic cardiotoxicities of mediastinal irradiation and doxorubicin. However, they have a better chance of recovering from CHF-related problems than adults do. Women, especially those younger than 50 years, are more likely to experience nausea and vomiting.

Assess the woman of childbearing age for pregnancy and explore her reproductive goals. Doxorubicin is a pregnancy category D drug and its potential effect on fertility is not known.

Lifestyle, Diet, and Habits

Assess the client for adequate nutritional intake. Malnutrition, particularly in children, potentiates cardiotoxicity. Also, assess the patient's anxiety about chemotherapy-related nausea and vomiting, which can substantially impair quality of life.

Environment

Be aware of the environment in which the drug will be administered. Doxorubicin is given in either an inpatient or outpatient setting because of the need to monitor adverse effects, especially the potential for extravasation, which requires prompt medical attention and necessitates patient education.

Nursing Diagnoses and Outcomes

- Risk for Infection related to suppressed bone marrow function
  Desired outcome: *The patient will be free from infection and will exercise caution to avoid exposure to sources of infection.*
- Risk for Injury related to cardiotoxicity, depressed bone marrow function, and associated bleeding
  Desired outcome: *The patient will not suffer from any acute or chronic cardiotoxicity and will be able to recognize and promptly report any of its clinical manifestations. In addition, the patient will attain pretreatment hematologic status. The patient will learn to monitor and manage situations that may induce bleeding.*
- Imbalanced Nutrition: Less than Body Requirements related to nausea, vomiting, and taste alterations
  Desired outcome: *The patient will remain adequately nourished because emesis control will be achieved by pharmacologic and nonpharmacologic means.*

TABLE 57.4 Agents That Interact with P Doxorubicin

Interactants	Effect and Significance	Nursing Management
digoxin	Decreased serum levels and therapeutic effect of digoxin	Monitor serum digoxin levels.
heparin	Precipitate formation if mixed together	Administer doxorubicin and heparin separately.
barbiturates	Increased plasma clearance of doxorubicin	Notify health care provider for dosage considerations.

- Impaired Skin Integrity related to possible extravasation and radiation recall

  Desired outcome: *The patient will recognize and report signs and symptoms that suggest an extravasation or recall reaction. The patient will receive the doxorubicin dose without vascular or tissue damage.*

Planning and Intervention

Maximizing Therapeutic Effects

Recent advances in drug development have made possible the use of cardioprotectants in conjunction with anthracycline therapy. One such drug is dexrazoxane (Zinecard). Dexrazoxane is a potent intracellular chelating drug that interferes with iron-mediated free radical generation, thought to be responsible for anthracycline-induced cardiotoxicity. It is indicated to reduce the severity and incidence of cardiomyopathy associated with doxorubicin in women with metastatic breast cancer who have received a cumulative dose of 300 mg/m^2 and who, in their prescriber's opinion, would benefit from continuing treatment with doxorubicin. Dexrazoxane and doxorubicin may be used concurrently in children. The recommended dose of dexrazoxane to doxorubicin is at a ratio of 10:1 (e.g., dexrazoxane, 500 mg, to doxorubicin, 50 mg). If prescribed, give this by slow IV push or rapid IV infusion before administering doxorubicin. Do not allow the total elapsed time from the beginning of the dexrazoxane infusion to the initiation of doxorubicin to be more than 30 minutes. The adverse effects of dexrazoxane at the recommended dose are mild; however, dexrazoxane could add to the myelotoxic effects of doxorubicin.

Minimizing Adverse Effects

Before initiating doxorubicin therapy, carefully assess the patient's cardiac and hematopoietic functions, because of the extensive effect of the drug on the systems involved. Implement strategies using dose administration and scheduling to modify the risk for cardiotoxicity. The recommended maximum cumulative lifetime dose of doxorubicin is 550 mg/m^2. However, if the patient has previously had myocardial irradiation or cytotoxic drug therapy, the cumulative lifetime dose should be lowered to 400 mg/m^2. Modifying the dose and dosing schedule of the patient can ameliorate the cardiotoxic adverse effects. Multiple daily doses rather than large single boluses of the drug can also minimize cardiac damage.

Dose reduction to a cumulative dose of 400 mg/m^2 is advocated for patients who have had or who are receiving concurrent radiation therapy or cyclophosphamide. With regard to extravasation, prevention is the key. Prevention requires that medical and nursing personnel be skilled in venous access techniques, perform meticulous monitoring during drug administration, and know actions to undertake promptly in case extravasation occurs. Use large veins, with a new peripheral line for vesicant administration. Extravasation can occur even with a good venous return and without the usual initial complaint of burning or pain at the injection site (see Chapter 36). Administer vesicants through the side port of a free-flowing IV set, allowing for dilution of drug and frequent blood return checks during administration. If the patient complains of any discomfort or if loss of blood return or swelling is noted, discontinue the vesicant administration immediately.

Providing Patient and Family Education

- Reassure patients that reddish urine after doxorubicin injection is a harmless and expected response to the drug. This reaction may happen within 1 to 2 days postinfusion.
- Explain that a substantial fraction of patients who receive this drug complain of acute nausea and vomiting. Reassure patients that proper antiemetics will be available, and tell them that they should ask for them if needed. Carefully review nonpharmacologic interventions, such as relaxation techniques, with patients and caregivers.
- Review signs and symptoms of extravasation. If a suspected extravasation occurs, provide and review a teaching card with directions for caring for an extravasation site, so that the patient can best participate in care. Reassure patients that adequate monitoring and follow-up, through telephone triage by the health care team, will be undertaken even in the home setting.
- Discuss with patients the signs and symptoms of other adverse effects, particularly cardiotoxicity and depressed bone marrow function, and encourage appropriate precautions. For example, encourage patients to keep appointments for cardiac function tests and caution against taking aspirin or drugs that contain aspirin, which may promote bleeding during suppression of bone marrow function.
- Remind patients who have had radiation therapy that recall reactions, manifested by redness, blistering, and hyperpigmentation, can have a delayed onset and should be reported promptly.

Ongoing Assessment and Evaluation

Advise the patient who continues taking doxorubicin to have periodic examinations of cardiac functions as ordered. Radionuclide ventriculography and echocardiography are useful methods to detect impending myocardial damage. Look for any significant changes in the ECG readings that might indicate potential problems, such as irreversible cardiac damage. Also assess the patient frequently for weight gain, presence of ankle edema, dyspnea, elevated blood pressure, and nonproductive cough, which are typical clinical signs of CHF.

Drugs Closely Related to P Doxorubicin

Doxorubicin HCl liposome (Doxil) is most commonly utilized for AIDS-related Kaposi sarcoma and ovarian cancer. The mechanism of action of doxorubicin HCl liposome

MEMORY CHIP

P Doxorubicin HCl

- Indicated for treating acute leukemias, soft-tissue and bone sarcoma, Hodgkin and non-Hodgkin lymphoma, breast and ovarian cancers, bronchogenic carcinoma
- Major contraindication: severe depression of bone marrow function
- Most common adverse effects: alopecia and nausea with vomiting
- Most serious adverse effects: cardiac damage, bone marrow depression, and extravasation
- Maximizing therapeutic effects: Administer dexrazoxane cardioprotectant therapy, if indicated.
- Minimizing adverse effects: Maintain maximum lifetime dose of 550 mg/m^2; if patient is receiving radiation or concurrent myelotoxic therapy, dose is 400 mg/m^2.
- Most important patient education: Warn patient of the appearance of red urine discoloration (harmless) after administration and of alopecia, which is reversible.

is described under Pharmacokinetics. Unlike the prototype, doxorubicin HCl liposome is not considered to be a vesicant because of the liposomal property of the drug. Instead, acute infusional hypersensitivity reactions have been reported in 10% of patients, necessitating slow administration over at least 30 minutes. Additionally, doxorubicin HCl liposome must be administered in D_5W instead of normal saline, and an in-line filter should not be used. A unique adverse effect of the drug that must be carefully assessed and managed is hand-and-foot syndrome. This condition is associated with erythema, edema, pain, and even desquamation. This condition can be dose limiting; however, once the drug is stopped, the condition resolves quickly.

Mitoxantrone, another antitumor antibiotic, is indicated for prostate cancer and AML. It works by causing cross-links and strand breaks in DNA, thus interfering with RNA and inhibiting topoisomerase II. Like doxorubicin, mitoxantrone is associated with cardiac toxicity and myelosuppression. Unlike doxorubicin, mitoxantrone is dark blue, and patients must be instructed that their urine and the sclera of the eyes can be colored blue-green for up to 72 hours after administration.

Drugs Significantly Different From P Doxorubicin

Bleomycin (Blenoxane) is an antitumor antibiotic. Unlike doxorubicin, it is neither an anthracycline nor a cell cycle–nonspecific drug. Bleomycin is used to treat lymphomas, squamous cell carcinoma, and testicular cancers. It is given by IV, subcutaneous, or intramuscular routes. The recommended dosage is expressed in either units or milligrams (1 unit = 1 mg). Bleomycin is known for its pulmonary toxicity. For this reason, use of this drug has become limited. The early clinical features of bleomycin toxicity are dyspnea and rales, which can progress to pneumonitis and pulmonary fibrosis and may be fatal.

The treatment of bleomycin-induced toxicity consists of discontinuing the drug and administering corticosteroids. The practitioner should review pulmonary function tests and chest radiographs at baseline and periodically thereafter to monitor for adequate pulmonary reserve. Patients should be advised to notify health care providers—especially anesthesiologists—that they have received bleomycin therapy, because pulmonary toxicity is enhanced by a high intraoperative fraction of inspired oxygen.

Other adverse effects are cutaneous toxicity, which is often seen as urticaria or erythematous swelling and phlebitis at the injection site caused by the irritant properties of bleomycin. Following drug administration, patients may complain of fever and chills. Acetaminophen administered in appropriate doses around-the-clock can help alleviate the fever and chills in the first 24 hours after drug administration. Patients may also have nausea and vomiting, general weakness, and, sometimes, hypotension. These symptoms are considered to be an idiosyncratic reaction, similar to anaphylaxis, and are noted rarely and mostly in lymphoma patients. A test dose of 2 U of bleomycin may be administered before the first two treatments. Test doses are not always predictive of hypersensitivity and precautions should still be followed in the absence of a positive test dose reaction. Premedication with acetaminophen and diphenhydramine may be helpful.

C HORMONES AND HORMONE ANTAGONISTS

The **hormones** and **hormone antagonists** (antihormones) are a diverse group of drugs that are beneficial in treating neoplasms. Their use predates the first chemotherapeutic agent (nitrogen mustard) as the oldest form of cancer treatment. Hormones are hormonal or hormone-like drugs that inhibit tumor proliferation by blocking or antagonizing the naturally occurring substances that stimulate tumor growth.

Some hormones alter the cellular environment and affect the permeability of the cell membrane in ways that affect cell growth. This group (see Table 57.1) consists of adrenocorticosteroids, androgens, estrogens, progestins, antiestrogens, antiandrogens, gonadotropin inhibitors, and aromatase inhibitors. Hormonal therapy is recognized mostly for its efficacy in treating neoplasms that originate from tissues in which growth is hormonally mediated, notably prostate and breast cancers. The clinical responsiveness of breast tumors to hormonal manipulations was demonstrated more than 100 years ago. Over time, hormonal treatment of breast cancer has been accomplished by ablative surgery (oophorectomy, adrenalectomy, and hypophysectomy) or pharmacologically by using hormonal and antihormonal therapy.

• C Antiestrogens

Antiestrogens are first-line therapy for treating breast cancer in postmenopausal women. They act as agonists by binding to the estrogen receptors in the target cells, making the

estrogen unavailable to the tumor. Tamoxifen is the most widely recognized antiestrogen. However, it is not a pure antiestrogen. Tamoxifen is a selective estrogen receptor modulator (SERM), one of a group of pharmacologic agents, often called "designer drugs," that produces estrogenic effects, alone or combined with antiestrogenic agents, at various sites in a woman's body. These sites include the breast, endometrium, cardiovascular system, brain, and bone. Two other SERM agents include Evista (Raloxifene) and Feresten (toremifene).

Tamoxifen possesses agonistic properties that stimulate endometrial proliferation, and it is known to induce estrogenic effects that are linked with thromboembolic events. These adverse effects have led to the search for pure antiestrogens, called selective estrogen receptor downregulators (SERDs). Fulvestrant (Faslodex), an SERD, is indicated as second-line therapy in postmenopausal women with metastatic breast disease. Because of its effectiveness and first-line use in treating advanced breast cancer, tamoxifen is the prototype antiestrogen drug.

Nursing Management of the Patient Receiving P Tamoxifen

Core Drug Knowledge

Pharmacotherapeutics

Tamoxifen (Nolvadex) is indicated as a first-line drug for treating advanced breast cancer in premenopausal and postmenopausal women. It is used in adjuvant therapy for the treatment of axillary node-negative breast cancer in women after mastectomy or segmental mastectomy, axillary dissection, and breast irradiation. In premenopausal women with metastatic breast cancer, tamoxifen is an alternative to oophorectomy and irradiation. It is the only drug approved to prevent breast cancer in high-risk women and to reduce the risk of contralateral breast cancer.

Pharmacokinetics

Tamoxifen is well absorbed, highly protein bound, and extensively metabolized in the liver after oral administration. It undergoes enterohepatic circulation, prolonging blood levels. It is taken up by tissues such as the lung, uterus, breast, brain, pancreas, and liver. It has a half-life of 7 to 14 days. Most tamoxifen is excreted in the bile and feces.

Pharmacodynamics

Tamoxifen, a potent nonsteroidal antiestrogenic drug, competes with estrogen for binding sites in tissues high in estrogen receptors, such as breast tissue. This mechanism deprives estrogen-sensitive tumors of estrogen. It may also stimulate the production of transforming growth factor-beta, which inhibits the growth of most breast cancer and other epithelioid cells.

Other favorable consequences of tamoxifen treatment have been reported; namely, increased bone mineral density in postmenopausal women and reduced cholesterol levels, which may account for a lower incidence of fatal myocardial infarction in women receiving adjuvant tamoxifen.

Contraindications and Precautions

Tamoxifen is contraindicated in patients with known hypersensitivity. Precautions should be observed when administering the drug to patients with myelosuppression and during pregnancy and lactation. Tamoxifen is a pregnancy category D drug. An increased incidence of endometrial changes, including hyperplasia, polyps, and endometrial cancer, has been reported with long-term tamoxifen therapy.

Adverse Effects

Short-term tamoxifen therapy is rarely associated with toxicity. Most patients taking this drug experience no toxicity whatsoever. These adverse effects, although they occur infrequently, are most common: hot flashes, particularly in premenopausal women, and mild nausea, which is transient and unaccompanied by vomiting. The severity of hot flashes diminishes with continued use of the drug. Other, less common adverse effects are headache, light-headedness, weight gain, vaginal bleeding and discharge, menstrual irregularities, fluid retention, visual side effects, and skin rash, all of which are reported in fewer than 1% to 2% of patients. Increased bone and tumor pain and a local **disease flare** (worsening of the disease) have been observed; they indicate that the tumor is responding to treatment. Hypercalcemia may occur but is infrequent. Data from long-term studies have clearly established the serious long-term effects of tamoxifen use, which include endometrial cancer, thromboembolic events (strokes and pulmonary embolism), and cataract formation requiring cataract surgery. Patients receiving long-term therapy should be monitored regularly. Adverse hematopoietic reactions are transient and uncommon, usually exhibited by thrombocytopenia.

Women at high risk for cancer or women with ductal carcinoma in situ who are receiving tamoxifen to prevent their risk of developing breast cancer are also at increased risk of cancer and thromboembolic events. Tamoxifen carries a Black Box warning that these women need special counseling to help them weigh the risks versus benefits of therapy.

Drug Interactions

Drug–laboratory test interactions have been reported with tamoxifen therapy, including elevated serum calcium and thyroxin levels. Other interactions are discussed in Table 57.5.

Assessment of Relevant Core Patient Variables

Health Status

Even though the adverse effects of tamoxifen are fairly mild, evaluate baseline hematopoietic test results, particularly platelet counts, to make sure that bone marrow function is adequate. Assess the tumor receptor status of the patient because the measurement of estrogen receptors provides important information for planning treatment. Also, screen the patient for a history of thrombophlebitis or endometrial cancer, which may modify the treatment plan. A baseline vision test may also be necessary.

TABLE 57.5 Agents That Interact with P Tamoxifen

Interactants	Effect and Significance	Nursing Management
oral anticoagulants	Increased risk of bleeding	Monitor prothrombin time. Notify health care provider for dose modifications. Monitor for signs of bleeding.
bromocriptine	Increased serum levels	Monitor tamoxifen serum levels.

Life Span and Gender

One of the most important issues confronting women receiving hormonal therapy is its effect on their sexual and reproductive health. Explore these concerns and discuss the various changes associated with tamoxifen therapy. Tamoxifen is the preferred adjuvant treatment for postmenopausal women who have breast cancer with nodal involvement and estrogen receptor–positive tumors. Assess the patient for pregnancy and explore the contraceptive practices of the patient because the drug can cause fetal harm.

Lifestyle, Diet, and Habits

Women taking tamoxifen experience no limitations in their functional capacities. Lifestyle is not normally affected, except possibly by physical changes, such as hot flashes, menstrual irregularities, weight gain, and vaginal bleeding. Explore with patients how these changes could affect their lifestyle. Although visual side effects are rare, caution patients about driving and performing tasks requiring visual acuity.

Environment

Be aware of the environment in which the drug will be administered. Tamoxifen is a fairly mild oral drug that does not usually require close monitoring. Patients take this drug at home and are instructed to have periodic checkups with their health care provider. Hematologic screenings can be done at an accredited laboratory that sends the findings to the prescriber for comparison with baseline values.

Nursing Diagnoses and Outcomes

- Pain related to discomfort produced by a flare reaction to drug therapy
  Desired outcome: *The patient will learn to recognize the signs and symptoms of a flare reaction and appreciate it as a positive response to tamoxifen therapy.*
- Reproductive and Sexual Dysfunction resulting from drug therapy
  Desired outcome: *The patient will be aware of the physical changes to reproductive and sexual functions. The patient will be accepting of these changes and will explore ways to enhance sexual and reproductive health.*
- Risk for Infection and Bleeding related to suppression of bone marrow function
  Desired outcome: *The patient will learn to recognize and report symptoms related to infection and bleeding and will implement measures to prevent unnecessary risks or injury that will compromise the hematopoietic and immune systems.*
- Risk for Impaired Skin Integrity related to skin rash and pedal edema
  Desired outcome: *The patient will report the appearance of skin rash and monitor peripheral edema from fluid retention. The patient will take steps to reduce edema from fluid retention, such as eating a low-salt diet.*
- Disturbed Sensory Perception (Vision and Balance) related to adverse effects of drug therapy
  Desired outcome: *The patient will recognize and report changes in visual acuity and other related symptoms, such as headache, dizziness, and light-headedness, to the caregiver. The patient will take the necessary precautions to avoid injury resulting from altered visual acuity.*
- Risk for Injury related to drug-induced hypercalcemia
  Desired outcome: *The patient will be knowledgeable about clinical manifestations of hypercalcemia, such as nausea, vomiting, constipation, decreased urine volume, malaise, and loss of muscle tone. The patient will also know to report these signs and symptoms immediately to the prescriber, who might consider the need for hospitalization. The patient's calcium level will normalize.*

Planning and Intervention

Maximizing Therapeutic Effects

Tamoxifen is very effective in treating metastatic breast tumors identified as estrogen receptor positive. This criterion is an important determinant in the patient's response to tamoxifen therapy. Ensure that the necessary testing is done to determine the patient's estrogen receptor status.

Minimizing Adverse Effects

Tamoxifen's adverse effects are generally mild and rare. To determine whether such effects occur, ensure monthly monitoring of blood counts, annual Papanicolaou smears, and regular visual function tests. The changes noted most often are those related to the menopausal symptoms and can be very bothersome, especially to premenopausal women. Teach these patients to implement comfort measures such as wearing absorbent cotton clothing, lowering the thermostat at home, avoiding caffeine and spicy foods, and exercising regularly. Discuss the patient's concerns and the effect of the adverse events on reproductive and sexual functions and quality of life. The occurrence of a disease flare is actually a positive sign of tumor response to the therapy. Advise the patient that she might experience initial bone and tumor

pain and an increase in tumor size. If these symptoms are bothersome, assist the patient in obtaining a prescription for pain medication.

Providing Patient and Family Education

- Instruct patients to report signs and symptoms of a disease flare to the prescriber. If signs and symptoms are distressing, obtain the necessary supportive medications for her.
- Teach patients to recognize and report changes in visual acuity and other related symptoms, such as headache, dizziness, and light-headedness. If periodic vision checkups are ordered, emphasize their importance.
- Remind patients to report immediately any clinical manifestations of hypercalcemia, such as nausea, vomiting, constipation, decreased urine output, malaise, and loss of muscle tone. Hypercalcemia may require hospitalization.
- Teach patients to recognize and report the appearance of skin rash and peripheral edema.
- Educate patients regarding likely changes in reproductive or sexual function, such as irregular or missed menstrual periods or unscheduled vaginal bleeding.
- Reassure patients that all of the above symptoms are mild and rarely occurring adverse effects of tamoxifen therapy. These symptoms do not usually require discontinuing the drug.
- Counsel patients about contraception and warn that the drug can cause fetal harm.
- Advise patients taking long-term tamoxifen therapy to have annual pelvic examinations and Papanicolaou screening and to note and report any unusual vaginal bleeding.

Ongoing Assessment and Evaluation

Throughout tamoxifen treatment, monitor the patient's blood count regularly. Although hypercalcemia is uncommon, evaluate serum calcium levels during therapy to make sure that appropriate measures are initiated to correct this condition should it occur. Also assess the patient's vision, because of the possibility for corneal changes and decreased visual acuity.

Drugs Significantly Different From P Tamoxifen

Adrenocorticosteroids

In addition to their cytotoxic effects, adrenocorticosteroids are used for their palliative benefits. For example, adrenocorticosteroids such as betamethasone, dexamethasone, and prednisone have anti-inflammatory properties and are useful in reducing the edema and associated symptoms in brain tumors. Adrenocortical steroids are effective in leukemias and lymphomas because of their suppressant effect on lymphocytes. Many of their adverse effects, such as increased appetite and a feeling of well-being, are an extension of their normal physiologic activity and are considered beneficial and palliative. Some of their adverse effects are glucose intolerance, peptic ulceration, manic psychosis, and suppression of cellular immunity, which predisposes patients to infection.

MEMORY CHIP

P Tamoxifen

- Indicated for advanced breast cancer in postmenopausal women and cancers of tissues having specific hormone receptors, such as the prostate gland
- Major contraindications: allergy to the drug, pregnancy, and lactation
- Most common adverse effect: occurrence of hot flashes, especially among premenopausal women
- Most serious adverse effects: risk of endometrial cancer and thromboembolic events associated with long-term therapy
- Maximizing therapeutic effects: Instruct the patient to take his/her pills bid, in the morning and evening. Drug should not be discontinued without consulting the physician or nurse.
- Minimizing adverse effects: Teach the patient to regulate the home environment to a cooler temperature; to wear loose, cotton, layered clothing (for hot flashes); to eat small, frequent meals and to stay away from spicy foods (for nausea and vomiting); and to notify the physician immediately if symptoms of muscle weakness, pain and swelling of legs and ankles, mental confusion, and constipation are noted.
- Most important patient education: Counsel women about the possible risks of endometrial cancer and to have regular gynecologic checkups.

Androgens, Estrogens, and Progestins

Androgens, estrogens, and progestins are used to treat cancers of tissues that have specific hormone receptors—for example, mammary tissue and the prostate gland. Because these drugs have a greater degree of specificity for these tissues, their effects inhibit proliferation of the tumor.

Androgens control the growth and development of the male sex organs and maintain secondary sex characteristics. This group affects the release of various endogenous hormones, namely testosterone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The two androgenic agents fluoxymestrone and testolactone are used palliatively for androgen-responsive recurrent breast cancer in postmenopausal women. These drugs are well tolerated, although they may exhibit adverse effects similar to those produced by the estrogens, including fluid retention, hypercalcemia, and liver impairment. Their most profound side effect is virilization in women, manifested by hirsutism, alopecia, acne, clitoral hypertrophy, and increased libido. Further discussion of testosterone is in Chapter 54, and luteinizing hormone is discussed again in Chapter 55.

Estrogens are necessary to develop and maintain secondary sexual characteristics, control the female menstrual cycle, and affect the maturation of long bones. They diffuse through the membrane of estrogen-responsive cells

and bind to and activate receptors in the cell nucleus. They are believed to change the hormonal milieu of the cells, making them less conducive to growth. Estrogen-responsive cells (those that are sensitive to estrogen) are located in the reproductive system, breasts, pituitary, hypothalamus, liver, and bone. However, not all of the tumors that arise in these organs are estrogen sensitive. In many patients, after the initial hormonal manipulation, even as the estrogen-responsive cells are being destroyed, the cells that are not responsive to estrogen continue to proliferate. Therefore, the response is neither complete nor permanent. Estradiol is an estrogen given orally to treat advanced prostate cancer, adenocarcinoma, and metastatic breast cancer. Estradiol is also available as a vaginal cream that is well absorbed through the skin and mucous membranes. Additionally it is supplied as a transdermal patch. The adverse effects include gynecomastia, voice changes, hirsutism, change in libido, fluid retention, nausea, vomiting, and thrombophlebitis. Further discussion of estrogens is in Chapter 56.

Progestins are natural or synthetic substances that affect the actions of progesterone, a steroid that counteracts the actions of estrogens. Megestrol acetate (Megace) is a progestin indicated for treating carcinoma of the breast, endometrium, and kidney. It is also used for the treatment of anorexia and cachexia associated with cancer. Medroxyprogesterone is the other agent used in patients with advanced endometrial cancer. These agents are contraindicated during pregnancy because they have been found to cause fetal genital abnormalities. Progestins are also discussed in Chapter 56.

Antiandrogens

Antiandrogens compete with testosterone for androgen-receptor binding sites on target cells. The most frequently used antiandrogenic agents are bicalutamide (Casodex), flutamide (Eulexin), and nilutamide (Nilandron). These agents are used for advanced stages of prostate cancer. Adverse effects are gynecomastia, diarrhea, hot flashes, breast pain, impotence, loss of libido, and abnormal liver function test results. The patient's liver function should be monitored if the patient is on prolonged therapy.

Gonadotropin-Releasing Hormone Analogues

The gonadotropin-releasing hormone (GnRH) analogues are goserelin acetate (Zoladex) and leuprolide (Lupron). LH and FSH are gonadotropins that stimulate hormone secretion by the gonads. They play an important role in the maturation of the germ cell. GnRH regulates the release of these hormones from the pituitary gland. Goserelin inhibits the secretion of gonadotropin. When patients are on prolonged therapy with this drug, their serum testosterone level is decreased to a level equivalent to that associated with surgical castration. This drug is an alternative treatment for males with advanced prostate cancer who do not wish to undergo orchiectomy or estrogen therapy. It is also used in advanced breast cancer. Goserelin is well tolerated. In men, adverse effects are hot flashes, sexual dysfunction, and fewer erections. In women, adverse effects are decreased bone mineral density, vaginal bleeding, and breast tenderness. Goserelin is available as a preloaded, disposable syringe with a 14-gauge needle that is injected subcutaneously into the upper abdominal wall. The other drug, leuprolide, has similar indications and also causes chemical orchiectomy in men who have metastatic prostate cancer. Leuprolide has fewer adverse effects than goserelin. It is available in three formulations: a subcutaneous injection, a depot suspension, and a suspension given intramuscularly. With both these medications, it is important to teach the patient the correct administration technique appropriate to the drug formulation and emphasize the importance of adhering to the dosage schedule. Two other drugs in this category indicated for the palliative treatment of advanced prostate cancer include; triptorelin (Trelstar), and histrelin (Vantas). Triptoerlin is available in a once monthly injection or a long acting injection given once every 84 days. Histrelin is inserted into the patient as a SQ implant that gives off continuous drug for 12 months. A drug similar but considered an antagonist is Degarelix (Firmagon). This drug is a new LHRH antagonist that was approved for use in 2008 to treat advanced prostate cancer. It is given monthly as an injection under the skin.

Aromatase Inhibitors

As tamoxifen became the mainstay for antiestrogen therapy in breast cancer, the role of aromatase was increasingly explored. Many breast cancers have estrogen receptors; the growth of these tumors is stimulated by estrogen. In postmenopausal women, the main source of estrogen is the conversion of precursors to estrogen (primarily estradiol); this conversion occurs through an enzyme called aromatase. Drugs in this class inhibit aromatase, thus decreasing the eventual levels of available estrogen. Anastrozole is a nonsteroidal aromatase inhibitor that is also considered an antiestrogen, similar to tamoxifen. It is indicated for the treatment of postmenopausal women who have locally advanced or advanced breast cancer that has and for those who have progressed after tamoxifen therapy. It is also approved for early breast cancer as adjuvant treatment. It is given orally and is well tolerated. It is important to discuss the patient's reproductive goals and warn patients that this drug can cause fetal harm. Anastrozole can interact with some herbal preparations. Two other aromatase inhibitors are Aromasin (exemestane) and Femara (Letrozole). The most common side effect of drugs in this category is joint pain. Aromatase inhibitors are often used first line or after treatment with tamoxifen to extend disease free survival. Aromasin is unique in that it inactivates aromatase.

MAXIMIZING CELL KILL: COMBINATION THERAPY

With rare exceptions, monotherapy in cancer is not curative because of drug resistance. Most cancers contain cells that are resistant to any single agent. In tumors that initially

BOX 57.6 FOCUS ON RESEARCH

Combination Therapy for Stage III Colon Cancer

Schmoll, H., Cartwright, T., et al. (2007). Phase III trial of capecitabine plus oxaliplatin as adjuvant therapy for stage III colon cancer: A planned safety analysis in 1,864 patients. *Journal of Clinical Oncology,* 25(1):102–109.

The Study

Researchers designed a study to compare the two adjuvant treatment options for stage III colon cancer in terms of toxicity and safety. Patients with the disease were randomly assigned to receive one of two regimens: either oral capecitabine plus intravenous oxaliplatin (XELOX) or a standard intravenous bolus of fluorouracil/leucovorin (FU/LV, as administered at the Mayo Clinic) on a 3-week cycle for eight cycles. The patient population consisted of 1,864 patients; of these, 938 received XELOX and 926 received FU/LV. Most treatment-related adverse events occurred at similar rates in both treatment arms. However, patients receiving XELOX experienced less diarrhea and alopecia, and more neurotoxicity, vomiting, and palmar planter syndrome than those patients receiving FU/LV. Compared with the FU/LV regimen, XELOX showed fewer grade 3/4 hematologic toxicities and more grade 3/4 gastrointestinal toxicities. Treatment-related mortality within 28 days from the last study dose was 0.6% in the XELOX group and 0.6% in the FU/LV group. In conclusion, this study proved that XELOX has a manageable tolerability profile in the adjuvant setting. Efficacy data will continue to be studied.

Nursing Implications

Nurses are challenged with understanding the toxicities of various regimens as well as the rationale for using one regimen over another. As more and more combination chemotherapy regimens are designed for various cancers, safety and toxicity data are extremely important when determining the most efficacious and tolerable regimen for the patient. Quality of life is an important consideration in the treatment of cancer. This study illustrates the importance of large randomized trials to answer questions of patient tolerability. Long-term survival data will also be an important next step in deciding the most appropriate regimen for this patient population. Nurses have a responsibility to assess carefully and to report any and all toxicities that patients experience so that these regimens can be fully understood and toxicities managed properly.

respond to an agent, further drug resistance may develop during treatment as a result of proliferation of pre-existing drug-resistant cells or because of increased mutations that lead to drug resistance. If a combination of drugs is used, cells that are resistant to one chemotherapy agent may be killed by another agent in the combination. Furthermore, many antineoplastic drugs are dose limited because of their cytotoxicity. The limits imposed by toxicities to the different organ systems are another rationale for using combination drugs to achieve better therapeutic outcomes.

Combination chemotherapy, first developed in the 1960s and 1970s, is one of the major advances in cancer therapy. It continues to guide the development of new treatment protocols for various malignancies. Combination therapy involves using two or more drugs proven effective against a tumor type (Box 57.6). It is considered superior to single-drug therapy because of higher tumor response rates and increased duration of remissions. The effectiveness of a particular antineoplastic drug is measured by objective criteria and tumor response (Box 57.7).

Many combination regimens in current use have proved to increase the response rate two to four times (Table 57.6). Two or more drugs can be administered simultaneously or in a preplanned sequence. In combination therapy, the response rates and survival are more dramatic because they accomplish the following objectives:

- Maximum cell kill within the range of toxicity tolerated by the patient
- A broader range of coverage against resistant cell lines in the heterogenous tumor population
- Minimal or slow development of new resistant cell groups

In designing successful drug combinations, the choice of drugs follows these principles:

- Selected drugs should be proven partially effective against the tumor when used alone.
- Ideally, the drugs used in combination are best if they do not have overlapping toxicities.
- The dosages and schedules for the various drugs should be maximized.
- Drugs should be administered at consistent intervals.
- Drugs should be selected to produce synergy.

Box 57.7 RATING TUMOR RESPONSE

How well a tumor responds to chemotherapy can be rated by the categories below.

Complete Response

All evidence of tumor (physical examination and radiologic studies) has disappeared and no new lesions have developed. Response must last for at least 4 weeks. The patient must have no cancer-related symptoms and all abnormal biochemical parameters must have returned to normal.

Partial Response

The sum of the product of the diameters of measured lesions decreases 50% or more for at least 4 weeks without cancer-related symptoms or weight or performance deteriorations. If there is no change in tumor size but the biochemical parameters decline by 80% or more, the patient is considered stable.

Stable Disease

Patients who do not meet the criteria for partial response but who are without signs and symptoms of progressive disease for at least 3 months comprise this category.

Progressive Disease

An increase exceeding 25% in the total area of the bidimensionally measured lesions, the appearance of new lesions, or greater or significant deterioration that cannot be attributed to treatment or medical conditions is considered disease progression.

TABLE 57.6 Common Combination Regimens

Acronym	Regimen	Indications
ABVD	Doxorubicin, bleomycin, vinblastine with dacarbazine	Hodgkin lymphoma
AC	Doxorubicin, cyclophosphamide	Breast cancer
BEP	Bleomycin, etoposide, cisplatin	Testicular cancer
BIP	Bleomycin, ifosfamide, cisplatin, mesna	Cervical cancer
CAF	Cyclophosphamide, doxorubicin, fluorouracil	Breast cancer
CAP	Cyclophosphamide, doxorubicin, cisplatin	Non–small-cell lung cancer
RCHOP	Rituximab, cyclophosphamide, doxorubicin, vincristine	Non-Hodgkin lymphoma
CHOP-BLEO	Add bleomycin to CHOP	Non-Hodgkin lymphoma
CMF	Cyclophosphamide, methotrexate, fluorouracil	Breast cancer
CP	Cyclophosphamide, cisplatin	Ovarian cancer
DHAP	Cisplatin, cytarabine, dexamethasone	Hodgkin's lymphoma
EAP	Etoposide, doxorubicin, cisplatin	Gastric cancer
EC	Etoposide, carboplatin	Small-cell lung cancer
FAC	Fluorouracil, doxorubicin, cyclophosphamide	Breast cancer
FAM	Fluorouracil, doxorubicin, mitomycin	Gastric cancer
FAMTX	Fluorouracil, doxorubicin, methotrexate, leucovorin	Gastric cancer
ITP	Ifosfamide, Taxol, cisplatin	Genitourinary cancer
IVAC	Ifosfamide, vincristine, doxorubicin, cyclophosphamide	Multiple myeloma
ICE	Ifosfamide, carboplatin, etoposide	Lung cancer
MAID	Mesna, Adriamycin (doxorubicin), ifosfamide, dacarbazine (MAI is also commonly used and excludes dacarbazine).	Sarcoma
MOPP	Mechlorethamine, vincristine, procarbazine	Hodgkin lymphoma
MVAC	Vincristine, doxorubicin, cyclophosphamide	Lung cancer
MVP	Mitomycin, vinblastine, cisplatin	Lung cancer

CHAPTER SUMMARY

- Cell cycle–nonspecific drugs exert their cytotoxic activity irrespective of the phase of the cell life cycle.
- Cell cycle–nonspecific drugs are considered more toxic than cell cycle–specific drugs.
- Alkylating drugs are radiomimetic.
- The nitrosoureas are alkylating agents that are highly lipid soluble.
- The antitumor antibiotics that are considered both anthracyclines and topoisomerase II inhibitors are daunorubicin, doxorubicin, and idarubicin. Mitoxantrone is a synthetic anthracenedione.
- The most feared adverse effect of anthracycline therapy is cardiotoxicity.
- Some prognostic factors relating to a patient's tolerance to acute emesis are age, gender, and method of drug administration.
- The different groups of hormones used in cancer therapy are the adrenal corticosteroids, androgens, antiandrogens, estrogens, antiestrogens, gonadotropin-releasing hormone analogues, progestins, and aromatase inhibitors.
- Combination chemotherapy is superior to single-drug therapy because it kills a maximum number of cancer cells within a toxicity range tolerated by the patient, it provides a broader range of coverage against resistant cells in the heterogenous tumor population, and it is characterized by minimal or slow development of new resistant cancer cells.
- Targeted therapies have been developed that work directly to prevent cancer cell development and growth. Because their primary effect is on cancer cells, these therapies are associated with fewer adverse effects than other chemotherapies.

QUESTIONS FOR STUDY AND REVIEW

1. What are anthracyclines, and which of the antitumor antibiotics are they?
2. Which cell cycle–nonspecific drugs are highly lipid soluble? What can they do?
3. What are the different groups of drugs used to control acute emesis?
4. What is the role of dexrazoxane in anthracycline therapy? How is it administered?
5. What are the characteristics of drugs that are useful for combination therapy?

Answers to Questions for Study and Review

Unit 1: Foundations for Drug Therapy in Nursing

Chapter 1: Nursing Management of Drug Therapy

1.1. The nurse assesses core patient variables in several ways: the patient interview, the physical assessment, and the medical record. Data on some of the variables can be obtained from more than one source.

1.2. Core drug knowledge contains basic pharmacologic facts about the drug. The nurse needs to know this information to administer drugs safely, to determine interactions with core patient variables, to devise strategies, to maximize therapeutic effects and minimize adverse effects, and to educate patients and their families.

1.3. Learning about a prototype drug gives the nurse information about a group of drugs instead of just one drug, which simplifies learning and helps the nurse organize drug information logically.

1.4. Core patient variables may affect the form the patient education should take (i.e., written, visual with pictures, or spoken), who in the family should be included in the teaching, and what content is most important to include in the teaching.

Chapter 2: Pharmaceuticals: Development, Safeguards, and Delivery

2.1. The *United States Pharmacopeia* (USP) and the *National Formulary* (NF) are compendia of drugs available in the United States. The drugs are listed by their official names.

2.2. The "omics" technologies use knowledge of a person's DNA sequencing to predict which drugs would be most efficacious or undesirable for that particular patient. It is proposed that individualizing pharmacotherapy will maximize therapeutic effects and minimize adverse effects.

2.3. Drugs are classified according to chemical composition, physiologic effect, or therapeutic use. Organizing a multitude of drugs into family groups—drug classes—with similar characteristics facilitates learning about an individual drug within the group. A general characteristic of the drug class is likely to apply to a single drug within the class.

2.4. The 1938 Food, Drug, and Cosmetic Act prohibited the marketing of new drugs before they had been properly tested for safety. It further stipulated that pharmaceutical companies had to submit an investigational new drug application to the government for review of a drug's safety before it could sell the product. The Durham-Humphrey Amendment provided further safeguards. This amendment distinguished between legend drugs (requiring a prescription) and over-the-counter drugs (not requiring a prescription) and required that labels of legend drugs carry the legend: "Caution—Federal law prohibits dispensing without a prescription." It further specified certain drugs that could not be refilled without a new prescription from the health care provider. The Canadian Narcotics Control Act (1961) regulated possession, sale, manufacture, production, and distribution of narcotics.

2.5. Clinical trials proceed after extensive animal testing provides initial evidence of the safety and efficacy of a new drug. Clinical trials have four phases. Phase I establishes optimal dosage range and pharmacokinetics. Phase II closely monitors study participants for the drug's effectiveness and adverse effects. Phase III begins if no serious adverse effects have been identified in phase II. Beginning in this phase, double-blind studies (in which neither the investigator nor the study subject knows whether the drug being administered is a placebo or the new drug being studied) establish the drug's clinical effectiveness, safety, and dosage range. Phase IV consists of postmarketing studies. Some drugs make it through all phases of clinical trials without problems, only to have severe adverse effects show up after they are used more widely in the general population. Examples of this phenomenon are the links uncovered between felbamate and aplastic anemia and between troglitazone and hepatic failure.

2.6. Controlled substances are drugs defined and categorized according to their abuse potential and dependence-producing liability.

The 1970 Controlled Substance Act requires an accounting of all controlled drugs on a special record and an accounting of all discarded or wasted medication. Another licensed nurse must countersign the special record filled out by a first. Furthermore, all controlled substances must be kept under double lock. Only authorized people have access to the keys.

2.7. All patients should be taught not to share drugs with anyone else, to follow directions for use that appear on the drug label, to avoid drinking alcohol with any prescription or over-the-counter drug, and not to take a drug after its expiration date.

2.8. The patient teaching plan for drug therapy should include the drug name and reason for use; the dosage (amount, frequency, duration of therapy, what to do about a missed dose or a double dose); administration route; special directions or procedures (for drug administration, drug stability, storage, disposal); minor adverse effects and reportable serious adverse effects; drug interactions (among drugs and foods); effects of other disease states on drug therapy; and self-monitoring techniques.

Chapter 3: Drug Administration

3.1. The most frequently used drug administration route is the enteral route for oral drugs.

3.2. An enteric coating prevents the drug from breaking down in the stomach and thus prevents GI irritation and inactivation of the drug by stomach acid. Sustained release may also occur with enteric coating.

3.3. The parenteral route may be recommended for a patient who is unable to swallow, is confused and uncooperative with oral medications, is unconscious, or has a physiologic need to keep the GI tract empty (e.g., in preparation for a diagnostic test or surgery, or to rest the tract). The parenteral route may be used when the drug has a high first-pass effect when administered orally, which eliminates most of the active drug, or when the drug will be inactivated by gastric acid.

3.4. The greatest risk for rapid drug toxicity is the intravenous route, especially in cases of continuous intravenous infusion.

Unit 2: Core Drug Knowledge

Chapter 4: Pharmacotherapeutics, Pharmacokinetics, and Pharmacodynamics

4.1. Pharmacokinetics is what happens to the drug as it moves through the body (i.e., the body's effect on the drug). Pharmacodynamics is the manner in which the drug produces its action in the body (i.e., the drug's effect on the body).

4.2. Lipophilic drugs are soluble in lipids, or fats. Because the cell membrane is composed primarily of lipids, being lipophilic allows a drug to pass through the cell membrane easily.

4.3. Hydrophilic drugs or particles are water soluble. Water solubility promotes excretion in the urine, which is water based.

4.4. Drugs attach to specialized receptors on the cell. Attachment to the receptor either turns on the receptor's specialized action or blocks other substances from attaching to the receptor.

4.5. One hundred percent of drugs that are given orally present to the liver first after absorption. If the drug is extensively metabolized, most of the drug dose will be lost before it enters the systemic circulation. Giving the drug by another route (such as the intravenous route or the sublingual route) bypasses the liver initially, allowing 100% of the drug dose to enter the systemic circulation.

4.6. In a person with renal insufficiency or hepatic dysfunction, the dose given may be lower than the typical dose given to other patients because improperly functioning kidneys cannot excrete drugs at the rate that is normally expected and a poorly functioning liver cannot metabolize drugs as rapidly. Both of these impairments increase the amount of circulating drug and prolong the effect from a drug dose. An increase in the amount of the circulating drug increases the therapeutic effects of the drug, but it also increases the risk for adverse effects.

4.7. A patient with decreased albumin levels who is receiving a drug that is known to be highly protein bound is at higher risk for adverse drug effects than a patient with normal albumin levels because drug that is bound to protein is not active. Only free drug is active and can create an effect. Because the protein albumin is low, there is no place for the drug to bind, and more drug than would normally be expected is free, active, and able to cause therapeutic and adverse effects.

Chapter 5: Adverse Effects and Drug Interactions

5.1. Rash, hives, redness, itching, swelling of the eyes or another body part, and difficulty swallowing or breathing (laryngeal edema) are all signs of allergic reactions to drug therapy. Complaints such as nausea or vomiting would more likely indicate adverse effects.

5.2. Changes in hearing and balance may naturally occur with aging, but they are also signs of ototoxicity. Thus, adverse effects could be misconstrued as age-related changes.

5.3. The circulating blood level of Drug A will be decreased. When Drug B stimulates the hepatic pathway, more of the isoenzyme

CYP3A4 will be active, leading to more metabolism of Drug A. As Drug A is metabolized at a faster than normal rate, the circulating level will decrease.

5.4. No, the circulating blood levels of the drug will differ. The effect of grapefruit juice on metabolism varies greatly among people because people have different amounts of CYP3A4 in their GI tract.

5.5. Owing to normal circulatory patterns, all the dose of the oral drug is presented initially to the liver, where damage may occur. When the drug is administered parenterally, the drug molecules first go to the heart, and then only about 25% of the molecules are sent to the liver. Because fewer drug molecules are present in the liver at any given time, less damage may occur.

5.6. The combination of these drugs will result in an additive CNS depressive effect, greatly increasing the risk for CNS toxicity.

5.7. As the nurse, you consider the possibility that Drug A and Drug B have had an interaction, producing decreased therapeutic response from Drug A. Look up both drugs and determine whether this is an accurate assessment.

Unit 3: Core Patient Variables

Chapter 6: Life Span: Children

6.1. In the infant and especially the neonate, immature liver function affects drug distribution. The neonate's immature liver produces fewer plasma proteins, especially albumin; many drugs bind strongly to albumin. The pharmacologic effects of drugs result from unbound, or free, drug. In the neonate and infant, more free drug is available because less drug is bound to plasma protein. This state results in increased blood levels of drugs and, in turn, more adverse effects and toxicity.

6.2. Body surface area is the external surface of the body expressed in square meters. The ratio of body surface area to weight is inversely proportional to length. Body surface area is determined to calculate the correct dose for many drugs given to pediatric patients.

6.3. An increased dose of some drugs may be given to the infant because the drug is diluted by the infant's higher body water content.

6.4. No. Some drugs have adverse effects only in children and are contraindicated in them. Most drugs are not supported by enough clinical study to determine what effects (therapeutic and adverse) they would have on a child. These drugs are used off-label in children. Caution and extra monitoring must be used when administering these drugs.

6.5. The correct dose is 250 mg every 12 hours. The dose is determined in the following manner:

25mg: 1kg:: x mg: 20kg (or can be written $\frac{25mg}{1kg} = \frac{xmg}{20kg}$); solving for x gives an answer of 500 mg per day.

As there are two doses in 24 hours (one dose every 12 hours), divide 500 mg by 2 to equal 250 mg per dose. The most common pediatric medication error is a misplaced decimal, resulting in a ten-fold error in the dose. In this case a misplaced decimal point could have resulted in a dose of 25 mg or 2500 mg being administered instead of 250 mg. To prevent administering the incorrect dose, double-check the dosage for each dose you administer, even though the physician and the pharmacist should have also calculated the dose. In some institutions, all doses are rechecked by two nurses; in others only certain medications are rechecked by two nurses, and the remaining drugs are double-checked by only one nurse.

6.6. Vastus lateralis or rectus femoris.

6.7. If past experiences were unpleasant, the child would more likely be fearful and anxious about this interaction or drug therapy. Because parents and sometimes other family members are normally responsible for seeing that the child receives the appropriate drug therapy at home, including family members in the planning and education relevant to drug therapy is crucial. Children also need to be involved, at an age-appropriate level, in their drug therapy.

Chapter 7: Life Span: Pregnant or Breast-Feeding Women

7.1. A drug assigned to FDA pregnancy category X should not be used because it is almost sure to harm the fetus. The benefits of drug therapy cannot compensate for the risk to the fetus.

7.2. Drugs that have low-molecular weight and are lipophilic and non-protein-bound will pass through the placenta's lipid membrane easily.

7.3. Gestational weeks 3 through 8 mark the period of organogenesis, which is when all major fetal organ systems are developing. Teratogenic exposure during this period may cause major malformations that are usually recognized at birth.

7.4. Physiologic changes in the renal system that increase drug excretion rates include an increase of 40% to 50% in blood flow. This increases filtration through the glomerulus about 50% and contributes to increased excretion rates.

7.5. Lipophilic or fat-soluble drugs will pass into breast milk due to the high fat content in breast milk.

Chapter 8: Life Span: Older Adults

8.1. Liver function and metabolism are impaired because of decreased mass of the liver, decreased

hepatic blood flow and hepatic tissue perfusion, and changes in the phases of metabolism.

8.2. Normal renal function decreases with aging. Drugs that depend on renal elimination are not excreted as quickly in the older adult. This leads to elevated circulating active drug levels, which place the patient at risk for adverse effects or drug toxicity.

8.3. Polypharmacy is the simultaneous use of multiple prescription and over-the-counter drugs by one person, and it puts the patient at increased risk for drug interactions, adverse effects, and nonadherence with drug therapy. Polypharmacy occurs frequently in older adults because they often experience multiple health problems related to organ and body system deterioration with advanced age.

8.4. Adverse drug effects often mimic many changes which frequently occur naturally with advanced age.

8.5. Activity affects absorption and distribution of some drugs. Dietary habits indicate whether a patient is able to swallow oral tablets or pills. Quality of life may be impaired because of adverse effects of drug therapy. The patient may have strict habits about when the drug therapy is taken; following the patient's normal routine may be less stressful. The patient's economic status, including drug insurance coverage, may affect whether he or she obtains the prescribed drugs regularly.

Chapter 9: Lifestyle: Substance Abuse

9.1. Alcohol is a CNS depressant. In combination with other CNS depressants, alcohol can produce additive pharmacologic effects of CNS depression.

9.2. Drug abuse is the excessive self-administration of a drug (often dependence producing) for other than therapeutic purposes. Drug misuse is the inadvertent incorrect use of a drug, often because the individual lacks knowledge of the drug. Addiction is physical dependence on a drug, which leads to serious physical and behavioral problems. Without the drug, physical symptoms of withdrawal begin to occur. Withdrawal is marked by a variety of physical effects, including nausea, muscle cramping, dysphoria, and convulsions. Characteristics of addiction include compulsive drug use, drug craving, and drug seeking. Psychological dependence (habituation) is an intense desire or craving for the drug when it is not available.

9.3. Factors that place an individual at risk for substance abuse include chronic pain; struggles with self-esteem issues and peer pressure; poverty and illiteracy among the socioeconomically underprivileged; wealth and influence among the very privileged; profession (health care providers); history of child abuse or sexual assault; and family history of substance abuse, including alcoholism.

9.4. Methadone is an opioid with a dependence-producing liability. During therapy, patients develop a dependence on methadone. Oral methadone dosing suppresses opioid withdrawal symptoms, and the drug has a long duration of action (24 hours), which are advantages of methadone therapy.

9.5. Hallucinogenic drugs distort perceptions and reality. Nursing interventions for a "bad trip" rely on decreasing sensory stimuli and providing for safety and support.

9.6. Two major substances that are abused are alcohol and nicotine (cigarettes). Categories of additional drugs of abuse include CNS depressants (alcohol, marijuana, opioids, sedatives and hypnotics, antipsychotics, and antianxiety drugs), CNS stimulants (cocaine, amphetamines, caffeine), and mind-altering or psychedelic drugs (LSD, mescaline, MDMA). Some individuals use drugs to alter thoughts and feelings

Chapter 10: Lifestyle, Diet, and Habits: Nutrition and Complementary Medications

10.1. Adverse drug–nutrient interactions are most likely to occur if medications are taken over long periods, if several medications are taken, or if nutrition status is poor or deteriorating.

10.2. Drugs and nutrients can interact and alter metabolism by acting as structural analogues, competing with each other for metabolic enzyme systems, altering enzyme activity, and contributing pharmacologically active substances.

10.3. Foods can alter drug absorption by changing the acidity of the digestive tract, stimulating secretion of digestive enzymes, altering rate of absorption, binding to drugs, or competing for absorption sites in the intestines.

10.4. Patients may not consider these substances to be potentially harmful or capable of interacting with prescribed drug therapy and therefore may not volunteer this information unless directly questioned.

Chapter 11: Environment: Influences on Drug Therapy

11.1. The nurse assesses for exposure to chemicals in the workplace, home, and community. Exposure to these chemicals is thought to be responsible for alteration of the hepatic drug-metabolizing enzymes, resulting in decreased drug efficacy, prolonged pharmacologic effects, or increased toxicity.

11.2. Alcohol, tobacco, or exposure to chemicals (e.g., industrial chemicals, pesticides) may adversely affect the pharmacokinetics of certain drugs by altering hepatic drug-metabolizing enzymes and altering drug responses, which increases the patient's risk for drug reactions.

11.3. The nurse inquires about the patient's home and workplace environment because they may have a bearing on drug therapy. The nurse also obtains a complete patient history that also documents lifestyle habits (e.g., ethanol, tobacco), which may affect drug therapy, as well as exposure to workplace chemicals; these factors all influence the hepatic drug-metabolizing enzymes. This information is important and will help the nurse determine whether the desired effect of drug therapy is achieved.

11.4. The nurse collects the medical information, including medication history, from the patient or patient's family and then ensures that the dosages are appropriate for the patient. The nurse then compares the current orders of the health care provider to the medication history and communicates any discrepancies to the health care provider. Medication reconciliation is performed each time the patient moves from one environment to another.

Chapter 12: Culture: Considerations in Drug Therapy

12.1. A culture is a background of customs and traditions, values, institutions, art, history, and folklore that is shared by a people. An ethnic group has a common heritage linked by race, nationality, or language.

12.2. An awareness of cultural differences alerts the nurse to assess for factors that might have an effect on drug therapy, such as current health status, genetic variations in pharmacokinetics, self-medication (with traditional or alternative medicines), and dietary practices. This awareness also assists the nurse in forming a therapeutic relationship, in communicating effectively with the patient and family, and in providing appropriate and effective teaching.

12.3. Obtain an interpreter or translator. Speak to the patient. Speak slowly. Do not shout or exaggerate your mouth movements. Allow time for the patient to think and respond. Use as few words as possible. Use as many words in the patient's language as possible. Use nonverbal language.

12.4. If the patient is present oriented, explain problems that may occur now, if medicine is not taken as directed. If the patient is future oriented, she or he will be more receptive to learning that the medication will prevent future problems if taken as directed.

12.5. The genetic background of Mexican Americans is quite varied. Their bodies may not handle drugs in the same way as Hispanics. Drug information that is related to findings for Hispanic people can be generalized only tentatively to Mexican Americans.

12.6. This patient is at risk to have more adverse effects from the drug therapy than other patients. With less metabolism, more drug remains in the circulation to be active and to cause adverse effects (as well as more therapeutic effects). Serum levels of the drug can be monitored to determine if the patient is reaching toxic levels of the drug. A lower dose of the drug is warranted if the patient's serum level of the drug increases significantly.

Unit 4: Peripheral Nervous System Drugs

Chapter 13: Drugs Affecting Adrenergic Function

13.1. Drugs that stimulate the SNS attach to and stimulate the adrenergic receptors, creating the same effects as endogenous neurotransmitters (NE, Epi, DA) that stimulate those receptors.

13.2. Beta-1 blockade slows the speed of conduction in the heart, decreases the force of contraction, and slows down the pulse rate.

13.3. Epinephrine stimulates all beta and alpha receptors. It will initially stimulate beta receptors and cause vasodilation to organs and skeletal muscle. With larger doses, the effects of alpha stimulation are evident and there will be vasoconstriction. When the alpha effects become predominant, they will override the beta effects.

13.4. Dopamine is often dosed based on the clinical response it produces. When urinary output increases to a desired amount, it can be determined that there is enough dopamine to dilate the renal artery and provide adequate perfusion to the kidney. Dopamine also will increase blood pressure from stimulation of alpha receptors. An increase in blood pressure also will allow more perfusion to the organs.

13.5. Prazosin is an alpha-1 blocker and thus causes vasodilation. This decreases peripheral resistance and lowers blood pressure.

13.6. Phenylephrine stimulates alpha-1 receptors causing vasoconstriction, and thus increasing peripheral resistance. This is how it raises blood pressure. When used in cold preparations, the vasoconstriction decreases nasal congestion temporarily.

Chapter 14: Drugs Affecting Cholinergic Function

14.1. Cholinergic stimulation in the eye produces miosis (smaller pupils) and decreases intraocular pressure.

14.2. Cholinergic stimulation of the GI track increases gastric tone and motility to promote digestion and movement through the GI tract and defecation. Additionally, there is more saliva produced to help to break down food that is eaten. GU stimulation results in the relaxation of the deltrusor muscle of the bladder so that voiding can occur. (PSNS is the "rest and digest" system.)

14.3. Extra stimulation of cholinergic receptors may cause the following CV problems:

14.4. Neostigmine inhibits the breakdown of acetylcholinesterase, which is responsible for breaking down acetylcholine. Because it is not broken down as quickly, more acetylcholine is available in the synapse to activate the cholinergic receptors, indirectly increasing the cholinergic stimulation and effects.

14.5. Symptoms of cholinergic crisis include nausea and vomiting, diarrhea, salivation, sweating, peripheral vasodilation, bronchial constriction, and (if not recognized and attended to initially) respiratory arrest. The antidote is the anticholiergic drug atropine.

14.6. Cholinergic effects on the heart include slowing the rate, (decreased pulse), slowing the speed of conduction (decreasing pulse and ECG changes), decreasing the force of contraction (decreasing cardiac output, which will decrease blood pressure).

14.7. The action of atropine on the heart rate is dose dependent. In doses of 0.4 to 0.6 mg, atropine causes a slight sinus bradycardia through vagal stimulation. In larger doses (1 to 2 mg), it causes sinus tachycardia secondary to inhibition of vagal control of the sinoatrial node in the heart. Atropine is mostly given for its ability to increase the heart rate.

Unit 5: Central Nervous System Drugs

Chapter 15: Drugs Relieving Anxiety and Promoting Sleep

15.1. Lorazepam intensifies the effects of GABA, a neurotransmitter that inhibits the nervous system.

15.2. No, it would not continue to be effective. Lorazepam, like all benzodiazepines, allows tolerance to the dose to develop with chronic use. When tolerance develops, a larger dose is needed to achieve the same therapeutic effect. Stopping a benzodiazepine, such as lorazepam, suddenly causes the patient to experience withdrawal symptoms. Additionally, recurrent anxiety or rebound insomnia is likely.

15.3. Lorazepam is metabolized to an inactive metabolite, which can then be excreted renally. Other benzodiazepines are metabolized to active metabolites. With lorazepam, the liver does not have to do as much work to convert the drug to a form that can be eliminated.

15.4. Older adults are more at risk for sedation, ataxia, and confusion than younger adults. This combination places them at increased risk for falling in their homes.

15.5. Triazolam has a very quick onset but also a very short half-life. Because the effects of the drug wear off quickly, the patient may have problems with waking up early in the morning and not falling back asleep easily.

15.6. Eszopiclone is the only drug for insomnia that is approved for long-term use (up to 6 months of use). Unlike the benzodiazepines, eszopiclone does not seem to produce tolerance, even with long-term use. Withdrawal symptoms are possible after discontinuation, but they are mild in comparison to those experienced from benzodiazepine withdrawal.

Chapter 16: Drugs Treating Mood Disorders

16.1. Selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, and monoamine oxidase inhibitors (MAOIs) are the three main classifications of antidepressants.

16.2. When depressed, a patient often lacks the energy to carry out plans for suicide. However, after beginning antidepressant therapy, a patient may experience increased energy before mood improves. Therefore, you must assess the patient for thoughts of self-harm and reassure the patient that the full effects of therapy have not yet occurred. Suicide precautions may have to be implemented to maintain patient safety.

16.3. It is important to continue antidepressant therapy even after symptoms of depression improve; otherwise, the depressive symptoms will come back.

16.4. Gastrointestinal distress is sometimes reported with sertraline therapy. This distress frequently lessens early on, as the patient's body adapts to the drug. Giving the drug with meals may also decrease gastrointestinal distress.

16.5. Adverse effects such as blurred vision, dry mouth, and constipation are the anticholinergic effects frequently associated with nortriptyline therapy.

16.6. The patient taking phenelzine must adhere to a strict diet that excludes foods high in tyramine, such as aged cheeses (especially blue, Camembert, Swiss, and Stilton), tap beers, and some types of meats (pepperoni, salami).

16.7. Symptoms of an MAOI-induced hypertensive crisis are flushing of the face, occipital headache, sweating, suddenly elevated blood pressure, and fever.

16.8. Although lithium is still the first choice for treating bipolar disorder, antiepileptics such as carbamazepine (Tegretol), valproic acid (Depakote), and gabapentin (Neurontin) are increasingly used as well.

16.9. In general, the therapeutic range of lithium is a serum concentration between 0.6 and 1.2 mEq/L.

16.10. Lithium toxicity usually presents as diarrhea, vomiting, unsteady gait, weakness, and slurred speech. Symptoms of toxicities usually appear when the serum level of lithium is greater than 2 mEq/L.

Chapter 17: Drugs Treating Psychotic Disorders and Dementia

17.1. Low-potency typical antipsychotic drugs are more likely to produce these adverse effects: sedation and anticholinergic effects. High-potency typical antipsychotic drugs are more likely to produce extrapyramidal symptoms as an adverse effect.

17.2. EPS—extrapyramidal symptoms—come from the relative lack of dopamine stimulation and relative excess of cholinergic stimulation. There are four major presentations of EPS: (1) Parkinson-like effects (pseudoparkinsonism), which are symptoms that are typically seen with Parkinson disease (cog-wheeling muscle rigidity, fine tremor, slow motor responses, shuffling gait, and a flat affect [a mask-like facial expression]); (2) akathisia (a constant feeling of restlessness); (3) acute dystonia; and (4) tardive dyskinesia (involuntary lip-smacking, chewing, mouth movements, tongue protrusion, blinking, grimacing, and muscle twitching of the limbs). Tardive dyskinesia, unlike the other EPS adverse effects, is usually permanent once it occurs.

17.3. Typical antipsychotics treat the positive symptoms of psychotic illness (delusions and hallucinations). Atypical antipsychotics treat the positive symptoms as well as the negative symptoms (flat or blunted emotions, lack of pleasure or interest in things [anhedonia], and limited speech). Atypical antipsychotics also produce very few adverse effects.

17.4. Acute dystonia involves prolonged muscular contractions and spasms, especially in the neck (arching and twisting), the larynx and pharynx (contractions and spasms that may occlude the airway), back (arching), and eye (eye-rolling up toward the back of the head). Although all of the symptoms can be painful and require medical attention, airway occlusion can be life-threatening and constitutes a medical emergency.

17.5. Teach that the adverse effect is usually transient. Suggest that instead of giving two equal-sized doses daily to a patient, the larger dose or the entire daily dose could be taken at bedtime. Also, the patient can be encouraged to be as active as possible during the daytime hours to help ward off sedation.

17.6. Rivastigmine is an acetylcholinesterase inhibitor, which prevents the breakdown of acetylcholine. When acetylcholine is not broken down, its action is prolonged on cortical cholinergic receptors and in the synapse; there is also more effective neuronal transmission. This increase in acetylcholine activity decreases the dementia found in mild to moderate Alzheimer disease.

Chapter 18: Drugs Treating Seizure Disorders

18.1. A seizure is hyperexcitation of the neurons in the brain producing changes in level of consciousness and/or involuntary muscle activity. A convulsion is the jerky, involuntary muscle movement that can occur during a seizure.

18.2. Phenytoin slows the influx of sodium through the sodium channels into the cell. Sodium influx changes the negativity of the cell and produces an action potential. Slowing the influx of sodium lengthens the time between action potentials. Both seizures and some types of cardiac arrhythmias are caused by excessive firing of cells.

18.3. A benzodiazepine such as diazepam or lorazepam is the first-line drug of choice in treating status epilepticus.

18.4. The half-life of phenytoin lengthens considerably as the dose increases, so the drug dose should be titrated in small amounts to avoid making too big a change in the blood drug level.

18.5. Phenytoin is highly protein bound. When there is a lack of serum protein (albumin), as in a patient with low serum albumin levels, more drug is free and active than would usually be expected from the dose. Because more drug is active, it is more likely to cause adverse effects.

18.6. Ethosuximide reduces absence seizures by inhibiting the influx of calcium ions when they travel through a special set of channels,

known as T-type calcium channels in the hypothalamus, the site of absence seizure formation.

18.7. Benzodiazepines suppress seizure activity by potentiating the effectiveness of the inhibitory neurotransmitter, GABA. Patients with seizures are believed to have a lack of GABA or an excess of glutamate, the opposing excitatory neurotransmitter.

Chapter 19: Drugs Producing Anesthesia and Neuromuscular Blocking

19.1. Producing general anesthesia with a single agent is not always desirable because too deep a level of unconsciousness may ensue. To overcome this limitation, a process called balanced anesthesia is used. Balanced anesthesia relies on a combination of drugs to produce loss of consciousness, analgesia, and muscle relaxation, while producing and maintaining a lighter stage of anesthesia. Drugs used in balanced anesthesia include inhaled or parenteral anesthetics, ultrashort-acting barbiturates, neuromuscular blocking agents, benzodiazepines, and opioid analgesics.

19.2. Patients need to be given anesthesia in a controlled environment, such as the operating suite or critical care unit. A cardiac monitor, blood pressure monitor, and ventilator must be available for immediate use. Full resuscitation capability is mandatory.

19.3. First, the emulsion is a great medium for bacterial growth. Be aware of how infusion time must be monitored as a safeguard against bacterial growth. Second, the emulsion vehicle contains soybean oil, glycerol, and egg phosphatide. Assess for hypersensitivity to any of these elements before the drug is administered.

19.4. Local anesthetic agents are relatively free of adverse effects if they are administered at an appropriate dosage and in the correct anatomic location. However, systemic and localized toxic reactions may occur, usually because of accidental intravascular or intrathecal injection or the administration of an excessive dose of the local anesthetic agent. Systemic reactions to local anesthetics primarily involve the central nervous system and the cardiovascular system.

19.5. Nondepolarizing neuromuscular junction (NMJ) blockers induce muscle flaccidity, whereas depolarizing NMJ blockers excite the muscle, promoting contraction until it can no longer receive neurocommunication and becomes paralyzed.

19.6. In discussing Mrs. Smith's prognosis, you need to remember that the patient may be paralyzed but not deaf. Because you do not know the outcome of the charge nurse's conversation, you may suggest moving the discussion to an environment where the patient cannot overhear the conversation.

19.7. Education of a patient undergoing surgical anesthesia with succinylcholine as an adjunctive therapy may focus on the patient's inability to speak, move, or breathe unassisted while using this drug. Reassure the patient that he or she will be monitored constantly for safety. Also, explain that uncomfortable side effects such as muscle ache can be relieved with acetaminophen.

Chapter 20: Drugs Affecting Muscle Spasm and Spasticity

20.1. A muscle spasm is defined as a sudden, violent, involuntary contraction of a muscle or group of muscles. Spasm is usually related to a localized skeletal muscle injury from acute trauma. Pain and interference with function attend muscle spasm, producing involuntary movement and distortion. Spasticity is a condition in which certain muscles are continuously contracted. This contraction causes stiffness or tightness of the muscles and may interfere with gait, movement, or speech. Damage to the portion of the brain or spinal cord that controls voluntary movement usually causes spasticity.

20.2. Cyclobenzaprine is chemically similar to amitriptyline. Combining these two drugs will increase anticholinergic effects. Monitor the patient for symptoms such as dry mouth, blurred vision, constipation, and urinary retention. Because cyclobenzaprine and diazepam are both CNS depressants, also monitor the patient for increased sedation. In the hospital, the bed should be in the lowest position with the side rails up. Caution the patient to call for help before attempting to ambulate. Assess the sedative effects before the patient drives a vehicle or performs tasks that require concentration.

20.3. Baclofen (Lioresal), diazepam (Valium), and dantrolene (Dantrium) can be used to manage spasm and spasticity. Dantrolene is generally reserved for patients with muscle spasticity.

20.4. Baclofen works at the spinal end of the upper motor neurons. Spasms caused by cerebrovascular accident (CVA) or Parkinson disease involve lesional or functional impairment of basal ganglia, which are above the spinal motor neurons.

20.5. Symptoms suggesting hepatitis in the patient on long-term

dantrolene therapy include loss of appetite, nausea or vomiting, yellowed skin or eyes, and changes in stool or urine color.

20.6. No, botulinum toxin would be a poor choice for this patient with an acute injury. Botulinum toxin is used to manage chronic pain that has not responded well to other medical or physical treatment. This patient needs quick relief, but the onset of action for botulinum toxin may take up to 2 weeks. Similarly, the duration of effect is up to 3 months, which is much longer than most acute musculoskeletal injuries last.

Chapter 21: Drugs Treating Parkinson Disease and Other Movement Disorders

21.1. Dopaminergics increase the amount of dopamine in the brain. Anticholinergics decrease the amount of acetylcholine in the brain. Both effects restore the necessary balanced antagonism of these two neurotransmitters.

21.2. A substantial amount of carbidopa is destroyed in the periphery of the body before it reaches the brain. Carbidopa decreases the amount of levodopa that is destroyed and increases the amount of levodopa that reaches the brain. Because more levodopa can pass the blood–brain barrier, a lower dose is needed to induce effects.

21.3. Neuroleptic malignant syndrome is characterized by rapid onset of marked rigidity, akinesia, tremor, and hyperpyrexia. It may occur if carbidopa-levodopa therapy is stopped abruptly.

21.4. A bradykinetic episode is associated with the eventual ineffectiveness of carbidopa-levodopa therapy. The episode, also called the on–off effect, is characterized by akinesia followed by a return of drug effectiveness. The patient is at risk for injury during these periods because hypotonia may occur.

21.5. Patients starting carbidopa-levodopa therapy should have a moderate amount of protein in divided portions throughout the day. They also should decrease their intake of pyridoxine, which is found in foods such as avocados, bananas, beef liver, oatmeal, halibut, chicken, pork, mashed potatoes, wheat germ, and sunflower seeds.

21.6. Throughout carbidopa-levodopa therapy, monitor patients for drug effectiveness, adverse effects, and the onset of new and progression of existing Parkinson symptoms.

21.7. Riluzole therapy aims to delay the need for tracheostomy or mechanical ventilation in the patient with amyotrophic lateral sclerosis (ALS).

21.8. Some of the most frequent adverse effects of riluzole are asthenia, dizziness, and vertigo. These are also signs of ALS progression.

21.9. Dietary restrictions associated with riluzole therapy include caffeine, food high in fat, and charcoal-broiled foods.

21.10. Glatiramer is a synthetic drug that modifies the immune system by acting as a decoy for autoimmune antigens that destroy the myelin sheath in the nervous system. Interferon beta is a drug developed by recombinant DNA technology. It works by decreasing levels of interferon gamma and other proinflammatory cytokines and increasing production of nerve growth factor.

21.11. All of the current drugs used to manage multiple sclerosis (MS) are administered parenterally. Some patients fear injections, and others do not have the manual dexterity or visual skill to self-administer parenteral drugs.

Chapter 22: Drugs Stimulating the Central Nervous System

22.1.

Short-Acting	Intermediate-Acting	Long-Acting
Ritalin	Ritalin SR	Metadate CD
Methylin	Methylin ER	Concerta
Methylin Chewable	Metadate ER	Ritalin LA
Focalin		Adderall XR
Dexedrine		
Dextrostat		
Adderall		

22.2. "Have you noticed any changes in behavior since your last visit?"

"Has your child complained of nervousness, insomnia, dizziness, or palpitations?"

"Has your child been eating meals regularly?"

"Have you noticed any changes in sleep since your last visit?"

"Tell me about your child's intake of caffeine-rich products."

"Has your child had any behavior problems at school?"

Observations should include height and weight measurements, blood pressure, and heart rate. Auscultate heart, lung, and bowel sounds. Palpate the thyroid. Coordinate periodic monitoring tests, including ECG, CBC, thyroid function tests, and blood glucose.

22.3. To adequately assess the effectiveness of dextroamphetamine, ask questions such as, "How many sleep attacks has your mother had today, yesterday, and on previous days?" "How many attacks per day was she having when you first brought her for treatment?" "Is your mother showing or complaining of any adverse

effects, like hypertension, insomnia, irritability, hyperactivity, or psychosis?"

22.4. This patient describes caffeine withdrawal syndrome. Assess the difference between caffeine intake during the week and on weekends. Suggest that the patient decrease the amount of caffeine ingested during the week.

22.5. An important component of health promotion is encouraging and supporting the patient's commitment to weight loss. Remind the patient that sibutramine is only one component of weight loss strategy. Behavior modification and exercise are equally important to reach the patient's weight loss goal. It is also important to ensure that the patient understands that sibutramine may increase blood pressure and to make arrangements for serial checks of blood pressure.

22.6. Sibutramine works systemically by blocking the reuptake of norepinephrine, serotonin, and dopamine, resulting in a feeling of satiety. Orlistat works by inhibiting the absorption of fats from the GI tract. It does not have a systemic action.

Unit 6: Analgesic and Anti-inflammatory Drugs

Chapter 23: Drugs Treating Severe Pain

23.1. Because morphine is a CNS depressant, it suppresses the respiratory drive and decreases the respiratory rate. Acute pain indicates that the pain is of a severe, episodic type, and not a chronic condition. When morphine is being used to treat acute pain in an opioid-naive patient, the patient has not developed any tolerance to the effects of the drug. This includes tolerance to the respiratory depressive effects of morphine. Therefore, giving morphine to someone who has respiratory depression increases respiratory depression and may cause respiratory arrest.

23.2. Patients who have been receiving morphine regularly every day for a long period (e.g., as for chronic pain) develop a tolerance to the respiratory depression that morphine may produce. They do not incur further respiratory depression from morphine. Patients with chronic pain who have a respiratory rate of 8 to 12 breaths/ minute may receive their next dose of morphine.

23. 3. Patients who abuse opioids or other CNS depressants may have cross-tolerance to the effects of morphine. For this reason, they may need a larger dose than other patients to achieve pain control.

23.4. A rescue dose is a dose of opioid used to treat breakthrough pain. It is ordered in addition to the baseline pharmacologic treatment for pain and is about 10% to 30% of the opioid dose the patient receives in 24 hours.

23.5. The half-life of naloxone is very short compared with the half-life of morphine and other opiates. Therefore, the effect of naloxone ends, and the respiratory depression from the opiates may recur. Multiple doses of naloxone may be necessary so that the patient does not revert to severe respiratory depression.

23.6. Codeine acts directly on the medullary cough center to depress the cough reflex. It also has a drying effect on the mucous membranes and can increase the viscosity of respiratory depression or arrest, because the patient is unable to independently clear his or her airway.

Chapter 24: Drugs Treating Mild to Moderate Pain, Fever, Inflammation, and Migraine Headache

24.1. Inhibition of certain prostaglandins interrupts the inflammatory cycle, thus decreasing pain and fever.

24.2. There are two isoforms of prostaglandins: COX-1 and COX-2. COX-1 maintains the functioning of many cells of the body. COX-2 is found mainly in areas of inflammation. Use of drugs that are nonselective, such as the NSAIDs, results in inhibition of both types of COX. When COX-1 is inhibited, the cytoprotective mechanism of the body is altered, and the patient is at a higher risk for adverse effects.

24.3. The most potentially serious adverse effects are bone marrow depression, blood dyscrasias, renal dysfunction, and hepatic dysfunction. These reactions can be decreased by careful assessment of medical problems and medications that contraindicate their use. Obtaining baseline laboratory tests and monitoring them throughout therapy will also decrease adverse effects. Teaching the patient the signs and symptoms of potential adverse effects and the importance of contacting the health care provider is another intervention to decrease the severity of adverse effects.

24.4. Aspirin is an irreversible inhibitor of cyclooxygenase; therefore, the antiplatelet action remains for the life of the platelet (8 days). NSAIDs are reversible inhibitors of cyclooxygenase, which means that the antiplatelet activity ceases when the blood levels decline. Aspirin is used in healthy people for protection from MI and stroke. NSAIDs do not offer protection from MI or stroke; they are actually associated with an increased risk of these disorders.

24.5. COX-2 inhibitors preferentially inhibit COX-2, decreasing inflammation. Because they do not affect COX-1 as much, their cytoprotective mechanism is not altered,

which results in a decreased risk of GI bleeding. The second major difference is that COX-2 inhibitors do not alter platelet aggregation.

24.6. The triptans decrease migraine pain by stimulating the 5-$HT_{1B/1D}$ receptors located on cranial blood vessels and sensory nerves of the trigeminal vascular system. The resultant vasoconstriction decreases the throbbing sensation in the head. Stimulating the 5-$HT_{1B/1D}$ receptors also inhibits the release of proinflammatory neuropeptides, resulting in decreased vascular inflammation.

24.7. The pharmacodynamics of the triptans is limited to stimulating the 5-$HT_{1B/1D}$ receptors. Ergotamine and dihydroergotamine also affect serotonergic, dopaminergic, and alpha-adrenergic receptors as well as stimulating uterine contraction and inducing nausea and vomiting.

Chapter 25: Drugs Treating Rheumatoid Arthritis and Gout

25.1. Salicylates, NSAIDs, and acetaminophen control only the symptoms of the disease. Disease-modifying antirheumatic drugs (DMARDs) have the advantage of actually halting the progression of inflammatory diseases and the potential damage they may cause.

25.2. The major disadvantage of DMARDs is the frequency of potentially serious adverse effects, such as depressed bone marrow function, hepatotoxicity, and renal toxicity. Another disadvantage is that most of the common DMARDs have a long period before results of the therapy can be noticed by the patient.

25.3. Joint destruction begins in the early stages of the disease, even before some patients have physical symptoms. Using DMARDs within 3 months of diagnosis halts the progression of the damage and ultimately can decrease the extent of damage.

25.4. The autoimmune and inflammatory processes of the body have many substances that continue the cycle. Multiple classes of drugs may be used because they have different mechanisms of action that can affect the immune response, the inflammatory response, or both responses at different sites of the cycle or affect different substances within the cycle.

25.5. Tumor necrosis factor (TNF) is a cytokine produced by macrophages and activated T cells, which play an important role in rheumatoid arthritis (RA) by mediating cytokines that cause inflammation and joint destruction.

25.6. TNF inhibitors should not be given to any patient with an active infection, and they should be given very cautiously to an immunocompromised patient. The potential adverse effect common to all these drugs is an increased risk of serious infections. These drugs alter the immune and inflammatory responses; thus, the patient may acquire a life-threatening infection.

25.7. The biologic drugs have the same type of serious adverse effects: severe infections and malignancy. When given concurrently, they do **not** increase the efficacy of treatment but substantially increase the risk for serious adverse effects.

25.8. Colchicine decreases the inflammatory process induced by gout; therefore, it is used in acute gout. Allopurinol increases the excretion of uric acid. It is used as a prophylactic medication.

Unit 7: Hematopoietic, Cardiovascular, and Renal System Drugs

Chapter 26: Drugs Affecting Blood Pressure

26.1. Lifestyle changes of antihypertensive therapy include stopping smoking, controlling weight, limiting sodium intake, increasing potassium and calcium intake, restricting alcohol use, increasing aerobic exercise, and limiting cholesterol levels.

26.2. Thiazide diuretics are very effective in controlling hypertension and in preventing the sequelae that accompany uncontrolled hypertension. They are as effective as other drug classes, in some cases more effective, and less expensive. They should be the drug of first choice, unless there are other compelling reasons to use another drug class.

26.3. The angiotensin-converting enzyme (ACE) inhibitors prevent the conversion of angiotensin I to angiotensin II, which is a potent vasoconstrictor. By preventing vasoconstriction, ACE inhibitors decrease peripheral vascular resistance and therefore lower blood pressure. The effect of angiotensin II on aldosterone production is also blocked, preventing the sodium and fluid retention that aldosterone produces.

26.4. Aldosterone receptor blockers (ARBs) block the action of angiotensin II from all the different pathways where it is formed, not just the single substrate altered by ACE inhibitors. These drugs are effective in lowering blood pressure. In addition they seem to block deleterious effects from angiotensin II at the end-organ stage. ARBs do not cause the chronic cough that ACE inhibitors cause, and they are better tolerated by some patients.

26.5. The black box warning for these drug classes warn that the drug may cause serious fetal harm and potential death if used during the second or third trimester of a pregnancy.

26.6. Hyperkalemia (elevated potassium).

26.7. The following are safety measures used when administering nitroprusside: Always use an IV pump, preferably a volumetric pump, to infuse nitroprusside. Never allow the infusion solution to run by gravity. Monitor blood pressure constantly. Assess for signs of cyanide toxicity, thiocyanate toxicity, and methemoglobinemia. Do not infuse maximum dosage for longer than 10 minutes.

26.8. Dopamine increases renal perfusion. As the kidney becomes adequately perfused, it resumes its normal functioning and produces urine at a normal rate. Urinary output indicates if the dose of dopamine is sufficient to adequately perfuse the kidneys. The systolic blood pressure should rise from dopamine administration. If the diastolic pressure rises greatly, or disproportionately, it indicates that the alpha-2 effects of dopamine are overriding the beta-2 and dopaminergic effects. The drug rate needs to be decreased if this occurs.

Chapter 27: Drugs Affecting Urinary Output

27.1. Before thiazide therapy for hypertension is started, blood pressure, pulse, presence of edema, weight, and urinary output should be assessed.

27.2. Conditions treated by diuretic therapy include hypertension, chronic heart failure, pulmonary edema, peripheral edema (various causes), renal stones (thiazides), renal disease, increased intraocular pressure, and increased intracranial pressure.

27.3. Fluid and electrolyte problems that are likely to occur in patients receiving thiazide or loop diuretics are hypokalemia, hyponatremia, hypochloremia, hypomagnesemia, hypercalcemia (thiazides), hypocalcemia (loop), hyperglycemia, hyperuricemia, and elevated cholesterol and triglyceride levels.

27.4. Loop diuretics work in the loop of Henle, where more sodium is usually absorbed. Because loop diuretics promote more sodium loss than in the distal tubule, more potassium is lost.

27.5. Osmotic diuretics are different from thiazide or loop diuretics because they are composed of a sugar that passes through glomerular filtration but is not reabsorbed. The osmotic pressure that results pulls water into the vascular space and traps it until it is excreted in the urine.

27.6. Carbonic anhydrase inhibitors are used primarily to treat chronic open-angle glaucoma.

27.7. Blockade of the muscarinic receptors in the bladder restricts the bladder's ability to contract.

Chapter 28: Drugs Affecting Lipid Levels

28.1. High-density lipoprotein (HDL) cholesterol is believed to offer some protection against heart attack and is known as "good" cholesterol.

28.2. Elevated serum cholesterol levels lead to fatty deposits, or atherosclerosis, in the arteries. These deposits narrow the lumen of the vessel, increasing peripheral resistance and thus increasing blood pressure.

28.3. The patient is at risk of drug interactions because lovastatin is metabolized by the CYP3A4 hepatic pathway. If the patient is receiving other drugs that are also metabolized by CYP3A4, the metabolism of lovastatin is decreased, and increased drug levels result. If the other drug therapy inhibits the CYP3A4 enzyme, metabolism of lovastatin is also reduced.

28.4. Liver enzyme levels are frequently elevated from lipid-lowering drug therapy, regardless of the class of drug. If the levels rise more than three times the upper limit, evaluate the patient closely for liver impairment; unexplained and continued elevations indicate that a dose adjustment (smaller dose) is required, or the drug therapy should be stopped.

28.5. Transient, moderately elevated creatine kinase (CK) levels (i.e., 3 to 10 times above the upper limit of normal) do not indicate serious muscle damage from lovastatin. If CK levels reach greater than 10 times the upper limit of normal and the patient has symptoms, therapy should be stopped. This is to prevent serious myopathy and rhabdomyolysis, which can be fatal.

Chapter 29: Drugs Treating Heart Failure

29.1. Primary effects of digoxin include positive inotropic effect (increased force of contraction), negative chronotropic effect (decreased rate), and negative dromotropic effect (decreased speed of conduction).

29.2. Diuretics, ACE-inhibitors, and beta blockers all decrease mortality from CHF and form the basis of drug therapy. The cardiac glycoside digoxin does not decrease mortality from CHF, but it does decrease morbidity and therefore improves the quality of life for patients with CHF.

29.3. Digoxin is excreted renally. Therefore, serum drug levels will rise in the patient with decreased renal function above those normally expected for the

dose administered. This makes the patient more at risk of having adverse effects. A smaller dose may be required.

29.4. Beta blockers block the effect of the sympathetic nervous system and cause vasodilation and decreased peripheral vascular resistance, which is helpful to patients with CHF. Beta blockers may also actually reverse the ventricular remodeling process that occurs in CHF by reducing left ventricular volumes and improving systolic function.

Chapter 30: Drugs Treating Angina

30.1. This prevents nitrate tolerance, which decreases the antianginal effects of the drug.

30.2. One every 5 minutes. Up to 3 tablets in 15 minutes may be given.

30.3. Nitroglycerin causes vasodilation, especially on the venous side. This allows blood to pool in the venous beds, decreasing blood pressure. The nurse should verify that the patient is not hypotensive prior to administering the drug.

30.4. Vasodilation of the vessels to the head has occurred in nurses from accidental exposure to nitroglycerin. Headache is a common adverse effect from this vasodilation.

30.5. Nitroglycerin decreases preload and afterload. This decreases the energy the heart must use to eject blood, thus decreasing the oxygen needs of the heart. Additionally, the coronary vessels are dilated, increasing blood flow to the heart. Circulation is also redirected to use the smaller vessels more, improving blood flow to the heart.

Chapter 31: Drugs Affecting Cardiac Rhythm

31.1. Ventricular arrhythmias (tachycardia and fibrillation) do not allow the ventricle to fill adequately with blood. The rapid contractions are also not effective at emptying the ventricle. Consequently, cardiac output decreases significantly. The body needs oxygenated blood to survive.

31.2. Proarrhythmia is the tendency of a drug to create a new arrhythmia or to exacerbate the arrhythmia it is supposed to be treating.

31.3. Antiarrhythmics alter the normal mechanisms that control heart rate and rhythm. Therefore, they can also cause an arrhythmia.

31.4. Class I antiarrhythmics depress phase 0. Class II antiarrhythmics depress phase 4 (depolarization). Class III antiarrhythmics produce a prolonged phase 3 (repolarization). Class IV antiarrhythmics depress phase 4 (depolarization) and lengthen phases 1 and 2 of repolarization.

31.5. Amiodarone is approved only for use in life-threatening arrhythmias such as recurrent ventricular fibrillation or recurrent, hemodynamically unstable ventricular tachycardia. It is also used as an unlabeled drug to treat atrial fibrillation.

31.6. Several electrophysiologic effects occur with the administration of amiodarone. An increased cardiac refractory period occurs, usually without influencing the resting membrane potential. Sinus rate decreases by 15% to 20%. The PR and QT intervals increase by about 10%. U waves appear and T waves are altered. These changes do not usually require discontinuation of amiodarone, although marked sinus bradycardia or sinus arrest and heart block can occur. QT prolongation can be associated with worsening of the arrhythmia, but this event is rare.

31.7. Amiodarone has a very long half-life. To quickly achieve a therapeutic level without waiting for steady state to occur, a loading dose is used. Because amiodarone is used for life-threatening arrhythmias, it is important to achieve a therapeutic effect as soon as possible so that the patient does not die.

31.8. Drink plenty of fluids and eat fresh fruits and vegetables. Include varied sources of fiber in the diet. Exercise if allowed by the physician. Discuss with physician the use of a stool softener (traps water in the stool).

Chapter 32: Drugs Affecting Coagulation

32.1. Heparin prevents fibrin formation. Warfarin interferes with the formation of prothrombin and factors VII, IX, and X.

32.2. An infusion control pump should be used to regulate the rate of heparin administration. Monitor activated partial thromboplastin time (aPTT) to prevent overdosage. Use general safety measures, such as placing the bed in a low position with the side rails up to prevent patient falls. Assess the patient regularly for signs of bleeding.

32.3. The aPTT should be monitored while the patient is receiving heparin. A therapeutic aPTT value is 1.5 to 2 times greater than the given control. The prothrombin time (PT) is monitored while the patient is taking warfarin. PT is considered therapeutic when it is approximately 1.5 times the given control or the INR value is between 2 and 3.

32.4. Warfarin interferes with the synthesis of vitamin K–derived clotting factors. Increases in vitamin K intake interfere with the action of warfarin if the increase occurs after the warfarin dosage has been titrated. Vitamin K does not affect the action of heparin.

32.5. Check for effectiveness of each therapy, as there may be a drug interaction via the P-450 system which may decrease the effectiveness of one or the other drug.

32.6. An anticoagulant lengthens clotting time and prevents future blood clots; thrombolytics break down a formed clot.

32.7. Antihemophilic factor (AHF) would be administered before and after surgery until the appropriate level of factor VIII is obtained, as determined by blood assays.

Chapter 33: Drugs Affecting Hematopoiesis

33.1. Erythropoietin, thrombopoietin, G-CSF, GM-CSF, and interleukin are the principal polypeptides and glycoproteins involved in hematopoiesis.

33.2. The kidneys produce erythropoietin, which is responsible for stimulating the production of red blood cells. When the kidneys are not functioning fully, they do not produce normal amounts of erythropoietin; thus, the patient becomes anemic.

33.3. The increased risk of infection can be fatal because the first line of defense against infection (the neutrophil) is decreased.

33.4. Platelets are fragments of large cells from the bone marrow called megakaryocytes. Thrombopoietin stimulates the production of megakaryocytes.

33.5. Fluid retention is the most common adverse effect from oprelvekin. Intake and output indicate if fluid retention is occurring. Additional fluid load can overburden the taxed heart and exacerbate the CHF, possibly causing pulmonary edema.

33.6. Thrombotic events can occur in patients with chronic renal failure receiving epoetin alfa; the risk increases when attempting to raise the hemoglobin and hematocrit to normal levels. The usual target range is 30% to 36% for hematocrit.

Unit 8: Respiratory System Drugs

Chapter 34: Drugs Affecting the Upper Respiratory System

34.1. Dextromethorphan and narcotic antitussive drugs have the same efficacy in alleviating cough. Narcotic antitussives are more sedating and have more potential adverse effects and more drug–drug interactions.

34.2. Antihistamines block the antigen– antibody reaction. In a viral syndrome, such as the common viral cold, there is no allergic reaction, only a viral infection.

34.3. Fexofenadine is a second-generation antihistamine that does not easily pass the blood–brain barrier. This results in less sedation than with first-generation antihistamines.

34.4. The advantage of inhaled antihistamines and steroids is that they act locally, are minimally absorbed, and thus induce few adverse effects.

34.5. Guaifenesin enhances the output of respiratory tract fluids by reducing the adhesiveness and surface tension of the respiratory fluids, allowing easier movement of the less viscous secretions. The result of this thinning of secretions is a more productive cough. With a more productive cough, the frequency of coughing should decrease.

Chapter 35: Drugs Affecting the Lower Respiratory System

35.1. Drugs can be grouped into mucolytic agents, such as acetylcysteine; bronchodilators, such as theophylline; and anti-inflammatory drugs, such as cromolyn sodium.

35.2. Theophylline acts by stimulating two prostaglandins, which results in smooth-muscle relaxation in both the bronchi and vasculature. Beta-adrenergic agonists are sympathomimetic agents. That means the drugs mimic the action of norepinephrine. In the lungs, norepinephrine stimulates bronchodilation. Anticholinergic agents block the action of acetylcysteine. When acetylcysteine stimulates the lungs, bronchoconstriction occurs; thus, when its action is blocked, the bronchi do not constrict.

35.3. Beta-adrenergic agonists, such as albuterol, have the quickest onset of action. They are referred to as "rescue drugs."

35.4. Glucocorticosteroids are the most powerful anti-inflammatory agents.

35.5. Both drugs are effective in reducing inflammation. Glucocorticoid steroids given orally have the potential to cause more adverse effects because they are systemic. Steroids given by inhalation have a local action; thus, they cause fewer adverse effects.

35.6. Cromolyn sodium works by stabilizing the mast cell. When the mast cell ruptures in response to an antigen, bronchoconstrictive substances such as histamine, bradykinin, serotonin, and leukotrienes are released. By stabilizing the mast cell, the drug prevents release of these substances. Glucocorticoid steroids have a multitude of actions. In the lungs, they decrease the effectiveness of inflammatory cells, thus keeping the bronchioles open. Leukotriene antagonists block the ability of leukotrienes to bind to their receptor sites. Because leukotriene binding to these sites is what causes bronchoconstriction, bronchoconstriction is blocked.

35.7. The beta-adrenergic agonist inhaler should be used first

because it has the fastest onset. It will open the bronchial tree, so that the other drugs can be dispersed farther into the lungs to exert their action.

Unit 9: Gastrointestinal Tract Drugs

Chapter 36: Drugs Affecting the Upper Gastrointestinal Tract

36.1. The cause of peptic ulcers is the bacterium *Helicobacter pylori.* Without treatment to kill these bacteria, the ulcers almost always recur.

36.2. Highly acidic foods such as tomato juice and highly spiced foods may worsen gastroesophageal reflux disease (GERD) symptoms and may keep the patient from feeling relief from the pain and discomfort of GERD.

36.3. Omeprazole may interact with other drugs that also are metabolized through the cytochrome P-450 pathway (e.g., cyclosporine, disulfiram, and benzodiazepines). This interaction may produce elevated levels of these other drugs because their metabolism is decreased. Because omeprazole causes prolonged and substantial decreases in gastric acidity, drugs that depend on an acid environment for absorption may not be absorbed as well.

36.4. H_2 antagonists reduce gastric acid production by blocking histamine at the H_2-receptor site of parietal cells, resulting in a reduction in the hydrogen ion concentration and volume of gastric acid. H_1 antagonists are not effective at these sites and have no effect on gastric pH but are effective in relieving symptoms of allergic reactions. H_2 antagonists have no effect on the H_1 receptor sites.

36.5. Aluminum and magnesium are commonly combined in a preparation to balance the constipating effects of aluminum with the diarrheal effects of magnesium.

36.6. Patients with chronic renal failure tend to have elevated phosphate levels. Aluminum carbonate binds with the phosphate to return the patient's serum phosphate levels to normal.

36.7. The main adverse effects of orlistat are the GI symptoms of oily spotting, flatus with discharge of stool, fecal urgency, fatty or oily stool, oily evacuation, increased defecation, and fecal incontinence.

36.8. Serotonin receptors of the 5-HT_3 type are located peripherally on the vagal nerve terminal and centrally in the chemoreceptor trigger zone (CTZ). Stimulation of these receptors brings on nausea and vomiting. During chemotherapy, special mucosal cells in the small intestine release serotonin, which stimulates these receptors. Ondansetron blocks these receptor sites, thus preventing nausea and vomiting.

Chapter 37: Drugs Affecting the Lower Gastrointestinal Tract

37.1. Chew simethicone tablets thoroughly before swallowing. Shake suspension forms before measuring. Take after meals and at bedtime.

37.2. The unpleasant effects of atropine, such as dry mouth and tachycardia, discourage abuse of the drug for opioid effects.

37.3. Stool softeners should be used. Bearing down to defecate (Valsalva maneuver) increases the pressure in the eye. Stool softeners decrease the need to do this when defecating.

37.4. No. The kidney that is not functioning optimally does not excrete magnesium. Hypermagnesemia may develop from the additional magnesium provided by magnesium hydroxide.

37.5. Lactulose pulls ammonia from the bloodstream into the digestive tract. Patients with severe hepatic disease have excessive ammonia in their blood. Lactulose will therefore decrease ammonia levels.

37.6. Alosetron is limited to women because insufficient data exist to support its use in men. Alosetron is associated with the risk of severe constipation and ischemic colitis, which is why it is limited to patients with severe symptoms of IBS, in which diarrhea is the primary symptom.

37.7. Serotonin is a primary neurotransmitter affecting the enteric tract, and it plays a role in visceral sensation and the normal functioning of the tract, including secretion and motility. Abnormalities in motility and visceral sensation correspond to the pathology of many of the symptoms of IBS.

Unit 10: Antimicrobial Drugs

Chapter 38: Principles of Antimicrobial Therapy

38.1. For antimicrobial therapy to be effective, the guiding principle is to use "the right drug for the right bug."

38.2. Antimicrobials may be classified by the type of organism they affect or by their mechanism of action.

38.3. Antimicrobials work by inhibiting cell wall synthesis, inhibiting protein synthesis, inhibiting nucleic acid synthesis, disrupting the cell membrane permeability, inhibiting metabolic pathways, or inhibiting viral enzymes.

38.4. Selective toxicity means that the drug harms the pathogen but does not harm the host cell.

38.5. In the human host, many bacteria keep other microbes, such as fungus, in check. When the "good" bacteria are killed by antimicrobials,

the nonsusceptible microbes can proliferate, causing an additional infection.

38.6. In the United States, the microbes that have developed substantial resistance include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and multiple drug– resistant *Mycobacterium tuberculosis* (MDR-TB), as well as microbes that cause nosocomial infections.

38.7. Nurses can help meet the objectives of the CDC's campaign by consistently using aseptic technique for all procedures; obtaining culture specimens appropriately; contacting the physician or other health care providers with culture and sensitivity results; ensuring adherence to isolation procedures for themselves, visitors, and the physician; documenting improvement or worsening of symptoms of infection; and washing hands between contact with patients.

38.8. The best way to limit the risk of a nosocomial infection is handwashing before contact with each patient.

Chapter 39: Antibiotics Affecting the Bacterial Cell Wall

39.1. Penicillins bind with penicillin-binding proteins (PCPs) located inside the bacterial cell wall. Binding at these sites alters the way the bacteria are able to build their cell walls by affecting the development of cross-bridges that give the cell wall its strength. As the cell wall weakens, the internal osmotic pressure of the bacteria changes to allow the cell to absorb water, swell, and then burst. The body's immune system completes the process of fighting the infection and cleans up debris from ruptured bacteria. Penicillins also "turn on" autolysin, an enzyme that actively promotes cell wall destruction.

39.2. Gram-negative bacteria have a cell wall envelope that actively keeps penicillin from entering the cell and binding to penicillin-binding proteins (PCPs). Penicillins cannot work if they cannot bind to these proteins.

39.3. Penicillins are classified by their spectrum of activity. The narrow-spectrum penicillins can eradicate a limited number of bacteria, the penicillinase-resistant penicillins are effective against bacteria that produce penicillinase, the aminopenicillins are effective against most gram-positive bacteria, and the extended-spectrum penicillins are specifically effective against *Pseudomonas* species.

39.4. Clavulanic acid, tazobactam, and sulbactam have very little antibacterial activity on their own. They fight beta-lactamase–producing bacteria by becoming "suicide agents." By binding to the active site of beta-lactamase, they enable penicillin to reach its target site within the bacterial cytoplasmic membrane and destroy the bacteria.

39.5. Imipenem, meropenem, and ertapenem are parenteral carbapenem beta-lactam antibiotics. They are all broad-spectrum, with imipenem having the broadest spectrum of the three. Meropenem (Merrem) and ertapenem (Invanz) are administered as single agents, whereas imipenem is combined with cilastatin (Primaxin) to reduce the potential for renal toxicity. Imipenem is indicated for severe resistant infections, especially nosocomial infections; meropenem is used for intra-abdominal infections and bacterial meningitis; and ertapenem is indicated to manage moderate to severe, complicated intra-abdominal infections, skin and skin structure infections, pyelonephritis, acute pelvic infections, and community-acquired pneumonia. The drugs all have similar contraindications, precautions, and adverse effects. Of the three, imipenem is most likely to cause seizures, especially in patients with pre-existing seizure disorders or insults to the brain such as head trauma. Ertapenem is the only carbapenem not indicated for use in children.

39.6. Cephalosporins can be grouped into four generations. As the generations progress from first to fourth, the drugs have increasing activity against gram-negative bacteria, increasing resistance to destruction by beta-lactamases, and increasing ability to reach the cerebrospinal fluid (CSF).

39.7. Beta-lactam antibiotics include penicillins, cephalosporins, monobactams, and carbapenems. They are called beta-lactam antibiotics because they all contain a beta-lactam ring that is responsible for their antibacterial activity.

39.8. Vancomycin is reserved for serious infections because of its ability to cause serious adverse effects, especially ototoxicity and nephrotoxicity.

Chapter 40: Antibiotics Affecting Protein Synthesis

40.1. Tetracyclines have limited use because of emerging bacterial resistance. They are also associated with food interactions that decrease the absorption of the drug. They may not be used by pregnant or lactating women or children younger than 8 years because of their potential to damage primary teeth.

40.2. Aminoglycosides are used only in serious infections because of their potential to cause serious toxicities, including ototoxicity, nephrotoxicity, and neuromuscular blockade.

40.3. The most serious adverse effects of chloramphenicol therapy are irreversible bone marrow toxicity and life-threatening blood dyscrasias.

40.4. An antibiotic affects any bacterium within its spectrum. In the body, some bacteria are used to keep other organisms under control. When those bacteria are affected, organisms such as yeast can overgrow.

40.5. Patients receiving clindamycin therapy should be advised to stop the medication immediately if these symptoms occur and contact the provider. These symptoms may suggest antibiotic-associated colitis, also known as pseudomembranous colitis or *Clostridium difficile* colitis, which is associated with overgrowth of *C. difficile.*

40.6. Quinupristin/dalfopristin is a parenteral agent that is active against *E. faecium* but not *E. faecalis,* both of which may cause bacteremia. Linezolid is active against both *E. faecium* and *E. faecalis.* Additionally, linezolid is offered as both parenteral and oral preparations. Because linezolid induces monoamine oxidase (MAO) inhibition, however, it has many more potential drug interactions in addition to food and beverage interactions.

Chapter 41: Drugs That Are Miscellaneous Antibiotics

41.1. First-generation quinolones are used only to treat uncomplicated urinary tract infections (UTIs). Second-generation fluoroquinolones have better gram-negative and systemic activity. Third-generation fluoroquinolones have extended activity against gram-positive pathogens but are less active than second-generation drugs against *Pseudomonas* species. In addition to having the spectrum of activity of third-generation fluoroquinolones, the fourth-generation drugs are also active against *Pseudomonas* species and anaerobic bacteria.

41.2. Fluoroquinolones inhibit DNA gyrase. This enzyme, essential for the replication of bacteria, has a counterpart in human cells, but the human enzyme is not affected by fluoroquinolones.

41.3. Ciprofloxacin should not be given to children younger than 18 years or to women who are pregnant or breast-feeding. Fluoroquinolones have caused cartilage deterioration in immature animals and may induce arthropathies in infants and children.

41.4. Compounds that contain aluminum, calcium, iron, magnesium, or zinc bind with ciprofloxacin. This affinity results in decreased absorption and bioavailability of ciprofloxacin.

41.5. Daptomycin is the first of a new class of antibiotic that works in a totally different way than other antimicrobial drugs. At this time, no mechanism of resistance to daptomycin has been identified, there are no known transferable elements, or plasmids, that confer resistance, and cross-resistance has not been reported. To keep bacteria from becoming resistant to daptomycin, it should be used only after other antibiotics have been unsuccessful.

41.6. Parenteral polymyxin B is used only in clinical situations in which patients have not responded to other less toxic drugs, because of its potential to induce serious nephrotoxicity.

Chapter 42: Drugs Treating Urinary Tract Infections

42.1. One of the most common uses for sulfamethoxazole-trimethoprim (SMZ-TMP) is prophylaxis and treatment of *Pneumocystis carinii* pneumonia (PCP). SMZ-TMP is frequently used for respiratory infections caused by *Haemophilus influenzae* or *Streptococcus pneumoniae.* In the respiratory tract, these microbes may cause bronchitis, sinusitis, or pneumonia. It is also an alternative treatment for *Legionella pneumophila* pneumonia. GI infections treated with SMZ-TMP include shigellosis and salmonellosis. SMZ-TMP concentrates in prostate and vaginal fluids and thus is useful in prostatitis and some types of vaginitis. SMZ-TMP is also effective for sexually transmitted diseases, such as acute gonococcal urethritis and oropharyngeal gonorrhea.

42.2. Sulfonamides interrupt the formation of folate, which is necessary for the microorganism's biosynthesis of DNA, RNA, and protein. If the microorganism does not rely on folate for this action, the drug is ineffective.

42.3. Antibiotics used to manage UTIs reach high concentration in serum; thus, they can be used for infections other than those of the urinary tract. Urinary tract antiseptics have a direct local action on urine and achieve only very low serum concentrations. Therefore, they are systemically ineffective and useful only in UTI.

42.4. UTIs cause several uncomfortable symptoms, including lower abdominal pain, dysuria, and a feeling of urgency. Phenazopyridine is an analgesic that decreases these symptoms in the bladder. It is generally used for a few days, until the antibiotic is able to decrease the bacterial count enough to decrease these symptoms.

42.5. Use aseptic technique and follow these steps:

- Wash your hands
- Cleanse the wound completely and remove any remaining medication.
- Remove dead or burned skin and other debris.
- Wear sterile gloves to apply a thin layer (about 1/16 inch) to the wound.
- After application, cover the wound with a dressing or leave it uncovered, as ordered by the health care provider.

Chapter 43: Drugs Treating Mycobacterial Infections

43.1. Patients with pre-existing hepatic disorders, renal insufficiency, or malnutrition, those who abuse drugs or alcohol, and those older than 35 years are at greatest risk of hepatitis resulting from isoniazid therapy.

43.2. Chemoprophylaxis consists of single-drug therapy with isoniazid to prevent active TB. The patient is asymptomatic, and the therapy continues for 6 to 12 months. Active TB therapy requires a multidrug regimen (usually isoniazid, rifampin, and pyrazinamide) and is used in patients with signs and symptoms of TB. Therapy may last up to 18 months.

43.3. TB bacilli have the ability to become resistant to all of the anti-TB drugs. Additionally, resistance develops because of the duration of therapy. Finally, multidrug resistance, or MDR, occurs because adherence to the complete duration of therapy is difficult. Patients repeatedly start and stop their drug therapies, allowing the bacillus to become resistant.

43.4. There are three major obstacles to successful therapy with rifampin. The first obstacle is adherence. Rifampin is given for up to 18 months to treat TB and for 12 months to treat leprosy. The second obstacle is the potential for serious adverse effects. Close monitoring and serial laboratory testing are necessary to ensure the safety of the patient. The third obstacle is the drug–drug interactions induced by rifampin. The patient must understand the importance of contacting the prescriber before taking any new medications, especially prescription medications.

43.5. All mycobacterial infections require lengthy treatment. Patients have difficulty adhering to long-term therapies, especially when the drug therapy does not make the patient feel different.

Chapter 44: Drugs Treating Fungal Infections

44.1. Amphotericin B may produce nephrotoxicity; an infusion reaction marked by headache, chills, fever, rigors, hypotension, bronchospasm, and nausea and vomiting; electrolyte imbalances; and anemia.

44.2. Adverse effects of fluconazole therapy include elevated liver enzyme levels, hepatotoxicity, exfoliative skin disorders, and Stevens-Johnson syndrome.

44.3. Azole drugs that can be used to manage systemic fungal infections include fluconazole, itraconazole, ketoconazole, and voriconazole.

44.4. Griseofulvin therapy make take up to 12 months. Because it can cause blood dyscrasias and hepatic injury, the patient should have a CBC and liver function tests monitored during therapy.

44.5. Most azole drugs inhibit the metabolism of drugs that use the CYP3A4 enzyme system. When the metabolism of a drug is inhibited, the serum concentration of the drug increases, resulting in an increased risk for adverse effects and toxicity.

Chapter 45: Drugs Treating Viral Infections

45.1. Few effective antiviral drugs exist because a virus must replicate within the host cell. Drugs that affect the virus may also affect the host cell and do substantial harm.

45.2. Acyclovir is phosphorylated into its active form by the enzyme thymidine kinase. In its active form, acyclovir competes for a position in the DNA chain of the herpesvirus and terminates DNA synthesis.

45.3. Acyclovir should be given cautiously to patients with renal disease, seizures, and other neurologic disorders.

45.4. The interferons are used in managing hepatitis. The FDA approves each type of interferon for a specific subtype of virus; however, the interferons may also be used “off-label” for another subtype.

45.5. HIV drug resistance may occur in chronic HBV patients with unrecognized or untreated HIV infection.

45.6. Amantadine and rimantadine are effective for the prophylaxis or management of influenza A, whereas oseltamivir and zanamivir are effective for both influenza types A and B.

45.7. Although oseltamivir and zanamivir are useful to decrease the symptoms of influenza, they do not replace the need for a yearly influenza vaccination for patients who are immunocompromised.

45.8. Ribavirin is not generally used in adults because adult patients are usually not affected by respiratory syncytial virus (RSV). Moreover, ribavirin is a teratogen and may produce testicular lesions.

45.9. Ribavirin is used to treat RSV, whereas palivizumab and RSV-IG are prophylactic drugs given to infants at risk for RSV.

Chapter 46: Drugs Treating HIV Infection and AIDS

46.1. Blood testing is used to diagnose HIV. To detect antibodies to HIV, the patient may have an EIA, ELISA, rapid HIV test, or oral HIV test. If the patient tests positive with the EIA or ELISA, a WB test or other confirmatory test is performed to ensure accurate results. To test for presence of the virus itself, a PCR test may be done.

46.2. HIV has an affinity for CD4 cells. These cells are important for normal immune function. Destruction of these cells strips the person of protection against common organisms.

46.3. The CD4 cell count is an indication of the current immunologic status of the patient. The CD4 cell count indicates the amount of damage to the immune system. A viral load count reflects disease progression.

46.4. HIV, like other viruses, has the ability to mutate and thus become resistant to a drug. Use of HAART attacks the virus during multiple stages of the viral replication process. This approach prolongs the time before the virus becomes resistant to a specific antiretroviral drug.

46.5. Anemia, granulocytopenia, and thrombocytopenia are adverse effects that indicate a need to stop zidovudine therapy.

46.6. Tests recommended before zidovudine therapy begins include CBC, blood chemistry profile, CD4 cell count, and viral load. Renal and hepatic function tests should be considered if pre-existing damage is suspected.

46.7. Lifestyle, diet, and habit assessments and interventions that are important when initiating zidovudine therapy include highlighting the importance of adhering strictly to drug therapy; teaching that drug therapy does not affect the transmissibility of the disease; advising a high-carbohydrate, moderate-protein, and low-fat diet; taking zidovudine on an empty stomach; exploring the dangers of substance abuse during therapy and otherwise; and overcoming financial constraints to obtaining the prescribed drugs.

46.8. Protease inhibitors (PIs) work at the last stage of HIV replication. They prevent HIV from being successfully assembled and released from the infected CD4 cell.

46.9. Although nonnucleoside reverse transcriptase inhibitors (NNRTIs) work at the same site as nucleoside reverse transcriptase inhibitors (NRTIs), their mechanism of action is very different. NRTIs constrain HIV replication by incorporating into the elongating strand of viral DNA, which causes chain termination. NNRTIs do not incorporate into viral DNA; instead, they inhibit replication directly by binding noncompetitively to reverse transcriptase.

46.10. Entry inhibitors work by binding to gp41, thereby blocking its ability to bind to other cells. If HIV cannot bind to a cell, it cannot enter the cell; thus, it cannot replicate.

46.11. Many infections that generally do little harm to humans may cause great morbidity and mortality in immunocompromised patients. In a person with a competent immune system, the infections are kept under control. In a person with an immunocompromised system, these minor microbes can create serious illness, blindness, and even death.

46.12. Once inside the CD4 T cell, HIV viral RNA utilizes reverse transcriptase to convert it into DNA. A viral enzyme called integrase then helps to hide HIV's DNA inside the cell's DNA. When this occurs, the cell can begin producing genetic material for new viruses. Inhibiting integrase prevents HIV DNA from entering healthy cell DNA.

Chapter 47: Drugs Treating Parasitic Infections

47.1. Vision examinations are important for patients receiving chloroquine because the drug has potential adverse ophthalmologic effects, including retinopathy. Retinopathy, which can lead to blindness, can progress even after the drug is discontinued.

47.2. Chloroquine is used cautiously in children because they are extremely susceptible to chloroquine toxicity. Fatalities have occurred with relatively small doses.

47.3. Baseline evaluations that should precede long-term antimalarial therapy include CBC, liver function tests, kidney function tests, eye examination, gross hearing evaluation, and ECG.

47.4. A patient with alcoholism should be monitored during antiparasitic therapy to detect hepatotoxicity. Many of the antiparasitic drugs have the potential for causing hepatic toxicity. Alcohol is also hepatotoxic. Therefore, patients with alcoholism may have an increased risk of the hepatic toxicity associated with these drugs.

47.5. Nurses and other health care providers should protect themselves when administering pentamidine because pentamidine frequently causes cough and bronchospasm during inhalation. Patients with immunodeficiency diseases are at high risk for respiratory diseases, such as tuberculosis. During pentamidine therapy, these patients may cough and spread airborne pathogens.

47.6. Before administering pentamidine, evaluate the patient's baseline vital signs. Then with the patient supine, infuse pentamidine over 60 minutes. After the infusion, monitor the patient's blood pressure until it is stable.

47.7. Studies of mebendazole have demonstrated that it causes birth defects in animals and would probably cause similar birth defects in humans.

Unit 11: Endocrine Drugs

Chapter 48: Drugs Affecting Corticosteroid Levels

48.1. The effects of glucocorticoids on metabolism are potent and varied. They include increased blood glucose concentrations, increased breakdown of protein and use of fatty acids for energy, and increased loss of calcium from bones.

48.2. Untreated acute adrenal insufficiency is life threatening. Signs and symptoms include hypoglycemia; anorexia, nausea, and vomiting; hypotension; fluid and electrolyte imbalance—dehydration, hyponatremia, and hyperkalemia; dehydration; and fatigue, weakness, and malaise. Untreated chronic adrenal insufficiency is not immediately life threatening but impairs the person's ability to cope with stress.

48.3. Cushing syndrome is a disease of adrenal hyperfunction. Chronic pharmacologic dosing of corticosteroids can lead to the same physiologic effects as adrenal hyperfunction. These effects are known as cushingoid characteristics and include fat stores in the face (moon face), glaucoma and cataract formation, hirsutism and masculinization, cervicodorsal fat (buffalo hump), extremity thinning and atrophy, abdominal striae, protuberant abdomen, truncal obesity, edema caused by sodium and fluid retention, and brittle bones. Any excess of corticosteroids, whether from endogenous or exogenous causes, can result in cushingoid characteristics.

48.4. Three major actions of the adrenal steroids are (1) metabolic effects on carbohydrate, protein, and fat metabolism; (2) anti-inflammatory and immunosuppressant effects; and (3) sodium-retaining activity associated with potassium loss. The first two actions are classified as glucocorticoid actions, and the third is a mineralocorticoid action.

48.5. The two major clinical uses of adrenal steroids are replacement therapy in endocrine deficiency states and anti-inflammatory or immunosuppressive effects in nonendocrine states such as asthma or organ transplantation.

48.6. Exogenous administration of glucocorticoids suppresses the hypothalamic-pituitary-adrenal (HPA) axis, resulting in the adrenal glands losing their ability to synthesize cortisol and other glucocorticoids. Too abrupt cessation of glucocorticoid use may produce a withdrawal syndrome (i.e., hypotension, hypoglycemia, myalgia, arthralgia, and fatigue), leading to acute adrenal insufficiency (addisonian crisis), circulatory collapse, shock, and death.

48.7. Benefits of alternate-day therapy are reduced adrenal suppression, reduced risk of growth retardation, and reduced overall toxicity and cushingoid changes. The likelihood of adrenal insufficiency is decreased because over the long interval between glucocorticoid doses, plasma glucocorticoids decline to a level that is low enough to permit some production of ACTH and some synthesis of cortisol by the adrenals. The disadvantages related to alternate-day therapy include difficulty with patient adherence, potential for subtherapeutic plasma levels, and inconclusive data that adverse effects are substantially decreased.

48.8. Glucocorticoids interact with several types of drugs. Drugs that decrease the serum concentration of glucocorticoid drugs include barbiturates, hydantoins, and rifamycins. Monitor for therapeutic efficacy of glucocorticoid drugs if these other drugs are given concurrently. Glucocorticoid drugs may decrease the effects of anticholinesterase drugs, oral anticoagulants, and salicylates. Monitor the efficacy of those drugs when given concurrently with a glucocorticoid drug. When glucocorticoid drugs are given with oral contraceptives, monitor for possible steroid toxicity. Potassium-increasing diuretics enhance prednisone's potassium depletion.

48.9. Fludrocortisone is used in the treatment of primary (Addison disease) and secondary adrenocortical insufficiency. It also is used to treat salt-losing adrenogenital syndrome. An unlabeled use is the management of severe orthostatic hypotension. Fludrocortisone possesses both mineralocorticoid and glucocorticoid properties.

48.10. Patient teaching with fludrocortisone is just like patient teaching with the glucocorticoids because fludrocortisone has both mineralocorticoid and glucocorticoid properties. The patient receiving fludrocortisone is at risk for acute adrenal insufficiency when he or she experiences stressful situations during or after drug therapy. Moreover, the patient can develop adverse cardiovascular effects of hypertension, edema, chronic heart failure,

and cardiomegaly from the mineralocorticoid actions of the drug. It is vital to stress the importance of regular follow-up visits with the prescriber and prompt reporting of adverse effects of dizziness, severe or continuing headaches, swelling of the lower extremities or feet, and unusual weight gain.

48.11. The major clinical indication for the adrenal steroid inhibitors is Cushing syndrome, which is a rare disorder of adrenal cortical hyperfunction. The prototype inhibitor is aminoglutethimide. Aminoglutethimide suppresses the function of the adrenal cortex and thus reduces the amount of endogenous cortisol.

Chapter 49: Drugs Affecting Blood Glucose Levels

49.1. Insulin lowers blood glucose levels by allowing glucose to leave the blood stream and enter the cells.

49.2. Glucagon helps regulate blood glucose levels. Falling blood glucose levels trigger the release of glucagon from the pancreas, as do sympathetic nerve impulses, exercise, infection, and trauma. In the liver, glucagon stimulates glycogenolysis and gluconeogenesis, resulting in a release of glucose into the blood. Glucagon helps to counterbalance the effect of insulin if insulin causes the blood glucose level to fall below normal.

49.3. A patient with type 1 diabetes mellitus has an absolute deficiency of endogenous insulin, and the disease can be controlled only by restoring insulin by injection. A patient with type 2 diabetes still has some natural insulin synthesis and secretion but the cells are resistant to insulin. This patient's diabetes can usually be controlled by diet, exercise, and oral antidiabetic drug therapy, although insulin may be required in some patients.

49.4. Peptides in the digestive enzymes of the GI tract will destroy the insulin molecule so insulin cannot be given orally.

49.5. The effect of too much insulin would most likely be hypoglycemia and, in its most severe form, an insulin reaction. Early signs and symptoms are neurologic in nature and include irritability, tremors, headache, fatigue and malaise, diaphoresis, and tachycardia. A later symptom may be loss of consciousness.

49.6. Combining regular and a longer acting insulin provides an immediate onset of insulin (from the regular) to lower the current blood sugar level as well as a sustained effect (from the longer acting insulin) to maintain the glucose in a normal range throughout the day.

49.7. Regular, lispro, aspart, and glulisine insulins can be used as supplemental doses (correctional doses).

49.8. NPH is an intermediate-acting insulin. It is a suspension and is cloudy. Its pharmacokinetics include a definite peak and trough so glucose control can vary. It is often dosed twice a day to achieve glucose control. Glargine is a long-acting insulin. It is not a suspension and is clear in appearance. Its pharmacokinetics do not include a peak and trough, so glucose control is more constant throughout the day. It is dosed once daily at bedtime.

49.9. Hypoglycemia.

49.10. Arcabose reduces the rate of digestion of complex carbohydrates. Less absorption of glucose occurs, because the carbohydrates are not broken down into glucose molecules. This decreases the blood glucose level.

49.11. Glucagon is used to increase the blood glucose level of patients experiencing severe hypoglycemia. In addition to knowing the symptoms of hypoglycemia the patient and family must be taught correct preparation and administration techniques as it is given SC or IM in the home setting. Furthermore, the family should be taught to provide supplemental carbohydrates as soon as possible after glucagons injection to restore liver glycogen and prevent secondary hypoglycemia.

Chapter 50: Drugs Affecting Pituitary, Thyroid, Parathyroid, and Hypothalamic Function

50.1. Calcium is used in many of the body's metabolic processes, including membrane transport processes, conduction of nerve impulses, muscle contraction, and blood clotting. Calcium levels are maintained within a narrow range by the interactions of parathyroid hormone, calcitonin, and vitamin D. These hormones alter calcium resorption from the intestine, affect osteoclast activity to alter the removal or deposit of calcium in bone, and affect the renal resorption of calcium.

50.2. A combination of neural and endocrine systems, originating in the hypothalamus, regulates central nervous system (CNS), autonomic nervous system (ANS), and endocrine functions. Major hypothalamic regulatory functions include somatic and visceral reactions, including temperature regulation, perspiration, GI activity, regulation of appetite and thirst, blood pressure, respiration, regulation of basic body rhythms (e.g., sleep and menstrual cycles), and complex behavioral

and emotional reactions (e.g., sexual behavior and defensive reactions of fear and rage). To promote homeostasis, the hypothalamus transmits stimuli to the pituitary gland, causing hormonal release or hormonal inhibition. When stimulated by the hypothalamus, the pituitary gland releases vasopressin (ADH) to regulate water balance in the system or oxytocin to increase uterine contractions or stimulate milk let-down. The anterior pituitary releases various stimulating hormones that increase the activity of other endocrine glands in response to hypothalamic releasing factors. These other endocrine glands regulate growth, development, and metabolism. The activity of both the hypothalamus and pituitary is carefully balanced through a series of negative feedback signals that maintain the levels of hormone present within an effective range.

50.3. Patients receiving somatropin will require it over the long term. It is administered only by injection. The patient and family need to learn sterile technique and proper methods for reconstituting and storing the solution. In addition, they need to learn how to administer the injection and recognize the importance of rotating sites to prevent complications and ensure adequate absorption.

50.4. Signs and symptoms of hypothyroidism include lethargy, slowing of mental processes, neuropathies, decreased heart rate, decreased cardiac output, eyelid drooping, periorbital edema, enlarged tongue, decreased appetite, constipation, increased cholesterol levels, decreased deep tendon reflexes, decreased renal blood flow with decreased output, hypermenorrhea, decreased libido, pale and puffy skin, dry and brittle hair, brittle nails, and intolerance to cold.

50.5. Gallium can be extremely nephrotoxic. The patient will have to have renal function test results and serum electrolytes monitored closely. Renal failure can further complicate the patient's electrolyte disturbances. The patient needs to be well hydrated during the 5 days of treatment to flush the drug through the kidneys as quickly as possible.

50.6. Calcitonin, salmon is from an animal source, and there is a risk for allergic reaction, especially in patients with a known history of allergic reaction to animal products. A skin test should be administered before the drug is given. If no reaction is noted within 15 minutes of the skin test, the drug can be used. The patient should be evaluated periodically for any sign of the development of an allergic reaction and should be asked to report fever, rash, lethargy, or difficulty breathing.

Chapter 51: Drugs Affecting Men's Health and Sexuality

51.1. The primary effects of testosterone are normal growth and development of the male sex organs and development and maintenance of the male secondary sexual characteristics (e.g., male hair distribution, hair texture and color, laryngeal enlargement and vocal cord thickening [voice deepening], and alterations in body musculature and fat distribution). Secondary effects of testosterone are retention of sodium, potassium, and phosphorus; decreased urinary excretion of calcium; stimulation of the growth of skeletal muscle tissue and enhancement of the growth of long bones in prepubescent boys; ossification of the epiphyseal growth plates; and stimulation of the production of red blood cells by enhancement of the production of erythropoietic-stimulating factor.

51.2. The main risk is premature ossification of the epiphyseal growth plate, resulting in stunted growth.

51.3. cGMP (when activated by nitric oxide) stimulates smooth-muscle relaxation and allows the inflow of blood into the erectile tissue in the penis. Sildenafil inhibits the isoenzyme (phosphodiesterase [PDE] type 5) that metabolizes cGMP. The decrease in the metabolism of cGMP allows cGMP to remain active longer, promoting more smooth-muscle relaxation and inflow of blood. This creates an improved and more sustained erection.

51.4. Finasteride is a pregnancy category X drug. Absorption through the skin is increased if the drug is crushed or broken.

51.5. Poor systemic absorption decreases the risk of adverse effects. Therapeutic effect is achieved without systemic absorption with topical minoxidil.

Chapter 52: Drugs Affecting Women's Health and Sexuality

52.1. Progesterone is used to treat amenorrhea and abnormal uterine bleeding because after ovulation, the ovarian follicle is transformed into the corpus luteum, which secretes a great deal of progesterone (and estrogens). This rise in progesterone makes the endometrium ready for implantation. As progesterone levels (and estrogen levels) rise, production of FSH and LH lowers. This prevents further ovulation. When fertilization does not occur, the corpus luteum disintegrates, and progesterone levels fall. Menstruation occurs. Thus, depending on the timing and duration of therapy, either ovulation can be blocked or menses can be initiated.

52.2. The serious adverse effects from estrogen therapy are: increased risk of endometrial

cancer, possibly increased risk of breast cancer, increased risk of thromboembolic disorders (including thrombophlebitis, MI, and pulmonary embolus PE), gallbladder disease, and hypertension.

52.3. Raloxifene can achieve the same effects as estrogen on increasing bone mineral density, and decreasing lipids. Raloxifene does not however have the same effects on uterine or breast tissue that estrogen does. Thus, the risk for endometrial and breast cancer is reduced. This is especially important for women who have high-risk factors for these cancers but also are at risk, or currently have, osteoporosis.

52.4. If a dose of an oral contraceptive is missed, it should be taken as quickly as possible; two tablets may be taken on the same day. Two missed pills should be made up over 2 days. If three consecutive pills are missed, the patient should begin a new cycle the day after the last pill was missed or 7 days after the last pill was taken. Another form of birth control should be used as a backup for at least 7 consecutive days of the new cycle and preferably for the rest of the cycle.

52.5. Instruct the patient to take alendronate at least 30 minutes before eating, drinking any beverage other than plain water, or taking any other medication. Swallow the medicine with 6 to 8 oz (180 to 240 mL) of plain water. Do not take with coffee, juice, or mineral water. The nurse should instruct the patient not to lie down for at least 30 minutes after swallowing the medication.

Chapter 53: Drugs Affecting Uterine Mobility

53.1. Slow upward titration of oxytocin more closely resembles oxytocin excretion, which naturally induces labor. Additionally, doing so minimizes adverse fetal and maternal effects.

53.2. The three phases of oxytocin response are 1) incremental phase (uterine activity increases evenly as the dose of oxytocin increases); 2) stable phase (uterine activity remains constant even if the oxytocin dose increases because the myometrial receptor sites are already full); and 3) hyperstimulation (the dose continually increases, the frequency of contractions increases, but the uterine pressure decreases so that the contractions are less effective).

53.3. Water intoxication can be fatal.

53.4. Nursing assessment that may help to minimize adverse oxytocin effects include maternal pulse rate, blood pressure, and fluid status; duration of contractions; time between contractions; fetal heart rate, and character of fetal movement.

53.5. Terbutaline is a beta agonist that selectively stimulates uterine receptors and stops uterine contractions.

53.6. If tachycardia, palpitations, and nervousness develop during terbutaline infusion, the nurse should slow the infusion, or possibly stop it, and notify the physician or nurse midwife.

53.7. Magnesium sulfate is the drug of choice to treat or prevent seizures associated with preeclampsia, eclampsia, and pregnancy-induced hypertension. It is also used off label to treat preterm labor.

53.8. Calcium gluconate.

53.9. The most common maternal adverse effects are: headache, hyporeflexia, weakness, thirst, flushing, and burning at infusion site. The most common fetal/neonatal adverse effects are: heart rate changes, neonatal hypotonia, and neonatal respiratory depression (possibly serious).

Unit 12: Immune System and Cancer Chemotherapy Drugs

Chapter 54: Drugs Affecting the Immune Response

54.1. Cytokines have the ability to activate and enhance host specific immune responses that are important for recognition of mutations (e.g., cancer cells) and transplanted tissue.

54.2. Interferons and interleukins are both naturally occurring biologic substances called cytokines or lymphokines because they are secreted by activated lymphocytes to create a cell-specific cytotoxic effect.

54.3. Interferons activate normal immunosurveillance properties, aiding in recognition of mutations evidenced as malignant cells. Also, their antiviral properties enhance their ability to destroy tumors that are viral in origin. In addition, their antiproliferative properties help them target rapidly proliferating cells, of which tumor cells are the most likely to demonstrate this property.

54.4. Interleukin-2 is a more potent cytokine that has greater proinflammatory activation, producing more infection and sepsis-like adverse effects. Use of interleukin-2 is also more limited than the interferons, because it does not have the same antiviral or antiproliferative properties.

54.5. Cyclosporine, a common macrolide polypeptide antibiotic agent with potent T lymphocyte–suppressing properties, is used to prevent and treat acute rejection in both solid organ and blood and marrow transplantation. It has also been used successfully to treat severe autoimmune disorders such as rheumatoid arthritis.

54.6. The three most common dose-limiting toxicities of cyclosporine are nephrotoxicity, neurotoxicity, and diabetes generation. Although hypertension

may frequently occur, it only sometimes necessitates changing to another agent.

54.7. The most common toxicity limiting therapeutic use of thalidomide is its teratogenic effects, necessitating careful candidate selection and monitoring while proactively providing contraception.

54.8. All patients prescribed thalidomide must enter the S.T.E.P.S. program and consent to therapy while agreeing to not get pregnant or impregnate another. They must also consent to frequent monitoring of their pills, health practices and education reinforcement.

Chapter 55: Targeted Therapies

55.1. Epidermal growth factor receptor (EGFR), vascular endothelial grown factor (VEGF-1, 2, and 3), platelet-derived growth factor beta (PDGF-beta), and transforming growth factor alfa (TGF-Alfa). Intracellular tumor targets that have been identified include: platelet-derived growth factor (PGDF-alfa), hypoxia-inducible factor (HIF), c-Raf, b-raf, and transforming growth factor (TGF).

55.2. Cost and patient adherence.

55.3. Targeted therapies interfere with specific extracellular and intracellular molecules and receptor sites involved with carcinogenesis and tumor growth or proliferation. Chemotherapy is toxic to the cell cycle phases of all cells in the body, therefore causing damage to non-cancerous cells, which leads to a number of toxicities.

55.4. CYP-enzymes play an important role in the metabolism of many of the kinase inhibitors, which can lead to drug interactions. Patients on kinase inhibitors should have a full review of all medications to ensure a maximum benefit and decreased toxicities.

Chapter 56: Drugs That Are Cell Cycle–Specific

56.1. The goals of chemotherapy are cure, control, and palliation.

56.2. The different strategies include adjuvant, induction, consolidation, neoadjuvant, palliative, salvage, and intensification therapy.

56.3. Malignant cells are characterized by the following features:

- Uncontrolled cell proliferation
- Decreased cellular differentiation
- Inappropriate ability to invade surrounding tissue
- Ability to establish new growth at ectopic sites

56.4. To expedite the handling of a spill and to minimize undue patient and employee exposure, well-equipped chemotherapy spill kits should be readily available. To manage spills of chemotherapeutic agents, it is necessary to adhere to the following recommended sequence:

- Post a sign immediately to warn people away from the exposed area.
- Don two pairs of powder-free latex gloves, a disposable gown, and a face shield.
- Wear a NIOSH-approved respirator.
- Place an absorbent pad over the spill to contain it.
- Pick up glass fragments with a scoop and dispose of in a puncture-proof container.
- Clean the area with a detergent three times, from the least contaminated to the most contaminated areas.
- Rinse the absorbed spill area with clean water. Repeat the washing and rinsing.
- Dispose of all cleanup equipment according to institutional policy for chemotherapy waste.
- Document the spill according to institutional policy; usually, spills of 5 mL or more are reportable. The following data should be included in the documentation: name of chemotherapy agent and approximate volume spilled, how spill occurred, procedures followed to contain and clean up spill, names of people who were exposed, and names of those who were notified of spill.

56.5. Exposure to chemotherapy can occur through the following routes: skin and mucous membrane absorption, inhalation, injection by needlestick, and ingestion.

56.6. The following steps should be taken:

- Stop the infusion immediately and restart the infusion at a new site.
- Apply warm or cold compresses as indicated to the extravasation site, and if prescribed, administer a local antidote, such as hyaluronidase, to minimize any tissue damage.
- Notify the health care provider.
- Rest and elevate the affected extremity for 48 hours.
- Apply a sterile dressing that allows the extravasation area to remain visible. Avoid any pressure to the site.
- Obtain a photograph of the site for baseline comparisons
- Document the following in the patient's medical record per institutional guidelines: date and time of extravasation, name of drug, approximate volume of infiltrate, needle gauge, site of extravasation, symptoms reported by the patient and assessed by the nurse, nursing measures implemented, name of health care provider notified, patient education provided, and nurse's signature.
- Consult the physician regarding need for referral to plastic surgeon, if appropriate.

56.7. The drug should never be administered by IV push or rapid IV infusion because doing so can cause hypotension.

56.8. Hypersensitivity or anaphylaxis-like reactions are manifested by hypotension, chills, fever, facial flushing, bronchospasm, dyspnea, and tachycardia.

56.9. Before administration of paclitaxel, check for premedication orders. To prevent severe reactions, premedication is necessary. Premedication usually consists of corticosteroids (dexamethasone), diphenhydramine, and an H_2-antagonist (e.g., cimetidine), which are given intravenously 30 minutes before the paclitaxel infusion.

Chapter 57: Drugs That Are Cell Cycle–Nonspecific

57.1. Anthracyclines are a group of antitumor antibiotics, which include doxorubicin, daunorubicin, their liposomal counterparts, epirubicin, and idarubicin.

57.2. The highly lipid-soluble nitrosoureas can cross the blood–brain barrier, which is critical in the treatment of central nervous system diseases.

57.3. The drugs used to control acute emesis are the serotonin antagonists (such as odansetron), the NK-1 antagonists (aprepitant), and the corticosteroids (dexamethasone). The anxiolytic lorazepam is an adjunct that may be added to combination therapy to treat emesis.

57.4. Dexrazoxane is a potent intracellular chelating drug that interferes with iron-mediated free radical generation, which is thought to be responsible for anthracycline-induced cardiotoxicity. It is used to decrease the incidence of cardiomyopathy in women with metastatic breast cancer who have received the maximum suggested dose of doxorubicin but would benefit from continuing treatment with doxorubicin. The recommended dose of dexrazoxane to doxorubicin is at a ratio of 10:1 (e.g., dexrazoxane, 500 mg, to doxorubicin, 50 mg). It should be given by slow IV push or rapid IV infusion before administering doxorubicin. The total elapsed time from the beginning of the dexrazoxane infusion to the initiation of doxorubicin should not be more than 30 minutes.

57.5. Drugs used in combination should have the following characteristics:

- Maximum cell kill within the range of toxicity tolerated by the patient
- A broader range of coverage against resistant cell lines in the heterogenous tumor population
- Minimal or slow development of new resistant cell groups

In designing successful drug combinations, the choice of drugs follows these principles:

- Selected drugs should be proven partially effective against the tumor when used alone.
- Ideally, the drugs used in combination are best if they do not have overlapping toxicities.
- The dosages and schedules for the various drugs should be maximized.
- Drugs should be administered at consistent intervals.
- Drugs should be selected to produce synergy.

APPENDIX

A

Diagnostic Imaging Agents

New medical test procedures continue to rely on diagnostic imaging agents. Common imaging agents include radiopaque contrast agents, such as barium sulfate; ionic iodinated imaging agents, such as diatrizoate meglumine; nonionized iodinated imaging agents, such as metrizamide; provocative agents, such as arginine; and skin testing agents, such as coccidioidin.

Radiopaque contrast agents highlight and provide contrast among internal structures. Iodinated imaging agents are composed of iodine compounds with radiopaque properties. Provocative agents provoke measurable responses that indicate disease or its absence. Skin testing agents help to identify allergic responses and other disorders.

As technology advances, more patients will undergo testing procedures with these agents. Nurses must be prepared to administer and monitor some of these agents and provide care for patients receiving them. Like therapeutic drugs, these diagnostic agents require special administration methods, produce adverse effects, and call for careful patient education. Such education of course requires a firm understanding of the interrelationship between core drug knowledge related to diagnostic drugs and core patient variables specific to the testing procedures. A summary of various pharmacologic test agents follows.

Drug (Trade) Name	Indications	Nursing Management
Imaging Agent		
barium sulfate suspensions (Baro-CAT, Prepcat, Entrobar) concentrated suspensions (Tomocat) powder (Baroflave) powder for suspension (Barosperse, Anatrast, Tonopaque)	GI diagnostics	Do not administer if obstruction of GI tract is suspected. Keep the patient fasting (NPO) for 8 h for oral administration. Provide mouth care for NPO patients. Administer cathartic or enema posttest as ordered. Assess GI status post-test; document passage of stool. Keep patient well hydrated to expel barium. Monitor for constipation, intestinal cramping, distention, diarrhea, and bowel obstruction..
Ionic Iodinated Imaging Agents		
diatrizoate meglumine (Gastrografin) diatrizoate sodium (Hypaque Sodium)	GI diagnostics, discography, urography, angiography, angiocardiography, arteriography, aortography, ventriculography, venography, venacavography, computed tomography (CT)	Assess for allergy to iodine, iodine compounds, foods that contain iodine, or dye allergy. Assess patient history of bronchial asthma; renal, hepatic, or thyroid disease; sickle cell disease. Notify the provider of any positive allergy or history before administering the drug. Monitor fluid and electrolyte status. Have emergency equipment available for possible allergic reactions. Monitor extravasation from injection site.
ethiodized oil (Ethiodol)	Hysterosalpingography	Same as diatrizoate meglumine When injected into lymph nodes, monitor for compromised pulmonary function. Monitor for infection in the insertion site and delayed wound healing.
iodipamide meglumine (Cholografin Meglumine)	Cholecystography, cholangiography	Same as diatrizoate meglumine
iothalamate meglumine (Conray, Conray 30, Cysto-Conray, iothalamate sodium (Conray 400, Glofil 125)	Cholangiography, urography, pyelography, cystourethrography, arthrography, angiography, angiocardiography, arteriography, aortography, CT, cholangiopancreatography, cystography	Same as diatrizoate meglumine

Continued

Drug (Trade) Name	Indications	Nursing Management
iopamidol (Isovue)	Urography, angiography, angiocardiography, arteriography, aortography, ventriculography, venography	Assess for history of iodine sensitivity. Assess for the following: seizure disorder, local or systemic infection, pheochromocytoma, multiple sclerosis, sickle cell anemia, severe cardiovascular disease, impaired hepatic function, active alcoholism. Notify the provider of any positive history prior to administering the drug. Assess pretest and post-test fluid and electrolyte balance.
iohexol (Omnipaque)	Urography, myelography, angiography, angiocardiography, arteriography, aortography, ventriculography, venography, CT	Monitor for CNS effects after test. Same as for iopamidol After intrathecal administration, elevate the head of the bed 45 degrees.
ioversol (Optiray)	Urography, angiography, arteriography, aortography, ventriculography, venography, CT	Same as for iopamidol
ioxaglate meglumine (Hexabrix)	Urography, arthrography, angiography, angiocardiography, arteriography, aortography, ventriculography, venography, hysterosalpingography, CT	Same as for iopamidol
Provocative Drugs		
Arginine (R-gene 10)	Evaluate pituitary growth hormone reserve	Assess for allergy or hypersensitivity reactions. Assess for sickle cell anemia and renal disease. Notify the provider of any positive history before administration of the test. Administer through an indwelling catheter to prevent extravasation. Draw blood sample at 30 min before and again immediately before the test. Draw blood sample at the initiation of the injection and at 30-min intervals for 2.5 h thereafter.
corticotropin (ACTH)	Evaluate adrenal function	Assess for porcine protein sensitivity. Notify provider of positive allergic response prior to administration of the drug. Advise low-carbohydrate diet for 48 h prior to day of testing. Keep patient NPO 12 h before test. Restrict patient's activity 12 h before test. Withhold the following medications: amphetamines, calcium gluconate, corticosteroids, estrogens, lithium, and spironolactone.
cosyntropin	Assist in diagnosing adrenocortical insufficiency	Assess for allergy to corticotropin or cosyntropin. Notify the provider of any positive allergy history before administration of the drug. The following drugs may interfere with test results: cortisone, hydrocortisone, estrogens, and spironolactone. Draw blood specimen 30–60 min after administration of cosyntropin.
edrophonium (Tensilon)Drug (Trade) Name	Assist in the diagnosis of myasthenia gravis Differentiate between cholinergic crisis and myasthenic crisis Evaluate therapy Indications	Withhold the following medications: anticholinergics, muscle relaxants, prednisone, procainamide, and quinidine. Have 1 mg atropine available to reverse possible severe cholinergic reactions. Interpretation timing: myasthenia gravis diagnosis, 45 s after administration; differentiation between cholinergic crisis and myasthenic crisis, 1 min after administration; and evaluation of treatment, 1 min after administration. Nursing Management
metyrapone	Evaluate hypothalamic-pituitary function	Same as gonadorelin
secretin (ChiRhoStim, SecreFlo)	Assist in diagnosing pancreatic exocrine disorders and gastrinoma	Assess for the following: allergies, asthma, anticholinergic therapy, inflammatory bowel disease, and vagotomy. Notify the provider of any positive history before administration of the test. Assist in the insertion of a double-lumen catheter. Administer test dose if the patient has a history of asthma or allergies; continue test if no reaction after 1 min. For pancreatic disorders: obtain gastrin and duodenal secretion samples taken during the first 60 min after secretin injection. For gastrinoma: draw blood sample during the first 30 min after secretin injection.

Continued

Continued

Drug (Trade) Name	Indications	Nursing Management
thyrotropin (Thyrogen)	Assist in diagnosing low thyroid reserve and subclinical hypothyroidism Differentiate between primary and secondary hypothyroidism Detect thyroid cancer Evaluate treatment	Assess for a history of angina pectoris, cardiac failure, hypopituitarism, adrenal cortical suppression, corticosteroid therapy, coronary thrombosis, untreated Addison disease, and hypersensitivity to thyrotropin. Notify the provider of any positive history before administration of the test. Monitor for signs of hypersensitivity reaction. Monitor for nausea, vomiting, headache, fever, tachycardia, and ventricular fibrillation.
Skin Testing Drugs		
Candida albicans	Detect delayed-type hypersensitivity(DTH) Evaluate the cellular immune response in patients suspected of having reduced cellular hypersensitivity	Administer by intradermal injection, being sure to produce a wheal. Evaluate for induration after 48 h. A positive DTH reaction consists of induration ≥5 mm.
coccidioidin	Assist in the diagnosis of coccidiomycosis Evaluate cell-mediated immune status	Assess for a hypersensitivity to thimerosal and those with erythema nodosum. Notify the provider of any positive history before administration of the test. Administer by intradermal injection, being sure to produce a wheal. Observe the patient for 15 min after the injection. Have epinephrine available in case an acute hypersensitivity reaction occurs. Assess for induration at the injection site 24 and 48 h after the injection. A positive reaction consists of induration ≥5 mm.
histamine	Used as a positive control in evaluation of allergenic skin testing	Assess for hypotension, severe hypertension, or severe cardiac, pulmonary, or renal disease. Histamine testing is contraindicated in these patients. Administer by intradermal injection, being sure to produce a wheal. Evaluate the site in 15–20 min.
histoplasmin	Assist in diagnosing histoplasmosis Differentiation of histoplasmosis from coccidioidomycosis, sarcoidosis, and other mycotic or bacterial infections Indications	Assess for a history of histoplasmosis or previous positive test results. Notify the provider of any positive history before administration of the test. Do not use more than 0.1 mL for testing, because larger doses may cause necrosis and ulceration. Have epinephrine available in case of severe reaction. Administer by intradermal injection, being sure to produce a wheal. Assess for induration at the injection site 48–72 h later. Nursing Management
mumps	Detect delayed hypersensitivity to mumps antigens Assess cell-mediated immunity	Assess for previous hypersensitivity to the test. Assess for allergy to eggs, egg products, or thimerosal. Assess for pregnancy. Notify the provider of any positive history before administration of the test. Administer by intradermal injection, being sure to produce a wheal. Assess for induration at the injection site 48–72 h later. In immunocompromised patients, a positive test result is any amount of induration. In immunocompetent patients, a positive test result is 5 mm or more of induration.
tuberculin	Assist in diagnosing tuberculosis Evaluate cell-mediated immune statu	Assess for previous positive test results. Notify the provider of any positive history before administration of the test. Administer by intradermal injection, being sure to produce a wheal. To avoid false-positive results, do not administer in an area of atopic dermatitis, sun-damaged skin, or ultraviolet treatment. Assess for induration at the injection site 48–72 h later. In immunocompromised patients, a positive test result is 5 mm or more of induration. In immunocompetent patients, a positive test result is 10 mm or more of induration.

APPENDIX B

Enzyme or Débridement Therapy

Enzymes and débridement agents are composed of proteins and similar substances. Having catalytic action, they are used to slow or speed organic processes, replace or supplement deficient enzymes, break down proteins (such as blood clots), and débride wounds.

The nurse administering enzyme or débridement therapy is responsible for understanding the drug's action and effects (core drug knowledge); assessing the patient's health history and physical condition (core patient variables); and planning and implementing associated patient education.

Drug (Trade) Name	Indications	Nursing Management
Enzymes		
alglucosidase alpha (Myozyme)	Treatment of Pompe disease	Monitor for anaphylaxis. Infusion-related reactions are common; decrease infusion rate for mild to moderate reactions. Monitor for rash, diarrhea, constipation, nausea, or vomiting. Infuse over 4 h; initiate at 1 mg/kg/h. If tolerated, increase by 2 mg/kg/h to a maximum rate of 7 mg/kg/h.
agalsidase beta (Fabrazyme)	Treatment of Fabry disease	Assess for mannitol hypersensitivity. If positive, advise health care provider before administering drug. Monitor for signs of allergic reactions such as difficulty breathing, closing of the throat, hives, rash, and itching. Monitor for signs of infusion reaction such as fever, shaking, chest tightness, high or low blood pressure, fast heartbeats, muscle pain, stomach pain, nausea or vomiting, dizziness, numbness or tingling, and headache. Administer pretreatment medications to minimize infusion reactions as ordered.
alglucerase (Ceredase)	Replacement of glucosylceramidase in patients with Gaucher disease (a congenital disorder of lipid metabolism)	Assess the patient's health history for an immune-deficiency disease and for unusual or allergic reaction to alglucerase, other drugs, foods, dyes, or preservatives. Determine whether the patient is pregnant, trying to get pregnant, or breast-feeding. Monitor for fever, chills, or stomach discomfort; nausea, vomiting; pain, burning, swelling, or irritation at the injection site.
galsulfase (Naglazyme)	Treatment of mucopolysaccharidosis	Pretreatment with antihistamines 30–60 min before infusion is recommended. Administer intravenously over 4 h. Monitor for swelling of the face, tongue, or lips, difficulty breathing or swallowing, chills, and rash. Monitor for injection site reactions.

Countinued

Countinued

Drug (Trade) Name	Indications	Nursing Management
bovine hyaluronidase (Hydase) human hyaluronidase (Hylenex)	Adjuvant drug to increase the absorption and dispersion of other injected drugs; for hypodermoclysis; and as an adjunct in subcutaneous urography for improving resorption of radiopaque agents	Change needle after each injection when used for extravasation. Monitor for urticaria, swelling, and injection site reactions. Do not inject directly on the cornea or into or around infected or inflamed areas. Incompatible with benzodiazepines, furosemide, and phenytoin.
idursulfase (Elaprase)	Treatment of Hunter syndrome	Monitor for anaphylaxis; have appropriate equipment readily available. Infuse over 1–3 h; do not exceed 8 h. Monitor for swelling of the face, tongue, or lips, difficulty breathing or swallowing, chills, and rash. Monitor for injection site reactions
imiglucerase (Cerezyme)	DNA recumbent enzyme used for Gaucher disease	Assess the patient's health history for an unusual or allergic reaction to imiglucerase and other drugs, foods, dyes, or preservatives; pregnancy or plans for pregnancy; and breast-feeding. Monitor for fever, chills, or stomach discomfort, nausea, or vomiting.
pancrelipase (Cotazym, Creon, Ilozyme, Pancrease, Viokase)	Same as pancreatin Has 12 times the lipolytic activity, 4 times the proteolytic activity, and 4 times the amylolytic activity of pancreatin	Administer pancrelipase orally. Products are not interchangeable. Administer delayed-release capsules containing enteric-coated spheres, microspheres, or microtablets by opening and mixing the contents with liquids or soft food. Advise patient not to chew or crush, to avoid destruction of enteric coating. The enteric coating will dissolve if in contact with food with a pH greater than 6. Powder drug form may be administered with liquids or mixed with food. Avoid inhaling the powder.
pegademase bovine (Adagen)	Replacement in patients with adenosine deaminase (ADA) deficiency	Give with caution to patients with thrombocytopenia or coagulopathy. Monitor for headache; also monitor injection site. Do not coadminister with vidarabine.
Débridement Agents		
collagenase (Santyl)	Chemical débridement of acute or chronic dermal ulcers and severely burned areas associated with necrotic material	Assess need for pain medication prior to treatment. Gently wash the site with normal saline, using sterile gauze. It is not necessary to remove previously applied collagenase. Apply the ointment within the boundaries of the wound. Do not let the tip of the tube touch anything.
dextranomer (Debrisan)	Cleansing of exudative wounds Treatment of decubitus or leg ulcers	Assess need for pain medication prior to treatment. Débride and cleanse wound by irrigation before applying 3´/d. Paste is easier to apply than beads. Apply dressing and seal on all four sides.
papain and urea (Accuzyme)	Enzymatic débridement agent for wounds such as diabetic or decubitus ulcers, burns, postoperative wounds, and traumatic or infected wounds	Assess need for pain medication prior to treatment. Gently wash the site with normal saline and sterile gauze. Do not use hydrogen peroxide solution, because it may inactivate papain. Apply the ointment within the boundaries of the wound. Do not let the tip of the tube touch anything.

APPENDIX

C

Enteral and Nutritional Supplements

Vitamins and minerals are substances that the body requires for essential metabolic reactions. Vitamins are either water soluble and excreted in the urine or fat soluble and capable of being stored in adipose tissue. The body cannot synthesize enough of these components to meet all of its needs. Therefore, vitamins and minerals must be obtained from animal and vegetable sources ingested as food. In a well-balanced diet, humans take in all they need. Only small amounts of vitamins and minerals are needed because they function as coenzymes that activate the protein portion of enzymes, which catalyze a great deal of biochemical activity.

Enteral nutritional support is required for patients unable or unwilling to ingest proper nutrients to support the body's needs or those whose needs exceed their ability to ingest sufficient nutrients. Enteral nutrition is also used in patients who require bowel rest from gastrointestinal disorders or recent bowel surgery. Enteral nutrition treats vitamin or mineral deficiencies, supplements the diet when needed, and provides specific therapeutic effects related to vitamin or mineral activity.

Enteral nutrition may be given as a continuous infusion, cyclic infusion, or intermittent infusion. Continuous infusions continue 24 hours a day. Cyclic infusions are delivered over a few hours. Intermittent infusions are given 3 to 6 times per day, generally lasting 30 to 60 minutes.

Enteral nutrients are classified in pregnancy category C and are contraindicated in cases of allergy to components of the vitamin or mineral, such as colorants, additives, or preservatives. Adverse effects to anticipate from enteral nutrition include nausea, diarrhea, and sometimes toxic reactions, particularly in instances of overdose. Monitor patients receiving enteral nutrition for aspiration. Aspiration pneumonitis can be fatal. Assess gastric residual frequently to avoid nausea and vomiting.

Assess core patient variables. The health history should disclose any condition that would contraindicate using enteral nutrition. The physical examination should include a skin evaluation, respiratory status, pulse rate, and blood pressure. Each enteral drug should be checked for special administration needs. The patient or family should be cautioned to avoid additional supplements in OTC products because overdose can occur. Patients also should be cautioned to avoid using mineral oil if they are taking fat-soluble vitamins.

Nutritional Component	Purpose	Nursing Management
Fat-Soluble Vitamins		
vitamin A (Aquasol A, Del-Vi-A) Preformed vitamin A is retinol. Provitamin A carotenoids are beta-carotene and alpha-carotene.	Treats vitamin A deficiency Necessary for growth and repair of body tissues Helps maintain integrity of skin and mucous membranes of the mouth, nose, throat, and lungs Assists in adaptation to light Aids in bone and teeth formation	Administer PO or IM. Protect IM vial from light. Teratogenic with excessive dosage. Watch for hypervitaminosis A: nausea, vomiting, hepatomegaly, splenomegaly, jaundice, CNS symptoms, including increased intracranial pressure.
vitamin D ergocalciferol (vitamin D2, Calciferol) cholecalciferol (vitamin D3, Delta-D) calcifediol (25-Hydroxy-D3, Calderol)	Used to manage hypophosphatemia, hypoparathyroidism, and resistant rickets Treats vitamin D deficiency Used to manage hypocalcemia and potential bone disease in patients receiving chronic renal dialysis	Administer as prescribed. Encourage balanced diet and exposure to sunlight. Do not use with mineral oil. Monitor calcium levels before administration and periodically during therapy. Discontinue if patient does not respond or if hypercalcemia occurs.

Continued

Nutritional Component	Purpose	Nursing Management
vitamin E (Aquasol E, Vita-Plus E, Softgels)	Reduces toxic effects of oxygen on the lungs and retinas in certain premature infants Treats severe vitamin E deficiency Maintains adequate levels of vitamin E during periods of stress and growth	Do not administer IV. Instruct patient to report fatigue, weakness, nausea, headache, blurred vision, diarrhea. If above adverse effects occur, stop vitamin therapy immediately.
vitamin K phytonadione (Mephyton, AquaMEPHYTON)	Treats hypoprothrombinemia due to vitamin K deficiency, overdose of anticoagulants or hemorrhagic disease of the newborn Given as prophylaxis for vitamin K deficiency in newborns	Administer Mephyton orally. Administer AquaMEPHYTON SC or IM. IV administration is possible, but only if the benefits outweigh the risks. If given IV, monitor for potential shock or respiratory or cardiac arrest. Monitor prothrombin time (PT) prior to and throughout therapy.
Water-Soluble Vitamins		
vitamin C (ascorbic acid) (Cebid, Vita-C, Cevalin, N'ice Vitamin C Drops)	Treats severe vitamin C deficiency (scurvy) Enhances wound and burn healing	Monitor combination and OTC products for vitamin C content. Be forewarned: many patients receive more than the recommended dose. Administer PO and, if necessary, IM, slow IV, or SC, depending on patient's condition. Keep in mind that dose may decrease effectiveness of anticoagulant therapy and increase adverse effects of oral contraceptives.
vitamin B_{12} (cyanocobalamin) (Ener-B)	Treats severe vitamin B12 deficiency, which may present as megaloblastic anemia, neuronal damage, or oral ulcerations and GI disturbances Used to prevent anencephaly, spina bifida, and neural tube defects in the developing fetus Used to prevent colorectal cancer Used to reduce plasma homocysteine levels	Administer PO, SC, or IM. Patients without intrinsic factor must receive drug IM. Monitor patient for mouth sores or skin breakdown. Monitor plasma vitamin B_{12} levels every 3–6 months. Monitor potassium levels for patients on long-term therapy.
vitamin B_3 (niacin) (Nicotinic Acid)	Prevents and treats pellagra, niacin deficiency, and hyperlipidemia in patients not responsive to diet therapy	Advise patient that he or she may feel sensation of warmth and flushing on administration, but sensation usually subsides within 24 h. Monitor serum lipid levels in patients being treated for hyperlipidemia. Encourage proper diet and exercise. Advise patient that adverse effects of nausea, abdominal pain, and diarrhea may occur and that taking vitamin with meals may relieve these problems.
vitamin B_6 (pyridoxine) (Nestrex, Beesix)	Treats severe vitamin B6 deficiency Prevents peripheral neuropathy with isoniazid therapy	Avoid administering to patients taking levodopa, because serious toxic interaction may result. Monitor for adverse effects, such as sensory neuropathic syndrome, marked by unsteady gait and somnolence. Provide safety measures if this effect occurs.
vitamin B_2 (riboflavin)	Treats severe vitamin B2 deficiencies Maintains adequate vitamin B2 levels during periods of stress or growth	Monitor patient for response to treatment. Warn patient that this drug may discolor urine yellow-orange; explain that the discoloration will subside when therapy discontinues.
vitamin B_1 (thiamine) (Thiamilate, Biamine)	Treats severe vitamin B1 deficiencies (e.g., beriberi) Prevents Wernicke-Korsakoff syndrome in alcoholics	Do not mix in alkaline solutions. Advise patient that this vitamin changes composition of sweat and body odor. Warn patient that a warm, flushing sensation may accompany administration, but sensation will subside quickly.

Continued

Nutritional Component	Purpose	Nursing Management
Minerals		
calcium (Calciday, Chooz, Dicarbosil, Oystercal, Tums)	Treats severe calcium deficiency Maintains calcium levels Reduces gastric acid levels Helps cardiac contraction during cardiac arrest	Administer with meals to decrease GI effects. Avoid combination with digoxin, thiazide, and oral contraceptives (toxicity may occur). Keep in mind that calcium may decrease absorption of atenolol, iron, quinolones, and tetracyclines. Avoid combining with high-fiber diets, oxalate, or zinc, because these combinations may decrease absorption. Combining with milk or dairy products may increase the risk of hypercalcemia. Monitor calcium levels in acute situations; also monitor for signs of hypercalcemia and hypophosphatemia. Caution patient to avoid OTC multiple-combination products that may increase risk of hypercalcemia.
iron (ferrous fumarate, gluconate, and sulfate) (Feostat, Feosol, Fer-In-Sol)	Treats severe iron deficiency Treats iron deficiency anemia Supplements epoetin alfa therapy	Avoid administering iron with tetracycline (decreases absorption of both), antacids, cimetidine, vitamin C, and chloramphenicol (decreases iron absorption). If appropriate, tell patient that absorption of levodopa, methyldopa, penicillamine, and quinolones is decreased if these drugs are taken with iron. Administer with food to relieve GI upset. Other adverse effects may include anorexia, vomiting, constipation, and green or dark stools. Dilute liquid form and have patient drink it through a straw to decrease dental staining. Keep out of reach of children. Serious toxicity can occur if accidentally ingested.
magnesium, citrate and hydroxide (Citrate of Magnesia, Milk of Magnesia)	Decreases gastric acidity when used as antacid Relieves mild constipation Evacuates colon when used before rectal/bowel examinations	Caution patients to read labels of OTC products carefully to avoid magnesium overdose. Forewarn patients that diarrhea may occur. When administering magnesium, recognize that combination with the following drugs will decrease their absorption: digoxin, penicillamine, amino quinolones, nitrofurantoin, and tetracyclines. Administer these drugs at least 2 h apart.
phosphorus (Neutra-Phos)	Dietary supplement for periods of growth or stress	Avoid using phosphorus if patient is on a sodium- or potassium-restricted diet. Reconstitute powdered drug form before administering. Monitor potassium level if patient is receiving potassium or using potassium-sparing diuretics. Caution patient that antacids and calcium vitamin D products may decrease phosphorus levels. Explain that adverse effects may include GI upset, diarrhea, dizziness, seizures, confusion, muscle cramps. Advise patient to stop taking drug and report excessive diarrhea if it occurs.
zinc (Orazinc, Verazinc, Zincate)	Supplements diet to treat or prevent zinc deficiency Speeds healing Treats rheumatoid arthritis, Wilson's disease, and common cold	Administer with food if GI upset occurs. Avoid high-fiber diets, calcium, and phosphates in combination; administer at least 2 h apart. Encourage patients to check OTC products to avoid zinc overdose. Caution patients that adverse effects may include nausea, vomiting, and diarrhea.

Continued

Continued

Nutritional Component	Purpose	Nursing Management
Enteral Supplements		
Contain: amino acids carbohydrates fats electrolytes vitamins trace elements	Supplements intake for anorectic patients, those with impaired swallowing, or those with digestive or absorptive disorders	Check placement of feeding tube prior to administration. Check order for continuous or intermittent administration. Check for residual per institution's protocol. Monitor for signs of aspiration. Check glucose. Monitor for signs of electrolyte imbalance.

APPENDIX D

Parenteral Nutrition

Parenteral nutrition (PN) is administration of essential proteins, amino acids, carbohydrates, vitamins, minerals, trace elements, lipids, and fluid through a central or other intravenous (IV) line. PN is used to improve or stabilize the nutritional status of cachectic or debilitated patients who cannot ingest or absorb oral nutrition to maintain their nutritional status. The exact composition of the PN solution is determined after a nutritional assessment and takes into account core drug knowledge related to the parenteral solution and core patient variables of the patient's current health status, age, and metabolic needs.

PN is contraindicated in anyone with known allergies to any of the solution's components. Many multiple-combination products are available, and a solution that is suitable for any patient can be given. Adverse effects that may accompany PN include mechanical problems (related to the IV line, such as pneumothorax, infections, air emboli, or emboli related to protein or lipid aggregations), infections related to the nutrient-rich solution and invasive administration, metabolic imbalances related to the composition of the solution, gallstone development (especially in children), and nausea (associated with administering lipids).

Before PN begins, perform a nutritional assessment with additional assessments made periodically during therapy. Core patient variables to include in the assessment are the patient's height, weight, dietary and medical histories, current illness, and current drug therapy regimens. Daily assessments include daily weights, fractional urine analyses, blood glucose levels every 6 to 8 hours, vital signs, strict intake and output, condition of the infusion pump and insertion site (checked at every shift), neurologic status, and blood chemistry values (to evaluate the effectiveness of therapy).

Parenteral solutions should be refrigerated until ready to be administered. Just before administration, check the solution's components against the prescribed components. Then, inspect the solution for abnormalities, such as precipitates, cloudiness, or color changes. The solution should not hang for more than 24 hours, after which it should be replaced. In most cases, inline filters are recommended to decrease the opportunity for bacteria or aggregates to be infused with the solution.

PN is used during pregnancy in patients whose conditions limit nutritional intake. Assess elderly patients carefully when receiving PN because they may not tolerate the increased volume or concentrated glucose solutions. Extreme caution must be used when giving intralipids to premature infants in whom hepatic clearance is decreased. Discontinue PN slowly by gradually reducing the infusion rate over several hours. Do not discontinue PN until an alternate source of nutrition has been established.

Patient and family education materials should focus on why PN is being given, the need for monitoring both the patient and the infusion equipment (pump and line) regularly, signs and symptoms to report to the health care provider—particularly chest pain, difficulty breathing, pain at the injection site, fever, and flu-like symptoms. Many patients now receive PN at home and must deliver their own infusions. These patients need special instructions in maintaining sterile technique and recognizing warning signs of infection or emboli to be reported immediately. Information about typical PN formulas follows.

PN Component*	Purpose	Nursing Management
Typical Central PN Solution (1 L)		
Provides 1,350 total nonprotein calories in 1,250-mL volume of solution with 25% dextrose concentration, 5% amino acid concentration, and osmolarity of 1,900 mOsm/L *Actual concentration and components of any PN solution are determined by the patient's current status and nutritional needs.*		
10% amino acids	Provides 50 g protein for growth and healing	Dosage: 500 mL Monitor blood pressure, cardiac output, blood chemistries, urine analyses to determine effect of intravascular protein pull.
50% dextrose	Provides 850 kcal for energy	Dosage: 500 mL Monitor blood glucose level. Evaluate injection site for signs of infection or irritation.
20% fat emulsion	Provides 500 fat calories, ready energy	Dosage: 250 mL Monitor for emboli; signs include shortness of breath, chest pain, deep leg pain, neurologic changes. Monitor for signs of increased vascular workload, especially in very young and very old patients.
sodium chloride	Provides sodium and chloride needed for various chemical reactions within the body	Dosage: 40 mEq Monitor cardiac rhythm and serum electrolyte levels.
calcium gluconate	Provides essential calcium for muscle contraction, blood clotting, and numerous chemical reactions	Dosage: 4.8 mEq Monitor cardiac rhythm, muscle strength, and serum electrolyte levels.
magnesium sulfate	Provides magnesium for various chemical reactions within the body	Dosage: 8 mEq Monitor blood pressure and serum electrolyte levels. Nursing Management
potassium phosphate	Provides needed potassium for nerve functioning and muscle contraction	Dosage: 9 mMol Monitor blood pressure, cardiac rhythm, muscle function, and serum electrolyte levels.
multivitamins	Provides essential vitamins to maintain cell integrity and promote healing	Dosage: 10 mL Monitor for signs of vitamin deficiency or toxicity.
trace elements: zinc, 3 mg copper, 1.2 mg manganese, 0.3 mg chromium, 12 mcg selenium, 20 mcg	Provides small amounts of elements essential for various chemical reactions in the body and maintenance of cell integrity and healing	Periodically monitor blood chemistry findings to determine adequacy of elemental replacement.
Typical Peripheral Parental Nutrition Solution (1 L)		
Provides 840 total nonprotein calories in 1,250-mL volume of solution with 10% dextrose concentration, 4.25% amino acid concentration, and osmolarity of 900 mOsm/L *Actual concentration and components of any PN solution are determined by the patient's current status and nutritional needs.*		
8.5% amino acids	Provides 41 g protein for growth and healing	Dosage: 500 mL Monitor blood pressure, cardiac output, blood chemistries, urine analyses to determine effect of intravascular protein pull.
20% dextrose	Provides 340 calories for energy	Dosage: 500 mL Monitor blood glucose level. Evaluate injection site for signs of infection or irritation.
20% fat emulsion	Provides 500 fat calories, ready energy	Dosage: 250 mL Monitor for emboli; signs include shortness of breath, chest pain, deep leg pain, neurologic changes. Monitor for signs of increased vascular workload, especially in very young and very old patients.

magnesium sulfate	Provides magnesium for various chemical reactions within the body	*Dosage:* 8 mEq Monitor blood pressure and serum electrolyte levels.
potassium phosphate	Provides needed potassium for nerve functioning and muscle contraction	*Dosage:* 9 mMol Monitor blood pressure, cardiac rhythm, muscle function, and serum electrolyte levels.
multivitamins	Provides a combination of essential vitamins to maintain cell integrity and promote healing	*Dosage:* 10 mL Monitor for signs of vitamin deficiency or toxicity.
trace elements: zinc, 3 mg copper, 1.2 mg manganese, 0.3 mg chromium, 12 mcg selenium, 20 mcg	Provides small amounts of elements essential for various chemical reactions in the body and maintenance of cell integrity and healing	Periodically monitor blood chemistry findings to determine adequacy of replacement.

*Multiple combination preparations are available commercially. Each preparation varies in the concentration of one or more components and should be checked carefully before administering.

APPENDIX E

Immunizations and Recommended Schedules

IMMUNIZATIONS

People develop immunity to disease either naturally or by receiving biologic drugs, such as vaccines. These formulations provide preformed antibodies to specific antigens, which provide passive immunity, or they stimulate the body to produce antibodies to an injected antigen, which then provide active immunity. Passive immunity does not provide long-term protection and must be repeated as needed. Active immunity provides long-term protection against various antigens.

Administration of a biologic product requires an understanding of core drug knowledge related to these preparations. For example, most biologic drugs should not be used during pregnancy or given when the patient has an acute infection. Specific formulations may be associated with allergies to other drugs and should not be used if the patient has these allergies. In addition, biologic drugs should be used with caution in instances of immunosuppression and chronic illness, after blood transfusions, and in combination with other biologic drugs. Adverse effects associated with these drugs include pain and swelling at the injection site, fever, flulike symptoms, lethargy, and fatigue.

Before administering any biologic formulation, review core patient variables—for example, the patient's health and medical history—for any condition that contraindicates using the vaccine, for any condition suggesting the need for extra caution, and for a history of systemic allergic or neurologic reactions to a previous injection of the vaccine. Perform a physical assessment that includes temperature, respiratory status, pulse rate, and blood pressure. Administer the biologic drug by the recommended route, using sterile technique, into the site recommended by the manufacturer. Give the patient or caregivers information on comfort measures (analgesics and antipyretics, warm compresses to the injection site), a written record of the drug/vaccine administered, and the dates on which to return for repeated immunizations.

Product (Trade) Name	Action and Purpose	Nursing Management
anthrax vaccine	Protects against the cytotoxic lethal and edema toxins of *Bacillus anthracis*	Administer subcutaneously. Shake thoroughly before use. Use different subcutaneous sites for each sequential injection. Do not administer to any patient who recovered from a previous clinical exposure to anthrax. Pregnancy category C
cytomegalovirus immune globulin (CytoGam)	Attenuation of CMV associated with organ transplantation	Administer intravenously within 72 h of transplantation and then on weeks 2, 4, 6, 8, 12, and 16 post-transplantation. Use in-line filter and infusion pump. Aseptic meningitis rarely occurs; monitor level of consciousness. Pregnancy category C
diphtheria and tetanus toxoids, combined, adsorbed (DT, Td, Decavac)	Active immunity against diphtheria and tetanus	Administer intramuscularly. Do not administer to patients <7 y of age. Do not give to treat acute tetanus or diphtheria or during acute infection. Pregnancy category unknown
diphtheria and tetanus toxoids and acellular pertussis vaccine, adsorbed—DTaP (Daptacel, Infanrix, Tripedia)	Active immunity against diphtheria, tetanus, and pertussis	Administer intramuscularly. Do not administer to patients >7 y of age. Use with caution if patient has history of adverse reaction to early injections.

(continude)

Product (Trade) Name	Action and Purpose	Nursing Management
diphtheria and tetanus toxoids and acellular pertussis vaccine (Boostrix)	Booster vaccine for adolescents 10–18 y of age	See above.
diphtheria and tetanus toxoids and acellular pertussis vaccine (Adacel)	Booster vaccine for adolescents and adults 11–64 y of age	See above.
diphtheria toxoid/tetanus toxoid/acellular pertussis/ *Haemophilus influenzae* type B conjugate vaccines (DTaP-HIB, TriHIBit)	Active immunity against diphtheria, tetanus, pertussis, and invasive diseases caused by *Haemophilus influenzae* type b	Administer intramuscularly. Do not administer to patients >7 y of age. Use with caution if patient has history of adverse reaction to early injections.
diphtheria toxoid/tetanus toxoid/acellular pertussis adsorbed/hepatitis B (recombinant)/inactivated poliovirus vaccine (Pediarix)	Active immunity against diphtheria, tetanus, pertussis, hepatitis B, and polio	Administer intramuscularly. Do not administer to any infant before the age of 6 wk or to persons 7 y of age and older.
haemophilus B conjugate vaccine (ActHIB, HibTITER, PedvaxHIB)	Prophylaxis against invasive *Haemophilus* B infection	Administer intramuscularly. Do not administer to any infant before the age of 6 wk or to persons 5 y of age and older.
H. influenzae B conjugated vaccine hepatitis B surface antigen (Comax)	Stimulates active immunity to *Haemophilus* B and hepatitis B	Administer intramuscularly. Administer only to children of HBsAg-negative mothers. Do not give to adults or to children with febrile illnesses.
hepatitis A vaccine (Havrix, Havrix Pediatric, Vaqta, Vaqta Pediatric)	Prophylaxis against hepatitis A	Administer intramuscularly. Do not administer to treat active infection. Pregnancy category C
hepatitis A/hepatitis B (Twinrix)	Prophylaxis against both hepatitis A and hepatitis B	Administer intramuscularly. Do not administer to treat active infection. Defer immunization for current febrile illness. Not approved for children under the age of 18 y. Pregnancy category C
hepatitis B vaccine (Energix-B, Energix-B pediatric, Recombivax-HB, Recombivax HB Pediatric/Adolescent)	Active immunity to infection caused by all subtypes of hepatitis B	Administer intramuscularly. Do not administer to treat active infection. Defer immunization during any active infection. Pregnancy category C
hepatitis B immune globulin (BayHep B, HyperHep B, Nabi-HB, Nabi-HB Nova Plus, Hepa Gam B)	Provides passive immunity for hepatitis B	Administer intravenously or intramuscularly. Potential drug-drug interaction with • Measles virus vaccine • Mumps virus vaccine • Rotavirus vaccine • Rubella virus vaccine • Smallpox vaccine • Varicella virus vaccine Pregnancy category C
human papillomavirus recombinant vaccine quadrivalent (types 6, 11, 16, 18) (Gardasil)	Prophylaxis against adenocarcinoma in situ of cervix; cervical cancer; cervical intraepithelial neoplasia, grades 1, 2, 3; genital warts; vaginal intraepithelial neoplasia, grades 2 and 3; vulval intraepithelial neoplasia (VIN), grades 2 and 3	Administer intramuscularly. Do not administer for treatment of active disease. Pregnancy category B

continude

Product (Trade) Name	Action and Purpose	Nursing Management
influenza vaccine (Fluarix)	nactivated virus vaccine for prevention of influenza in adults	Administer intramuscularly. Contraindicated for patients with known systemic hypersensitivity reactions to • eggs • egg products • egg or chicken proteins Defer vaccination for patients with an active neurologic disorder. Pregnancy category C
influenza virus vaccine (Fluogen, Fluzone, Flu-Shield)	Stimulates active immunity to influenza virus antigens in people at high risk for developing complications from influenza	Administer intramuscularly. Do not give to patients with allergy to • chicken eggs • feathers • chicken dander. Do not administer with other vaccines or to patients with acute respiratory infections. Monitor for toxicity if combined with theophylline or warfarin.
influenza virus vaccine (FluLaval)	Vaccine for the prevention of influenza in adults 18 y and older	See above.
intranasal influenza vaccine (FluMist)	Stimulates the production of antibodies to prevent influenza types A and B.	Administer in October or November each year. Be sure you are using the current year's vaccine. Use for patients between 5 and 49 y of age. Do not administer to patients with immune disorders, because the vaccine contains live, attenuated influenza viruses that may cause serious infections in immuno compromised patients. Do not administer to patients with underlying chronic disorders such as diabetes mellitus, renal failure, or sickle cell disease, because these conditions predispose the patient to serious infections. Do not administer to patients with reactive airway diseases such as chronic obstructive pulmonary disease (COPD) or asthma, because bronchospasm may occur. Do not administer to children and adolescents (5–17 y of age) receiving aspirin or aspirin-containing therapy, because it may cause Reye syndrome with aspirin and wild-type influenza infection. Pregnancy category C
nfluenza vaccine H5N1	Vaccine against the H5N1 influenza virus (Avian flu or Bird flu)	Approved for use in the event the current H5N1 avian virus develops the capability to become pandemic
measles (rubeola) virus vaccine (Attenuvax)	Stimulates active immunity in those never infected with measles	Administer subcutaneously. Contraindicated for patients with • acute infection or febrile illness • allergy to neomycin • blood dyscrasias • malignant neoplasms • immunodeficiency Caution women of childbearing age to defer pregnancy for 3 mo after vaccination. Use caution in patients allergic to chicken products. Do not administer within 1 mo of any live virus vaccine, except women who have received postpartum Rho(D) immune globulin and are susceptible to rubella.

continude

Product (Trade) Name	Action and Purpose	Nursing Management
		Refrigerate vaccine and protect it from light. Extensive drug-drug interaction potential Pregnancy category C
measles, mumps, rubella vaccine, live (MMR-II)	Stimulates active immunity to measles, mumps, and rubella in children older than 15 mo	Administer subcutaneously. Contraindicated for patients with • acute infection or febrile illness • allergy to neomycin • blood dyscrasias • chronic high-dose corticosteroid use • current therapy with alkylating agents or antimetabolites • malignant neoplasms • immunodeficiency • radiation therapy • untreated TB Do not give during pregnancy, and caution women of childbearing age to defer pregnancy for 3 mo after vaccination. Give cautiously to patient with allergy to eggs. Do not give within 1 mo of other live vaccines or 3 mo of blood transfusion, except women who have received postpartum Rho(D) immune globulin and are susceptible to rubella. Refrigerate and protect vaccine from light. Extensive drug-drug interaction potential Pregnancy category C
measles, mumps, rubella, varicella vaccine (ProQuad)	A combination live virus vaccine to prevent measles, mumps, rubella, and chickenpox	See above.
meningococcal polysaccharide vaccine (Menomune-A/C/Y/W-135)	Prophylaxis for meningococcal infectious disease	Administer subcutaneously. Contraindicated for patients with • hypersensitivity to thiomersal • any acute illness Do not give concurrently with whole-cell pertussis or whole-cell typhoid vaccines. Pregnancy category C
meningococcal vaccine (Menactra)	Immunization for adolescents and adults (11–55 y of age) against *Neisseria meningitidis* serogroups A, C, Y, and W-135	See above. Five documented cases of Guillain-Barré syndrome (GBS) after vaccination.
mumps virus vaccine, live (Mumpsvax)	Stimulates active immunity to mumps virus in patients older than 12 y	Administer subcutaneously. Contraindicated for patients with • acute infection or febrile illness • allergy to neomycin or gelatin • blood dyscrasias • immunosuppressive therapy • pregnancy • untreated TB Do not give during pregnancy, and caution women of childbearing age to defer pregnancy for 3 mo after vaccination. Do not give within 1 mo of other live vaccines. Give cautiously to patients with a sensitivity to eggs. Refrigerate vaccine and protect it from light. Extensive drug-drug interaction potential Pregnancy category C

continude

Product (Trade) Name	Action and Purpose	Nursing Management
palivizumab (Synagis)	Monoclonal antibody that interferes with the ability of respiratory syncytial virus (RSV) to replicate in and infect cells; prevents RSV infection in high-risk pediatric patients	Administer 15 mg/kg IM once monthly during RSV season (November through April) to high-risk children <24 mo of age. Do not administer to patients with known murine protein hypersensitivity or to patients with anaphylactic reactions to murine proteins. Monitor closely for allergic reactions. Have epinephrine available.
pneumococcal vaccine (Pneumovax 23, Pnu-Imune 23)	Prophylaxis for pneumococcal infection	Administer intramuscularly. Avoid accidental intradermal administration, because it may cause a severe local reaction. Give cautiously to patients with severe cardiopulmonary disorders because a systemic reaction is potentially harmful. Defer vaccination in patients with moderate to severe acute illness. Pregnancy category C
poliovirus vaccine, live, oral, trivalent—OPV, TOPV, Sabin (Orimune)	Stimulates active immunity to prevent poliomyelitis caused by poliovirus types 1, 2, and 3	Administer orally. Do not administer to patients sensitive to streptomycin, neomycin, or polymyxin B. Do not administer to any patient who experienced anaphylaxis within 24 h of a previous dose. Defer vaccination in patients with acute febrile illness. Refrigerate or freeze vaccine; thaw before use. Caution unimmunized adults about risk of exposure to children receiving TOPV. Extensive drug-drug interaction potential Pregnancy category C
poliovirus vaccine inactivated—IPV, Salk (Ipol)	Stimulates active immunity; given to patients unwilling or unable to take oral vaccine	Administer subcutaneously. See other management measures for live vaccine above.
rabies vaccine (HDCV, Imovax Rabies)	Pre-exposure rabies immunization for patients at high risk Postexposure antirabies regimen given with rabies immunoglobulin	*Preexposure:* Administer 1 mL IM on days 0, 7, 21, and 28. *Postexposure:* Give 1 mL IM on days 0, 3, 7, 21, and 28. Refrigerate vaccine. If titer values are low, booster may be needed. Pregnancy category C
respiratory syncytial virus immune globulin (RS-VIG, RespiGam)	A polyclonal human hyperimmune globulin that relies on passive transfer of antibodies from healthy adults with especially high levels of antibodies directed against RSV.	Administer 750 mg/kg IV once monthly during RSV season (November through April) to high-risk children <24 mo of age. Monitor for allergic reaction, symptoms of aseptic meningitis, and fluid overload. Monitor for infusion-related symptoms such as dizziness, flushing, changes in blood pressure, anxiety, palpitations, chest tightness, dyspnea, abdominal pain, pruritus, myalgia, or arthralgia. Slow the infusion rate should any occur.
rotavirus vaccine, live (RotaTeq)	Prophylaxis for gastroenteritis due to rotavirus	Administer orally. Give cautiously to patients with • acute febrile illness • history of gastrointestinal disorders • immunocompromised infants • infants with blood or plasma transfusion within 42 d Extensive drug-drug interaction potential Pregnancy category: Fetal risk cannot be ruled out.

Product (Trade) Name	Action and Purpose	Nursing Management
rubella virus vaccine, live (Meruvax II)	Stimulates active immunity against the rubella virus	Administer subcutaneously. Contraindicated for patients with • acute infection or febrile illness • allergy to neomycin or gelatin • blood dyscrasias • chronic high-dose corticosteroid use • immunodeficiency, especially HIV antibody positive • immunosuppressive therapy • untreated TB Do not give during pregnancy, and caution women of childbearing age to defer pregnancy for 3 mo after vaccination. Give cautiously to patient with allergy to eggs. Do not give within 1 mo of other live vaccines or 3 mo of blood transfusion, except women who have received postpartum Rho(D) immune globulin and are susceptible to rubella. Refrigerate and protect vaccine from light. Extensive drug–drug interaction potential Pregnancy category C
tetanus toxoid (TE Anatoxal Berna)	Active immunity against tetanus	Administer intramuscularly. Do not administer to patients < 7 y of age. Do not give to treat acute tetanus. Defer vaccination during acute infection. Pregnancy category C
vaccinia immune globulin	Treat complications of smallpox vaccination	Administer intravenously. Contraindicated for patients with • isolated vaccinia keratitis • history of severe reaction to other immunoglobulins • IgA deficiency Give cautiously in these circumstances: • patients predisposed for acute renal failure • patients with any degree of pre-existing renal insufficiency • diabetes mellitus • volume depletion • sepsis • paraproteinemia • patients who are at least 65 y of age, or • patients who are receiving known nephrotoxic drugs. Monitor vital signs continuously during administration. Delay administration of live virus vaccines such as polio, measles, mumps, and rubella for at least 6 mo. Pregnancy category C
varicella virus vaccine, live (Varivax, Zostavax)	Stimulates active immunity against the chickenpox virus	Administer subcutaneously. Contraindicated for patients with • anaphylactic reaction to neomycin or gelatin • current therapy with alkylating agents, antimetabolites, or high-dose corticosteroids • blood dyscrasias • immunodeficiency, especially HIV antibody positive • immunosuppressive therapy • malignancy • pregnancy • radiation therapy • untreated TB

Product (Trade) Name	Action and Purpose	Nursing Management
		Give cautiously to patients with febrile illness, recent transfusions (within 5 mo), or recent administration of immune globulins. Do not give salicylates for up to 6 wk after vaccine. Extensive drug-drug interaction potential Pregnancy category C Zostavax is for adults only; the subcutaneous injection *must* be administered within 30 min of its removal from the refrigerator.
yellow fever vaccine (YF-Vax)	Immunity for travelers to areas where yellow fever is endemic	Administer subcutaneously. Contraindicated for patients with • hypersensitivity to eggs or chicken protein • immunosuppression • children <6 mo of age Extensive drug–drug interaction potential Pregnancy category C

IMMUNIZATION SCHEDULES FOR THE UNITED STATES AND CANADA

The recommended schedules for administering immunizations to infants, children, and adolescents in the United States and Canada are as follows:

DEPARTMENT OF HEALTH AND HUMAN SERVICES • CENTERS FOR DISEASE CONTROL AND PREVENTION

Recommended Immunization Schedule for Persons Aged 0–6 Years—UNITED STATES • 2007

Vaccine ▼ / Age ▶	Birth	1 month	2 months	4 months	6 months	12 months	15 months	18 months	19–23 months	2–3 years	4–6 years
Hepatitis B[1]	HepB	HepB		see footnote 1	HepB				HepB Series		
Rotavirus[2]			Rota	Rota	Rota						
Diphtheria, Tetanus, Pertussis[3]			DTaP	DTaP	DTaP		DTaP				DTaP
Haemophilus influenzae type b[4]			Hib	Hib	*Hib*[4]	Hib		Hib			
Pneumococcal[5]			PCV	PCV	PCV	PCV				PCV	PPV
Inactivated Poliovirus			IPV	IPV	IPV						IPV
Influenza[6]					Influenza (Yearly)						
Measles, Mumps, Rubella[7]						MMR					MMR
Varicella[8]						Varicella					Varicella
Hepatitis A[9]						HepA (2 doses)				HepA Series	
Meningococcal[10]										MPSV4	

Range of recommended ages

Catch-up immunization

Certain high-risk groups

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2006, for children aged 0–6 years. Additional information is available at http://www.cdc.gov/nip/recs/child-schedule.htm. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at **http://www.vaers**, **hhs.gov** or by telephone, **800-822-7967**.

1. Hepatitis B vaccine (HepB). *(Minimum age: birth)*

At birth:

- Administer monovalent HepB to all newborns before hospital discharge.
- If mother is hepatitis surface antigen (HBsAg)-positive, administer HepB and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth.
- If mother's HBsAg status is unknown, administer HepB within 12 hours of birth. Determine the HBsAg status as soon as possible and if HBsAg-positive, administer HBIG (no later than age 1 week).
- If mother is HBsAg-negative, the birth dose can only be delayed with physician's order and mother's negative HBsAg laboratory report documented in the infant's medical record.

After the birth dose:

- The HepB series should be completed with either monovalent HepB or a combination vaccine containing HepB. The second dose should be administered at age 1–2 months. The final dose should be administered at age ≥24 weeks. Infants born to HBsAg-positive mothers should be tested for HBsAg and antibody to HBsAg after completion of ≥3 doses of a licensed HepB series, at age 9–18 months (generally at the next well-child visit).

4-month dose:

- It is permissible to administer 4 doses of HepB when combination vaccines are administered after the birth dose. If monovalent HepB is used for doses after the birth dose, a dose at age 4 months is not needed.

2. Rotavirus vaccine (Rota). *(Minimum age: 6 weeks)*

- Administer the first dose at age 6–12 weeks. Do not start the series later than age 12 weeks.
- Administer the final dose in the series by age 32 weeks. Do not administer a dose later than age 32 weeks.
- Data on safety and efficacy outside of these age ranges are insufficient.

3. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP). *(Minimum age: 6 weeks)*

- The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose.
- Administer the final dose in the series at age 4–6 years.

4. *Haemophilus influenzae* type b conjugate vaccine (Hib). *(Minimum age: 6 weeks)*

- If PRP-OMP (PedvaxHIB® or ComVax® [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required.
- TriHiBit® (DTaP/Hib) combination products should not be used for primary immunization but can be used as boosters following any Hib vaccine in children aged ≥12 months.

5. Pneumococcal vaccine. *(Minimum age: 6 weeks for pneumococcal conjugate vaccine [PCV]; 2 years for pneumococcal polysaccharide vaccine [PPV])*

- Administer PCV at ages 24–59 months in certain high-risk groups. Administer PPV to children aged ≥2 years in certain high-risk groups. See *MMWR* 2000;49(No. RR-9):1–35.

6. Influenza vaccine. *(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 5 years for live, attenuated influenza vaccine [LAIV])*

- All children aged 6–59 months and close contacts of all children aged 0–59 months are recommended to receive influenza vaccine.
- Influenza vaccine is recommended annually for children aged ≥59 months with certain risk factors, health-care workers, and other persons (including household members) in close contact with persons in groups at high risk. See *MMWR* 2006;55(No. RR-10):1–41.
- For healthy persons aged 5–49 years, LAIV may be used as an alternative to TIV.
- Children receiving TIV should receive 0.25 mL if aged 6–35 months or 0.5 mL if aged ≥3 years.
- Children aged <9 years who are receiving influenza vaccine for the first time should receive 2 doses (separated by ≥4 weeks for TIV and ≥6 weeks for LAIV).

7. Measles, mumps, and rubella vaccine (MMR). *(Minimum age: 12 months)*

- Administer the second dose of MMR at age 4–6 years. MMR may be administered before age 4–6 years, provided ≥4 weeks have elapsed since the first dose and both doses are administered at age ≥12 months.

8. Varicella vaccine. *(Minimum age: 12 months)*

- Administer the second dose of varicella vaccine at age 4–6 years. Varicella vaccine may be administered before age 4–6 years, provided that ≥3 months have elapsed since the first dose and both doses are administered at age ≥12 months. If second dose was administered ≥28 days following the first dose, the second dose does not need to be repeated.

9. Hepatitis A vaccine (HepA). *(Minimum age: 12 months)*

- HepA is recommended for all children aged 1 year (i.e., aged 12–23 months). The 2 doses in the series should be administered at least 6 months apart.
- Children not fully vaccinated by age 2 years can be vaccinated at subsequent visits.
- HepA is recommended for certain other groups of children, including in areas where vaccination programs target older children. See *MMWR* 2006;55(No. RR-7):1–23.

10. Meningococcal polysaccharide vaccine (MPSV4). *(Minimum age: 2 years)*

- Administer MPSV4 to children aged 2–10 years with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7):1–21.

The Recommended Immunization Schedules for Persons Aged 0–18 Years are approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/nip/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2006, for children aged 7–18 years. Additional information is available at http://www.cdc.gov/nip/recs/child-schedule.htm. Any dose not administered at the recommended age should be administered at any subsequent visit, when indicated and feasible. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and other components of the vaccine are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the respective Advisory Committee on Immunization Practices statement for detailed recommendations. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

1. Tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap).
(Minimum age: 10 years for BOOSTRIX® and 11 years for ADACEL™)
- Administer at age 11–12 years for those who have completed the recommended childhood DTP/DTaP vaccination series and have not received a tetanus and diphtheria toxoids vaccine (Td) booster dose.
- Adolescents aged 13–18 years who missed the 11–12 year Td/Tdap booster dose should also receive a single dose of Tdap if they have completed the recommended childhood DTP/DTaP vaccination series.

2. Human papillomavirus vaccine (HPV). *(Minimum age: 9 years)*
- Administer the first dose of the HPV vaccine series to females at age 11–12 years.
- Administer the second dose 2 months after the first dose and the third dose 6 months after the first dose.
- Administer the HPV vaccine series to females at age 13–18 years if not previously vaccinated.

3. Meningococcal vaccine. *(Minimum age: 11 years for meningococcal conjugate vaccine [MCV4]; 2 years for meningococcal polysaccharide vaccine [MPSV4])*
- Administer MCV4 at age 11–12 years and to previously unvaccinated adolescents at high school entry (at approximately age 15 years).
- Administer MCV4 to previously unvaccinated college freshmen living in dormitories; MPSV4 is an acceptable alternative.
- Vaccination against invasive meningococcal disease is recommended for children and adolescents aged ≥2 years with terminal complement deficiencies or anatomic or functional asplenia and certain other high-risk groups. See *MMWR* 2005;54(No. RR-7):1–21. Use MPSV4 for children aged 2–10 years and MCV4 or MPSV4 for older children.

4. Pneumococcal polysaccharide vaccine (PPV). *(Minimum age: 2 years)*
- Administer for certain high-risk groups. See *MMWR* 1997;46(No. RR-8):1–24, and *MMWR* 2000;49(No. RR-9):1–35.

5. Influenza vaccine. *(Minimum age: 6 months for trivalent inactivated influenza vaccine [TIV]; 5 years for live, attenuated influenza vaccine [LAIV])*
- Influenza vaccine is recommended annually for persons with certain risk factors, health-care workers, and other persons (including household members) in close contact with persons in groups at high risk. See *MMWR* 2006;55 (No. RR-10):1–41.
- For healthy persons aged 5–49 years, LAIV may be used as an alternative to TIV.
- Children aged <9 years who are receiving influenza vaccine for the first time should receive 2 doses (separated by ≥4 weeks for TIV and ≥6 weeks for LAIV).

6. Hepatitis A vaccine (HepA). *(Minimum age: 12 months)*
- The 2 doses in the series should be administered at least 6 months apart.
- HepA is recommended for certain other groups of children, including in areas where vaccination programs target older children. See *MMWR* 2006;55 (No. RR-7):1–23.

7. Hepatitis B vaccine (HepB). *(Minimum age: birth)*
- Administer the 3-dose series to those who were not previously vaccinated.
- A 2-dose series of Recombivax HB® is licensed for children aged 11–15 years.

8. Inactivated poliovirus vaccine (IPV). *(Minimum age: 6 weeks)*
- For children who received an all-IPV or all-oral poliovirus (OPV) series, a fourth dose is not necessary if the third dose was administered at age ≥4 years.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.

9. Measles, mumps, and rubella vaccine (MMR). *(Minimum age: 12 months)*
- If not previously vaccinated, administer 2 doses of MMR during any visit, with ≥4 weeks between the doses.

10. Varicella vaccine. *(Minimum age: 12 months)*
- Administer 2 doses of varicella vaccine to persons without evidence of immunity.
- Administer 2 doses of varicella vaccine to persons aged <13 years at least 3 months apart. Do not repeat the second dose, if administered ≥28 days after the first dose.
- Administer 2 doses of varicella vaccine to persons aged ≥13 years at least 4 weeks apart.

The Recommended Immunization Schedules for Persons Aged 0–18 Years are approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/nip/acip), the American Academy of Pediatrics (http://www.aap.org), and the American Academy of Family Physicians (http://www.aafp.org).

Drug-Induced Photosensitivity

Lead author: Kelly M. Shields, Pharm.D.

Drugs Reported to Cause Photosensitivity Reactions [1-11]

Therapeutic Class	Drugs	Comments
Antihistamines	cetirizine (*Zyrtec*), cyproheptadine (*Periactin*), diphenhydramine (*Benadryl*), loratadine (*Claritin*), promethazine (*Phenergan*)	Reactions have been seen both with topical and systemic administration of antihistamines.
Anti-infectives	Fluoroquinolones: ciprofloxacin (*Cipro*), gemifloxacin (*Factive*), levofloxacin (*Levaquin*), lomefloxacin (*Maxaquin*), moxifloxacin (*Avelox*), norfloxacin (*Noroxin*), ofloxacin (*Floxin*) Tetracyclines: demeclocycline (*Declomycin*), doxycycline (*Vibramycin*), minocycline (*Minocin*), oxytetracycline (*Terramycin*), tetracycline (*Achromycin*) Others: azithromycin (*Zithromax*), capreomycin (*Capastat*), ceftazidime (*Fortaz*), cefazolin (*Ancef*), cycloserine (*Seromycin*), dapsone, ethionamide (*Trecator-SC*), isoniazid (*Nydrazid*), metronidazole (*Flagyl*), nalidixic acid (*NegGram*), pyrazinamide, sulfamethoxazole/trimethoprim (*Bactrim*), sulfasalazine (*Azulfidine*), sulfisoxazole (*Gantrisin*)	Lomefloxacin has higher incidence than other quinolones, no reports with gatifloxacin. Tetracyclines- reactions seen most often with demeclocycline. Cefazolin reaction was noted in one case report with concurrent gentamicin use.
Antifungals	flucytosine (*Ancobon*), griseofulvin (*Fulvicin, Gris-PEG*), terconazole (*Terazol*) voriconazole (*VFEND*)	
Antiretroviral	ritonavir (*Norvir*), saquinavir (*Fortovase, Invirase*), zalcitabine (*Hivid*)	Reactions seen in less than 2% of patients.
Antimalarial	chloroquine (*Aralen*), hydroxychloroquine (*Plaquenil*), pyrimethamine (*Daraprim*), pyrimethamine/sulfadoxine (*Fansidar*), quinine	Limited reports of reactions exist.
Antivirals	amantadine (*Symmetrel),* acyclovir (*Zovirax*)	About 1% incidence.
Antineoplastics	bexarotene (*Targretin*), capecitabine (*Xeloda*), dacarbazine (*DTIC*), epirubicin (*Ellence*), fluorouracil (*5-FU*), interferon alfa (*Intron A, Alferon-N*), methotrexate (*Mexate*), pentostatin (*Nipent*), procarbazine (*Matulane*), tretinoin, oral (*Vesanoid*), vinblastine (*Velban, Velbe*)	Incidence varies from 1% to 5% by agent.
Antiplatelet	clopidogrel (*Plavix*)	Only one case report.

Therapeutic Class	Drugs	Comments
Cardiovascular	Thiazide diuretics: bendroflumethiazide (*Corzide*), chlorthalidone (*Thalitone*), hydrochlorothiazide (*Microzide*), hydroflumethiazide (*Diucardin*), indapamide (*Lozol*), methyclothiazide (*Enduron*), metolazone (*Zaroxolyn*), polythiazide (*Renese*) Diuretics, Other: furosemide (*Lasix*), triamterene (*Dyrenium*) Antihypertensives: captopril (*Capoten*), diltiazem (*Cardizem, Tiazac*), enalapril (*Vasotec*), nifedipine (*Procardia*), sotalol (*Betapace*) Statins: fluvastatin (*Lescol*), lovastatin (*Mevacor*), pravastatin (*Pravachol*), simvastatin (*Zocor*) Other: amiodarone (*Cordarone, Pacerone*), fenofibrate (*Tricor*), quinidine	Any combination product with hydrochlorothiazide has a risk of photosensitivity. Incidence of photosensitivity with amiodarone is about 10%.
Anticonvulsants	carbamazepine (*Tegretol*), felbamate (*Felbatol*), gabapentin (*Neurontin*), lamotrigine (*Lamictal*), oxcarbazepine (*Trileptal*), topiramate (*Topamax*), valproic acid (*Depakene*)	Incidence is generally low ranging from 0.1% to 1%.
Antipsychotics	Antipsychotics,Phenothiazines: chlorpromazine (*Thorazine*), fluphenazine (*Prolixin*), perphenazine (*Trilafon*), prochlorperazine (*Compazine*), thioridazine (*Mellaril*), trifluoperazine (*Stelazine*) Antipsychotics, Other: clozapine (*Clozaril*), haloperidol (*Haldol*), loxapine (*Loxitane*), olanzapine (*Zyprexa*), quetiapine (*Seroquel*), risperidone (*Risperdal*), thiothixene (*Navane*), ziprasidone (*Geodon*)	Phenothiazines-reactions most common with chlorpromazine (incidence of 2% to 3%).
Antidepressants	Tricyclic Antidepressants: amitriptyline (*Elavil*), amoxapine (*Asendin*), clomipramine (*Anafranil*), desipramine (*Norpramin*), doxepin (*Sinequan*), imipramine (*Tofranil*), maprotiline (*Ludiomil*), nortriptyline (*Pamelor*), protriptyline (*Vivactil*), trimipramine (*Surmontil*) Selective serotonin reuptake inhibitors: citalopram (*Celexa*), escitalopram (*Lexapro*), fluoxetine (*Prozac*, *Sarafem*), fluvoxamine (*Luvox*), paroxetine (*Paxil*), sertraline (*Zoloft*) Antidepressant, Other: bupropion (*Wellbutrin*), mirtazapine (*Remeron*), nefazodone (*Serzone*), trazodone (*Desyrel*), venlafaxine (*Effexor*)	In the case of most of these drugs, incidence of photosensitivity has not been definitely attributed to the antidepressant. No reports noted with escitalopram, but included because structurally related to citalopram.
Sedative/Hypnotics	alprazolam (*Xanax*), chlordiazepoxide (*Librium*), zaleplon (*Sonata*), zolpidem (*Ambien*)	Incidence ranges from 0.1% to 1%.

Therapeutic Class	Drugs	Comments
Analgesic Agents	NSAIDs: celecoxib (*Celebrex*), diclofenac (*Voltaren, Cataflam*), diflunisal(*Dolobid*), etodolac (*Lodine*), ibuprofen (*Motrin*), ketoprofen (*Orudis*), mefenamic acid (*Ponstel*), meloxicam (*Mobic*), nabumetone (*Relafen*), naproxen (*Anaprox*), oxaprozin (*Daypro*), piroxicam (*Feldene*), rofecoxib (*Vioxx*), sulindac (*Clinoril*), valdecoxib (*Bextra*) Other: cyclobenzaprine (*Flexeril*), dantrolene (*Dantrium*), sumatriptan (*Imitrex*)	
Hormones	Oral contraceptives, corticosteroids	
Antidiabetic Agents	Sulfonylureas: acetohexamide (*Dymelor*), chlorpropamide (*Diabinese*), glimepiride (*Amaryl*), glipizide (*Glucotrol*), glyburide (*DiaBeta, Micronase*), tolazamide(*Tolinase*), tolbutamide (*Orinase*)	
Skin Agents	benzocaine (*Americaine*), coal tar, hexachlorophene (*PHisoHex*), isotretinoin (*Accutane*), methoxsalen (*Uvadex, Oxsoralen*), minoxidil (*Rogaine*), tacrolimus (*Prograf, Protopic*), tazarotene (*Tazorac*), tretinoin, topical (*Renova, Retin-A*) Sunscreen agents: PABA, cinnamates, benzyphenones	Isotretinoin incidence is 5% to 10%.
Miscellaneous	chlorhexidine (*Peridex, Hibiclens*), gold salts, selegiline (*Eldepryl*), thalidomide (*Thalomid*)	
Vitamins	pyridoxine (Vitamin B6), Vitamin A	Based on case reports.
Dietary Supplements	bitter orange, chlorella, dong quai, gossypol, gotu kola, St. John's wort	Limited reporting of adverse reactions with dietary supplements makes this listing incomplete.

Many of the drugs listed in the proceeding table were labeled as photosensitizing based on unclear data. Unclear and incomplete reporting of adverse drug reactions lead to this confusion. Chemicals that are planar, tricyclic, or polycyclic absorb ultraviolet light, which lead them to be classified as photosensitizer drugs.[10]

Types of Photosensitivity

Drug-induced photosensitivity may present in a variety of ways. Most reactions are generally classified as either phototoxic or photoallergic. Photoallergy is a relatively rare, immunological response, which is not dose-related. The allergy develops after multiple days of continuous exposure. It occurs when light causes a drug to act as a hapten, triggering a hypersensitivity response. The reaction usually manifests as pruritic and eczematous.[10-13]

Phototoxic reactions are chemically-induced reactions when the drug absorbs UVA light and causes cellular damage. This reaction can be seen with initial exposure to a drug, may be dose-related, and doesn't demonstrate cross-sensitivity. It usually has rapid onset and manifests as an exaggerated sunburn. This reaction will be seen only on skin areas exposed to the sun.[10-13]

Management of Photosensitivity

Prevention of photosensitivity reactions is based on patient education. Patients should be educated to minimize sun exposure. Use of UVA-protective sunscreens and physical barriers such as clothing can provide additional light protection.

Sunscreens that provide UVA coverage include: avobenzone, dioxybenzone, oxybenzone, titanium dioxide, zinc oxide. Remind patients of the need to frequently reapply while in the sun. Patients should definitely be counseled to avoid sources of high-intensity light such as tanning beds. Additionally, as some reactions may be dose-related, a decrease in dose may be considered to help minimize the reaction or possibly selection of an alternative agent.

An acute attack may be managed in a number of different ways based on severity. A mild reaction may be handled similarly to a sunburn, with skin protectants and topical or systemic analgesics.[12] Patients may also benefit from application of cooling creams or gels. If patients have blisters that are broken, antibacterial creams may be necessary to prevent infection.[10] Severe reactions may be handled by oral or topic corticosteroids.[13] Antihistamines may also alleviate pruritus associated with reactions.

APPENDIX G

Drugs Affected by Grapefruit Juice

Grapefruit juice inhibits the CYP450 3A4 system in the liver, which can cause a decrease in the metabolism of many drugs. Decreasing the metabolism of the drug can lead to increased serum drug levels and toxicity. If any of these drugs is being given, the patient should avoid the use of grapefruit juice. If the combination cannot be avoided, space the drug as far away from the grapefruit juice as possible during the day and monitor the patient closely for signs of drug toxicity. If a patient has been stabilized on one of these drugs and suddenly begins to develop signs of drug toxicity, ask the patient specifically if he has been drinking grapefruit juice. If a patient is receiving one of these drugs, a key point of patient education should be to avoid the use of grapefruit juice.

17 beta-estradiol
albendazole
alfentanil
alprazolam
amiodarone
amprenavir
atorvastatin
budesonide
buspirone
carbamazepine
clarithromycin

Cytochrome P450 Drug Interactions

Detail-Document #220233

Cytochrome P450 Drug Interactions

—Last updated April 2006—

The characterization of drug interactions by metabolic pathways is complex. Just because a medication interacts with one substrate of a particular cytochrome P450 pathway, does not mean it affects all substrates of that isozyme. Genetics, age, nutrition, stress, liver disease, hormones, and other endogenous chemicals also influence drug metabolism. Additional influences on drug interactions include drug dosing issues (timing of dose, sequence of administration, route of administration and duration of therapy) and specific drug features (narrow therapeutic index, high extraction ratio, multiple metabolic pathways).

In the table that follows italics denote those substrates, inhibitors, and inducers that have been involved in a drug interaction of clinical relevance and/or are associated with strong drug interaction warnings which may require intervention (e.g., dose alteration, monitoring, or avoidance). This table is not comprehensive as new information is constantly being identified.

CYP1A2

--------Substrates--------		--------Inhibitors--------		--Inducers--
acetaminophen	*methadone*	amiodarone	methoxsalen	*carbamazepine*
amitriptyline	mexiletine	atazanavir	mexiletine	charbroiled food
caffeine	mirtazapine	*cimetidine*	*nalidixic acid*	lansoprazole
chlordiazepoxide	naproxen	*ciprofloxacin*	norethindrone	omeprazole
cinacalcet	nortriptyline	citalopram	*norfloxacin*	*phenobarbital*
clomipramine	olanzapine	*clarithromycin*	omeprazole	*phenytoin*
clopidogrel	ondansetron	diltiazem	*oral contraceptives*	*primidone*
clozapine	propafenone	echinacea	paroxetine	*rifampin*
cyclobenzaprine	propranolol	*enoxacin*	tacrine	*ritonavir*
desipramine	*ramelteon*	*erythromycin*	ticlopidine	*smoking*
diazepam	riluzole	ethinyl estradiol	tipranavir	*St. John's wort*
duloxetine	*ropinirole*	*fluvoxamine*	*troleandomycin*	
erlotinib	ropivacaine	*isoniazid*	*zileuton*	
estradiol	*tacrine*	ketoconazole		
flutamide	*theophylline*			
fluvoxamine	*tizanidine*			
haloperidol	verapamil			
imipramine	*(R)-warfarin*			
levobupivacaine	zileuton			

CYP2C9

--------Substrates--------		--------Inhibitors--------		--Inducers--
amitriptyline	montelukast	*amiodarone*	ketoconazole	*aprepitant*
carvedilol	naproxen	atazanavir	leflunomide	*carbamazepine*
celecoxib	nateglinide	*chloramphenicol*	lovastatin	*phenobarbital*
clomipramine	omeprazole	*cimetidine*	*metronidazole*	*phenytoin*
desogestrel	*phenytoin*	clopidogrel	modafinil	*primidone*
diazepam	piroxicam	cotrimoxazole	omeprazole	*rifampin*
diclofenac	*ramelteon*	cranberry	paroxetine	*rifapentine*
dronabinol	rosiglitazone	delavirdine	sertraline	*ritonavir*
fluoxetine	sildenafil	disulfiram	sulfonamides	*St. John's wort*
flurbiprofen	sulfamethoxazole	efavirenz	ticlopidine	
fluvastatin	tamoxifen	fenofibrate	tipranavir	
formoterol	tolbutamide	*fluconazole*	*voriconazole*	
glimepiride	torsemide	fluorouracil	*zafirlukast*	
glipizide	valdecoxib	*fluoxetine*		
glyburide	valsartan	fluvastatin		
ibuprofen	vardenafil	*fluvoxamine*		
imipramine	*voriconazole*	gemfibrozil		
indomethacin	*(S)-warfarin*	ginkgo		
irbesartan	zafirlukast	imatinib		
losartan	zileuton	*isoniazid*		
mefenamic acid		itraconazole		
meloxicam

Detail-Document #220233

CYP3A4

--------Substrates--------			-----Inhibitors-----		--Inducers--
alfentanil	*erythromycin*	oxybutynin	acitretin	*metronidazole*	aminoglutethimide
alfuzosin	escitalopram	*paclitaxel*	*amiodarone*	methylprednisolone	*amprenavir*
almotriptan	esomeprazole	pantoprazole	*amprenavir*	*miconazole*	*aprepitant*
alprazolam	*estrogens, oral contraceptives*	*pimozide*	*aprepitant*	mifepristone	*carbamazepine*
amitriptyline		pioglitazone	*atazanavir*	*nefazodone*	dexamethasone
amiodarone	*eszopiclone*	prednisolone	*cimetidine*	*nelfinavir*	*efavirenz*
amlodipine	*ethinyl estradiol*	prednisone	ciprofloxacin	nicardipine	*ethosuximide*
amprenavir	*ethosuximide*	progesterone/ progestins	*clarithromycin*	*nifedipine*	*garlic supplements*
aprepitant	etonogestrel		*cyclosporine*	norethindrone	glucocorticoids
atazanavir	*etoposide*	quetiapine	danazol	*norfloxacin*	glutethimide
atorvastatin	exemestane	*quinidine*	*delavirdine*	norfluoxetine	griseofulvin
beclomethasone	*felodipine*	quinine	*diltiazem*	oxiconazole	*modafinil*
bepridil	*fentanyl*	rabeprazole	diethyl-dithiocarbamate	pomegranate	nafcillin
bexarotene	fexofenadine	*ramelteon*	*efavirenz*	prednisone	*nevirapine*
bromocriptine	finasteride	*ranolazine*	*erythromycin*	*quinine*	*oxcarbazepine*
budesonide	flutamide	repaglinide	ethinyl estradiol	*ranolazine*	*phenobarbital*
buprenorphine	*fluticasone*	*rifabutin*	*fluconazole*	*ritonavir*	*phenytoin*
buspirone	fluvestrant	rifampin	fluoxetine	*roxithromycin*	*primidone*
busulfan	galantamine	*ritonavir*	*fluvoxamine*	*saquinavir*	*rifabutin*
cannabinoids	haloperidol	salmeterol	gestodene	*sertraline*	*rifampin*
caffeine	hydrocodone	*saquinavir*	*grapefruit*	Synercid	*rifapentine*
carbamazepine	hydrocortisone	*sertraline*	*indinavir*	*telithromycin*	*ritonavir*
cevimeline	ifosfamide	sibutramine	imatinib	*troleandomycin*	*St. John's wort*
chlorpheniramine	imatinib	*sildenafil*	*isoniazid*	*verapamil*	
cilostazol	imipramine	*simvastatin*	*itraconazole*	*voriconazole*	
cinacalcet	*indinavir*	*sirolimus*	*ketoconazole*	*zafirlukast*	
cisapride	*isradipine*	*solifenacin*		*zileuton*	
citalopram	*itraconazole*	sorafenib			
clarithromycin	*ketoconazole*	*sunitinib*			
clindamycin	lansoprazole	*tacrolimus*			
clomipramine	letrozole	*tadalafil*			
clonazepam	levobupivacaine	*tamoxifen*			
clopidogrel	*lidocaine*	*telithromycin*			
clozapine	lopinavir	temazepam			
cocaine	loratadine	testosterone			
colchicine	losartan	*tiagabine*			
cyclobenzaprine	*lovastatin*	tinidazole			
cyclophosphamide	*methadone*	*tipranavir*			
cyclosporine	methylprednisolone	*tolterodine*			
dapsone	miconazole	toremifene			
darifenacin	*midazolam*	tramadol			
delavirdine	mifepristone	*trazodone*			
desogestrel	mirtazapine	*triazolam*			
dexamethasone	modafinil	trimetrexate			
dextromethorphan	mometasone	valdecoxib			
diazepam	montelukast	*vardenafil*			
dihydroergotamine	nateglinide	*verapamil*			
diltiazem	*nefazodone*	*vinblastine*			
disopyramide	*nelfinavir*	*vincristine*			
docetaxel	nevirapine	vinorelbine			
dofetilide	*nicardipine*	*voriconazole*			
dolasetron	*nifedipine*	*(R)-warfarin*			
donepezil	*nimodipine*	zaleplon			
doxorubicin	*nisoldipine*	zileuton			
dronabinol	nitrendipine	ziprasidone			
dutasteride	norethindrone	zolpidem			
efavirenz	omeprazole	zonisamide			
eplerenone	*ondansetron*				
ergotamine	*oral contraceptives*				
erlotinib

CYP2C8			
--------Substrates--------		-----Inhibitors-----	--Inducers--
amiodarone	*repaglinide*	anastrozole	carbamazepine
benzphetamine	retinoic acid	*gemfibrozil*	*phenobarbital*
carbamazepine	retinol	nicardipine	rifabutin
docetaxel	rosiglitazone	quercetin	*rifampicin*
fluvastatin	tolbutamide	sorafenib	*rifampin*
isotretinoin	tretinoin	sulfaphenazole	
paclitaxel	verapamil	sulfinpyrazone	
phenytoin	warfarin	trimethoprim	
pioglitazone	zopiclone		

* In addition to the references listed below, information from product labeling was also utilized.

Users of this document are cautioned to use their professional judgment and consult any other necessary or appropriate resources prior to making clinical judgments based on the content of this document. Our editors have researched the information with input from experts in government agencies, and national organizations. Information and Internet links in this article were current as of the date of publication.

adrenergic, 166–167
in blood pressure regulation, 487–488
types of, 719
bacterial, 808
benzodiazepine, 226
cholinergic, 197–198, 198t
dopaminergic, 182–184, 361
drug interactions with, 52–53
muscarinic, 197f, 198–199, 198t
nicotinic, 197f, 197–198, 198t
in older adults, 99
opioid, 406f, 410
oxytocin, 1154, 1158f
pain, 405, 406f
sensitivity of, 53
RECOMBINATE (a**ntihemophilic factor**), 664t, 665–666
Recommended dietary allowances, of vitamins, 134
Reconciliation, medication, 142–143
Rectum, drug administration to, 39, 77, 1023
Rectus femoris muscle, for injection, in pediatric patients, 74
Red blood cells. *See* Erythrocytes
Red clover, drug interactions of, 651t, 662t
"Red man syndrome," vancomycin-induced, 833
Re-entry phenomenon, in arrhythmias, 610–611, 612f
REFLUDAN (**lepirudin**), 648
Reflux, gastroesophageal. *See* Gastroesophageal reflux disease
Refractory emesis, 1253b
Refractory period, in cardiac cycle, 610, 611f
REGITINE (**phentolamine**), 177, 185t, 188, 515t, 518–519
REGLAN. *See* **Metoclopramide**
REGONOL (**pyridostigmine**), 201t, 211
Regular insulin, 1041–1052, 1042t
adverse effects of, 1044, 1047
contraindications and precautions with, 1044
core drug knowledge for, 1041, 1043–1044, 1044t
core patient variable assessment for, 1044–1045, 1046b
drug interactions of, 1044, 1044t
insulins different from, 1051–1052
insulins related to, 1050–1051, 1050t
nursing diagnoses and outcomes of, 1046
ongoing assessment and evaluation of, 1049–1050

patient and family education on, 1048–1049, 1049b
pharmacodynamics of, 1044
pharmacokinetics of, 1043–1044
pharmacotherapeutics of, 1041, 1043
planning and intervention for, 1046–1049, 1047b
REGULAR SS (**docusate sodium**), 793t, 796
REGULOID (**psyllium**), 793t, 796
Regurgitation, in gastroesophageal reflux disease, 747
Rehabilitation units, drug therapy in, 141–142
RELAFEN (**nambumetone**), 442t, 448
Relapse, in substance abuse, 127–128, 127b, 128b
Relaxation therapy, for pain, 409t
RELENZA (**zanamivir**), 936–937, 936t
RELPAX (**eletriptan**), 453t, 456
REM (rapid eye movement) sleep, 221–222
REMERON (**mirtazapine**), 245t, 246t, 255
REMICADE (**infliximab**), 472t, 475, 802, 1196t, 1204
Remifentanil, 326t, 329, 422
REMINYL (**galantamine**), 201t, 212, 289t, 291
Renal cell carcinoma, 1176t
Renal tubular absorption, 527
Renal tubular secretion, 527
RENESE (**polythiazide**), 531, 537
Renin-angiotensin-aldosterone system, 488, 488f, 529, 1012
REOPRO (**abciximab**), 657–658, 1193, 1202
Repaglinide, 1042t, 1056
drug interactions of
erythromycin, 849t
somatropin, 1080t
sulfamethoxazole-trimethoprim, 884t
Repolarization, 609–610
Reproductive system, thyroid hormone effects on, 1075t
REQUIP (**ropinirole**), 364t, 370
RESCRIPTOR (**delavirdine**), 959t, 962–963
Rescue doses, for breakthrough pain, 418–419
Reserpine, 514
drug interactions of, 369, 390t
for older adults, 102t
Resins
potassium-removing, 631–633, 632t
properties of, 15
Resistance
antibiotic, 807–809, 808b
chloroquine, 986, 987f, 988t
Resistance assay, for HIV, 948–949
Respiration
control of, 383, 383f
definition of, 714
Respiratory beta agonists, 182
Respiratory depression, morphine-induced, 418b
Respiratory distress syndrome, 1015t
Respiratory syncytial virus infections
antivirals for, 940
pathophysiology of, 928–929
Respiratory system (lower), 712–740
anti-inflammatory agents, 712, 716–719
bronchodilators for. *See* Bronchodilators; *specific drugs*
conditions affecting. *See also specific conditions, eg,* Asthma ; Bronchitis
gas exchange in, 714

contraindications and precautions with, 649
core drug knowledge for, 649–650, 650t, 651t
core patient variable assessment for, 650–651
drug interactions of
acetaminophen, 450t
aminoglutethimide, 1028t
amiodarone, 625
aprepitant, 777
celecoxib, 449
ciprofloxacin, 871t
dantrolene, 355t
erythromycin, 850t
etoposide, 1232, 1233t
fluconazole, 918t
griseofulvin, 922t, 923
in history, 6
imatinib, 1206t
isoniazid, 895t
levothyroxine, 1089t
lovastatin, 563t
mesalamine, 801t
methimazole, 1092t
omeprazole, 753t
orlistat, 771t
prednisone, 1019t
saquinavir, 968t
sertraline, 249t
somatropin, 1080t
sulfamethoxazole-trimethoprim, 884t
tetracycline, 858t
zafirlukast, 739t
drug therapy, 66b
drugs different from, 653
nursing diagnoses and outcomes of, 651
ongoing assessment and evaluation of, 652
pharmacodynamics of, 649
pharmacokinetics of, 649
pharmacotherapeutics of, 649
planning and intervention for, 651, 652
raloxifene, 1149
site of action of, 639f
WARFILONE. *See* **Warfarin**
Water, body, in pediatric patients, 72, 72t
Waterbrash, in gastroesophageal reflux disease, 747
Web sites. *See* Internet
Weight
excess, 384–386, 385b, 386b, 394–397
management of, lipase inhibitors for, 744, 749, 769–772, 770t, 771t
in pediatric dose calculation, 70, 70b, 71f, 72, 76
WELCHOL (**colesevelam**), 568
WELLBUTRIN. *See* **Bupropion**
WELLFERON, 947
WELLFERON (**interferon beta-1a**), 375t, 376
Whipworm infections drug
pathophysiology of, 986
therapy for, 1002t
White Americans, culture of, 152–153
White blood cells. *See* Leukocytes
Wild carrot, drug interactions of, 651t
Wild lettuce, drug interactions of, 651t
Willow, drug interactions of, 651t
Willowbark, adverse effects of, 136t
WINSTROL (**stanozolol**), 1115
Wintergreen, drug interactions of, 651t
Withdrawal syndrome, 112
in alcohol use, 127b
in antiepileptic drug use, 303b
in opioid use, 115
in sedative-hypnotic use, 115
in sertraline use, 252–253
in stimulant use, 115
Women's health and sexuality, 1126–1150
breast-feeding. *See* Breast-feeding
contraceptives, 1142–1146. *See also* Oral contraceptives
intrauterine, 1145–1146
transdermal, 1144–1145
vaginal ring, 1145
estrogens. *See* **Estrogen(s)**
hormone deficiencies, 1129–1130
menopause, 1130
menstrual cycle, 1128–1129, 1129f
osteoporosis, 1130, 1146–1150
physiology of, 1128–1129, 1129f
pregnancy. *See* Pregnancy
progestins. *See* **Progesterone;** Progestin(s)
uterine motility. *See* Uterine motility
Women's Health Initiative trial, 1132, 1134b
World Health Organization, analgesic ladder of, 409, 409f
Worm infestations. *See* Helminthic infections

WYAMINE (**mephentermine**), 172t, 182
WYCILLIN (**penicillin G procaine**), 818, 819t, 823b

X

XANAX. *See* **Alprazolam**
Xanthine derivatives, 712, 727–732, 728t, 730t, 731b. *See also* **Theophylline**
XATRAL (**alfuzosin**), 185t, 188, 1122
XELODA (**capecitabine**), 1222t, 1227, 1227b
XENICAL. *See* **Orlistat**
Xerostomia, 200t
XIBROM (**bromfenac**), 442t, 448
XIGRIS (**drotrecogin alfa**), 664
XOLAIR (**omalizumab**), 735t, 737
XOPENEX (**levalbuterol**), 721t, 725
XYLOCAINE. *See* **Lidocaine**
Xylometazoline, 699t
XYZAL (levocetirizine), 702t

Y

Yarrow, drug interactions of, 651t
Yeasts, 906, 906f
Yin and yang concep, 154
YOCON. *See* **Yohimbine**
YODOXIN (**iodoquinol**), 994t, 997
YOHIMBEX. *See* **Yohimbine**
Yohimbine, 1120
  drug interactions of
    captopril, 503t
    eplerenone, 510t
    furosemide, 539t
    hydrochlorothiazide, 535t
Yttrium-90 ibritumomab tiuexetan, 1205

Z

Z lines, in muscle, 344
Zafirlukast, 738–740
  adverse effects of, 738
  contraindications and precautions with, 738
  core drug knowledge for, 738–740, 739t
  core patient variable assessment for, 738–739
  drug interactions of, 738, 739t
    theophylline, 730t
  drugs related to, 740
  nursing diagnoses and outcomes of, 739
  ongoing assessment and evaluation of, 740
  pharmacodynamics of, 738
  pharmacokinetics of, 738
  pharmacotherapeutics of, 738
Zalcitabine, 954t
Zaleplon, 234
ZANAFLEX (**tizanadine),** 345t, 352, 871t
Zanamivir, 936, 936t, 936–937
ZANOSAR (**streptozocin**), 1247t, 1257
ZANTAC. *See* **Ranitidine**
ZANTRYL (**phentermine**), 394t, 770t, 772
ZARONTIN. *See* **Ethosuximide**
ZAROXOLYN (**metolazone**), 531, 567–568, 1225t
ZDV. *See* **Zidovudine**
ZEBETA (**bisoprolol**), 186t, 192, 577, 595
ZEGERID. *See* **Omeprazole**
ZELAPAR (**selegiline**), 264–265, 364t, 368–369
ZEMPLAR (**paricalcitol**), 1101t, 1105
ZEMURON (**rocuronium**), 335t, 337
ZENAPAX (**daclizumab**), 1203
ZERIT. *See* **Stavudine**
ZESTRIL (**lisinopril**), 496t, 504, 576
ZETIA (**ezetimibe**), 567
ZEVALIN (**yttrium-90 ibritumomab tiuexetan**), 1205
ZIAGEN (**abacavir sulfate**), 951t, 957
Zidovudine, 950–959, 951t, 954t
  adverse effects of, 952–953, 952t
  contraindications and precautions with, 952
  core drug knowledge for, 950, 952–953, 953t–954t
  core patient variable assessment for, 953–956, 956b
  drug interactions of, 953, 953t, 954t
    amphotericin B, 911t
    pentamidine, 1000t
    sulfamethoxazole-trimethoprim, 884t
  drugs related to, 957–959
  nursing diagnoses and outcomes of, 956
  ongoing assessment and evaluation of, 956–957
  pharmacodynamics of, 952
  pharmacokinetics of, 950, 952
  pharmacotherapeutics of, 950
  planning and intervention for, 956
  in pregnancy, 955b
Zidovudine-emtricitabine, 976
Zidovudine-lamivudine, 951t, 976
Zidovudine-lamivudine-abacavir, 951t
Zileuton, 730t, 740
ZIMULTI (**rimonabant**), 208
ZINACEF (**cefuroxime**), 828t, 831
Zinc, 871t
Zinc (endogenous), function of, 135
ZINCATE (**zinc**), 871t
ZINECARD (**dexrazoxane),** 1260
Ziprasidone, 269, 288
  drug interactions of, antipsychotics, 276t
ZITHROMAX. *See* **Azithromycin**
ZOCOR. *See* **Simvastatin**
ZOLADEX (**goserelin**), 1249t, 1265
