Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in his or her clinical practice.

PREFACE

"How will I ever learn all of this?" and "Where do I begin?" are questions that nursing students frequently ask themselves and their faculty when beginning to study pharmacology. The subject is indeed vast for novices in the profession who lack the skills to organize drug information appropriately. Students feel overwhelmed by all of the isolated pieces of drug information they must learn. Consequently, they lose sight of "the forest for the trees."

PROTOTYPE APPROACH

For years, many pharmacology faculty have favored a prototype approach to teaching pharmacology. This method encourages identification of "the major trees" and facilitates recognition of "the forest." Use of a prototype, a drug that is representative of a class (or group) of drugs, helps students because it offers a systematic approach to grouping drug data, while beginning to recognize individual drug names. It gives students a "method" of learning and organizing large amounts of information. *Drug Therapy in Nursing, Fourth Edition,* is designed and written by faculty who themselves teach nursing pharmacology using the prototype approach. At last, nursing pharmacology faculty have a text that matches the way they teach. *Drug Therapy in Nursing, Fourth Edition,* is that text!

CLINICAL JUDGMENT AND CLINICAL APPLICATION

Drug Therapy in Nursing, Fourth Edition, is unique in that it presents a totally nursing-focused framework to support the teaching and learning of nursing pharmacology. Learning the pharmacology facts about different drug prototypes is only half of the knowledge nursing students need. Because they're learning to be nurses, they must understand how to apply this knowledge to patient care. Nurses must learn to think critically, evaluate information, and make decisions. However, this essential aspect of knowledge application has never been thoroughly addressed in nursing pharmacology texts. Frequently, students view *nursing application* of drug knowledge as less important than learning the hard drug facts. This thinking is fostered when the pharmacology textbooks they use present the nursing process after or apart from drug knowledge in a brief paragraph or chart. *Drug Therapy in Nursing, Fourth Edition,* fully integrates core drug knowledge with core patient information, appropriately stressing, as no other text does, the relationship between the two bodies of information.

As with all other factual, scientific, or medical information used by nurses, students must learn to integrate this knowledge into their practice and apply it to patient care. Applying drug information to patient care may overwhelm students because every patient is different, with different responses, positive or negative, to the same drug therapy. If the student sees each patient situation as an isolated case, learning is again hampered. This text provides a systematic framework for assessing and evaluating patient responses that change in accord with health, age, gender, lifestyle, and other factors. This important *patient focus* is strengthened by use of the nursing process framework. Pharmacologic facts are integrated into nursing, to help the student apply knowledge to practice, safely administer drugs, educate patients, and begin to make the journey from novice to expert.

USE OF A SYSTEMATIC FRAMEWORK

The authors of *Drug Therapy in Nursing, Fourth Edition,* present a systematic framework for drug therapy with every prototype drug. The framework consists of two basic areas of information: first, core drug knowledge and core patient variables; and second, actions of the nurse using this knowledge.

Core Drug Knowledge highlights the important drug facts about a prototype drug. Core drug knowledge includes pharmacotherapeutics, pharmacokinetics, pharmacodynamics, contraindications and precautions, adverse effects, and drug interactions.

Core Patient Variables identify the major topics that should be assessed in every patient to determine special considerations that need to be taken into account when administering a drug to a patient. Core patient variables include health status; life span and gender; lifestyle, diet, and habits; environment; and culture and inherited traits. The text presents the relevant variables for each particular prototype.

The nurse uses knowledge about the drug and knowledge about the patient to maximize the therapeutic effect of the drug, minimize the adverse effects of the drug, or provide patient and family education. The authors of this text call what the nurse does with knowledge about the drug and the individual patient "nursing management of drug therapy."

ORGANIZATION

Drug Therapy in Nursing, Fourth Edition, has twelve units. The first three units address the principles and process of nursing management of drug therapy, and the basics of core drug knowledge and patient-related variables. The next nine units present the nursing management of drugs affecting various body systems and disease states. Appendices are now located on the text website on thePoint.

Unit 1, Foundations for Drug Therapy in Nursing, consists of three chapters. Chapter 1 explains the framework for the text and how this framework relates to the application of drug knowledge to clinical practice. **This is a crucial chapter for students and faculty to read so that they will best understand the content in the rest of the text.** The remaining chapters address basic pharmaceutical knowledge, drug development and its related safeguards, and drug delivery, and the modes of drug administration.

Unit 2, Core Drug Knowledge, includes two chapters that present the basics of pharmacology: pharmacotherapeutics, pharmacokinetics, and pharmacodynamics; and adverse effects and drug interactions.

Unit 3, Core Patient Variables, includes seven chapters that highlight information pertinent to patient assessment relevant to drug therapy. This is not an exhaustive list of every aspect that can be considered by these variables. The topics include life-span issues (children, pregnant or breast-feeding women, and older adults); lifestyle, diet, and habits issues (substance abuse, dietary considerations, and complementary medication use); environment (influences on drug therapy); and culture and inherited traits (considerations in drug therapy). The core patient variable of health status is not presented, as this includes all physiology, pathophysiology, disease states, and their related treatments.

Units 4 through 12 present drugs affecting the various body systems and drugs used to treat diseases and their symptoms.

The Appendices, found online at thePoint under faculty and student resources present essential information on diagnostic imaging agents, enzymes and débridement therapy, enteral and nutritional supplements, parenteral nutrition, immunizations and immunization schedules for the United States, drugs causing photosensitivity, drugs that interact with grapefruit juice, and drugs metabolized by the P450 system. Emphasis is given in the appendices to the nursing management of these drug therapies.

PEDAGOGY

- **Chapter Learning Objectives** identify key content within the chapter to help direct student learning.
- **Key Terms** identify terms that are key to understanding each chapter's contents.
- **Pathophysiology information,** which summarizes information relevant to drug therapy, is included to assist with understanding and critical thinking.
- **Black Box warnings** from the FDA labels are included in the discussion of each prototype when applicable.
- **Separate chapters** are included on drugs affecting fungal and viral infections, with revised expanded content.
- **Chapter Summaries** highlight the most important information presented in the chapter.
- **Questions for Study and Review** encourage the student to reflect on the important aspects of the chapter. Answers are provided at the back of the book.

NEW TO THIS EDITION

- All chapters have been updated and include new drugs approved by the FDA.
  - The chapter sequence has been reorganized to promote student comprehension and learning.
  - Totally revised chapters on adrenergic and cholinergic drugs to address areas typically confusing to students
  - Separate chapter with expanded content on chemotherapy drugs that affect a specific targeted cell.
- Black Box warnings from the FDA labels have been added to the memory chips when applicable.
- NCLEX style questions have been added to many of the chapters in the Study Guide.

KEY FEATURES

- **Concept Maps** introduce the student to all drugs that will be mentioned in the chapter. Each map identifies the drug class, its prototype, and drugs in the class that are similar to or different than the prototype. Concept maps also refer the student to other chapters if related drugs are covered elsewhere.
- **Physiology Figures** illustrate physiologic processes relevant to the drug class and link drug actions to physiology.
- **Memory Chips** assist students in studying and preparing for clinical practice, providing a quick reference of key points for each prototype drug.
- **Focus on Research** boxes highlight current research in pharmacology. The implications for nursing practice are addressed for each article.
- **Community-Based Concerns** highlight nursing issues related to drug therapy carried out in patients' homes and communities.
- **Critical Thinking Scenarios** challenge students to develop critical thinking skills for applying pharmacology knowledge to patient care. Answers are provided for instructors on thePoint.
- **Drug Summary Tables** relate pharmacotherapeutics and general dosage data to pharmacokinetic parameters.
- **Drug Interaction Tables,** for every prototype drug, highlight known drug–drug and drug–food interactions. When diagnostic and laboratory test values are affected by drug use, this information is pointed out as well.

TEACHING/LEARNING PACKAGE

These excellent ancillary materials make teaching and learning even easier!

Resources for Instructors

The following tools are available upon textbook adoption to instructors on http://thePoint.lww.com/aschenbrenner4e.

- The **Test Generator** lets you generate new tests from a bank containing over 800 NCLEX-style questions to help you assess your students' understanding of the course material.

- **Lesson Plans** organize all ancillary resources by learning objective to assist in preparing your lessons.
- An **Image Bank** contains illustrations from the book in formats suitable for printing and incorporating into PowerPoint presentations and Internet sites.

In addition, an extensive collection of materials is provided for each book chapter:

- **Pre-Lecture Quizzes** are quick, knowledge-based assessments that allow you to check students' reading before you begin your instruction. Answers are also provided.
- **PowerPoint Presentations** provide an easy way for you to integrate the textbook with your students' classroom experience, either via slide shows or handouts. Multiple-choice and True/False questions are integrated into the presentations to promote class participation and allow instructors to use i-clicker technology.
- **Guided Lecture Notes** walk you through the chapters, objective by objective, and provide you with corresponding PowerPoint slide numbers.
- **Discussion Topics** (and suggested answers) can be used as conversation starters or in online discussion boards.
- **Assignments** (and suggested answers) include group, written, clinical, and web assignments.
- **Case Studies** for every drug chapter in the book are provided to help your students apply their knowledge to clinical scenarios.

Valuable learning tools for students are available on Student Resources online via ThePoint include:

- **NCLEX-Style Review Questions** for every chapter feature traditional and alternative-format NCLEX-style questions.
- Appendices to support drug information found in text.
- Concepts in Action animations illustrating pharmacologic and pharmacokinetic mechanisms bring the text to life.
- Watch and Learn video clips demonstrate important concepts related to medication administration and preventing medication errors, teaching students habits for careful clinical practice.
- **Dosage Calculation Quizzes** provide review of dosage calculation concepts to further promote patient safety
- **Monographs** of the 100 most commonly prescribed drugs, a **Spanish–English Audio Glossary,** and an **NCLEX Alternate Item Format Tutorial** are also provided.

In addition to these resources, the following are also available exclusively on thePoint:

- **Drug Class Review Exercises,** based on the Concept Maps in the text, are interactive drag-and-drop exercises that allow students to place the drugs in their appropriate drug classes and hear the drug names pronounced.
- Additional animations and video clips related to physiology and pathophysiology concepts offer students additional tools for review.
- **Journal Articles,** corresponding to every book chapter, offer students access to current research available in Lippincott Williams & Wilkins journals.

Study Guide

***Study Guide to Accompany Drug Therapy in Nursing,* Fourth Edition,** authored by Diane Aschenbrenner and Samantha Venable, has been carefully designed to complement the textbook. The study guide is unique in that the text book authors have written the study guide, which is not often the case with student study guides. The study guide truly is designed to help students master important content. Information is reviewed according to the types of knowledge presented in each textbook chapter (e.g., key terms, physiology and pathophysiology, core drug knowledge, core patient variables, and nursing management). The *Study Guide* provides students further study and learning opportunities through various techniques, such as multiple-choice questions, matching, decision trees, and case studies that encourage critical thinking and the application of knowledge. Students move through the levels of learning, beginning with knowledge of terms and acquisition of facts, and progressing to the application of knowledge in each chapter. Answers for all of the exercises are provided at the end of the study guide to assist students with independent study. This edition features additional NCLEX questions for every chapter. Visit thePoint for further information.

Nursing Management of Drug Therapy

Learning Objectives

At the completion of this chapter the student will:

1. Identify the defining components of core drug knowledge.
2. Identify the defining components of core patient variables.
3. Define nursing management of drug therapy.
4. Describe how the prototype approach to drugs is a helpful learning tool.
5. Differentiate the three main sources of data used in assessment of core drug variables.
6. Describe how core drug knowledge and core patient variables are used in nursing management of drug therapy.
7. Explain general strategies for maximizing the therapeutic effects of drug therapy.
8. Explain general strategies for minimizing adverse effects of drug therapy.
9. Identify the importance of patient and family education in drug therapy.
10. Discuss how to evaluate drug therapy and its nursing management.
11. Describe the varied settings in which nurses use nursing management techniques to assist patients receiving drug therapy.

Nurses have a vital role in managing drug therapy for people with medical conditions. The nurse uses knowledge about the drug (core drug knowledge) and knowledge about the individual patient (core patient variables) to maximize the therapeutic effects of the drug, to minimize the adverse effects of the drug, and to provide patient and family education. The term *patient* is used in this text to identify the person who is taking the drug. It should not be interpreted to mean that drug therapy or the nursing management involved occurs solely in an acute, inpatient setting. Most drug therapy now occurs outside of hospitals.

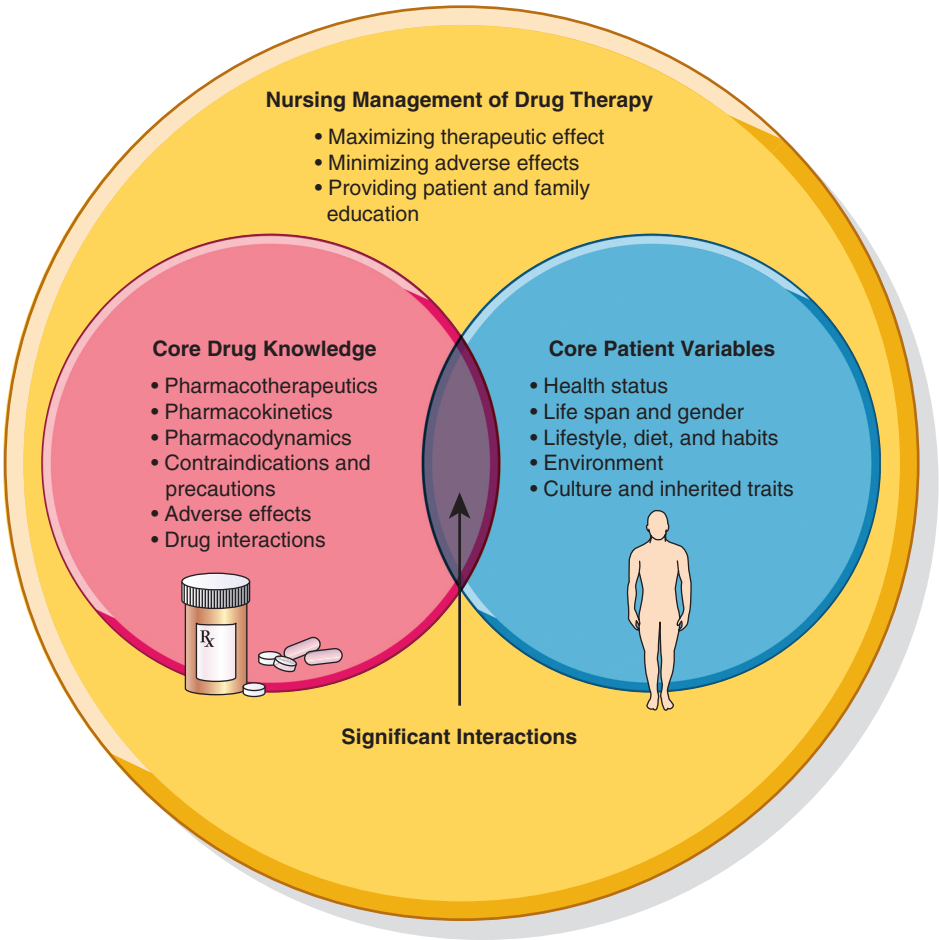
Nurses apply pharmacology (i.e., the scientific body of drug knowledge) to meeting the assessed care needs of the patient. The pharmacologic facts relevant to each drug, termed **core drug knowledge,** are:

- **Pharmacotherapeutics:** the desired therapeutic effect of the drug
- **Pharmacokinetics:** the changes that occur to the drug while it is inside the body
- **Pharmacodynamics:** the effects of the drug on the body
- **Contraindications and precautions:** conditions under which the drug should not be used or must be used carefully with monitoring
- **Adverse effects:** unintended and usually undesired effects that may occur with use of the drug
- **Drug interactions:** effects that may occur when the drug is given along with another drug, food, or substance

These components of core drug knowledge are discussed in more depth in Chapters 4 and 5.

In addition to knowing the pharmacologic facts about each drug that a patient receives, nurses assess the patient for factors that may or will interact with drug therapy. These areas of assessment, termed **core patient variables,** are:

- **Health status:** the presence of disease, illness, and allergy; chronic conditions causing system or organ dysfunction; diminished memory or mental capacity
- **Life span and gender:** age, physiologic development, reproductive stage, and gender
- **Lifestyle, diet, and habits:** amount of activity and exercise; sleep–wake patterns; occupation; financial resources or access to health insurance coverage to offset the cost of the drug, or both; eating preferences and patterns; use or abuse of substances (e.g., nicotine, alcohol, and illegal drugs); use of over-the-counter (OTC) drugs; use of alternative health practices (e.g., herbal medicine, folk remedies); and ability to read and write
- **Environment:** location in which the drug therapy will be administered, such as hospital, home, or long-term care facility; properties of the physical environment that may



• FIGURE 1.1 Relationships among core drug knowledge, core patient variables, and nursing management of drug therapy. The nurse considers both the core drug knowledge and the core patient variables to provide appropriate nursing management of drug therapy.

alter a drug's action or effect, induce adverse effects from a drug, or set limitations on whether the drug may be administered in that setting; and exposure to potentially harmful substances, or a pathology induced from a harmful environmental substance, that requires drug therapy for treatment

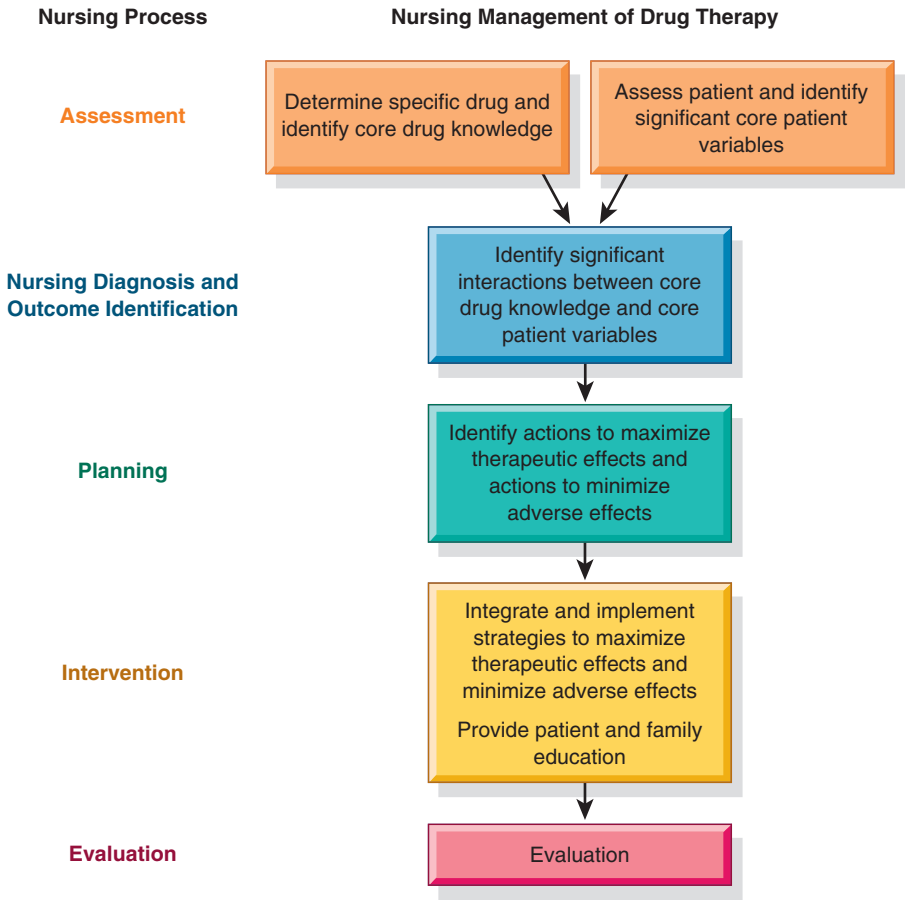
- **Culture and inherited traits:** religious, social, and ethnic backgrounds that may affect the individual's receptiveness to drug therapy; also, genetic traits that affect a drug's pharmacokinetic and pharmacodynamic properties

The nurse considers the core drug knowledge and the core patient variable categories and determines potentially important interactions between them. An important interaction is an area in which key elements of the drug overlap—or potentially may overlap—with specific patient factors, thus requiring nursing management. **Nursing management of drug therapy** is the process of planning and implementing actions that will maximize the therapeutic effects and minimize the adverse effects of a drug. The nurse also considers these important interactions when planning and providing patient and family education relevant to the drug therapy. Finally, the nurse evaluates the effectiveness of both the drug therapy and the nursing interventions. Thus, the nurse applies knowledge in an individualized manner to meet the care needs of a particular patient receiving a particular drug therapy. Figure 1.1 shows how the interactions between core drug knowledge and core patient variables can be used to manage therapy.

Nursing management of drug therapy helps ensure quality and comprehensive nursing care. It occurs in all settings, including hospitals, long-term care facilities, outpatient centers and clinics, health care providers' offices, and patients' homes. Some aspects of nursing management are more relevant to a particular setting than others are; for example, considering the patient's lifestyle is more important for the nurse when drug therapy occurs in the home than when it occurs in a hospital.

MANAGING DRUG THERAPY THROUGH THE NURSING PROCESS

The nurse uses the nursing process when managing the care of a patient receiving drug therapy. The nursing process is a series of steps in which the nurse assesses and identifies a patient's response to health-related problems and then plans and implements interventions to manage the problem and promote a healthful outcome. The six steps of the nursing process are assessment, diagnosis, outcome identification, planning, intervention, and evaluation. Figure 1.2 shows how the nursing process corresponds to the phases of nursing management of drug therapy.



• FIGURE 1.2 Relationship of nursing management of drug therapy to the nursing process.

Assessment

Assessment of Core Drug Knowledge

Nurses need to know about all drugs a patient is taking, including prescribed and OTC drugs. In any given month, almost 45% of the U.S. population will receive one prescription drug; a little under 18% will receive three or more prescription drugs. Prescription drug use increases with each age group, with approximately 85% of adults aged 65 and older receiving one prescription and over half receiving three or more prescriptions in a month (National Center for Health Statistics, 2007).

The first step for a nurse is to identify the core drug knowledge relevant to a patient's drug therapy. The nurse needs to be familiar with every drug the patient is taking, to determine whether interactions with core patient variables are likely to occur and consider what nursing management is required. Although memorizing information on every available drug would be difficult, if not impossible, the nurse is responsible for using available, current drug references to review unfamiliar data before administering the drug or instructing the patient to self-administer the drug.

In the assessment phase, the nurse identifies the drug to be administered and its prototype. Currently there are thousands of generic and brand name prescription drugs sold in the United States. Additionally, there are numerous combination drugs, prescription and OTC, as well as brand new drugs introduced every year. The sheer volume of drug forms makes it impossible for the nurse to memorize up-to-date information regarding nursing management of every drug. An efficient way to learn and understand as much as possible of the vast information about drugs is to use a prototype approach. A **prototype drug** is typical of a group of drugs within a drug class. For example, hydrochlorothiazide is a prototype drug that represents all of the thiazide diuretics (a class of drugs in this class that increases urine output). By learning the core drug knowledge about the prototype, the nurse then knows something about related drugs. Prototypes are typically the first drug of a class. Occasionally, as other drugs in a class are developed, the "original" is not used as frequently in practice. The preference for one particular drug over another is also influenced by regional patterns and trends. This text generally uses the original, or classic, drug in a class as the prototype drug. If this drug is not widely used anymore, another representative drug of the class is used.

Assessment of Core Patient Variables

In drug therapy, the nurse assesses the current health status of the patient and gathers data on other core patient variables to identify those that are relevant to the individual patient. Assessment of the core patient variables also allows the nurse to predict (to some degree) the future needs of the patient. Data for this assessment come from three sources: (1) the patient interview and history, (2) the physical examination, and (3) the medical record, which includes current laboratory and other diagnostic findings. Pertinent findings are then assimilated to form a current, accurate picture of the patient's needs regarding drug therapy. These facts establish a baseline for the patient's treatment and care.

The Patient Interview and History

Most assessment data come from an assessment interview, in which the patient responds to questions. To be most effective, the nurse asks open-ended questions. Open-ended questions allow the patient to give details and explanations, whereas closed-ended questions require a single or particular response. Although closed-ended questions are a quick way to obtain information, they limit the depth of a response.

An example of an open-ended question is, "What kind of drug allergies do you have, if any?" An example of a closed-ended question is, "Are you allergic to penicillin?" The second question limits the patient's response to "Yes" or "No." Although this response answers the immediate question, important information can be missed. Open-ended questions may elicit the information that the patient is allergic to ampicillin. This fact is important to know because people who are allergic to ampicillin may also be allergic to penicillin (Penicillin and ampicillin are both antibiotics with similar chemical structures.). Closed-ended questions are most useful in emergency situations and when particular information must be determined quickly. An open-ended approach is preferable during the assessment interview if time and the patient's physical state permit.

Follow-up questions must be asked whenever the patient responds in a closed-ended manner. If, for example, the patient identifies an allergy to a particular drug, the nurse asks the patient to describe the allergic event. Using this technique, the nurse gains additional information with which to evaluate the patient's response. The patient may believe an event or response is a sign of an allergy, when in fact it may be a normal response to or an adverse effect of the drug. For example, if the patient describes a rash occurring on the third day of taking a drug, this may indicate a true allergy. However, if the patient describes a rash that occurred 6 weeks after completing a drug, a drug allergy is unlikely.

The nurse seeks information on several topics during the assessment interview (Box 1.1) and then determines which core patient variables are relevant to the drug therapy being planned for the individual.

Health Status

A patient's health status includes information about illnesses, diseases, chronic conditions, and allergies. This information allows the nurse to assess functioning of body systems and organs. Impaired functioning may interact with or alter the action of a drug. Pharmacotherapeutics, pharmacokinetics, and pharmacodynamics may all be affected. For example, if the patient has kidney disease, and the drug is excreted through the renal system, the drug will not be eliminated as rapidly as it would in someone with normal kidney function. Because the drug is not eliminated as quickly, the drug levels may remain higher than normally expected. The patient may then exhibit increased therapeutic effects from the drug or be at increased risk for adverse effects. Patients with impaired functioning of a body system or organ may have

special educational needs for drug therapy. For example, patients with impaired vision, hearing, or dexterity or those with decreased memory or mental capacity need educational materials tailored to meet their particular needs.

A complete drug history is necessary to assess the health status of the patient adequately and to assess a patient's needs and knowledge accurately regarding current or proposed drug regimens. Components of a complete drug history are given in Box 1.2. In the drug history interview, the nurse seeks information about current drug therapy, including the drug name, dose, and time last given. Any new drugs prescribed should not interact adversely with a current drug regimen. In addition, patients who are admitted to acute or long-term care facilities must continue the drug therapy they have been taking. Information about recently used drugs is also important because some drugs have long-lasting effects that may interact with a newly administered drug. Finally, the patient's drug therapy may have direct bearing on the understanding and interpretation of data obtained from physical assessment and laboratory findings. The data may indicate an expected therapeutic effect, an adverse effect, or an interaction between drugs. For example, knowing that a patient regularly takes the anticoagulant warfarin (Coumadin) would explain why the patient's clotting time is prolonged. Knowing that a patient is currently taking digoxin (Lanoxin), a drug that slows the heart rate, may explain why that person is experiencing adverse drug effects, such as extreme bradycardia with nausea and weakness.

Asking a patient to describe why he or she is taking the drug provides a great deal of information about the learning needs of that patient. The nurse may find that the patient has an excellent knowledge base or, conversely, that the patient has inadequate information or misconceptions concerning drug therapy. One patient may state that the drug is a diuretic to treat hypertension; another patient may state that the drug is a fluid pill; and another patient may have no understanding of what the drug does or why it was prescribed. Patients have different learning needs that require different approaches from the nurse.

Lack of adherence to prescribed drug therapy is very important to determine. However, merely confirming lack of adherence is not enough; the nurse needs to explore the reason the patient has stopped taking drug therapy as ordered. A patient may have stopped taking a drug for a variety of reasons. The patient may no longer have a medical indication for the drug, or the patient may have had an adverse reaction. The drug may have been discontinued on the advice of the prescriber, or the patient may have discontinued it independently. People may independently stop taking a drug because they think they no longer need it, they think it is not effective, they are experiencing unpleasant adverse effects, the prescription ran out and they cannot get to the pharmacy, or they cannot afford the drug.

Allergies are another aspect of the drug history that must be identified correctly and documented carefully in the medical record. Drug, food, and environmental allergies should be noted. Although allergies are an individual aspect of health status, they are usually considered part of the complete drug history and thus are discussed as part of the drug history rather than as a separate element. Health care providers need to know the patient's allergies so that they do not prescribe or administer drugs to which the individual is allergic. Ask the patient to describe the symptoms of the allergic reaction and note them in the appropriate area of the patient's record. True allergic reactions include formation of rash or hives, itching, redness, swelling, difficulty breathing, and anaphylactic shock. Nausea and vomiting, however, are adverse effects of drug therapy. In addition to drug allergies, food or environmental allergies must be identified and documented. Elements of some foods are found in some drugs; for example, iodine is an element of many contrast media used in radiologic studies. Environmental allergens, if present, may complicate the health status of the individual. The nurse also gathers data about the patient's use of OTC drugs; these preparations may interact with prescribed drugs and alter their effect or produce adverse effects.

Life Span and Gender

During assessment, the nurse determines the patient's developmental level, ability to read and write, and ability to understand directions. This information is needed to plan patient education on drug therapy, including the nurse's approach and teaching methods.

Determining the stage of the reproductive cycle of female patients is important. If a drug is extremely toxic to the fetus, women of childbearing age need to be cautioned not to become pregnant while taking the drug. If a woman is past childbearing age (postmenopausal), a drug that is toxic to the fetus may be used. Certain drugs may cross the placenta, affecting fetal growth and development and sometimes causing birth defects or teratogenic effects. Therefore, if the woman is already pregnant, alternative drug therapy is usually indicated. Additionally, assessment for breast-feeding is important because some drugs cross into breast milk and will have some effect on the infant and the mother.

Lifestyle, Diet, and Habits

The nurse asks questions about a patient's lifestyle because of its potential effect on drug therapy. For example, the patient's levels of exercise and general activity may influence drug effect. Patients who are very active and who exercise are likely to have better circulatory systems than those who are inactive. These lifestyle choices affect the distribution of drugs within the body. People who are very active may also be more likely to incur accidental injury than other, less active people. Their increased incidence of injury would put them at greater risk than their more sedentary peers for certain adverse drug effects, such as prolonged bleeding with warfarin, an anticoagulant.

Information on normal dietary intake is useful because food or food elements interact with certain drugs. For example, monoamine oxidase inhibitors (a class of antidepressants) interact with tyramine-rich foods (e.g., aged cheese, tap beers) and can induce a hypertensive crisis. Some foods affect the absorption and action of a drug; for example, milk interferes with the absorption of tetracycline, an antibiotic. Many drugs can increase or decrease appetite or alter taste sensations. The nurse needs to assess the patient for these potential effects.

Because instructions for taking many drugs include whether they should be taken with food, the nurse needs to know how frequently and regularly the patient eats. If a drug is to be taken three times a day with food and the patient eats three meals a day, the patient may be instructed to take the drug with meals. However, if the patient normally eats only one or two meals a day or eats five or six meals a day, and this pattern was not assessed, the patient will not receive the correct dosage if the instruction to take with meals is followed.

Sleep and rest patterns and occupation are important to assess because they also have a bearing on drug therapy. People who work nights and sleep during the day will need the timing of their drug dosages varied because a daytime schedule is usually recommended for taking drugs, to enable uninterrupted sleep at night. Knowledge of the patient's customary rest patterns provides a baseline to determine whether drug therapy is therapeutic (e.g., a drug given to induce sleep) or whether an adverse drug effect (e.g., insomnia) is occurring. Certain occupations may place the patient at risk for injury and consequently at risk for adverse effects from some drugs.

The patient's use of street drugs, alcohol, cigarettes, and caffeine must be determined because these substances can affect some drug actions or alter the health or physiologic functioning of the patient. For example, a cigarette smoker may have respiratory disease. Cigarette smoking also alters the pharmacokinetics of some drugs, such as theophylline, a bronchodilator.

Economic factors may determine whether the patient will adhere to prescribed drug therapy; therefore, these factors should be assessed. If the drug is very expensive and the patient cannot afford the drug or health insurance to offset or defray drug costs, the patient's inability to purchase the drug may preclude his or her adherence to therapy. A little more than $200 billion is spent yearly in the United States on prescription drugs; 12% of the amount an individual pays for health care is spent on prescription drugs and $25 billion is paid as an out-of-pocket (i.e., not covered by insurance) expense by the patient (National Center for Health Statistics, 2007).

Environment

The nurse assesses the home setting or living environment because it may give clues to the patient's adherence to the drug regimen or to potential risks from the therapy. For example, if a patient is receiving a drug that causes dizziness as an adverse effect, stairs in the house may pose a risk for falls. If the home does not have running water, a patient may be unable to adhere to instructions about handwashing before self-injection of insulin. General factors to assess include cleanliness, lighting, adequate heat, water, and refrigeration. A home visit by a visiting or home health nurse may be the most accurate way to obtain this information.

Environmental factors outside of the home may also affect drug therapy. Environmental elements or substances in the environment may predispose the patient to adverse drug effects. Direct sunlight, for example, may cause sunburn when the patient is prone to photosensitivity from tetracycline, an antibiotic.

The nurse needs to determine the environment in which the drug will be administered. Some drug therapy occurs only in certain environments or settings (e.g., general anesthetics are given only in an operating room). Other drugs, such as oral antibiotics, may be used in all health care settings, including the patient's home. The strategies selected to maximize therapeutic effect or minimize adverse effects may depend on the drug administration environment. Materials selected for patient and family teaching may also depend on the environment in which drug therapy occurs. Patients may start drug therapy in one environment and continue therapy in another—for example, the hospital and then the home—or therapy may be lifelong, as with antidiabetic agents. The patient may begin taking a drug in a hospital and continue taking it in a subacute care center or at home. Planning for discharge of a patient from an acute care setting begins the day of admission. Therefore, during assessment, the nurse must gather data that will be important in meeting the goals of drug therapy once the patient is discharged. Where the patient will go after discharge will alter the education required. If the patient will receive drug therapy at home, the nurse needs to assess the home as previously described.

Some home drug therapies, such as intravenous (IV) therapy, may require special equipment, technologies, or skills. In these cases, the nurse assesses the ability of the patient or responsible caregiver to administer drug therapy safely and effectively. Additional assessments are made about the ability to take appropriate actions if a problem occurs. For example, the nurse needs to know whether the patient or caregiver can describe the actions he or she would take if an infection occurred as a result of IV therapy. The nurse can assess this information by asking hypothetical questions about typically encountered problems and having the patient or caregiver describe how to handle the problem described.

Culture and Inherited Traits

Culture and inherited traits is the last core patient variable to include in the health history and drug assessment. This text uses the term *culture* in its broadest interpretation, which may not directly reflect the definition given by some sociologists or anthropologists. Religious restrictions or cultural practices may affect the patient's acceptance of prescribed drug therapy. Christian Scientists, for example, who believe in healing through prayer, may not accept drug therapy to manage hypertension. Patients with some ethnic backgrounds may have altered responses to particular drug therapies. African Americans, for example, exhibit a diminished therapeutic response to antihypertensive agents, such as angiotensin-converting enzyme inhibitors.

Recently, it has been determined that there may be individual variation to drug therapy. These variations are inherited but are not related to racial or ethnic backgrounds. Instead, they are caused by genetic variations. These unique genetic variations may not be evident until a patient begins therapy with a particular drug; that is, they cannot be predicted ahead of time. Many of these variations are related to the P-450 isoenzyme system. Specific knowledge about the effects of genetic variation on drug therapy is currently in its infancy. Genetic research is being conducted to identify the presence or absence of various isoenzymes in individuals. Knowing whether a patient lacks a specific isoenzyme used in metabolizing a particular drug before starting drug therapy would enable the therapy to be tailored to the patient's needs, preventing possible adverse effects.

The Physical Examination

After completing the health history interview, the nurse performs the second part of the assessment—the physical examination. The physical examination focuses on the core patient variables of health status and life span and gender and should be comprehensive. The patient's history and present complaints (the main reason for seeking health care) usually dictate which body systems require in-depth assessment.

General observation will provide some information on health status. Approximate age and, depending on the stage, pregnancy can be determined by general observation as well. Physical assessment of the systems (e.g., the respiratory system) will provide information about disease or illness.

Baseline data, such as vital signs, height, and weight, must be measured. Ideally, the height and weight are taken directly by the nurse or someone delegated by the nurse (rather than asking the patient for this information). An accurate measurement of body size is an important factor in computing the correct dose of many drugs. During emergencies, this information may be estimated.

The nurse closely inspects the skin of all patients for rashes and documents their appearance and location. Failure to do so could result in the rash being misinterpreted as a drug reaction. If IV drugs may be ordered, other areas to inspect closely are the peripheral blood vessels. If a history of IV drug abuse is reported, scarring or inflammation of the vessels may be present. In such cases, the nurse can anticipate potential problems with IVs.

The nurse must analyze all gathered data in terms of the specific current and proposed drugs, identifying any actual and potential problems related to providing drug therapy.

The Medical Record

In addition to the patient interview and history and physical examination, a review of the patient's medical record and test results provides complete assessment data for the core patient variables. The medical record provides information about the patient's health status, lifestyle, diet, habits, and environment.

Areas of the medical record that are specifically important include laboratory and other diagnostic test results. For drug therapy, pertinent findings may include blood levels of a drug or test results related to drug action. For example, blood glucose levels are pertinent findings in diabetic patients

*Ranges for normal laboratory test values may vary according to the health care setting, the laboratory performing the test, and the testing equipment. This information should be considered a basic guide. Nurses need to be familiar with normal ranges used in the facility or agency in which they work.

receiving insulin to control hyperglycemia. A computed tomography scan report indicating the tumor burden of a patient receiving chemotherapy is also a relevant finding. The nurse reviews all diagnostic findings, paying special attention to those findings relevant to body systems at risk for adverse effects from currently used drugs (Table 1.1).

Past medical records may be used to verify the patient's drug history. Moreover, they may provide details relevant to the patient's current treatment. Patients may forget previous drug reactions, past illnesses, family histories, and other essential baseline information, but these data may be available in previous medical records. Review of the medical record is important regardless of whether the drug is administered in a hospital, extended care facility, outpatient center, or the patient's home. This part of the assessment can be done either before or after the interview and physical examination.

Nursing Diagnoses and Outcome Identification

Data that have been gathered throughout the patient's assessment are interpreted by the nurse according to their relevance to drug therapy. The nurse reviews the core drug knowledge and the core patient variables from which significant interactions may be generated. The nursing diagnoses and patient outcomes are names or labels given to these interactions.

Nursing diagnoses are based on classifications proposed by the North American Nursing Diagnosis Association (NANDA). The diagnosis may reflect a current, actual problem or the risk for developing a problem related to drug therapy. A patient may be receiving a drug that addresses a current problem, yet use of this drug may put the patient at risk for developing other problems. For example, a patient has a nursing diagnosis of Chronic Pain related to cancer. If the patient is taking morphine to control the pain, the diagnoses related to the drug therapy would be Risk for Injury related to sedation from narcotic drug use and Constipation related to adverse effects of morphine. Selected nursing diagnoses pertaining to drug effects are given in Box 1.3.

CRITICAL THINKING SCENARIO

IDENTIFYING CORE PATIENT VARIABLES

1. Propose questions to ask patients who tell you that they are allergic to a drug.
2. Your patient, a 75-year-old man living on a fixed income from a Social Security pension, is to be discharged on a new drug for hypertension. In assessing core drug knowledge for the patient's drug therapy, you identify adverse effects of dizziness and dry mouth. Identify the core patient variables that you would evaluate most carefully for relevance to this patient's drug therapy.

In addition to diagnoses that reflect current or potential problems from effects of drugs, many other types of drug-related diagnoses may be appropriate. The diagnosis of Deficient Knowledge may be appropriate if a new drug has been prescribed. Ineffective Therapeutic Regimen Management may be appropriate if the individual has not been taking drug therapy as prescribed because he or she has misunderstood the directions. Ineffective Coping may be a nursing diagnosis for a patient who continually forgets to take a prescribed drug for a chronic condition (e.g., insulin for diabetes). Nursing diagnoses are highly individualized and cannot be predicted from prescribed drug therapy alone. Reputable textbooks devoted specifically to nursing diagnosis contain additional information.

The next phase of the nursing process is outcome identification—that is, determining the desired results of nursing interventions. Outcomes develop from the data gained in assessment and the diagnosis selected. A plan for a patient receiving drug therapy would identify outcomes related to the patient's specific drug regimen.

Planning

Once the important interactions between the core drug knowledge and the core patient variables have been identified, the nurse devises strategies to maximize the therapeutic effects and minimize the adverse effects of the drug therapy. The nursing process step of planning is used. Planning begins with identifying interventions necessary to reach the desired outcome. Planning continues by defining what needs to be done to achieve the identified outcomes.

Maximizing Therapeutic Effects

To maximize the therapeutic effects of any given drug therapy, the nurse must know what the desired therapeutic effects are and how they are achieved. Strategies appropriate for the patient are then used to promote these effects. Although these strategies are drug specific, a few general principles exist:

- Administer the drug in a manner that will promote its absorption. A drug administered orally may be given with meals or on an empty stomach, depending on the drug. When giving a drug parenterally, use the appropriate administration technique for the desired route. A route different from that prescribed may alter absorption and the desired effect. For example, if an intramuscular injection is accidentally given subcutaneously, absorption will be slower and the onset of the therapeutic effect delayed.
- Administer the drug at the appropriate time to maintain blood levels of the drug that will promote therapeutic effects.
- Monitor laboratory values, when appropriate, to determine that the prescribed dose achieves a therapeutic drug level.

Minimizing Adverse Effects

Many of the nursing care strategies are directed at minimizing the adverse effects of drug therapy. Again, the strategies are specific to the drug, but some are common to all drug therapy:

- Before initiating drug therapy, verify that the patient is not allergic to the drug and that the drug is not contraindicated for this patient for some reason.
- Administer the drug in a manner consistent with standard safety protocols. For example, some drugs must be administered intravenously at a regular, steady rate, and the use of an IV infusion controller, or pump, is considered standard for these drugs.
- Monitor the patient and relevant laboratory findings closely for evidence of known adverse effects from drug therapy. Patients at high risk for developing a particular adverse effect should be monitored especially carefully.
- Discontinue or withhold a drug if the laboratory findings warrant doing so. Notify the prescriber of the findings and your actions.
- Report evidence of adverse effects to the prescriber as soon as possible.
- Modify administration techniques, when appropriate, to decrease the incidence of adverse effects. For example, if the drug causes the patient gastrointestinal distress on an empty stomach, administer the drug with food.
- Implement appropriate techniques for certain drugs to detect the onset of adverse effects. For example, monitor blood pressure before administering each dose of an antihypertensive drug to determine whether the blood pressure has decreased too much to administer the drug.

Intervention

The next phase of the nursing process is intervention: performing the plan. With intervention, the nurse integrates the devised strategies into the nursing care plan for the patient receiving drug therapy. These strategies are relevant to the physical act of drug administration and to patient and family education about drug therapy, an essential part of implementing any therapeutic plan. The nurse integrates the recognized interactions of the core drug knowledge and the core patient variables into this patient and family education. Thus, the education is specific to the drug therapy and specific to the patient's needs.

Core Drug Knowledge

The nurse has a crucial role in educating patients and their families about drug therapy. The goal of patient education is for the individual patient to understand the drug and its effects well enough to self-medicate safely and effectively and to monitor the **drug response** (i.e., the anticipated therapeutic and adverse effects). Basic drug therapy education should include the name of the drug, the reason the drug was prescribed (pharmacotherapeutics), the intended effect of the drug (pharmacodynamics), and important adverse effects that may occur and should be reported to the nurse or health care provider. If the patient will be taking the drug at home, he or she also needs to know when, how frequently, and for how long to take it; how to store it; and what to do if a dose is missed. In addition, the patient must be aware of any special concerns regarding other drugs or foods taken (drug interactions) and trained in any special techniques needed for self-administration of the drug to maximize therapeutic effects or minimize adverse effects. This information is obtained from the prescription and from the core drug knowledge of pharmacokinetics and pharmacodynamics.

Core Patient Variables

Any or all of the core patient variables may have a bearing on the educational needs of the patient or the family. Patient variables may affect which educational materials should be provided and the format or method of presentation.

Health Status

Education related to the core patient variable of health status includes information about those activities that must be performed while the patient receives the drug to maintain health or to detect early changes in health that are related to adverse effects of the drug. For example, there may be a need for periodic laboratory tests, such as monitoring levels of theophylline (a bronchodilator) or monitoring bleeding time in a patient receiving an anticoagulant. Periodic examination or assessment by a health care provider may also be required, for example, to monitor blood pressure when the patient is receiving antihypertensives.

The current health status of the patient must also be considered. The following are questions a nurse considers when designing a patient education program for drug therapy:

- Has any current disease or condition impaired any organ or system functioning, leaving the patient at risk for certain adverse effects? If so, information on these adverse effects should be emphasized during educational sessions.
- Does the patient have impaired vision that may prohibit reading drug labels or contribute to making errors, such as misreading the number "3" as a "5" in the instruction, "Take 3 times a day"? A vision problem may also indicate that educational material cannot be presented in written form to this patient.
- Does the patient have a hearing loss that may interfere with the comprehension of oral teaching?
- Does the patient have difficulty with small motor movements, perhaps because of arthritis in the hands? If so, difficulty in opening drug bottles may be a problem.
- Does the patient remember spoken conversations well? If not, written education may be effective. If memory loss is severe, adherence to the prescribed drug regimen may be difficult to achieve, and devices or systems developed to help the patient remember to take the correct drugs at the correct time may be indicated.
- Does the patient have the mental capacity to understand the information presented on drug therapy? If not, another person may have to be responsible for administering the drug to the patient.

Life Span and Gender

The life span variable becomes important when a drug therapy has the potential to produce adverse effects on a developing fetus. Women of childbearing age need to be educated not to become pregnant while taking certain drugs. Age is also an important consideration when determining a patient education approach. For example, drug education for a preschooler will most likely be directed to the parents, whereas education for an adolescent is directed so that the adolescent becomes an active partner in the educational process.

Lifestyle, Diet, and Habits

When planning patient education, consider lifestyle and behavioral changes the patient may need to make during drug therapy because of the action or adverse effect of the drug. For example, a patient taking narcotics for pain will be drowsy because the drug depresses the central nervous system. This patient is cautioned not to drive a car or operate potentially hazardous machinery while taking the drug. A patient receiving an antihistamine for an allergic reaction may also experience drowsiness as an adverse drug effect and should be similarly cautioned. Other lifestyle changes may be indicated, such as avoiding alcohol or cigarettes because they may alter a drug's effect. For example, cimetidine is less effective in decreasing gastric acid production in a patient who smokes cigarettes while taking this drug.

The patient's lifestyle determines the value placed on patient education. The nurse may consider the patient education information important, but if the patient does not share this view, the educational process will not be very effective. The nurse needs to determine what the patient wants to know about the drug and what the patient believes has the most significance for him or her. Ideally, the educational process begins with the nurse giving answers to the patient's questions, even if the nurse believes that other, unasked questions may be more important. Meeting the needs of the patient will increase the effectiveness of the education and promote receptivity to additional teaching at a later time.

The nurse must consider the patient's learning style when selecting an approach to patient education. Some people are visual learners, and the use of videotapes may be a better teaching medium for them than printed information. Other

Box1.4 PATIENT EDUCATION GUIDELINES

When preparing educational materials for patients receiving drug therapy, the nurse includes guidelines on the following:

- Drug name: generic and trade names
- Purpose of the drug
- Contraindication to taking the drug
- When to take the drug (time, frequency)
- Duration of treatment
- How to take the drug
- What to do if a dose is forgotten
- Special instructions related to lifestyle changes while on the drug
- Hazardous activities to avoid while on the drug
- Any dietary restrictions or additions
- Drug-food interactions
- Drug-drug interactions, including those that may result from over-the-counter drugs
- Adverse effects and instructions on what to do about them
- Special storage needs if applicable
- Special directions for drug disposal
- Therapeutic monitoring needed while taking the drug
- Periodic laboratory tests needed while taking the drug
- Precautions related to pregnancy or lactation
- Health care providers who should be notified about the drug therapy (e.g., dentist, by patient taking an anticoagulant)
- Advisability of carrying or wearing a drug alert card or medical identification
- Period of time drug remains active after discontinuing therapy

people need to be physically involved in their learning, and role-playing or demonstration and return demonstration may be better educational techniques for them.

When using written educational materials, the nurse must consider the patient's literacy level: Can the patient read and write in the language used in those materials? Written materials are appropriate for individuals who can read. However, they must be at the patient's reading level. If appropriate, standardized drug information sheets may be used. Many health care settings distribute these sheets for patient use. Additionally, some drug references are available that are designed to be photocopied and given to patients. If a standard information sheet is unavailable, the nurse can create one or simply write down instructions for taking the drugs along with a dosage schedule (Box 1.4).

Environment

Environment is an important consideration when educating a patient and family about drug therapy. The extent of teaching will vary, depending on the environment in which the patient receives the drug. Although some education is required regardless of the setting, more information is necessary if the patient will be taking the drug at home. These patients must know about all aspects of the drug so that its administration can be safely and effectively self-managed. If another person—family member or someone else—will be responsible for the patient's drug therapy at home, that person needs to be included in the educational process. It is also important to confirm that the patient will be able to adhere to the prescribed drug therapy in the home setting. Considerations for safe and effective home-based drug therapy are given in Box 1.5.

The physical properties of the home may also affect the patient education required; the home setup may increase the

Box 1.5 SAFE AND EFFECTIVE HOME-BASED DRUG THERAPY

Patient and Family Assessment

The nurse needs to assess the ability of the patient or responsible others to manage drug therapy safely at home, by considering:

- Ability to see and read labels
- Ability to remember dosage schedule
- Ability to open medication containers
- Ability to perform any special techniques required for drug administration

Home Assessment

The nurse also needs to assess the following aspects of the home environment:

- Safe storage areas for keeping medications out of the reach of small children who may live in or visit the patient's home
- Adequate refrigeration if the medication needs to be chilled
- Convenient and safe storage areas for equipment, particularly the equipment needed to administer medication (e.g., intravenous [IV] pumps and controllers, nebulizers)
- Adequate and secure disposal containers for medication or equipment

Tools Promoting Adherence and Safety

On the basis of the assessment, the nurse might provide or suggest one or more of the following to assist the patient or family in adherence to the prescribed drug therapy in a safe and effective manner:

- Clear, written instructions for medication administration
- Memory aids, such as a calendar, dosage chart with space to document that the dose was taken, setting a kitchen timer or a watch alarm to sound at the time medication is due, or a clock-faced picture with the appropriate medication doses identified at the correct times
- An organized, convenient system for accessing medication such as
  - Keeping all medication containers in a bowl, in a small box, or on a special shelf
  - Dispensing one day's medication in a pill box, a commercially available organizer, or the individual compartments of an empty egg carton
  - Numbering or color-coding drug containers if the patient has a reading or language problem
- An organized, convenient system for storing drug delivery equipment (syringes, alcohol wipes, transdermal patches, drug pumps, IV tubing, and so forth), such as a box, a plastic storage container with a snap-on lid, or clean, dry glass jars with screw tops
- An impervious, puncture-proof container with properly fitting lid for safe disposal of needles, syringes, and other equipment, such as coffee cans or plastic milk jugs

risk for injury or adverse effects from a drug. For example, if the home has scatter rugs, the patient needs to be educated about the increased risk for falls while receiving drug therapy that may cause an unsteady gait.

Culture and Inherited Traits

When educating the patient and family about drug therapy, the nurse needs to be sensitive to the patient's cultural frame of reference. A person's religious and ethnic background influences his or her beliefs about health, wellness, and the role of drug therapy in maintaining or restoring health. Cultural background may also influence communication patterns and determine the appropriate family member to be involved in educational sessions. Depending on the culture, this person may or may not be the patient. The patient's cultural background is neither right nor wrong. To provide effective education, the nurse must consider cultural issues and modify content or presentation accordingly. The nurse must adapt to meet the patient's needs. If it has been determined that the patient has a unique response to a particular drug therapy, then the patient education must also be individualized.

Evaluation

Like the nursing process, nursing management of drug therapy ends with evaluation. At the end of the established time frame for achieving an expected outcome, the nurse measures the patient's progress. Was the outcome or goal achieved? Was the nursing management effective? These two measurements are not the same. An outcome can be achieved despite an ineffective plan. For example, a patient may not have adverse effects from drug therapy despite the nurse's not thoroughly identifying actions to minimize adverse effects. Or the management may have been appropriate, although the goal was not achieved. For example, the patient may experience an adverse drug effect even though the nurse appropriately identified and implemented strategies to minimize adverse effects. In evaluating the effectiveness of drug therapy, one of the most important aspects to consider is whether the drug achieved the desired effect. For example, an antihypertensive drug is given to lower blood pressure. Did the blood pressure drop to a safe and normal range? If so, then the evaluation shows that drug therapy was effective.

If the patient does not achieve the expected outcomes, the nurse must reassess to identify the barriers to success. Perhaps the nurse missed an important interaction between the core drug knowledge and the core patient variables. Perhaps the nurse did not identify a core patient variable. Perhaps the teaching strategies used were not effective for this patient, and a different approach should be attempted. Perhaps the identified outcome is not appropriate for this patient, or the outcome may be appropriate but the time frame inadequate. Evaluation is not merely determining whether the goals were achieved or the management was effective. The evaluation must identify the reason behind any treatment failure and the steps to achieve desired results effectively.

CLINICAL PATHWAYS

Nursing management of drug therapy may be used in clinical pathways (also known as critical pathways). A clinical pathway is an interdisciplinary approach to care that establishes common protocols for patients with the same medical diagnoses. These pathways specify the responsibilities, actions, and time frame required of each discipline (e.g., nursing, medicine, physical therapy, pharmacy, respiratory therapy) to meet the objectives required to complete the care plan.

Clinical pathways provide a standard of care for all patients with the same diagnosis. The pathway accounts for the drugs ordered as a treatment for or response to a specific condition. For example, the clinical pathway for a patient with deep vein thrombosis (a blood clot) usually has drug therapy beginning with the anticoagulant heparin. After 3 to 4 days, the patient usually receives an oral anticoagulant, such as warfarin sodium, to lengthen the bleeding time and prevent blood clots from forming. When the patient's blood tests indicate that the oral anticoagulant is at a therapeutic level, heparin therapy stops. If the patient meets the requirements of the pathway in the time specified, the therapy is evaluated as effective.

Nursing management of drug therapy still occurs with the use of the clinical pathway. Clinical pathways are not substitutes for nursing assessment and judgment. Assessing core drug knowledge and core patient variables, identifying their significant interactions, developing strategies to maximize therapeutic effects and minimize adverse effects, and providing patient and family education not only form the basis of astute nursing care but also contribute to early identification of a patient at risk for "falling off" the clinical pathway. Early identification of the patient at risk alters plans of care, prevents complications, and minimizes additional inpatient days.

CHAPTER SUMMARY

- Core drug knowledge, which consists of basic pharmacologic facts about each drug, is composed of pharmacotherapeutics, pharmacokinetics, pharmacodynamics, contraindications and precautions, adverse effects, and drug interactions.
- Core patient variables are features that make a patient unique at any given time.
- The nurse determines which of the patient's core patient variables are relevant to a particular drug therapy. They include health status; life span and gender; lifestyle, diet, and habits; environment; and culture and inherited traits.
- The nurse determines which significant interactions will occur between the core drug knowledge and the core patient variables. The nurse then recommends strategies based on those interactions to maximize the therapeutic effect and minimize the adverse effects of drug therapy. The nurse integrates these strategies into a nursing plan of care. Patient and family education is also based on the interactions between core drug knowledge and core patient variables. This process is nursing management of drug therapy.

- A prototype drug is a drug that is representative of a class of drugs. Acquiring the core drug knowledge about the prototype provides the nurse with information about several other drugs in the same class as the prototype drug. Acquiring core drug knowledge organizes and simplifies learning about many different drugs.
- In providing nursing management of drug therapy, the steps of the nursing process are used. Nursing management of drug therapy occurs in all health care environments, including acute care, long-term care, and home and community settings.
- A thorough drug assessment provides the baseline information needed for effective nursing management of drug therapy. It includes the patient history, physical assessment, and examination of the medical record.
- Nursing diagnoses and outcomes are labels given to the identified interactions between core drug knowledge and core patient variables.
- Nursing diagnoses for patients receiving drug therapy reflect current or potential problems relevant to the therapy.
- Expected outcomes define the units of measure by which to gauge the effectiveness of drug therapy.
- Patient and family education is a crucial aspect of nursing management of drug therapy. Individualized education proceeds from the baseline core drug knowledge and core patient variables.
- Drug therapy is evaluated as effective if the desired effect of the drug occurs. The nurse also evaluates whether the management plan was effective. If conclusions drawn from the evaluation show that the drug effect or the management plan was not achieved, the nurse must determine why and then respond accordingly.
- An important goal of home-based drug therapy is for patients and caregivers to acquire the knowledge and skills needed to implement drug therapy safely and effectively. The nursing management of drug therapy must take the home setting into consideration. Education is structured so that patients and caregivers can assume maximal responsibility for administering and monitoring drug therapy safely and effectively.

QUESTIONS FOR STUDY AND REVIEW

1. How does the nurse assess core patient variables?
2. Why does the nurse need to assess the core drug knowledge of each drug a patient receives?
3. How does learning core drug knowledge about prototype drugs help the nurse?
4. How do the core patient variables affect the patient education that is provided?

Pharmaceuticals: Development, Safeguards, and Delivery

Learning Objectives

At the completion of this chapter the student will:

1. Identify key concepts relevant to nursing management in pharmacotherapy.
2. Compare and contrast the four main sources of drugs and biologic products.
3. Describe the differences in the ways that drugs are named.
4. Explain the significance of drug classifications.
5. Identify sources of drug information.
6. Describe the scope of nursing responsibilities related to pharmacology.
7. Discuss the application of the nursing process related to pharmacology.
8. Describe the intent, scope, and benefits of drug standards and legislation.
9. Identify several references and resources that list standards regulating drug development, distribution, and use.
10. Explain new drug development and the role of nurses in clinical trials.
11. Differentiate between over-the-counter and legend (prescription) drugs.
12. Discuss the significance of the 1970 Controlled Substance Act and its relationship to nursing practice.

What is a drug? By definition, a drug is any chemical that can affect living processes. Virtually all chemicals can be considered drugs because when given in large enough amounts, all chemicals will have some effect on life.

Drugs have been used throughout the ages, even in prehistoric times. The sciences of botany, physiology, quantitative chemistry, and gene mapping have enabled modern pharmacology to excel. Today, researchers examine rain forests and jungles for sources of new drugs to treat diseases. Scientists of the 21st century are able to develop new drugs through chemical synthesis, manipulation of enzymes and hormones, and genetic engineering, making pharmacology a complex science with a vast drug-manufacturing component. Highlights of advancements in pharmacology during the 20th century include the use of computer technology, which facilitates rational drug design and replaces some animal studies, and biotechnology, which permits the targeting of specific drug action and expands drug development procedures. One technique, receptor isolation, expands the potential for developing drugs with greater selectivity and reduced toxicity. Cell culture techniques permit the study of drug action at cellular and molecular levels. Immunochemistry leads to diagnosis that is more accurate and to the treatment of formerly untreatable diseases. The new drug classes that sometimes result from such advances in pharmacology provide novel means to treat and manage disease. Because pharmacotherapy is an integral piece of Western medicine, it is imperative that today's nurse understands the development, safeguards, and delivery of drugs.

SOURCES OF DRUGS

As we have learned more about drugs and how they affect the human body, pharmaceutical companies have focused on four sources of current drug products: plants, animals, synthetic chemicals, and genetically engineered chemicals.

Plants

Drug sources from the plant world date to primitive times. Common drugs from plants include digitalis (purple foxglove), morphine (opium poppy), and vincristine (periwinkle). Drugs that come from plants are classified according to their physical and chemical properties:

- *Alkaloids* (alkaline substances) react with body acids to form a salt, which is readily soluble in body fluids.
- *Glycosides* contain a carbohydrate or sugar molecule.
- *Gums* are mucilaginous secretions—usually polysaccharides—with the ability to attract and hold water.
- *Oils* are insoluble in water and are classified as volatile or fixed. Volatile oils, which are derived strictly from plants, evaporate when exposed to air. Fixed oils, also known as fatty oils, are derived from both animals and plants; their consistency varies with temperature.
- *Resins* are solid or semisolid, water insoluble, organic substances of vegetable origin that are commonly used as laxative or caustic agents.

Animals

Traditionally, drugs from animal sources include agents such as insulin, pituitary hormones, some vitamins, antibiotics, and biologic agents (such as vaccines and immune serums). Today, genetically engineered hormones (including insulin, pituitary hormone, and erythropoietin) are rapidly replacing animal-based drugs. The advantage of genetically engineered drugs is their purity. Because no foreign proteins are involved, they do not induce antibody production.

Synthetic Chemicals

Most drugs used today are either partially or wholly synthetic chemical compounds that have been produced in a laboratory. A partially synthetic agent contains a derivative of a natural substance combined with a pure chemical. An example is penicillin V, known as Pen-Vee K. The penicillin molecule, which is unstable in gastric acid, is modified so that it can be given orally. An advantage of synthetic drugs is that they are pure chemicals and, unlike drugs from a natural source, are unaffected by pharmacodynamic changes—namely, deterioration in potency and stability. Another advantage of synthetic agents is that they are usually less expensive to produce than drugs from a natural source.

Genetically Engineered Chemicals

Genetically engineered drugs are drugs developed with DNA technologies. The Human Genome Project's complete sequencing of the genetic code has ushered in a new era of "omics" technology, providing new strategies to diagnose, treat, and prevent disease. *Genomics* is the study and identification of genes and gene function. This new knowledge has enabled researchers to manipulate the chemical formulas of drugs to produce more specifically targeted drugs with fewer adverse effects. *Proteomics* is the study of protein structure and function. The term *proteome* describes the entire complement of proteins in a given biological organism or system at a given time (Wasinger et al., 1995). Proteomic technology is essential in biomarker discovery. A biomarker can be a substance that is introduced in an organism as a means to examine organ function—such as a radioactive isotope used to evaluate perfusion of heart muscle—to detect particular disease, or to indicate exposure to various environmental substances. In genetics, a biomarker is a fragment of DNA sequence that is associated with a specific disease. *Transcriptomics* is the study of the transcriptome, the complete set of RNA transcripts produced by the genome at any one time. Transcriptomics aids in understanding the development and differentiation of a cell or an organism as well as its adaptation to variable conditions. This information can be used when a single biomarker is not sufficient to differentiate between similar diseases. *Metabonomics* is the study of metabolic responses to drugs, environmental changes, and diseases. In pharmacotherapy, metabonomics can possibly predict an individual patient's response to drug treatment.

Pharmacogenomics is the application of the "omics" technology for the prediction of the sensitivity or resistance

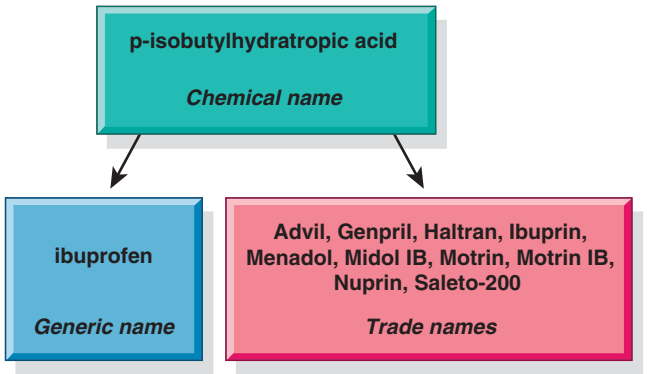
of an individual patient's disease to a specific drug or a group of drugs. **Pharmacogenetics** is the study of how genetic variables affect the pharmacodynamics of a drug in a specific patient. In the general population, 75% to 80% of people, known as extensive metabolizers, have genetic variations that do not affect drug metabolism. Ten percent to 15% of the population, referred to as poor metabolizers, have genetic variations that decrease their enzyme system's ability to metabolize certain drugs into their active form. This results in a poor response to the medication, even if the dose is increased. Ultrarapid metabolizers comprise 1% to 10% of the population. The enzyme system in these patients works rapidly, resulting in an increased concentration of the drug in the blood, which increases the potential for adverse effects.

Pharmacogenetic testing is a reality. Current testing is focused on substrates of the P-450 enzyme system. The importance of CYP enzymes in the metabolism of several antidepressant and antipsychotic drugs suggests that pharmacogenetic testing may aid in medication selection or dosing, resulting in maximal therapeutic effects and minimal adverse effects. Pharmacogenetic testing may be helpful in a variety of clinical situations, especially the management of cancer and HIV-positive patients. The future of pharmacogenetic testing will depend on economic and developmental considerations by the pharmaceutical industry.

The "omics" technologies have opened the door to the development of many drugs and treatments that had been only imagined in the past. These new technologies have the potential to identify drug targets, evaluate toxicity, classify diseases, evaluate formulations of specific drugs, assess drug response and treatments, and develop personalized medicines. The downside to drugs developed using these new technologies is the high cost of development, which is reflected in the high cost of the drug to the consumer.

DRUG NOMENCLATURE

All drugs are known by at least three names: a chemical name, a generic name (sometimes called the official name), and a trade name (Figure 2.1).



• FIGURE 2.1 A drug called by another name may still be the same drug. Nomenclature is a core feature of pharmacology. The three configurations illustrate various names for the same drug.

The **chemical name** of a drug precisely describes the drug's atomic and molecular structure, using exact chemical nomenclature (language) and terminology. The chemical name, which is usually long and complex, is not practical for everyday use but is useful to chemists and biochemists.

The **generic name** of a drug is also known as its nonproprietary name. Each drug has only one generic name, which identifies the drug's active ingredient. As a general rule, generic names are less complicated than the chemical names from which they are derived, but they are more complicated than trade names. Generic names are easily recognizable because the first letter of the name is typically not capitalized. In some cases, the prefix or suffix of the generic name may indicate the class of the drug. For example, the generic names of most beta-blocking agents end in "-olol." Similarly, the generic names of HMG-CoA reductase inhibitors have "-statin" as the suffix. The generic name of a drug also often serves as the drug's official name. The **United States Adopted Names Council** assigns an official name to each drug, as mandated by the United States government in 1962. These names are published in the ***United States Pharmacopeia*** and the ***National Formulary.***

The **trade name**, also known as a brand or proprietary name, is given to a drug by its manufacturer. Trade names, which are usually easy to say and remember, are protected by trademark. The symbol™ or ® after the trade name indicates that the drug molecule and name are registered by the drug manufacturer, and the use of the drug and its name are restricted to the drug's manufacturer. The manufacturer receives a 17-year patent on the drug, which provides an opportunity to recover part of the costs used in research, development, and testing of the drug. The trade name is easily recognizable because the first letter is capitalized and the™ or ® symbol may be present. Unless governed by patent protection, any drug can be marketed in different formulations and by multiple drug companies. Consequently, the number of trade names a drug has can be extensive.

Implications for Nurses

Name recognition is important in drug therapy. The nurse has the responsibility of accurately transcribing drug orders, administering the drugs correctly, and documenting the patient's response. Usually, a drug is ordered by the generic name because numerous brand names may exist for the same drug. Health care practitioners and prescribers typically order drugs by generic names to avoid confusion between brand names that look and sound alike. Examples of proprietary names that may cause confusion include:

- Serzone (nefazodone) for depression and Seroquel (quetiapine) for schizophrenia
- Lamictal (lamotrigine) for epilepsy, Lamisil (terbinafine) for nail infections, Ludiomil (maprotiline) for depression, and Lomotil (diphenoxylate) for diarrhea
- Taxotere (docetaxel) and Taxol (paclitaxel), both for chemotherapy

- Zantac (ranitidine) for heartburn, Zyrtec (cetirizine) for allergies, and Zyprexa (olanzapine) for mental conditions
- Celebrex (celecoxib) for arthritis and Celexa (citalopram) for depression.

To prevent an error when administering any drug, the nurse checks the drug name at least three times—before, during, and after obtaining the drug. If the names used for the order and those on the drug label are different (e.g., trade name and generic equivalent), the nurse must verify that the two names refer to the same drug before administering the drug.

To decrease the potential for medication errors, many hospitals have implemented a pharmacy bar-code system. When entering the hospital, the patient receives a bar-coded identification wristband that can transmit information to the hospital's computer. The nurse uses a bar-code scanner to scan the patient's wristband and the medications to be given. If the patient record and the medication do not match, a warning box appears on the computer screen. Despite the use of this system, the nurse should still triple-check all drugs prior to administration.

DRUG CLASSIFICATIONS (FAMILIES)

Drugs that share similar characteristics are classified as a pharmacologic group or family. Because thousands of drugs are available today, studying them as individual agents would be an overwhelming task. Fortunately, drugs can be systematically classified into a reasonable number of drug groups known as **drug classifications** (or drug classes).

Drugs that share similar characteristics can be classified in several ways: by chemical composition, physiologic effect (on body systems), and therapeutic uses or actions (clinical indications). For example, the **chemical composition** of a drug such as morphine sulfate describes its chemical base of opium. Morphine sulfate, therefore, is classified as an opiate or opioid. The **physiologic classification** of a drug describes its effects on body systems; therefore, morphine sulfate is classified as a central nervous system depressant. The **therapeutic classification** of a drug describes the drug by its use in therapy; therefore, morphine sulfate is also known as an opioid narcotic analgesic. Thus, any one drug may belong to more than one drug class (family), depending on the classification system being used.

SOURCES OF DRUG INFORMATION

Because pharmacology is a dynamic science, new drugs are continually being developed, and new uses for existing drugs are frequently discovered. Nurses need reliable and up-to-date drug reference information. Awareness of reliable resources and the specific type of information provided in those resources enables the nurse to be efficiently and completely informed about safe drug administration and new therapeutic developments. Many drug-oriented publications help fill the need of nurses, health care providers, pharmacists, and others for current and detailed drug information. To be fully informed in a clinical situation, the nurse may have to consult several references (Table 2.1).

TABLE 2.1 Sources of Drug Information

Resource	Features	Evaluation and Commentary
Official Pharmacopeia		
The United States Pharmacopeia (USP) and National Formulary (NF)	Drugs listed by official name Primary focus on sources, chemistry, physical properties of drugs; tests for identity, purity, and assay (measurement); and official storage requirements	• Federal Pure Food and Drug Act (1906) adopted USP and NF as official pharmacopeia • Published every 5 years with periodic supplements • Formerly listed drugs deleted and replaced by newer or better drugs, or drug listing removed after high incidence of toxicity reported • More useful as a drug reference to the pharmaceutical industry than to the nursing profession
Unofficial Compendia		
American Hospital Formulary Service (AHFS) Drug Information	Includes extensive drug information, particularly on drug classes Presents objective overviews of individual preparations of drugs available in the United States	• Published annually and updated with periodic supplements • Highly regarded drug reference
Facts and Comparisons	Provides concise but thorough monographs organized by drug class Begins each class section with a therapeutic overview, followed by additional sections organized by chemical classifications Offers comparisons of drugs (including over-the-counter [OTC] products)	• Updated monthly with supplemental entries • Available in print, online, or PDA format • Generally more usable than the Physician's Desk Reference (PDR) • Published by Facts and Comparisons, St. Louis, MO

SAFEGUARDS IN DRUG DEVELOPMENT, MANUFACTURE, AND DISTRIBUTION IN THE UNITED STATES

Most nurses administer drug therapy as part of their daily routine, and advanced practice nurses (such as nurse practitioners) may prescribe and dispense medications as well. Every state has its own Nurse Practice Act that fully describes nursing activities involving drug therapy. Nurses should be familiar with the Nurse Practice Act in their state because these acts define nurses' roles and responsibilities. Similarly, familiarity with governmental safeguards that promote drug safety, reliability, and uniformity helps nurses administer drug therapy safely and appropriately. These regulations help to ensure that commercially available drugs are safe and effective.

New drugs are being developed at an unprecedented rate. Any new drug that comes to market undergoes years of testing to determine the drug's pharmacologic properties and its potential for toxicity.

Standards for Drug Purity and Content

Since 1820, the ***United States Pharmacopeia*** (USP) has been the source for standards of strength, quality, purity, and preparation of medicinal compounds. In 1888, the American Pharmaceutical Association began publishing another resource, the ***National Formulary*** (NF), which expanded this effort to set national standards for drug quality. Before that time, there was little need for standard resources because of

the scarcity of effective drugs. In 1906, the Pure Food and Drug Act was passed, and the USP and NF compendiums became the official drug standards in the United States. Passage of the Pure Food and Drug Act in 1906 and the Food, Drug, and Cosmetic Act in 1938 protected the public from adulterated or mislabeled drugs and empowered the federal government to enforce these standards. The legislation required drug manufacturers to follow these standards to ensure that drugs were uniform, pure, and reliable. Later, amendments (1941–1945) to the Pure Food and Drug Act required that biologic products used as drugs (such as insulin and some antibiotics) be certified on a batch-by-batch basis by a government agency.

The USP is the current authoritative source for drug standards and is revised every 5 years by a group of experts in chemistry, microbiology, nursing, pharmaceutics, and pharmacology. Drugs are deleted when their clinical use shows unacceptably high toxicity or when newer, more effective agents are developed. Originally, the USP restricted its data to single drugs, and the NF was a reference for mixtures and formulas. Gradually, both reference books were expanded to include both single drugs and multiple-drug mixtures, and the two books have since been combined; the reference is now called the *United States Pharmacopeia–National Formulary*.

Legislation for Drug Safety and Efficacy

Federal legislation protects the public from drugs that are impure, toxic, ineffective, or not tested before marketing. The primary purpose of federal legislation is to ensure safety.

Pure Food and Drug Acts

The history of drug regulation reflects several medical and public health events. The **Pure Food and Drug Act of 1906** became law mostly because of revelations of unsanitary and unethical practices in the meatpacking industry and because of the many potent and dangerous drugs on the market. Although many of these drugs contained opioids (e.g., opium, morphine, or heroin), no law required the manufacturer to list the ingredients on the product label. In addition, the Pure Food and Drug Act designated the USP and NF as the official standards and empowered the federal government to enforce those standards.

The **Federal Food, Drug, and Cosmetics Act of 1938** (FFDCA) was enacted largely in response to a considerable number of deaths (more than 100) caused by the marketing of a drug called elixir of sulfanilamide, which was not adequately tested for safety before marketing. Elixir of sulfanilamide contained the solvent diethylene glycol, which investigations later revealed to be nephrotoxic. The FFDCA established the Food and Drug Administration (FDA) as the agency for monitoring and controlling drug manufacturing and marketing, allowed the FDA to prohibit the marketing of any drug judged to be incompletely tested or dangerous, and stipulated that drugs must be labeled. According to the FFDCA, the drug label must contain the following:

- No false or misleading statements
- The suggested dose and frequency of use
- The name and business address of the manufacturer/packer or distributor
- The amount of all dependency-producing drugs in a product and the statement, "Warning: May Be Habit Forming"
- The kind, quantity, and percentage of certain specified ingredients that could be harmful (e.g., drugs containing alcohol, atropine, or digitalis)
- Complete, understandable directions for safe use and warnings against unsafe use by children, pregnant women, and people with contraindicating pathologic conditions

Kefauver-Harris Amendment

In the early 1960s, a drug-related tragedy altered drug-testing methods and expanded the scope of legislation regulating drugs. Based on results of animal testing, the sedative drug thalidomide was marketed across Europe as a nontoxic hypnotic. Hundreds of pregnant women who took the drug gave birth to infants with phocomelia, a condition characterized by severely shortened, deformed, or missing limbs. Thalidomide was not a widespread problem in the United States because the drug had been withheld by the FDA. Nonetheless, some babies with thalidomide-associated deformities were born in the United States to women who used the drug after obtaining it outside the country.

The thalidomide tragedy was one of the events that led to substantial changes in how drugs are regulated in the United States: requirements for more extensive testing of new drugs for teratogenic effects, stipulations that manufacturers prove both drug safety and efficacy, and passage of the 1962 Kefauver-Harris Amendment to the 1938 FFDCA. The Kefauver-Harris Amendment tightened controls on drug safety, especially experimental drugs, stating that adverse reactions and contraindications must be cited and included in the literature. Additionally, the amendment ordered evaluation of the testing methods used by manufacturers, specified the process for withdrawal of approved drugs when safety and effectiveness were in doubt, and mandated the establishment of the clinical efficacy of new drugs before marketing. The law applied to both new and existing drugs. Furthermore, all drugs marketed between 1938 and 1962 were required to be tested for effectiveness to remain on the market. The Kefauver-Harris Amendment also authorized the FDA to establish official names for drugs, and in the early 1960s, the United States Adopted Names Council was established to ensure uniform drug nomenclature.

Procedure for Drug Development and Approval

Years of research and millions of dollars go into the development of a new drug. The first step in the development of a new drug is in the discovery or synthesis of a potential new drug

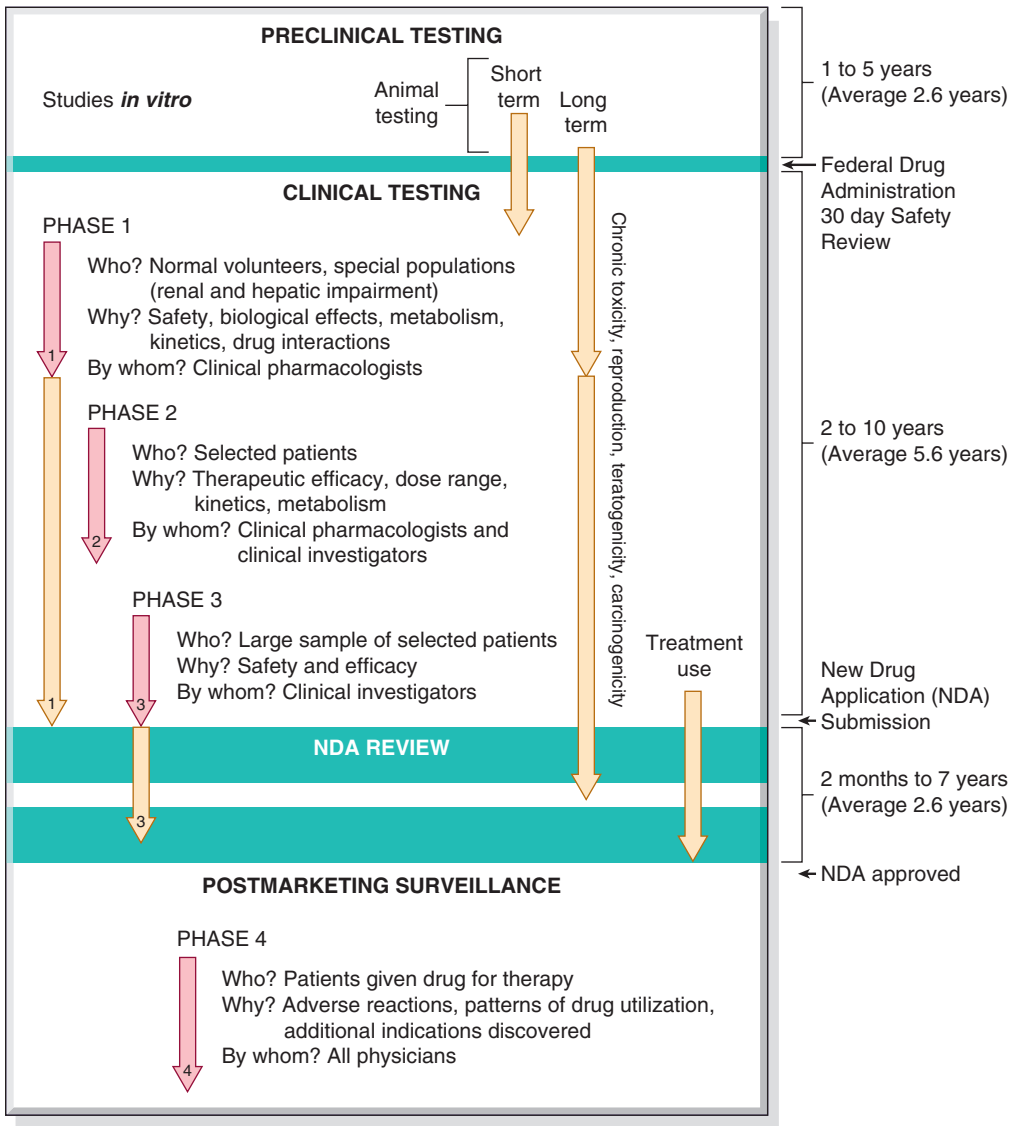
molecule. Once a potential new drug molecule is developed, it must be subjected to a battery of preclinical tests and clinical trials before it can be approved for use as a therapeutic agent. **Preclinical trials** are designed to provide basic safety, bioavailability, pharmacokinetic, and initial efficacy data about the drug and are carried out in animal subjects in the laboratory setting. Preclinical testing lasts approximately 3½ years. For every 1,000 compounds that enter laboratory testing, only one makes it to human testing.

Clinical Trials

At the conclusion of preclinical testing, the drug manufacturer submits the safety and effectiveness data from animal studies to the FDA in what is known as an investigational new drug (IND) application. The IND includes the following:

- All known information about the biologic, chemical, pharmacologic, and toxicologic properties of the new agent
- Precise details of how the drug is manufactured and storage requirements to preserve its stability
- The name and qualifications of each investigator who will participate in the clinical trial
- A signed affidavit by each investigator attesting that the study will be adequately supervised and that study volunteers have given informed consent
- Study protocols (guidelines) that clearly define how the drug is to be administered to study subjects (e.g., dose, route, duration) and what specific observations will be made during the clinical trial

If approved, the investigational new drug then undergoes clinical trials in humans. **Clinical trials** occur in four phases (I–IV) and may require from 5 to 9 years for completion (Figure 2.2). Phases I through III take place before a new drug is marketed. Phase IV testing is completed after marketing begins. Recently, the FDA has changed its policy to include women in early clinical trials (phases I and II), to determine whether differences in female physiology (e.g., menstrual cycle, menopause) influence pharmacotherapeutics, pharmacodynamics, and pharmacokinetics.



• FIGURE 2.2 Phases of Drug Development in the United States

Phase I

Phase I testing introduces the drug into humans. While most testing is done on healthy volunteers, some patients may also participate in phase I testing. The goal of this testing is to determine the metabolic and pharmacologic actions of the drug in humans as well as the adverse effects that occur with increasing doses, and, if possible, to gain early evidence of the drug's effectiveness. This information is used to design well-controlled, scientifically valid phase II studies. The Center for Drug Evaluation and Research (CDER) can prohibit the study drug from continuing to phase II testing for reasons of safety.

Phase II

Phase 2 studies are well-controlled, closely monitored, and conducted in a small cohort of several hundred people. The goal is to obtain some preliminary data on the effectiveness of the drug for a particular indication or indications in patients with the disease or condition. Results from the long-term animal studies are reviewed and compared with the human results—especially concerning the effects, if any, on fertility and reproduction.

Phase III

Phase III testing includes both controlled and uncontrolled trials. This widespread testing is also intended to uncover some infrequent or even rare adverse effects that sometimes affect only a small portion of the population. In this phase, several hundred to several thousand patient volunteers are enrolled in double-blind studies (studies in which neither the patient nor the researcher knows whether the drug or a placebo was given) and crossover-design studies (studies comparing the study drug with an existing drug). These studies are monitored closely to evaluate the safety and effectiveness of the drug.

Nurses are generally most involved in this phase of clinical trials and may be responsible for administering investigational drugs to patients. Patients must be fully informed about the potential risks and benefits associated with the intended study. One of the nurse's roles is to address how patients feel about the clinical trial, because these feelings may affect the quality and integrity of the investigation. Individual personal responses to an investigational drug may vary considerably. Some patients taking an investigational drug may believe that it is better than existing forms of therapy because it is new. These patients may have unrealistic expectations about the drug's usefulness or actions. Others may be more reluctant to participate in the study because they feel like "guinea pigs." Most patients tend to respond in a positive way to any therapeutic intervention by interested and caring health care personnel. This positive result is called the **placebo response** and may involve objective physiologic and biochemical changes as well as changes in subjective complaints (e.g., stomach upset, insomnia, sedation) associated with the disorder being treated. The placebo response occurs relatively consistently in 20% to 40% of patients in almost all studies.

If the drug proves safe and effective through the first three phases of the clinical trial, the manufacturer may then apply for a new drug application (NDA). All clinical data, as well as the earlier preclinical data, are reviewed by the FDA. Approval of the NDA means that the drug may be marketed. The FDA now requires analysis by gender in almost all NDAs. Research has identified pharmacokinetic differences between men and women that may be harmful to women if dosages are not adjusted accordingly. Because the distribution patterns of fat differ in men and women, many dosing schedules have been found to be excessive, and even harmful, in women.

Phase IV

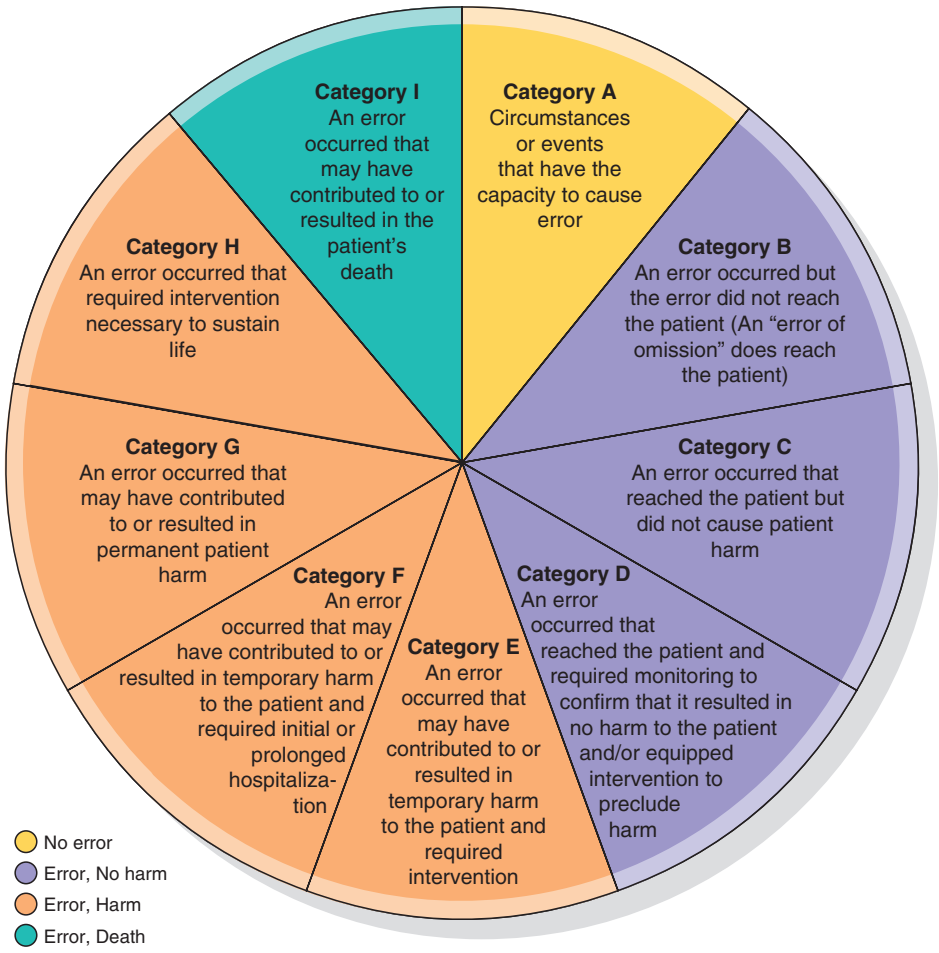
Once a drug goes on the market, the FDA conducts postmarketing surveillance to monitor the drug for safety and any new developments while it is in widespread distribution. If safety problems appear, the agency limits the drug's approved uses or removes the drug from the market. In addition to postmarketing surveillance, the FDA may direct the drug company to do additional clinical drug trials during phase IV, especially for those drugs approved on the fast track. Another area of considerable interest in this phase is the effect of the drug on elderly patients and children, because these groups are usually excluded from early clinical trials.

During phase IV, the pharmaceutical company that markets the drug keeps careful records on the results of therapy and must advise the FDA of any adverse effects and other effects on therapy. Occasionally, reports of toxicity occur with enough frequency that precautions for use are expanded and emphasized. For example, felbamate (Felbatol), a drug used to treat seizures, was found to cause aplastic anemia. Sometimes a drug is removed from the market because of serious side effects, as was the case with terfenadine (Seldane).

In recent years, the FDA and the USP have begun several programs to ensure adequate postmarketing surveillance of drugs. These programs rely heavily on health care practitioners, including nurses, pharmacists, and physicians, to report problems or suspected problems with drug products to the FDA or USP. Examples of these programs include MedWatch and the Practitioners' Reporting Network.

MEDWATCH

The MedWatch program, sponsored by the FDA, encourages voluntary reporting from health professionals and consumers about adverse effects from drug products or medical devices directly to the FDA by mail, electronic mail (*www.fda.gov/medwatch*), or fax. Suspicion that a medical product may be related to a serious event is sufficient cause for a health professional to submit a MedWatch report. The goals of MedWatch are to increase awareness of serious reactions caused by drugs or medical devices, to facilitate the reporting of adverse reactions, and to provide the health care community with regular feedback about product safety issues.



DEFINITIONS

Harm
Impairment of the physical, emotional, or psychological function or structure of the body and/or pain resulting therefrom.

Monitoring
To observe or record relevant physiological or psychological signs.

Intervention
May include change in therapy or active medical/surgical treatment.

Intervention Necessary to Sustain Life
Includes cardiovascular and respiratory support (e.g., CPR, defibrillation, intubation, etc).

PRACTITIONERS' REPORTING NETWORK

The **Practitioners' Reporting Network** sponsored by the USP involves four coordinated reporting programs:

- The USP Drug Product Problem Reporting Program specifically targets drug packaging and is dedicated to reporting problems with unclear labeling, defective packaging, poor product quality, suspected counterfeiting, or product tampering.
- The USP Drug Product Problem Reporting Program for Radiopharmaceuticals targets problems with adverse effects or quality of radioactive drugs.
- The Medication Errors Reporting Program looks for actual or potential medication errors that may involve labeling, packaging, miscalculations, or misinterpretation, as well as other problems in drug nomenclature, marketing, advertising, or use of abbreviations. To rank medication errors according to severity, the National Coordinating Council for Medication Error Reporting and Prevention developed the Medication Error Index to assist health care professionals in evaluating the extent of harm caused by an error (Figure 2.3).
- The Medical Device and Laboratory Product Problem Reporting Program looks at quality, performance, and safety of medical devices.

The Approval Process

Only about 10% of new drugs that begin clinical trials prove safe and effective enough to win regulatory approval. Approving a drug for therapeutic use involves a long, complex, and expensive process. On average, it takes 12 years and

Box2.1 STREAMLINING THE DRUG APPROVAL PROCESS

Because of the high cost of research and development, many new and promising drugs never become available for consumers, primarily because of money: Manufacturers project that not enough revenue will be generated by drug sales to cover the cost of drug development.

Orphan Drugs

The 1982 Orphan Drug Act provides certain tax benefits to companies that invest in drugs useful in the diagnosis, treatment, or prevention of rare diseases, termed **orphan drugs**. Other legislation defined these rare diseases as those affecting fewer than 1 of every 200,000 people in the United States or diseases that may affect more than 1 of every 200,000 people but with no reasonable expectation that the company will recover development costs from sales within the United States.

Treatment Investigational New Drugs (Compassionate Use Protocol)

This process allows an investigational drug to be administered to patients who are desperately ill but are not enrolled in its clinical trial. Drugs that qualify for a Treatment IND have demonstrated preliminary evidence of the drug's efficacy and the drug is intended to treat a serious or life-threatening illness or disease.

Accelerated Development/Review

This is a highly specialized mechanism for speeding the use of drugs that promise significant benefit over existing therapy for serious or life-threatening illnesses. The manufacturer must continue clinical testing after the drug is approved to provide proof that the drug provides therapeutic benefit to the patient.

Parallel Track

Under this policy, patients with AIDS whose condition prevents them from participating in controlled clinical trials can receive investigational drugs shown in preliminary studies to be promising.

$350 million for a new drug to be approved. The preclinical, clinical, and FDA review processes may be accelerated (fast-tracked) when an urgent need is perceived. In recent years, certain laws and protocols have been initiated to speed the drug approval process (Box 2.1).

Legislation to Promote Truth in Advertising

In 1912, Congress passed the Sherley Amendment to the 1906 Federal Pure Food and Drug Act, which prohibited drug manufacturers from making fraudulent therapeutic claims about their products. The FFDCA of 1938 bolstered this amendment by providing labeling requirements for the first time. Manufacturers were required to use standard drug nomenclature, and the presence and amount of certain potentially toxic drugs (including atropine, alcohol, or opiates) had to be disclosed. Directions for safe use and dosage had to be listed, and the manufacturer's or distributor's name had to be clearly marked. False or misleading statements were prohibited from appearing on the label.

Today, the Federal Trade Commission regulates the advertisement of medications aimed at the general public. The FDA regulates advertising of medications to medical personnel and relies on reports from practitioners and its own investigators to uncover abuses and fraud. Drug companies can be sanctioned for promoting the use of drugs in a manner that is not consistent with the agency-approved package insert.

The stated intent of the FDA is not to regulate medical practice but to guarantee the safety, purity, effectiveness, and reliability of drugs sold in the United States. However, the agency also aims to prevent manufacturers from promoting so-called off-label or unlabeled uses of drugs, in part to encourage the development of proper safety and efficacy data. Sanctions may also be imposed if a manufacturer advertises exaggerated claims of efficacy or reduced adverse effects in its product.

Legislation Regarding Controlled Substances

The Harrison Narcotic Law of 1914 legally defined the term *narcotic* and provided the first effective regulation regarding the manufacture and distribution of certain drugs known for their abuse potential, including cocaine, marijuana, and opium. The 1970 Comprehensive Drug Abuse Prevention and Control Act (also called the Controlled Substances Act, or CSA) established the Drug Enforcement Agency (DEA), formerly known as the Bureau of Narcotics and Dangerous Drugs (BNDD) of the United States Department of Justice, as the regulatory body responsible for the safe distribution and control of potentially addictive drugs. This act, which was designed to remedy the escalating problem of drug abuse, categorized and controlled drugs according to their abuse potential and medical usefulness on a scale of I to V, hence the term **controlled substance.** This act also defined the terms

CRITICAL THINKING SCENARIO

CANDIDATE FOR A NEW DRUG

Steve Smith has had AIDS for the past 10 years. He is being considered for treatment with a new drug during phase III clinical trials. Steve expresses concern about taking a new drug, especially in view of his declining health status and what he has heard about a shortened clinical evaluation process for AIDS drugs; he asks you, "What does the term 'new drug' mean?" What is your response?

TABLE 2.2 Schedule of Controlled Substances

Category	Abuse Potential	Dependance Liability	Examples	Rules Governing Prescription
C-I	High	Severe	Heroin, hashish, LSD, GHB	• No accepted medical use in the U.S. • There is a lack of accepted safety for use of the drug or other substance under medical supervision.
C-II	High	Severe	Amphetamines, some opioid narcotics (e.g., morphine, meperidine), dronabinol, short-acting barbiturates (e.g., pentobarbital, secobarbital)	• Requires tamper-proof prescription. • Telephone orders not accepted • Refills not allowed. Additional medication requires new prescription.
C-III	Moderate	Moderate	Some opioid narcotics (e.g., codeine, hydrocodone), some CNS stimulants, anabolic steroids	• A written or telephone order is acceptable. • May be refilled 5 times within 6 months from the date of issue • Prescription must be rewritten after 6 months or 5 refills.
C-IV	Low	Limited	Benzodiazepine anxiolytics, anticonvulsants, muscle relaxants, and sedatives; nonbenzodiazepine hypnotics and intermediate-acting barbiturates. Opioid narcotics such as propoxyphene or pentazocine	• Same as C-III drugs
C-V	Limited	Lowest	Antidiarrheal preparations with diphenoxylate and loperamide; small amounts of narcotics such as codeine used as antitussives	• Many of these drugs may be obtained without a prescription.

drug dependency and *drug addiction* and established education and treatment programs for drug abuse.

Under the CSA, five categories, known as schedules, were established, and controls were placed on prescribing, dispensing, and storing drugs in health care facilities according to the scheduled category (Table 2.2).

Drugs may be moved from one schedule category to another. For example, propoxyphene, which was originally assigned a C-V rank, was reassigned to the more restrictive C-IV category because of its popularity for misuse, abuse, and overdose. Tetrahydrocannabinol (THC, the active ingredient in marijuana)—ranked in the C-I category for many years—was moved to C-II because of its legitimate clinical use as a powerful antiemetic to relieve the adverse effects of cancer chemotherapy.

Nursing Management of Controlled Substances

The prescribing, dispensing, and storing of controlled substances is subject to considerably greater governmental control than the use of conventional prescription drugs. Procedures are precisely defined by law for virtually every step from manufacture to administration to wasting or discarding. Many hospitals use an automated system to electronically track the use of stock drugs, including controlled substances. In some health care environments, these automated systems are not used, and the nurse must document the administration of a narcotic on a narcotic log sheet. When using a narcotic log sheet, the nurse must document the following:

- Date and time of administration
- Drug name and dose
- Patient's name
- Prescriber's name
- Administering nurse's name

In a health care facility that does not use an automated system, stock supplies of narcotics must be kept in double-locked storage cabinets. Keys to the cabinet are restricted to licensed nurses, who are also responsible for the accurate accounting of all narcotics. The nurse finishing a shift and the nurse beginning a shift generally perform the narcotic count together to ensure an accurate account of all controlled substances.

The handling of controlled substances is a nursing responsibility that should never be taken lightly. Transfer of a C-II, C-III, or C-IV drug to anyone other than the person for whom it is prescribed is a crime. Violation of the CSA can result in a fine, imprisonment, or both. Any nurse who violates the CSA is also subject to loss of the nursing license and the right to practice nursing.

Legislation Regarding Drug Distribution

The Durham-Humphrey amendments (1952) to the 1938 FFDCA separated drugs for the first time into two major classifications: nonprescription drugs and prescription drugs.

Prescription drugs, also known as **legend drugs**, must be identified by the legend (inscription) on the container: "Caution: Federal law prohibits dispensing without a prescription." Containers of controlled substances must also display an additional warning label: "Caution: Federal law prohibits the transfer of this drug to any person other than the patient for whom it was prescribed." The Durham-Humphrey amendments further specify procedures for the distribution of prescription drugs. A prescription from a licensed practitioner is required before the drug can be dispensed, and refills are not permitted without authorization of the prescriber.

Labeling

Labeling, according to the USP, is the written, printed, or graphic matter affixed to an immediate container, package, or wrapper in which the medication is enclosed. Informational sheets that are not attached (such as patient information/instruction sheets) are not considered part of the label. The prescription label remains a primary source of information to patients about the proper use of their medications. Cautions regarding use and storage are usually on auxiliary labels, and some medications require their use. The following are examples of auxiliary labels:

- Avoid prolonged or excessive exposure to sunlight or sunlamp while taking this medication.
- Avoid the use of grapefruit juice with this product.
- Avoid the use of laxatives with this product.
- Do not take this drug if you are pregnant or suspect that you may be pregnant.
- Do not take with dairy products or antacids, or ingest these products within 1 hour before or 2 hours after taking this medication.
- Do not use past the expiration date.
- May cause drowsiness. Alcohol may intensify this effect. Use care when operating a car or dangerous machinery.
- Must be refrigerated/do not freeze.
- Take all of this medication/complete the full course of therapy.
- Take on empty stomach, at least 1 hour before or 2 hours after meals.
- Take with full glass of water.

Online Pharmacies

Consumers are increasingly going online to meet their prescription drug needs. While online pharmacies are convenient, they are not always safe. A recent analysis of 118 online pharmacies found that only 51 (43.2%) of them stated their precise location and that ninety-six (81.4%) did not require a medical prescription from the customer's physician (Orizio, 2009). Selling prescription drugs without a valid physician–patient relationship is a consumer health risk. For example, Ryan Haight, 18, died on February 12, 2001, after overdosing on Vicodin, which he had purchased from an Internet pharmacy without a prescription. H.R. 6353, The Ryan Haight Internet Pharmacy Consumer Protection Act of 2008 amends the Controlled Substances Act with respect to the sale of controlled substance drugs through the Internet. The overall effect of this law is to restrict the delivery, distribution, or dispensing of controlled substances by means of the Internet without a valid prescription obtained through a provider in a one-to-one in-person medical evaluation.

Nongovernmental Institutional Controls

Health care institutions, such as hospitals and skilled nursing facilities, may adopt additional regulations to ensure safe drug therapy and drug distribution. The Joint Commission for accreditation of hospitals and healthcare organizations is a watchdog group that provides the impetus for additional regulation. The Joint Commission sets the standards for quality of patient care and accreditation of health care institutions.

Generally, regulations to meet these standards of care for drug therapy vary greatly among institutions, but most guarantee that the therapy prescribed for any patient is continually reviewed for appropriateness, safety, and efficacy. Examples of these regulations include automatic discontinuation of antibiotic orders after 7 to 10 days of treatment or automatic discontinuation of narcotic or controlled substance orders after 48 to 72 hours. Institutional regulations exist to prevent prolonged, costly, and sometimes inappropriate administration of drugs. Development and implementation of such policies usually requires a collaborative effort among the nursing, pharmacy, and medical staffs.

EFFECT OF LEGAL AND INSTITUTIONAL CONTROLS ON NURSING MANAGEMENT OF DRUG THERAPY

Nurses need to be familiar not only with institutional protocols for safe and effective drug administration but also with official and professional regulations and laws. Drug laws and nurse practice acts vary from state to state, and these regulations define nursing responsibilities related to drug safety and effectiveness in patient care. Nurses must be familiar with the current regulations in their states and in their practice settings. Nurses can stay up to date by regularly consulting with representatives of regulatory bodies, arranging in-service training and information sessions, and understanding the policies of their own agencies.

In professional practice, nurses must adhere to and obey established drug control laws and protocols. They must avoid advising patients on the use of drugs, and they cannot provide drug therapy without proper authorization. Within the institution, nurses are responsible not only for drug security (to prevent unauthorized use or accidental loss) but also for the safe administration of drugs. Infraction of the laws and protocols that protect and promote patient safety may result in the loss of one's nursing license.

PATIENT EDUCATION AS A SAFEGUARD IN DRUG THERAPY

Educating patients is a key safeguard in drug therapy. Educating patients about drug therapy improves adherence to drug therapy and promotes therapeutic outcomes. In other words, patients who understand the prescribed drug regimen have the best chance of achieving the maximum benefit from it.

Patient education requires a nurse to have skills in gathering data, individualizing instructions, prompting and supporting the patient, and assessing and evaluating the pharmacotherapeutic response for determining patient outcomes. An effective patient teaching program parallels the nursing process—the nurse assesses the patient's learning needs, formulates a diagnosis, identifies a desired outcome, develops and implements a teaching plan, and evaluates the teaching and learning that have occurred. Strategies for enhancing patient education are given in Box 2.2.

Patient Learning Needs

Learning needs for drug education vary among patients, as does each patient's adherence to the prescribed treatment regimen. Some variations result from clinical factors, such as the nurse–patient relationship. Others are related to the scope or complexity of drug therapy in relation to pharmacotherapeutic, pharmacokinetic, and pharmacodynamic parameters; contraindications, precautions, and adverse effects of therapy; and the potential for drug interactions with undesired effects. Variations may also relate to core patient variables: health status (Box 2.3); life span and gender; lifestyle, diet, and habits; environment; and culture and inherited traits.

Teaching Focus and Content

Because each patient processes information differently, the nurse attempts to individualize and communicate information so that the patient or the caregiver can understand it and act on it appropriately. If possible, the nurse prepares written or audiovisual materials for the patient to consult as needed (see Chapter 1, Box 1.4).

Box 2.2 STRATEGIES FOR ENHANCING PATIENT EDUCATION

- Avoid jargon; communicate in short words and sentences.
- Include written information using diagrams and illustrations.
- Promote understanding with repetition and reinforcement.
- Relate new information to the patient's existing knowledge and previous experiences.
- Highlight and recap important information. Ask the patient to repeat the instructions or demonstrate new techniques.

Box2.3 ASSESSMENT: ANOTHER SAFEGUARD

To ensure the patient's safe adherence to drug therapy and to formulate an effective, relevant drug teaching plan, the nurse needs not only to assess the patient's learning needs, but also the patient's health history, asking about the following:

- Allergies or idiosyncratic reactions to drugs or foods
- Chronic conditions
- Drugs and other medications currently used (including vitamins, other supplements, and over-the-counter drugs)
- Pregnancy status now and future plans (for women of childbearing age)
- Use of alcohol, caffeine, nicotine, or illicit substances

Evaluating and Documenting Educational Outcomes

Evaluation and documentation of patient education include time of teaching, content of teaching, the patient's response to the teaching session, an evaluation of the patient's grasp of the subject matter, and an assessment of unmet or future learning needs. Like documentation of drug therapy and other nursing care, documentation of patient education activities becomes part of the clinical and legal record, serving as a reference for other health care professionals and helping guide future educational efforts.

Consumer Drug Information on the Internet

Patient education about drug therapy is particularly important in light of the explosive growth of the Internet, which has created countless opportunities for patients to access health-related information, products, and services. The Internet has forever changed the way many consumers obtain prescription drugs and health information. Opting for the convenience and privacy of the information-rich Internet, consumers have increasingly gone online for information on diseases and medications.

The quality of information provided on some Internet sites has become a concern for health care providers. Consumers may have difficulty recognizing the difference between accurate drug information and personal web pages that have biased opinions from nonmedical personnel. Because sites with the most accurate drug information frequently charge for their services, consumers may not be as likely to access these sites. Because information obtained from an Internet site may conflict with information provided by the health care provider, patients are counseled to discuss contradictory information they obtain from a website with the health care provider before changing a medication regimen.

IMPORTANCE OF NURSING MANAGEMENT OF DRUG THERAPY

The importance of pharmacotherapy in nursing practice continues to grow. Nurses are legally responsible for the drugs they administer and for safe drug administration. When

caring for patients with acute health problems, the nurse is the health care provider who usually administers drugs. This function becomes substantially more demanding as more new drugs enter the marketplace, multiple-drug therapies grow more complex, and drug delivery systems become more sophisticated. Safe drug administration requires a thorough understanding of therapeutic drug actions and adverse drug reactions.

In some clinical settings, nurses are allowed to modify drug regimens according to specifically designed protocols, and almost all states now allow advanced practice nurses to prescribe drugs. Future nursing practice will likely involve the prescribing of selected drugs.

Application of the nursing process to the pharmacologic aspects of patient care is especially important because long-term use of drug therapy is frequently necessary to control chronic disease processes. Nursing management in drug therapy may be considered an applied science because it relies on knowledge and principles from many different disciplines, such as anatomy and physiology, anthropology, biochemistry, mathematics, microbiology, organic chemistry, psychology, and sociology.

CHAPTER SUMMARY

- Sources of drugs include plants, animals, minerals, and chemical substances.
- Each drug is identified by at least three names, including the chemical name; the generic (nonproprietary) name, which is a contraction or shortening of the chemical name; and the trade or brand (proprietary) name. In the United States, official names are assigned by the government and are usually the same as the generic name.
- Drugs that share similar characteristics are classified in several ways: by clinical indications, effects on body systems, or chemical composition.
- Drug classifications (also known as families) emphasize common characteristics of each grouping, usually identify a prototype drug, and facilitate the association of new drugs within an established family as new drugs become available.
- Sources of drug information include pharmacopeias, which are official sources; compendiums, which are unofficial sources; product-insert literature from pharmaceutical firms; published reports; and findings in journals and electronic databases.
- The development and delivery of drugs are guided by federal legislation that is continually being updated.
- The approval process for a new drug is lengthy and expensive. It involves four phases of clinical trials.
- The FDA program MedWatch takes reports from health professionals and consumers about adverse reactions and disseminates information about those reactions as well as information about labeling changes and other safety issues.
- Educating patients is a key safeguard in drug therapy. The nurse implements strategies that optimize patient learning.

QUESTIONS FOR STUDY AND REVIEW

1. What is the purpose of the USP and the NF?
2. What is the purpose of the "omics" technologies?
3. How are drugs classified? What is the purpose of placing drugs in classifications?
4. Discuss the purpose and intent of government regulations, such as the Food, Drug, and Cosmetics Act, and the Durham-Humphrey amendments,. What safeguards do these laws provide?
5. Explain the purpose and extent of clinical trials. Identify some advantages and disadvantages to clinical trials.
6. What are controlled substances? What are some nursing implications related to administering a controlled substance? What special precautions are required for handling controlled substances?
7. Identify some points about safe drug use that should be taught to all patients.
8. What kinds of information about drugs should be included in the patient teaching plan?

Drug Administration

Learning Objectives

At the completion of this chapter the student will:

1. Describe the three routes for administering drugs.
2. Differentiate systemic and local effects related to the various routes of drug administration.
3. Describe the variety of oral forms of enteral drugs.
4. Differentiate the three main methods of parenteral drug administration.
5. Describe the methods of topical administration.
6. Describe how the route of administration interacts with core drug knowledge.
7. Describe how the route of administration interacts with the core patient variables.
8. Describe nursing interventions to maximize therapeutic and minimize adverse effects based on drug administration route.

Drug therapy can be administered by several different routes or methods. These routes of administration require different preparations or forms of a drug. Most drugs are available from the drug manufacturer in multiple forms. The selection of the route and form is based on the interaction between core drug knowledge and core patient variables. In managing drug therapy, nurses use this information to assess patient needs, plan care, administer drugs, and evaluate the effectiveness of therapy. This chapter describes the different routes of drug administration, explains the different forms of drug preparations, and shows how the route and drug form interact with the core drug knowledge and the core patient variables.

DRUG ADMINISTRATION ROUTES: GENERAL CONSIDERATIONS

The three basic routes of drug administration are enteral, parenteral, and topical. (Some authorities place topical in the parenteral category.)

- The **enteral route** uses the gastrointestinal (GI) tract for the ingestion and absorption of drugs. The most common method of administering drugs through the enteral route is orally. The enteral route also includes drugs that are administered through a nasogastric (NG) or a gastrostomy (G) tube.
- The **parenteral route** avoids or circumvents the GI tract and is associated with all forms of injections: intramuscular (IM), subcutaneous (SC or SQ), and intravenous (IV). Less commonly used parenteral routes than IM, SC, and IV are intradermal (into the dermis), intrathecal (into the cerebrospinal fluid), intra-articular (into a joint), and intra-arterial (into an artery).
- The **topical route** is technically another parenteral route because it also bypasses the GI tract. Drugs administered topically are applied to the skin or mucous membranes, including those of the eyes, ears, nose, vagina, rectum, and lungs.

Drugs are administered for their local or systemic effects. For example, most drugs applied topically to the skin or mucous membranes exert their effect at that site, which is called a **local effect.** An example is corticosteroid cream applied to relieve the itch from a rash. However, certain drugs given topically are absorbed by the skin and distributed throughout the body systems to produce a **systemic effect.** Drugs given for a systemic effect by any route must be capable of being transported into the blood and distributed through the body to a location distant from the administration site. An example is fentanyl, the narcotic used for pain relief, which is imbedded in a transdermal patch and applied to the skin.

Drugs administered by a route other than the enteral route have the advantage of avoiding the first-pass metabolism in the liver. Drugs administered enterally are absorbed from the stomach and small intestine. However, they first pass through the liver, the primary organ for drug metabolism, before being distributed throughout the body. Drugs administered parenterally and even some topical drugs are transported directly into the blood, thereby bypassing the liver. (See Chapter 4 for a complete discussion of the first-pass effect and the processes of pharmacokinetics.)

ENTERAL ROUTE AND FORMS

The enteral route involves using the GI tract for the administration and absorption of drugs. Enteral drugs, particularly oral drugs, are manufactured and prepared in a variety of forms, including solid tablets and capsules and liquid elixirs and syrups. Because the oral route of administration is the most common enteral route, oral dosage forms are the most common preparations. They are convenient, economical, and easy to use.

Some oral drugs, such as antacids and laxatives, are given for their local effect in the GI tract, but most are given to achieve a systemic effect. In most cases, patients can reliably self-medicate with oral drug forms.

Oral Drug Forms

Tablets

A **tablet** is a solid dosage form that is prepared by compressing or molding a drug into various sizes and shapes. In many cases, tablets are scored; that is, designed to be easily broken at a point so that one half or one quarter of the dose may be given. Unless a tablet is scored, it should never be broken because doing so could result in inaccurate dosage.

The active ingredients in tablets are commonly mixed with lactose or other sugars, binding agents, or other inert materials to facilitate manufacturing and ensure stability of the preparation. When the patient swallows the tablet, esophageal peristalsis propels it to the stomach, where it dissolves and releases the drug into the gastric contents.

Drugs that are appropriate for use in tablet form have some limitations. First, the drug must be stable in gastric contents. Because gastric juices may be highly acidic, drugs that rapidly degrade in acid environments may not be administered as conventional tablets. An additional consideration is flavor because the tablet will begin to dissolve as soon as it is placed in the mouth. Drugs determined by the pharmaceutical company to be bitter, irritating, or unpleasant tasting are not usually manufactured in conventional tablet form because they would be accepted poorly by patients. These limitations can be overcome by using a special coating on the tablet.

An **enteric coating** is a wax-like layer that is used on some tablets. This layer resists the acid environment of the stomach but dissolves in areas in which the local pH is neutral or slightly alkaline (e.g., the small intestine). Enteric coatings may be used to protect acid-labile drugs, to provide a sustained-release dose, or to guard against local adverse effects from a drug. Other types of commonly used coatings include film or sugar. Both of these coatings are used

to protect the patient from bitter or unpleasant-tasting drugs. These coatings do not impart any time-release characteristics.

Sustained-release (also called controlled-, timed-, extended-, or prolonged-release) tablets are formulated to release a drug slowly over an extended period, rather than rapidly like conventional tablets. Sustained release occurs by several methods:

- Layers of enteric coatings may be applied, and the drug is released in response to changes in the surrounding pH of the GI fluid.
- The tablet may be formulated to release the drug in a steady, controlled manner.
- The tablet may be formulated to release the drug in a series of pulsations.

In most cases, the total dose of drug in a sustained-release preparation is higher than that found in a regular tablet. The patient may safely take the higher dose because it is released in a controlled fashion, thereby preventing any adverse effects from overdosage.

Sublingual and Buccal Tablets

Sublingual and buccal preparations are tablet forms that are not used as often as oral tablets. These small, hard, compressed tablets are designed to dissolve rapidly in the vascular mucous membranes of the mouth. **Buccal** tablets are placed in the buccal pouch (between the cheek and gum), and **sublingual** tablets are placed under the tongue. Sublingual and buccal tablets must be relatively nonirritating, flavorless, and highly water soluble.

Because the buccal and sublingual areas are highly vascular, drugs are quickly absorbed into the bloodstream, and a rapid onset of drug effect occurs. At the same time, drugs administered in this way avoid the first-pass phenomenon because they are not ingested into the GI tract. Although these formulations typically are considered oral forms because they are placed in the mouth, most experts think of the sublingual and buccal forms as parenteral preparations because they are not absorbed in the GI tract. Others consider them a variation of the topical route.

Troches

Troches, also called pastilles or lozenges, are commonly used to achieve a local effect in the mouth or pharynx (throat). The drug is embedded in hard candy or another suitably flavored vehicle that the patient holds within the mouth, where it slowly dissolves. Antitussives, anti-infectives, local anesthetics, antihistamines, and analgesics are administered this way.

Capsules

Capsules are solid dosage forms in which the drug is usually encased in a shell of hard or soft gelatin. When the patient swallows the capsule, the drug is carried to the stomach, where the gelatin capsule quickly dissolves and releases the drug into the gastric contents. Because the active ingredients are enclosed in gelatin, foul-tasting drugs can be easily administered in capsules. Another advantage is that many patients find gelatin capsules easier to swallow than tablets. Unlike tablets, capsules cannot be easily divided or broken into equal pieces, so one disadvantage is that dosage may not be as flexible.

The most common capsules encase a powdered drug. Soft, elastic capsules are somewhat thicker and may be used to encase a drug paste, semiliquid, or liquid (provided the drug itself does not dissolve the capsule). In addition, the contents may be altered in one of several ways to produce a sustained-release dosage form as follows:

- Layers of enteric coatings may be applied to the drug particles, producing what is commonly known as microencapsulation. The drug is released in response to changes in the surrounding pH of the GI fluid. The rate of release is controlled by varying the thickness of the layers around the drug particles.
- The capsule may be formulated to release the drug in a steady, controlled manner from a matrix of drug encased in a slowly dissolving substance, such as wax.
- The drug is bound to ion-exchange resins, chemical compounds that form insoluble complexes within the capsule. Changes in the local environment, such as altered electrolyte content or pH, cause the drug to be released slowly from the resin matrix.

Like their tablet counterparts, sustained-release capsules may contain higher doses than those found in regular-release forms, but the patient may safely take the higher dose because the drug is released in a controlled fashion.

Syrups

A concentrated solution of sugar, such as sucrose, in water is known as a **syrup.** Most syrups that contain 65% or more sucrose are also resistant to mold, yeasts, and other microorganisms, and they have a reasonable shelf life with no need for refrigeration. Occasionally, sucrose may crystallize out of solution, clouding the syrup or giving it the appearance of particulate matter.

Elixirs

An **elixir** is a clear hydroalcoholic mixture that is usually sweetened or otherwise pleasantly flavored. Most elixirs contain ethanol and water, but glycerin, sorbitol, propylene glycol, flavoring agents, aspartase, and even syrups may also be found in elixirs. The alcohol content of elixirs varies greatly and can exceed 25%. Elixirs are stored at room temperature, and the alcohol content usually prevents the growth of any mold or other microorganisms. Elixirs should always be clear. Cloudiness indicates contamination.

Emulsions and Suspensions

Many drug preparations use mixtures of two chemically incompatible substances. These preparations may be administered orally. Rarely, they may be used topically.

An **emulsion** is created when two liquids that do not mix well are combined, and one liquid distributes uniformly

through the other. Because these mixtures tend to separate rapidly, remember to shake the preparation well immediately before measuring a dose and to administer the dose soon after pouring and measuring. To enhance the stability of the mixture, an emulsifying agent is added. Most emulsions consist of a nonaqueous agent (oil or lipid phase) dispersed with an aqueous (water) agent. In general, nothing should be added to emulsions because additives may adversely affect the stability of the mixture.

A **suspension** is a drug preparation consisting of two agents: a finely divided solid dispersed within a liquid. The stability of the preparation depends on the ability of the dispersing medium to wet the solid particles. Surface-active agents may be used.

Nasogastric or Gastrostomy Tube Forms

Patients who cannot swallow but who have a functioning GI tract may have an NG (nasogastric) or G (gastrostomy) tube in place. An NG tube is a soft, flexible tube that is advanced through a nostril and into the stomach for administering food, fluids, and drugs, usually for a short time. An NG tube presents a risk for aspiration from gastric reflux because the tube prevents the gastroesophageal sphincter from closing. A G tube is surgically inserted into the stomach for administering food, fluids, and drugs to patients who need long-term care. Sometimes a G tube is inserted via a procedure called a percutaneous endoscopic gastrostomy; these tubes are then referred to as PEG tubes. Providing drugs and foods through a G tube is preferred over an NG tube because the G tube method leaves the gastroesophageal sphincter intact. Regurgitation is less likely with a G tube than with an NG tube.

Drugs administered through a tube should be either liquid or crushed and in a liquid vehicle. A liquid drug form is preferred because research has shown that this form causes less clotting of tubes than crushed and dissolved drugs. However, if a liquid form is not available, the tablet may be crushed as long as it is not an enteric-coated or sustained-release preparation. Sustained-release or enteric-coated tablets are never crushed.

Nursing Management in Enteral Drug Administration

Core Drug Knowledge

Although the oral method of drug delivery is most common, not all drugs can be administered orally. Gastric acids and enzymes destroy many drugs; others simply may not be absorbed.

Absorption may begin in the stomach, but most absorption of orally administered drugs occurs in the small intestine. Food may interfere with the dissolution and absorption of certain drugs, especially enteric-coated drugs, because of the considerable variation in individual gastric emptying times and therefore in the length of time a drug spends in the stomach.

Assessment of Relevant Core Patient Variables

Health Status

A primary consideration for administering an oral drug is the patient's condition. Can the patient tolerate an oral drug? Patients who are vomiting, uncooperative, or unconscious or whose condition requires that they receive nothing by mouth (i.e., no oral food or fluid) are not suited for oral drug therapy. Alternate routes should be used. If the patient cannot swallow at all but has a working GI system, the drug may be given through an NG or a G tube. If patients can take oral drugs but have difficulty swallowing tablets, pills, and capsules, the drugs may be crushed and mixed in a few milliliters of water or liquid or in a tablespoon of jelly, applesauce, or pudding. Large volumes of fluid or food are avoided because the patient must consume the full volume to receive the full drug dose. Alternately, a liquid drug form may be substituted. Sublingual drugs may be administered even to unconscious patients because these drug forms are so rapidly absorbed by the vasculature.

Life Span and Gender

The high sugar content of syrups can mask unpleasant drug flavors, making syrups useful vehicles for administering drugs orally to both adults and children. Because they usually contain little or no alcohol, syrups are especially good vehicles for drugs administered to children. Because of the potentially high alcohol content, elixirs are usually not used in children or in adults who should avoid ethanol.

Environment

Oral drug forms are easily self-administered by patients and can be used in home environments and acute or long-term care settings.

Planning and Intervention

Maximizing Therapeutic Effects

Capsules with sustained-release pellets in them can be opened and the pellets sprinkled on food or mixed with a liquid; the patient must eat or drink all the food or fluid.

Because emulsions and suspensions have a tendency to separate, they should be shaken well immediately before measuring a dose and then administered promptly.

Drugs administered through an NG or G tube are instilled slowly without excessive force. Some may be allowed to flow in by gravity. The tube is flushed with 10 to 30 mL of water before and after drug administration to ensure that the patient receives the full dose and to maintain the patency of the tube.

Minimizing Adverse Effects

Drugs that have enteric coatings and drugs in sustained-release form should never be chewed, crushed, or broken. Doing so increases the risk for adverse effects, including toxicity, because a higher dosage of the drug is available all at once.

Repeated doses of sucrose-containing syrups may increase the risk for gingivitis or dental caries. Good oral hygiene should accompany the use of syrups. Also, patients

Box3.1 FIVE RIGHTS OF DRUG ADMINISTRATION

In managing drug therapy safely and effectively, the nurse must heed the five rights of drug administration:

right	Patient
right	Drug
right	Time
right	Dose
right	Route

with diabetes may need to monitor their glucose levels closely if they are receiving large doses of drugs in syrups.

Before administering drugs through an NG or G tube, the tube is assessed for proper placement. In addition, the head of the patient's bed is elevated to help prevent aspiration from reflux. If the patient is also receiving tube feedings, the nurse reviews information on the specific drug because some drugs are not absorbed well with tube-feeding formulas. When a tube-fed patient needs such a drug, the feeding must be shut off for a time both before and after drug administration.

To help maintain safety during drug administration, the nurse must closely follow the cardinal rules of drug administration (Box 3.1). These rules are known as the Five Rights; recently some authors have added a sixth right: documentation, and others have added a seventh: right reason for administration to improve patient safety. Adding additional "rights," however, provides no guarantee of increased patient safety from drug therapy. The Institute for Safe Medication Practices states that the five rights should only be considered as broadly stated goals or desired outcomes of safe medication practices. The five rights in themselves do not ensure medication safety. Neither do they offer procedural direction on how to achieve these goals. Most importantly they ignore the larger issues of interdisciplinary actions and the system problems which produce most medication errors (Institute for Safe Medication Practices, January 2007). The nurse assumes individual accountability for safe drug administration by engaging in behavior that follows nationally accepted standards of practice and institutionally prescribed behaviors designed to achieve the goals of the five rights. These accepted standards of practice include the following:

To administer a drug to "the right patient" the nurse should use two unique patient identifiers (such as the name and the patient history number, never the room number). To administer the "right drug," at the "right time" using the "right route," the nurse must be able to read and interpret the medication order correctly. Standard abbreviations are frequently used in medication orders (Table 3.1). The nurse must know these abbreviations. Some abbreviations are likely to be misinterpreted and cause medication errors, these should be avoided. (Joint Commission on Accreditation, 2005) (Table 3.2) Additionally, nurses need to confirm that every ordered drug is appropriate for

this person. Errors in listing the correct medications for a patient frequently occur as the patient moves between environments, such as from an intensive care unit to a general unit, or from the hospital to an extended care facility. For information on reducing errors related to changing environments, see Chapter 11.

To administer the "right dose," dosage calculation is often necessary. The most accurate method for doing dosage calculations is to use a calculator. Any drug dosage calculation book contains all of the necessary specific information. Many institutions require that all drug calculations be confirmed by two nurses before drug administration to prevent drug errors. Information about calculating pediatric doses is provided in Chapter 6. Occasionally, the nurse may need to convert the unit of measurement for the drug to another unit of measurement (Table 3.3).

PARENTERAL ROUTE

The parenteral route is associated with all forms of drugs administered by a syringe, needle, or catheter. The three most commonly used parenteral routes are intramuscular, subcutaneous, and intravenous.

Intramuscular Administration

The **intramuscular** (IM) technique involves injecting drugs into certain muscles. This method requires specific knowledge of anatomy and aseptic technique. Because muscles have a good blood supply, drugs that are injected into a muscle move directly into the bloodstream without having to be broken down and absorbed, as oral drugs processed by the GI tract must be. Thus, the onset of action with intramuscular injections is faster than with oral administration. Similarly, because muscles have more blood vessels than subcutaneous tissue, the onset of action after IM injection occurs more rapidly than after subcutaneous injection.

Drugs such as oils or irritating chemicals can be administered intramuscularly in solutions or suspensions. Many injectable drugs are dry powders and must be reconstituted before administration, possibly requiring a specific amount of diluent. Thin and watery solutions given intramuscularly move promptly into the blood vessels. Because suspensions or drugs with an oil base are thicker or more viscous than water-based solutions, they do not move as quickly into the blood vessels. With these oil-based suspensions, a deposit of the drug is formed within the muscle that is slowly released into the bloodstream.

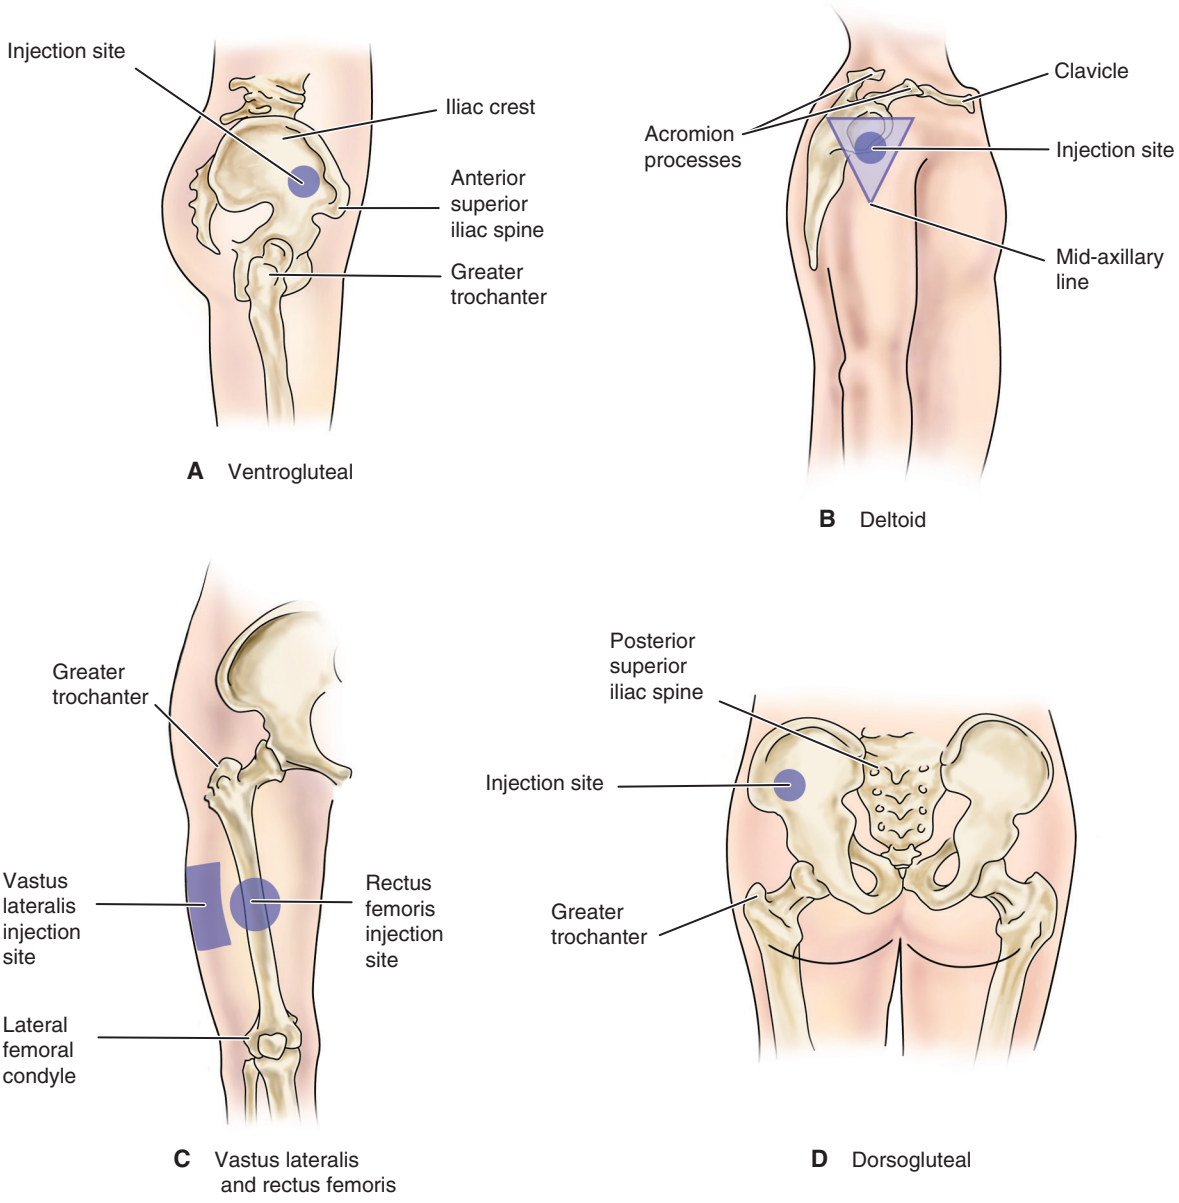
The sites for IM injection are the ventrogluteal, deltoid, rectus femoris, and vastus lateralis muscles (Figure 3.1). Site selection is based on characteristics of the drug, such as viscosity, and characteristics of the patient, such as age and size. While the dorsogluteal site was used frequently in the past, injection in the dorsogluteal site carries a risk for damaging the sciatic nerve if the injection site is not located properly. Many experts and nursing fundamental texts no longer recommend using this site, and some state that it should be used only as a last resort. For a number of years the ventrogluteal site has been the most recommended in the literature (as it is the safest deep muscle), but it continues to be the least used in practice (Floyd, S. & Meyer, A., 2007; Greenway, K., 2004; Nicoll, L. & Mesby, A., 2002; Roger, M. A. & King, L., 2000; Beyer, S. & Nichol, L., 1996). The ventrogluteal is free of major nerves and blood vessesls, can accommodate large volumes of medication, and all types of medications including highly viscous and irritating medications. So why have nurses been hesitant to utilize this site? Research indicates the reasons are diverse but include: insufficient teaching about site use during nursing education, lack of confidence in identifying the site, students imitating the practices of older nurses instead of practices taught in school, old habits, and lack of belief that it is safer than other sites (Floyd & Meyer, 2007).

The needle length chosen for injection should be long enough to enter the muscle, not the subcutaneous tissue. Patients who are overweight or obese may need longer needles than other patients to correctly place the medication (Zaybak, Gunes, Tamsel et al, 2007). Consult your nursing practice textbooks for more information on the specific techniques used for administering intramuscular injections.

Subcutaneous Administration

Subcutaneous (SC) drugs are administered under the skin into fat and connective tissue. These drugs must be highly soluble, low volume (less than 2 mL in a good-sized adult), and nonirritating (to prevent tissue damage, tissue necrosis, and sterile abscess formation). Distribution of the drug is through the capillaries and is less rapid than by the IM route. Distribution slows if the patient has inadequate peripheral circulation or if the drug is administered into scar tissue, which is avascular; onset will therefore be delayed.

The SC route may be used for vaccines, insulin, heparin, and narcotics. The sites used for this route are the upper, lateral arm; anterior thigh; abdomen; and midback above the scapula (although this last is infrequently utilized) (Figure 3.2). Not all medications given subcutaneously utilize all of these sites for administration. Correct administration into the subcutaneous tissue and not the muscle requires an assessment of the amount of subcutaneous tissue and correct needle



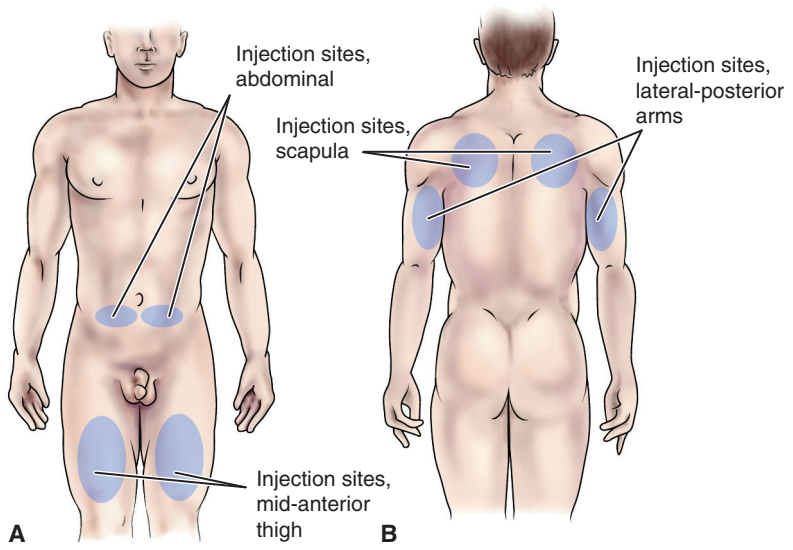
• FIGURE 3.1 Anatomic landmarks and intramuscular (IM) injection sites: (**A**) ventrogluteal; (**B**) deltoid; (**C**) vastus lateralis and rectus femoris; (**D**) dorsogluteal (site of last resort; use should be limited).

length selection (Annersten & Willman, 2005). The size of the individual determines the angle of injection. Refer to nursing practice textbooks to review SC injection techniques. Specific information on administration of special drugs, such as insulin and heparin, are included in the chapters on these drugs (Chapters 49 and 32, respectively).

Intravenous Administration

The **intravenous** technique administers a drug directly into the bloodstream, bypassing the need for absorption from the GI tract or transportation from other parts of the body, such as muscle or subcutaneous tissue. IV administration ensures prompt, sometimes immediate, onset of action and eliminates the uncertainty associated with varied absorption rates from other routes. The IV route is advantageous in that it

- Has immediate effect (e.g., nitroprusside lowers blood pressure in hypertensive crisis).
- Allows administration of a large volume of drug (e.g., with certain antibiotics, such as cefoxitin).
- Avoids tissue irritation or injury resulting from IM or SC administration (e.g., with chemotherapeutic drugs, vasopressors such as norepinephrine [Levophed], or cardiac glycosides such as digoxin [Lanoxin], because the blood buffers the drug).



• FIGURE 3.2 Subcutaneous (SC) injection sites: (**A**) anterior view: abdominal, mid-anterior thigh; (**B**) posterior view: scapula (infrequently used), lateral-posterior arms.

- Is acceptable when no other route is possible (e.g., in an unconscious patient).
- Circumvents impaired circulation.
- Has the potential for prolonged, continuous administration of solutions, such as lidocaine (Xylocaine) to control cardiac arrhythmias, which can be titrated (adjusted in small increments upward or downward) for the desired effect.

The IV route is also, however, one of the most dangerous routes. Once the drug has been given, it cannot be retrieved, nor can its distribution through the body be slowed or stopped.

Peripheral Drug Delivery

A peripheral vascular access device, usually an angiocatheter or a butterfly set, is placed to give drugs intravenously. Intravenous drug solutions may be run through tubing into the access device, either continually or intermittently.

Prescribed drugs may be given by continuous IV infusion to maintain a certain blood level of the drug. They are ordered either in volume (milliliters [mL]) per hour or strength (milligrams [mg], micrograms [mcg], or units [U]) per hour. Aminophylline, lidocaine, and heparin are examples of drugs that are given continuously to achieve maximum therapeutic effect. The rate of continuous infusion for drugs should be maintained by use of an IV pump or controller.

IV drugs may also be given intermittently. When the patient receives continuous IV fluids and is also receiving intermittent IV drug therapy, the drug is given through a secondary IV tubing or through a volumetric dose chamber administration set, also called a metered-dose infusion set. When a secondary IV tubing is used to administer an IV drug, the tubing is added to the main line tubing, usually at a Y port. Adding secondary tubing is called "piggybacking" because the tubing with the drug rides on top of the primary fluid tubing. Antibiotics are frequently given intermittently by **intravenous piggyback** (IV piggyback). Such drugs are diluted in a small volume of IV solution (usually 50 to 100 mL of sterile normal saline solution or 5% dextrose in water for an adult) and infused over 30 to 90 minutes (according to the specific drug). The main IV infusion then resumes at the original preset rate.

Volumetric-dose chamber administration sets connect to the main bag of IV fluid and are connected to IV tubing that in turn attaches to the peripheral venous access device. Volumetric-dose chamber administration sets can be used to run continuous infusions, in which fluid leaves the chamber and is replaced with fluid from the IV bag, or they can infuse only what is currently inside the chamber until manually refilled. When drugs are added to the chamber for infusion, the set is adjusted to infuse only what is in the chamber. When the drug is infused, the set may be returned to a continuous infusion, or refilled with only the main IV solution. These sets are primarily used when fluid restrictions are important, such as with pediatric, elderly, or critically ill patients. No matter the method, intermittent infusions of medications are, like continuous infusion, normally administered via an IV pump or controller.

Certain IV drugs, whether given by piggyback or through a metered-dose infusion set, may be incompatible with an existing continuous IV infusion. If this situation arises, the tubing should be flushed with 10 mL of an appropriate solution (usually sterile normal saline) before and after administration of the drug.

If intravenous drugs are prescribed intermittently, and other fluids are not running constantly, the access device is capped to prevent blood from coming out and bacteria from entering the body. This cap may be permanently attached to a small extension tubing set. This tubing is secured to the peripheral device. An access device equipped this way is called "locked," or the patient is said to have a "lock" in place.

Drug infusion locks are used for patients who require intermittent IV drugs but do not need continuous IV fluid

administration. As with piggybacks, the drug is usually diluted in 50 to 100 mL of solution. When the drug infusion is complete, the tubing is disconnected from the lock, allowing the patient increased ease of movement. The lock is kept patent (open, without blood clotting occurring), with small volumes of either normal saline (0.9% sodium chloride) solution or heparin pushed through the lock on a routine basis, usually every 8 hours. Depending on the solution that is used for flushing, the lock device is commonly called a saline lock or a heparin lock. Saline locks are flushed with 0.5 to 2 mL of sterile normal saline solution. Heparin locks are flushed with 10 to 100 U heparin. The nurse should be familiar with established institution protocols regarding the exact method for flushing drug infusion locks.

Direct administration into a vein or an established drug infusion lock of a concentrated drug in a very small amount of solution (usually 1 to 2 mL) is called an **intravenous push** (IVP or IV push). The drug is pushed into the vein very slowly over at least 1 minute. The exact amount of time depends on the drug and the dose. Drugs given by IVP may be used for intermittent dosing or for treating emergencies, such as cardiac arrest.

Central Access

Certain patients may require IV access for a prolonged time, or they may not be able to have peripheral vascular access devices inserted. Devices used for these patients include single or multilumen central venous catheters and implantable venous access ports. A central venous catheter is inserted by the health care provider into a vein (jugular or subclavian) near the heart. The catheter may have as many as three lumens to allow the administration of various solutions and drugs. Peripherally inserted central lines (PICs) or peripherally inserted midlines can be inserted by nurses specifically skilled in the technique. These also may be multilumen lines, and drugs may be delivered continuously, intermittently, or by IVP.

An implantable vascular access port (VAP) is surgically implanted under the skin with the distal end inserted into a large central vein. A special needle (a Huber needle) is used to suffuse the drug into the port. These ports are used for intermittent infusions of, for example, antineoplastic drugs. Use of a VAP requires advanced skills and expertise on the part of the nurse.

Other Parenteral Delivery Routes

Other parenteral routes are the intradermal, intra-articular, intra-arterial, and intrathecal routes. These routes of parenteral administration are not as common as the IM, SC, and IV routes.

Intradermal injections are made into the dermis just below the epidermis. This technique is used primarily for local anesthesia and for sensitivity tests, such as allergy and tuberculin tests. A small needle (25- or 27-gauge) and small-volume syringes (less than 1 mL) are used for intradermal injections. The most common sites for intradermal injections are the medial forearm and the back over the scapula because the skin is thinner there.

An **intra-articular** injection is performed only by a skilled practitioner and involves injecting a drug into a joint. Corticosteroids are typically administered by intra-articular injection to relieve pain in an acutely inflamed joint. The effect is local. Nurses do not commonly administer medications by this route.

Intra-arterial drug administration requires a surgeon to insert a catheter into an artery leading directly to the targeted treatment area. The drug is delivered under positive pressure through the catheter. The positive pressure overcomes the pressure within the arterial system. For example, powerful undiluted chemotherapeutic agents can be delivered directly to a tumor by way of the artery that feeds it. Intra-arterial ports can also be implanted by a surgeon.

In **intrathecal** administration, a drug is delivered into the cerebrospinal fluid. It may be administered directly into the spinal subarachnoid space (a spinal) or outside the subarachnoid space (an epidural). Drugs are introduced into these areas by a catheter placed by specially trained health care providers. The drugs most commonly administered by this route are local anesthetics, antibiotics, and radiographic contrast media. This route is commonly used to deliver an anesthetic during labor and delivery. Pain relief can also be achieved with drugs given via this route by the nurse or by the patient using a patient-controlled analgesia device.

Nursing Management in Parenteral Drug Administration

Parenteral administration may be selected for a variety of reasons. This route allows drugs to be distributed directly to the vascular system without having to be absorbed by the GI tract and sent to the liver before circulating. This route also avoids the erratic absorption associated with the movement of the drug through the GI tract. Drugs that are highly metabolized by the first-pass mechanism can be given in smaller doses when given parenterally rather than orally because the parenteral route presents more drug to the vascular system initially than the enteral route does. Some drugs are almost completely metabolized during the first pass, so the parenteral route is chosen exclusively for these drugs. Moreover, drugs that are rapidly destroyed by GI secretions can be given parenterally to promote their effectiveness. Parenteral routes may also be necessary because of the GI irritant nature of the drug. Drugs administered by the parenteral routes have a faster onset of action than those administered orally or topically.

Assessment of Relevant Core Patient Variables

Health Status

A parenteral route may be chosen because the patient cannot tolerate oral drugs, cannot swallow, or has a condition that warrants resting the GI tract or keeping it empty.

Muscle mass must be sufficient for the volume of a drug given intramuscularly. The gluteal muscle mass can deteriorate if the person does not walk (e.g., because of paralysis), and in such cases it should be avoided as a site for IM injections. The patient's veins must be able to accept a venous access device if drugs are to be given intravenously. When peripheral access devices cannot be inserted, central venous access devices may be used.

Life Span and Gender

Infants have small muscle mass. The largest muscle mass at birth is the vastus lateralis, which is the preferred site for IM injections in infants, although the rectus femoris may also be used. The deltoid is never used for IM injections in infants. The gluteal muscles develop with walking and usually are not used for injections until the child has been walking for 1 year.

Elderly people have decreased muscle mass overall and decreased tissue elasticity, which may result in drugs oozing from injection sites. Muscle mass must be determined before IM injections.

Lifestyle, Diet, and Habits

Parenteral forms of drugs are more expensive than oral forms. Parenteral administration requires specialized skills, equipment, and education. Placing IV access devices into peripheral veins may be difficult in patients who are IV substance abusers.

Environment

Patients, particularly diabetic patients who receive insulin, can be taught to give themselves SC injections at home. The techniques for IM injections can also be taught to patients and their families for home use, although this practice is not as common. IV administration of drugs usually occurs in an acute or a long-term care setting; however, it can also be performed in the home setting with a home health nurse administering the drug therapy.

Planning and Intervention

Maximizing Therapeutic Effects

Selecting the appropriate-sized syringe and needle is key to administering an IM or SC injection. Selection is based on the patient, the type of required injection, the administration site, and characteristics of the drug (how viscous, how irritating, and how much volume).

CRITICAL THINKING SCENARIO

CHOOSING THE RIGHT DRUG ADMINISTRATION SITE

Georgia Govans, 79 years old, is admitted with osteomyelitis of the hip, a severe infection, after a recent repair of a hip fracture. She has a temperature of 101°F (38.3°C) on admission and a history of severe peripheral vascular disease.

1. Which route will most likely be chosen to administer antibiotics to this patient?
2. Select and support a choice of drug delivery method based on the patient's history and her drug requirements.

A continuous IV drug infusion should be monitored to ensure that therapeutic blood levels are achieved and that drug therapy is effective. After administration of an intermittent IV drug, the lock must be flushed to maintain patency. If heparin is used to keep the lock patent, flushing the lock is usually necessary before drug infusion with sterile normal saline solution, and then again after the infusion before flushing with the heparin. Flushing is necessary because many drugs are incompatible with heparin.

Minimizing Adverse Effects

To minimize adverse effects and drug errors, the nurse follows the five rights of drug administration when administering parenteral drug therapy. To prevent infections, the drug, all parts of the syringe that have come into contact with the drug, and the shaft of the needle that enters the patient's body must be sterile. Meticulous administration technique is necessary because most parenteral drugs enter the bloodstream readily, quickly spreading any organisms introduced with the injection.

Site selection is important because incorrect placement of the needle may damage blood vessels or nerves. Knowledge of the muscles, visible or palpable anatomic landmarks, and location of major nerves and blood vessels in the underlying tissue is an absolute necessity for safe administration.

The oils and irritating chemicals found in the solutions or suspensions of some parenteral drugs may be dangerous if given intravenously. Care must be taken by careful site selection and aspiration before injection to prevent inadvertently administering an IM drug into a blood vessel.

To prevent bacterial growth, reconstituted drugs usually require refrigeration if they are not completely used after dilution. The reconstituted drug container must be labeled with the patient's name, dilution date, and volume and type of diluent used.

When administering drugs that are very irritating to the tissues, the nurse may use an injection technique known as the Z-track method to prevent the drug from seeping up from the muscle into the subcutaneous tissue. Subcutaneous tissue is displaced to one side before inserting the needle into the muscle. The drug is then injected, the needle is withdrawn, and the subcutaneous tissue is allowed to go back into place. Consult your nursing practice texts for more detailed information.

Patients receiving drugs with powerful effects on the body such as dopamine (which increases cardiac output), and heparin (an anticoagulant) by continuous IV infusion must be closely monitored. The adverse effects of these drugs can be serious or life threatening. The rate at which such drugs are administered must be regulated carefully by using an IV pump or controller. Newer forms of pumps have "smart" software that help prevent medication errors because they are programmed with the hospital defined dosing limits and other clinical advisories to help nurses remember the "rules" regarding safe administration of high risk drugs. If nurses bypass the safety technology imbedded in the pump then medication errors can still occur (Institute for

Safe Medication Practices, April 2007). Because the drug enters the bloodstream directly, blood levels of the drug can rise above desired therapeutic levels quickly. Blood levels, therefore, should be closely monitored.

TOPICAL ROUTE AND FORMS

The topical route of drug administration involves applying drug preparations to the skin or mucous membranes, including the eyes, ears, nose, rectum, vagina, and lungs. The primary advantage is that topical drugs usually act locally, although some can have systemic effects. A disadvantage of topical drugs is that most are intended for only one specific site. For example, ophthalmic drugs are used only in the eyes, and dermatologic drugs are used only on the skin. Drugs that can be administered in topical forms include antibiotics, antiseptics, antifungals, anti-inflammatory agents, antipyretics, vasodilators, hormones, antismoking agents, analgesics, antiemetics, and débriding agents.

The most common and widely used topical agents are applied to the skin. Dermatologic preparations come in several forms: lotions, creams, liquids, ointments, and emollients. Emollients are applied liberally to dry skin. Most drugs applied to the intact skin have primarily local effects because little drug is absorbed through the outer epidermis. Absorption increases under the following circumstances:

- The skin is abraded or denuded.
- The drug is added to a specific solvent because only lipid-soluble substances are absorbed through the intact skin.
- The medicated skin is covered by an occlusive dressing (e.g., in treatment for psoriasis).

Most dermatologic drugs are applied in a thin layer or in a measured amount (topical nitroglycerin is applied in inches). Single-dose, adhesive-backed drug applications, called transcutaneous or transdermal drug delivery systems, are currently available. Some examples of the transdermal drug delivery route include nitroglycerin (Nitro-Dur) for patients with coronary artery disease, scopolamine (Transderm-Scop) for patients who suffer from motion sickness, and fentanyl (Duragesic) for patients with severe pain. Although this drug form can be expensive, its ability to avoid first-pass effects is an advantage. The transdermal system is convenient and usually requires less frequent application than other forms.

Drugs administered to the eye take the form of drops or ointments that are applied to the rim of the lower lid. Drugs administered in the ear are in the form of drops. Drugs administered through the rectum are either in suppositories (waxy, bullet-shaped systems that dissolve in the body from body heat) or ointments. Drugs administered into the vagina are in the form of suppositories, creams, foams, liquids, or tablets (moistened before insertion to promote dissolving inside the body).

Drugs given into the nose are in liquid sprays, drops, or aerosol preparations. Inhalers, another form of aerosolized therapy, are used for respiratory conditions and have an effect on the lungs but are inhaled through mouth breathing. Patients should shake the inhaler well, exhale fully, and then inhale while pushing down on the inhaler to activate it. They should breathe in the puff of drug and hold the breath for several seconds before exhaling. The timing of this technique is difficult for many patients. The use of a spacer, which acts as a reservoir for the drug, is helpful for many patients. The patient activates the inhaler, and the drug enters the spacer. The patient then breathes in from the spacer. If multiple puffs of the inhaler are ordered, the patient should wait 1 to 2 minutes between puffs. The inhaler and the patient's mouth should be rinsed after drug administration.

Nursing Management in Topical Drug Administration

Assessment of Relevant Core Patient Variables

For the most part, assessment involves inspecting the skin for integrity. If the skin is not intact, aseptic technique becomes an important factor in infection control.

Planning and Intervention

To maximize therapeutic effects and minimize adverse effects, the nurse should wear gloves or use an applicator when administering dermatologic drugs, to avoid infecting the patient and to protect his or her own skin from the drug. If the skin is broken, the nurse needs to use sterile technique when applying a dermatologic drug to prevent introducing bacteria and other organisms into the body. If an adverse effect occurs with drugs given by a transdermal system, removing the patch usually relieves the symptoms.

To promote safe administration of topical drugs, the nurse must again observe the five rights of drug administration (see Box 3.1).

CHAPTER SUMMARY

- The three routes of drug administration are enteral, parenteral, and topical.
- The drug route may produce systemic effects, local effects, or both.
- Oral drugs may be available in sustained-release or enteric-coated form to delay onset of action of the drug.
- Food, fluids, and other drugs may alter the absorption of enteric drugs.
- The parenteral route avoids the GI tract and the irregularities of absorption, including the first-pass effect. The most common methods of parenteral drug administration are the IM, SC, and IV routes.
- Onset of drug action is more rapid with the parenteral than with the enteral route.
- Patient characteristics (age, weight, muscle mass) and drug characteristics (volume, viscosity, irritability) are considered when selecting a site for IM drug administration.
- Administration of IV drugs may be through continuous drip, intermittent infusion, or IVP methods into peripheral

or central venous access devices. IV drugs are normally administered via a pump or controller to maintain a steady, safe rate of drug delivery.
- Topical drugs include those that are applied to the skin and mucous membranes of the eyes, ears, nose, rectum, and vagina.

QUESTIONS FOR STUDY AND REVIEW

1. Which route of drug administration is most frequently used?
2. What is the advantage of an enteric-coated tablet?
3. Why might a parenteral route of a drug be prescribed instead of an enteral route?
4. Which parenteral technique poses the greatest risk for rapid drug toxicity to a patient?

Pharmacotherapeutics, Pharmacokinetics, and Pharmacodynamics

Learning Objectives

At the completion of this chapter the student will:

1. Define pharmacotherapeutics, pharmacokinetics, and pharmacodynamics.
2. Describe the processes used as drugs move throughout the body.
3. Understand how the chemical makeup of a drug and the internal chemistry of the body affect a drug's ability to cross cell membranes.
4. Identify factors that affect absorption of drug molecules.
5. Describe factors that influence the distribution of drug molecules.
6. Discuss factors that may alter metabolism.
7. Identify how drug molecules are excreted from the body.
8. Identify the main mechanism drugs use to produce their effects on the body.
9. Describe the variables that influence the dose of a drug that is administered.

The nurses' role in drug therapy involves more than passing the appropriately ordered drug to the right patient. The nurse must understand how drug therapy creates its effects in the body (both positive and negative) and be able to critically assess the patient's response to drug therapy. In order to do this, the nurse needs to know basic pharmacologic facts. These facts make up the Core Drug Knowledge related to a particular drug. As in all bodies of knowledge, there is a "language" of words that is specific to pharmacology and drug therapy. The nurse needs to understand this language and be able to correctly use the words in order to read and interpret written drug material and scholarly articles as well as to clearly communicate with pharmacists, physicians, and other health professionals about drug therapy. This chapter examines the pharmacotherapeutics, pharmacokinetics, and pharmacodynamics in Core Drug Knowledge; it is the basis, along with Chapter 5, for understanding all of the drug information presented in the rest of the text.

PHARMACOTHERAPEUTICS

Pharmacotherapeutics is the achievement of the desired therapeutic goal from drug therapy. Essentially, it is the clinical purpose—the indication—for giving a drug. The terms *indications* and *therapeutics* are often substituted for the more formal term *pharmacotherapeutics*. For example, when a person has hypertension, we give drugs to lower the blood pressure to a normal level. In this way we treat, or manage, a chronic condition. The desired pharmacotherapeutics can also be used to induce a cure. For example, when a patient has a bacterial infection, we give an antibiotic that kills the infecting organism. The desired therapeutic effect of a drug can also be to prevent a problem. An example of this type of use is when a patient has had total joint replacement surgery. Because this procedure increases the patient's risk for developing a thrombus (blood clot), drug therapy with anticoagulants is used to prevent this undesirable outcome. Whatever the clinical or medical reason is for prescribing a drug, the pharmacotherapeutics is the desired outcome of administering that drug.

Generally, the pharmacotherapeutics of a drug is determined through clinical drug trials. Findings from these studies are submitted to the governmental agency that oversees approval of new drugs. In the United States, this agency is the Food and Drug Administration (FDA). If the clinical studies indicate that the effect a drug has on the desired outcomes of treatment is statistically significantly better than that achieved by a placebo (an inactive substance), the drug is approved for a particular indication or indications. This information is included when labeling the drug and in printed material about the drug. (For more information on clinical trials see Chapter 2)

After a drug is approved, however, it may be legally prescribed for a use that is not indicated on the label (referred to as **off label use**), if the prescriber believes it to be of benefit. Many "off label" uses of drugs are based on the findings of additional research studies that are performed and reported in the professional literature. Case reports published in the literature may also support off-label uses of a drug. Off label uses may become standard pharmacotherapeutic uses of a drug. The official drug label is modified only if the drug company goes back to the FDA with additional information and requests that a new pharmacotherapeutic indication be added. After an official review, the FDA may decide to alter the drug label. Because this process can be lengthy and expensive for the drug company, the company may not seek relabeling, even if the drug is commonly used in practice in this way. Nurses should not be overly concerned about off-label uses as long as the literature supports such use or the prescriber can explain why this drug is being used for a patient who does not have a condition for which the drug is indicated. Nurses do need to question all orders if the intended pharmacotherapeutics of a drug does not correlate with the patient's reason for receiving drug therapy. Such questions are necessary to help prevent medication errors in which the wrong drug has been prescribed. Nurses are also legally responsible for understanding the pharmacotherapeutics of all drugs that they administer.

PHARMACOKINETICS

Pharmacokinetics is the movement of the drug particles inside the body and the processes that occur during this movement. In general, pharmacokinetics is the effect of the body on the drug. Pharmacokinetics is made up of four phases: absorption, distribution, metabolism, and excretion. **Absorption** is the movement of the drug from the site of administration into the bloodstream. **Distribution** is movement of the drug through the bloodstream, into the tissues, and eventually into the cells. **Metabolism** is the conversion of the drug into another substance or substances. **Excretion** is the removal of the drug, or what the drug became after metabolism, from the body. The effects from metabolism and excretion of the drug together are technically referred to as elimination; however, in practice most clinicians use the term elimination in place of excretion.

Drug molecules move during all phases of pharmacokinetics. To move throughout the body, the drug must cross membranes. Cells in most membranes are very close together, without much space between the cells. The membrane of the cell itself is made up mostly of lipid molecules. Drugs cross cell membranes in one of three ways. First, they can pass between the spaces or channels between the molecules in the membrane. Drug molecules can only cross a cell membrane this way if they are very small. Second, drugs can pass through the membrane with the help of a transport system. This method may or may not require the use of energy. Third, drugs can penetrate the membrane directly. To be able to penetrate the membrane, the drug must be lipophilic (soluble in lipids). Direct penetration is the method used by most drugs to cross the cell membrane.

The chemistry of the drug particles will also affect the movement of particles throughout the body. A drug particle is a molecule formed from different elements; the electrons are shared between the atoms in the molecule. In some drug

molecules, although the elements are bound together, the positive charges (protons) and the negative charges (electrons) are grouped away from each other. These charged molecules are termed polar molecules. Although the charge in polar molecules is unevenly distributed (a region of the molecule is negatively charged and another region is positively charged), such molecules have an equal number of positive and negative charges, so that they have no net charge. Polar molecules are hydrophilic (soluble in water), not lipophilic. Therefore, polar drug molecules are not able to penetrate cell membranes. Nonpolar molecules are lipophilic; therefore, nonpolar molecules are able to penetrate cell membranes.

Ions are molecules that carry a net charge (either positive or negative). Very small ions move through the channels on the cell membranes (the spaces between molecules). Other ions do not cross the cell membrane. Some molecules that normally do not carry a charge can be induced to carry a charge, depending on their environment. The process of inducing a molecule to carry a charge is called ionization because ions have a net charge. Acids give up a positive charge in a basic (alkaline) environment. Bases accept a positive charge in an acidic environment. Movement of molecules through a membrane occurs as long as the environment does not cause the molecules to ionize (i.e., become charged molecules). For most molecules, once they have become ionized they cannot pass through the cell membrane. If the environment promotes ionization, movement through the membrane stops. When the pH on either side of a membrane differs, drug molecules tend to move to the side where ionization will occur. Once the molecules become ionized they cannot move back through the membrane. This process is termed ion trapping or pH portioning. Altering the pH on one side of a membrane thus alters the movement of the drug molecules.

Absorption

Several variables affect the completeness and rate of drug absorption. The completeness of absorption is the portion of the drug that is absorbed. Drugs given orally may not be completely absorbed because of other drugs or food that the patient is ingesting. The rate of absorption of a drug depends on the route of administration. The rate of absorption is also affected by the speed at which the drug dissolves, known as the rate of dissolution.

- Drugs that are administered orally generally take the longest to be absorbed because they must be broken down into small particles before they can move into the bloodstream. The presence of other drugs or food may also impair the rate of oral drug absorption.
- Drugs given parenterally are already dissolved and in a liquid form and therefore are absorbed more rapidly than drugs given orally.
- Drugs that are administered subcutaneously or intramuscularly are absorbed into the small capillaries fairly rapidly. Intramuscular absorption is somewhat more rapid than subcutaneous absorption.
- Drugs that are administered intravenously are placed directly into the bloodstream and are not technically absorbed, although some sources refer to intravenous drugs as being instantly absorbed.

Large surface areas increase the rate of absorption. Drugs administered orally are thus absorbed primarily in the small intestine, which has a larger surface area than the stomach, although some absorption occurs in the stomach. Blood flow also affects the rate of absorption—the greater the volume of blood flow, the faster the rate of absorption. Absorption speeds up with increased blood flow because increased flow carries more absorbed drug molecules away into the general circulation; in its place is blood without any particles of drug. Thus, the high concentration of drug moves into the blood where there is a low concentration of drug. Patients who have impaired circulatory systems absorb drugs less rapidly than those with normally functioning systems. Lipid solubility also alters absorption. Drugs that are more lipid soluble usually are absorbed more rapidly than others because they can cross the lipid cell membranes easily. Finally, when pH differences between the site of administration and the plasma favor the drug molecules becoming ionized in the plasma, absorption is more rapid than when the molecules do not become ionized.

Finally, the physiologic condition of the patient affects drug absorption. Core patient variables that affect drug absorption are summarized in Box 4.1.

Distribution

The distribution of a drug throughout the body depends on three factors: blood flow to the tissues, the drug's ability to leave the blood, and the drug's ability to enter cells.

Once a drug is absorbed, it is transported to the tissues and cells through the circulatory system. In healthy individuals, all tissues are well perfused; thus, drug molecules can easily be distributed throughout the body. However, pathophysiologic changes in the vascular system (such as narrowed, stiff, or occluded vessels) impair the distribution of drug molecules. This impairment may or may not affect distribution enough to decrease the therapeutic effect of the drug. For example, in a patient with peripheral vascular disease, circulation to the heart is not usually greatly impaired, although circulation to the legs and feet is. In this patient, a drug given for an altered cardiac rhythm may not be distributed well into the tissues in the legs, but plenty of drug molecules reach the heart, so that the drug is capable of achieving the desired pharmacotherapeutic effect. However, a drug given to treat cellulitis of the foot may not have adequate distribution to achieve the desired pharmacotherapeutic effect because of the impaired circulation in the lower extremities.

Some tissues have little or no blood supply. Scar tissue is avascular, and adipose (fat) tissue has a poor blood supply. Two types of pathologic conditions—abscesses (pus-filled pockets surrounded by normal tissue) and solid tumors—have very limited blood supply, especially to their centers. Because drug therapy does not distribute well to these areas,

Box 4.1 DRUG ABSORPTION AND CORE PATIENT VARIABLES

Health Status

- Any change in health status related to circulation, condition of the GI tract, or pH of body fluids (e.g., disease, trauma, strenuous physical exercise, or drug therapy) can reduce drug absorption. The condition of the gastric and intestinal surfaces affects oral drug absorption.
- Contact time, surface area of contact, and the condition of the absorptive surface may increase or decrease the amount of drug absorbed. For example:
  - Large surfaces (e.g., pulmonary alveolar epithelium, intestinal mucosa) absorb drugs rapidly.
  - Decreased absorptive surface from damage (e.g., radiation), disease (e.g., inflammatory bowel disease), or surgery (e.g., surgically shortened intestine) lessens drug absorption.
- Absorption from the GI tract depends on factors such as gastric volume, GI pH, gastric emptying time, intestinal transit rate, gastric motility, and GI enzyme levels.
  - Delayed transport from the stomach to the intestine (e.g., food in the stomach) will dilute the drug and increase the contact time by slowing gastric emptying.
  - Decreased GI motility (e.g., constipation) permits increased drug contact time with the GI mucosa, enhances drug dissolution, and allows extra time for absorption, which may lead to increased drug effects and toxicity.
  - Increased intestinal motility (e.g., diarrhea), will move a drug very quickly through the GI tract, reducing the amount of time the drug remains in contact with the GI mucosa and impairing drug absorption.
- The quality of blood flow to the site of absorption affects how much of the drug is absorbed.
  - Increased blood flow (e.g., application of heat or massage) enhances intramuscular and subcutaneous drug absorption because of the resulting increase in circulation.
  - Absorption slows when blood flow decreases (e.g., shock or vasoconstriction).
  - Some muscles normally have greater blood supply; for example, a drug injected into the deltoid muscle will be absorbed faster than one injected into the gluteus muscle because of the greater blood flow to the deltoid muscle.

Life Span and Gender

- Ingested solids versus liquids empty more slowly from women's stomachs.
- Gastric acidity is lower in women.
- Women have lower gastric levels of alcohol dehydrogenase.

Lifestyle, Diet, and Habits

- Diet may stimulate digestive enzymes and alter the gastric and intestinal mucosa.
- Generally, drugs ingested with food are absorbed slower than drugs taken on an empty stomach.
- Some drugs and food form complexes that cannot pass through the mucosal lining of the GI tract (e.g., tetracycline antimicrobials that bind with calcium, magnesium, iron, aluminum), and thus effective blood levels may not be reached.
- Some drugs are destroyed by the high acidity and peptic activity of gastric digestive enzymes.

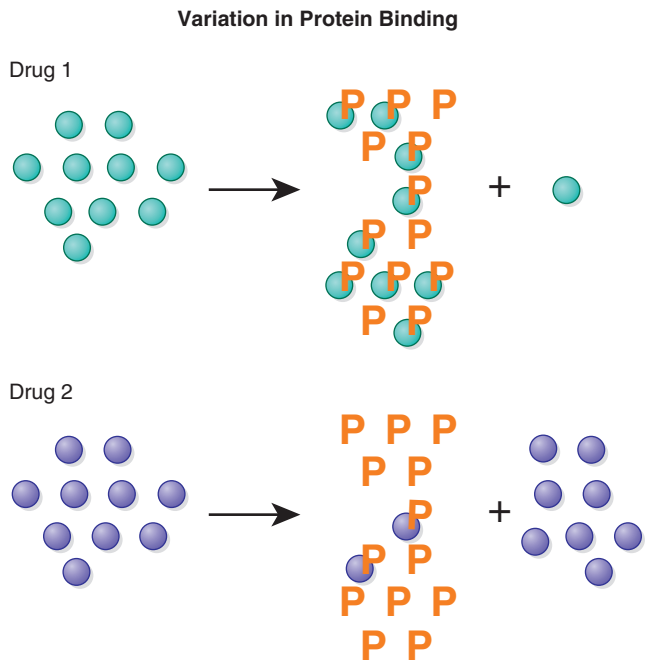
it is difficult to treat problems that may develop (such as infections in the adipose tissue) or the pathology itself (i.e., the abscess or tumor) by drug therapy alone.

Once the drug has moved through the blood to the tissues, it must leave the bloodstream to enter the tissue itself. This transition is necessary because most drugs do not produce their effect while in the blood. The drug leaves the vascular space in the capillary bed. Because the cells of the capillary walls have fairly wide spaces between them, the drug molecules simply move between the cells to leave the capillaries and enter the tissues.

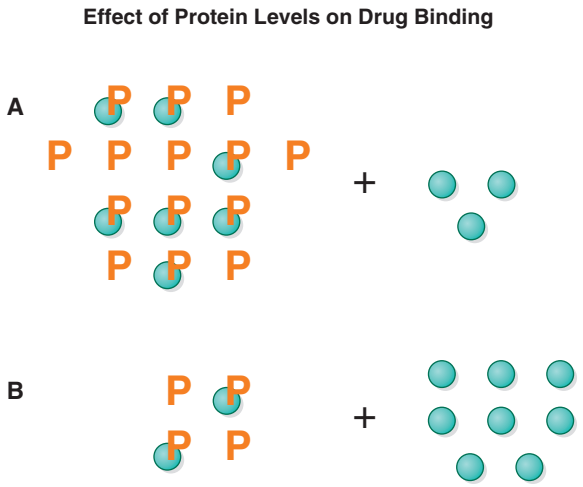
Protein Binding

Protein binding of drugs affects their distribution and is an important concept to understand. Drug particles form reversible bonds with proteins in the blood, most specifically albumin. Because albumin is a large molecule, it cannot pass through capillary walls. Therefore, when the drug particle is attached to the albumin, the drug is prevented from passing through the capillary walls. Different drugs have different affinities, or attractions, to protein molecules. Some drugs are so attracted to protein that almost all of the drug will bind with protein if the protein is available. These drugs are classified as highly protein bound. Other drugs have so little attraction that hardly any of the drug will bind with the available protein. Only drug molecules that are unattached to protein are capable of moving to their site of action (distribution) and achieving the desired therapeutic effect.

Another way of saying this is that only the free drug is active. Consider two drugs, A and B. Drug A is 95% protein bound; Drug B is 25% protein bound. This means that for every 100 molecules of Drug A, 95 molecules will be bound



• FIGURE 4.1 Drug 1 (•) is highly protein (P) bound. Little of the drug is free and active. Drug 2 (•) has low protein binding. A great deal of the drug is free and active.



• FIGURE 4.2 (**A**) High protein binding (P) of a drug allows only a few drug molecules to be free and active. (**B**) When serum protein levels are below normal, the drug molecules have nowhere to bind. The number of drug molecules that are free is thus greater than would be normally expected. More therapeutic effects and adverse effects are likely to occur.

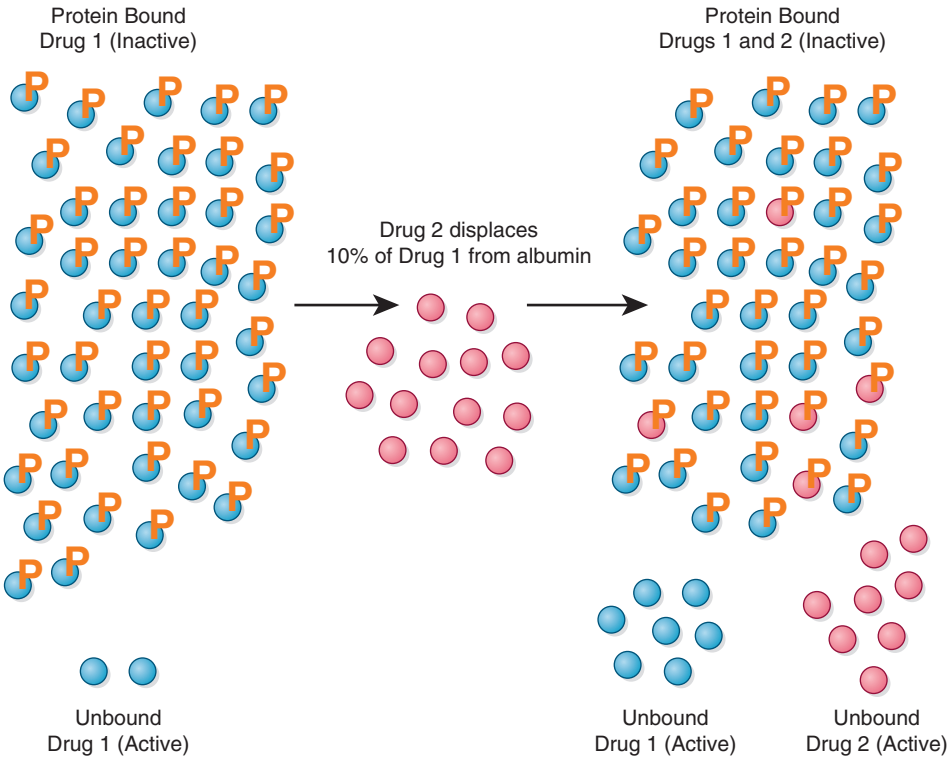
with protein, and 5 molecules will be free and active. For every 100 molecules of Drug B, however, 25 will be bound to protein, and 75 will be free and active. Drug A may therefore require a larger dose than Drug B to achieve the same therapeutic effect, because not as many of the molecules from each dose can distribute through the body and be active (Figure 4.1).

Protein binding can be compared with ninth-grade students at a school dance. If most of the students are interested in dancing, only a few of them are free to do as they please and to move about (and potentially cause trouble). If, however, most of the students are not that interested in dancing, then many are free to do as they please. The odds are increased that what they choose to do may be seen as troublesome to the teachers.

The bonds between the drug and protein molecules are not permanent. The bonds will dissolve in time, and the drug molecules will become free and active. Other drug molecules may then form a bond with the protein molecule. The length of time the drug is bound varies, based on properties of the drug. In keeping with our analogy of a dance, students may dance with each other for quite some time, or for only one song. They then separate and choose new partners, or they may remain free.

Drug dosages are calculated by the drug manufacturer based on the protein-binding characteristics of the drug. When the recommended dose is determined by the manufacturer, it is based on normal protein levels being available in the blood. When the patient has a lower-than-expected protein level (e.g., as a result of malnutrition, liver failure, or severe burns), the distribution of the drug is altered. Even if the drug normally has a high affinity for protein (i.e., it is highly protein bound), if protein is lacking, not as much drug can be bound. Less drug is bound because there is no place for the drug molecule to go. When less drug is bound, more drug is free and can be distributed to its site of action, thereby causing increased therapeutic, and possibly increased adverse, effects (Figure 4.2).

Because different drugs have different affinities for albumin, the administration of more than one drug simultaneously may also alter protein binding and consequently affect distribution of both drugs. For example, a particular drug is being administered. Part of that drug is bound to protein. Now, a second drug is also given, and it has a higher attraction to albumin than the first drug has. The second drug will bump or displace the first drug in order to bind with the protein (Figure 4.3).



• FIGURE 4.3 Consequence of drug displacement from albumin and other plasma proteins. Some drugs (e.g., "Drug 1") are greater than 90% bound to plasma proteins. The "free" (unbound) drug molecules, but not the bound molecules, are available to act at receptors. "Drug 2" displaces only five molecules of Drug 1, which more than triples the serum concentration of free (active) Drug 1. This increase could be fatal if Drug 1 has a narrow margin of safety. Displacement of drugs that are less highly protein bound is less significant. For example, if Drug 1 were 50% bound and 50% free, displacement of 10% of the bound fraction would increase the free fraction from 50% to 55%. This small increment is unlikely to be clinically relevant.

Displacement means that more of the first drug is free and active and will be distributed (compared to the distribution that occurred when the first drug was the only drug being administered). The dosage of the first drug may have to be decreased to prevent excessive therapeutic or adverse effects as long as the second drug is simultaneously prescribed.

In summary, protein binding plays an important role in distribution of active drug molecules. Changes in the expected protein-binding capabilities of a drug, either from pharmaceutical properties of other drugs or from patient-related variables, alter the effectiveness of drug therapy.

Blood–Brain Barrier

The capillary bed that services the brain is different from other capillary beds and affects distribution of a drug to the brain. Instead of wide spaces between the cells in the capillary walls, the cells are packed tightly together. This structure prevents drug molecules, and other foreign substances, from passing through and entering the brain. This system is called the **blood–brain barrier.** The purpose of the blood–brain barrier is to keep toxins and poisons from reaching the brain. This protective mechanism normally promotes health, but occasionally it prevents treatment of problems. For example, many antibiotics cannot cross the blood–brain barrier, making treatment of life-threatening infections of the brain, such as bacterial meningitis, difficult.

The way the blood–brain barrier works can be likened to a driver trying to exit a highway during rush hour. Imagine that you are driving in the far left lane of a three-lane highway. To exit the highway at one of the exit ramps, you must cross two lanes of traffic. If the traffic is light and there are great distances between the cars, exiting the highway can be accomplished easily. However, if the traffic is heavy and bumper to bumper, it is almost impossible to cross the other lanes to exit. In order to exit, you need to convince other drivers to let you pass through their lanes. You also might be able to move to the exit with the help of a police officer who is directing traffic.

In most tissues, the capillary walls have large spaces between the cells, like the times when the traffic is light and there are large spaces between the cars on the highway. In the brain, however, the cells that form the walls of the capillaries are packed together, like the cars on the highway during rush hour. Only drug molecules that are lipophilic (i.e., able to merge) or that have a transport system (i.e., a police officer directing traffic) can penetrate the barrier and get to the other side.

Placental Membrane

The placental membrane, which separates the maternal circulation from the fetal circulation, is not a barrier like the blood–brain barrier. Any drug that can pass through a membrane can pass through the placenta. In order to pass through the placenta, a drug must be lipophilic, not ionized, and not protein bound.

Core patient variables that influence drug distribution are summarized in Box 4.2.

Box 4.2 DRUG DISTRIBUTION AND CORE PATIENT VARIABLES

Health Status

- Hepatic dysfunction decreases the manufacturing of albumin.
- Conditions such as hypoalbuminemia, hepatic disease, and renal disease can decrease the extent of drug binding, particularly of acidic and neutral drugs. A diseased liver cannot synthesize the protein building blocks needed for albumin production. Thus, there is a greater concentration of free drug and a greater risk of increased drug response and toxicity.

Life Span and Gender

- At birth, the blood–brain barrier is not fully developed; this causes an increased vulnerability of the infant to CNS poisons and greater sensitivity to drugs that act on the brain in comparison with older children and adults.
- In pregnant women and fetuses, some drugs may be distributed to and bind with receptor sites in such a way that tissues may be adversely affected. For instance, bones and teeth, which contain calcium, can accumulate substances that bind with calcium (e.g., tetracycline antibiotics).
- Blood albumins are not thought to possess a gender-dependent predilection, although levels of some globulin proteins (e.g., corticosteroid-binding and sex-hormone binding) are lower in women. Although the small differences in protein levels between the genders are unlikely to be clinically significant, lower blood albumin levels may increase the effect of drugs that are normally highly protein bound.

Lifestyle, Diet, and Habits

- Poor dietary intake of necessary nutrients and protein (e.g., malnutrition) will contribute to low circulating albumin levels. This will increase the displacement of drugs that are normally highly protein bound into the circulation, where they can produce effects.
- Alcohol abuse directly affects the liver in its ability to function normally.
- Obesity significantly influences distribution of drugs that are highly lipophilic (e.g., anesthetics, barbiturates). The drug will move to the fat cells, and circulating levels of the drug will be decreased.

Metabolism

Metabolism of drugs occurs primarily in the liver. Some metabolism also occurs in other tissues, most notably the small intestine mucosa, lungs, kidney, brain, olfactory mucosa, and skin. The small intestinal mucosa is a major metabolic organ for some drugs and greatly reduces the oral bioavailability of some drugs before they can reach the general circulation. An example is nifedipine, a cardiovascular drug used to treat angina and hypertension. Physiologic factors that impair the functioning of the liver, such as hepatitis and cirrhosis, decrease the ability of the liver to metabolize drugs. Other core patient variables that affect drug metabolism are given in Box 4.3.

When drugs are metabolized, they are changed from their original form to a new form. Therefore, metabolism is sometimes referred to as **biotransformation**. Drugs are

Box 4.3 DRUG METABOLISM AND CORE PATIENT VARIABLES

Life Span and Gender

- Drug metabolism in patients whose enzymatic metabolic systems are either immature or functioning less efficiently (e.g., neonates, children, and older adults) is highly variable but is usually diminished. Decreased drug metabolism places the patient at increased risk of adverse effects from the drug.

Lifestyle, Diet, and Habits

- Malnutrition may prolong drug effects as a result of poor hepatic microsomal metabolism.
- In obese people, phase II transformations tend to occur more rapidly, thereby necessitating higher drug dosages.
- Drug effects may be intensified if the specific drug places the person at nutritional risk by producing anorexia, increased appetite, nausea and vomiting, nutritional deficiencies, stomatitis, or toxic reactions, for example.
- Diet may contribute to individual variations in drug metabolism. Charcoal-broiled foods and cruciferous vegetables induce one CYP isoenzyme, whereas grapefruit juice inhibits one.
- Exposure to cigarette smoke and pesticides may cause a more rapid metabolism of some drugs because of enzyme induction.

Environment

- Reduced partial pressure of oxygen at higher altitudes may affect enzymatic reduction systems.
- Environmental pollutants may affect induction or inhibition of hepatic enzymes.
- Light is a key modulator in the regulation of metabolic pathways and in specific settings may affect drug response (e.g., intensive care units that commonly remain constantly lit).

generally metabolized from substances that are lipophilic into substances that are hydrophilic. The ability of a drug to become soluble in water is important because it allows the drug to be excreted through the renal system.

Metabolites

A product of metabolism is called a **metabolite**. *Drugs that are metabolized are generally changed into an inactive form,* having no effect on the body as they travel throughout the body waiting to be excreted. *Occasionally, a drug is metabolized into an active metabolite*. This active substance can achieve an independent effect on the body, which can be either therapeutic or adverse. For example, after metabolism, codeine is changed to morphine, which is a stronger analgesic than codeine. So the active metabolite of codeine provides additional pain relief to the patient. Metabolism can convert a drug that has little or no therapeutic effect in its original form into the active, helpful form. Drugs that are inactive until metabolized into an active form are called **prodrugs.** An example of a prodrug is primidone, used to control seizures. Primidone's primary anticonvulsant effect comes from the drug being metabolized into phenobarbital and PEMA, both strong anticonvulsants. Finally, an active metabolite may cause a different and potentially harmful effect from that of the original drug. An example of a drug with a harmful metabolite is meperidine, an analgesic, whose active metabolite is neurotoxic and without pain-relieving properties.

Rates of Metabolism and the First-Pass Effect

Metabolism occurs at different rates for different drugs. Some drugs are highly metabolized, meaning that every time drug molecules are circulated to the liver (about 25% of the cardiac output is sent to the liver), a large percentage of the drug molecules is metabolized. Other drugs are metabolized at slower rates, and a smaller percentage is metabolized each time the drug molecules circulate through the liver. Keep in mind that the percentage of drug that is metabolized each time the drug circulates, or passes, through the liver is the same, but the total number of drug molecules that are metabolized will be different (Table 4.1). The percentage of the drug that is metabolized with each pass through the liver is

TABLE 4.1 Effect of the Liver on Drug Metabolism

Number of Drug Molecules Throughout the Body (Other Than Liver)	Number of Drug Molecules Sent to the Liver	Number of Passes Through the Liver	Number of Drug Molecules Metabolized in Liver	Percentage of Drug Metabolized	Number of Drug Molecules Leaving Liver After Metabolism	Total Number of Drug Molecules (Molecules Leaving Liver plus Molecules in General Circulation)
—	100	First	25	25%	75	75
56.25	18.75	Second	4.68	25%	14.07	70.32
52.74	17.58	Third	4.40	25%	13.18	65.92
49.44	16.48	Fourth	4.12	25%	12.36	61.80
46.35	15.45	Fifth	3.86	25%	11.59	57.94

For this hypothetical drug given orally, 25% of the drug is metabolized every time the drug circulates to the liver for metabolism. Note that the percentage of drug metabolized stays the same each time but the total number of drug molecules metabolized varies. Why is there less drug returning to the liver than was left after the previous pass and metabolism? This is because only about 25% of any given cardiac output will be sent to the liver; the rest of the drug is sent elsewhere in the body from the heart. Note that the most extensive metabolism occurs with the first pass of the drug through the liver.

an inherent trait of the drug itself. Highly metabolized drugs may lose their therapeutic effectiveness quickly, especially drugs that are administered orally. After an oral drug is broken down and absorbed into the circulatory system, the first place the blood travels is to the liver, through the portal vein. Thus, drugs that are highly metabolized lose much of their effectiveness during this first pass through the liver, before they reach general circulation. This loss of effectiveness is called the **first-pass effect.** Drugs that experience a high first-pass effect may need higher oral doses to achieve a therapeutic level of circulating drug. To avoid the first-pass effect or the need for high oral doses of a drug, drugs that are highly metabolized are often given by another route that bypasses the liver initially. For example, the drug may be given intravenously. None of the drug given intravenously will initially go to the liver; all of it will return to the heart. From the heart, slightly more than 25% of the drug will be sent to the liver, where a percentage of it is metabolized.

P-450 System

Metabolism is predominantly achieved by specific microsomal enzymes called the cytochrome P-450 system, or, more commonly, the **P-450 system**. This system is a combination of several types of cytochromes, called families. Of these, only three families—CYP1, CYP2, and CYP3—are involved in drug metabolism. The other enzymes in the P-450 group metabolize naturally occurring substances, such as fatty acids. Scientists have been able to identify specific members of each cytochrome family. These members are identified by a number representing "family" a letter (representing the subgroup) and another number (representing the specific isoenzyme) (e.g., CYP1A2). Most of the P-450 system is located in the liver and this is the primary site of drug metabolism. Isoenzymes can also be found in other organs, however, such as those in the small intestine mucosa, and are responsible for the metabolism that occurs in these locations.

The total number of isoenzymes present in the body is not divided equally between the three families. The enzyme subgroup CYP3A is the most common in both the liver and in the small intestine and is responsible for the metabolism of most drugs; the next most prevalent subgroup in both sites is CYP2C (Paine et al., 2006) (Figure 4-4).

Some drugs either induce or inhibit the P-450 system, altering metabolism of other drugs (see Appendix G online). Usually, just one P-450 family is affected. Drugs that induce a hepatic enzyme increase the amount of that enzyme present in the liver. Induction is accomplished most frequently by stimulating enzyme synthesis. When a large quantity of one of these enzymes is present, more metabolism can occur through this pathway. Drugs that are metabolized by this pathway (also referred to as substrates of the enzyme) will therefore be metabolized more rapidly than drugs that are not. This increase in metabolism rapidly decreases the amount of circulating, active drug. Some drugs can induce the enzymes necessary for their own metabolism and thus can increase the rate of their own metabolism. Drugs that

inhibit a particular hepatic enzyme slow the metabolism that occurs through this pathway, causing an increase in the amount of circulating, active drug. Metabolism returns to normal after the inducing or inhibiting drug is no longer administered, although it may take several days after an inducer is discontinued.

When two or more drugs are metabolized by the same hepatic enzymatic pathway, the drugs compete with each other for action from the enzyme. This competition results in at least one of the drugs having its metabolism impaired. To understand this concept entirely, consider the analogy of using the Internet through a dial-up connection. When there are few customers online, getting connected and using the online services is easy. However, when demand is very high, it may be difficult to get connected at all, and once connected, you may be abruptly disconnected, losing your ability to use the online services. Similarly, when the demand is high for the services of a particular hepatic enzyme, not every drug will receive attention immediately.

Drugs that affect the P-450 system are responsible for many drug interactions, as discussed in more detail in Chapter 5.

A number of patient related variables influence the presence and activity of the P-450 system. Genetic variations of the specific isoenzymes account for differences in rate of

metabolism and drug clearance in some individuals receiving drug therapy. Multiple genes regulate the activity of P-450 enzymes. The isoenzyme CYP2D6, while it accounts for only 2% to 5% of all hepatic P-450 isoenzymes, is very important to consider because it metabolizes about one fourth of all clinically used medications (Harvard Mental Health Letter, 2009). Genetic polymorphisms (variations) of this isoenzyme result in people being poor metabolizers, intermediate metabolizers, extensive metabolizers, or ultrarapid metabolizers of drugs. The majority of the population are extensive metabolizers via this isoenzyme, so this is considered the norm. About 5% to 10% of American whites are poor metabolizers via this enzyme; about 1% to 10% are ultrarapid metabolizers (Mulder et al., 2007; Bernard et al., 2006). In comparison, between 2% and 7% of African Americans are poor metabolizers, and about 5% are ultrarapid metabolizers. Asian populations have an extremely low incidence (1% or less) of the genetic variations that create poor metabolizers or ultrarapid metabolizers (Data on Asian Americans is not specifically available.) (Bernard et al., 2006). Patients who are poor metabolizers of a particular drug will have higher circulating levels of that drug than would be normally anticipated. These higher levels can produce additional therapeutic as well as adverse effects. Patients who are ultrarapid metabolizers of a drug will have lower circulating levels of the drug than would be normally anticipated and may not achieve the desired therapeutic response from a dose; larger doses may be warranted.

The presence and activity of different isoenzymes, varies by the sex of the patient. For example there is more CYP 3A4 in the liver of women than in men, but this difference does not seem apparent in the GI system (Paine et al., 2005). Women are known to have more active 3A4, 2A6, and 2B6, less active 1A2,2E1 and no difference in activity with 2C9 and 2D6 (Anderson, 2008), although these differences may or may not be clinically significant. Some research indicates that sex alone does not contribute substantially to the large variation of metabolism via P-450 that is seen between individuals. (He et al., 2006). More research is needed to confirm the exact interaction between sex, P-450 variations, and drug metabolism.

Some foods and herbs may also interact with the P450 system. Grapefruit and its juice is well known to decrease the amount of the P-450 isoform 3A that is available in the intestines, but not in the liver. Consequently it decreases the metabolism of drugs that rely on that enzyme system for metabolism and raises circulating levels of that drug. St John's Wort, an herb used to treat depression, has the opposite effect from grapefruit. See Chapter 5 for more discussion of drug interactions via the P-450 system. While most of the research has been done on the effect of a food or herb on drug effectiveness, it should be remembered that P-450 reactions may go both ways, and that a drug may decrease the therapeutic effects that may occur naturally from some herbs or foods (Yarnell & Abascal, 2007).

It has been postulated that inflammation may alter the presence of some P-450 isoenzymes. One study of children with inflammatory bowel disease (Crohn's disease) found that they had significantly higher levels of CYP 3A4 and CYP3A5 than children without Crohn's disease. These variations may explain why medication given to treat Crohn's doesn't always achieve a therapeutic response (Fakhoury et al., 2006)

Decreased internal temperature of a patient may alter the action of the P-450 during metabolism. A review of the literature by Tortorici et al. (2007) found that

> …mild to moderate hypothermia decreases the systemic clearance of cytochrome P-450 metabolized drugs between 7% and 22% per degree Celsius below 37°C during cooling. The addition of hypothermia decreases the potency and efficacy of certain drugs… [there is] evidence that the therapeutic index of drugs is narrowed during hypothermia.

As hypothermia is sometimes intentionally induced in patients who have cardiac arrest out of the hospital, these patients should be screened carefully for drug adverse effects once they are in the hospital.

Excretion

Excretion is the process of removing a drug, or its metabolites, from the body. The most common route for drug excretion is through the urine. Other routes include bile in the GI tract, expired air from the lungs, breast milk, sweat from the skin, and saliva. Sweat and saliva are not therapeutically important routes of excretion, however.

Diseases and pathophysiologic changes in the kidney, such as renal failure, decrease the effectiveness of the kidney in drug excretion. Other patient variables that affect drug excretion are discussed in Box 4.4.

Processes Involved in Renal Excretion

Three processes are involved in renal excretion of drugs. The first is glomerular filtration. Drugs come to the kidney

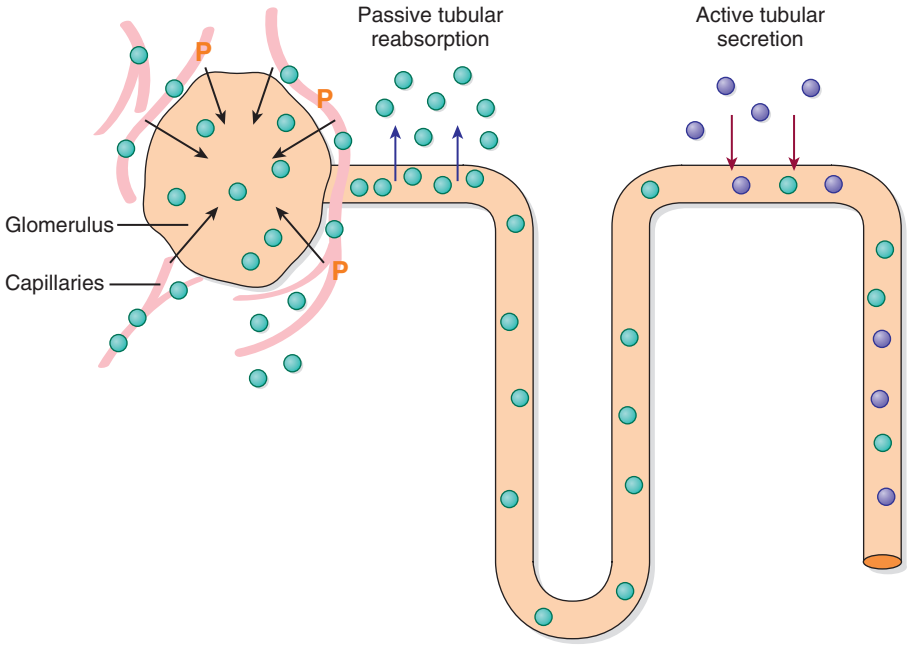
Box 4.4 DRUG EXCRETION AND CORE PATIENT VARIABLES

Health Status

- Renal impairment or renal failure decreases a drug's elimination from the body. If renal excretion is an important route of its elimination and the drug is given on a regular dosing schedule, its slowed removal from the body will produce a greater accumulation of drug in the body with an increased likelihood of additional therapeutic and adverse effects.
- If cardiac output is decreased, the kidney may not be perfused adequately, decreasing the glomerular filtration rate as well as excretion of drugs.
- Hepatic compromise or dysfunction will also decrease the elimination of drugs.
- Drug therapy may produce nephrotoxicity as an adverse effect. Therefore, the renal elimination of all other drugs may be decreased.

Life Span and Gender

- In elderly patients, the rate of drug clearance is reduced.
- Some drugs have different rates of clearance depending on the sex of the patient.



• FIGURE 4.5 Renal excretion of drugs. Most drugs pass easily through the capillary walls and enter the tubules of the nephrons. Large molecules, such as proteins, cannot pass. Because of concentration gradients, some drug molecules will passively move back into the circulatory system (passive tubular reabsorption). Some drugs are actively moved into the tubule to be excreted.

through the capillaries surrounding Bowman's capsule. This capillary network is the glomerulus. Most drug particles pass easily through the spaces of the capillary walls into the urine in the proximal tubule. Only very large particles, such as proteins, cannot pass. Drug molecules bound to protein will therefore also not be filtered.

The second process is passive tubular reabsorption. Because a concentration gradient now exists, with more drug particles in the urinary tubule than in the bloodstream, the drug particles will try to move from the area of greater concentration to that of lesser concentration. Remember that for a drug to move through a membrane, it must be lipophilic. Therefore, for a drug to be able to move through the membranes separating the tubular and vascular structures, it must still be lipophilic. If it has been changed by metabolism into a form that is not lipid soluble (meaning that it is now an ion or a polar compound), passive tubular reabsorption cannot occur. Instead, the drug remains in the urine and is excreted.

The third process that affects excretion is active tubular secretion. Active transport systems in the renal tubule work to move some drugs from the blood and into the urine (Figure 4.5). There is one active transport system for organic acids and one for organic bases.

Factors That Affect Renal Excretion

Because ions cannot be passively reabsorbed from the tubule, drug excretion can be increased if the pH of the urine encourages the drug to become an ion. Remember that acids will ionize in basic environments and bases will ionize in acidic environments. Therefore, if another drug or some other agent is introduced that makes the urine more basic, acidic drugs will be ionized and not reabsorbed. Drug overdosage or ingestion of a poison is often treated in this way to promote excretion of the drug before it can harm the patient.

Overuse of the active transport system also affects excretion. Two drugs that rely on the active transport system for excretion will compete with each other for places on the transport system. As the transport system becomes overloaded, some of the drug particles will remain in the blood until they can be moved by the transport system. This residual portion will increase the circulating time of active drug in the body and slow the excretion of both drugs. This process is much like people waiting to ride a shuttle from the parking lot to a building. The shuttle bus has a limited number of seats and can travel only so fast between the two points. During the times when crowds are infrequent, everyone can find a seat on the shuttle without waiting. However, during rush hour, when crowds are large, not everyone can find a seat on the shuttle immediately. Some people will have to wait for their transportation to the building.

Two drugs can be given together to deliberately slow the rate of excretion of one or both of the drugs. A common example of this approach is giving probenecid, a drug used to treat gout, along with a penicillin or cephalosporin, antibiotics that are used to treat infections. In this situation, the probenecid is used not for its normal pharmacotherapeutic effect but solely to slow the rate of active transport and excretion of the antibiotic. This means that the antibiotic remains in the blood and can continue to be active for a longer time than when given without the probenecid.

Factors That Affect Biliary Excretion

A factor that affects excretion of drugs through bile is enterohepatic recirculation. Some of the bile that leaves the liver and enters the intestine is reabsorbed back into the portal circulation and returned to the general circulation. Drug molecules that are in the bile are also reabsorbed. This process lengthens the time the drug is present in the bloodstream and can produce an effect.

Other Pharmacokinetic Concepts

Half-Life

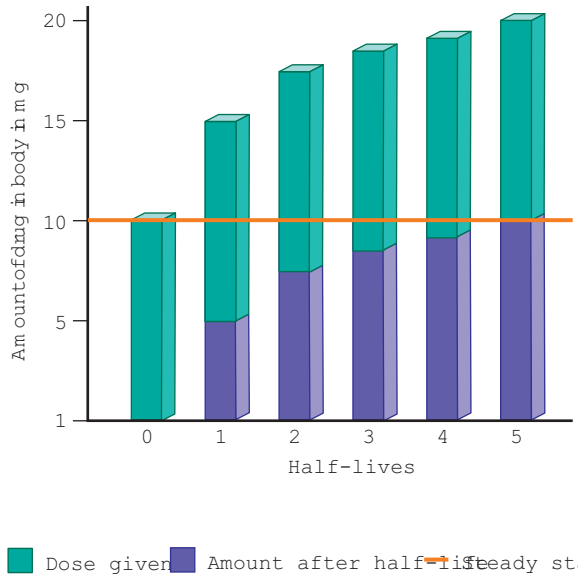
The combined processes of metabolism and excretion are responsible for elimination of a drug from the body. The amount of time that is required to remove half (50%) of the blood concentration of a drug is called **half-life**. Drugs have various half-lives, based on their pharmacologic properties and rate of metabolism and excretion. Some drugs have half-lives measured in minutes; others have half-lives measured in days. It is important to understand that in one half-life, a set percentage of the drug molecules present in the blood will be eliminated, not an absolute set number of drug molecules. For example, if 1,000 drug molecules are present in the blood, 500 drug molecules will be left after one half-life. If there are 500 molecules, 250 will be left after one half-life. If there are only 10 drug molecules, 5 molecules will be left after one half-life. Each half-life removes 50% of the drug stored in the body; the number of molecules varies depending on the total load of drug in the body. If the rate of metabolism and excretion of a drug is slower than normal in an individual (for example if a patient has liver or renal failure) then the time to achieve a half life may be lengthened.

Steady State

There is a point at which the amount of drug being administered and the amount being eliminated balance off. Essentially, this balance means that what comes in equals what goes out. This balance creates a stable level of the drug in the blood called **steady state.** Technically, a 100% steady state cannot be achieved if a particular drug is given more than one time. However, the balance is almost even between the drug amount administered and that eliminated. At five half-lives, 97% of steady state will be achieved; therefore, steady state has been traditionally defined as five half-lives. However, most of steady state (94%) is achieved in four half-lives. In terms of clinical response from a given drug level, a drug at 94% of steady state will not achieve substantially less therapeutic effect than a drug at 97% of steady state. Because of this similarity in clinical response, it is now frequently stated that it takes four to five half-lives for steady state to be achieved.

When a particular dosage of one drug (i.e., a dose) is given at set repeated intervals (i.e., dosing intervals), it takes between four and five half-lives of the drug for the dose to equal the elimination rate of the drug. Imagine that the half-life of Drug A is 1 day and that 10 mg of Drug A is administered daily. On the second day, after one half-life, 5 mg of the drug is eliminated. An additional 10 mg dose is taken, raising the total amount of the drug in the body to 15 mg (50% × 10 = 5; 5 + 10 = 15). The next day (after two half-lives), 7.5 mg of drug remains in the body. When that day's dose is administered, the total amount of drug in the body becomes 17.5 mg. The following day (after three half-lives), the body has 8.75 mg left. When the daily dose is given, the total amount in the body becomes 18.75 mg. The next day, four half-lives will have taken effect, leaving 9.375 mg of the drug in the body, which is 94% of the daily dose of 10 mg. Another dose is administered, bringing the amount to 19.375 mg. On the fifth day (after five half-lives), 9.6875 mg of the drug remains, which is 97% of the 10-mg daily dose. Thus, somewhere between four and five half-lives, the daily dosage is essentially the same as the amount left in the bloodstream after elimination (in = out) (Figure 4.6).

Although a larger amount (dose) of a given drug elevates the drug level found in the blood after steady state is achieved, increasing the dose has no effect on how *quickly* steady state can be achieved. Achievement of steady state is not based on drug dose. Steady state is achieved based on the amount of *time* required for four to five half-lives to occur,



• FIGURE 4.6 With each half-life, 50% of the drug in the body is eliminated. Note that steady state (in = out) is achieved in four to five half-lives.

CRITICAL THINKING SCENARIO

HALF-LIFE AND DRUG DOSING

Gayle Herbert is 80 years old and has a history of renal insufficiency and chronic heart failure. She is receiving digoxin, a drug that strengthens the force of the heart's contraction, for chronic heart failure. Digoxin undergoes almost no metabolism but is primarily eliminated by renal excretion. The dose of the digoxin is to be increased, starting today. The half-life of digoxin is 30 to 40 hours.

1. If the new dose of digoxin were given orally once a day, how long would it take for the drug to reach steady state? Will Ms. Herbert's renal insufficiency affect the time to reach steady state?
2. Ms. Hawkins is also 80 years old and receives digoxin, but she does not have renal insufficiency. Would you expect Ms. Herbert's dose to be the same, less than, or greater than Ms. Hawkins' dose of digoxin? Why?

Answers for Critical Thinking Scenarios are found on the website: http://thepoint.lww.com/Aschenbrenner4e

and half-life is related to the rate of elimination of the drug, which is an inherent property of the drug. Similarly, increasing the frequency of drug administration (i.e., dosing) *does not affect how quickly* the drug achieves steady state. Steady state is still achieved in the same amount of time: four to five half-lives. The full pharmacotherapeutic response of a particular drug dose is measured when the drug has achieved steady state. Every time the dose is adjusted, it takes between four and five half-lives before the drug achieves steady state for that dose and for the full therapeutic effect to be assessed. This fact is important to remember when dose adjustments (up or down) are being considered in order to achieve a desired therapeutic effect. If the dose is modified before steady state is achieved, it is difficult to predict exactly what blood level will be achieved and, in turn, what therapeutic effect will be achieved from a drug dose. The result may be a blood level that is too low to be therapeutic or one that is too high, leading to adverse effects.

Consider, for example, giving captopril to treat a hypertensive episode. The half-life of captopril is about 2 hours. This half-life means that in 10 hours, half of the drug administered will have been eliminated and the full effect of the initial dose of captopril will be evident. Let's say, however, that 4 hours after the drug is administered, the patient's blood pressure remains somewhat elevated. Two half-lives have occurred in this time. The physician orders a larger dose of captopril to be administered now. Twenty-five percent of the first dose remains in the patient's body after two half-lives. This residual drug is added to the new, larger dose. Later, the patient is found to be hypotensive, from too much effect of the medicine. In this particular case, not enough of the first dose had been eliminated before a second, but larger, dose was given. The combination created too high a blood level of the captopril. The drug did what it was intended to do: it lowered the blood pressure. But it lowered it too much. Had the dose been the same during the second administration of the drug, it is likely that the blood pressure would have dropped but stayed in the normal range. Decisions to alter the dose of a medication can most likely be made after four half-lives, because this point is essentially steady state. Even after three half-lives, 90% of steady state has been achieved, which may be enough when making a clinical judgment to change the dose of the drug.

What can be done if you need the therapeutic effect from a drug quickly and can't wait to achieve steady state? A larger dose than usual may be given initially. This is called a loading dose. Then after one half life, the drug level remains in therapeutic range, even though the drug has not yet reached steady state. See later in this chapter for more information on loading and maintenance doses and therapeutic range.

Clearance

Several pharmacokinetic factors work together to affect the rate at which drug molecules disappear from the circulatory system. This rate is called **clearance** or clearance rate of a drug. Renal excretion and hepatic metabolism are the major modes of clearance. Some drugs are primarily cleared by one mechanism rather than the other. For other drugs, the two mechanisms are both actively involved in clearance.

The gender of the patient can also alter the clearance of some drugs. Some drugs are cleared more rapidly in women (e.g., clozapine, erythromycin, and theophylline), whereas others are cleared more rapidly in men (e.g., lorazepam, acetaminophen, and digoxin). Slower clearance means that the drug particles stay in the circulation longer, increasing the half-life and the potential for increased therapeutic and adverse effects from the drug. It is important to recognize that even though a drug's clearance is shown to be statistically altered, this statistical difference does not necessarily create a clinical difference.

PHARMACODYNAMICS

Pharmacodynamics is the biological, chemical, and physiologic actions of a particular drug within the body and the study of how those actions occur. Essentially, it is how the drug affects the body. The pharmacodynamics of a drug are responsible for its therapeutic effects and sometimes its adverse effects. The pharmacodynamics of a drug can be affected by the age of the patient (Box 4.5).

Drugs cannot create new responses in the body; they can only turn on, turn off, promote, or block a response that the body is inherently capable of producing. Understanding the pharmacodynamics of a drug is critical to being able to understand and critically assess a patient's response to drug therapy.

Drug–Receptor Interactions

Most drugs create their effects in the body by attaching to special sites, called **receptors,** on cells. At the receptor site, the drug is able to stimulate the cell to act in a way that the cell is designed to act. Drugs do this by attaching to the body's receptors for intrinsic elements such as hormones, neurotransmitters, or other internal methods of regulating cell function. Although each cell has many different receptor sites, the receptor sites do not all produce the same effects

Box 4.5 PHARMACODYNAMICS: EXAMPLES OF AGE-RELATED CHANGES

- Increased myocardial sensitivity to anesthesia
- Increased analgesic effect from opioids
- Increased sedative effect from benzodiazepines (or other CNS depressants)
- Increased anticoagulant effect from anticoagulant therapy
- Exaggerated responses to cardiovascular drugs (normal homeostatic responsiveness is altered)

Note: When administering drug therapy to an older adult, the nurse should be alert to the possibility of moderate reductions in drug clearance and the potential for exaggerated pharmacodynamic responsiveness.

when stimulated. Each type of receptor is responsible for producing a particular effect in the cell. Drug molecules are able to attach only at certain receptors, and the receptors to which they attach determine the effect produced. Other drugs match up with different receptors, thus producing different effects.

When drug molecules attach to a receptor, they can stimulate the cell to act. Drugs that act in this way are described as **agonists,** meaning that they promote a function. Alternately, by attaching to a receptor, drug molecules can prevent something else from attaching and causing an effect. Drugs that act in this way are described as **antagonists** or **blockers**. Consider a busy parking garage at a mall. If other drivers have parked in all of the parking spaces before you get there, you are prevented from parking and going into the mall to shop. As you circle around waiting for a driver to leave a spot, you are in competition with all of the other drivers who are circling, looking for spots. At some point, a driver will vacate a parking space. If you are close by, you will be able to park and go in and shop. If other cars are closer, they will get the spot and again block you from parking. This scenario is similar to how drugs block receptor sites.

A drug may latch onto a site to prevent a hormone or a neurotransmitter from attaching to the cell and turning on a function. If the drug is on the receptor, the other chemical cannot also be on the receptor. This fact is helpful when excessive internal stimulation of the cell causes the patient to experience pathologic changes. For example, in a patient with excessive stomach acid, the receptors in the stomach known as histamine-2 (H_2) receptors are overactivated, and the patient feels GI distress. When drugs called H_2 antagonists are given that attach to H_2 receptors and block the acid from attaching to the receptors, the person has a decrease in symptoms and feels better. The example of the parking garage also brings up an important point about drugs at receptor sites. The bonds that are formed are almost always temporary. When the drug molecule is no longer attached to the receptor, other drug particles may then attach, or the internal substance may then attach, to the receptor. Because there is competition for the receptor sites, the chemical that is present in the largest amount, either the drug or the internal regulator, is the most likely to be near an open receptor and attach to the receptor site. Most drugs that are antagonists are competitive; only a very few are not.

There are two theories about drug–receptor interactions: the single occupancy theory and the modified occupancy theory.

Single Occupancy Theory

The single occupancy theory has two aspects. First, the intensity of the body's response to the drug is directly related to the number of receptors occupied by the drug. The more receptors occupied, the stronger the response that is produced. Second, the maximum response occurs when all of the receptors have drug molecules attached. This theory does not explain, however, how two different drugs, each of which can attach to the same type of receptors, can produce different degrees of effect from stimulating the receptor. We know from common usage that different drugs need different doses to achieve their therapeutic effects. If you have two drugs that each relieve headaches, but the standard dose of Drug A is 20 mg and the standard dose of Drug B is 100 mg, there are obviously more drug molecules of Drug B than of Drug A. Thus, Drug B is attaching to and stimulating more receptors than Drug A, yet they both work to relieve a headache. Additionally, we know that, with some drugs, a ceiling effect occurs: at some point, no matter how much more drug you give, you cannot get any additional therapeutic response. Yet it would seem that if all of the receptors are occupied, a maximal effect should be seen. The single occupancy theory, which assumes that all drugs have identical abilities to bind with receptors and that all drugs, once bound, have identical abilities to influence the functioning of the receptor, cannot be the only explanation for the way that drugs create an effect at receptor sites.

Modified Occupancy Theory

The modified occupancy theory is based on different assumptions about how drugs work at receptors. It states that different drugs have different strengths of attractions, or **affinity,** for receptor sites. Drugs with high affinity are strongly attracted to a receptor; drugs with low affinity are not very strongly attracted to a receptor. Drugs with strong affinity attach to a receptor even if not many drug particles are available. Drugs with low affinity attach only if large numbers of drug molecules are present. A comparison can be made with going to a movie. If you are very interested in seeing a particular movie, you'll make sure you go, even if you go alone or with only one friend. If you're not too interested in a movie, you'll go, but only if all your other friends are going, too. Thus, low doses of a drug with high affinity for a receptor will bind with that receptor and produce an effect.

Another assumption of the modified occupancy theory is that drugs, once attached to a receptor, have different abilities to stimulate the receptor. A drug's ability to stimulate its receptor is termed its **intrinsic activity.** Drugs with high intrinsic activity cause strong reactions from the receptor; drugs with low intrinsic activity cause low reactions from the receptor. A drug with high affinity and high intrinsic activity is able to produce a strong effect from a small amount of drug.

Changes in Receptor Sensitivity

Receptors are not static; they can change or modify their response to a stimulus. Such change occurs when a receptor is continuously stimulated to act or continually inhibited from action. Receptor response can be modified either by changing the number of receptors on the cell or by changing the sensitivity of the current receptors.

Continual stimulation from an agonist usually makes the receptor desensitized to the drug and thus less active. Continual blockage from an antagonist usually makes the receptor become hypersensitive and much more likely to react.

Nonreceptor Responses

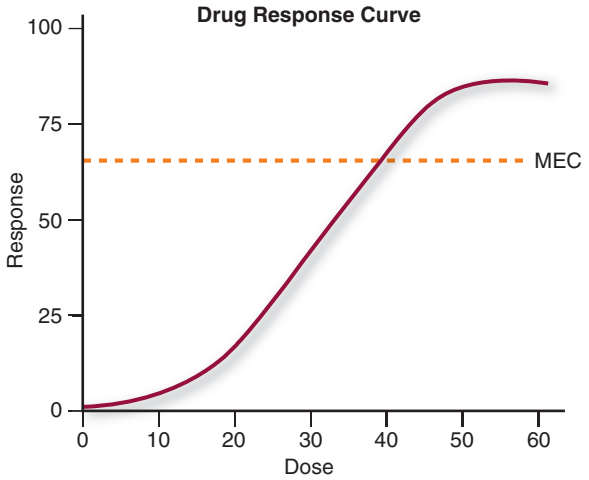
Although most drug effects are related to drug–receptor responses, some drugs exert their effect by reacting physically or chemically with other molecules in the body. For example, antacids create their effect by mixing with stomach contents to raise the pH, making it less acid. Another example is heparin, an anticoagulant. Heparin interferes with the conversion of prothrombin to thrombin (which is needed to form a stable clot) by inactivating factor X.

VARIABLES THAT INFLUENCE THE DOSE OF A DRUG

Potency and Efficacy

From the drug–receptor theories, we see that the dose and characteristics of a drug have some relation to the pharmacotherapeutic effect achieved with drug therapy. A certain level of drug must be present in the body to produce an effect at all. This level is called the minimum effective concentration (MEC). After the MEC is reached, the strength of the response to a drug increases proportionately as more drug is given, until a plateau is reached and no additional therapeutic effect can be achieved, no matter the dose. When this relation between drug dose and response is plotted on a graph, it is referred to as a dose–response curve (Figure 4.7).

The amount of a drug that must be given in order to produce a particular response—its relative pharmacologic activity—is called the **potency** of a drug. A drug that is highly potent requires little of the drug to produce its effect. The affinity of a drug is related to its potency. Drugs with high affinity for a receptor need little drug to bind to the receptor and are thus highly potent drugs. How well a drug produces its desired effect is called **efficacy**. The efficacy of a drug is related to its intrinsic activity. Drugs with high intrinsic activity have greater efficacy.



• FIGURE 4.7 As the dose of a drug is increased, more response from the drug is achieved. Once the drug reaches the minimum effective concentration (MEC), a therapeutic effect can be observed. At a certain point, increasing the drug's dose fails to produce any greater response, and the curve flattens out. This point is the maximal efficacy of the drug.

Potency is not the same as efficacy. Two drugs may have different potencies but the same efficacy. For example, it might take 25 mg of Drug A to lower elevated blood pressure but 50 mg of Drug B to lower blood pressure by the same amount. Both drugs have equal efficacy, but Drug A is more potent than Drug B because fewer milligrams are needed to achieve the effect. Is the more potent drug the better drug? Not necessarily. Rarely is potency the most important consideration when selecting a drug. If the less potent drug, which is equal in efficacy, can be administered in a similarly sized pill as the more potent drug, patients and prescribers will view the drugs similarly. Other important considerations include the cost of each drug and the adverse effects from each one. If the less potent but equally effective drug is less expensive or is better tolerated by the patient, it will be the preferred drug. If the necessary route of administration is different, this consideration may also make one drug more desirable than the other. For example, if the more potent drug is administered only intravenously, but the less potent drug can be given orally, the less potent drug will usually be preferred when the patient is receiving drug therapy at home.

If drugs have similar potencies, but different efficacies, the drug that has better efficacy is usually preferred because this drug does a better job of achieving the desired therapeutic effect. However, if the largest effect that the drug can achieve (the maximal efficacy) is greater than the patient's clinical status warrants, a drug with a lower maximal efficacy may be chosen. For example, morphine has a higher maximal efficacy for relieving pain than acetaminophen. If the patient has postoperative pain at a surgical incision site, the morphine, with a higher maximal efficacy, is appropriate. If the patient has only a mild headache, the morphine is not appropriate, but the acetaminophen is.

ED_{50}, Maintenance, and Loading Doses

Because people are unique, how individuals respond to a drug dose varies. To determine what dose of a medicine should be given as the "usual dose," the distribution of doses needed to produce a response in a large and varied number of people is statistically calculated. The dose that is required to produce the therapeutic response in 50% of the population is called the effective dose 50% (ED_{50}). This dose is considered the standard or typical dose and is usually chosen as a starting dose. Once a dose is chosen and administered consistently over time (e.g., every day), it is called the **maintenance dose.** Patients who are started on drug therapy using the standard maintenance dose arrive at steady state after four to five half-lives. The full therapeutic effect of any dose is achieved at steady state. For drugs that have long half-lives, achieving steady state may take days or weeks. The patient's medical condition may warrant immediate and full drug effect, however, in order to maintain health or life. When this is the case, a larger dose than usual is given initially. This initial large

dose is called a **loading dose.** After one half-life, half of the administered dose is still available. The loading dose is computed so that after some of the drug is eliminated, the drug concentration in the body is still in the therapeutic range. The large initial loading dose is often divided into two or three portions, which are given more frequently than maintenance doses are administered. This dosing prevents the initial amount circulating in the patient from being so high that the patient experiences adverse effects.

Therapeutic Index

Just as people vary in the dose of a drug they need to achieve an effective therapeutic response, they vary as to the dose that will produce death. The lethal dose is computed in a laboratory setting and analyzed statistically. The point at which the dose would be fatal in 50% of the population receiving that dose is called lethal dose 50% (LD_{50}). To determine the safety of a drug, the LD_{50} is compared with the ED_{50}. The relation of LD_{50} to ED_{50} is called the **therapeutic index**. Therapeutic index can be explained by this equation, where TI represents the therapeutic index:

$$TI = \frac{ED_{50}}{LD_{50}}$$

If the amount of a drug required to be the ED_{50} is similar to the amount that is the LD_{50}, the mathematical ratio of the two values will equal a number close to one. For example, if the ED_{50} is 99 mg and the LD_{50} is 100 mg, the therapeutic index would be computed this way:

$$TI = \frac{99}{100} \text{ or } TI = 0.99, \text{ which can be rounded to } 1$$

When the ED_{50} and the LD_{50} do not differ by much, the drug is considered to have a narrow therapeutic index. These drugs are not very safe and are therefore difficult to dose because the dose needed to be effective in half of the population will also kill half of the population. Drugs used in practice do not have a therapeutic index as narrow as in this example. However, the closer the two numbers are to each other, or the closer that the TI is to 1.00, the more difficult it is to use the drug to treat patients. For some types of conditions, however, the only appropriate drug is one that has a narrow therapeutic index. When patients receive these drugs, they must be closely monitored for adverse effects because adverse effects will become evident before death occurs. The current blood level of the drug is also monitored closely to make sure that the drug stays in the therapeutic range.

Thankfully, most drugs have a wide therapeutic index. A wide therapeutic index means that the amount required to be effective is very small, compared with the amount required to be lethal; for example:

$$TI = \frac{25}{1000} \text{ or } 0.025$$

In this example, the disparity between the ED_{50} and the LD_{50} is large. The therapeutic index is not close to 1.0. This drug is easy to dose; fatal effects are unlikely to occur because the LD_{50} is 400 times greater than the ED_{50}. Although this patient should be monitored for adverse effects, he or she is not at high risk for experiencing a problem, unlike the patient receiving a drug with a narrow therapeutic index.

Nurses will not need to compute the therapeutic index. Furthermore, the numerical quotient of the comparison of the ED_{50} and the LD_{50} will not be published in the drug literature. Rather, the drug literature will state that the drug has a narrow therapeutic index. If the drug does not have a narrow therapeutic index, usually no mention is made.

DRUG DOSAGE AND BLOOD CONCENTRATION

As previously stated, a minimum effective concentration of a drug (the MEC) is required to achieve the desired pharmacotherapeutic effect. As drug levels within the body increase, the patient is more likely to experience adverse effects from drug therapy. For some drugs, these adverse effects may be very serious and potentially harmful to the patient. The goal of drug dosing is to give a dose that places the drug concentration above the MEC but below the level at which adverse effects occur. This range is called the **therapeutic range**.

To help determine whether a drug's dose is adequate to be in the therapeutic range, but not so high as to cause adverse effects, blood levels of the drug are often measured. Although most drugs do not achieve their therapeutic effect within the blood, blood samples are used because they are fairly easy to obtain. For many types of drugs, it would be too difficult to measure samples at the site of drug action. For example, drugs that alter cardiac function would require samples of tissue from the heart. Blood levels of a drug can be used, however, only if the relationship between the amount of drug circulating in the blood and the effects of the drug in the body are known. This information is not known for all drugs; therefore, blood samples are not drawn for every type of drug therapy. Acceptable target blood levels have been determined for most drugs that produce serious adverse effects.

Nurses need to monitor drug blood levels if samples are drawn and must notify the physician or nurse practitioner if the level indicates that the patient is not in the therapeutic range or is greatly above the therapeutic range. Nurses should also seek orders for a blood level of a drug if a patient appears to be experiencing adverse effects. Because blood levels reflect the changes that have occurred from drug metabolism and excretion, it is important to note the exact time the last dose of the drug was administered on the drug blood level specimen slip. This record enables the laboratory to consider the pharmacokinetics of the drug during analysis.

The therapeutic range can only be considered an average, much like the temperature of 98.6°F is an average normal body temperature. Some patients experience the therapeutic effects from a drug when their blood levels show that the

drug is at "subtherapeutic" levels, whereas others experience adverse effects while the blood levels of the drug are in the "normal" range. This is due to genetic variations in individuals that alter the body's pharmacokinetic responses to a drug. The drug blood level is only one piece of data that must be considered when evaluating the patient's response to drug therapy. Changes to a drug's dose should be based on the total picture of the patient's response to therapy. Treat the patient, not the lab value.

CHAPTER SUMMARY

- Pharmacotherapeutics is the clinical purpose or indication for giving a drug.
- Pharmacokinetics is the effect of the body on the drug. It is made up of four phases: absorption, distribution, metabolism, and excretion. Absorption is the movement of the drug from the site of administration into the bloodstream. Distribution is movement of the drug through the bloodstream and eventually into the cells. Metabolism refers to the changing of the drug into another substance or substances (i.e., metabolites). Excretion is the removal of the drug or its metabolites from the body. Metabolism and excretion are considered together as elimination of a drug. Most commonly in practice, however, the clinician uses the term elimination as a synonym excretion.
- The blood–brain barrier is the body's natural defense to keep toxins and poisons from reaching the brain. It also may prevent the distribution of needed drug molecules from reaching their target.
- Drugs have different affinities for protein molecules, especially albumin, in the blood. Drugs that are highly protein bound have a lower proportion of their molecules available to produce the desired therapeutic effect. Only the free drug is active.
- Metabolism of drugs occurs primarily in the liver. Liver metabolism is predominantly achieved by specific liver enzymes, known as the P-450 system. The P-450 system also metabolizes some drug in the small intestine. Some drugs can induce this system, increasing their own or other drugs' metabolism. When multiple drugs are metabolized by the same P-450 family, the metabolism of all the drugs is normally decreased. Anything that impairs liver functioning also decreases drug metabolism. Decreased metabolism leads to increased circulating levels of the drug, more therapeutic effect, and possibly more adverse effects.
- Drugs that are administered orally pass through the liver before going to the general circulation. If the drug is highly metabolized, a high first-pass effect occurs. This effect substantially decreases the amount of drug that is distributed to the body.
- The kidney is the primary organ responsible for drug excretion. There are three processes that affect the excretion of drugs in the urine: glomerular filtration, passive tubular reabsorption, and active tubular secretion. Anything that decreases kidney function decreases drug excretion, leading to increased circulating blood levels of the drug.
- Half-life of a drug is the amount of time needed to eliminate (by metabolism and excretion) half of the drug molecules currently in the body.
- Steady state is when the continuing dose of a drug is in balance with the elimination rate of the drug, that is, when the amount of drug entering the body equals the amount being removed. Steady state is achieved after four to five half-lives. Achievement of steady state is not related to the dosage of the drug or the frequency of drug administration.
- Most drugs create their effects in the body by attaching to special sites, called receptors, on cells. At the receptor site, the drug is able to stimulate the cell to act in a way that the cell is designed to act. Drugs that stimulate the cell to act are known as agonists. Drugs that attach to receptors to prevent other substances from attaching and "turning on" the cell are called antagonists or blockers.
- The single occupancy theory and the modified occupancy theory help to explain how drugs achieve their effects at receptors.
- Potency of a drug refers to how *much* of a drug is needed to create the desired therapeutic effect. Efficacy of a drug refers to how *well* the drug creates the desired therapeutic effect. Drugs may have different potencies but the same efficacy. Efficacy is a more important consideration than potency when selecting a particular drug.
- Loading doses are larger-than-normal doses used when therapy is initiated with drugs that have very long half-lives. The purpose of the loading dose is to achieve quickly a blood level of the drug that is in therapeutic range even though the drug has not reached steady state.
- Maintenance doses are the doses administered regularly throughout therapy.
- The therapeutic index is a measurement of the safety of the drug. Drugs that are described as having a narrow therapeutic index do not have much difference between the effective dose and the toxic or lethal dose. Patients receiving these drugs need to be monitored very closely for adverse effects. They also need to have their drug blood levels monitored closely.
- Drug dosages are adjusted to maintain a therapeutic level of the drug. Drug blood levels are one way of determining whether a dose needs to be either increased or decreased.

QUESTIONS FOR STUDY AND REVIEW

1. What is the difference between pharmacokinetics and pharmacodynamics?
2. What is the advantage of a drug being lipophilic during the distribution phase of pharmacokinetics?
3. Why are drugs metabolized to a hydrophilic form?
4. How do most drugs achieve their effect within the body?
5. Why would a drug that has a high first-pass effect be given by a route other than the oral route?

6. If a patient has renal insufficiency or poor hepatic functioning, how might the dose of a drug be adjusted? Why?
7. Your patient is receiving a drug that is known to be highly protein bound. The laboratory reports for this patient indicate that the albumin level is below normal. How might this affect the patient's risk for adverse effects of the drug therapy? Why?

Adverse Effects and Drug Interactions

Learning Objectives

At the completion of this chapter the student will:

1. Identify the core drug knowledge of adverse effects and drug interactions.
2. Identify how adverse effects and drug interactions may alter the pharmacokinetics and pharmacodynamics of drug therapy.
3. Define the major toxicities that may occur as adverse effects.
4. Identify core patient variables related to adverse effects and drug interactions.
5. Relate the core drug knowledge of adverse effects and drug interactions to core patient variables.
6. Generate a nursing plan of care based on the interactions between core drug knowledge and core patient variables for adverse effects and drug interactions.
7. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects and drug interactions in drug therapy.
8. Determine key points for patient and family education about adverse effects and drug interactions.

In a perfect world, a perfect drug would produce only its desired therapeutic effect. Its effective dose would be easy to determine, it would be totally safe, and it would be so well tolerated that everyone who took it would adhere to and comply with the prescribed therapy. Alas, this is not a perfect world, and there is no perfect drug. All drugs can produce undesirable effects, some of them mild and annoying, others life threatening. Drugs also can produce altered effects because of interactions with other drugs, foods, or substances such as herbs and botanicals. These unexpected and nontherapeutic effects from drug therapy cause many patients to stop taking their prescribed drug therapy.

An **adverse effect** of drug therapy is a usually undesirable effect other than the intended therapeutic effect. It may occur even with normal drug dosing. An adverse effect may result from too much of a therapeutic effect (e.g., hypotension that may result from antihypertensive drug therapy) or from other pharmacodynamic effects of the drug (e.g., beta blockers are given for their effect on the heart, but they also have an effect on the bronchial tree). These effects are usually dose dependent and predictable. Adverse effects may also occur independently of the dose and be unpredictable. The term *adverse effect* encompasses all nontherapeutic responses to drug therapy and is used throughout this text.

A **drug interaction** occurs when two drugs or a drug and another element (such as food) have an effect on each other. This interaction may increase or decrease the therapeutic effect of one or both of the drugs, create a new effect, or increase the incidence of an adverse effect.

To maximize therapeutic effect, minimize adverse effects and drug interactions, and plan for appropriate patient and family education, nurses need to understand adverse effects and drug interactions and use this knowledge in their management of drug therapy. This chapter deals with these aspects of core drug knowledge.

ADVERSE EFFECTS

Every drug can produce adverse effects. Many adverse effects, such as nausea, are mild and bothersome perhaps only to the patient. Others, including liver failure, are serious or even life threatening. Serious adverse effects lead to the withdrawal of a small number of drugs from the market every year. A drug is withdrawn not because it was approved without testing—clinical studies are done on all drugs under development, and all adverse effects in the study participants are identified. Sometimes, however, complete knowledge of adverse effects cannot be obtained until the drug has been used for a longer time than the length of the trial or by more people than were included in a trial. Sometimes, adverse effects can be identified only when used extensively by patient populations that may not have been adequately represented in the study population, such as older adults, or patients with certain disease processes (e.g., renal disease).

It is important for nurses and other health care professionals to be alert for adverse effects from drug therapy. Sometimes, determining whether an adverse effect has occurred as a result of drug therapy is difficult. Adverse effects may be mistaken for changes associated with aging or disease pathology. For example, slight memory loss may be attributed to changes with aging, or hyperglycemia may be attributed to uncontrolled diabetes rather than to an adverse effect.

Serious adverse reactions (e.g., death or potential fatality, significant disability, requires or prolongs hospitalization, congenital anomaly, or requires intervention to prevent permanent damage) from a drug, especially a newly approved drug, should be reported to a national database, such as the MedWatch reporting system sponsored by the FDA through its website (FDA website)Reporting of serious adverse effects is necessary for corrective action to take place; examples of actions that may be taken to protect the public include revising the drug label, adding Black Box warnings for health care providers to highlight the most serious warnings (Box 5.1), creating patient Medication Guides that are dispensed with each filled prescription of a drug, or, if needed, withdrawing the drug from the market. Medication Guides are provided for drugs with potential serious adverse effects (Box 5.2). Alternative therapy without these potential serious adverse effects may not exist for many drugs. The underlying assumption is that these drugs may be safely used if patients know what symptoms warrant immediate consultation with the prescriber.

Box5.1 BLACK BOX WARNINGS

What Exactly is a Black Box Warning?

- A method of flagging a serious warning so that prescribers do not miss seeing it
- The warning is placed at the top of the drug label information with a black border printed around it.
- Printed materials and online databases that provide information about drugs all must show the Black Box warning.

Does a Black Box Warning Mean That the Drug is Too Dangerous to Use?

- No, it means that special and careful monitoring for onset of a problem is required for its appropriate use. All drugs carry risks of adverse effects, and many of these may be small but serious or life threatening, such as blood dyscrasias or liver failure.
- Sometimes the warning is used to emphasize that the use of the drug should be limited to patients only with certain conditions or who meet certain guidelines.
- Examples of drugs that have Black Box warnings:
  - SSRIs and other antidepressants
  - Most chemotherapeutic drugs
  - Some antibiotics (e.g., the aminoglycosides such as gentamicin, chloramphenicol, and the lincosamides such as clindamycin)

  - The antidiabetic drug metformin

Box5.2 WHAT IS AN FDA MEDICATION GUIDE?

A Medication Guide is a tool designed to assist patients and their families to be active participants in their care by recognizing early signs or symptoms of serious adverse effects. These guides are required only for a limited number of drugs where a serious adverse effect is possible but can be minimized or avoided if medical assistance is sought as soon as the symptoms appear. As the person receiving drug therapy may not recognize the symptoms in themselves, families need to be educated about these signs and symptoms. Patients and families need to be taught to read these educational materials every time they have a prescription filled, as the information in them may change.

Allergic Responses

Adverse effects that are not predictable or dose related are caused by allergic or idiosyncratic responses. An **allergic response** is an immune system response. If the body interprets the drug as a foreign substance (antigen) and forms antibodies against the drug, the immune system initiates the antigen–antibody response when the drug is taken again. This response involves the release of histamine, which is responsible for many symptoms of allergy: redness, itching, swelling, rash, and hives. The allergic response may change over time, and symptoms may become more severe each time the drug is introduced into the body. The most serious allergic response is called **anaphylaxis.** During anaphylaxis, changes occur throughout the body, including constriction of bronchial smooth muscles (bronchospasms), vasodilation, and increased vascular permeability. The symptoms of anaphylaxis include acute respiratory distress, marked hypotension, edema (most importantly laryngeal edema), rash, tachycardia, cyanosis, and pale, cool skin. Convulsions may occur. If anaphylaxis is untreated, death is likely. Treatment includes the administration of vasopressor agents to increase the blood pressure; bronchodilators to open the airway (most often epinephrine, which is both a vasopressor and a bronchodilator); antihistamines to block the effects of the released histamine (such as diphenhydramine); corticosteroids, which have anti-inflammatory effects and reduce swelling; oxygen therapy to treat cyanosis; and intravenous fluids to help support blood pressure. Endotracheal intubation and mechanical ventilation are often needed to support an open airway and respiration.

Idiosyncratic Responses

Idiosyncratic responses to a drug are another form of adverse effect. These responses are unusual and in fact may be the opposite of what is anticipated. They are sometimes called *paradoxical effects*. Idiosyncratic responses are related to an individual's unique response to a drug, rather than to the dose of a drug. They are considered to be genetically predetermined. The genetically inherited trait of responding to general anesthetics by developing malignant hyperthermia is an example of an idiosyncratic response to drug therapy.

Historically, different terms have been used to differentiate mild from serious nontherapeutic drug effects. The term *side effect* typically referred to a minor effect (such as nausea), whereas the term *toxic effect* referred to a more serious, potentially life-threatening effect (such as impaired renal function). In reality, the distinction between the terms is often blurry, and classification in one or the other category is somewhat arbitrary. For that reason, the newer, current term in pharmacologic literature is *adverse effect,* which is used to describe all undesired effects. Some practitioners still use the term *side effect* as a synonym for *adverse effect*.

Toxicities

Specific patterns or groups of symptoms related to drug therapy that carry risk for permanent damage to an organ or system and that may result in death are called *toxicities*. The organ or system that is affected is used to name the toxicity (as in neurotoxicity, nephrotoxicity, cardiotoxicity). Drug toxicities are now listed *as a type of adverse effect* from a drug (e.g., nephrotoxicity is an adverse effect of aminoglycoside antibiotics). When two or more drugs taken by a patient can produce the same toxicity, the risk that the patient will develop the drug toxicity increases. The most commonly referenced drug toxicities are: neurotoxicity, hepatotoxicity, nephrotoxicity, ototoxicity, cardiotoxicity, and immunotoxicity A description of these drug toxicities follows.

Neurotoxicity, sometimes referred to as central nervous system (CNS) toxicity, is a drug's ability to harm or poison a nerve cell or nerve tissue. Signs and symptoms of neurotoxicity include drowsiness, auditory and visual disturbances, restlessness, nystagmus (involuntary cyclic movement of the eyeballs), and tonic-clonic (grand mal) seizures. Neurotoxicity can occur after exposure to drugs and other chemicals and gases (e.g., alcohol, solvents, insecticides, industrial vapors, and pollutants). Injury to the CNS is largely irreversible because the highly differentiated neurons of the brain cannot divide and regenerate. Immature nervous systems (e.g., fetal and neonatal nervous systems) can easily be damaged by drugs that produce neurotoxicity.

Hepatotoxicity is damage to the liver. Manifestations of hepatotoxicity include hepatitis, jaundice, elevated liver enzyme levels, and fatty infiltration of the liver. Hepatic anatomy and hepatic function both contribute greatly to the high susceptibility of the liver to toxicants. Blood draining from the stomach and small intestines is delivered directly to the liver by the hepatic portal vein. As a result, the liver is exposed to relatively large concentrations of ingested drugs or other potentially toxic substances. If the drug that was absorbed and is now present in the blood is hepatotoxic, liver damage will likely occur because of the large number of drug molecules presented to the liver. The liver is also responsible for metabolizing most drugs. If liver damage occurs, the drug will not be metabolized as efficiently, leaving more circulating drug to cause further liver damage.

Damage to the kidneys is called **nephrotoxicity.** Decreased urinary output, elevated blood urea nitrogen, increased serum creatinine, altered acid-base balance, and electrolyte imbalances can all occur with kidney damage. The renal system is similar to the hepatic system in that it is susceptible to poisoning because of its anatomy and function. The cells within the proximal tubule are frequently damaged by nephrotoxic drugs. These cells are responsible for filtering, concentrating, and eliminating toxic as well as nontoxic materials; as water is reabsorbed instead of eliminated, the concentration of drug molecules in the tubule rises, thereby increasing the potential for damage.

Ototoxicity is damage to the eighth cranial nerve. Structures of the inner ear that may be affected include the cochlea (responsible for hearing) and the vestibular and semicircular canals (responsible for balance). Ototoxicity may or may not be reversible. Signs and symptoms of ototoxicity include tinnitus, which is a buzzing or ringing sound in the ear, and sensorineural hearing loss. Also called nerve deafness, sensorineural hearing loss usually begins with the loss of high-frequency sound and may worsen until low-frequency sound is also difficult to hear. Other signs and symptoms, particularly of vestibular toxicity, include light-headedness, vertigo, a spinning sensation from a seated position, and nausea and vomiting.

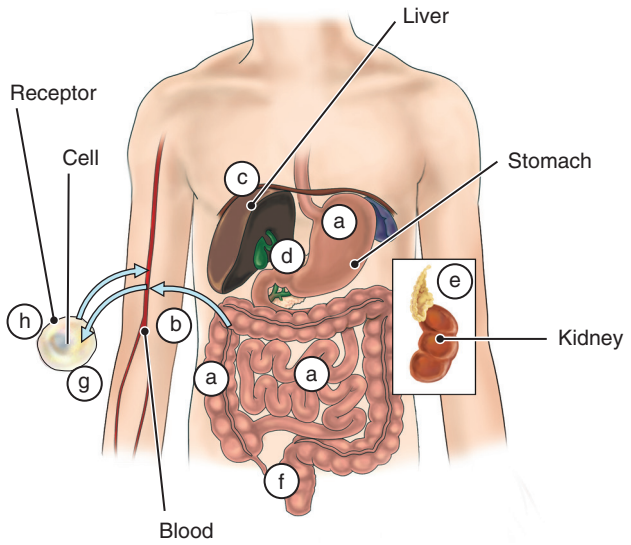
Irregularities in cardiac rhythms and conduction, heart failure, and even damage to the myocardium may result from an adverse effect known as **cardiotoxicity.** Exactly how some drugs produce cardiotoxicity is unknown. Older adults, who have less effective hearts than younger adults, and children younger than 2 years, whose hearts are still growing, are most susceptible to cardiotoxicity from drugs.

When the immune system is significantly affected by drug therapy, the condition is called **immunotoxicity.** A wide variety of drugs can affect the immune system. Some may cause immunosuppression, whereas others may directly destroy immune system components. The effect of both kinds of immunotoxicity may be an increased incidence of bacterial, viral, and parasitic infections.

DRUG INTERACTIONS

Drug interactions occur when one drug (Drug A) is affected in some way by another drug (Drug B), a food, or some other substance that is taken concurrently. The effect may be to increase the therapeutic or adverse effects from Drug A or to decrease the therapeutic or adverse effects from Drug A. Rarely, a new and different effect may be induced.

Drug interactions may be beneficial (e.g., when the interaction increases the therapeutic effect of a drug or decreases its adverse effects). Sometimes, drugs are ordered specifically to bring about the desired drug interaction. For example, probenecid, a drug used to treat gout, is given to patients without gout to prevent the renal excretion of penicillin, thus allowing the penicillin to circulate longer and produce additional therapeutic effects.



• FIGURE 5.1 Drug interaction sites within the body. Drug interactions can occur in numerous body sites. Absorption can be enhanced or reduced in the gut (**a**); protein binding can be affected within the vasculature (**b**); metabolism can be affected in the liver (**c**); excretion can be affected through bile (**d**), through the kidney (**e**), or in feces (**f**); tissue binding of one drug can be affected by another (**g**); and finally, drugs may have an effect through action on specific receptors (**h**).

Negative effects from drug interactions are those that decrease the therapeutic effect or increase the adverse effects of a drug. For example, consuming foods high in tyramine (such as smoked meats) while taking a monoamine oxidase inhibitor (MAOI) antidepressant can lead to pronounced elevation of blood pressure and may induce a hypertensive crisis. Drug interactions that alter the circulating level of one of the drugs are especially worrisome if the drug has a narrow therapeutic index (see Chapter 4). In this case, a slight elevation of the blood level of the drug may produce serious adverse effects, whereas a slight decrease in the blood level may cause the drug to become nontherapeutic.

Drug interactions may take place in any phase of pharmacokinetics—absorption, distribution, metabolism, or excretion. Drug interactions can also change the pharmacodynamics of a drug or the adverse effects of the drugs. When two drugs can both independently cause the same adverse effect, there is an increased risk for that adverse effect when both drugs are taken. Drug interaction sites in the body are shown in Figure 5.1 and are discussed throughout the sections that follow.

Drug Interactions Affecting Pharmacokinetics

Drug Interactions Affecting Absorption

Drug absorption is often decreased because of drug interactions. If a drug binds with another substance in the gastrointestinal (GI) tract, less of the drug is available to be absorbed. For example, milk and antacids bind with the antibiotic tetracycline and prevent its absorption. This binding of a drug is termed *chelation*. Because drug absorption is related to how long the drug is present in the GI tract, changes in GI transit time alter drug absorption. Therefore, drugs such as laxatives,

which hasten the transit time, can decrease the absorption of other drugs that are present in the GI tract at the same time. Finally, the mere presence of food in the GI tract can delay or reduce the absorption of many drugs.

Drug absorption may also be increased as a result of a drug interaction or the presence of food in the GI tract. For example, antacids increase the pH of the stomach contents. A less acidic environment decreases ionization of drugs that are basic, which promotes absorption of these drugs.

The exact extent of changes in drug absorption caused by drug interactions is often difficult to predict. The nurse needs to monitor for signs of decreased or less than anticipated drug effect to determine if there might be a drug interaction. Monitoring is warranted especially if the drug regimen changes (a new drug is added or one is stopped). Sometimes, separating the administration times of the two drugs by at least 2 hours is enough to prevent binding and loss of absorption and effectiveness. Other times, an increased dose of the affected drug may be indicated.

Drug Interactions Affecting Distribution

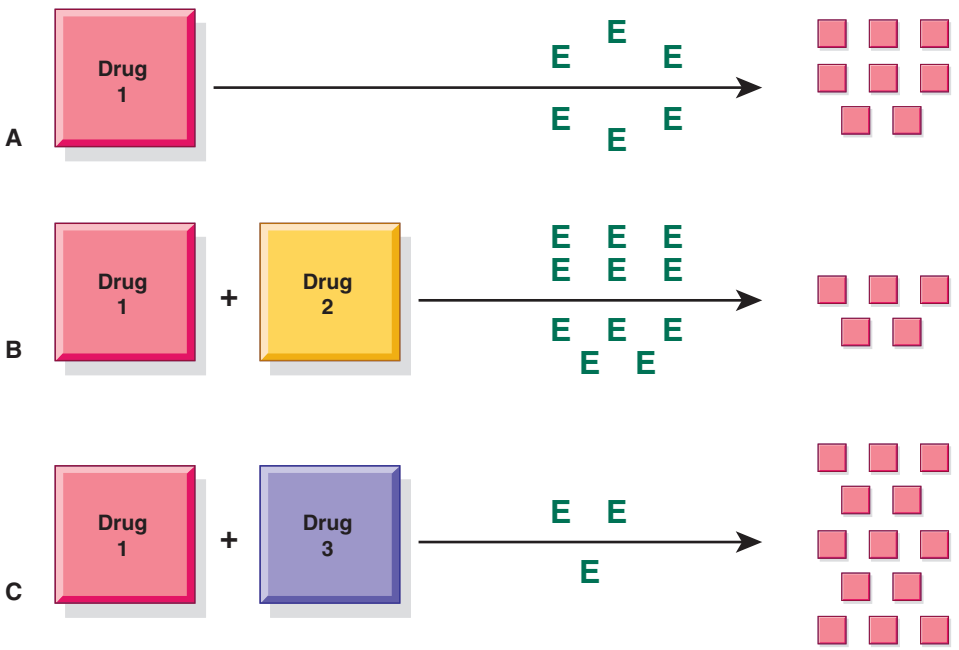
Distribution is affected by two types of drug interactions. The first is competitive protein binding. When two drugs compete for the same protein receptors, the drug that has a higher affinity for the site will displace the other drug. Thus, one of the drugs will have more free and active molecules to be distributed through the body than would normally be anticipated. (Protein binding is discussed in more detail in Chapter 4.)

The second way that drug distribution can be affected by drug interactions is when a drug alters the extracellular pH. A drug that increases the pH of the extracellular fluid (i.e., makes the extracellular fluid more basic) increases the ability of acidic drugs to ionize in the extracellular space. Remember that drugs will cross a membrane in order to be ionized, but once ionized the drug cannot move back through the membrane. In the example above, acidic drugs move from the low-pH (acidic) environment found within the cells into the higher-pH (basic) environment in the extracellular space in order to be ionized. Once ionized, the drugs are trapped on that side of the membrane. Thus, drug distribution is altered.

Drug Interactions Affecting Metabolism

Probably the most important and common drug interaction is one that alters the metabolism of a drug. Most metabolism occurs in the liver, some also occurs in the small intestine. As you recall from Chapter 4, metabolism of drugs is related to the cytochrome P-450 system. Some drugs either induce or inhibit the P-450 system (see Appendix G online), thus altering the metabolism of other drugs (Figure 5.2). Usually, just one P-450 family is affected.

Drugs that induce a hepatic enzyme increase the amount of that enzyme in the liver. Induction of the P-450 system is accomplished most frequently by stimulating synthesis of the enzyme. When one of the hepatic enzymes is present in greater quantities than the others, more metabolism by this pathway can occur. Drugs that are metabolized by this pathway (also referred to as drugs that are substrates of the enzyme) are therefore metabolized more rapidly, which in turn rapidly decreases the amount of circulating, active drug. Some drugs can induce the enzymes necessary for their own metabolism and thus can increase the rate of their own metabolism. Drugs that inhibit a particular hepatic enzyme slow the metabolism that occurs through this pathway, causing an increase in the amount of circulating, active drug. Metabolism will return to normal after the inducing or inhibiting drug is no longer administered, although the return to normal may not occur until several days after an inducer is discontinued.



• FIGURE 5.2 Drug interactions affecting P-450 metabolism. (**A**) Normal drug metabolism through the P-450 isoenzymes for Drug 1. (**B**) Drug 2 induces the P-450 system, increasing metabolism of Drug 1. Less Drug 1 than normal is left to circulate after this drug interaction. (**C**) Drug 3 inhibits the P-450 system; thus, metabolism is decreased for Drug 1. More Drug 1 than normal is left to circulate after this drug interaction.

If two drugs that affect the cytochrome P-450 system must both be administered to a patient, the dose of one of the drugs may have to be adjusted. When two or more drugs are metabolized by the same hepatic enzyme pathway, they compete with each other for the action of the enzyme. This competition results in impaired metabolism of one or more of the drugs. Consider the analogy of using the Internet through a dial-up connection. When few customers are online, it is easy to be connected and to use the online services. However, when there is very high demand, getting connected may be difficult, and once connected, you may be abruptly disconnected, losing the ability to use the online services. Similarly, when the demand is high for the services of a particular hepatic enzyme, not every drug will receive attention immediately.

In addition to drugs altering the metabolism of other drugs, grapefruit juice is known to inhibit CYP3A4. Remember that the P-450 isoenzymes responsible for drug metabolism are found not only in the liver but also in the intestinal wall. Grapefruit juice has an effect on CYP3A4 found in the intestinal wall, but not in the liver, and acts by blocking its function. The inhibition of CYP3A4 decreases the GI metabolism of many drugs, which allows more of the drug to be absorbed, resulting in substantially higher blood levels than if grapefruit juice were not consumed. Metabolism of many varied drugs such as calcium channel blockers (used to treat hypertension), statins (used to lower blood lipid levels), and antihistamines (used to prevent allergic reactions) is effected by grapefruit juice. Because the amount of CYP3A4 in the intestine varies among individuals based on genetic variations, the degree to which grapefruit juice alters drug metabolism also varies. In some people, the effect is great; in others, the effect is minimal. The more CYP3A4 that is present in the GI tract, the more drug metabolism can be increased. The effect also appears to be dose dependent (i.e., the more grapefruit juice a person drinks, the more inhibition of CYP3A4 that occurs). If the patient regularly drinks grapefruit juice before drug therapy is started, the drug dosage can be adjusted to obtain a therapeutic level or therapeutic effect. In this case, the patient can safely continue to drink grapefruit juice. Problems arise, however, when a patient intermittently drinks grapefruit juice or starts to drink it after drug therapy has been started. In these situations, the grapefruit juice may alter drug levels unpredictably, and the potential exists for substantial elevations that may cause adverse effects. Patients who did not consume grapefruit juice before the initiation of drug therapy should avoid drinking it once drug therapy has begun. See Appendix F online for a list of drugs that interact with grapefruit juice.

Some herbs and botanicals may also affect the CYP3A4 enzyme. St. John's Wort, for example, is a potent inducer of CYP3A4 and enhances the metabolism of drugs that are substrates of this enzymatic pathway. Drugs that are substrates of the CYP3A4 enzymatic pathway include protease inhibitors (used to treat AIDS), oral contraceptives, tricyclic antidepressants, and the immunosuppressant cyclosporine. Table 10.2 lists other possible drug interactions with herbs.

Alcohol and nicotine also alter the metabolism of some drugs. Nicotine is known to induce some isoenzymes in the P-450 system. A high blood alcohol level impairs the liver's ability to metabolize other drugs. Chronic use of alcohol may also induce some hepatic isoenzymes. Chronic alcoholism damages the liver permanently, decreasing drug metabolism.

Age also appears to decrease either the effectiveness of the P-450 enzymes or the number of enzymes available. The half-life of drugs processed by hepatic P-450 enzymes is typically 50% to 75% longer in adults older than 65 years than in younger adults (Ginsberg et al., 2005). This longer half-life is likely related to decreasing liver function that occurs with aging.

Inherited genetic variations of P-450 isoenzymes (termed genetic polymorphism) also effect how quickly or slowly a drug may be metabolized as well as its potential to cause drug interactions. These variations can often be attributed to the ethnicity of the patient (Bernard et al., 2006). Genetic profiling to determine whether a person has a CYP isoenzyme variation that produces poor metabolism of a drug (leading to higher than normal circulating levels, increased therapeutic effects, and increased adverse effects) or ultrarapid metabolism of a drug (leading to lower than normal circulating levels and failure to achieve the therapeutic response) could be used to determine the best drug dose for an individual. The dose would thus be tailored to decrease the risk of adverse effects and drug interactions and to promote optimal desired effects.

Genotyping for specific isoenzymes will not, however, indicate whether a particular drug will or will not work in a given patient (Pestka et al., 2007). Genetic profiling is currently expensive and still in its infancy. For genotyping to be relevant for patient care, specific patient populations (those most likely to have P450 interactions from drug therapy) should be screened, rather than all patients. For example, CYP 2D6 is known to be responsible for the metabolism of many drugs, and there are many normal variations to its presence. Psychiatric, psychogeriatric, and geriatric populations are commonly treated with at least one drug that is metabolized by CYP 2D6, so this group may be more likely to benefit from genotyping before drug therapy is started (Mulder et al., 2007; Pestka et al., 2007). CYP 2C9 variation is responsible for much of the adverse effects from the anticoagulant warfarin. See Box 5.3 to learn how research on this genetic variation is shaping dosing patterns for warfarin.

Drug Interactions Affecting Excretion

Drugs can alter renal filtration, renal reabsorption, or renal secretion. In doing so, they may alter the excretion of other drugs. Glomerular filtration is dependent on blood flow to the kidney. Drugs that decrease cardiac output decrease the amount of circulating blood that is sent to the kidneys. Renal reabsorption of a drug is dependent on whether a drug is ionized. Drug-induced changes in urinary pH affect whether other drugs are ionized and excreted or remain nonionized and are reabsorbed. Renal secretion uses a transport system to move the drug molecules into the urine for excretion.

If two drugs are dependent on the same transport system, the excretion rate of both is slowed.

Drug Interactions Affecting Pharmacodynamics

Drug interactions may affect the pharmacodynamics of one or both drugs administered. The overall effect may be positive or negative. Drug interactions can occur when both drugs act at the same receptor or at different receptors. Drugs that act at the same receptor compete to be attached to the receptor. The drug that has the weaker affinity for the receptor will not be able to exert its therapeutic effect, as discussed in Chapter 4. Drugs that act in different ways, or at different receptors, can interact in several ways. They may create an additive effect, a synergistic effect, a potentiated effect, or an antagonistic effect.

Additive Effect

An **additive effect** occurs when two or more "like" drugs (in terms of therapeutic effect) are combined, and the result is the sum of the drugs' effects. If written as an equation, this concept would be expressed as: 1 (Drug A) + 1 (Drug B) = 2. An additive effect may be intentional or may unintentionally cause harm. Consider the following two examples:

- Codeine and acetaminophen work differently to reduce pain. When these two analgesic drugs are combined, the additive effect is better control of pain (compared with that resulting from the use of either drug alone).
- Alcohol and salicylates, such as aspirin, can both cause GI bleeding. When a salicylate and alcohol are consumed together, the risk for GI bleeding is greatly increased because each agent independently can cause GI bleeding.

Synergistic Effect

A **synergistic effect** occurs when two or more "unlike" drugs (in terms of therapeutic effect or mechanism of action) are used together to produce a combined effect, and the outcome is a drug effect greater than either drug's activity alone. As an equation, this concept would be expressed as: 1 (Drug A) + 1 (Drug B) = 3. Just like an additive interaction, a synergistic interaction may be intentional or may unintentionally cause harm. Consider the following examples:

- A beneficial synergistic effect occurs when two different types of antibiotics that work in very different ways are combined, such as penicillin G and an aminoglycoside antibiotic. This approach is commonly used in the treatment of subacute bacterial endocarditis.
- When three different types of antihypertensive drugs—an alpha-adrenergic blocker (a vasodilator), a beta-adrenergic blocker (a sympatholytic), and a diuretic—are combined, the antihypertensive effect is better than with any drug alone.
- A harmful synergistic effect is represented by the interaction between drugs that depress the CNS, such as morphine and alcohol; this interaction causes additional CNS depression that may be fatal.

Potentiated Effect

Potentiation best describes an interaction in which the effect of only one of the two drugs is increased. In other words, a drug that has a mild effect enhances the effect of a second drug. As an equation, this concept would be represented as ½ (Drug A) + 1 (Drug B) = 2. For example, when the antiemetic drug hydroxyzine, which has some CNS depressant effects and produces mild analgesic effects, is combined with a narcotic analgesic such as morphine, the pain-relieving ability of the morphine is increased without increasing the dose of the morphine.

Antagonistic Effect

An **antagonistic drug interaction** is the opposite of a synergistic effect. It results in a therapeutic effect that is less than the effect of either drug alone because the second drug either diminishes or cancels the effects of the first drug. As an equation, this concept would be expressed as: 1 (Drug A) + 1 (Drug B) = 0. For example, when the heparin antagonist protamine sulfate (a strong basic anticoagulant) is given as an antidote for heparin (a strong acidic anticoagulant) to halt heparin-induced bleeding, a stable salt forms, resulting in a loss of anticoagulant activity for both drugs. Antagonistic interactions can also occur at receptor sites when one drug is an agonist and the other drug is an antagonist for the same receptor, such as with morphine, a narcotic agonist, and naloxone, a narcotic antagonist used to correct narcotic overdosage.

DRUG INCOMPATIBILITIES

Drug incompatibilities are similar to drug–drug interactions in that a chemical inactivation or physical reaction occurs. This reaction may involve two or more drugs, inside the body or outside, before they are administered. While administering drugs parenterally (intravenously, intramuscularly, or subcutaneously), the nurse is especially alert to the possibility of drug incompatibilities and drug interactions. The most common kinds of incompatibilities are chemical and physical.

Chemical Incompatibilities

Chemical incompatibilities between drugs change both the drug's structure and its pharmacologic properties. The alteration may be beneficial. For example, heparin and protamine sulfate (a heparin antagonist) form an ionic bond that lacks any anticoagulant activity. Conversely, the chemical incompatibility may also be harmful; for example, combining multivitamins and antibiotics in the same intravenous (IV) solution changes the solution's pH and inactivates the antibiotic.

Physical Incompatibilities

Physical incompatibilities occur when two drugs are mixed together. The mixture results in the formation of a precipitate. Phenytoin and a diluent containing dextrose, for example, produce a cloudy, white precipitate. This kind of reaction usually interferes with the pharmacologic activity of one or both drugs.

This is one of the reasons that manufacturers provide specific instructions for preparation, dilution, and addition of drugs to other solutions. These instructions should be followed carefully.

IMPLICATIONS FOR NURSING MANAGEMENT

When administering drug therapy, the nurse's main focus is on ensuring a beneficial outcome by maximizing therapeutic effects, minimizing adverse effects and drug interactions, and providing appropriate drug education for the patient and family. Beneficial outcomes are achieved by relating core drug knowledge to core patient variables throughout the nursing process. Understanding how core drug knowledge and core patient variables interact to affect outcome is important because these interactions may predispose the patient to adverse effects from drug therapy.

Nursing Management of the Patient Receiving Drug Therapy

Assessment of Core Patient Variables

Health Status

Concurrent medical conditions may increase the risk for adverse effects from drug therapy. For example, if a patient has diminished renal function and then takes a drug that may cause nephrotoxicity, the patient is more likely to develop adverse effects, even with a therapeutic dose. A patient's chronic health condition may also necessitate drug therapy that may interact with other drug therapy or promote adverse effects. For example, a patient with AIDS may be taking drug therapy that carries the risk for hepatotoxicity. If this patient develops tuberculosis, he or she will need to take additional drug therapy, which also may cause hepatotoxicity.

Life Span and Gender

A patient's age can greatly increase the risk for adverse effects from drug therapy. The liver and kidneys of both young children and older adults do not function as well as those of young adults. As a result, those populations are at increased risk for adverse effects and drug interactions. In addition, older adults are more likely to be receiving polypharmacy for multiple chronic illnesses and thus are more likely to experience drug interactions.

In some drug therapy women are known to have more significant adverse effects than men. This may be related to a sex difference in pharmacokinetics (including P-450 differences), pharmacodynamics, or even the dose concentration within the body. This is because the dose of most drugs are not based on weight; when men and women receive the same dose of a drug the circulating concentration of a drug will be less in men because men generally weigh more than women (Anderson, 2008). The P-450 system is altered with pregnancy; CYP1A2 activity is decreased and CYP2D6 and CYP3A activities are increased during pregnancy. The nurse should assess how any drug therapy received by a pregnant woman is metabolized. Drugs that are metabolized via these pathways may need dosage adjustments by the physician (Tracy et al. 2005). Adverse effects from drug therapy taken by a pregnant woman may affect the unborn child. Many drugs can also be passed in breast milk, causing adverse effects in the infant. Life span issues are discussed in more detail in Chapters 6, 7, and 8.

Lifestyle, Diet, and Habits

What and when a patient eats and drinks and the patient's various habits and choices (e.g., the use of tobacco, alcohol, caffeine, street drugs, or over-the-counter herbs and botanicals) may influence the effects of drug therapy, either positively or negatively. For this reason, remember to ask patients about diet and other habits when performing a drug history or when providing patient education on prescribed drug therapy. Then inform patients about possible interactions and describe how to maximize therapeutic effects or prevent or minimize adverse effects and drug interactions. (For more information on how lifestyle, diet, and habits influence drug therapy, see Chapters 9 and 10.)

Environment

The patient's environment may increase the likelihood that a certain adverse effect will occur. For instance, some antibiotics can cause the adverse effect of photosensitivity. Even brief exposure to sunlight or strong ultraviolet light can cause severe sunburn, hives, or a rash. Other drugs (e.g., anticholinergics, belladonna alkaloids) reduce the body's tolerance to heat or inhibit the body's ability to reduce temperature by perspiration. These types of drugs may make the patient vulnerable to heat stroke in hot weather or during exercise.

The environment in which drug therapy is administered can also play a role in the early detection of adverse effects. For example, a critically ill patient receives drug therapy under close supervision, which could lead to early detection of any adverse effects. However, a person who is receiving drug therapy in a community setting may be more at risk for adverse effects because the early signs of the adverse effect may not be identified as easily as they would be in a clinical setting. The relationship of environment to drug therapy is discussed in more detail in Chapter 11.

Culture and Inherited Traits

Researchers are beginning to study responses to drug therapy that are genetically determined in various ethnic and racial populations. These responses may place the patient at greater risk for adverse effects or drug interactions than the rest of the global population. Box 5.3 describes one study that focused on the metabolic activity of the P-450 system in Caucasian, African American, and Hispanic men and women. Culture and inherited traits and the ways that they influence drug therapy are discussed in more detail in Chapter 12.

Nursing Diagnoses and Outcomes

Nursing diagnoses are related to specific adverse effects of the ordered drug therapy and to drug interactions. Outcomes

Moving Research Findings Into Clinical Practice

The Study

It has been known for years that getting the correct dose of the anticoagulant drug warfarin can be difficult in many people and many people suffer with significant bleeding from warfarin therapy. These problems are related to changes in the metabolism of warfarin via CYP 2C9. One-third of patients receiving warfarin metabolize it quite differently than expected. Research has shown that some of the unexpected response to warfarin depends on a patient's variants of the genes CYP2C9. A systematic review of clinical trials examining two variant allelels of CYP 2C9 and the consequent effect on warfarin metabolism was conducted. Nine studies (2,775 patients) were included in the meta- analysis. Twenty percent of the patients carried a genetic variation on CYP2C9. These patients required a mean reduction of 27% in the dose of warfarin from "standard doses" to achieve therapeutic effects without adverse effects (such as serious bleeding). Patients with genetic variations of CYP2C9 had a higher relative risk for bleeding than patients without the genetic variation.

Nursing Implications

In 2007 the US Food and Drug Administration modified the label of warfarin to highlight these findings, and other research findings relative to genetic variation increasing the risk of adverse effects from warfarin in patients. This relabeling was unique in emphasizing how genetic variation of a P450 isoenzyme alters patient response to therapy and should be considered when starting warfarin therapy. Currently, FDA sponsored research is still underway to determine which patients would most benefit from genetic testing, and if a dosing algorithm can be devised to decrease unintentional bleeding while still achieving therapeutic effectiveness. In the near future it is likely that nurses will play a role in genetic testing of patients and may need to confirm that genetic testing has been accomplished prior to starting a patient on warfarin therapy.

are directed at preventing or minimizing either occurrence without harm to the patient. Some examples include the following:

- Risk for Infection related to drug-induced myelosuppression
  Desired outcome: *The patient will not develop infection while on drug therapy.*
- Imbalanced Nutrition: Less Than Body Requirements, related to drug-induced nausea, vomiting, anorexia, stomatitis
  Desired outcome: *Despite adverse effects, the patient will receive enough nourishment to meet physiologic needs.*
- Risk for Poisoning (Toxicity) related to use of drug with a narrow therapeutic index
  Desired outcome: *The patient will receive drug therapy without harmful or poisonous effects.*

Planning and Intervention

Maximizing Therapeutic Effects

When drug interactions are intentional and desirable, it is important to give the drugs at the prescribed time intervals. They should be administered at the same time if necessary to achieve the interaction. When drug interactions are not desired but both drugs are needed for therapy, the doses must be administered at different times to promote the therapeutic effect of each drug.

Minimizing Adverse Effects

To help protect the patient from serious adverse effects and drug interactions, obtain a drug history from the patient, beginning with a list of all drugs that the patient has taken. Drug references or databases may then be consulted for complete descriptions of known or suspected drug interactions.

If a patient is taking a drug that may interact in the GI tract (including P-450 interaction from grapefruit juice) with another drug in the current regimen, the drugs should not be coadministered but their administration times should be staggered. If that is not sufficient to minimize an interaction contact the prescriber about changing one of the ordered drugs. If the drug interaction occurs systemically (such as in the P-450 system in the liver) staggering the doses will not be sufficient. Contact the prescriber about possibly changing one of the ordered drugs: sometimes a different drug in the same drug class does not pose the interaction. If both drugs are required, additional monitoring of the patient or dose adjustment of one of the drugs may be warranted. If the interaction is potentially serious, the prescriber should be consulted before you or the patient begins administering the new drug. When a patient is receiving two or more drugs and either unexpected effects or no therapeutic effects occur, you should suspect that a drug interaction may have occurred and investigate fully.

If administering two or more medications parenterally, check the label information for drug compatibility to determine if the same IV tubing or syringe can be used for both medications. Do not check for drug interactions on the label as this is referring to systemic interactions (e.g, via the P-450 system).

Throughout therapy, monitor the patient for signs and symptoms of interactions and adverse effects and for alterations in health status that increase the risk for adverse effects. If a drug interaction is known to increase or decrease the circulating level of one of the drugs, serum drug levels are monitored to determine whether therapeutic levels are being maintained.

Providing Patient and Family Education

Before and throughout drug therapy, inform the patient and family about adverse effects and drug interactions. Initial instruction includes teaching the patient how to minimize the occurrence of these effects and how to cope with them. In addition, teach the patient which effects to expect, which to report to the prescriber, and which require immediate medical attention.

CRITICAL THINKING SCENARIO

SUSPECTED ADVERSE EFFECTS

You are a nurse working in an emergency room of a community hospital. A patient with diabetes is brought in with complaints of nausea and abdominal pain. On physical assessment, she is found to have an enlarged, tender liver. Her liver enzymes are substantially elevated. She is to be hospitalized. During your assessment, you learn that the patient was started on a newly approved drug for her diabetes 3 months ago.

1. How would you determine whether her symptoms were known adverse effects from the drug therapy?
2. You determine that her symptoms are not listed as known adverse effects, but you still feel concerned that they may be related to her drug therapy. What action would be appropriate based on your suspicion?

Ongoing Assessment and Evaluation

During drug therapy, continue to monitor for adverse effects and drug interactions, including allergic responses. Also consider the possibility of a drug interaction each time a new drug is added to the treatment plan. If none of these effects occurs and the therapeutic effect has been achieved, drug therapy is evaluated as successful.

CHAPTER SUMMARY

- Adverse effects are all unintended effects of drug therapy. All drugs have adverse effects. Adverse effects may be very mild and merely bothersome or serious and life threatening.
- Adverse effects are usually predictable or dose related. Adverse effects that are not predictable or dose related are attributable to allergic responses or idiosyncratic responses. The most serious allergic response is called anaphylaxis, which can be fatal if not treated.
- Adverse effects that carry the risk for permanent damage or death and form specific patterns or groups of symptoms related to drug therapy are called toxicities. The major drug toxicities are hepatotoxicity, nephrotoxicity, neurotoxicity, cardiotoxicity, ototoxicity, and immunotoxicity.
- Drug interactions occur between two drugs or a drug and food or another substance, such as alcohol. Some drug interactions are beneficial, whereas others are harmful.
- Drug interactions may affect any aspect of pharmacokinetics: absorption, distribution, metabolism, or excretion.
- An important and common drug interaction is one that alters the metabolism of a drug by either inducing or inhibiting the P-450 system. Drug–drug interactions usually alter the P-450 system in the liver, whereas interactions between drugs and grapefruit juice primarily alter the P-450 enzymes in the GI tract.
- Drug interactions may also alter the pharmacodynamics of drug therapy. Two or more drugs may compete for the same receptor site, or they may work in different ways in the body with conflicting or cumulative results. Drugs that act in different ways, or at different receptors, may create an additive effect, a synergistic effect, a potentiated effect, or an antagonistic effect.
- Nurses must understand the core drug knowledge of adverse effects and drug interactions because these phenomena interact with the core patient variables during drug therapy. Recognizing the potential for these interactions allows the nurse to plan care in a way that will maximize the therapeutic effects, minimize the adverse effects, and provide effective patient and family education.

QUESTIONS FOR STUDY AND REVIEW

1. You are assessing a patient's drug history. The patient tells you that she is allergic to a particular drug. List the symptoms that would indicate that the response was a true allergic response and not an adverse effect of drug therapy.
2. Your patient is 75 years old and is receiving a drug that may cause ototoxicity. Describe why it may be difficult to determine whether adverse effects are occurring.
3. Your patient is receiving two drugs. Drug A is metabolized by the CYP3A4 hepatic system. Drug B induces the CYP3A4 hepatic system. What effect will Drug B have on the circulating blood level of Drug A?
4. Two patients each receive the same dose of the same drug that is metabolized in the GI tract by the CYP3A4 system. Each patient drinks a glass of grapefruit juice. Will the effect of the grapefruit juice on circulating drug levels be identical in both patients? Why or why not?
5. Describe why hepatotoxic drugs may produce more liver damage when given orally than when given parenterally.
6. Your patient receives three different drugs that all produce CNS depression. Explain what effect this combination will have on the pharmacodynamics of these drugs.
7. Your patient has been on Drug A to lower his blood pressure and has been obtaining a therapeutic effect from the drug. The patient's blood pressure has been in a normal range for several days. Then, the patient develops an infection and is started on Drug B. Within 24 hours, the patient is hypertensive again. What assessment would you make?

Life Span: Children

Learning Objectives

At the completion of this chapter the student will:

1. Identify key areas of core drug knowledge for children that differ from those for adults.
2. Explain why calculating drug dosages for children is different from calculating dosages for adults.
3. Describe methods for calculating dosages for children of different ages.
4. Identify key core patient variables for children and explain how they differ from those for adults when considering drug therapy.
5. Discuss key developmental variables for each of the pediatric age groups (infant, toddler, preschooler, school-aged, and adolescent) that affect how the nurse administers drug therapy.
6. Propose some common nursing diagnoses related to drug therapy in children.
7. Describe key nursing interventions to promote maximal therapeutic effects and minimal adverse effects during pediatric drug therapy.
8. Identify key points to include in educating patients and families about pediatric drug therapy.

When implementing pediatric drug therapy, the nurse must remember that children are different from adults in many ways. Although some drugs and administration routes are similar in adults and children, the nursing management of drug therapy varies greatly. For example, physiologic differences in children and the child's immature body systems, greater fluid composition, and smaller size all affect the core drug knowledge. These differences can exaggerate or diminish the pediatric patient's response to drug therapy, making some drug actions and outcomes less predictable in the child than in the adult.

Additionally, in children, core patient variables differ from those in adult patients and from child to child because of the differences across the developmental stages of childhood. The **pediatric patient** is usually defined as younger than 16 years and weighing less than 50 kilograms.

This chapter focuses on core drug knowledge that is relevant and unique to pediatric patients and on core patient variables that emphasize children's needs according to developmental changes. Special issues in managing pediatric drug therapy are explored, including maximizing therapeutic effects, minimizing adverse effects, and educating patients and families.

Nursing Management of the Pediatric Patient

Core Drug Knowledge Related to Children

Pharmacotherapeutics

Therapeutic indications and effects for many drugs are similar for children and adults. Not all drugs that are labeled as safe for adults, however, have been labeled as safe for children; of all approved drugs, only about 20% are approved for pediatric use (Luo et al., 2007). One reason for this is that few drugs have been adequately tested in clinical trials on pediatric patients. Historically, it was considered unethical to enroll children in randomized, controlled drug studies. Because drugs in development were not tested on children, they were not labeled as approved for use in children. As a result, pediatricians must often prescribe medications for off-label uses in children (Aschenbrenner, 2006). An off-label use is when a drug is used for a purpose not clearly stated on its label but the prescriber has reason to believe the drug will produce the desired therapeutic effect (see Chapter 4 for a complete discussion of off-label use of drugs). A recent study of hospitalized children found that at least one drug was used off label in almost 79% of these patients (Shah et al., 2007).

Compounding this problem of off-label uses was a lack of financial incentives for drug manufacturers to retest drugs already on the market to obtain approval for use in children. In recent years, however, the thinking has changed so that it is now considered unethical to *exclude* children from drug studies and not to include child-specific prescribing information on labels for drugs used in children. To meet this need, the United States Congress passed the Best Pharmaceuticals for Children Act in 2001; this Act was reauthorized in 2007 (Aschenbrenner, 2006). This act provides several avenues for drugs already on the market to

Box6.1 CALCULATING PEDIATRIC DRUG DOSAGES

Body Surface Area Method

Step 1. Determine the body surface area (BSA) of the child. It is measured in meters squared. A standard formula is used. Computations should be made with a calculator.

$$\text{BSA} = \sqrt{\frac{\text{Weight in kg} \times \text{Height in cm}}{3{,}600}}$$

Example: Child weighs 10 kg and is 45 cm tall

1. Multiply weight in kilograms by height in centimeters.
2. Divide product by 3,600.
3. Enter square root sign on calculator.
4. Round the BSA to the nearest hundredth.

$$\text{BSA} = \frac{10 \times 45}{3{,}600}$$

$$= \frac{450}{3{,}600}$$

$$= \sqrt{0.125}$$

$$= 0.35 \text{ m}^2$$

Step 2. Determine dose using the computed BSA and this formula:

$$\frac{\text{Child's BSA}}{1.7\,\text{m}^2\,(\text{average adult BSA})} \times \text{Usual adult dose} = \text{Child's dose}$$

Example: Child's BSA = 0.35 m^2, and usual adult dose is 100 mg.

$$= \frac{0.35 \text{ m}^2}{1.7 \text{ m}^2} \times 100$$

$$= 20.588\ (20.59) \text{ mg is child's dose.}$$

Body Weight Method

Usual dose (in mg): 1 kg :: needed dose (in mg): weight of child in kg, solve for the needed dose

Example:

Usual dose is 10 mg/1 kg and child weighs 18 kg

$$10 \text{ mg} : 1 \text{ kg} :: \chi \text{ mg} : 18 \text{ kg} \quad \chi = 180 \text{ mg}$$

be tested in clinical drug trials in children. Labeling changes are occurring based on findings from these new studies. At the end of December 2008, 159 drugs had been tested for use in children and been relabeled. The list of the drugs that have been studied for use in children and the summaries of medical and clinical pharmacology reviews is available on the FDA website (http://www.fda.gov/cder/pediatric/labelchange.htm). Until all drugs have been tested and labeled for use in children, nurses need to be aware that off-label use will occur. When a drug is prescribed off-label, the full therapeutic and adverse effects, as well as appropriate dosing, may be unknown.

Even when a drug has the same labeled therapeutic uses in adult and children, a major difference is the appropriate drug dosage for different age groups. Committing drug dosages to memory is difficult and unnecessary because child weights vary considerably. Unlike most adult drug dosages, almost all pediatric drug dosages are based on the weight of the child in kilograms. Dosage is usually specified in milligrams of drug per kilogram of body weight (mg/kg).

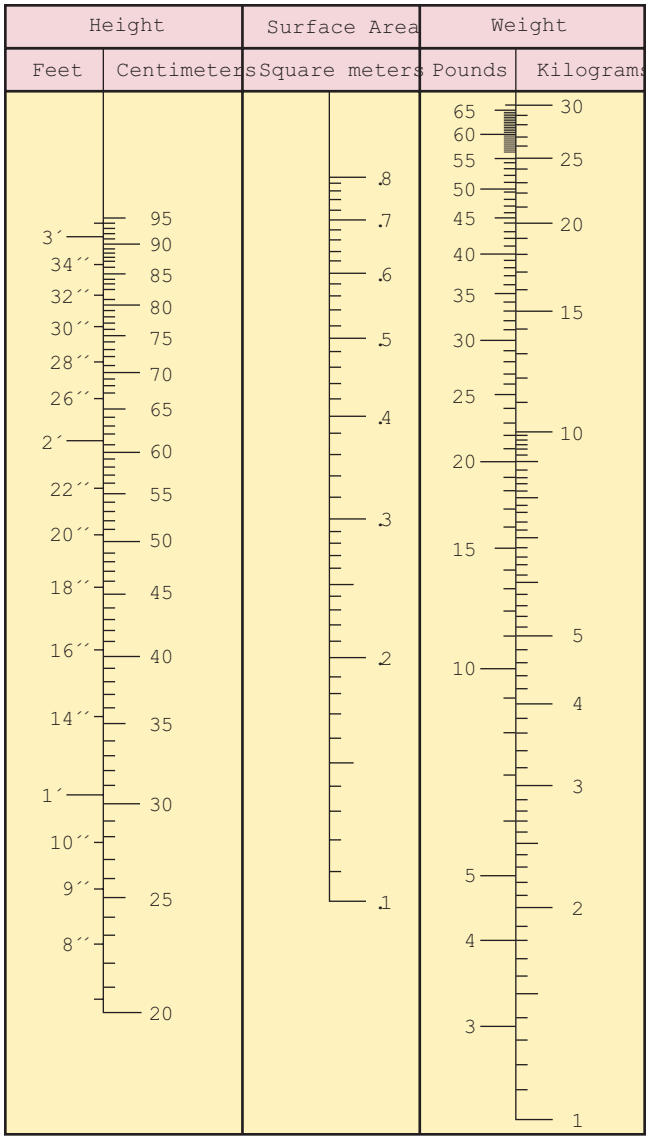
When a child dose is not specified, it can be determined from the adult dose based on the body surface area of the child. The **body surface area** is the external surface of the body expressed in square meters. The ratio of body surface area to weight is inversely proportional to length; therefore, the infant or young child who is shorter and weighs less than the adult has relatively greater surface area than would be expected from the weight. Body surface area is calculated using a standard formula, found in Box 6.1.

Body surface area can also be determined by using a nomogram (Figure 6.1). A **nomogram** is a chart or a graph that shows relationships between numerical variables. A representative nomogram used to estimate body surface area in children may have several columns of calibrated measures representing height, surface area, and weight. Body surface area is calculated by drawing a line across the columns to connect the patient's height with the patient's weight. The point at which the line intersects the central surface area column is the patient's *estimated* body surface area. Using a nomogram is less accurate than using the formula to determine body surface area.

Once body surface area is determined, the dosage can be computed using the formula in Box 6.1. A child's drug dosage may also be determined by comparing the child's weight to the recommended dose per kilograms of weight. Administering the correct drug dosage is crucial in pediatric drug therapy. The child's small and immature body systems make overdosages potentially lethal. Drugs with high potential for toxicity, such as anticancer drugs, are more likely to have their dosage determined by body surface area than by only the weight of the child.

Pharmacodynamics

A drug's mechanism of action is the same in all individuals at all ages. However, what distinguishes individual responses is the ability of the organ systems to function



• FIGURE 6.1 A pediatric nomogram is a device for estimating body surface area in children. To use it, draw a line from the child's height to the child's weight. The point at which this line intersects the surface area in the middle is the child's estimated body surface area.

fully and appropriately. In very young children, immature organ systems have less than optimal functioning, which may necessitate increasing or decreasing drug doses to prevent toxicity and to achieve a therapeutic drug level.

Pharmacokinetics

A child's age, growth, and maturation can affect how the body absorbs, distributes, metabolizes, and excretes a drug. By understanding how drugs affect pediatric patients differently from adult patients, the nurse can help maximize the therapeutic effects of a drug and minimize adverse effects. Dosages must often be lowered to account for immature or impaired body systems in neonates and infants.

ABSORPTION

Absorption of a drug depends on various factors. In the pediatric patient, age, disease process, dosage form, route

of administration, and foods and drugs present in the child's body have an effect on drug absorption.

The infant's gastrointestinal (GI) tract is less acidic and thus has a higher pH than that of an adult. Moreover, a premature infant's immature GI tract secretes less acid than the full-term newborn's or older child's. As the GI tract matures, the gastric pH decreases and the GI tract becomes more acidic, reaching adult values at approximately 1 year of age. These differences in pH affect drug absorption. For example, a drug such as digoxin is very well absorbed in an acidic environment. Therefore, less digoxin would be absorbed from the premature infant's GI tract than from the older child's or adult's GI tract.

Route of administration also affects absorption. Drugs administered intramuscularly (IM) or subcutaneously (SC) are affected by age. For example, the rate of absorption may be decreased in the infant or child because of erratic blood flow from the immature peripheral circulation. The neonate's blood flow is particularly slow and erratic. Conversely, increased absorption of topical drugs is common in pediatric patients, especially infants. Compared with adults, infants and children have a greater body surface area. The infant's skin exhibits greater permeability as well. An increased body surface area combined with increased permeability result in increased absorption of topical agents, which may result in adverse effects that usually do not occur in the adult patient.

DISTRIBUTION

In a pediatric patient, drug distribution processes can differ from those in an adult because of differences in body water and fat, immature liver function, and an immature blood–brain barrier.

Differences in Body Water and Fat. Compared with adults, children, especially infants, have a higher concentration of water in their bodies and a lower concentration of fat. Newborns have the greatest proportional water content, followed by infants, children, and then adults (Table 6.1). Because infants and children have a greater proportion of body water, water-soluble drugs are diluted to a greater degree, and for this reason, it is important to assess the amount of water in the body of an infant or child before administering water-soluble drugs. The drug moves to areas of water throughout the body, not just in the blood, resulting in lower concentrations of the drug in the blood. With drugs such as gentamicin, proportionately increased dosages may be required to achieve or maintain therapeutic levels.

To a lesser degree, fat-soluble drugs are affected by the proportionately lower fat in the infant and child. Fat distribution increases with age; thus, fat-soluble drugs are distributed to a greater degree in the adult. Because fat-soluble drugs are not widely distributed in the infant's or child's body, greater blood concentrations may result, leading to toxicity.

Immature Liver Function. In the infant and especially in the neonate, immature liver function affects drug distribution. The neonate's immature liver produces fewer plasma proteins, especially albumin; acidic drugs bind strongly to albumin. Pharmacologic effects of drugs result from unbound (i.e., free) drug. In the neonate and infant, more free drug is available because less drug is bound to plasma proteins. The result is increased blood levels of drugs, which in turn can cause greater adverse effects and toxicity in infants. Drug binding to serum proteins reaches adult levels by 6 months of age.

Multiple drugs administered to an infant may compete for the same binding sites, resulting in higher blood concentrations of both drugs or of the drug with less affinity for the binding site. Other naturally occurring substances in the body can also compete for fewer binding sites in the pediatric patient. For example, bilirubin, which may increase during the neonatal period, binds with plasma proteins. When a sulfonamide is administered to the neonate who has an increased bilirubin level, it competes with bilirubin for binding sites, leaving more bilirubin free in the blood. Rarely, the bilirubin level can increase to a dangerous level, resulting in bilirubin accumulation in the central nervous system (CNS), a life-threatening condition called **kernicterus.**

Immature Blood–Brain Barrier. The blood–brain barrier prevents drugs in the general circulation from passing to the circulation of the brain, thereby protecting the brain from toxic substances. At birth, the blood–brain barrier is not fully developed. Therefore, newborns are particularly vulnerable to CNS toxicity. In the newborn, the effect of drugs that act on the CNS (e.g., phenobarbital and morphine) is intensified. In addition, infants experience exaggerated CNS responses to other drugs targeted for other body systems.

METABOLISM

The liver metabolizes most drugs. However, the immaturity of the neonatal and infant liver results in decreased or incomplete metabolism of many drugs, which may necessitate lower drug dosages or an increased interval between doses to achieve appropriate blood levels. In children with liver disease, drug metabolism is further complicated by the liver's inability to detoxify drugs. A child with an immature liver or compromised liver function is at risk for drug toxicity.

Drugs requiring oxidation for metabolism are frequently more rapidly metabolized in children than in adults because

TABLE 6.1 Proportional Water Content Across the Life Span

Infant	Approximately 85%

Two years old	60%
Adult	50%–60%

children have a faster resting respiratory rate. These drugs include phenobarbital, phenytoin, and the methylxanthines (e.g., theophylline and caffeine). With these types of drugs, children may require higher dosages or more frequent administration schedules than adults do to maintain therapeutic blood levels.

EXCRETION

Most drugs are eliminated from the body through the urine. Drug elimination requires a functioning renal system, and its effectiveness depends on glomerular filtration rate, tubular reabsorption, and maturity of the renal system. In children with impaired renal function, drug dosages should be altered to achieve and maintain therapeutic drug levels.

The neonate, especially the preterm infant, has immature kidneys, and renal excretion of drugs is slow. Drug dosages and therapeutic drug levels must therefore be monitored closely to prevent toxicity. In addition, the reduced glomerular filtration rate and decreased tubular secretion and reabsorption during the first 6 months of life extend the half-life of many drugs (e.g., penicillins, sulfonamides, and cephalosporins). Drugs with a narrow margin between effective and toxic doses must be administered at longer dosage intervals to prevent toxicity. At about 3 months of age, the infant's kidneys can concentrate urine at the adult level, but urinary excretion remains low until the child is about 30 months old, when the kidneys become functionally mature.

A few drugs are excreted through the biliary tree into the intestinal tract. Biliary blood flow is decreased during the first few days of life, during which careful monitoring of drug levels and signs and symptoms of toxicity is imperative.

Contraindications and Precautions

As stated above, most drugs prescribed to children are prescribed off-label and have never been clinically tested for efficacy, unique pharmacokinetics, or adverse effects in children. Off-label usage therefore requires cautious administration and careful, frequent assessments of the child. Some drugs are known to be dangerous in children and are labeled as such; these drugs are contraindicated. The core drug knowledge must be determined for each drug before the drug can be administered to a child.

Adverse Effects and Drug Interactions

Adverse effects of some drugs are more severe and more likely to occur in children because of the immature body systems of children. Newborns and young children may experience serious adverse effects either from direct administration of a drug or through their mother's use of a medication. In a review of adverse effects in infants and children younger than 2 years that were reported to the United States Food and Drug Administration (FDA) between 1997 and 2000, approximately 3.5% of the adverse effects accounted for half of the reported deaths in children. About one fourth of the total adverse effects reported were related to exposure from the mother during pregnancy, delivery, or lactation (Moore et al., 2002).

Other adverse effects on body systems occur only at specific phases of development. For example, tetracycline administered to a child between the ages of 4 months and 8 years will stain the permanent teeth. Glucocorticoids given to a child of any age will suppress growth if the child has not matured to full adult size. Drug receptor sensitivity varies with age; it may be increased or decreased for certain drugs. This variability may promote adverse effects and may necessitate lower or higher drug dosages than would normally be expected (see Chapter 5).

Drug interactions in children are similar to those occurring in adults.

Assessment of Core Patient Variables Related to Children

Health Status

A child's disease process can affect absorption of drugs from the GI tract. Diarrhea, for example, decreases intestinal transit time and therefore decreases the time available for drug absorption. Children with hepatic or renal disease cannot metabolize or excrete drugs as easily as other children and are more prone to adverse effects from drugs. As with adults, any chronic disease or condition may alter the effects of certain drugs and must be seriously considered in drug therapy.

Life Span

Always consider the developmental stage of the pediatric patient. In planning appropriate drug administration methods, explain the treatment and enlist the child's cooperation. If doing so is not possible, seek appropriate assistance to administer the drug therapy safely. Developmental considerations are especially important when communicating with the child. To elicit cooperation and obtain necessary information, communication must be at an appropriate level of understanding for the child. The following are age-appropriate considerations in administering drugs to infants and children. Box 6.2 provides more information regarding pediatric drug routes.

INFANTS (BIRTH TO 12 MONTHS)

Some infants with a well-developed sucking reflex may willingly swallow a pleasant-tasting liquid drug through a bottle nipple. Other babies may spit out oral medicine, making it difficult to administer a full dose. Administer infant drops by gently squeezing the child's cheeks to open the mouth, and then placing the drops in the buccal pouch to ensure they will be swallowed. Drugs may be given to infants in rectal

CRITICAL THINKING SCENARIO

CALLING ON CORE DRUG KNOWLEDGE FOR CHILDREN

You are caring for a premature newborn in the nursery. The newborn is receiving intravenous antibiotic therapy to treat an infection. Which specific aspects of core drug knowledge do you think will most help you anticipate any adverse effects of drug therapy?

Box6.2 SPECIAL PRECAUTIONS FOR PEDIATRIC DRUG ROUTES

One way to promote a good outcome when administering drug therapy is to call on your knowledge of normal growth and development in children and your knowledge of safe administration techniques for specific routes.

Oral Route

- Drug volume should not exceed that which can be swallowed by a very small mouth. The drug dose should be mixed in a small amount of liquid so all of the dose is taken.
- Avoid adding a drug dose to formula. The infant may refuse future feedings because of the foul taste.
- Balance dosage schedules with feeding schedules. Consider whether the drug should be given with meals or on an empty stomach. Check for the possibility of a food-drug interaction.

Intramuscular Route

- Assess whether a less painful route is possible.
- If the IM route is unavoidable, apply a topical, local anesthetic, such as a lidocaine and prilocaine combination (EMLA cream), to numb the injection site.
- Locate anatomic landmarks and boundaries of injection sites.
- Evaluate muscle mass, skin condition, and potential complications related to the child's diagnosis.
- Rotate injection sites as needed, and use appropriate equipment and techniques.
- Seek help to hold the child still while administering the IM injection.

Intravenous Route

- Minimize initial pain on starting the IV by applying a topical anesthetic.
- Check the IV insertion site hourly for infiltration in infants and children.
- Monitor fluid status for signs of overload (risk is greatest in neonates and young infants because of their immature kidney function).
- Double check dosage calculations with another nurse.
- Control the IV infusion rate by using either a volumetric pumps with a microdrip calibrated chamber or a syringe pump. If the infusion pump is one of the new "smart" pumps (i.e., containing computer software that includes specific drug information and policies and procedures related to administering that particular drug) do not "work around" or turn off the safety features.
- Supply no more than 1 hour's worth of fluid when administering a continuous IV drip with an infusion pump (in case the pump malfunctions).
- Engage the lock feature on a volumetric pump to prevent unauthorized changes in the drop rate.

suppository form if necessary. However, to avoid expulsion of the suppository before the drug is absorbed, you may need to hold the child's buttocks together for a short time.

If the IM route must be used, choose the smallest gauge of needle appropriate for the drug. The preferred injection site for infants and children up to age 3 years is the vastus lateralis. This muscle is on the side of the thigh in the upper outer quadrant of the area between the greater trochanter and the knee. The vastus lateralis has few nerves and blood vessels and forms the largest muscle mass in this age group.

Normally, a ⅜-inch needle is used for the vastus lateralis in infants; if one is not available, a needle no larger than ⅝ inch should be used. With the longer needle, modify the angle of injection from the usual 90 degrees to 45 degrees toward the frontal plane of the knee. The 45-degree angle ensures that the needle does not traverse the blood vessel.

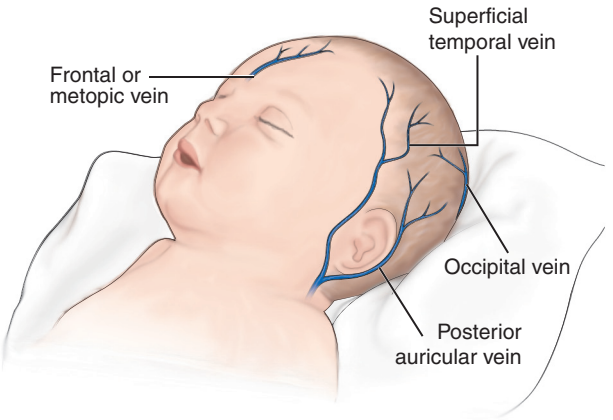
The rectus femoris is another possible injection site. This muscle is located near the vastus lateralis but is anterior mid-thigh; inject the needle at a 90-degree angle at this site.

In infants, neither the deltoid nor the dorsogluteal muscle site is used because the muscle masses are too small and undeveloped. The ventrogluteal muscle site, which is large at birth, is not recommended for use in infants because problems encountered in positioning the child make it difficult to locate the muscle site accurately.

Drugs may be administered intravenously to the infant through a peripheral site. These intravenous (IV) sites differ from those used for adults. Ideally, select a site that is easy to access and that poses the least risk to the patient. In the neonate and infant, the scalp's many superficial veins offer easy access. The superficial temporal vein just in front of the pinna of the ear and the metopic vein in the middle of the forehead are relatively easy to find and are less risky for patients (Figure 6.2). Other suitable IV sites for infants and older children include the vessels in the nondominant hand, forearm, upper arm, feet, and antecubital fossa. Distal IV sites are used first and are moved proximally as necessary. The feet also provide good IV sites and are used in infants.

TODDLERS (13 MONTHS TO 3 YEARS)

Toddlers can swallow liquid forms of drugs, and older toddlers can chew oral drugs. Because toddlers experience



• FIGURE 6.2 The scalp is an excellent site for intravenous (IV) therapy in the neonate and infant. The superficial temporal vein and the metopic vein in the central forehead are the preferred sites because they are easy to find and reasonably safe.

anxiety when separated from their parents, having a parent nearby usually helps the child's cooperation during drug therapy. Attempt to elicit cooperation from the toddler but be prepared for the toddler to resist. A toddler's resistance may be associated with a past experience, such as unpleasantly flavored drugs or a painful injection.

Toddlers are also likely to be anxious or uncooperative during administration of rectal suppositories because of their experiences with toilet training and sphincter control. Toddlers have vivid imaginations but limited understanding of how the body works. A common fear is that important body contents will leak out from an injection site. As with infants, the vastus lateralis and rectus femoris remain the IM injection sites of choice for toddlers.

When IV drug therapy is necessary for toddlers, the scalp veins are still appropriate and can be used up to age 18 months. By this time, hair follicles mature and skin layers thicken, making IV access more difficult. Although the scalp provides excellent IV access, it is not the first choice because of the anxiety it causes parents. Parents feel uneasy because of the scalp's close proximity to the brain and because the area must be shaved at the IV site. If a scalp vein must be used and the site shaved, ask the parents whether they would like to save the hair, and collect it for them if desired. Saving their child's hair makes the procedure less distressing to some parents. For toddlers, as for infants, other peripheral IV sites are also used. If possible, try to avoid using the foot so as not to impede the toddler's mobility or cause undue frustration. The foot veins are used, however, in children who need to be immobile.

PRESCHOOLERS (3 TO 5 YEARS)

Preschoolers are often uncooperative during drug administration. Strategies for enlisting cooperation include offering choices (e.g., between liquid medicines or chewable tablets) when feasible. Heightened awareness and the fear of punishment or body mutilation in this age group may influence the child's perception of and cooperation with drug therapy. Nurses (and parents) should always reassure preschoolers that the drug is to help them feel better and keep them healthy.

When an IM injection must be given, the use of topical anesthetic creams (e.g., EMLA) to numb the site reduces pain in preschoolers during the injection. Several sites may be used for IM injections in preschoolers, most commonly the vastus lateralis, rectus femoris, and ventrogluteal sites. The ventrogluteal site is free of major nerves and blood vessels and is characterized by deep muscle mass. It is located above the greater trochanter between the anterior superior iliac spine and the posterior iliac crest. The drug is injected into the gluteus medius muscle, which is in the ventrogluteal site. Injection in the gluteus medius is less painful than injection in the vastus lateralis. *The dorsogluteal site is generally not recommended because of potential damage to the sciatic nerve if the site is not chosen with precision*. When IV drug therapy is necessary, peripheral sites are selected for the preschooler. Scalp veins are no longer used.

SCHOOL-AGED CHILDREN (6 TO 12 YEARS)

The school-aged child is often very cooperative. As with the preschooler, offer choices to help the school-aged patient exercise control. The school-aged child's greatest fears of drug therapy are usually related to negative past experiences. School-aged children can tolerate warning of drug therapy without becoming fearful and anxious. The school-aged child takes pride in accomplishments such as receiving an injection without incident.

Oral drugs may still be provided in liquid form or chewable tablets. Many school-aged children can also swallow pills. Generally, if rectal drug forms must be used, the school-aged child will feel embarrassment. School-aged and older children, like adults, must be ensured privacy at all times throughout the procedure.

The ventrogluteal site is recommended for an IM injection in the school-aged child, but the vastus lateralis and rectus femoris sites may also be used in this age group. The dorsogluteal site is again not generally recommended. Although it is not the preferred administration site, the deltoid muscle may also be used for small volumes of drugs (0.5 mL) or vaccines. This site is often considered less painful than the ventrogluteal site.

ADOLESCENTS (13 TO 16 YEARS)

An adolescent's ability to cooperate is highly developed and much like an adult's. Offer adolescents control whenever possible and let them make choices. Also offer support and encouragement without treating adolescents like children. Adolescents are more likely to cooperate and participate in drug therapy when they have a complete understanding of the treatment regimen. Adolescents are particularly sensitive about their bodies and their independence. Therefore, privacy and control are important issues to consider when administering drug therapy to this age group.

Routes of administration are similar to those for adults. Oral forms of drug therapy include tablets or pills. Suppositories can be used, but the adolescent is likely to be embarrassed. IM injection sites are usually the same as for adults unless the adolescent is particularly small. Careful examination is necessary to ensure that adequate muscle mass is available for IM injection. Any of the muscles may be used depending on patient size and drug characteristics. The dorsogluteal site should be used *only as a last resort*. Site selection for IV therapy in adolescents is the same as for adults.

Lifestyle, Diet, and Habits

The infant's primary food intake is milk and formula. These substances decrease acidity and thus increase gastric pH. Drug absorption is usually affected by pH levels; therefore, food and drug interactions are a primary concern when administering oral drug therapy to infants.

In school-aged children and adolescents, assess for the use and abuse of substances such as caffeine, alcohol, tobacco, and street drugs. During drug therapy, these substances cause the same complications in children as in

adults. Adolescence is a time of experimentation, which may include experimentation with legal and illegal substances. Preadolescents may also experiment with these substances. Try to elicit this information from all school-aged or adolescent patients throughout drug therapy because potential adverse effects or interactions of these substances may cause serious complications. Regardless of the patient's age and appearance, never assume that the child does or does not use or abuse certain substances. Pose questions regarding substance use in the health assessment interview in a nonjudgmental, matter-of-fact manner.

Question the parent regarding the use of herbal therapy. Use of alternative therapies has become common, and their use is frequently not reported to the primary care provider. Studies of pediatric patients in various settings indicate that 8% to 45% of the patients had received herbal preparations from their families (Soo et al., 2005; Martel et al., 2005; Lanski et al., 2003) Patients and their families often do not consider these therapies "medications" or may not realize how they can interact with prescribed drug therapy. One study in a pediatric emergency department found that most of the parents did not know if the herbal products had any adverse effects or if they could interact with prescribed medication. Less than half of the parents had discussed the use of herbs with their child's primary care provider (Lanski et al., 2003).

Also consider the economic circumstances of the patient and family. Are the parents concerned about paying for the child's drug therapy? Are insurance and other resources available?

Environment

Children may receive drug therapy in any setting, although some types of drugs may be administered primarily in one setting or another, just as in the adult population. Children receiving drug therapy at home need to have a parent or guardian responsible for ensuring that the child receives the prescribed therapy. General considerations about the home need to be assessed just as they are assessed for adults. Does the home have electricity, a refrigerator, and indoor plumbing?

An important additional question to ask of the parent or caretaker is whether the home has a safe place to store prescription and nonprescription drugs away from children. Childhood ingestion of drugs is a serious concern because many drugs have serious adverse effects or may cause poisoning in children. Unintentional ingestion of over-the-counter drugs is a serious problem. McFee and Caraccio (2006) found that a grandparent was often the source of unintentional exposures to medications in children under six years of age. They found that the most important factor was the accessibility of the drug to the child; the sites with easiest access were tables or countertops (46%), low shelves (29%), and pocketbooks left on the floor or furniture (17%). Whether or not the drug was in a childproof container did not significantly affect whether accidental ingestion occurred.

Culture and Inherited Traits

The family's beliefs greatly affect a child's attitude and adherence to the therapeutic regimen. Questions and assessment concerns to consider include the following:

- Does the child's cultural background suggest suspicions about or taboos against drug therapy?
- Do health practices in the child's family rely on other forms of healing, such as using herbal or natural medicines, acupuncture, prayer, or mysticism?
- Do family religious beliefs directly conflict with the use of drug therapy?

The child's cultural background and heritage must be considered quite seriously when planning drug therapy (see Chapter 12). Additionally, some children may have inherited genetic differences in their P-450 systems which may alter drug therapy.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes related to specific drug therapy for children are much the same as they are for adults. However, many drug therapies are burdensome for families to maintain, present special concerns, or pose risks to a child's normal growth and development. Common nursing diagnoses and outcomes may include the following:

- Delayed Growth and Development
  Desired outcome: *The patient will achieve normal growth and development during drug therapy.*
- Ineffective Family Therapeutic Regimen Management
  Desired outcome: Family members will master effective management strategies of the patient's drug regimen.
- Caregiver Role Strain
  Desired outcome: *The patient and family will develop effective coping skills to avoid, reduce, or relieve stress on family caregivers.*

Planning and Intervention

Maximizing Therapeutic Effects

Administering drugs safely and effectively to children requires an understanding of pediatric anatomy and physiology, the patient's developmental and cognitive levels, and the child's diagnosis and prognosis. Use this knowledge to select appropriate drug administration sites, equipment, and administration techniques. When offering a child choices for the sake of gaining his or her cooperation during drug administration, present only those choices that truly exist. For example, do not ask a preschooler if he or she would like to take medicine now if the child does not really have the choice to refuse. Instead, ask which drug the child wants to take first or how many bandages the child would like to apply after an injection.

ORAL DRUG THERAPY

Although usually not painful, administration of oral medications can be traumatic, especially when the drug flavor is foul and the child protests. Many pediatric drugs come

in liquid form and are drawn up into a syringe (without a needle) for accurate measurement. The drug can then be transferred to a medicine cup for older, cooperative children who prefer this way of receiving the drug.

If the patient cannot swallow pills, some pills can be crushed and dissolved in a liquid or soft food (such as applesauce, gelatin, or ice cream) that masks the flavor of the drug. Dilute the drug in the smallest amount of liquid or food possible to ensure that the child receives the full dose and does not leave any in the residue. Another method of masking bad-tasting drugs for children is to offer a flavored ice pop or ice chips to help numb the taste buds and promote cooperation.

Work carefully with the child to ensure that all of the drug is taken. If the child drools or spits out some of the drug, calculate the amount of drug lost. If the total is considerable, report the estimated amount lost to the prescriber and obtain an order for a replacement dose. For drugs that pose a high risk for toxicity, another dose is unlikely to be ordered. For example, when digoxin (which slows the heart) is given to children with congestive heart failure, an overdose can be lethal.

PARENTERAL DRUG THERAPY

To ensure accurate parenteral drug delivery, choose age-appropriate equipment. For example, the length and gauge of a needle must be suited to the child's age and growth level. A needle that is too long for the child's size delivers a drug into the muscle rather than into the subcutaneous tissue, thereby speeding the rate of absorption. An institution's adoption of standard drug concentrations for infusions and purchasing the new "smart" infusion pumps (which contains computer software that includes specific drug information and policies and procedures related to administering that particular drug) have also been found to be valuable in reducing IV medications errors.

RECTAL DRUG THERAPY

Always give the patient and family a full explanation of the need to administer a drug rectally and ask the child to attempt to retain the drug for as long as possible. As always, take into consideration the developmental level of the child with the rectal administration of drugs. To allow time for the drug to be absorbed, dissuade young children from going to the bathroom and encourage them to participate in a quiet activity. Older children and adolescents need to have their privacy maintained during the administration of rectal suppositories.

Minimizing Adverse Effects

PREVENTING MEDICATION ERRORS

Medication errors are the most common type of error in the medical care of children. Most of these errors can be prevented through appropriate actions by the individual health-care providers (physician, pharmacist, and nurse) and by health care systems, such as hospitals. Medication errors in children are more likely to be life threatening than medication errors in adults, even though their rate of occurrence is similar. Children are more at risk because they have not physiologically matured. Immature liver or renal function, for example, can increase the circulating level of a drug beyond what would be expected in adults. The younger the child, the less likely the body organs function maximally, so infants and premature infants are at the highest risk of serious adverse effects from drug therapy and medication errors. Hughes and Edgerton's (2005) research review identifies the children most likely to be involved in a medication error. These include children:

- Younger than two years old
- In intensive care units, especially neonatal intensive care units
- In Emergency Departments between the hours of 4 and 8 AM or on weekends, with the highest risk for those children who are seriously ill
- Who are receiving chemotherapy
- Who are receiving IV medication
- Whose weight was not documented

Pediatric medication errors are most likely to occur in the prescribing phase and the administration phase of drug therapy. One study of rural, northern California emergency rooms found that in the most acutely ill children more than half of medications prescribed were associated with some sort of medication error (Marcin et al., 2007). As mentioned previously, many drugs are not specifically labeled for use in children. Therefore, the efficacy, correct dose, and possible adverse effects may not be known for the drug when used in pediatric patient populations, and medication errors may result. Incorrect dosage is the most common error. When determining a drug dosage, remember that muscle mass, body water, fat content, gastric pH levels, and liver function vary greatly from the child to the adult. These variations affect the pharmacokinetics of the drug and must be considered when determining the correct dosage. Overdosage of many drugs can cause serious or even fatal effects in children. Also remember that the pediatric drug dosage is not merely a reduced adult dosage; rather, it is calculated by specific equations adjusted to the child's weight and body surface area (see Box 6.1). It is important to be proficient at using these mathematical formulas in computing the correct dose.

Of all the problems that may contribute to an incorrect dose, the most common involve errors in math during dosage calculation. Dosage calculation can involve several steps, and a mathematical error can occur at each step. Because a pediatric dose is calculated as a percentage of an adult dose, the computed pediatric dose often includes a decimal point. Misplacement of the decimal point results in a ten-fold error: either too much drug (ten times as much), or too little drug (one tenth of what it should be). *Ten-fold errors are the most common dosing error in children*. Because infants and young children require extremely small doses due to their size and immature body systems, a dose that is ten times too large may be lethal. Because mathematical computation of a drug dose is common in pediatric dosing but rare with adults, children are most likely to incur a

ten-fold medication error. In addition to misplaced decimal points, errors in computing can also lead to serious medication errors. Most of the problems in dosage calculation are related to the following:

- Inability to identify the correct mathematical calculation or sequence of calculations to perform to obtain the correct answer
- Poor math skills related to using fractions, percentages, decimals, and ratios
- Infrequent use of calculation formulas
- Inexperience in applying dosage calculation formulas to actual clinical practice (Hughes & Edgerton, 2005)

Even when the pediatric drug dose is calculated correctly, it may be incorrect for a particular child based on the child's illness or current physiologic state. For example, drug calculations for premature newborns (those born at less than 30 weeks' gestation) must consider not only their current weight, but also physiologic characteristics found in this age group: lower gastrointestinal motility, higher levels of extracellular body water, lower total body fat, and decreased plasma protein binding. Because of these factors, premature newborns require much smaller doses than if only weight or body surface area were considered. Children who weigh between 40 and 50 kg (the cutoff size for a pediatric patient) may in some cases be eligible for adult doses; the standardized pediatric dose conversion formulas may be less useful for these patients (Hughes & Edgerton, 2005).

Strategies to reduce the incidence of medication errors in children require efforts from both the individual health care provider and the health care system. These strategies include:

- *Always weigh the child before administering any medication*. Since most pediatric dosage is based on the weight of the child, it is not safe to give any medication without knowing the child's accurate weight. Documenting the patient's weight in kilograms, not pounds, should be standard procedure throughout the institution. Reweigh the child as indicated by disease or physical condition if the weight is likely to change (e.g., a child with cancer may lose weight due to his disease process or from an adverse effect of drug therapy) (Hughes and Edgerton, 2005; US, Pharmacopeia, 2009; American Academy of Pediatrics Guideline, 2003, reaffirmed 2007).
- *Standardize as much as possible throughout a health care system*. Standardized medication order sheets should include entry spaces for weight, age, and allergies. Standardized concentrations of high-risk drugs administered by IV infusion, such as opioids, heparin, insulin, potassium, and chemotherapy, should be used whenever possible as these prevent computation errors. Avoid use of nonapproved abbreviations and the apothecary system of measurement, as these are likely to be misinterpreted and cause errors. Standardization of equipment, such as scales and infusion pumps, will prevent errors between units or services. See Box 6.3 for research on this topic

BOX 6.3 FOCUS ON RESEARCH

Standardization and Technology Decrease Medication Errors

Taylor, J. A., Loan, L. A., Kamara, J., Blackburn, S., & Whitney, D. (2008). Medication administration variances before and after implementation of computerized physician order entry in a neonatal intensive care unit. *Pediatrics*, 121(1):123–128.

The Study

The frequency of medication administration variances before and after the implementation of computerized physician order entry (CPOE) was studied via a prospective before/after observational study in one neonatal intensive care unit (NICU). A medication administration variance was defined as a discrepancy between the physician order and the medication given. Medication administration variances included: drug ordered but not given, drug given but not ordered, drug given at the wrong time (i.e., more than 1 hour before or after ordered time), wrong dose given (i.e., more than 10% greater than prescribed dose), or given via the wrong route. The reasons for variances in medication administration were attributed to: intentional violation (generally when a nurse delayed an oral medication to coincide with infant's feeding schedule), pharmacy problem (delay in drug delivery, delivery of wrong drug), prescribing problem (incomplete or confusing order), administration mistake, intravenous access issues, and nurse busy with acutely ill child. Nurses were observed administering medications in the NICU before and after the introduction of CPOE in the unit. Variances related to administration via the wrong route were completely eliminated after implementation of CPOE and variances due to the wrong time were significantly lower after the implementation of CPOE. Administration of medications at the wrong time accounted for more than half of all observed variances and almost half of these were from pharmacy problems or prescribing problems. Although the initial period after roll out of the CPOE had higher incidences of variance than pre CPOE, when this initial period was not considered, there was more than a two fold reduction in the rate of administration variances after CPOE compared to before CPOE start up. Even with these decreases, a variance occurred approximately 10% of the time after CPOE use.

Nursing Implications

While CPOE have built in warnings and blocks to help prevent many common errors of prescribing such as ordering the wrong dose, the final step where an error can be made or prevented is in the actual administration of the drug by the nurse. This research shows that healthcare technology such as the CPOE can help to decrease much of the errors that occur in this phase of drug therapy. Most of the errors that still occur are due to a dose being given late. Understanding that this problem can be related to pharmacy or prescribing problems helps to identify system wide concerns that impair drug administration accuracy. When a dose is given late intentionally, it can be argued that this "error" is not dangerous, but rather a reflection of the nurse's professional judgment. This indicates that standardized times for drug administration may need to be modified at times to be in the patient's best interest. Nurses should be involved in CPOE software development to help differentiate these reasons for late drug administration. The fact that variance still occurs after CPOE use indicates the complexity of drug administration. More research in this area in warranted.

(Hughes & Edgerton, 2005; US Pharmacopeia, 2009; American Academy of Pediatrics (AAP) Guideline, 2003, reaffirmed 2007; Kozer, Scolnik et al., 2005; Coco, King & Slattery, 2005; White, Veltri, & Fackler, 2005; and Larsen & Parker et al., 2005).

- *Use computerized drug order entry systems where possible*. These systems help prevent medication errors made by misinterpreting illegible handwriting. These systems also can compute the correct dose based on built-in algorithms as well as built-in safety checks to confirm appropriateness of ordered drug dosages (US Pharmacopeia, 2009 and AAP Guideline, 2003, reaffirmed 2007).
- *Use reliable drug information sources to determine the recommended dose*. If the drug label does not include a recommended pediatric dose, a computerized pharmacology database or current printed drug information references may be used. Although many nursing drug references give dosage ranges for children as well as adults, they usually do not include dosages specific to preterm and full-term neonates. When administering drugs to these patients, use a pediatric drug guide that gives ranges of pediatric dosages in mg/kg of body weight or by dose for all children.
- *Double-check each calculated dose for accuracy*. It is recommended that the pharmacist check the dose, even if it was ordered via a computer order entry system. As the nurse is the last person involved in drug delivery, the nurse is the last person to find a potential drug calculation error as well as the last person who might make an error. The nurse is responsible for ensuring the accuracy of a prescribed drug dose before it is administered. For safety, even when drug doses were previously computed by the physician, pharmacist, or both, *always double-check dosage calculations before administering any dose to a child*. Certain hospital protocols may require two nurses to independently double-check a dose prior to administration of medications that pose a high risk of injury to the child, such as chemotherapy, anticoagulants, insulin, or opioids. Inservice programs can be provided to ensure that all health care professionals are capable of accurately performing pediatric dosage calculation (Hughes & Edgerton, 2005; US Pharmacopeia, 2009; AAP Guideline, 2003, reaffirmed 2007).
- *Measure and deliver oral medications via oral syringes only, never via syringes used to administer parenteral injections*. This precaution prevents oral medications from accidentally being given by the wrong route (US Pharmacopeia, 2009).
- *Involve the family in drug administration*. Families of children need to be aware of the drug therapy that is prescribed for the child. By being knowledgeable about the indication, dose, and frequency of medication administration, families become active partners with the rest of the health care team in preventing medication errors (Hughes & Edgerton, 2005).
- *Communicate the drug therapy plan clearly when different nurses will be caring for the patient*. Medication errors are most likely to occur at points of transition such as at shift change or in patient transitions between units or from the hospital to another institution or to home (Hughes & Edgerton, 2005). (See Chapter 11 for more information.)

Nurses are viewed by all members of the health care team as having primary responsibility for ensuring patient safety. Thus, you are essential in decreasing the incidence of pediatric medication errors. Nurses have a responsibility to do two things. The first is to incorporate the above recommendations into daily practice. The second is to participate in hospital-wide safety committees to help institute system-wide recommendations.

While many of the serious adverse effects and medication errors in pediatric patients occur in acute care settings, many also occur in the home setting. See the discussion under Patient and Family Education for more information on preventing these types of errors.

REDUCING PSYCHOLOGICAL STRESS AND ANXIETY

Some adverse effects in pediatric drug therapy involve psychological distress of the child or parent. Consider age-related emotional needs when selecting appropriate communication techniques to help allay anxiety and negative, stress-provoking feelings regarding drug therapy. For school-aged children and adolescents, address feelings and discuss and answer questions as simply and honestly as possible.

Although infants do not converse, they do communicate nonverbally. Parents are helpful in providing a history of the infant's experiences, behaviors, and schedule, and they can also provide an interpretation of the infant's nonverbal cues. Infants are very much in tune with their parents and can sense their feelings. If the parents are anxious, the infant is likely to be anxious as well. Therefore, offer parents reassurance and full explanations regarding procedures and rationales. During therapy, the parents may comfort the infant by maintaining eye contact, gently stroking the head, or talking in soothing tones. Parents are not asked to restrain the infant but should be at hand to comfort the child. After drug therapy is administered, they should cuddle and comfort the child.

Because toddlers need to view drug therapy as positively as possible, they should be comforted and praised after receiving a drug regardless of whether they were cooperative or uncooperative. Whatever their behavior, they should never be referred to as a "bad boy" or "bad girl." Toddlers take pride in their accomplishments, and positive feedback and praise enhance their sense of self-esteem.

Play therapy is useful for reducing a child's anxiety and promoting understanding of drug therapy. To familiarize the child with an administration procedure, encourage role-playing with dolls and appropriate medical equipment.

During role-playing, further encourage the child to express any feelings of anxiety or anger.

For preschoolers and school-aged children, take care to explore the child's experiences with the health care system. These experiences strongly influence the behavior of these children, which, like the behavior of toddlers, are accepted without value judgments. Similarly, take advantage of opportunities to provide positive feedback and avoid negativity.

Providing Patient and Family Education

A crucial step in administering pediatric drug therapy is educating the child, the parents, and other family members or caregivers. Providing honest and detailed explanations and rationales helps reassure those caring for the child. Patient and family education is especially important if drug therapy continues when the child returns home. Many pediatric medication errors occur unintentionally in the home setting because the parent does not adequately understand the drug, its effects, and the best manner to dose the drug. Parents need to be taught specific drug information, including the name of the drug, what it is for, how it works, its adverse effects, and the exact dose for the child. This information should be provided in writing. Parents should be taught exactly how to measure and administer the medication to their infant. Teach the parent to use a measured-oral-dosing syringe, and have the parent demonstrate dosing with the equipment. Include the child in drug education and provide age-appropriate explanations. Children have a right to appropriate information regarding any medicine they take. Including children in drug education, starting at an early age, helps them to grow into the role of informed consumers. The position paper *Ten Guiding Principles for Teaching Children and Adolescents About Medicines* issued by the United States Pharmacopeia encourages educating children about drug therapy. Additional resources for teaching children about medications, including guidelines for creating age-appropriate teaching materials, are also available from the United States Pharmacopeia website.

Education for infant patients is directed solely toward the parent. Medication errors can result in serious adverse effects in infants. Overdosing can result from a miscalculation of the dose, an incorrectly measured dose, double-dosing (from multiple caregivers each providing a dose), administration of doses too closely together, or administration of the drug by the wrong route. For toddlers, fully explain the rationale for drug therapy and type of administration in private, away from the toddler. Give toddlers a very brief, straightforward, honest explanation immediately before they receive drug therapy and especially before an invasive procedure. The information is supplied just before a procedure so that little time is left for their fears and anxiety to escalate.

Preschoolers require simple explanations. They often understand more than they can articulate. The information on the drug therapy should be accurate but brief. Giving preschoolers a simple description of the medication administration procedure and calmly informing them—for example, telling them that they might feel a momentary "pinch" or "stick"—is generally sufficient to prepare them. For preschoolers, just as for toddlers, supply the information immediately before a procedure so that there is little time for their fears and anxiety to escalate. Parents or primary caregivers are usually permitted to be with the child during the procedure.

The school-aged child can understand somewhat more in-depth explanations and will ask many specific questions regarding drug therapy. Answers and explanations are honest and as detailed as necessary for the patient and parents. Information is provided on what the child wants to know, not just what the health care provider believes the child should know.

Adolescents are treated like adults with regard to full explanations and rationale for drug therapy. Invite adolescents to be involved in these discussions and encourage them to ask questions and express their feelings. Stress the importance of therapeutic adherence because adolescents are at the age when they assume more responsibility for their own health and well-being. Many adolescents take responsibility for scheduling and administering their own drug therapy.

At a minimum, include the following in initial education for school-aged children, adolescents, and parents:

- Generic and trade names of drugs
- Rationale for drug therapy
- Description of the intended therapeutic drug effect
- Route by which drug will be administered
- Schedule and duration of administration
- Potential adverse effects
- Special drug-related precautions or restrictions (e.g., relating to exercise or diet)

In addition, educate as many family members or other caregivers as possible. Doing so promotes accurate and safe drug administration to the child at home and ensures that sources of information about the child's drug history are easily found, especially in an emergency.

School-aged children and adolescents typically require instruction in proper techniques for self-administering drug therapy. For example, children with diabetes need to learn how to select injection sites and administer injections. Children with asthma need instruction in using respiratory inhalers. Other patients may need instruction in how to mix, shake, or otherwise prepare drugs before measuring the dose.

Give parents and pediatric patients as much opportunity to practice drug administration techniques as possible while you observe and offer feedback. For example, techniques are re-evaluated frequently during admissions to the hospital or at scheduled medical visits, because problems related to poor

BOX 6.4 COMMUNITY BASED CONCERNS

Minimizing accidental ingestion and overdosing in children:

- Measure drug with medication spoon or cup not with a household spoon.
- Keep all drugs (including OTC drugs) out of the reach of children (more than 3 feet off of the ground). Be sure all family members and caregivers are aware of this need.
- Do not throw used transdermal patches of medication where a child can reach it because young children will likely put it into their mouths.
- Do not tell children that medicine is candy.

technique frequently arise. Providing parents with a dosing spoon or syringe with a line marked at the correct dose and asking them to again demonstrate how they measure the dose is an effective technique for teaching how to measure a dose properly. Spoken instructions on administering the drug are much less effective.

Emphasize to parents and children the importance of administering a drug at the appropriate times and continuing therapy for the full course of treatment. Sometimes, parents stop administering a drug once the child no longer exhibits signs or symptoms of an illness, which is especially true if the child protests or has difficulty taking the drug. Stress to the parents that interrupting drug therapy before treatment is completed may cause problems such as recurrence of an infection or development of a drug-resistant infection.

As accidental drug ingestion and poisoning in young children frequently is from a grandparent's medication, nurses should assess ALL patients as to whether they have exposure to young children. All parents and grandparents should be taught to keep medications out of the reach of children (i.e., higher than 3 feet). (See Box 6.4 Community Based Concerns)

The best way to prevent adverse effects from drug therapy is to minimize the need for it. The importance of general health education to parents (such as the importance of vaccination, use of safety seats, and hand washing to prevent infections) cannot be overemphasized.

Ongoing Assessment and Evaluation

Nursing management of drug therapy in a child is considered effective when the developmental needs of the patient have been met, the care has involved the family, and the drug has achieved its therapeutic effect without adverse effect to the child. Children who are receiving drug therapy for chronic conditions need to be reassessed frequently and evaluated during regular yearly pediatric checkups to ensure that they are safely adhering to prescribed drug therapy, self-administering drug therapy as indicated, and growing and developing normally while undergoing drug therapy.

CHAPTER SUMMARY

- Children are different from adults both physically and emotionally, and these differences seriously affect the planning of safe and effective drug therapy.
- Most drugs have not been tested for efficacy or safety in children and thus are prescribed off-label to children. Additional monitoring for adverse effects from drug therapy is necessary when drugs are used off-label.
- A child's age, growth, and development are crucial considerations in relating core drug knowledge with core patient variables in drug therapy.
- A child's age, weight, body surface area, water content, and fat content must be considered when determining the proper dose of a drug. Drug dosage is calculated for each child, using mathematical formulas. Most drug dosages are calculated based on the child's weight. No medication should be administered unless the current weight is documented on the chart.
- Pediatric dosages must be accurate because even small errors can cause adverse effects, toxicity, or death. A misplaced decimal point results in a ten-fold dosing error. This is the most common dosage calculation error occurring in children. The nurse independently verifies all dosage calculations made by other health care providers prior to administering each dose.
- To maximize the therapeutic effect of any drug, the nurse must ensure that all of the appropriate dose is administered by the desired route.
- Many of the adverse effects of drug therapy can be avoided or minimized by ensuring that the child receives the appropriate drug dosage calculated specifically for him or her. Nurses should have access to a pediatric drug reference, guide, or electronic data base that gives the pediatric ranges for drug doses, including those for preterm and full-term neonates.
- In addition to determining the correct dose for a child, pediatric medication errors can be prevented by standardizing as much as possible within a hospital setting, using computerized order entry whenever possible, using the appropriate administration equipment, involving the family in medication administration, and carefully communicating the drug therapy plan at points of transition in care.
- One of the adverse effects in pediatric drug administration is psychological distress in the child or parent. The nurse who uses knowledge of age-related emotional needs and communication techniques can greatly help relieve this emotional distress and enhance compliance with drug therapy.
- Patient and family education regarding drug therapy should include information needed to help the child take the drug safely and effectively. Teaching involves giving honest and straightforward explanations about drug therapy, answering questions, allaying patient and family anxiety, and emphasizing the importance of drug compliance. Parents should be taught how to measure a correct dose at home and how to use the appropriate measuring/dosing tool.

QUESTIONS FOR STUDY AND REVIEW

1. How does the neonate's and infant's liver function affect drug distribution?
2. What is body surface area? How is body surface area utilized in pediatric drug therapy?
3. What dose adjustment might be expected when a water-soluble drug is given to an infant?
4. Are all drugs that are safe for adults also safe for children?
5. A three-year-old child is hospitalized and is to receive amoxicillin, an antibiotic. The recommended dose is 25 mg/kg/day in divided doses every 12 hours. The child weighs 20 kg. What is the correct dose that should be administered every 12 hours? What should you do to prevent the most common pediatric medication error when administering the amoxicillin?
6. What is the appropriate site of an IM injection for an infant?
7. Why is it important to assess the preschooler's or school-aged child's past experience with health care providers and drug therapy? Why is patient and family education important with pediatric patients?

Life Span: Pregnant or Breast-Feeding Women

Learning Objectives

At the completion of this chapter the student will:

1. Identify how core drug knowledge of drug therapy in pregnant or breast-feeding patients may vary from core drug knowledge in other life-span groups.
2. Identify how normal physiologic changes with pregnancy alter the pharmacokinetics of drug therapy.
3. Define teratogenic effect and its relevance in managing drug therapy in the pregnant patient.
4. Differentiate the classifications of drugs for use in pregnancy.
5. Describe why adverse effects of drug therapy may be overlooked in pregnant patients.
6. Identify how the pregnant or breast-feeding patient's core patient variables in drug therapy may vary from the core patient variables of other life-span groups.
7. Relate the core drug knowledge to core patient variables when providing drug therapy in pregnant or breast-feeding patients.
8. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drug therapy in pregnant or breast-feeding patients.
9. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects in drug therapy in pregnant or breast-feeding patients.
10. Determine key points for patient and family education in drug therapy for pregnant or breast-feeding patients.

Although the prevalence varies, drug therapy during pregnancy is common. Nursing management of drug therapy for pregnant women is challenging for several reasons. The main issue is that nursing care is needed for both the patient and the fetus because most drugs pass through the placental membrane to the fetus (usually by diffusion) or through breast milk to the infant.

Drug therapy in pregnant women is used primarily for two reasons: to treat a preexisting medical condition or to treat complications that arise during pregnancy. Although drug therapy may be indicated during pregnancy or during **lactation** (the secretion of breast milk), nursing management must focus on both the therapeutic effects on the patient and the potential adverse effects on the developing fetus or infant being breast-fed.

The nurse must know about the physiologic changes that occur during pregnancy and how they may alter the patient's response to a drug. The nurse must also understand the adverse effects of certain drugs on the developing fetus. Although adverse effects of drug therapy to the breast-fed infant are generally less severe than those to the fetus during pregnancy, the nurse must also be familiar with the potential adverse effects from drug therapy during lactation.

This chapter presents core drug knowledge and core patient variables that pertain to pregnancy and lactation. In addition, some general guidelines are presented for maximizing therapeutic effects, minimizing adverse effects, and providing patient and family education for any drug therapy.

Nursing Management of the Pregnant or Breast-Feeding Patient

Core Drug Knowledge

Pharmacotherapeutics

Pharmacotherapeutics are no different in a pregnant woman than in a woman who is not pregnant. The important consideration in drug therapy for pregnant women is the potential adverse effects on the developing fetus. A clear clinical indication for drug therapy must exist before a drug is prescribed or self-administered. Although the range for most drug dosages remains the same for the pregnant patient, the nurse must always consider the risk for fetal effects. The lowest therapeutic dose of a drug should be administered to the pregnant woman to help minimize fetal effects.

Some health problems occur secondarily to pregnancy and require drug therapy. These problems include **preeclampsia** (a serious hypertensive condition that can develop during pregnancy) or **eclampsia** (a life-threatening condition resulting from uncontrolled preeclampsia, involving cerebral edema and convulsions). **Gestational diabetes,** a form of diabetes that develops during pregnancy, may also occur. Occasionally, if the fetus has a health problem, drugs are administered to the pregnant woman with the intent of treating the fetus as the drug passes through the placenta. For example, digoxin (a drug that slows the heart rate and strengthens the force of contraction) is administered to the mother to treat fetal tachycardia and congestive heart failure in the fetus.

Pharmacokinetics

Several physiologic and anatomic changes occur during pregnancy. They can alter the pharmacokinetics of drugs and involve the endocrine, gastrointestinal (GI), cardiovascular, circulatory, and renal systems.

ABSORPTION

Changes in the GI system are influenced by pregnancy hormones and mechanical pressure from the growing uterus. Progesterone decreases gastric tone and motility and prolongs stomach emptying time, which may alter the pharmacokinetics of orally administered drugs. Progesterone also promotes functional respiratory system changes during pregnancy. Tidal volume increases 30% to 40%, with a 50% increase in minute volume by term. These increases, along with the pulmonary vasodilation that occurs during pregnancy, enhance the absorption of drugs that are inhaled.

DISTRIBUTION AND METABOLISM

Hemodynamic changes in the cardiovascular system alter heart rate, cardiac output, venous and arterial blood pressures, blood volume, circulation, and coagulation. The heart rate increases about 10 to 15 bpm above baseline as a result of a 40% increase in blood volume. A 50% increase in plasma volume causes a hemodilution of plasma albumin, which potentiates changes in drug distribution. Plasma lipid levels increase throughout pregnancy as a result of the more complete absorption and decreased elimination of fats during pregnancy. These changes in lipid levels may alter drug transport mechanisms and drug distribution. Drugs are distributed by the circulatory system to the fetus by passing through the placenta, usually by diffusion. Drugs may compete with the hormones of pregnancy for albumin-binding sites, which may result in a larger amount of unbound (or free) drug in circulation, leaving the drug available to cross the placental membrane and enter the fetal circulation. Drugs that are lipophilic (fat soluble) and not bound to protein pass easily through the placenta's lipid membrane.

Drugs are also distributed into breast milk. Drugs that are widely distributed throughout the mother's body are usually minimally passed into breast milk, producing low drug concentrations in breast milk. Other drugs, such as those with increased lipid solubility and low protein binding (e.g., central nervous system [CNS] agents), pass more easily and may produce high drug concentrations in breast milk. Lipophilic drugs pass easily because breast milk contains a high percentage of fat. Drugs that are not highly protein bound have more active, free drug molecules in the bloodstream, which can then diffuse into breast milk. Other drugs that are more likely to diffuse into breast milk include drugs with lower molecular weights and those with organic bases; these drugs may become "trapped" in breast milk because of its low pH, producing high drug concentrations.

Not all drugs present in breast milk are well absorbed by the neonate. Drug levels in breast milk are not equivalent to drug levels in the mother's blood, and so drugs with poor bioavailability usually do not achieve high concentrations in the neonate's circulation. A breast-feeding infant usually ingests less than 2% of the mother's total dose.

Drug metabolism is not altered by pregnancy or breast-feeding.

EXCRETION

Changes in renal function during pregnancy result from changes in renal plasma flow, glomerular filtration rates, and renal tubular reabsorption. By the third trimester, the renal blood flow has increased 40% to 50% from the pre-pregnancy level. Increases in renal plasma flow cause greater capillary pressures, requiring an increase in filtration through the glomerulus. The glomerular filtration rate increases by approximately 50% and contributes to increased excretion rates. Therefore, drug excretion rates may be increased during pregnancy.

Pharmacodynamics

Two dramatic physical changes occur in the mother during pregnancy: by 32 weeks' gestation, cardiac output is increased by 50%; and from the second trimester on, arterial blood pressure is decreased. These conditions necessitate careful evaluation of a drug's pharmacodynamics.

Contraindications and Precautions

Some drugs and vaccines are contraindicated during pregnancy, and others should be given with caution if they pose a threat to the developing fetus by passing through the placenta (Box 7.1). Some drugs and vaccines can cause **teratogenic** effects (physical defects) in the developing fetus. See Table 7.1 for a list of known teratogenic drugs. For example, antiepileptic, phenytoin (Dilantin), a hydantoin, is known to cause **fetal hydantoin syndrome.** This syndrome is characterized by craniofacial abnormalities, limb defects, growth deficiency, and mental deficiency (Hansen & Smith, 1975). These abnormalities are believed to occur because phenytoin competes for folic acid–binding sites.

The precise effects of drug therapy on the fetus are mostly undetermined. A review of all drugs approved in the United States between 1980 and 2000 found that the teratogenic risk in human pregnancy was still undetermined for more than 90% of those drugs. The longer the drug had been on the market, the more likely it was that the exact teratogenic risk was unknown (Lo & Friedman, 2002).

A drug is traditionally identified as a teratogen based on the findings of animal teratology studies. This method is problematic because animal models are frequently poor predictors of whether a drug is a human teratogen. Nonhuman primates are good predictors of human teratogenicity because they are the most genetically similar to humans; however, nonhuman primates are rarely used in experiments because of the expense involved. Rodents are used most frequently in teratology studies, but unfortunately they are very dissimilar to humans in terms of their physiology, metabolism, and ontogenetic development. Although animal studies do not provide all of the information in determining teratogenicity of a drug, they currently are the most-used tool to screen drugs for their potential to cause human birth defects. Clinical studies in pregnant women have not been done because of ethical concerns about experimentation on the fetus.

The ultimate assessment of drug safety during pregnancy, unfortunately, comes from the use of the drugs in humans. To address the need for more information about how

BOX 7.1 COMMUNITY BASED CONCERNS

Smallpox Vaccine

In collaboration with the Food and Drug Administration (FDA) and the Department of Defense in the United States, the Centers for Disease Control and Prevention (CDC) established the National Smallpox Vaccine in Pregnancy Registry. In 2003 after the military began vaccinating military personnel against smallpox. The registry includes women found to be pregnant when vaccinated, those who became pregnant within 28 days of vaccination, and those who, while pregnant, were in close contact with a person who had received the smallpox vaccine within the past 28 days. Women reported to this registry will are monitored throughout the pregnancy and at the conclusion of the pregnancy to document pregnancy outcomes. Fetal vaccinia, a rare but serious infection manifested by skin lesions and internal organ involvement, can result in fetal or neonatal death or premature birth. Historically, there have been 50 reported cases world wide of fetal vaccinia. Evaluation of pregnancy registry data from 376 exposed women from 2003 to 2006 did not find an increased incidence of: pregnancy loss, preterm birth, or birth defects. And no cases of fetal vaccinia were identified (Ryan & Seward, 2008).

While the analysis of the pregnancy registry data is reassuring, it is a very small sample size and should not be construed to mean there are no risks if a pregnant woman receives the vaccine. The CDC and the FDA continue to recommend that women should be screened for pregnancy before vaccination. Women who are pregnant or might become pregnant within 4 weeks after vaccination should not be vaccinated against smallpox unless there is active circulating disease because of the risk for fetal vaccinia, which is a rare but serious infection of the fetus. Fetal vaccinia is manifested by skin lesions and internal organ involvement and can result in fetal or neonatal death or premature birth. Smallpox vaccine has not been clearly shown to cause other teratogenic effects or other adverse effects in the fetus or newborn. People who have close personal contact with a pregnant woman should also not be vaccinated.

The CDC has recommended that screening for pregnancy before vaccination is paramount to preventing exposures in pregnant women. The screenings that have occurred as part of the current immunization campaign against smallpox appear to have been effective in minimizing exposure of pregnant women to the vaccine.

TABLE 7.1 Examples of Drugs or Drug Classes Known or Highly Suspected to Be Teratogenic

Teratogenic Drug or Drug Class	Indication
Alkylating agents (cyclophosphamide)	Cancer
Androgenic hormones(danazol)	Hormone replacement
Antiepileptics (valproic acid, carbamazepine, phenytoin)	Seizure control in epilepsy
Antimetabolities (methotrexate)	Cancer; Crohn's disease; rheumatoid arthritis; ectopic pregnancy; termination of early pregnancy (combined with misoprostol)
Anti–thyroid (propylthioracil, methimazole)	Hyperthyroidism
Anxiolytic (diazepam)	Anxiety, seizure control, pre-procedure relaxation
Coumarin (warfarin)	Anticoagulant
Estrogens (diethylstilbestrol)	Hormone replacement
Fluconazole	Anti-fungal
Lithium	Mood stabilizer in bipolar disease
Misoprostol	Intestinal ulcer from NSAID use; off label use for cervical ripening and induction of labor; medical termination of early pregnancy (when combined with mifepristone)
Oral contraceptives	Birth control
penicillamine	Cystinuria and rheumatoid arthritis
Retinoids (isotretinoin)	Recalcitrant cystic acne
Radioactive iodine (sodium iodide-128)	Hyperthyroidism
SSRI antidepressants (paroxetine, fluoxetine, sertraline)	Depression
Thalidomide	Cancer; leprosy

drugs affect a pregnancy, the United States Food and Drug Administration (FDA) has established Pregnancy Registries. There are also pregnancy registries in other countries, and there are some that are global,with enrollees from around the world. Women who take medication during pregnancy for a chronic or acute condition may elect to join one of these registries. A complete list is found on the FDA web site. The information gleaned regarding pregnancy outcomes is added to a national database, whose purpose is to provide more definitive information about the teratogenic affects of various drug therapies and the margins of safety with drug exposure during pregnancy. There are several limitations of these registries. These include: small sampling size that doesn't represent the desired population; voluntary enrollment which may skew the results; enrollment in more than one registry could lead to over or under estimation of risk; medical records are not always examined to validate data; small sample sizes may not be able to detect small or moderate risks; and the inability to detect that the underlying maternal condition and not the drug is the cause of the fetal injury because women with the condition but not receiving drug therapy are excluded from the registry (Wyszynski, 2009). Compiling data from multiple registries can be problematic because the statistical analysis performed on reported data are not identical, and some registries may provide poorer quality information due to protocols that are not epidemiologically sound (Kennedy, Uhl, & Kweder, 2004)

PREGNANCY CATEGORIES

Drug manufacturers are required by law to include information in a drug's label about possible risks if the drug is administered to a pregnant or breastfeeding woman. In 1980, the FDA developed a categorical ranking based on research findings to help classify drugs by the risks posed to the fetus, weighed against the potential benefits to the pregnant woman. The categories are A, B, C, D, and X (Box 7.2).

Box7.2 FDA PREGNANCY CATEGORIES

Category A: Controlled human studies in pregnant women fail to demonstrate a risk to the fetus.

Category B: Animal studies fail to demonstrate fetal risk, but there are no controlled human studies in pregnant women; or animal studies demonstrate fetal risk that was not confirmed in controlled human studies in pregnant women.

Category C: Animal studies demonstrate fetal risk, and there are no controlled human studies in pregnant women to rule out fetal risk, or there are no animal or human studies. Drugs are given if the benefit justifies risk.

Category D: Controlled human studies demonstrate positive evidence of fetal risk. In life-threatening situations, the benefit may be acceptable despite the risk.

Category X: Controlled human studies demonstrate fetal risk. The fetal risk outweighs any possible benefit. Use in pregnant or potentially pregnant women is contraindicated.

Categories A and B (and to some extent, C) are generally based on increasing risk. Categories D and X (and to some extent, C) are based on risk versus potential benefit. These categories have been found to be confusing to health care providers for a number of reasons including:

- The categories do not supply enough information for providers and consumers to make informed decisions about drug therapy.
- The FDA, in trying to keep the categories simple, has grouped together drugs that do not have identical risks.
- The alphabetical progression leads people to believe that the seriousness of the risk increases with each letter, which is not correct.

To provide clearer and more relevant information for a prescriber to use in decision making, the FDA announced in 2008 that elimination of the five categorical rankings (A, B, C, D, and X) would begin in 2009. In its place the FDA will include on drug labels a narrative summary of effects for both pregnancy and lactation. Under both the revised pregnancy and lactation subsections of the label there will be a fetal/newborn risk summary, clinical considerations (such as points for patient education or management while on drug therapy), and a data section (where clinical trial data is described in detail). Information from pregnancy exposure registries will be included, if available. The new labels are appearing first for newly approved drugs. Drugs that were approved for use prior to 2009 will have their labels updated over several years. This means that nurses will see two different forms of pregnancy and lactation information on drug labels for awhile, and thus must be familiar with both (Aschenbrenner, 2008).

> So why does every nurse need to understand this? While its importance might seem most obvious for those who work clinically with pregnant women, women of child bearing age are in every specialty and environment, be it a medical-surgical unit, oncology unit, operating room, home health, or outpatient center… [The] nurse is the last person to check the medication's appropriateness before the patient receives the drug. And because it is has been estimated that nearly half of all pregnancies are unplanned (FDA. Briefing document, 2003) nurses must know the ramification of giving any drug to a pregnant woman. If a drug has serious teratogenic risks then the patient must be screened for pregnancy prior to starting drug therapy. One final contributing reason as to why this is important information is that nurses are asked about drug safety in pregnancy and lactation from everyone- from patients, family members, friends, and neighbors. If nurses are going to be able to explain these changes to patients, they have to understand them (Aschenbrenner, 2008).

LACTATION CATEGORIES

In 2005, the American Academy of Pediatrics Committee on Drugs published its updated recommendations on drugs and breast-feeding (American Academy of Pediatrics, 2005). The report identifies several categories of drugs (and other agents) and their potential to cause problems with breast-feeding, which are as follows:

- Cytotoxic drugs that may interfere with cellular metabolism of the nursing infant (including cyclophosphamide, cyclosporine, doxorubicin, and methotrexate)
- Drugs of abuse for which adverse effects on the infant during breast-feeding have been reported (including amphetamines, cocaine, heroin, marijuana, and phencyclidine)
- Radioactive compounds that require temporary cessation of breast-feeding
- Drugs for which the effect on nursing infants is unknown but may be of concern (Table 7.2)
- Drugs that have been associated with significant effects on some nursing infants and should be given to nursing mothers with caution (Table 7.3)
- Maternal medication usually compatible with breast-feeding
- Food and environmental agents that may also have effects on breast-feeding

All contraindicated drugs have been reported to cause signs and symptoms in the infant or produce an adverse effect with lactation. The American Academy of Pediatrics states that this list is not complete and recommends that all drugs of abuse should be avoided by lactating women, even though reports of neonatal adverse effects are not found in the literature for all substances. If a breast-feeding woman is receiving any radioactive compounds, such as those used for treating malignant tumors or an overactive thyroid gland, the patient should pump her breasts during the time that breast milk is radioactive and discard that milk in a biohazard container designed for radioactive materials. Breast-feeding can resume when the drug is stopped and the breast milk contains no radioactivity.

Drugs with unknown effects on the neonate that may be of concern include psychotropic drugs (antianxiety drugs, antidepressants, and antipsychotic drugs). These drugs appear in low concentrations in breast milk after maternal ingestion. However, these drugs have long half-lives, and because of immature hepatic and renal function in newborns, the drugs or some of their metabolites may reach measurable amounts in nursing babies' plasma and tissues and in organs such as the brain. The longer the nursing mother receives psychotropic drugs, the greater is the risk of harmful effects in the infant. Nursing mothers should be informed that if they take one of these drugs, the infant will be exposed to it. These drugs affect neurotransmitter function in the developing CNS, and the long-term neurodevelopmental effects that can occur from newborn exposure are unknown. It is possible that psychotropic drugs may impair the short-term or long-term function of the CNS. See Table 7.2 for a full list of drugs for which the effect on nursing infants is unknown but may be of concern.

Drugs that are associated with significant neonatal effects after breast-feeding and that should be used with caution include the over the counter drugs aspirin and

clemastine (Tavist). The blood concentration of these drugs may become high enough to be of clinical importance in the breast-fed infant. The reported effects for these drugs include CNS changes, cardiovascular changes, and GI problems. See Table 7.3 for a full list of drugs associated with significant neonatal effects.

Infant exposure via breast milk may be of concern for a larger numbers of infants than previously believed, although there is limited research on this. A recent survey at one US hospital found that breastfeeding women were much more likely to use medications than pregnant women ($p<0.0001$) and a third of these women took medications rated as possible or probably unsafe or whose safety was unknown (Stultz et al., 2007).

Often, drugs identified as being compatible with breast-feeding are not part of large research studies. Rather, information is obtained from single case reports or a small series of reports. However, *most drugs that are taken by the mother for treatment are believed to pose no harm to the breast-fed newborn*. Breast-feeding confers many advantages to the baby and is encouraged by health professionals and public health officials.

Adverse Effects

The two major considerations when evaluating adverse effects of drug therapy in pregnant women are common side effects of pregnancy and the adverse effect that maternal drug therapy can have on the fetus. Symptoms such as nausea and vomiting, light-headedness or hypotension, constipation, heartburn, urinary frequency, heart palpitations, and fatigue may mask the adverse effects of drug therapy in pregnant patients, making adverse effects more difficult to assess. When considering the effects of drugs on the fetus, several factors are important, including dose and duration of drug therapy, the type of adverse effect that may appear, and when during pregnancy the drug is taken. The timing of drug exposure is critical because. Teratogens act during critical periods of embryonic or fetal development.

BOX 7.3 FOCUS ON RESEARCH

Pregnancy and Prescribed Teratogenics

Andrade, S. E., Raebel, M. A., Morse, A. N., Davis, R. L., Chan, K. A., Finkelstein, J., et al. (2006). Use of prescription medications with a potential for fetal harm among pregnant women. *Pharmacoepidemiology and Drug Safety,* 15(8):546–554.

The Study

This study was designed to estimate the prevalence of pregnant American women taking a prescription drug that has a potential for fetal harm. This was a retrospective study using the automated databases of eight health maintenance organizations in the United States. Women who delivered a baby between January 1996 and December 2000 were included in the study. Women who had received ovulation stimulants or who had a preterm delivery were excluded from the analysis. Of the 114,165 women whose records were examined, 1.1% of them received a teratogenic drug within the 270 days before delivery. A larger percentage (5.8%) received an FDA category D or X drug; these drugs were mostly prescribed and used in early pregnancy.

Nursing Implications

Using a teratogenic drug during pregnancy has potential risks for the infant. Many women are prescribed these drugs in early phases of pregnancy when the developing fetus may be most at risk of congenital defects. Nurses should look up the pregnancy information related to all drugs they administer. Nurses need to confirm the pregnancy status of any patient of childbearing age prior to dispensing any drug that has known teratogenic effects. Nurses also need to educate women desiring to become pregnant about the risks of teratogenic drug effects to help prevent exposure to a teratogen prior to the woman knowing she is pregnant.

Teratogens that create injury to large number of cells in the early embryo in the preimplantation phase most likely will result in loss of the pregnancy (Buhimschi & Weiner, 2008).

The critical period of **organogenesis,** during which the major fetal organs form, is from implantation up to approximately day 58 to 60 after conception. If drugs that cause teratogenic effects are administered during this period, major malformations of fetal organ systems may result (see Table 7.1). If possible, drug therapy should be delayed until after this time. Unfortunately, most women do not realize they are pregnant or do not seek prenatal care until after this early period; thus, accidental exposure to teratogens may occur (Box 7.3).

After 60 days, the embryonic phase is complete, and the fetal phase begins. This phase continues through the remainder of the pregnancy, during which fetal exposure to drugs continues to have the potential for harm. The fetal effects that may occur are of four primary types:

- Damage to structures or organs that were formed normally during organogenesis
- Damage to systems undergoing tissue development
- Growth retardation
- Fetal death or stillbirth

Combinations of these effects may also occur. Damage to the fetus may be caused by teratogens but may also be caused by agents that have no apparent potential to produce abnormal development. An example is coumarin derivatives used as anticoagulants, which may produce eye and brain defects from hemorrhagic accidents in the fetus. Growth retardation is the most common fetal effect. However, it is difficult to determine whether this effect is caused by the drug therapy or the primary condition for which the drug therapy is prescribed. For example, there are case reports of fetal growth retardation when the mother received the antihypertensive drug propranolol, but untreated hypertension is also associated with this condition.

Additionally, some drugs create adverse neonatal effects (Table 7.4). These agents do not normally cause teratogenic effects but instead create a situation that makes it difficult for the neonate to adapt to life outside the uterus. Examples

TABLE 7.4 **Selected Nonteratogenic or Minimally Teratogenic Drugs with Adverse Fetal Effects or Breast Feeding Effects**

Nonteratogenic Drug or Class	Adverse Fetal Effects	Breast Feeding Effects
acetaminophen	Possible link between drug, gastroschisis, and small bowel atresia if mother is genetically predisposed and fetal exposure occurs during early pregnancy	Compatible with breast feeding
corticosteroids	Cleft lip (evidence is weak); increased risk of neonatal sepsis (suggested but not confirmed); suppression of fetal breathing, movement, impaired myelination, intrauterine grown restricitohn, and microcephaly	No adequate reports or well controlled studies in breast feeding
diphenhydramine	No evidence of fetal risk; May cause neonatal depression if given during labor	Infant may demonstrate irritability
labetalol	Large doses given IV can cause bradycardia, hypoglycemia, hypotension, pericardial effusion, myocardial hypertrophy, and fetal death due to acute hypotenison	Breast fed infants are normotensive
tetracycline	cause yellow-gray-brown discoloration of the permanent adult teeth	Considered compatible with breast feeding

are floppy infant syndrome from the use of benzodiazepines (antianxiety agents) near the time of delivery and premature closing of the ductus arteriosus from the use of nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin (Indocin).

The risk for adverse effects of drug therapy on the breast-feeding infant are not as great as those relating to drug therapy during pregnancy because the breast-feeding infant usually ingests less than 2% of the total dose of the drug given to the mother. The dose the infant receives depends on the amount of drug excreted into breast milk, the daily volume of milk ingested, and the average plasma concentration of the mother. Unfortunately there has been limited research on drug concentrations in breast milk. How the infant metabolizes and excretes the drug also contributes to the circulating volume of the drug in the infant (Buhimschi & Weiner, 2009a). At this time there are limited numbers of drugs that are contraindicated with breast feeding (see lactation categories above). More research is needed to know whether the administration of a particular drug poses a risk to the breast-feeding infant.

Drug Interactions

Drug interactions are unchanged during pregnancy and breast-feeding.

Assessment of Core Patient Variables Relevant to Pregnancy and Breast-Feeding

Health Status

Several considerations must be taken into account when assessing health status during pregnancy. First, if the patient has a preexisting condition that requires drug therapy, the health care providers must consider whether the prescribed drug therapy will have adverse effects on the fetus. Second, any adverse effects the pregnancy may have on the mother's health must be identified because they may require changes in drug therapy. Third, if the pregnancy does induce changes in health status that require new drug therapy, any adverse effects of this drug therapy on the fetus will have to be determined.

Pregnant women, especially those being treated with drug therapy, must be assessed for preexisting conditions. Give special attention to any cardiovascular problems because the cardiovascular system undergoes many changes and stresses during pregnancy. The pregnancy may necessitate changes in drug selection or dosage. Also assess the woman's use of over-the-counter drugs, which may pose risks to the fetus.

Seizure disorder is important to consider during pregnancy. A woman with a seizure disorder who is planning a pregnancy must first seriously consider how antiepileptic drug therapy might affect the fetus. Many traditional, established antiepileptics are commonly believed to have teratogenic potential because of their mechanism of action. These teratogenic effects include congenital abnormalities such as neural tube defects, specific facial and other deformities, and mental impairment. However, stopping all drug therapy for the pregnant woman with epilepsy is not necessarily advisable because seizures and status epilepticus, which can occur when drug therapy is stopped, are responsible for most excess maternal deaths in women with epilepsy (i.e., deaths in women with epilepsy beyond what would be expected to occur statistically). Controversy exists regarding what harm maternal seizures can cause the fetus. Some clinical experts have hypothesized that seizures in a pregnant woman may cause fetal hypoxia, leading to CNS damage. This "between a rock and a hard place" reality demonstrates the difficulty of making drug therapy decisions that are in the best interest of both the mother and the baby.

If antiepileptics must be continued during pregnancy, drug selection is important. However, the literature offers limited clear guidance as to drug selection based on risk to the infant. Typical or classic antiepileptic drugs such as phenytoin have generally been considered to be teratogenic since the 1970s (Hansen & Smith, 1975) and the drugs carry warnings on their labels related to risks of teratogenicity. Newer research seems to indicate that phenytoin use during pregnancy increases the risk of congenital malformation at about the same rate as not treating epilepsy during pregnancy.(Harden, 2008; Vajda, 2008; Battino & Tomson, 2007).

Most of the newer classes of anti epileptic drugs do not have a high risk for teratogenetic effects, with one exception. There seems to be agreement that valproic acid (Depakote) should be avoided, as it has been linked to higher incidences of congenital abnormalities, especially neural tube defects, than other antiepileptic drugs. Teratogenic risk increases with the daily dose of valproic acid with higher risk from daily dosage over 1,000 mg/d. The risk from valproic acid is compounded with low serum folate levels (Buhimschi & Weiner, 2009a). Exposure to multiple antiepileptic drugs (polytherapy) increases the risk of adverse effects in the fetus; combining valproic acid with any other drug increases the risk the most (Harden, 2008; Pennell, 2008; Battino & Tomson, 2007). The literature also supports that valproic acid, as well as phenytoin and phenobarbitol diminish cognitive ability of the child exposed in utero; polytherapy also increases this risk (Harden, 2008). *The safest choice appears to be for women to maintain therapy to control their seizures with the smallest dose and monotherapy when at all possible* (Harden, 2008; Vajda, 2008; Battino & Tomson, 2007). Antiepileptics may be discontinued for select patients upon medical consultation.

Another health condition that may warrant assessment is depression. Pregnancy and postpartum periods are considered times of high risk for depression due to hormonal changes, especially if the woman has a previous history of depression. Untreated depression can impair the mother–infant bond and create emotional problems in the child. Research indicates that only 18% of women with depression disorder seek treatment during pregnancy and postpartum (Marcus, 2008). Untreated depression can have negative effects during pregnancy such as: inadequate weight gain, under utilization of prenatal care, increased substance use, and premature birth. Infants of depressed mothers may have lower birth weight, a decreased Apgar score, smaller

head circumference, and be small for their gestational age (Marcus, 2008; McClanahan, 2009). Antidepressants treat depression, but with the increased use of antidepressants, concerns have arisen about the effects these drugs might have during pregnancy and breast-feeding. There is little definitive information on this subject to date. A literature review found such inconsistent findings regarding whether or not selective serotonin reuptake inhibitors (SSRI), a class of antidepressants, increase teratogenic risks that the only conclusion was that the teratogenic potential of these drugs was unproven (Gentile & Bellantuono, 2009).

Diabetes, whether preexisting or developed during pregnancy, is another important condition to consider. Women may have type 1 or type 2 diabetes before pregnancy or they may develop diabetes temporarily during pregnancy, this is called gestational diabetes. In gestational diabetes, the secretion of placental hormones (human placental lactogen, cortisol, progesterone, and catecholamines) causes the pregnant woman to develop insulin resistance as the pregnancy progresses. Whatever the type of diabetes, hyperglycemia may result, which requires either an increase in insulin therapy for those women already receiving it (i.e., type 1) or initiation of insulin therapy for those with type 2 or gestational diabetes. Because hyperglycemia is believed to increase the incidence of congenital anomalies (particularly during the first trimester), the primary goal for the pregnant patient is to maintain normal blood glucose levels. Historically, insulin is the drug of choice for controlling blood glucose levels because it does not cross the placenta and does not pose concerns for adverse effects. Recently research supports the use of the oral antihyperglycemic drug glyburide to treat gestational diabetes. Glyburide, unlike other drugs in its class, has been found to have a very low incidence of moving through the placenta into the fetal circulation; the exact mechanism of this is unknown currently (Kimber-Trojnar et al., 2008). Glyburide may have altered pharmacokinetics in pregnant women, as one study showed 50% less plasma concentrations in this possible (Herbert et al., 2009). This may account for why glyburide has a reported success rate in gestational diabetes of 80% to 85% (Kimber-Trojnar et al., 2008). Evidence in the literature supports the use of glyburide for gestational diabetes and does not show a higher incidence of maternal or fetal complications from using it instead of insulin (Coustan, 2007; Nicholson et al., 2008; Moretti et al., 2008; and Nicholson et al., 2009) Some experts disagree about the safety of glyburide (Kimber-Trojnar et al., 2008). The use of another oral antihyperglycemic, metformin, has not been studied as much as glyburide, and the limited findings are inconclusive as to whether it is an appropriate treatment for gestational diabetes (Coustan, 2007; Nicholson et al., 2009). After the neonate is delivered, maternal glucose levels should return to baseline levels, and insulin or glyburide therapy is usually no longer necessary for women who did not need them before becoming pregnant.

Another change in health status that may occur during pregnancy is **hyperemesis gravidarum,** commonly called pernicious vomiting of pregnancy. While nausea and vomiting are common in up to 80% of normal pregnancy, hyperemesis gravidarum is potentially life threatening and affects up to 1.5% of pregnant women (Bottomley & Bourne, 2009). Dehydration, ketonuria, and vitamin deficiency can be complications. When hyperemesis gravidarum is severe, antiemetic drug therapy is needed to control the vomiting. Although there is insufficient research evidence to demonstrate the most effective therapy, safety data supports the use of antihistamines (such as diphenhydramine (Benadryl), Meclizine, Dramamine, which also has antiemetic effects), phenothiazines (a drug class with antiemetic and antipsychotic properties that block dopamine receptors), and metoclopramide (a drug that promotes gastric emptying and promotes peristalsis; it is used as an antiemetic because it blocks peripheral dopamine receptors which cause nausea) (Bottomley & Bourne, 2009). The literature also supports the use of steroids such as prednisolone (Sheehan, 2007). Some sources have shown that the selective serotonin antagonist antiemetics such as ondansetron may be helpful and do not appear to cause teratogenic effects, but the research is very limited with these drugs (Einarson et al., 2004; Sheehan, 2007).

Preeclampsia is another serious condition that can develop and require drug therapy during pregnancy. This hypertensive condition of pregnancy typically develops after the 24th gestational week. Preeclampsia is characterized by a triad of symptoms—hypertension, edema, and proteinuria. Uncontrolled preeclampsia may lead to eclampsia, a condition characterized by cerebral edema and convulsions. The primary goal of preeclampsia treatment is to prevent eclampsia and stabilize the patient until the fetus reaches maturity. Treatment for preeclampsia is aimed at decreasing CNS irritability and reducing maternal blood pressure to enhance placental and maternal circulation to the organs. Drug therapy for preeclampsia includes magnesium sulfate, which is the drug of choice for preventing convulsions, and hydralazine, a drug used to treat hypertension. Other drugs used in treating hypertension in preeclampsia include diazoxide, nifedipine, and labetalol.

Another condition secondary to pregnancy that may occur is thrombus formation. The decreased venous return and increased levels of clotting factors and fibrinogen that are characteristic in pregnancy produce a state of hypercoagulation, which increases the risk for clot formation. Pregnant women who develop thrombosis are treated with the anticoagulant heparin.

Life Span and Gender

Teenage pregnancy continues to be a problem in the United States. Adolescents are prone to experimentation with various substances, both legal and non-legal. Teenagers may also not realize they are pregnant or may not admit to pregnancy till late in the pregnancy, therefore not receiving adequate prenatal care. These issues combined may create problems for the mother and infant. Nurses assess for these behaviors.

Lifestyle, Diet, and Habits

The lifestyle, diet, and habits of pregnant or breast-feeding women can have a serious impact on the course of the pregnancy and the development of the fetus or infant. For example, alcohol is a known human teratogen. **Fetal alcohol syndrome** is a serious pattern of teratogenic effects seen in infants born to women who may have consumed alcohol chronically during pregnancy. Fetal alcohol syndrome is marked by specific physical malformations at birth and severe growth retardation, mental retardation, and microcephaly. Cocaine abuse is also known to cause adverse fetal effects and is suspected to be a human teratogen. Opiate abuse does not appear to significantly increase the risk for congenital anomalies, but other adverse outcomes are associated with the use of opiates, including abruptio placentae, neonatal withdrawal, preterm birth, and fetal growth retardation. Smoking tobacco also has adverse fetal effects, most notably fetal growth retardation.

Environment

Although some changes in health status that occur in pregnancy require drug therapy administered in the hospital setting, such as magnesium sulfate for preeclampsia, most drug therapy given during pregnancy or breast-feeding is administered in the patient's home.

Culture and Inherited Traits

Cultural beliefs may affect whether a woman accepts certain drug therapies while she is pregnant or breast-feeding. Assess for these beliefs when managing drug therapy in the pregnant or breast-feeding woman. For more about the effects of culture on pharmacotherapeutics (see Chapter 12).

Nursing Diagnoses and Outcomes

Nursing diagnoses formulated for the pregnant or breast-feeding patient receiving drug therapy are similar to diagnoses made for patients with other concerns relating to life span. The main difference is that for the pregnant or breast-feeding woman, the nursing diagnosis must address the needs of both the patient and her child. Relevant nursing diagnoses may include the following:

- Risk for Injury to the fetus related to adverse effects of maternal drug therapy
  Desired outcome: *The patient will demonstrate therapeutic drug effects with minimal adverse effect to the fetus or infant by avoiding unnecessary drugs throughout pregnancy and lactation and by using nonpharmacologic measures to relieve common discomforts of pregnancy.*
- Anxiety related to perceived danger of drug therapy to fetus or infant
  Desired outcome: *The patient's anxiety will be minimal during drug therapy.*
- Risk for Injury to the patient related to failure to receive needed drug therapy because of its potential adverse effects on the fetus or infant
  Desired outcome: *The patient will not sustain an injury from choices made about receiving drug therapy.*

Planning and Intervention

The nurse and other health care providers have a responsibility to the pregnant patient to consider the risk-to-benefit ratio of drug therapy, to educate the childbearing patient regarding possible teratogenic effects, and to support the patient's decision to accept or refuse drug therapy.

Maximizing Therapeutic Effects

If a prescribed drug therapy does not have adverse effects for the developing fetus or the child of the breast-feeding woman, emphasize this absence of known risk when teaching patients. Women may be reluctant to take needed drug therapy if they believe it may be harmful to the fetus.

Minimizing Adverse Effects

Limiting drug use in pregnancy decreases maternal and fetal adverse effects. No drug can be considered absolutely safe when administered during pregnancy, although general guidelines can assist the health care provider with decisions relating to drug therapy. Women of childbearing age should always be assessed for pregnancy before any drug therapy is initiated. During pregnancy, nonpharmacologic alternatives to drug therapy should be used if possible, especially for common discomforts of pregnancy, such as nausea and vomiting, light-headedness or hypotension, constipation, heartburn, urinary frequency, heart palpitations, and fatigue. If drug therapy is required, first check the drug's FDA pregnancy category or drug label information to determine safety. An evaluation of the risks versus the benefits shows whether administering a drug is justified. When a drug is to be administered, consult with the prescriber so that the minimum therapeutic dose is used for as short a time as possible. If possible, drug therapy is delayed until after the first trimester of pregnancy, during which all major fetal organ systems are forming, especially if the drug has the potential for causing teratogenic effects.

Monitor the pregnant woman and the fetus for both therapeutic and adverse effects of drug therapy. If prolonged drug use is necessary and poses risk to the woman or fetus, monitor serum levels of the drug to detect elevations that may lead to adverse effects. Dosage adjustments or discontinuation of the drug may be needed to reverse adverse effects or prevent toxicity. To reduce the risk for adverse effects, only drugs that are absolutely necessary are administered when complications of pregnancy occur. To help relieve typical discomforts of pregnancy, teach the patient

CRITICAL THINKING SCENARIO

ENSURING DRUG SAFETY DURING LACTATION

Your patient, a breast-feeding mother, tells you that she frequently gets stress headaches and takes aspirin for them. She would like the aspirin to have as little effect on the baby as possible. What questions might you ask her? What advice can you offer her?

how to use nonpharmacologic strategies, such as eating dry crackers first thing in the morning to prevent nausea.

When evaluating a patient, be careful to distinguish discomforts of pregnancy (e.g., nausea, vomiting, heartburn, light-headedness, urinary frequency, heart palpitations) from possible adverse drug effects. In addition, the pediatrician should be informed about maternal drug therapy. Knowledge of fetal exposure to drugs assists the pediatrician in making appropriate health care decisions regarding the neonate.

When questions and concerns arise regarding drug therapy and breast-feeding, similar strategies are used to prevent adverse effects. The various approaches include using nonpharmacologic remedies, determining the safest drug possible based on the amount of the drug that is transferred to breast milk and the possible neonatal effects, and assessing blood concentrations of the drug in the breast-feeding infant. Each drug administered to the lactating patient is evaluated for its potential adverse effects on the neonate, and the nurse also assesses the infant for adverse effects of the drug. Other methods used to reduce neonatal drug exposure include scheduling drug therapy just after breast-feeding or before the infant is going to sleep for a long time. Some drugs, such as antineoplastic drugs and drugs of abuse, are contraindicated during lactation, and breast-feeding is discontinued if the patient is taking any of these drugs. Agents such as general anesthetics, sedatives, and radioactive compounds required for a short-term diagnostic test should be cleared from the patient's circulation before she resumes breast-feeding. The nurse must know the drug's half-life and duration of action to be able to determine when breast-feeding can begin again. The risks to the neonate must be balanced against the advantages of the drug to the woman.

Providing Patient and Family Education

The nurse's role in counseling about pregnancy and fetal drug effects ideally begins before pregnancy. This counseling helps women make informed choices about drug therapy and helps minimize the risk for accidental exposure to teratogens in the early stages of pregnancy (from conception to day 60). Informing women of childbearing age about fetal drug effects can help them make decisions about planning pregnancy and about what to do when they become pregnant. The Organization of Teratology Information Specialists produces patient education sheets about many medications. These sheets are available online, and many are in Spanish and French in addition to English.

Patient and family education during pregnancy and breast-feeding is primarily focused on adverse effects to the fetus and infant. If the woman has used a drug before learning that she is pregnant, she will need information regarding to what degree of risk the fetus has been exposed, if any. Each pregnant patient should be given information on a drug's effects, both therapeutic and adverse, and should be permitted to make an informed decision about whether to receive the drug therapy.

The pregnant patient should also be taught how to anticipate adverse effects of drug therapy and distinguish them from normal pregnancy-related problems. Instruct the patient to notify the health care provider if adverse drug effects occur. The woman who is lactating also is informed of possible adverse effects of drug therapy on the infant and is instructed to report those findings immediately to the health care provider.

Ongoing Assessment and Evaluation

Nursing management of drug therapy during pregnancy and lactation is considered effective when maternal therapeutic needs have been met without harm to the fetus or the breast-feeding infant. Other measures of effective drug therapy include successful patient- and family-oriented drug education and assessment findings indicating that the mother and child are not experiencing adverse drug effects.

CHAPTER SUMMARY

- Drug therapy may be indicated for pregnant or lactating women to manage preexisting or newly developed conditions. Although therapeutic effects may be achieved in the woman, drug therapy may adversely affect the fetus or infant.
- The physiologic changes that occur during pregnancy may alter drug absorption, distribution, and elimination.
- Some drugs are contraindicated in pregnancy, and caution is advised for using others because drugs may pass through the placenta to the fetus and cause teratogenic effects. The potential fetal risks must be compared with maternal benefits when drug therapy is required.
- The effects of most approved drugs on a developing human fetus are not known. Voluntary enrollment by pregnant women in Pregnancy Registries for different drug therapies is one new mechanism for gaining knowledge about drugs and their effects on the developing fetus.
- Drugs may be excreted into breast milk, although the total received by the infant is a small percentage of the maternal dose. The nurse should be familiar with the prescribed drugs and the substances of abuse that are contraindicated during breast-feeding.
- Symptoms of pregnancy may mask adverse effects of drug therapy in the mother. Discomforts commonly associated with pregnancy, such as nausea and vomiting, light-headedness or hypotension, constipation, heartburn, urinary frequency, heart palpitations, and fatigue, are also frequent adverse drug effects.
- Limiting drug use during pregnancy and lactation decreases maternal and fetal adverse effects. Nonpharmacologic alternatives to drug therapy should be used if possible, particularly when treating the common discomforts of pregnancy.
- Substances of abuse are contraindicated during pregnancy and lactation because they can cause serious teratogenic effects, such as fetal alcohol syndrome, or harm the breast-feeding infant.
- The minimum therapeutic dose should be used for as short a time as possible during pregnancy. If possible, drug therapy should be delayed until after the first

trimester of pregnancy, during which the fetal organ systems are forming.
- Both the pregnant patient and the fetus should be monitored for therapeutic and adverse effects of drug therapy, and that practice should continue for the lactating patient and breast-feeding infant.

QUESTIONS FOR STUDY AND REVIEW

1. Which FDA pregnancy category rating includes the criterion "The fetal risk outweighs any possible benefit," and what does that mean?
2. Explain what types of drugs are most easily transferred across the placenta to the fetus.
3. Explain why gestational weeks 3 through 8 are considered critical when drug administration is considered during pregnancy.
4. Describe the physiologic changes in the renal system that increase drug excretion rates.
5. Why are lipophilic drugs more likely to enter breast milk than nonlipophilic drugs?

Life Span: Older Adults

Learning Objectives

At the completion of this chapter the student will:

1. Identify how core drug knowledge of drug therapy in older adults may vary from core drug knowledge for younger adults.
2. Identify how normal physiologic changes with aging alter pharmacokinetics of drug therapy.
3. Define polypharmacy and its relevance in managing drug therapy in the older adult.
4. Describe why adverse effects of drug therapy may be overlooked in older adults.
5. Identify how the older adult's core patient variables in drug therapy may vary from the younger adult's core patient variables.
6. Relate the interaction of core drug knowledge to core patient variables when providing drug therapy in older adults.
7. Generate a nursing plan of care based on the interactions between core drug knowledge and core patient variables for drug therapy in older adults.
8. Describe nursing interventions to maximize therapeutic and minimize adverse effects in drug therapy in older adults.
9. Determine key points for patient and family education in drug therapy for older adults.

polypharmacy

The **older adult** (or **geriatric patient**) is defined as a person who is 65 years of age or older. This population is divided into three subgroups: the young-old (65 to 74 years), the middle-old (75 to 84 years), and the old-old (85 years and older). Of these, the old-old group is the fastest growing and most medically needy and will generate the greatest consumption of societal resources for the next half century. Older adults comprise about 15% of the U.S. population, and this percentage is rising, but they receive more than one-third of all the drugs that are prescribed (Fulton, 2005; Ballentine, 2008).

Many older adults are independent and in generally good health. They may receive drug therapy for chronic conditions (many of them related to normal aging changes), but their physiologic conditions are well controlled, and they do not consider themselves "sick." However, some older adults are not independent and are in poor or compromised health. These are the **frail elderly,** a term that describes all people older than 65 years who have one or more debilitating conditions. Being frail and elderly places a person at higher risk for developing serious adverse drug effects.

Many physiologic changes occur with normal aging, which is accompanied by a decline in general organ and system function. In general, aging organs and body systems are less responsive than young ones to a drug's effect. Age-related changes affect the patient's response to drug therapy because both the therapeutic and the adverse effects are altered. This state creates specific risks and needs for the older adult receiving drug therapy. To manage drug therapy safely and effectively in the older adult, the nurse must be aware of these changes. The nurse also needs to be aware that many older adults take multiple prescribed and over-the-counter (OTC) drugs. Taking several drugs simultaneously is called **polypharmacy**. Polypharmacy is also considered taking more medications than are clinically indicated. It is not uncommon for older adults to receive 5 or more prescription drugs as well as over-the-counter drugs. Polypharmacy is increasing even though it is known to increase the risk for morbidity and mortality in older adults (Hajjar et al., 2007)

This chapter presents the ways that core drug knowledge and core patient variables may be altered because of age. This chapter also presents general guidelines for maximizing therapeutic effects, minimizing adverse effects, and providing patient and family education for the older adult.

Nursing Management of Older Adults

Core Drug Knowledge

Pharmacotherapeutics

The pharmacotherapeutics of drug therapy for older adults is similar to that for younger adults. Some drug therapies are more frequently used than others in older adults because their therapeutic effects offset the decreased functioning of body organs and systems that occurs with normal aging. Older adults are prone to certain disease processes or pathologic conditions, such as chronic heart failure, chronic renal disease, and hypertension; certain drug therapies used to treat these conditions are used frequently in older adult patients.

Pharmacokinetics

The processes of drug absorption, distribution, metabolism, and excretion may be affected or impaired by the normal physiologic changes of aging. Changes in the gastrointestinal (GI), cardiovascular, and circulatory systems; reduced body mass; and disturbances in liver and kidney function can alter the pharmacokinetics of drug therapy. Box 8.1 identifies these age-related physiologic changes in the older patient. Such changes ultimately affect the extent and duration of systemic availability of a drug and the possibility and probability of adverse drug effects.

ABSORPTION

Although absorption seems to be the least affected pharmacokinetic process during aging, several physiologic changes related to absorption affect drug therapy. In the older adult, increased gastric pH levels, decreased rate of blood flow, decreased GI motility, and reduced body surface area may influence the rate of absorption. However, the degree to which these factors affect absorption is unclear. Disease processes are more likely than age-related changes to alter an older adult's absorption patterns.

With age, the GI tract undergoes several changes that can alter oral drug absorption or affect bioavailability. For example, the stomach's response to food decreases, typified by reduced gastric acidity. Drugs that require an acidic environment to dissolve may take longer to disintegrate and be absorbed by the body; this delay may ultimately decrease systemic availability of a drug.

Circulation problems (e.g., reduced blood flow to organs) and reduced surface area of the GI tract are common in older adults. Drug absorption from the GI tract is highly dependent on both blood flow to the GI tract and the surface area of the GI tract; consequently, the extent or rate of drug absorption may be decreased in older adults. Additionally, decreased blood flow to tissues and muscles can alter the absorption of drugs administered subcutaneously or intramuscularly in older adults. Altered absorption can be further complicated by disease processes, such as peripheral vascular disease. Therefore, an intramuscular (IM) drug injection in the older adult may produce erratic blood concentrations because of changes in tissue perfusion and reduced muscle mass (another common age-related change).

Because GI motility decreases in older adults, substances take longer to move through the GI tract. Because of the extended GI transit time, a drug is in contact with the GI membranes for a longer time; therefore, the extent of drug absorption increases. For many drugs, the effects of increased contact time with the GI membranes are balanced by the effect from the decreased surface area.

The overall effects of aging on the GI tract result in a slowed drug absorption rate yet allow for the extent of drug absorption to be almost as complete as that in younger adults. However, this slowing in the rate of absorption not only results in slower onset of action but also alters the intensity of peak response because peak serum drug concentrations are blunted by the slowed absorption. Such an effect on the rate and extent of drug absorption may or may not have immediate clinical consequences, but the patient may require an increase in drug dosage if therapeutic effects decrease substantially below desired levels.

DISTRIBUTION

Several physiologic factors affect the distribution of a drug in older adults, including decreased body mass, reduced levels of plasma albumin, and a less effective blood–brain barrier. Other age-related factors that may affect drug distribution include declining cardiac output, extreme changes in body weight, poor nutrition, dehydration, inactivity, and extended bed rest.

The body mass of a person decreases with age. In the older adult, the proportion of body fat increases as the percentage of lean muscle mass decreases. Consequently, body water decreases in proportion to the total body weight. The higher proportion of body fat to lean muscle mass and decreased body water can substantially alter the distribution patterns of most drugs, depending on whether they are fat-soluble or water-soluble. In older adults, a highly fat-soluble drug (e.g., diazepam [Valium], an antianxiety drug) exhibits an increased volume of distribution; this increase results in a prolonged distribution phase, a prolonged half-life, and an increased duration of action. The increased volume of distribution for a given drug dose means that concentrations are lower in the blood but higher in the tissues. Therefore, when diazepam is given to older patients, one can anticipate a greater response to the drug and a greater likelihood of adverse effects than in a young adult.

In contrast to fat-soluble drugs, highly water-soluble drugs (e.g., gentamicin, an antibiotic) exhibit a decreased volume of distribution because of the decrease in total body water in the older patient. Even at standard doses, more of these drugs circulate in the blood, making toxic blood levels a potential hazard.

Plasma levels of the protein albumin, which is produced by the liver, also are reduced in the elderly, often by as much as 13%. The reduced plasma albumin level reflects declining metabolic activity in the liver. Plasma albumin is responsible for binding, transporting, and distributing many drugs throughout the body, particularly acid-based drugs. In contrast, amounts of plasma alpha-1-acid glycoproteins, which principally bind and transport alkaline-based drugs, are not depressed in older adults. Hence, the acid or alkaline base of drugs can cause significant alterations in the older patient's response to drugs. In addition, when plasma albumin levels decline in the older adult, fewer binding sites are available for drugs. This scarcity of binding sites results in higher concentrations of unbound forms of a drug, which increases target organ exposure, pharmacologic activity, and the risk of adverse effects. Although higher concentrations of free drug also increase the amount of the drug available for metabolism and renal excretion, normal age-related decreases in liver and kidney function offset any increase in these pharmacokinetic processes. Overall, low plasma protein levels place older adults at increased risk of adverse effects from drug therapy. This risk is especially high when the drug is normally highly protein bound. An example is the anticonvulsant phenytoin (Dilantin), a highly protein-bound drug. Polypharmacy further complicates the effects of decreased albumin levels in older adults. Recall that highly protein-bound drugs compete for protein-binding sites even in younger patients. When fewer sites are available to start with, and several drugs must compete for fewer sites, the drugs may be unable to locate a protein-binding site. Ultimately, the effects of drug therapy increase because more free or unbound drug is available to be active.

Age-related changes in the central nervous system (CNS) can alter drug distribution. Normally, the blood–brain barrier prevents drugs from affecting the brain, but with advancing age, the efficiency of the blood–brain barrier declines. This decline permits higher levels of drug than normal to penetrate the brain.

METABOLISM

The liver's efficiency at metabolizing substances gradually declines throughout the aging process. In the older adult, three major physiologic changes greatly affect the efficiency of the liver. First, the size of the liver changes, and the number of metabolically active hepatocytes may decrease as much as 50%. Most change occurs when adults are in their 60s or 70s. Second, because cardiac output declines with age, blood flow to the liver declines as well. With less blood-borne oxygen

available, the liver's capacity to remove many metabolic byproducts is reduced. Third, the overall ability of the liver to metabolize drugs and other chemicals is reduced.

Normal hepatic metabolism of substances occurs in two major phases. Phase I metabolic reactions include oxidation, reduction, and hydrolysis of drug molecules. During phase I, the liver creates metabolites that may retain some degree of pharmacologic activity. Phase II reactions combine the drug or other metabolites produced in phase I with highly water-soluble forms of acetate, glucuronic acid, sulfate, or an amino acid. These reactions produce an inactive metabolized form of the drug that is excreted in the urine or feces. Ultimately, most phases I and II reactions make drugs more water-soluble, which restricts their access to the tissues, promotes removal from the body, and thereby terminates pharmacologic activity.

Aging affects the efficiency of both phases of metabolic activity but tends to alter phase I more than it alters phase II reactions. Because drug metabolism is slowed by reduced oxidation in phase I, drug blood levels are higher and drug half-lives are extended in older adults. This effect usually alters the appropriate dose and dosing interval and the duration of adverse effects. For example, when elderly adults receive a benzodiazepine (e.g., to relieve anxiety or promote sleep), they may experience associated cognitive impairments, such as sedation, confusion, and decreased mental alertness, for a longer time than normal after drug therapy ceases. Often, standard half-life parameters are inaccurate for the elderly patient. Nurses obtain age-related drug half-life information to evaluate drug responses accurately in older patients. Nurses who are unfamiliar with age-related differences may mistakenly interpret an older patient's altered cognitive function as a normal sign of aging rather than as a residual drug effect.

EXCRETION

Efficient renal function is a crucial factor in ensuring drug clearance from the blood and excretion from the body, and in terminating drug action. Aging can substantially decrease renal efficiency by altering the two main processes by which the kidneys remove drugs from the blood: glomerular filtration and renal tubular secretion. Both of these processes decline in efficiency with age and ultimately result in slower drug excretion and altered drug half-life.

One of the standard markers for renal function is the serum creatinine concentration, which reflects creatinine clearance from the blood by way of glomerular filtration. Despite the decline in the efficiency of glomerular filtration in the older patient, serum creatinine levels often remain in the normal range (Table 8.1). The normal range is maintained because creatinine production declines in the older patient as muscle mass decreases; therefore, less creatinine overall exists in the older adult to be filtered. These so-called normal creatinine levels can be misleading and should not be interpreted as an indication of normal renal function in elderly patients.

17–24	140	0.808
25–34	140	0.808
35–44	133	0.813
45–54	127	0.829
55–64	119	0.837
65–74	109	0.825
75–84	96	0.843

*Ccl_{cr} = (140 – age) (weight)/(72) (serum creatinine)

NOTE: Women also demonstrate a similar decline in Ccl_{cr} with age. Ccl_{cr} for women is about 85% of values in men.

Pharmacodynamics

Decreased organ efficiency in the older adult alters pharmacodynamic responses. Because absorption is prolonged in the older adult, response to single doses of drugs is commonly delayed substantially. For example, the older adult taking aspirin for intermittent joint pain usually experiences a longer onset of action than normal. This delayed onset is not experienced for drugs that the older adult takes on a regular basis because doses taken at regular intervals maintain steady blood levels.

Most drug responses are based on the drug–receptor interaction. A patient's response to a particular drug depends on how efficiently that drug's receptor system operates or on the number of available receptors for that drug. An example of this interrelationship is the elderly patient and the beta-adrenergic receptor system. As a result of aging, the beta-adrenergic receptor system seems to operate less efficiently and possibly with fewer receptors. This decline in efficiency explains why the older adult is typically less responsive to beta-adrenergic agonists (stimulants), such as isoproterenol (Isuprel), a bronchodilator. Age-related changes affect the parasympathetic muscarinic-receptor system as well. Generally, the older adult has an increased response to anticholinergic drugs, such as atropine, and to the anticholinergic effects of drugs such as tricyclic antidepressants.

Decreases in the number of receptors are also associated with decreases in the respective neurotransmitters themselves. Older patients, for example, have decreased amounts of the neurotransmitters dopamine and acetylcholine.

Contraindications and Precautions

Although drug contraindications are generally similar for older adults and younger adults, some drugs carry label warnings specific to older adults. Some diseases or conditions that may contraindicate certain drug therapies are more likely to occur in older adults. Moreover, because of the older adult's decreased renal function and possibly metabolic function, many drugs should be used with caution. Some drugs or drug classes cause substantially more adverse effects in older adults than in other age

populations. These drugs are generally considered inappropriate for older adults; however, with proper clinical management, monitoring, and dose limitations, these drugs may be used if necessary.

The Beers Criteria are an evidenced based, standard tool for the identification of potentially inappropriate medications in older adults. Originally formulated in 1997, this reference was updated in 2003. Based on a thorough review of the literature, questionnaires sent to practitioners, and review of an expert panel, it lists 48 medications or classes of medications that should generally be avoided in older adults. These drugs either are ineffective or pose unnecessary higher risks for older adults, and safer alternatives are available. See Table 8.2 for the updated Beers Criteria. The criteria also name 20 diseases or conditions in which specific medications should be avoided (Fick et al., 2003).

Use of inappropriate drugs may be a substantial problem in the current health care system. Small studies have found that between 32% and more than 50% of community-dwelling adults received at least one inappropriate prescribed drug (Gallagher et al., 2008; Rossi et al., 2007), and a large retrospective study of nearly 18,000 people found that 40% of the community-dwelling older adults had filled prescriptions for at least one inappropriate drug and 13% had filled two or more inappropriate prescriptions. Furthermore, those who received an inappropriate drug were significantly more likely to experience an adverse effect than those who received only appropriate drugs (14% versus 4.7%, $p<0.001$) (Fick et al., 2008). Polypharmacy (5 or more drugs) increased the risk for receiving an inappropriate drug Research has found that between 30% and 50% of patients receiving an inappropriate drug came to the emergency room and/or became hospitalized (Nixdorff et al., 2008). And a recent study of hospital prescribing showed that almost half of older adults were prescribed at least one potentially inappropriate drug; 6% received three or more potentially inappropriate drugs. These drugs are more likely to be prescribed to patients with myocardial infarction or heart failure, and to men rather than women. Cardiologists were much more likely than geriatricians or hospitalists to prescribe a potentially inappropriate drug that could produce severe adverse effects (Rothberg et al., 2008). Some small research studies argue that while the Beers' criteria of potentially inappropriate drugs is one important factor contributing to adverse effects, emergency room visits, and hospitalization for older adults in the community, it may not be the best single predictor of adverse drug effects that occur in a hospital setting; rather, polypharmacy upon admission is the best predictor (Page & Ruscin, 2006; O'Mahony & Gallagher, 2008). Larger clinical research studies are needed to clarify the best practice for minimizing adverse drug effects for hospitalized older adults.

The nurse needs to work closely with physicians, nurse practitioners, and pharmacists to minimize the use of drugs that are generally contraindicated in older adults, by seeking safer alternative drug therapy as well as minimizing unnecessary polypharmacy.

At the same time, the nurse must realize that there will be occasions when an "inappropriate" drug will be used because it is the best therapy to treat the older adult. During these occasions, the nurse will need to work closely with the rest of the health care team, the patient, and the family in providing clinical care to minimize potential adverse outcomes to the patient.

Adverse Effects

Although the same adverse effects from any given drug therapy will occur in older adults as in other age groups, physiologic changes in older adults place them at greater risk for certain adverse effects. Adverse drug effects are an important cause of hospital admissions in older adults. Adverse drug effects are also a serious concern for older adults who receive medication in ambulatory care settings.

Because of the less effective blood–brain barrier, older adults may be more vulnerable to CNS adverse effects, such as increased depressant or sedative activity of drugs. Research also indicates that CNS drugs decrease cognitive functioning of older adults (Box 8.2). In addition, decreased dopamine concentrations in the brain of older adults render them more susceptible to parkinsonian effects of dopamine antagonists, such as the phenothiazine antipsychotics and metoclopramide. Older adults are also more responsive to anticholinergic drugs and drugs with anticholinergic adverse effects (see Chapter 14).

Depending on the severity of these adverse responses, drug dosages may be limited or contraindicated for a particular patient.

Drug-induced behavioral changes often affect the older adult. Sometimes, they occur unexpectedly. For example, when beginning drug therapy with a sedative or a benzodiazepine to treat anxiety, the older patient may experience an effect that is the opposite of the intended effect. This effect is known as **paradoxical excitement,** whereby the patient is wide awake and hyperactive rather than calm and relaxed.

Determining whether an older patient is experiencing an adverse effect or a normal age-related health problem is difficult. Age-related health problems often mimic the adverse effects of drug therapy. For example, hearing loss can be a sign of aging, or it can be a serious adverse effect of some antimicrobial drugs (e.g., gentamicin). Loss of balance and unsteadiness while walking are often experienced by older patients and may be confused with the adverse effects of some drugs that cause dizziness or light-headedness. Clearly, the nurse needs to distinguish between these two conditions.

Drug Interactions

Drug interactions are the same for older adults as for other populations, but because older adults tend to take more drugs, they are at higher risk for interactions. It is

TABLE 8.2 Revised Beers Criteria for Potentially Inappropriate Medication Use in Older Adults: Independent of Diagnoses or Conditions

Drug Class and Specific Agent	Concern	Severity Rating (High or Low)
Analgesics and Anti-inflammatories		
propoxyphene (Darvon) and combination products (Darvon with ASA, Darvon-N, and Darvocet-N)	Drug that offers few analgesic advantages over acetaminophen, yet has the adverse effects of other narcotics.	Low
indomethacin (Indocin and Indocin SR)	Of all available NSAIDs, this drug produces the most CNS adverse effects.	High
pentazocine (Talwin)	Narcotic analgesic that causes more CNS adverse effects, including confusion and hallucinations, more commonly than other narcotic drugs. Additionally, it is a mixed agonist and antagonist.	High
meperidine (Demerol)	This drug is not an effective oral analgesic in doses commonly used. It may cause confusion and has many disadvantages compared to other narcotic drugs.	High
ketorolac (Toradol)	Immediate and long-term use should be avoided in older people, because a significant number have asymptomatic GI pathologic conditions.	High
Long-term use of full-dosage, longer half-life, non-COX- selective NSAIDs: naproxen (Naprosyn, Avaprox, and Aleve), oxaprozin (Daypro), and piroxicam (Feldene)	These have the potential to produce GI bleeding, renal failure, high blood pressure, and heart failure.	High
Antiemetics		
trimethobenzamide (Tigan)	One of the least effective antiemetic drugs, yet it can cause extrapyramidal adverse effects.	High
Muscle Relaxants and Antispasmodics		
methocarbamol (Robaxin), carisoprodol (Soma), chlorzoxazone (Paraflex), metaxalone (Skelaxin), cyclobenzaprine (Flexeril), and oxybutynin (Ditropan) (Do not consider the extended-release Ditropan XL.)	Most muscle relaxants and antispasmodic drugs are poorly tolerated by elderly patients, because they cause anticholinergic adverse effects, sedation, and weakness. Additionally, their effectiveness at doses tolerated by elderly patients is questionable.	High
orphenadrine (Norflex)	This drug causes more sedation and anticholinergic adverse effects than safer alternatives.	High
Benzodiazepines (used for sleep, anxiety, seizures)		
flurazepam (Dalmane) [sleep]	This hypnotic has an extremely long half-life in elderly patients (often days), producing prolonged sedation and increasing the incidence of falls and fractures. Medium- or short-acting benzodiazepines are preferable.	High
Doses of short-acting benzodiazepines: doses greater than lorazepam (Ativan), 3 mg; oxazepam (Serax), 60 mg; alprazolam (Xanax), 2 mg; temazepam (Restoril), 15 mg; and triazolam (Halcion), 0.25 mg	Because of increased sensitivity to benzodiazepines in elderly patients, smaller doses may be effective as well as safer. Total daily doses should rarely exceed the suggested maximums.	High
Long-acting benzodiazepines: chlordiazepoxide (Librium), chlordiazepoxide-amitriptyline (Limbitrol), chlordiazepoxide-clidinium (Librax), diazepam (Valium), quazepam (Doral), halazepam (Paxipam), and clorazepate (Tranxene)	These drugs have a long half-life in elderly patients (often several days), producing prolonged sedation and increasing the risk of falls and fractures. Short- and intermediate-acting benzodiazepines are preferred if a benzodiazepine is required.	High
Antidepressants		
amitriptyline (Elavil), chlordiazepoxide-amitriptyline (Limbitrol), and amitriptyline-perphenazine (Triavil)	Because of its strong anticholinergic and sedation properties, amitriptyline is rarely the antidepressant of choice for elderly patients.	High
doxepin (Sinequan)	Because of its strong anticholinergic and sedating properties, doxepin is rarely the antidepressant of choice for elderly patients.	High
Daily fluoxetine (Prozac)	This drug has a long half-life, which increases the risk of excessive CNS stimulation, sleep disturbances, and increasing agitation. Safer alternatives exist.	High

TABLE 8.2 Revised Beers Criteria for Potentially Inappropriate Medication Use in Older Adults: Independent of Diagnoses or Conditions *(continued)*

Drug Class and Specific Agent	Concern	Severity Rating (High or Low)
Antianxiety (other than benzodiazepines)		
meprobamate (Miltown and Equanil)	This is a highly addictive and sedating anxiolytic. People using meprobamate for prolonged periods may become addicted and may need to be withdrawn slowly.	High
Antipsychotics		
thioridazine (Mellaril)	This drug has a greater potential for CNS and extrapyramidal adverse effects.	High
mesoridazine (Serentil)	This drug has CNS and extrapyramidal adverse effects.	High
Sedatives (non-benzodiazepine)		
All barbiturates (except phenobarbital) except when used to control seizures	When used in this way, these drugs are highly addictive and cause more adverse effects than most sedative or hypnotic drugs in elderly patients.	High
Other Psychotropic Drugs		
ergot mesyloids (Hydergine)	These agents have not been shown to be effective in the doses studied.	Low
Antiarrhythmics		
disopyramide (Norpace and Norpace CR)	Of all antiarrhythmic drugs, this is the most potent negative inotrope and therefore may induce heart failure in elderly patients. It is also strongly anticholinergic. Other antiarrhythmic drugs should be used.	High
digoxin (Lanoxin) (should not exceed 0.125 mg/d except when treating atrial arrhythmias)	Decreased renal clearance may lead to increased risk of toxic effects.	Low
amiodarone (Cordarone)	This drug is associated with QT interval problems and a risk of provoking torsades de pointes. It has a lack of efficacy in older adults.	High
Other Cardiovascular Drugs		
cyclandelate (Cyclospasmol)	This drug has not been shown to be effective in the doses studied.	Low
isoxsupine (Vasodilan)	This drug is ineffective.	Low
Anticoagulants/Antiplatelets		
Short-acting dipyridamole (Persantine). Do not consider the long-acting form (which has better properties than the short-acting form in older adults), except for patients with artificial heart valves.	This drug may cause orthostatic hypotension.	Low
ticlopidine (Ticlid)	This drug has been shown to be no better than aspirin in preventing clotting and may be considerably more toxic. Safer, more effective alternatives exist.	High
Antihypertensives		
methyldopa (Aldomet) and methyldopa-hydrochlorothiazide (Aldoril)	These drugs can cause bradycardia and can exacerbate depression in elderly patients.	High
reserpine at doses >0.25 mg	This drug can induce depression, impotence, sedation, and orthostatic hypotension.	Low
guanethidine (Ismelin)	This drug causes orthostatic hypotension. Safer alternatives exist.	High
guanadrel (Hylorel)	This drug causes orthostatic hypotension.	High
doxazosin (Cardura)	This drug may cause hypotension, dry mouth, and urinary problems.	Low
Short-acting nifedipine (Procardia and Adalat)	This drug may cause hypotension and constipation.	High
clonidine (Catapres)	This drug may cause orthostatic hypotension and CNS adverse effects.	Low
Antidiabetic		
chlorpropamide (Diabinese)	It has a prolonged half-life in elderly patients and could cause prolonged hypoglycemia. Additionally, it is the only oral hypoglycemic agent that causes syndrome of inappropriate antidiuretic hormone (SIADH) secretion.	High

Drug Class and Specific Agent	Concern	Severity Rating (High or Low)
Gastrointestinal Drugs		
GI antispasmodic drugs: dicyclomine (Bentyl), hyoscyamine (Levsin and Levsinex), propantheline (Pro-Banthine), belladonna alkaloids (Donnatal and others), and clidinium-chlordiazepoxide (Librax)	GI antispasmodic drugs are highly anticholinergic and have uncertain effectiveness. These drugs should be avoided (especially for long-term use).	High
Long-term use of stimulant laxatives: bisacodyl (Dulcolax), cascara sagrada, and Neoloid except in the presence of opiate analgesic use	These drugs may exacerbate bowel dysfunction.	High
Mineral oil	This agent has the potential for aspiration and adverse effects. Safer alternatives are available.	High
cimetidine (Tagamet)	This drug has CNS adverse effects, including confusion.	Low
Anticholinergics and Antihistamines		
chlorpheniramine (Chlor-Trimeton), diphenhydramine (Benadryl), hydroxyzine (Vistaril and Atarax), cyproheptadine (Periactin), promethazine (Phenergan), tripelennamine, dexchlorpheniramine (Polaramine)	All nonprescription and many prescription antihistamines may have potent anticholinergic properties. Non-anticholinergic antihistamines are preferred in elderly patients when treating allergic reactions.	High
Diphenhydramine (Benadryl)	This drug may cause confusion and sedation. It should not be used as a hypnotic, and when used to treat emergency allergic reactions, it should be used in the smallest possible dose.	High
Amphetamines and Anorexics		
	These drugs have potential for causing dependence, hypertension, angina, and myocardial infarction.	High
Anti-infectives		
nitrofurantoin (Macrodantin)	This drug has the potential to cause renal impairment. Safer alternatives are available.	High
Vitamins, Minerals, Electrolytes		
ferrous sulfate (>325 mg/d)	Doses >325 mg/d do not dramatically increase the amount absorbed but greatly increase the incidence of constipation.	Low
Hormones		
methyltestosterone (Android, Virilon, and Testred)	This drug is associated with the potential for prostatic hypertrophy and cardiac problems.	High
desiccated thyroid	There are concerns about cardiac effects from this hormone preparation. Safer alternatives are available.	High
estrogens only (oral)	There is evidence of the carcinogenic (breast and endometrial cancer) potential of these agents and lack of cardioprotective effect in older women.	Low
Diuretics		
ethacrynic acid (Edecrin)	This agent may cause hypertension and fluid imbalances. Safer alternatives are available.	Low

BOX 8.2 FOCUS ON RESEARCH

Inappropriate Drugs in Older Adults and Cognitive Decline

Wright, R. M., Roumani, Y. F., Boudreau, R., et al. (2009). Effect of central nervous system medication use on decline in cognition in dommunity-dwelling older adults: findings form the Heatlh, Aging, And Body Composition Study. *Journal of the American Geriatric Society, 57*(2): 243–250.

The Study

The Health, Aging and Body Composition Study, begun in 1996, examined how age-related changes in weight and body composition (e.g., amount of muscle present in the body) influenced health. Two thousand seven hundred thirty-seven healthy older adults were enrolled in the study sponsored by the National Institutes of Health. The study was a longitudinal cohort study set in Pittsburgh, Pennsylvania and Memphis, Tennessee. This aspect of the study evaluated whether combined use of multiple central nervous system (CNS) medications over time was associated with cognitive changes. The subjects had normal cognitive level at the start of the study as measured by the Modified Mini-Mental State Examination (referred to as 3MS); their scores were 80 or better out of a possible 100. Use of a CNS medication (benzodiazepine, opioid, antipsychotics, or antidepressants), the duration of use, and the dose were determined at baseline, (year one) and years three and five. The 3MS was administered at each of those times. By year five, more than one-fourth of them demonstrated cognitive decline and CNS use increased from 13.9% at baseline to 15.3% and 17.1% at years three and five. Combination use of more than one CNS drug and a higher dose of the drug were associated with more cognitive decline in the older adults studied.

Nursing Implications

This research highlights the risks to older adults when potentially inappropriate drugs are given to them. CNS drugs such as the ones monitored are included in the potentially inappropriate medication list in the Beer's Criteria. However, the Beer's Criteria does not list cognitive decline from these drugs, so these findings add to the potential concerns related to using these drugs in older adults. Adverse effects from drug therapy cause substantial morbidity and mortality in older adults. Although many adverse effects cannot be prevented, nurses should be vigilant to help protect patients from those that *are* preventable. Nurses should question any medication order in which an inappropriate drug appears to have been ordered for the patient. If patients require a drug that is on the Beer's list, especially a CNS drug, the dose should be kept as low as possible and the duration of use should be as short as possible to minimize adverse effects. Patients who demonstrate a cognitive decline should have their drug therapy carefully evaluated. It should not be assumed that changes in cognitive function are related to aging, as it may be a drug-related effect.

not uncommon for older adults to be taking between 8 and 12 prescribed and OTC drugs to treat a variety of diseases. Often, the combination of so many different drugs causes serious drug interactions. For example, a patient who is taking a total of 10 different prescriptions and OTC drugs risks 45 different two-drug combinations that could interact to produce an adverse effect. Drug interactions can decrease the effectiveness of one or both of the drugs or increase the risk of adverse effects. Drug interactions are common in older adults.

Assessment of Relevant Core Patient Variables Related to Older Adults

Health Status

Aging is associated with a decline in normal bodily maintenance and function. The major organ systems (cardiovascular, respiratory, GI, genitourinary, endocrine, and others) all become much less efficient with advancing age and cause a multitude of health problems that often require drug therapy. When assessing the older patient's health status, assess for polypharmacy, which has the potential for causing serious drug interactions and adverse effects. The compromised health status of the older adult can further alter the pharmacokinetics of certain drugs and is of equal concern. In such cases, assess the functional ability of the older adult's body systems and determine whether the patient has any diseases that may affect prescribed drug therapy. Pay particular attention to cardiovascular, hepatic, and renal problems, because these problems can greatly alter the patient's responses to drug therapy.

When assessing the older patient's renal function status, remember that normal laboratory value ranges may be deceptive. As discussed, the older patient with compromised renal function may have serum creatinine levels or blood urea nitrogen (BUN) levels in the normal range. Hence, normal serum creatinine or BUN levels are not a true indicator of the older patient's renal status.

Assessment should always include a thorough inventory of all the drugs the patient is currently taking, dosage, and dosing schedule. This inventory helps alert the nurse to any possible drug interactions. The nurse also should confirm that the medications the patient is taking matches the prescribed therapy listed in the health care record. This assessment should occur at every visit, in all health care settings, and every time the patient transitions from one setting to another (e.g., from intensive care to a general unit, from hospitalization to discharge home, or to a long-term care facility). This type of assessment is termed **medication reconciliation**. It may be done via a list of drugs or via direct observation by having the patient present all of their medications to the nurse. Determine if the patient can identify

CRITICAL THINKING SCENARIO

THINKING ABOUT AGE-RELATED CORE PATIENT VARIABLES

Antonio Mendez, a 70-year-old man with type 1 diabetes mellitus, has been admitted to your unit for the second time in a month with diabetic ketoacidosis. His blood glucose level on admission is elevated, at 600 mg/dL. The prescriber writes an order for 15 U of NPH insulin mixed with 5 U of regular insulin every morning. As the patient's nurse, you are assessing why this patient continues to have elevated blood glucose levels. What relevant core patient variables should you investigate with this patient?

each drug and its purpose. Older adults frequently identify their pills by appearance rather than name. Use of generic drugs may confuse older adults as these drugs do not have the distinctive shape and colors found in trade name drugs (Ballentine, 2008). Gaps in the knowledge of older adult patients indicate that teaching about drug therapy is needed.

In addition, assess whether the older adult patient is taking the medication as prescribed. When taking a drug at home, older adults may take the medication more often than indicated or less often than indicated. This is termed **nonadherence**. Nonadherence with therapy is not usually related to a patient's refusal to take the drug therapy as prescribed, but usually is associated with a variety of other reasons. Medication adherence rates can be as low as 50% for chronic conditions (Bazian Report, 2005; Roehl et al., 2006). This is because there are a high number of daily prescribed medications required, making the regimen confusing as well as expensive. Adherence is therefore difficult in patients who have difficulty remembering to take all of their different drugs, or who may have difficulty remembering which drug to take for which health problem at what time. Another reason for nonadherence or poor adherence when there is polypharmacy is if patients do not feel they can afford a medication. Other reasons for nonadherence include physical deficits that prevent accurate self administration (e.g., poor eyesight, or decreased fine motor ability to open pill bottles), anticipation of or actually experiencing adverse effects, and a general lack of understanding of the rationale for drug therapy. If a generic drug is prescribed by one prescriber and the identical trade name drug by another prescriber, the older adult may take both if they are unaware that they are the same drug. If a patient does not have the physical ability to travel to a pharmacy, he or she may not be able to obtain a filled prescription. All of these reasons can contribute to nonadherence. Information from the assessment indicates what information the nurse needs to emphasize in patient education.

Ask the older adult patient about all OTC drugs, because many patients do not consider these medicines "drugs" and may not mention them unless specifically asked. For example, many older adults take laxatives to relieve constipation, a common problem associated with age-related slowing of GI motility. Most older patients are unaware that laxatives can interact with and complicate prescribed drug therapy by decreasing absorption of some drugs. Unless specifically asked about laxative use, the patient may not volunteer the information.

Lifestyle, Diet, and Habits

Because lifestyle, diet, and habits of the older adult affect the pharmacokinetics and pharmacodynamics of drug therapy, assess several basic areas of daily living, such as how active the patient is and what his or her daily routine includes. Moderate, regular exercise promotes circulation, absorption of drugs given intramuscularly or subcutaneously, and distribution of drugs through the GI tract.

Dietary patterns and habits are also important. If older adults have difficulty swallowing solid food and eat only soft or chopped foods, they may need to have oral drugs (such as pills or tablets) crushed and mixed with a diluent for swallowing or have the drugs prescribed in a liquid form.

The use of alternative medications, such as herbs and botanicals, has increased with older adults as it has with the general population. Almost 13% of older adults use herbal products such as glucosamine, echinacea, or garlic, yet half do not report this use (Roehl et al., 2006; Bruno & Ellis, 2005). Because older adults tend to take more prescribed medications than other age groups, they are at higher risk for drug interactions if they take alternative medications. Ask the older patient if he or she takes any alternative medications and then document the findings. Documentation is important to help all health care providers identify any potential drug–herb interactions.

Another important assessment is how drug therapy and the related adverse effects have altered the older adult's lifestyle or impaired the quality of life. How have the activities of daily living been impaired? How have adverse effects interfered with the patient's involvement in community or family events? Some drugs place the older adult at risk for injury and therefore can greatly limit the quality of life. For example, drugs that cause dizziness or light-headedness when standing put the older patient at great risk for falls and broken bones. Drugs that cause postural hypotension, such as many antihypertensives, have been associated with falls and hip fractures.

The mental status of older patients is extremely important to their quality of life. Many older patients are depressed because they are lonely or have limited ability to function and participate in life's enjoyments. Sometimes, drug therapy can further decrease the older patient's quality of life because of adverse drug effects. Depression, delirium, dementia, and low self-esteem are commonly cited adverse effects of drug therapy.

Habits regarding drug therapy should be considered when planning drug administration in the hospital. Assess whether the older adult patient has a preferred schedule for taking drug therapy at home, because it may be more therapeutic to maintain the patient's established routine and dosage schedule than to readjust them to fit hospital routines. Maintaining the same drug schedule not only promotes similar drug actions and reactions but also helps reduce stress and anxiety in older patients who may have difficulty adjusting to changes in routine.

Because older adults typically have fixed incomes, question patients to determine whether their health insurance includes payment or partial payment for drug therapy. Coverage may influence whether the older patient can afford the prescribed drug therapy. As mentioned, many older patients take several drugs for various health problems, and drug therapy may be extremely costly; therefore, patients may not be taking the drugs as prescribed because they do

not feel they can afford them. Confirm that patients are able to afford needed medications. If the patient does not have adequate financial resources or does not have health insurance with a prescription benefit, help the patient gain access to reduced-price medications. Pharmaceutical companies have programs that provide assistance to those with very low incomes, and government assistance programs are also available. It may be necessary to work with social workers to meet this patient need.

Environment

Assessing the older patient's environment is another important element when considering drug therapy. Determine whether the patient lives alone or with other family members or caregivers who can help obtain and administer drug therapy if needed. Other considerations are as follows:

- Is the pharmacy accessible to the older adult?
- Can the patient drive or take a bus to the pharmacy, or is someone available to go for him or her?
- Does the pharmacy make deliveries?

If ready access is not available, it may be necessary to make referrals to other sources for drug therapy, such as mail-order pharmacies.

Culture and Inherited Traits

Whenever assessing older adults, be sensitive to beliefs and cultural values that may have an effect on drug therapy. Some ethnic or cultural groups still practice folk medicine, preferring home remedies or herbal treatments to traditional drug therapy. These patients may be skeptical or afraid of new or unfamiliar methods of drug therapy. Moreover, they may not understand the drug regimen. Among cultural groups that may practice folk medicine are Eastern Europeans, Hispanic Americans, Native Americans, Asians, some African Americans, and some patients from remote or rural areas of the United States, such as Appalachia, the Ozark Mountains, or Alaska. Additionally, the number of some of the cytochrome P-450 isoenzymes, needed for drug metabolism, may vary based on genetic inherited traits that are not transmitted along race or ethnic lines. This may place some older adults at increased risk for adverse effects from some medications.

Nursing Diagnoses and Outcomes

Nursing diagnoses specific to drug therapy in older adults are similar to those for patients in other age groups. However, because of age-related health problems of older patients, decreased organ functioning, and polypharmacy, some diagnoses more commonly apply. They include the following:

- Risk for Injury related to adverse effects of drug therapy stemming from polypharmacy, inappropriate prescribing, or drug interactions secondary to increased therapeutic effect, delayed elimination, and prolonged drug half-life from altered pharmacokinetics.

Desired outcome: *The older adult patient will not sustain an injury while on drug therapy.*

- Ineffective Therapeutic Regimen Management because of impaired memory, lack of financial resources, impaired physical abilities, complex drug regimen, inability to physically obtain prescribed drugs, or lack of understanding of drug regimen.

Desired outcome: *The patient will effectively manage the therapeutic regimen with the help of appropriate resources.*

Planning and Intervention

Maximizing Therapeutic Effects

For any drug therapy to be therapeutic, the appropriate dose must be taken at the appropriate times. The more complicated the overall therapeutic regimen, the greater the likelihood of poor adherence to the drug therapy. Remember, nonadherence does not always mean that the patient directly refuses to follow the recommended drug therapy schedule. It may indicate that the patient cannot adhere to the prescribed drug course for various reasons. It is necessary to determine the true cause of nonadherence in order to make an appropriate plan of care.

Nurses and prescribers can improve adherence by making drug regimens as easy to follow and as uncomplicated as possible. For example, some drugs are available in sustained-release forms that can be taken once or twice a day, rather than four or more times a day. Some combination drug forms are available that incorporate two drugs, allowing the patient to take only one preparation instead of two. Consult the health care provider for appropriate orders if such options are available for the patient's specific drug therapy.

When new drug therapy begins, plan a new drug schedule to coincide with other prescribed schedules whenever possible. If the patient already takes a drug three times a day with meals, and the new drug must be taken once a day, the patient should take the new drug with breakfast when other drugs are taken. In this way, the patient need not remember another time to take a drug. This kind of planning promotes therapeutic adherence.

After simplifying drug therapy as much as possible, verify that the patient can remember to take the drug. If an older adult patient is having trouble remembering which drug should be taken at which time, assist the patient by creating memory aids. Pill boxes are available with compartments labeled by the hours of the day or by meal times (B, L, D), as are pill boxes labeled with days of the week. The patient places each drug in its appropriate slot at the beginning of the day and can then easily check whether each dose was taken on schedule. An inexpensive adaptation of the commercial pill box is an egg carton with hand-labeled hours of the day on each egg compartment.

When recommending types of drug preparations for each patient, consider which form can be self-administered easily. A chewable tablet or a liquid may be easier to take if the patient has difficulty swallowing pills. If a choice of dosage

forms is possible, consult the prescriber about selecting the form that is most easily used. To improve the ability to self-administer drug therapy correctly, advise the patient of options that can be requested from the dispensing pharmacy. For example, containers with easy-to-remove, non-childproof caps and large-print labels promote therapeutic adherence for patients with arthritis or vision impairments. Also, verify that the patient can obtain prescriptions and refills from the pharmacy independently or has the necessary assistance.

Older adults must be monitored diligently for initial and continuing therapeutic drug effects. To detect improvements or deterioration in the patient's condition, perform periodic comparative assessments of current and previous status and identify changes in therapeutic effectiveness that may necessitate a dosage adjustment.

Patients cannot benefit from drug therapy if they do not receive the proper prescribed drug therapy. As medication regimens become more complex, it is likely that the patient's medical record may not accurately reflect the current drug therapy that the patient is receiving. Medications that have been newly added may be missing, or medications that were discontinued may still appear. Inaccurate drug names, doses, routes, or frequency of administration may also be present. Every time patients change the environment where they receive drug therapy, an error can occur. This is true whether a patient is transferring from one hospital inpatient unit to another, is being admitted to or discharged from the hospital to home or an extended-care facility, or is being seen at an outpatient clinic or office where drug therapy is prescribed and then will return home. The nurse at each point of care should be responsible for medication reconciliation. Although electronic records are generally considered to be more reliable than paper records, research has found that electronic records are not 100% accurate either (Kaboli et al., 2004), so medication reconciliation is still indicated. (For more information on medication reconciliation, see Chapter 11.)

Minimizing Adverse Effects

Some older adults are more at risk of medication-related problems. Those most at risk include: those over age 85, those who take 1 or more medications or more than 12 doses of a medication per day, or those who have at least 6 active chronic medical diagnoses, especially renal impairment (Roehl et al., 2006), as chronic conditions change the pharmacokinetics of drug therapy and chronic conditions frequently require 3 or more drugs for treatment. Whenever possible, alternatives to drug therapy should be considered as the initial treatment for problems. For example, if the older adult complains of difficulty sleeping, encouraging some mild exercise during the day (e.g., walking) or suggesting minor dietary changes (e.g., avoiding large meals near bedtime) may be enough to promote sleep. Sedatives and other drug therapy should be used only if absolutely necessary, and then in low doses (see Table 8.2). Reducing the number of prescribed medications decreases the risk of adverse drug effects and drug interactions.

Drugs should be used with great caution in older adults because these patients exhibit a narrower **benefit: risk ratio** than younger adults. A benefit: risk ratio is the margin between desired therapeutic effects and adverse consequences of drug therapy. Obviously, the beneficial therapeutic outcomes must be considered in relation to the associated physical risk factors.

Because the renal and metabolic systems of most older adults do not function as efficiently as those of younger patients in metabolizing and eliminating drugs from the body, older adults are at increased risk for drug overdose or toxicity. Because of diminished renal function in older patients, closely monitor for signs and symptoms of possible drug toxicity when the patient is taking drugs (e.g., digoxin, a drug that slows the heart rate) that do not undergo significant metabolism. When potentially nephrotoxic drugs (e.g., gentamicin, certain cephalosporin antibiotics, and nonsteroidal anti-inflammatory drugs) are used, be particularly careful because the older adult is especially prone to rapid onset of action and severe nephrotoxicity. Monitor serum blood levels to detect whether toxic drug levels are developing.

Additionally, distinguish carefully between the normal signs and symptoms of aging and the onset of adverse effects from drug therapy. Some adverse effects—impaired cognition or memory, or alterations in mood—mimic signs of aging. For example, the patient who falls repeatedly may be experiencing drug-induced light-headedness or drowsiness from benzodiazepines, used to treat anxiety or as sleep aids. Those with difficulty communicating may be experiencing aphasia as a result of antipsychotic drug therapy. Refer to a computerized drug data base or consult with the pharmacist for assistance in determining whether behaviors or symptoms exhibited by the older adult stem from adverse drug reactions or drug interactions.

Many older patients demonstrate atypical adverse effects that mimic signs of aging and paradoxical effects. If drug-induced symptoms are misinterpreted by the nurse, proper interventions may be neglected, and the older adult may unnecessarily suffer long-term effects. Unless the nurse knows the patient's history, health status, and potential adverse effects of the drugs the patient is taking, he or she will not be able to distinguish between drug-induced symptoms or excessive therapeutic effect and age-related problems.

Obtain a current drug profile and an accurate history of the patient's usual abilities and changes in abilities or health status. By establishing this baseline information, it is possible for the nurse to be alert to any new signs and symptoms in the patient that could be drug related. Ask older adults if they believe they are having adverse effects from drug therapy because they are frequently correct in recognizing such effects. If the older adult patient has any communication impairments, talk with family members or others who know the older adult patient well to determine the patient's baseline behaviors.

BOX 8.3 COMMUNITY BASED CONCERNS

Identification and Management of Polypharmacy Problems

- Question the patient about any and all drug therapy that he or she is taking or has taken in the past. Remember to ask about any non-prescribed, over-the-counter (OTC) preparations.
- Ask to see the drug bottles to verify the physician's or nurse practitioner's orders and evaluate the patient's knowledge about the drugs. Frequently, patients will pull out plastic bags or boxes full of drugs.
- Read the labels carefully. Attempt to identify drugs unknown to the patient or unclear prescriptions. If the prescriptions have changed frequently, or the patient has a long history of chronic health problems, the drug labels may be worn, faded, or difficult to read.
- Determine which drug prescriptions and OTC preparations are for current use. Some patients keep drugs for problems they no longer have. Due to expense, patients may not want to dispose of these; if you cannot get rid of them, then at least separate them from drugs currently in use.
- Determine if there are any duplications of a prescription. Many times patients see more than one physician or nurse practitioner, who may each prescribe the same medication. The patient may not realize this, especially if one of the prescriptions is listed with a generic name and another with a trade name.
- Determine whether therapy can be simplified. Consult with the physician or nurse practitioner as indicated.
- Look up all drugs to determine if any drug interactions are possible between the drugs currently being used. Consult with the physician or nurse practitioner as indicated.
- Assess the patient and family carefully for changes that have occurred since drug therapy began. The onset of new problems may actually be adverse effects from a medication.
- Assist the patient in creating a time schedule to take all prescribed drugs appropriately but in accordance with the patient's lifestyle. Use memory aids as needed.

In addition, become familiar with the core drug knowledge regarding possible adverse effects and drug interactions of the patient's specific drug therapy. Monitor the older patient carefully for development of adverse effects caused by physiologic changes or polypharmacy. If the older adult shows any signs of adverse effects, seek appropriate changes in the drug therapy. Box 8.3 discusses the identification and management of polypharmacy problems.

Help devise a drug schedule that minimizes the risks of adverse effects. For example, if the patient is to take a drug that causes sedation, the dose may be given at bedtime, if possible, to avoid daytime drowsiness and to lessen the risk of falling. In general, the prescriber may start the older adult's therapy with a low dose and increase the dose gradually as needed to reach a therapeutic level. Once the desired therapeutic effects occur, the dosage can be stabilized at that level. Using the minimal therapeutic dosage minimizes the risk for adverse effects.

Providing Patient and Family Education

Educate patients about drug therapy in various ways. Written instructions regarding drug use and times of administration may be developed and emphasized to help prevent confusion. This education is especially important when patients are receiving several drugs.

Also, teach patients and families about expected or possible adverse effects and how to differentiate between them and normal signs of aging. Help patients understand which adverse effects should be reported immediately to the health care provider or nurse practitioner. In addition, teach patients and families methods to assist with accurate dosage and administration of drugs. Because the post-hospital regimen of drug therapy may be complex for the older adult, efforts should be made to determine as early as possible which drugs will be prescribed for home use to allow adequate time for thorough patient and family education about the drug therapy.

Ongoing Assessment and Evaluation

Because the physiologic changes associated with aging often greatly alter the pharmacologic properties of drug therapy, assess the older patient continually for therapeutic and adverse effects of drug therapy. In many situations, also assess the home environment and family support to determine the older patient's ability to adhere to drug therapy. Consistent and regular monitoring of the older patient is extremely important because of polypharmacy, which is common in older patients and puts them at high risk for drug interactions, decreased therapeutic effects, and nonadherence. Drug therapy is effective in the older adult when therapeutic effects are achieved without serious adverse effects that diminish quality of life.

CHAPTER SUMMARY

- Older adults share common age-related changes and risk factors that alter drug administration, dosage, and expected response to drug therapy.
- Aging alters all of the pharmacokinetic processes, placing older adults at increased risk for adverse drug effects.
- Serum creatinine levels often remain in the normal range despite impaired kidney function.
- Pharmacodynamics of drug therapy may be decreased in older adults because of changes in the receptor systems. Older adults also have decreased amounts of the neurotransmitters dopamine and acetylcholine.
- Some drugs or drug classes produce more adverse effects in the older adult, partly related to decreased organ functioning. Dose modifications and close clinical monitoring are necessary if these drugs must be used in older adults.
- Many signs and symptoms of health problems in older adults result from the normal aging-related decline in organ or system function. These symptoms often mimic the adverse effects of drug therapy. The nurse must be careful to distinguish between the normal signs and symptoms of aging and the onset of adverse effects from drug therapy.

- Three main concerns with drug therapy in older adults are polypharmacy, inappropriate drug prescription, and nonadherence with therapy.
- Polypharmacy is an important concern in older adults because it greatly increases the risk of drug interactions and adverse effects
- Inappropriate drugs are all too frequently included in the older adult's drug regimen. These drugs are described in the Beer's criteria; they increase adverse effects, emergency room visits, and hospitalizations for older adults. They are more likely to be prescribed if the patient is receiving polypharmacy.
- Nonadherence with drug therapy is when a patient does not take a drug as prescribed but takes too much or too little of a prescribed drug. Multiple factors contribute to nonadherence such as forgetfulness, complexity of the drug regimen, cost of drug therapy, physical inability to open medication packaging, and inability to travel to the pharmacy.
- Nurses can promote older patients' adherence to prescribed drug therapy by minimizing the use of drug therapy when possible, simplifying the therapeutic regimen as much as possible, titrating doses upward gradually as prescribed to minimize adverse effects, helping with drug administration scheduling, assisting with memory aids if needed, and providing teaching and instructions in writing.
- Medication reconciliation will help to rectify inappropriate drug prescription, prevent drug interactions, and correct accidental overuse of a prescribed drug.
- Nurses need to assess patients' circumstances and cultural preferences or barriers to determine whether patients have the means and ability to obtain and comply with prescribed treatments, dietary recommendations, daily routine, and activity levels that can affect drug therapy.

QUESTIONS FOR STUDY AND REVIEW

1. Describe the effects of aging on the liver and its functioning.
2. How do normal changes in the renal system place the older adult at risk for adverse effects from drug therapy?
3. What is polypharmacy? Why is it an important issue for the nurse to consider in older adult patients?
4. Why are adverse drug effects often overlooked in older adults?
5. Why is it important to consider the core patient variables of lifestyle, diet, and habits with older adults receiving drug therapy?

Lifestyle: Substance Abuse

Learning Objectives

At the completion of this chapter the student will:

1. Describe the scope of substance abuse in the United States.
2. Identify etiologic factors associated with substance abuse.
3. Identify frequently abused drugs and list common medical problems associated with abuse of these drugs.
4. Describe the pharmacologic basis for physical and psychological drug dependence, tolerance, and addiction.
5. Explain the adverse effects associated with chronic abuse of alcohol, cocaine, marijuana, and opioids.
6. Discuss the nursing management of patients who abuse substances, including alcohol, cocaine, marijuana, hallucinogenics, and opioids.

Key Terms

abstinence syndrome
addiction
cross-dependence
cross-tolerance
habituation
physical dependence
psychedelic
psychoactive
psychological dependence
substance abuse
tolerance
withdrawal syndrome

Lifestyle, diet, and habits are core patient variables that exert some of the most important effects on a patient's response to drug therapy. The use of substances such as alcohol, tobacco products, and illicit or "street" drugs can seriously complicate drug therapy as well as the patient's general condition. Box 9.1 summarizes highlights from a national survey concerning the use of alcohol, tobacco, and illicit drugs in the United States.

Substance abuse is the inappropriate and usually excessive self-administration of a drug substance for nonmedical purposes. Drugs with a high abuse potential have the ability to stimulate compulsive drug-seeking behavior. Contemporary substance abuse has pervasive economic, legal, medical, moral, psychological, religious, and social implications. Substance abuse occurs throughout the life span and cuts across all racial, socioeconomic, ethnic, and cultural groups. Furthermore, factors in the patient's environment, family, or community can influence susceptibility to substance abuse and lead to drug addiction.

Drug **addiction** is a complex process involving interactions among the drug (availability, cost, pharmacology, toxicology); the user (personal resources, psychiatric profile, temperament); and society (family and peer influences, positive and negative advertising, and social attitudes). Broadly speaking, drug addiction alters the patient's life in a harmful way; for example, drug-related activity may result in a jail sentence.

Substance use and abuse interact with drug therapy in several ways:

- Drug therapy may become drug abuse.
- Chronic abuse may create health problems that require treatment with additional drug therapy.
- Treating or preventing symptoms of withdrawal from a substance may require drug therapy.
- Concurrent use of a substance may interact with drug therapy prescribed for a physiologic problem.

This chapter discusses various factors involved in substance abuse, several commonly abused drug categories and how they affect the body, and nursing management of substance-abusing patients.

CAUSES OF SUBSTANCE ABUSE

Dopamine Hypothesis

Scientists have demonstrated that a link exists between the neurotransmitter dopamine (especially DA-D3) and drugs of abuse and that dopamine plays a key role in a wide range

BOX 9.1 COMMUNITY BASED CONCERNS

How Many Substance Abusers?

Substance Abuse and Mental Health Services Administration (SAMHSA) National Survey on Drug Use & Health is the primary source of information on the prevalence, patterns, and consequences of alcohol, tobacco, and illegal drug use and abuse in the general U.S. civilian noninstitutionalized population, aged 12 years and older. The following information is highlighted in the 2009 report:

- In 2009, an estimated 21.8 million Americans, or 8.7% of the population aged 12 years or older, were current illicit drug users. Current drug use means use of an illicit drug during the month preceding the survey interview.

Drug	Number of Users
Marijuana	16.7 million
Psychotherapeutics (pain relievers, stimulants, tranquilizers, sedatives)	7 million
Cocaine	1.6 million
Hallucinogens	1.3 million
Inhalants	0.6 million
Heroin	0.2 million

- Gender
  - Males (10.8%) more than females (6.6 %).
- Age
  - The highest rate was among persons aged 18 to 20 (22.2 %).
  - Ages 12–17: 10 %
  - Ages 18–25: 21.2%
  - Ages 26–29: 14.4%
  - Ages 65 or older: 0.9 %.
- Race/ethnicity
  - American Indian or Alaska Native: 18.3%
  - Two or more races: 14.3%
  - Black or African American: 9.6%
  - White: 8.8%
  - Hispanic or Latino: 7.9%
  - Asian: 3.7%
- Educational status
  - college graduates: 6.1%
  - attended college but no degree: 9.8%
  - high school graduates: 8.8 percent
  - Non-high school graduates: 10.2%
- Employment status
  - unemployed: 17%
  - part time employment: 11.5%
  - full time employment: 8%
- Geographical Area
  - West: 10.3%
  - Northeast: 9.2%
  - Midwest: 7.9%
  - South: 7.8%
- In 2009, an estimated 69.7 million Americans aged 12 or older were current users of a tobacco product. This represents 27.7 percent of the population in that age range.
- In 2009, slightly more than half of Americans aged 12 or older reported being current drinkers of alcohol (51.9%). Approximately 6.8% of these drinkers defined themselves as a "heavy drinker" defined as 5 or more drinks on the same occasion on each of 5 or more days per week.

of addictions. Dopamine is associated with feelings of pleasure and elation. Dopamine levels can be elevated by a hug or kiss, a word of praise, a winning poker hand, or the effects of a drug. Cocaine use stimulates a surge of dopamine in an addict's brain, which essentially triggers the cocaine high. Research studies have demonstrated that in dopamine-rich areas of the brain, nicotine behaves in a manner remarkably similar to that of cocaine. Brain imaging technology can track increases in dopamine and link them to feelings of euphoria. This dopamine hypothesis gives rise to the recognition that there may be a clear biologic basis for drug dependence.

Current research focuses on the persistence of addiction, despite pharmacological and psychosocial treatment. The current hypothesis is that chronic addiction changes molecular and cellular mechanisms within a number of forebrain circuits, resulting in the deterioration of neural processes that normally serve affective and cognitive functioning.

The major drugs of abuse mimic the structures of neurotransmitters. Neurotransmitters serve as a basis for every thought and emotion, for memory, and for learning; they carry the signals between all the neurons in the brain. At a purely chemical level, every enjoyable experience amounts to an explosion of dopamine in the brain.

Several other factors, including physiologic, genetic, developmental, and environmental factors, play a role in determining why some people abuse substances. Box 9.2 explores factors that may place people at risk for substance abuse.

Physiology

The physiologic effects of drugs with a high potential for abuse involve the body's adaptation to the toxic effects of the drugs at the biochemical and cellular level. Several physiologic changes characterize this process: tolerance, physical dependence, and psychological dependence. It is important to note that tolerance or physical dependence alone does not imply addiction.

Box9.2 WHO'S AT RISK FOR SUBSTANCE ABUSE?

- Family factors that influence early childhood:
  - Chaotic home environment
  - Ineffective parenting
  - Lack of nurturing and parental attachment
  - Child abuse or sexual assault
- Factors outside of the family:
  - Poor social coping skills
  - Poor school performance
  - Association with a deviant peer group
- Individuals with chronic pain (e.g., back, joint, musculoskeletal disorders) who may occasionally misuse or abuse their prescribed drugs
- Individuals with a family history of substance abuse
- Teenagers—especially if they are dealing with self-esteem issues
- The socioeconomically disadvantaged—they may be desperate to "escape their world," selling and using drugs to survive
- Health care professionals (e.g., physicians, nurses, pharmacists) who have easy access to drugs and may begin using drugs or substances to promote sleep or arousal, decrease physical discomfort, and manage stress and anxiety

Tolerance

With drug use over time, tolerance develops. **Tolerance** occurs when the body develops a natural resistance to the drug's physical or euphoric effects, making it necessary to take increasing doses more frequently to achieve the desired effect. When a patient becomes tolerant to a class of drugs, **cross-tolerance** may also occur, meaning that tolerance to a drug in a particular class may also occur to other drugs in the same class. For example, tolerance to clonazepam (Klonopin) may result in tolerance to diazepam (Valium). Cross-tolerance does not extend to drugs in another class. For example, tolerance to clonazepam, a benzodiazepine, would not induce tolerance to meperidine (Demerol), an opiate drug.

Physical Dependence

Physical dependence occurs when changes in body cells, secondary to tolerance, cause the body to "need" the drug for homeostasis. Abstinence results in a withdrawal syndrome. Physical dependence is related to the amount and duration of drug abuse. The higher the dose and the longer the duration, the more physically dependent the patient becomes. Drugs associated with a high degree of physical dependence include heroin, morphine, alcohol, benzodiazepines, barbiturates, nicotine, and caffeine.

Physical dependence alone does not define addiction. A patient may be physically dependent on a drug without showing behavior patterns associated with addiction. For instance, a patient with chronic pain syndrome may be dependent on opioid drugs. However, this dependence on opioid drugs does not constitute an addiction. In reality, taking these drugs enhances the patient's quality of life.

Patients may also experience **cross-dependence.** When patients are dependent on a specific drug in one drug class, they may also be dependent on a similar drug in the same class. For example, if a patient who is dependent on clonazepam does not have access to that drug but is able to obtain diazepam, the patient will not experience a withdrawal syndrome.

Abstinence syndrome, or **withdrawal syndrome,** develops when dependent drug use is stopped abruptly. This interruption results in physical signs and symptoms of withdrawal as the body tries to return to "normal." Signs and symptoms of withdrawal syndrome are specific to the class of drug abused and are generally the opposite effects of the drug action. The severity of withdrawal syndrome is directly correlated with the degree of physiologic dependence and duration of use.

Psychological Dependence

Psychological dependence, thought by some experts to be the most important factor in addiction, involves the compulsive use of, and craving for, a drug. It results from the direct influence of drugs on brain chemistry. The drug causes an altered state of consciousness and distorted perceptions that are pleasurable and satisfying to the user. The recollection of these pleasurable feelings, along with the physiologic changes caused by tolerance and the fear of withdrawal symptoms,

reinforces continued use of the drug. Thus, patients with a psychological addiction are motivated by the feelings the drug provides, rather than the body's need for the drug.

Genetics

Genetic factors also play an important role in drug dependence, and this genetic vulnerability varies. For example, certain genes may predispose a person to, or protect the person from, alcoholism.

Several studies emphasize the effects of heredity and maintain that the disease of addiction—a chronic, progressive, recurrent, incurable, and potentially fatal condition—is a consequence of genetic deficiencies in brain tissues or neurotransmitters. For example, a vast body of evidence from studies of alcoholism suggests that genetic factors are more influential than environmental factors and that alcoholism is a multifactorial disorder in which biologic and genetic factors interact. These conclusions are supported by animal research (breeding of "alcoholic" rats), studies of twins (alcohol metabolism, alcohol drinking patterns, each twin's response to alcohol), and studies of adoptees whose biologic parents suffered from alcoholism.

Development and Environment

Developmental and environmental influences can trigger changes in brain hormones. For example, chronic stress can decrease brain levels of neurotransmitters, such as metenkephalin, dopamine, norepinephrine, and serotonin. Many sociologic studies suggest that physical or emotional stress caused by abuse, anger, peer pressure, and other environmental stressors can cause people to seek and sustain use of mind-altering drugs, leading to drug dependence. Several kinds of developmental and environmental factors may influence a person's substance abuse, including personality traits, mood disorders, availability of drugs, cultural attitudes, and socioeconomic circumstances.

Personality Traits

No absolute addictive personality has been identified, and the ability to respond to stress and peer pressure varies among people. However, substance abusers are frequently described as having a low tolerance for frustration, being impulsive and manipulative, and experiencing fears of failure. Feelings of inadequacy, resentment, hostility, and anger are other common characteristics thought to predispose a person to substance abuse. People with one or several of these personality traits may use substances to escape from reality or to relieve emotional discomfort.

Mood Disorders

The literature and clinical findings provide evidence that mood disorders have a major effect on health status, quality of life, and likelihood of substance abuse. Patients with mood disorders (e.g., depression and anxiety, dependent personality, antisocial personality) are more likely to become substance dependent or substance abusers at some time in their lives.

Patients who have depression or anxiety and who cannot cope with life's daily pressures and problems may try to escape from a mental or physical environment perceived as anxiety ridden, bleak, and joyless. People with a dependency disorder are unable to face everyday experiences independently. Instead, they use drugs to help them feel powerful and secure. Often, this behavior pattern becomes a vicious cycle. Larger or stronger amounts of drug may be needed to resolve the discomfort. People who have an antisocial personality may initially use substances to help them relate socially and to relieve their loneliness. The effects of alcohol and drugs may provide the courage to be social and have fun.

Availability of Drugs and Drug Diversion

Availability of a drug is an important factor in developing and maintaining abuse. Drugs are readily available in hospitals and clinics, which helps explain, in part, the potential for drug abuse among health care providers, nurses, and pharmacists. Although diversion of prescription drugs is a relatively small aspect of the overall drug abuse problem, drug diversion is estimated to cost employers and insurance companies $25 billion annually.

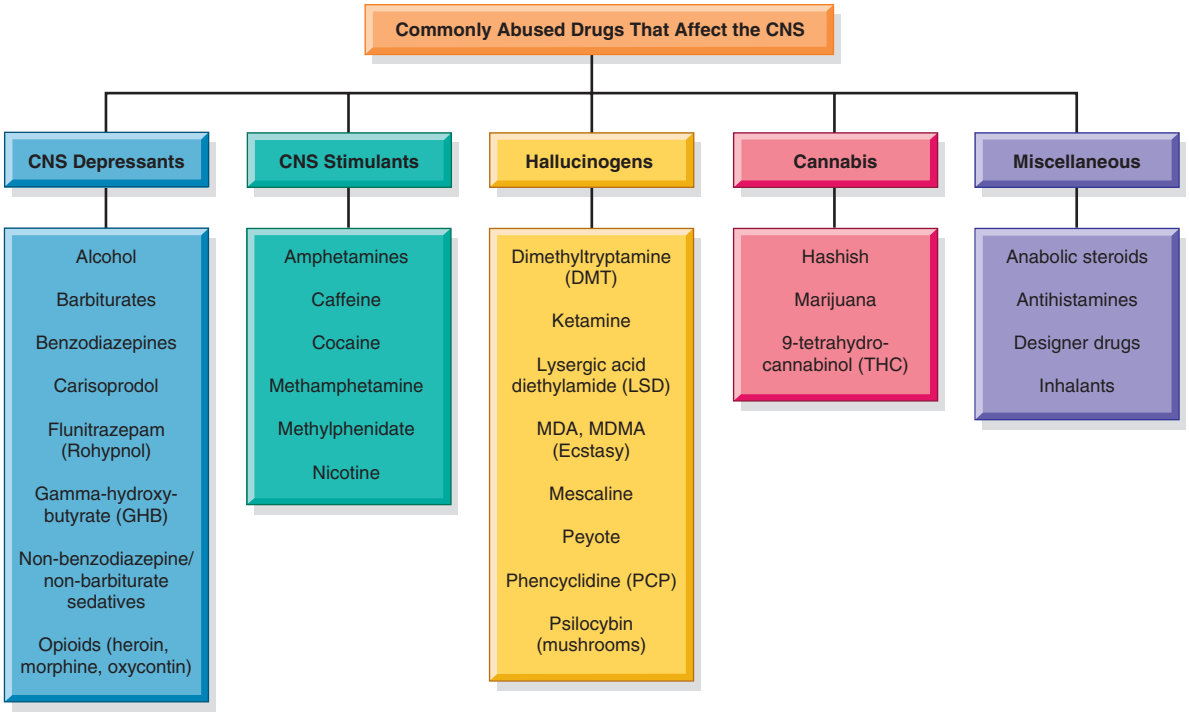
The most commonly diverted prescription medications are scheduled controlled substances, including stimulants (e.g., methylphenidate), narcotic analgesics (e.g., oxycodone), and central nervous system (CNS) depressants, especially benzodiazepines. The most abused, nonscheduled drug in the United States is carisoprodol (Soma), a centrally acting muscle relaxant. Carisoprodol is metabolized to meprobamate—a C-IV antianxiety agent. Illicit uses of carisoprodol include taking it with diphenhydramine, hydrocodone, or methadone; the combination of these drugs produces a heroin-type high.

Socioeconomic Circumstances

Economic circumstances have made drug abuse a major problem in many cities and towns across the United States. Some people may use or traffic drugs to escape harsh surroundings of poverty and illiteracy and change their perceptions of reality. In contrast, those who are not economically disadvantaged may use psychoactive drugs as a form of recreation, rather than an escape from their environment. Common reasons for using drugs include altering mood, exploring feelings, promoting social interaction, escaping boredom, stimulating creativity, improving physical performance, or enhancing the senses.

SUBSTANCE ABUSE AND THE CENTRAL NERVOUS SYSTEM

Virtually all abused drugs have some effect on the CNS and, with continued use, result in a physiologic or a psychological dependence, otherwise known as **habituation**. However, used with medical supervision, many drugs that affect the CNS have a therapeutic influence. These drugs are invaluable therapeutically because of the very specific physiologic and behavioral changes that result. Drugs that selectively affect



• FIGURE 9.1 Selected drugs of abuse.

the CNS may be used for analgesic, antiepileptic, antipyretic, antiemetic, or anorectic purposes or to suppress movement disorders. These drugs can also be used without altering consciousness to treat mood and thought disorders.

However, the excessive use of these drugs can have adverse effects when their use leads to dependence. In combination with alcohol, additive pharmacologic effects may occur after administration of all antihistamines, anxiolytics, CNS depressants, and opioids. Commonly abused drugs that affect the CNS are classified into five main categories:

1. CNS depressants
2. CNS stimulants (**psychoactive** drugs)
3. Hallucinogens (**psychedelic** drugs)
4. Cannabis
5. Miscellaneous drugs

A miscellaneous category of abused substances includes inhalants such as airplane or model glue, gasoline, or nitrous oxide; designer drugs such as analogues of fentanyl; antipsychotic drugs such as lithium; anabolic or androgenic steroids such as testosterone analogues; and over-the-counter (OTC) drugs, such as diet pills and antihistamines, that contain caffeine and phenylpropanolamine. Figure 9.1 depicts selected drugs of abuse.

CRITICAL THINKING SCENARIO

CONSIDERING SUBSTANCE ABUSE AMONG PROFESSIONALS

As a nursing student, you may become aware of health care professionals who jeopardize their careers and their patients' safety by using drugs inappropriately.

1. Give some reasons why you think that a colleague might misuse drugs.
2. What is your responsibility when you know a colleague is misusing drugs?

Central Nervous System Stimulants

The most commonly abused CNS stimulants include cocaine and methamphetamine. These CNS stimulants initially increase heart rate and blood pressure. The more potent stimulants energize muscles, decrease appetite, cause some degree of mental and physical alertness, produce feelings of self-confidence, and induce some degree of euphoria. Psychoactive drugs, particularly cocaine and methamphetamine, affect nerve impulses by disrupting the normal functioning of stimulatory neurotransmitters—dopamine, norepinephrine, and serotonin. The body responds to more frequent and higher doses of the drug by releasing smaller quantities of these neurotransmitters. Excess amounts can cause insomnia, hypertension, and cardiovascular problems—especially if a person has a sensitivity to the drug. Intoxication with amphetamines, cocaine, hallucinogens, and marijuana may cause panic attacks. Prolonged use may lead to anxiety, confusion, dependency, depression, exhaustion, anhedonia (inability to experience normal pleasure), irritability, paranoia, and violence as the body's own neurotransmitters are depleted. Synthesis of the depleted neurotransmitters may take months to occur after chronic, heavy use.

The CNS stimulants have a wide range of effects that increase their potential for abuse. Caffeine, nicotine, amphetamines, and cocaine increase alertness and energy, lessen drowsiness and fatigue, increase concentration and thinking,

alleviate moodiness, and impart a "high" or happy feeling. All stimulant drugs pose a risk of both physical and psychological dependence.

Caffeine is categorized as a mild CNS stimulant. It is found in coffee, tea, cocoa, colas and other soft drinks, and chocolate. It is also found in many OTC products, such as analgesics and weight-control products.

Nicotine is a highly addictive drug found in tobacco products such as cigarettes, cigars, pipe tobacco, and snuff. Tobacco use is the principal cause of preventable morbidity, disability, and premature death in the United States. Studies indicate that lung and oral/pharyngeal cancer and cardiovascular disease mortality from tobacco use is lower in states that have adopted a comprehensive tobacco control program; California and New Jersey are two examples. Because nicotine is highly addictive, many people require nicotine replacement in order to successfully stop smoking. Nicotine is available in a variety of formulations including a nasal spray, buccal lozenge, buccal chewing gum, and transdermal patch. Some of these formulations require a prescription, but many are available OTC.

Amphetamines are anorexiants used medically in short-term use for treating obesity, narcolepsy (a chronic disorder characterized by recurrent attacks of drowsiness and sleep during daytime), and attention deficit hyperactivity disorder (ADHD). Drug abusers typically take large oral doses or inject amphetamine—known as "speed"—for an intense "rush" that lasts only a short time. Studies have demonstrated that abnormal brain chemistry associated with methamphetamine abuse is evident months after the drug abuse has stopped. Brain scans have demonstrated reduced *N*-acetyl-aspartate compounds in the basal ganglia. Although no direct correlation is known, these reduced *N*-acetyl-aspartate levels are associated with a variety of diseases, including dementias, epilepsy, multiple sclerosis, brain tumors, and cerebral infarction.

Cocaine, another popular drug of abuse, produces a powerful but short-acting effect. Cocaine is not only psychologically addicting but also physically addicting because of its effect on neurotransmitters. The life-controlling effect of cocaine can lead an addict to exclude everything from his or her life except the pursuit of cocaine. A cocaine habit can cost an addict thousands of dollars a week to maintain.

Methamphetamine (meth), a psychostimulant drug, has become a national problem. It is the most frequently abused stimulant. Meth is easily produced using household chemicals and basic chemistry laboratory instruments. The "recipe" is found readily on the Internet. Meth targets the central nervous system by stimulating the release of dopamine. It also stimulates the release and blocks the reuptake of both norepinephrine and serotonin, but to a lesser degree than dopamine. It is more powerful than cocaine and has a longer half-life, which prolongs its intoxicant effects.

As a general rule, intoxication with stimulant drugs is more dangerous than withdrawal. Acute intoxication may cause severe and prolonged seizure activity, whereas withdrawal symptoms include nausea, sleep disorders, cravings, depression, irritability, agitation, and fatigue. Withdrawal symptoms occur within 24 hours and can last as long as 1 week or more.

Central Nervous System Depressants

Small doses of CNS depressants decrease heart rate, respiration, and reaction time, although initially they induce some euphoria. They relax the muscles, suppress physical and mental pain, diminish inhibitions, and promote sedation. CNS depressants, such as the opioids, can also decrease muscular coordination and energy and cause constipation, depression, nausea, vomiting, physical dependence, and withdrawal symptoms if used to excess.

Commonly abused CNS depressants include alcohol, barbiturates, and benzodiazepines. Sedative-hypnotic drugs can cause physical and psychological dependence. Regular use of these drugs over a long period leads to drug tolerance and a need for larger and larger doses to achieve the desired effect.

Alcoholism is the number one drug problem in America. Alcohol abuse and dependence are associated with 100,000 deaths annually in the United States, cause 30% of all traffic fatalities, and affect approximately 10% of Americans at some point in their lives (Up to Date, 2008). Because of its complex nature, alcoholism is difficult to define. Generally, people are considered alcoholics if their lifestyle is dominated by acquiring and consuming alcoholic beverages and if this behavior interferes with personal, professional, social, or family responsibilities and relationships. The Diagnostic and Statistical Manual of Mental Disorders (DSM IV) defines alcoholism as a maladaptive pattern of use associated with 3 or more of the following:

- Tolerance
- Withdrawal
- Substance taken in larger quantity than intended
- Persistent desire to cut down or control use
- Time is spent obtaining, using, or recovering from substance
- Social, occupational, or recreational tasks are sacrificed
- Use continues despite physical and psychological problems

Barbiturates, once the mainstay of sedative-hypnotic drugs, are also used as anesthetics and antiepileptics. Many barbiturates are short-acting drugs, which helps explain the problem with abuse; that is, the person needs to use more drug to sustain the desired effect. Examples of barbiturates habitually used include pentobarbital, secobarbital, and amobarbital. Methaqualone has been withdrawn from the market and is no longer legally manufactured.

Benzodiazepines, which were initially developed as an alternative to the highly dependency-producing barbiturates, are longer-acting drugs. However, they still cause physical and psychological dependence if taken regularly over a prolonged period. Benzodiazepines, which are used primarily to relieve anxiety and to provide a hypnotic, or sedative, effect, are widely prescribed and therefore readily available. Some common benzodiazepines habitually used are diazepam, alprazolam, clorazepate, clonazepam, and lorazepam.

TABLE 9.1 Clinical Findings in Alcohol Withdrawal

Symptoms	Onset After Last Drink
Tremulousness, anxiety, headache, nausea/vomiting, diarrhea, palpitations, anorexia, diaphoresis	6–36 hours
Tonic-clonic seizures	6–48 hours
Hallucinosis (visual, auditory or tactile)	12–48 hours
Delirium tremens (delirium, agitation, tachycardia, hypertension, fever, and diaphoresis	48–96 hours

Abrupt withdrawal from long-term use of sedative-hypnotic drugs should never be attempted because withdrawal symptoms are serious and potentially fatal. Withdrawal symptoms include agitation, dysphoria, insomnia, vomiting, diarrhea, ataxia, hallucinations, acute psychosis, muscle and abdominal cramps, anorexia, and seizures. These symptoms may occur 12 to 72 hours after the last use of the drug and may last up to 14 days.

Like the sedative-hypnotic drugs, abrupt withdrawal from long-term alcohol abuse may trigger a withdrawal syndrome that ranges from simple tremors to seizure activity and delirium. Symptoms may occur in as little as 6 hours or as long as 96 hours (see Table 9.1).

Opioids

Opioids (also known as narcotic analgesics) are commonly prescribed to relieve pain, suppress coughing, enhance anesthetic effect for surgery, and relieve severe diarrhea. These narcotic drugs have a high potential for abuse and are extremely addicting both physically and psychologically. Frequently used and abused opioids include heroin, opium (paregoric), morphine, meperidine (Demerol), hydromorphone (Dilaudid), codeine, pentazocine (Talwin), and propoxyphene (Darvon). Administered orally, heroin and morphine undergo first-pass metabolism and have only one third to one sixth the effect of heroin or morphine administered parenterally. Therefore, abusers of these drugs usually administer them by injection or inhalation.

All opioids affect the CNS and cause cerebral changes, mood changes, confusion, euphoria, and analgesia. Regular use of narcotics over several weeks usually results in tolerance to the drug's effects. Withdrawal effects from narcotics induce muscle pain, nausea and vomiting, abdominal cramps, and diarrhea. Although these symptoms can be severe, they are not generally lethal. However, death may occur if the patient becomes severely dehydrated and experiences profound electrolyte imbalances. Withdrawal symptoms occur within 8 to 12 hours and can persist for up to 10 days.

Tranquilizers

Certain tranquilizing drugs, known as "date rape" drugs, have made headlines. They are Rohypnol and gamma-hydroxybutyrate (GHB). Rohypnol is the trade name for flunitrazepam—a sedative-hypnotic benzodiazepine that produces muscle relaxation and amnesia. Although this drug is classified as a depressant, it can induce aggression, excitability, and even death. Outside the United States, Rohypnol is legally manufactured and is prescribed for the short-term treatment of severe sleep disorders. It is widely available in Europe, Mexico, and Colombia but is neither manufactured nor approved for sale in the United States. Rohypnol is 10 times more potent than diazepam (Valium). Rohypnol is a tasteless and odorless drug that dissolves clear in liquids, making it difficult to detect. Because of its illicit use, the manufacturers of Rohypnol reformulated the drug so that it turns blue in liquids. Unfortunately, many mixed drinks and punches are themselves dark in color, making these drinks ideal vehicles for administering the drug to unsuspecting victims. Rohypnol induces slowing of psychomotor performance, muscle relaxation, decreased blood pressure, sleepiness, and amnesia. Some of the adverse effects associated with use are drowsiness, headaches, memory impairment, dizziness, nightmares, confusion, and tremors.

GHB is a powerful, rapidly acting CNS depressant initially developed as an anesthetic agent in the 1960s. Produced naturally by the body in small amounts, the physiologic function of GHB is unclear. GHB, which became an FDA Schedule I Controlled Substance in March 2000, is abused for its ability to produce euphoric and hallucinogenic states and for its alleged function as a growth hormone, which releases agents to stimulate muscle growth. The popularity of GHB stems from its ease of manufacture—home chemistry kits and instructions can be found on the Internet. Like Rohypnol, GHB is a colorless, tasteless, and odorless drug that dissolves in liquids. Effects occur in 15 to 30 minutes and last for 3 to 6 hours. Adverse effects associated with GHB include nausea, vomiting, delusions, depression, vertigo, hallucinations, seizures, respiratory distress, loss of consciousness, slowed heart rate, lowered blood pressure, amnesia, and coma. The margin between GHB's anesthetic dose and its lethal dose is very narrow. Since 1995 there have been 73 documented deaths related to GHB. Between 1998 and 2000, there were 4,969 GHB emergency room admissions reported.

Because of concern about Rohypnol, GHB, and other similarly abused sedative-hypnotics, Congress passed the Drug-Induced Rape Prevention and Punishment Act of 1996 in October of that year. This legislation increased federal penalties for using any controlled substance to aid in sexual assault.

Hallucinogens

Hallucinogenic drugs have pronounced mental and emotional effects because they distort the way the brain interprets sensory information. They can also mimic certain mental illnesses such as schizophrenia. Included in this category are the naturally occurring substances (marijuana, mescaline, and psilocybin) and the synthetic substances (lysergic acid diethylamide [LSD], dimethyltryptamine [DMT], and phencyclidine hydrochloride [PCP]). Psychedelic drugs are, with the exception of marijuana, not used medically. Psychedelics

do not cause physical dependence, and only marijuana has been shown to produce psychological dependence.

Relatively new amphetamine-derivative drugs with special stimulatory effects on the brain are termed hallucinogenic amphetamines (e.g., 3,4-methylenedioxymethamphetamine [MDMA], "Ecstasy"). These drugs can be inhaled, injected, or swallowed. They cause a long-lasting reduction in the brain's supply of serotonin and produce powerful psychic changes.

Another drug, ketamine, an anesthetic used in animals, is used frequently for conscious sedation in humans. It produces some emergent hallucinogenic effects (hallucinations and sensory distortion) that immobilize the user and detach him or her from reality. Ketamine does not depress the circulatory or respiratory systems. Its effects are equivalent to those of being severely inebriated.

Inhalants

The term "inhalants" refers to products that can be abused by inhaling them through the nose or mouth to achieve an intoxicating effect (Box 9.3). Because they are easily accessible, inexpensive, and easy to conceal, inhalants are some of the first substances abused. These substances can be inhaled in various ways. Common methods include inhaling directly from containers (products such as rubber cement or correction fluid), sniffing fumes from plastic bags held over the mouth and nose, or sniffing a cloth saturated with the substance.

Effects of inhalant use resemble alcohol inebriation. As the user inhales, the body becomes starved of oxygen. As a compensatory effect, the heart rate increases in an attempt to increase blood flow to the brain. The user initially experiences stimulation, a loss of inhibition, and a distorted perception of reality and spatial relations. After a few minutes, the senses become depressed, and a sense of lethargy arises as the body attempts to stabilize blood flow to the brain, usually referred to as a "head rush." Users can become intoxicated several times over a few hours because of these chemicals' short-acting, rapid-onset effect. Many users also experience headaches, nausea, vomiting, slurred speech, loss of coordination, and wheezing.

Box 9.3 COMMONLY ABUSED COMMERCIAL PRODUCTS

Adhesives: Model airplane glue, rubber cement, household glue
Aerosols: Spray paint, hair spray, air freshener, deodorant, fabric protector
Anesthetics: Nitrous oxide, ether, chloroform
Cleaning agents: Dry cleaning fluid, spot remover, degreaser
Food products: Vegetable cooking spray, whipped cream, and other products in aerosol containers (nitrous oxide "whippets")
Gases: Butane, propane, helium
Solvents: Nail polish remover, paint thinner, typing correction fluid and thinner, toxic markers, pure toluene, toluol, cigarette lighter fluid, gasoline

The nurse should suspect inhalant abuse when observing paint or stains on the body or clothing, spots or sores around the mouth, red or runny eyes and nose, chemical odor on the breath, a drunken or dazed appearance, loss of appetite, excitability, and irritability.

Tolerance and physical dependence may occur with heavy or long-term use. Withdrawal symptoms may include sweating, rapid pulse, hand tremors, insomnia, nausea, vomiting, physical agitation, anxiety, hallucinations, and grand mal seizures.

Designer Drugs

These drugs are similar in chemical structure to existing drugs and are developed with relative ease in illegal laboratories. They are extremely potent, and when used recreationally, they have addictive capabilities greater than those of existing drugs. For example, alpha-3-methyl fentanyl (the street version of fentanyl), which may be represented as "China white" (heroin), is 35 times more potent than heroin. Fentanyl, a narcotic analgesic legitimately used during and after surgery, is an example of an existing drug "designed" into another form. These analogues of existing substances, which offer similar psychoactive properties, are primarily designed to bypass federal regulation and control by means of their chemical formulations, which differ from those of existing drugs and are thus not covered by existing laws. Two meperidine analogues that have appeared on the street include MPPP (1-methyl-4-phenyl-4-propionoxypiperidine) and PEPAP (1-[2-phenylethyl]-4-acetyloxypiperidine). They are often marketed as "new heroin." MPPP is popular among drug abusers because when it is injected, it produces a euphoria similar to that produced by heroin. An impurity formed during the illicit manufacture of MPPP, called MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), destroys brain cells and much of voluntary muscular movement. MPTP produces a crippling condition that closely resembles Parkinson disease.

Anabolic Androgenic Steroids

Anabolic androgenic steroids are synthetic formulations of the male hormone testosterone. The abuse of these drugs in men and women to increase strength and enhance athletic performance is widespread. Anabolic androgenic steroids also have a dramatic effect on emotions and make the user feel more confident and aggressive. Continued use of anabolic androgenic steroids may lead to emotional instability, rage, depression, or psychosis. Serious health problems are associated with both short- and long-term use of anabolic androgenic steroids. These problems include sex hormone imbalances (including amenorrhea or erectile dysfunction), changes in secondary sexual characteristics (e.g., gynecomastia, hypomastia, testicular atrophy, and ovarian atrophy), permanent sterility, hepatic cancer, and myocardial infarction. In light of the risks associated with these substances, many athletic organizations have banned their use.

Nursing Management In Commonly Abused Drugs

The nurse's role in substance abuse involves having core knowledge related to specific drugs and to abuse prevention, assessing potential or actual abuse, and formulating nursing diagnoses related to the assessment findings. Once the nurse has gathered the data and developed nursing diagnoses, outcome criteria can be identified, and interventions can be implemented. Finally, the nurse evaluates whether the outcome criteria have been met and what further patient care is needed. It is important for the nurse to have open, unbiased observation for the potential abuse of drugs by all patients, regardless of gender, age, ethnicity, education, or socioeconomic status.

Core Drug Knowledge in Alcohol Abuse

Pharmacokinetics

Alcohol, known clinically as ethanol (ETOH), does not require digestion before absorption. It is completely absorbed by the stomach and small intestine within 2 hours of ingestion. However, food in the stomach decreases the effects of alcohol, delays gastric emptying time, and retards absorption from the small intestine. Once in the systemic circulation, alcohol is immediately distributed to the rest of the body at a rate proportional to blood flow and water content. Consequently, high concentrations in the brain, liver, lung, and kidney develop rapidly. Once absorption is complete, brain and blood alcohol levels are very similar.

The liver metabolizes alcohol by two different pathways—using the enzyme alcohol dehydrogenase and the microsomal ethanol-oxidizing system (MEOS). In the average adult, 90% to 98% of an ingested dose of alcohol is converted to acetaldehyde by alcohol dehydrogenase. The acetaldehyde is then oxidized to acetate by aldehyde dehydrogenase. The acetate is finally oxidized in the liver to carbon dioxide and water. These actions primarily take place in the cytoplasm and mitochondria of the hepatocyte. The remaining 2% to 10% is excreted unchanged in the urine and expired air. The average rate of metabolism of alcohol by non-tolerant people is 100 mg/kg of body weight per hour (or 7 g/h in a person who weighs 70 kg).

People with chronic alcoholism metabolize alcohol by way of the MEOS, which occurs primarily in the endoplasmic reticulum. Metabolism of ethanol by this pathway produces an end product of acetaldehyde and free radicals, both of which damage liver cells. Metabolism by this pathway is also dangerous because cytochrome P-450, an enzyme that is integral to the pathway, is required by the liver to transform toxins, drugs, and excess fat-soluble vitamins. If P-450 is being used to metabolize alcohol, it cannot perform its other tasks. The result is susceptibility to organ damage from other toxins, drugs, and vitamins. Alcohol is excreted in urine by the kidneys, in the breath by the respiratory system, and in sweat by the skin.

Pharmacodynamics

Alcohol adversely affects many body systems (Box 9.4). Alcohol is thought to interfere with the transmission of nerve impulses at synaptic junctions, although this exact mechanism is unclear. It is similar in action to that of general anesthetics and probably exerts its action on the brain by dissolving in neuronal plasma membranes rather than by acting on a specific receptor.

Like the general anesthetics, alcohol sequentially depresses the CNS (i.e., the cerebrum, cerebellum, spinal cord, medulla). However, the excitatory stage of alcohol is longer, and the anesthetic stage is equivalent to toxicity. The margin between alcohol's anesthetic dose and its lethal dose is very narrow.

Adverse Effects

Alcohol depresses the CNS. However, the depressant effects may appear to be stimulatory because alcohol depresses the higher centers of the brain, causing people to shed behavioral and social inhibitions. The degree of depression produced is directly proportional to the quantity of alcohol consumed. Table 9.2 presents blood alcohol levels and stages of intoxication.

Awareness of these two effects may depend on the excitability of the CNS at the time of drug administration, which is influenced by the environmental setting in which the drug is used and the personality of the user. For example, in a quiet, nonsocial environment, the excitatory influence may be impaired, and the drug's CNS depressant effects of sedation and drowsiness may dominate. In a social setting, where sensory input is increased, the effects of low doses of alcohol may be perceived as stimulation because the drinker may demonstrate talkativeness, increased self-confidence, and a release of usual inhibitions.

Alcohol impairs muscular coordination. It increases the heart rate and dilates the blood vessels, causing body heat loss and, in low doses, lowers the blood pressure, which is thought to reduce the risk for myocardial infarction in patients with high levels of high-density lipoproteins. However, with large

TABLE 9.2 **Blood Alcohol Levels and Stages of Intoxication**

Blood Alcohol Level (mg/dL)	Physical and Behavioral Effects
<50	Body sway, euphoria, excitement, impaired judgment, incoordination, increased sociability, loss of inhibitions
50–100	Disturbed gait, impaired ability to operate machinery (e.g., motor vehicles), increased reaction time, increasingly impaired judgment, distractibility, slurred speech
100–140	Ataxia, increasingly impaired mental and motor skills, impaired short-term memory
140–200	Inability to operate a motor vehicle, staggering gait

>300	Severe respiratory and cardiovascular depression, coma, death

doses of alcohol, dangerous levels of cardiovascular depression can occur. Prolonged alcohol use causes hypertension and cardiovascular damage such as alcoholic cardiomyopathy.

Alcohol irritates the gastrointestinal (GI) tract by causing an increase in digestive enzymes. Ulceration of the gastric mucosa is a serious complication of excessive alcohol consumption. Alcohol also causes altered bowel function, inducing either constipation or diarrhea. The risk of developing alcoholic liver disease is related to the quantity and duration of alcohol consumption. Excessive alcohol consumption creates fatty deposits in the liver. These deposits can damage and scar the liver and lead to complications, such as cirrhosis, ascites, esophageal varices, and portal hypertension. Excess alcohol consumption inhibits antidiuretic hormone and therefore increases urine production. Finally, alcohol disrupts endocrine functions, causing alterations and fluctuations in blood glucose, catecholamine, and aldosterone levels. Alcoholics are frequently immunologically compromised, with an increased risk of mortality resulting from cancers of the upper GI tract and liver. Additionally, patients with alcohol abuse behaviors are frequently malnourished, resulting in hypoalbuminemia. Patients with hypoalbuminemia have altered protein-binding ability. Thus, the potential for adverse effects and drug toxicity during any type of drug therapy is increased.

Drug Interactions

Alcohol has no nutritional value, and it interferes with the absorption of vitamins and minerals. Alcohol can affect iron absorption, folate activities, and platelets. These harmful effects can result in a variety of anemias. Table 9.3 gives more information about drug interactions with alcohol.

Core Drug Knowledge in Cocaine Abuse

Cocaine is derived from the leaves of *Erythroxylon coca*. It is available in two forms: crystalline cocaine hydrochloride and highly purified cocaine alkaloid. Cocaine hydrochloride is usually administered orally, intravenously, or by nasal insufflation because it is water soluble and unstable when exposed to heat. The alkaloid form of cocaine—called "crack" because of the popping sound it makes when the crystals are heated—is stable on exposure to heat but is water insoluble; therefore, it is usually administered by inhalation. On the street, pure cocaine is diluted or "cut" with other substances to increase its quantity and thereby increase profits to the sellers.

Freebasing consists of converting the cocaine alkaloid to a freebase rock form using a solvent such as diethyl ether. This rock is then heated, and the fumes are inhaled. This practice is potentially dangerous because the fumes are potent and diethyl ether is flammable; in addition to the risk of burns, many users report being addicted after only one use. Treatment for cocaine addiction is difficult because of the extreme physical and psychological dependence associated with its use.

Pharmacokinetics

Cocaine is rapidly absorbed into the bloodstream, regardless of whether it is snorted, inhaled, or injected. Cocaine has a 1- to 2-minute onset of action and a 30-minute duration of action after smoking or intravenous (IV) injection; peak effects after inhaling cocaine occur in 30 to 60 minutes, with a duration of action of several hours. Cocaine is only 30% to 40% bioavailable after oral administration, and GI absorption may continue for several hours. Orally administered cocaine has a slower onset of action, approximately 1 hour.

Cocaine is extensively metabolized in the liver and the blood. Metabolites may be detected in the urine for 2 or more days. Because cocaine is so rapidly metabolized in the liver, the user must inhale, inject, or smoke the drug approximately every 30 minutes to maintain the high. Cocaine is characterized by tachyphylaxis (a rapidly decreasing response to a physiologically active substance following administration of a few doses). Therefore, its psychoactive effects diminish rapidly, despite its continued presence in the plasma.

The elimination half-life for cocaine is similar for all forms of administration—about 50 minutes for the oral route, 80 minutes for the intranasal route, and 60 minutes for the IV route.

Cocaine enters breast milk and may have negative effects on nursing infants. Potential adverse effects include irritability, vomiting, diarrhea, tremors, and seizure activity.

Pharmacodynamics

Cocaine has pronounced effects on the central and peripheral nervous systems. It impairs the uptake of norepinephrine and epinephrine by presynaptic nerve endings, thus activating the adrenergic systems and causing hypertension, tachycardia, and vasoconstriction. Cocaine interferes with serotonin uptake, causing dramatic alterations in the sleep–wake cycle

TABLE 9.3 Agents That Interact with Alcohol

Interactants	Effect and Significance	Nursing Management
Analgesics (e.g., aspirin)	Combination may cause severe stomach irritation	Monitor for upper or lower GI bleeding.
Anesthetics*	Potentiation of the anesthetic effect	Observe during patient's recovery from anesthetic effects. Recovery may be prolonged.
Anticoagulants	Potentiation of the anticoagulant effect, leading to possible hemorrhage	Observe for signs of bleeding: bruising, black tarry stools.
Antiepileptics	Accelerated antiepileptic drug metabolism	Monitor for poor seizure control. Also monitor for seizures and provide for patient safety.
Antidiabetics, hypoglycemics	Unpredictable; rise or fall of blood glucose level	Monitor blood glucose levels regularly.
Antihistamines	Additive sedative effects; increased incidence of accidents due to drowsiness and increased response time	Ensure patient safety.
Antihypertensives	Additive hypotensive effects	Monitor blood pressure. Explain strategies for coping with orthostatic hypotension.
Antipsychotics* (e.g., phenothiazines)	Significant respiratory depression	Monitor breathing. Provide respiratory assistance if needed.
Barbiturates	Significant synergistic effects with alcohol	Monitor for severe respiratory depression.
Diuretics	Significant increased hypotensive effects due to antidiuretic hormone and diuresis	Monitor fluid and electrolyte levels. Caution patient about orthostatic hypotension.
Narcotics*	Synergistic, intensified CNS depressant effects	Provide respiratory support if significant respiratory depression occurs.
Sedative-hypnotics*	Additive effects; adverse effects on alertness and performance	Ensure patient safety.
Vitamins	Continuous alcohol use interferes with vitamin absorption and synthesis	Monitor for nutritional deficiencies (thiamine, folate, B_{12}) and paresthesias.

*These are potentially hazardous when ingested by a heavy drinker, patient with long-term alcoholism, or patient recovering from alcoholism.

and evoking feelings of intense energy. It also impairs dopamine reuptake, thus activating the dopaminergic system and causing euphoria, thereby strongly reinforcing use. With long-term use, dopamine becomes progressively depleted from nerve endings, causing the dysphoria that is so prominent during withdrawal. Dopamine depletion and dysphoria frequently lead to drug craving, causing a very high rate of relapse. Cocaine also interferes with sodium ion activity in peripheral nerves, causing local anesthetic actions.

Adverse Effects

Adverse reactions to cocaine include:

- CNS stimulation, including severe agitation, anxiety, excitement, paranoid psychosis, and seizures
- Cardiovascular effects, including atrioventricular arrhythmias, severe hypertension, cardiomyopathy, coronary and peripheral vasoconstriction, myocardial infarction, and intestinal or renal ischemia
- Pulmonary complications, including pneumothorax, pulmonary edema, and respiratory arrest
- Metabolic complications, including disseminated intravascular coagulation, hepatotoxicity, hyperthermia, renal failure, and rhabdomyolysis
- Complications of nasal inhalation, including anosmia, nasal mucosal atrophy, nasal septal necrosis, and rhinorrhea

High doses of pure cocaine in freebase form (crack) can overtax the cardiovascular system and cause sudden death from acute myocardial infarction or rupture of the aorta. Cocaine sensitizes cardiac cells and causes an increase in contractility. Corresponding high levels of epinephrine secondary to excitement from cocaine cause the person to be particularly susceptible to cardiac arrest.

Core Drug Knowledge in Opioid Abuse

Heroin, the most abused opioid in the United States, is a synthetically manufactured drug that possesses morphine-like pharmacologic activity. It has a poor oral availability; therefore, abusers often begin by smoking the drug. As the

abuser becomes tolerant to the drug, he or she begins to use the drug by IV injection. When abusers can no longer find a site for IV injection, they will start subcutaneous administration, also known as "skin-popping." Pure heroin is very expensive and dangerously powerful. For these reasons, street heroin is usually mixed with fillers, such as sugars, starches, or quinine, resulting in a mixed substance that contains only 1% to 10% heroin.

Pharmacokinetics

The rate of heroin's absorption by the bloodstream depends on the method of administration. Absorption rate increases from oral use to IV injection. Typically, effects are felt within about 30 minutes after oral administration and within a range of 5 to 15 minutes after smoking or injecting. Depending on the dose, the effects of injected heroin persist for approximately 4 to 6 hours. Most heroin is converted to morphine and excreted by the kidneys. Insignificant quantities of unconverted heroin may be found in urine and feces. Heroin also enters breast milk. The nursing infant may experience tremors, restlessness, vomiting, and poor feeding.

Pharmacodynamics

Heroin acts on the body in a manner similar to that of other opioids. An intense rush follows IV administration of heroin. This rush subsides in a few minutes, and the effects resemble those following oral dosing. The abuser feels relaxed, carefree, and somewhat dreamy but is able to carry on with many normal activities. Taking daily doses of heroin (at least 24 mg) usually results in a clinically significant dependence in a few weeks.

Adverse Effects

The pathophysiologic effects of heroin are also similar to those of the other opioids (see Chapter 23); however, the degree of some effects is greater. An overdose of heroin may result in severe respiratory depression, pulmonary edema, coma, and possibly death. Some pathophysiologic effects specific to IV heroin use include infection with human immunodeficiency virus (HIV) or hepatitis from contaminated needles, toxic reactions to contaminants injected along with the heroin, vasculitis, and thromboembolic complications.

Core Drug Knowledge in Marijuana Abuse

The most commonly abused psychedelic drug is marijuana, which is derived from the hemp species, *Cannabis sativa*. Marijuana refers to the entire plant chopped and dried; the more potent hashish is the dried resinous exudate of the flowering tops.

The major ingredient of marijuana is 9-tetrahydro-cannabinol (THC). The THC concentration in the average marijuana cigarette has increased substantially during the past 3 decades. A typical marijuana cigarette delivers a dose of THC ranging from 2.5 to 5 mg.

Pharmacotherapeutics

An oral form of marijuana, dronabinol (Marinol), is now used in the United States to treat anorexia in patients with acquired immunodeficiency syndrome (AIDS) and for reducing nausea and vomiting in patients with cancer who are undergoing chemotherapy. Studies are ongoing related to its effectiveness in reducing intraocular pressure associated with glaucoma.

Pharmacokinetics

The systemic availability of THC after smoking is about 25%, with a peak plasma concentration occurring after 10 to 30 minutes. The duration of the entire effect is about 2 to 3 hours. The effectiveness of THC after oral ingestion is less than after smoking it: systemic availability is less (6% to 20%), onset of CNS effects is 30 to 60 minutes, peak plasma concentrations are reached within 2 to 3 hours, and the duration of action is about 4 to 6 hours for psychoactive effects and more than 24 hours for appetite stimulant effects.

THC is converted quite rapidly to a pharmacologically active metabolite, 11-hydroxy-9-THC. Further metabolism yields an inactive metabolite (11-nor-9-carboxy-9-THC), which is excreted in the urine. The plasma half-life of THC is approximately 13 days, and the urinary elimination half-life of 11-nor-9-carboxy-9-THC is approximately 10 days. However, the concentrations of these metabolites do not correlate well with THC's clinical effects and are poor predictors of behavioral impairment or intoxication. The slow urinary elimination provides an ideal marker for detecting marijuana use in drug testing.

Pharmacodynamics

The mechanism of action of THC is unknown; however, antiemetic and other pharmacologic effects occur within minutes of use. THC produces minor cognitive effects, such as an altered sense of time, a period of euphoria followed by sedation, less discriminate hearing, and enhanced visual stimuli.

Adverse Effects

Some of the adverse effects of THC include decreased myocardial oxygen supply, a dose-related increase in heart rate (20 to 50 bpm after one or two marijuana cigarettes), and impaired fertility. Cannabinoid receptors are concentrated most heavily in the cerebellum, the part of the brain that controls motor coordination, and in the hippocampus, which governs learning and memory. Large numbers are also found in the cerebral cortex, the seat of higher thinking, and lesser numbers are scattered in the immune system. They are largely absent from the brainstem regions that govern heartbeat and respiration. At high levels of intake, a cannabis psychosis may occur, and regular heavy cannabis users may suffer repeated psychotic episodes and personality changes. Chronic use of THC appears to cause permanent brain damage, as evidenced by loss of short-term memory, decreased motivation, impaired performance of simple and complex motor tasks, development of acute

anxiety that may reach panic proportions, and severe psychological dependence.

Although smoking marijuana is often thought to be relatively safe compared with smoking tobacco, the smoke is virtually identical in both cases. Smoking marijuana involves inhaling larger volumes of smoke and holding the breath as much as four times longer than with tobacco, which ultimately makes smoking three to four marijuana joints a day equivalent to smoking one pack of tobacco cigarettes a day.

Tolerance to the effects of marijuana develops quite slowly. Evidence that marijuana is addictive has been obscured partly because THC is readily stored in body fat, and marijuana users who quit are often "weaned" off the drug slowly as small amounts continue to filter into the bloodstream. However, several studies have shown that a "flu-like" syndrome occurs during withdrawal from marijuana. The National Institute of Drug Abuse (which funds most of the marijuana research in the United States) estimates that 100,000 people seek treatment every year for marijuana dependency.

Core Drug Knowledge in Hallucinogen Abuse

Although often associated with the 1960s, LSD and PCP are still used. LSD is taken orally, and PCP can be taken orally, smoked, or injected. Tolerance develops with continued use of these drugs. However, psychological dependence is rare, and physical dependence does not occur. In addition, no specific withdrawal syndrome is associated with these drugs. LSD and PCP have no accepted medical use and are classified as FDA Schedule I drugs.

Pharmacokinetics

The effects of LSD and PCP usually occur 30 to 90 minutes after ingestion or inhalation and can last between 8 and 12 hours. The effects depend on the amount taken, the user's personality, the user's mood and expectations, and the setting in which the drug is used.

PCP is rapidly metabolized in the liver to inactive metabolites. Large doses of PCP may result in accumulation of large amounts of non-metabolized PCP in the urine. PCP has a half-life of 30 minutes to 1 hour in small amounts and of 1 to 4 days in large doses.

Pharmacodynamics

The mechanism of action is unclear, although some experts think serotonin-antagonistic activity within the brain is responsible for its hallucinogenic properties. Alterations in sensory perception, distortions of size, body image distortions, and surreal feelings of separation of body parts are prominent features of LSD intoxication. Sensory input is also enhanced, which creates vivid visual illusions, hallucinations, and intensely colored visual images.

Adverse Effects

Subjective effects and mood changes are quite variable with LSD. A dream-like state with feelings of good humor, euphoria, relaxation, and a sense of wonderment may predominate. Conversely, "bad trips" may occur. These consist of dysphoria, nervousness, anxiety, disorientation, hallucinations, panic attacks, and severe psychotic attacks. LSD produces adrenergic effects, most notably hypertension, hyperpnea, tachycardia, hyperthermia, pupillary dilation, and hyperreflexia. Diaphoresis, salivation, lacrimation, nausea, and vomiting may also occur.

Dopaminergic and anticholinergic effects on the body occur with PCP use. In addition, this drug shares some of the dysphoric properties of the opioids. After low doses, the user has a sense of thinking and acting swiftly. Moods may range from euphoria and a sense of "bouncing" to depression. Larger doses cause changes in mood, which are quite unpredictable and labile. A sense of unreality predominates. Under the influence of PCP, a person may experience a "bad trip" and become irrational, extremely combative, and violent. The lack of pain secondary to its anesthetic effect seems to exaggerate the person's perception of his or her own strength. In some cases, PCP can cause severe psychoses, seizures, respiratory depression, intracerebral hemorrhage, hyperpyrexia, and death.

Flashbacks—hallucinatory episodes that occur days to years after taking the drug—occur with LSD and PCP use. Prolonged psychotic episodes (lasting several days to several months) with visual hallucinations have been precipitated by LSD and PCP.

Core Drug Knowledge in Inhalant Abuse

Inhalants, another type of psychedelic drug, are volatile chemicals and gases that produce behavioral effects and are subject to abuse. Commonly abused inhalants include model glue, spray paint and hair spray propellants, cleaning solvents, gasoline, and kerosene (see Box 9.3). Nonmedical nitrous oxide is another popular inhalant.

These substances are generally sniffed from rags, paper or plastic bags, gauze, or ampules. Long-term inhalant abuse can cause permanent CNS, hepatic, renal, and bone marrow damage and greatly reduced mental and physical abilities.

Pharmacokinetics

Inhalants are rapid-acting substances. Their effects are almost immediate. The duration of the effect depends on the substance used. For example, the effects of glue, paint, or gasoline usually last several or more hours, whereas the effects of nitrous oxide typically last less than 5 minutes. The effects of amyl nitrate (or butyl nitrate) last from a few seconds to several minutes.

Pharmacodynamics

Inhaling volatile chemicals and gases produces a short-lived, mild intoxication that typifies the early stages of anesthesia. These agents produce a sense of exhilaration and lightheadedness. Judgment, vision, memory, and perception of reality are impaired. These substances are slightly hallucinogenic and cause CNS depression because of the hypoxia they induce. Abusive, violent behavior has also been known to occur in people who abuse inhalants.

Adverse Effects

Psychological dependence can develop, but physical dependence is rare. Tolerance to the substance can develop over time, and more of the substance is needed over time to produce the same effect.

Toxicities depend on the properties of the individual solvents. The consequences of inhaling these substances can be severe. Abuse of inhalants has been implicated in severe brain damage, cancer, neuropathies, kidney failure, liver damage, respiratory failure, and cardiac arrest.

Assessment of Core Patient Variables in Substance Abuse

Health Status

When the nurse suspects that a patient may be abusing substances, a physical, psychological, and functional health assessment is performed. Focus on the physical, psychological, emotional, and functional status of the patient (Table 9.4).

Substance abuse screening may be easily incorporated into a health habits survey, with questions moving from legal and less stigmatized substances, such as caffeine, nicotine, and alcohol, to inquiries about street drugs. Ask questions about drug use or abuse, which should cover lifetime experience, because recovering users remain at risk for relapse. In addition, take a complete health and drug history. During this time, try to obtain as much information about legal and illegal drug use as possible. When providing this information, the patient may use street names to refer to particular drugs or drug classes. Therefore, it is necessary to be familiar with commonly used street names for legal and illicit drugs (Table 9.5). At this time, also ask the patient about any family history of substance abuse. During the physical assessment, convey a nonjudgmental attitude, which may encourage the patient to communicate. A person is more likely to open up to someone who appears open and nonjudgmental. Do not assume someone is or is not a drug user. There is no stereotypical drug user. People who abuse drugs are from all socioeconomic and cultural backgrounds.

Life Span and Gender

Substance abuse throughout the life span poses serious problems for patients, families, and the community.

EFFECTS IN PREGNANCY

An estimated 10% of infants are exposed to illicit drugs during the gestational period. When alcohol, caffeine, and nicotine are considered, some researchers report as many as 33% of all pregnant women have used a psychoactive drug during pregnancy.

Alcohol use during pregnancy increases the risks of spontaneous abortions, fetal demise, problematic pregnancies, lower birth rate, and neonates who are slower to grow postnatally. Specific toxic effects of alcohol on the developing fetus are known as fetal alcohol syndrome (FAS). The incidence of FAS in some parts of the United States is estimated to be as high as 1 in 300 births. It is a common cause of preventable birth defects. FAS causes growth deficiency, CNS dysfunction, craniofacial abnormalities, microcephaly, and other major organ defects. Neither has any amount of alcohol been established as safe during pregnancy or lactation, nor has any time during pregnancy been determined as safe for drinking it. Alcohol is teratogenic, but unlike other teratogens, alcohol does not uniformly affect all fetuses exposed to it.

Fetal physiology differs from neonatal and adult physiology. These differences suggest that maternal ingestion of psychoactive substances may produce a more dramatic effect in the fetus.

Fetal nourishment occurs through the placenta. To reach the fetus, drugs in the maternal environment must cross over the continuous lipid membrane of the placenta. Substances with a molecular weight of less than 600 (such as alcohol and cocaine) cross over easily. Drug effects may persist for a greater length of time in the fetal environment because fetal blood is moderately acidotic and contains fewer protein-binding sites, and undeveloped hepatic function decreases the fetus' ability to metabolize and excrete the substance. Although excretion occurs through the placenta, the drug may be recirculated throughout the amniotic fluid before it is excreted.

The effects of opioid abuse during pregnancy include preterm birth, intrauterine growth retardation, and low birth weight. Cocaine use during pregnancy has disastrous effects on the fetus; it causes potent vasoconstriction that reduces placental blood flow by about 50%. This reduction results in fetal hypoxia and alters the maternal–fetal nutrient exchange. Fetal effects of maternal cocaine and methamphetamine use include abruptio placentae, preterm labor and delivery, intrauterine growth retardation, microcephaly, low birth weight, and cerebral infarction. Fetal exposure can be recognized in a neonate who exhibits a withdrawal syndrome characterized by tremor, poor feeding, increased muscle tone, abnormal sleep patterns, and high-pitched crying.

Women who use alcohol, opioids, cocaine, and methamphetamine should be counseled to avoid breast-feeding because these drugs are concentrated in breast milk.

EFFECTS IN INFANCY

Opioid-exposed infants experience several common complications: hypoglycemia, septicemia, and hyperbilirubinemia. In addition to metabolic problems, term infants are at risk for pneumonia and meconium aspiration. Preterm and full-term infants alike experience withdrawal symptoms. Narcotic abstinence syndrome, which contributes substantially to neonatal morbidity, is characterized by CNS hyperirritability, GI dysfunction, increased muscle tone, respiratory distress, tremor, and vague autonomic symptoms such as fever, skin mottling, sneezing, and yawning. Initially, some infants may require drug therapy and treatment in the neonatal intensive care unit. Some symptoms may persist for 3 or 4 months or more.

TABLE 9.4 Characteristics of Selected Drugs of Abuse

Drug	Method of Use	Intoxication Effects	Symptoms of Overdose	Health Consequences
Alcohol	Oral	Bloodshot and watery eyes, alcohol breath, motor incoordination, slurred speech, elevated blood pressure, nystagmus, mood swings and irritability, sedation	Severe vomiting or vomiting while "sleeping" or passed out and not waking up after vomiting; not responding to verbal or tactile stimulation; ataxic gait; slow, labored breathing; cold, clammy skin; rapid pulse; respiratory depression or arrest	Hypertension, GI bleeding, liver dysfunction, pancreatitis, gastric cancer
Benzodiazepines	Oral IV	Same as barbiturates	Same as barbiturates	Confusion, dizziness, impaired coordination/memory/ judgment, fatigue, addiction
Cannabis	Smoked Oral	Euphoria, slowed thinking/ reaction time, confusion, impaired balance/ coordination	Fatigue, paranoia, acute psychosis	Impaired memory/learning, anxiety, panic attacks, cough, frequent respiratory infection, increased heart rate, addiction
Cocaine	Snorted Smoked Injected	Increased heart rate/blood pressure/temperature, mental alertness, feelings of exhilaration, energy, pupil dilation, motor agitation	Agitation, paranoia, acute psychosis, seizures, respiratory failure, stroke, death	Reduced appetite, nausea, headaches, rapid/irregular heartbeat, chest pain, heart attack, stroke, convulsions
Flunitrazepam (Rohypnol)	Oral	Reduced pain/anxiety, feelings of well-being, lowered inhibitions, slowed pulse/ breathing, decreased blood pressure, poor concentration	Respiratory depression and arrest, death	Confusion, fatigue, memory loss for time under the drug's effects, impaired coordination/memory/ judgment, visual/ gastrointestinal disturbances, urinary retention
Methamphetamine	Oral Injected Snorted Smoked	Euphoria, hallucinations, hyperthermia, hyperreflexia, increased alertness, increased physical activity, insomnia, paranoia, tachycardia, restlessness	Restlessness, tremor, muscle twitches, rapid breathing, confusion, hallucinations, panic, aggressiveness, unexplained muscle pain or tenderness, muscle weakness, fever or flu symptoms, irregular heartbeat, seizure activity, and dark-colored urine.	Long-term neuron damage, heart attack, stroke, seizure disorder, fetal harm during pregnancy, xerostomia, progressive periodontitis, requires long-term psychological therapy to overcome intense cravings.
Methylphenidate	Oral Injected Snorted Smoked	Increased or decreased blood pressure/heart rate, mental alertness, energy, feelings of exhilaration	Vomiting, agitation, tremors, hyperreflexia, muscle twitching, convulsions (may be followed by coma), euphoria, confusion, hallucinations, delirium, sweating, flushing, headache, hyperpyrexia, tachycardia, palpitations, cardiac arrhythmias, hypertension, mydriasis, dryness of mucous membranes	Reduced appetite, digestive problems, rapid/irregular heartbeat, heart failure
Nicotine	Smoked Chewed	Increased heart rate/blood pressure, mental alertness, energy, feelings of exhilaration	Agitation, anxiety, seizures	Reduced appetite, rapid/irregular heartbeat, adverse pregnancy outcomes, chronic lung disease, cardiovascular disease, stroke, cancer, addiction
Opioids	Oral Injected Smoked Snorted	Apathy, euphoria, pinpoint pupils, sedation	Unconsciousness, respiratory depression and arrest, death	Collapsed veins, infection of the heart lining and valves, abscesses, cellulitis, liver disease and pulmonary complications such as pneumonia.
PCP and analogues	Oral Injected Smoked Snorted	Increased or decreased heart rate and blood pressure, impaired motor function, numbness	Violent behavior, paranoia, seizures, acute psychosis, heart failure, death	Memory loss, nausea or vomiting, loss of appetite, depression, panic, aggression, violence
Hallucinogens	Oral Snorted Smoked	Altered perception and feelings, tremor, numbness, insomnia, loss of appetite, weakness	Acute psychosis, death (frequently from trauma)	Chronic mental disorders, flashbacks

Peyote	Button, mesc, mescal, cactus
Psilocybin	Shrooms, magic mushrooms
PCP	Angel dust, Hog, love boat

EFFECTS IN CHILDHOOD

Children of people with alcoholism face a broad range of problems that vary in severity and are associated with all phases of the life span. They are at risk for a range of cognitive deficits, especially those related to verbal ability, ADHD, antisocial personality disorder, anxiety, and depression. The prevalence of alcoholism is higher than normal in all first-degree relatives of patients with alcoholism, and on average, children of people with alcoholism are three to five times more likely to develop alcoholism than children of people who do not have alcoholism. Many children of alcoholics develop intensely resilient personalities.

EFFECTS IN ADOLESCENCE

The greatest physical and emotional changes occur during adolescence. The struggle toward independence is a time of great conflict, and rebellion is common during this period. Common forms of rebellion include style of dress and appearance, although rebellion can take destructive forms, such as illicit drug use and excessive alcohol drinking.

Several risk factors have been identified for adolescent substance abuse:

- Family constitution and stressful family events
- Poor parent–child relationships
- Low self-esteem
- Psychological disturbances, such as depression
- Low academic motivation
- Other problem behaviors
- Absence of religion
- High level of thrill-seeking behavior
- High family and peer substance use
- Early tobacco use

EFFECTS IN OLDER ADULTS

In the United States, adults who are 65 years and older are the fastest-growing segment of the population. Retirement often brings changes in the older person's societal role as well as a decrease in social and financial status. Declining health, financial problems, and illness and death of family and friends are common losses of aging. Depressive symptoms related to these losses are common in older people. For some, alcohol or drug use becomes a way of coping with age-related changes, which normally cause physiologic changes. These changes have an important effect on how the body metabolizes drugs. Reductions in blood flow with age may result in an inability of the liver and kidneys to process drugs as efficiently as in youth; benzodiazepines, for example, are metabolized at about half the rate seen in a younger person, making these drugs more difficult to use in the older population.

Alcohol- and drug-related medical problems may not be recognized because multiple medical problems are common in the elderly, and they may be mistaken for age-related problems. Confusion, depression, falls and other accidents, idiosyncratic reaction to prescribed drugs, inattention to self-care, incontinence, labile moods, and malnutrition are all conditions that can be related either to normal age-related changes or to the use of alcohol or drugs.

Environment

As with other chronic drug use, heavy and chronic use of cocaine and methamphetamine is especially accompanied by dysphoria and anhedonia. Former substance abusers are at risk for relapse because the perceived cure for the dysphoria is more drug use. Recurrence of symptoms and intense drug craving may occur even after long abstinence. Environmental triggers may produce intense desire for the drug even after years of recovery.

Culture and Inherited Traits

Some populations, most notably East Asians and American Indians, exhibit an unusual response of facial flushing, vasodilation, and tachycardia after consuming ethanol. These people have a genetic deficiency in the enzyme aldehyde dehydrogenase, which leads to an accumulation of acetaldehyde even after consuming relatively small amounts of ethanol.

Nursing Diagnoses and Outcomes

A comprehensive nursing assessment yields subjective and objective data helpful in formulating nursing diagnoses and desired outcomes relevant to short- or long-term drug history and actual or potential health problems related to substance abuse. Nursing diagnoses may vary according to which substances are used and what symptoms appear. In addition to Deficient Knowledge, Disturbed Sensory Perception (Visual and Auditory), and Risk for Poisoning, additional typical nursing diagnoses and outcomes may include the following:

- Ineffective Denial related to impaired ability to accept consequences of behavior
  Desired outcome: *The patient will acknowledge an alcohol or substance abuse problem; explain the psychological and physiologic effects of alcohol or drug use; abstain from alcohol and drug use; state recognition of the need for continued treatment; express a sense of hope; use alternative coping mechanisms to cope with stress; and have a plan for high-risk situations for relapse.*
- Risk for Other-Directed Violence related to drug or alcohol abuse
  Desired outcome: *The patient will demonstrate control of behavior with assistance from others; have a decreased number of violent responses; and describe causation and possible preventive measures.*
- Ineffective Health Maintenance related to substance abuse
  Desired outcome: *The patient will identify barriers to health maintenance and will engage in (or verbalize an intent to engage in) health maintenance behaviors, including abstinence and sobriety.*
- Self-concept Disturbance related to self-destructive behavior (substance abuse)
  Desired outcome: *The patient will appraise self-situations in a realistic manner without distortions; verbalize and demonstrate increased positive feelings; and demonstrate healthy adaptation and coping skills.*

Planning and Intervention

In general, nursing interventions involve maximizing the therapeutic effects of the treatment plan, minimizing factors that may contribute to resumption of substance abuse, and providing patient education to help the patient cope with denial and recognize the importance of his or her substance abuse problem.

Maximizing Recovery

Initial nursing interventions in acutely intoxicated patients are generally directed toward preventing life-threatening or debilitating effects from the substance itself or its withdrawal. These nursing interventions evolve from the specific physiologic and psychological effects of the particular substance. For example, if the patient is experiencing hallucinogenic and CNS-stimulant intoxication or withdrawal, monitor vital signs and mental status and provide a quiet, dim, nonstimulating, nonthreatening environment. Additional monitoring focuses on emotional status and possible seizure activity.

Because physical or psychological withdrawal symptoms may follow abrupt cessation of a substance, the first intervention is medical detoxification if the person entering treatment is currently under the influence of drugs. Physiologic symptoms associated with drug withdrawal may be treated with various pharmacotherapies. For example, diazepam or lorazepam is used to modify the symptoms of alcohol withdrawal and prevent the seizures it can precipitate. Clonidine (Catapres) is frequently used to manage the symptoms of opioid and cocaine withdrawal.

Minimizing Relapse

For alcohol, cocaine, or narcotic abusers, treatment is lifelong, and relapses do occur. However, several therapies may promote motivation to remain substance free and increase the patient's chances for success. They include psychotherapy, support groups, and administration of withdrawal and anticraving drugs. Nursing management strategies in alcoholism are summarized in Box 9.5.

Some patients who have withdrawn from alcohol and who desire to achieve continued sobriety may elect to take the drug disulfiram (Antabuse). Its effects rely on a drug interaction (between ethanol and disulfiram) to produce unpleasant and undesirable symptoms as a deterrent to alcohol ingestion. The very unpleasant symptoms of a disulfiram–ethanol reaction include facial flushing, throbbing headache, hyperventilation, tachycardia, palpitations, nausea and copious vomiting (within 60 minutes after alcohol ingestion), hypotension, shortness of breath, vertigo, syncope, confusion, and profuse diaphoresis. In very severe reactions, myocardial infarction, cardiovascular collapse, unconsciousness, convulsions, and even death may occur.

Another drug used to assist with continued sobriety is naltrexone (ReVia). Naltrexone is available as an oral tablet that is given three times per week or an injectable drug that is administered monthly. This drug is also used to manage opiate addiction. Although the mechanism of action is not fully understood, it is theorized that blocking the opioid receptors by naltrexone may result in the blockade of the neurotransmitters in the brain that are believed to be involved with alcohol dependence. The most common adverse effects associated with naltrexone are dizziness, headache, anorexia, and nausea.

Box 9.5 NURSING MANAGEMENT STRATEGIES IN ALCOHOLISM

Nursing interventions are modified according to the problems and complications encountered in patients with alcoholism. Some general interventions follow.

Acute Alcohol Intoxication

- Maintain an open and adequate airway.
- Support respiration and blood pressure.
- Alleviate hypoglycemia, ketoacidosis, dehydration, and neurologic deficit by administering glucose and IV fluids containing potassium, magnesium, phosphate, and vitamins (thiamine, pyridoxine, and folic acid).

Alcohol Withdrawal Syndrome

- Administer drug therapy as prescribed (e.g., primarily benzodiazepines—chlordiazepoxide or lorazepam) to suppress the withdrawal syndrome.

Chronic Alcoholism

- Inform the patient of the necessity for complete abstinence from alcohol use, including alcohol in "benign" products such as cough syrups and food flavoring (vanilla extract).
- Refer the patient and family to social and environmental support groups, such as Alcoholics Anonymous, Alateen, Al-Anon.
- Teach about preventive medical and pharmacologic treatments, such as aversion therapy with disulfiram (Antabuse), hypnotherapy, psychotherapy, and treatment programs in private or public clinics outside of a hospital setting.

The newest drug approved by the FDA for the treatment of alcoholism is acamprosate (Campral). Acamprosate works by stabilizing the balance between CNS glutamate and GABA. Common adverse effects include GI distress and CNS effects such as anxiety, insomnia, and depression.

Patients withdrawing from cocaine addiction may be treated with amantadine (Symmetrel), bromocriptine (Parlodel), buprenorphine (Buprenex), carbamazepine (Tegretol), desipramine (Norpramin), and lithium. These drugs have been used clinically with varying degrees of success.

Treatment for heroin addicts is possible. However, the process is slow, and some methods used are somewhat controversial. Box 9.6 discusses the treatment of heroin addiction.

Treatment for marijuana abuse consists mainly of nonpharmacologic interventions combined with an exercise program to help deal with withdrawal symptoms and cravings for the drug.

Because no addiction results from LSD or PCP use, no withdrawal syndrome results, and no treatment is required. Treatment for LSD and PCP abuse is necessary only when the user experiences a bad trip. Box 9.7 provides guidelines for intervening on a "bad trip."

Treatment for acute inhalant intoxication is similar to that for CNS depressant overdose. Patients need oxygen and other respiratory assistance. They should not receive any

Box9.6 TREATING HEROIN ADDICTION

For many substance abusers, overcoming heroin or other opioid addiction is a long and difficult process. Over the years, many treatment interventions have been proposed and used with varying degrees of success, failure, and controversy.

Methadone (Dolophine, Methadose)

Oral methadone is substituted for heroin at a dose sufficient to suppress opioid withdrawal and then, theoretically, reduced by 50% every other day. This treatment effectively suppresses withdrawal symptoms and has a long duration of action (24 hours). About 1 mg of methadone is equivalent to 1.5 mg heroin.

Methadone treatment is controversial for several reasons: some practitioners argue that methadone therapy simply substitutes one addicting substance for another. Although the goal is to be drug free, many patients continue to take methadone rather than be tapered from the drug. Additionally, illicit methadone markets have developed because of the widespread use of methadone programs and the fact that patients are allowed to take larger quantities home and make fewer clinic visits.

Clonidine (Catapres)

Clonidine, an adrenergic agonist and antihypertensive drug, is useful in treating mild heroin dependence and withdrawal. It suppresses the sensory nervous system and the hyperactivity that accompanies withdrawal. Clonidine facilitates withdrawal in two ways: it may be substituted for methadone (after methadone facilitates withdrawal) and then withdrawn, or it may be used with the long-acting opioid antagonist naltrexone (ReVia) as a substitute for methadone. Ultimately, the clonidine is withdrawn, leaving the patient solely on naltrexone.

Naltrexone (ReVia)

A recent treatment option for heroin addiction is long-term naltrexone. Naltrexone is a long-acting narcotic antagonist. An oral dose of 50 mg effectively blocks the receptors for 24 hours so that heroin has no effect and the patient experiences no real pleasure from taking the drug. The decision to "do drugs" must be made a day in advance.

Buprenorphine (Buprenex, Suboxone, Subutex)

Buprenorphine, a semisynthetic mixed opiate agonist-antagonist, is the first therapy approved for in-office prescribing for opioid dependence under the federal Drug Addiction Treatment Act of 2000. In supervised drug rehabilitation programs, it is administered as a sublingual tablet. In unsupervised programs, buprenorphine is given as an oral drug combined with naloxone (an opioid antagonist). If the buprenorphine tablet is dissolved in water and injected, the full antagonistic effect of naloxone occurs. This effect does not occur when the drug is taken orally. In contrast to methadone, buprenorphine is given three times per week.

Psychiatric Treatment and Support Programs

Traditional psychiatric treatment has been relatively ineffective for heroin and other opioid addicts. Therapeutic communities led by health care professionals and ex-addicts appear to be somewhat more effective in treating recently detoxified users. These organizations help restructure the addict's lifestyle and orientation through leadership, group help, and self-help.

Box9.7 INTERVENING ON A "BAD TRIP"

Nursing interventions for managing the terrifying perceptions and hallucinations or "bad trips" resulting from LSD or PCP use rely on decreasing sensory stimuli and providing comfort and support. Some guidelines follow:

LSD

- Place the patient in a quiet room to decrease sensory stimuli.
- Remain with the patient, and help the patient to calm down by talking to him or her while panic and agitation are at a peak. This approach will help to alleviate fear and anxiety.
- Administer tranquilizers, barbiturates or benzodiazepines, or nicotinic acid as prescribed to counteract the chemical effects of LSD. Do not administer phenothiazines. They may induce hypotension, confusion, and an increased panic reaction because of their influence on the anticholinergic-like effects of LSD.

Ketamine (or PCP)

- Put the patient in a dark, quiet room, and closely observe him or her.
- Avoid verbal communication because any sensory stimuli may cause further reaction and agitation.
- If pharmacologic therapy is prescribed (e.g., benzodiazepines), administer as directed. As with bad LSD trips, phenothiazines should be avoided because of their addictive anticholinergic effects.

vasopressor therapy, such as injected epinephrine, because the interaction between a vasopressor and an inhalant may trigger serious arrhythmias.

Providing Patient and Family Education

After identifying a substance abuse problem, intervene by assisting the patient and family to develop ways to prevent substance abuse, such as communicating and reinforcing healthy coping strategies and stress-reduction behaviors; recognizing the patient's values, beliefs, and support systems; and identifying and encouraging contact with self-help groups, community resources, rehabilitative organizations, and support groups.

Help family members identify their feelings and responses to the substance abuse problem and cope with these feelings. Refer them to counseling services and emotional support groups. Entry into substance abuse treatment programs is frequently through an evaluation and referral center.

This is also an opportune time to teach the family more about the hazards of substance abuse. Explain that relapses may occur and that support groups (e.g., Alcoholics Anonymous, Alateen, Narcotics Anonymous) exist for helping the patient and family members to deal with relapses and to work through new problems related to recovery and altered relationships. The goal of treatment—longer and longer periods of abstinence and sobriety—is emphasized. Relapse prevention includes teaching patients to identify and manage feelings, recognize high-risk situations, and develop effective coping strategies.

Ongoing Assessment and Evaluation

Health consequences of substance abuse are usually manifested by changes in physiologic and behavioral functioning; therefore, evaluative guidelines related to detoxification, withdrawal, and rehabilitation correspond to signs that the patient has returned to normal physiologic and psychological functioning.

Nurses and other health care professionals have a community responsibility to provide information about substance abuse. Meeting this responsibility may involve providing information and counseling or referring patients, friends, and neighbors to treatment resources. Be familiar with the community resources, and keep up-to-date on common drug abuse problems and their treatment.

Recovery is lifelong and requires total abstinence from the abused substance. The recovering person can never return to controlled use without rekindling the addiction.

CHAPTER SUMMARY

- Substance abuse is a substantial problem nationwide and worldwide.
- Strong evidence supports a dopamine hypothesis of drug abuse and addiction and a biologically inherited tendency toward alcoholism.
- Drug abuse is a complex biopsychosocial problem that does not lend itself to simple solutions.
- Characteristics of drug abuse include tolerance, physical dependence, and psychological dependence.
- Drugs of abuse are categorized as CNS stimulants, CNS depressants, hallucinogens, cannabis, and miscellaneous drugs.
- The most commonly abused drugs are alcohol, cocaine, heroin, marijuana, caffeine, and nicotine.
- The nurse's role in substance abuse involves understanding core drug knowledge related to specific drugs, preventing abuse, assessing potential or actual abuse, and formulating nursing diagnoses related to the assessment findings.
- The nurse is pivotal in maximizing recovery, minimizing relapse, and providing patient and family education.

QUESTIONS FOR STUDY AND REVIEW

1. What adverse effects can occur if alcohol is taken concurrently with barbiturates, benzodiazepines, or other CNS depressants?
2. Define the following: drug abuse, drug misuse, addiction, physical dependence, and psychological dependence.
3. What factors place a person at high risk for substance abuse?
4. Methadone maintenance for opioid addiction is controversial. Why is this so?
5. Describe nursing interventions for a person experiencing a hallucinogenic "bad trip."
6. Name several drugs that are frequently associated with abuse, and propose some reasons that they are abused.

Lifestyle, Diet, and Habits: Nutrition and Complementary Medications

Learning Objectives

At the completion of this chapter the student will:

1. Discuss the role of nutrition in health maintenance.
2. Identify common nutritional factors affecting drug efficacy.
3. Identify common ways that drug therapy may alter nutritional status.
4. Differentiate prescribed uses of vitamins and herbal and botanical preparations from nonprescribed uses.
5. Identify core patient variables that increase the risk of the occurrence of drug–nutrient interactions.
6. Identify key aspects of nursing management to maximize therapeutic effect and minimize adverse effects from drug interactions with diet, diet supplements, and herbal and botanical preparations.

The core patient variable of lifestyle, diet, and habits represents the way a person lives his or her life and the choices he or she makes to accept or reject behaviors that influence health. In drug therapy, this variable is assessed according to how these factors interact with the prescribed drug therapy. This chapter focuses on normal dietary habits, including the use of herbal, botanical, and nutritional supplements.

The core patient variable of diet interacts with the patient's health in several ways. First, a well-balanced diet may prevent chronic illness and therefore indirectly decrease the need for drug therapy. Additionally, a well-balanced diet influences the pharmacokinetics of many drugs. Second, the nutritional status of a patient can be altered by a chronic disease or as an adverse effect of drug therapy. Nutritional supplements and herbal or botanical preparations may also be taken to increase wellness or to meet normal nutritional needs. Lastly, certain foods, beverages, dietary supplements, and herbal or botanical preparations can affect the absorption and effectiveness of some drugs or produce an adverse effect. These points are discussed in this chapter.

DIETARY FACTORS AFFECTING DRUG EFFICACY

Health status in general has a nutritional base. A proper, well-balanced diet provides a healthy person with an adequate supply of nutrients. Predicted drug response in the body is based on the ideal of a body that has the normal balance of elements, including dietary factors. When dietary factors are altered, drug therapy may produce different effects in the body than would normally occur.

Several factors related to malnutrition are believed to alter drug disposition. Box 10.1 describes various pharmacokinetic and nutrient interactions. Protein levels are one important factor. Diminished protein status results in lower amounts of plasma proteins and can substantially increase the concentration of free drug available. Because only free drug is active, this increase in free drug increases the drug's pharmacologic effect and the risk of adverse effects. Adequate protein levels are especially important for drugs that are normally highly protein bound. As explained in Chapter 4, albumin is the most important protein, in terms of drug action, because most protein binding by drugs occurs with albumin molecules. Drug binding to albumin is also affected by high-fat meals and fasting. Both of these situations lead to high serum levels of free fatty acids that compete with the drug for albumin-binding sites. Additionally, a diet poor in proteins may inhibit the biotransformation of drugs because protein deficiency may make drug-metabolizing systems less effective.

Malnourished people exhibit decreased oxidative metabolism and reduced glomerular filtration rate, potentially increasing blood concentrations of the drug or an active metabolite. This nutritional state increases the effect of the drug and the potential for adverse effects.

Box 10.1 PHARMACOKINETIC AND NUTRIENT INTERACTIONS

Absorption

- Changing the acidity of the digestive tract (e.g., rapid-acting carbohydrates, such as candy, cause sustained- or timed-release medication to dissolve too quickly)
- Stimulating secretion of digestive enzymes (e.g., griseofulvin is absorbed better when taken with foods—especially fat—that stimulate the release of digestive enzymes)
- Altering the rate of absorption (e.g., acidic foods and beverages interfere with nicotine absorption from nicotine gum used for smoking cessation; aspirin is more slowly absorbed when taken with food)
- Binding to drugs (e.g., calcium binds to tetracycline, limiting drug absorption)
- Competing for absorption sites in the intestines (e.g., dietary amino acids interfere with levodopa absorption)

Distribution

- Changing binding of drug allows more free drug in bloodstream (low protein)

Metabolism

- Acting as structural analogues (e.g., anticoagulants and vitamin K)
- Competition for metabolic enzyme systems (e.g., phenobarbital and folate)
- Altering enzyme activity and contributing pharmacologically active substances (e.g., monoamine-oxidase inhibitors and tyramine)

Excretion

- Changing the acidity of the urine (e.g., vitamin C can alter urinary pH and limit the excretion of aspirin)

Dietary factors that promote obesity have an indirect effect on drug therapy. Body composition is an important consideration in determining drug response. For example, distribution of fat-soluble drugs is increased in obese and the elderly because of the increased proportion of adipose tissue to lean body mass.

Excessive intake of vitamins may also adversely affect the action of some drugs. For example, increased

CRITICAL THINKING SCENARIO

MALNUTRITION AND DRUG ACTION

Larry Willis, a 35-year-old homeless man, is brought to the emergency department by the police, who found him collapsed and having a seizure on the street. He is malnourished. He is admitted to the hospital and started on a standard dose of phenytoin, a drug used to prevent seizures, which is a highly protein-bound drug. He is showing signs of adverse effects from the phenytoin.

Use your knowledge of the effect of diet on drug actions to determine why this man is having adverse effects.

pyridoxine intake may adversely affect the therapeutic effect of levodopa by increasing its metabolism. Increased or decreased intake of some elements may alter the absorption or reabsorption of a drug. For example, changes in the dietary intake of sodium alter the reabsorption of lithium in the renal tubule. Significant decreases in dietary sodium result in extra lithium being reabsorbed, higher circulating levels of lithium, and potential drug toxicity from elevated lithium levels.

Food and nutrient intake can affect drug excretion by changing the urinary pH. For example, acidic drugs are more rapidly excreted in alkaline urine. A diet rich in meat or in vegetables may also influence the urine pH—either acidic or basic—and in this way the renal excretion of drugs may be changed considerably because drugs are generally either weak organic acid or bases. Conversely, drugs may also interfere with the availability and use of certain nutrients (e.g., vitamins, electrolytes, or trace elements); this interaction may occur with the long-term administration of certain drugs (e.g., antibiotics, oral contraceptives, anticonvulsants, laxatives) or the chronic consumption of alcohol. Deficiency of certain nutritional factors or even diseases may be the consequence of such interactions.

A particular food, or the manner in which food is prepared, can also affect drug disposition. For example, grapefruit juice is a potent inhibitor of the intestinal cytochrome P-450 3A4 system (specifically, CYP3A4-mediated drug metabolism), which is responsible for the first-pass metabolism of many medications. This interaction can lead to increases in bioavailability and corresponding increases in serum drug levels. Appendix G describes drugs that interact with grapefruit or its juices. Cruciferous vegetables (broccoli, brussels sprouts, cabbage, cauliflower, rutabaga, turnips, kohlrabi, and kale, as well as greens such as mustard and collards) markedly induce chemical oxidations when added to the diet and increase drug metabolism. The polycyclic hydrocarbons—similar to those found in cigarette smoke—generated from charcoal broiling of foods may increase drug metabolism. As you remember, inducing drug metabolism results in a lower serum concentration (or a subtherapeutic level) of the drug.

Finally, the time that food and beverages are consumed in relation to the time drugs are taken may alter the effectiveness of the drug therapy. Some drugs must be taken on an empty stomach to promote absorption; some drugs bind with certain types of foods, which prevents drug absorption; and some drugs must be taken with food for best results.

DRUG THERAPY AND NUTRITIONAL STATUS

Drugs potentially affect the status of almost every nutrient. Particularly important to consider are vitamin A and the B vitamins folate and pyridoxine because intake of these vitamins is often marginal and many commonly used drugs affect them. Some drugs affect nutrient metabolism and excretion by an "antivitamin" process. They inhibit the synthesis of specific enzymes by competing for the vitamins or vitamin metabolites necessary to their structure. For example, the antineoplastic drug methotrexate is a folic acid antagonist. Without folic acid, synthesis of deoxyribonucleic acid (DNA) is inhibited, cell replication ceases, and cell death results. A drug may also form a complex with a nutrient, thereby making it unavailable for use by the body. For example, the antituberculosis drug isoniazid forms a complex with pyridoxine, interfering with its metabolism and resulting in vitamin B_6 deficiency.

Other "antivitamin" drugs include hydralazine and L-dopa (which affect levels of vitamin B_6) and the coumarin anticoagulants (which block the action of vitamin K to prolong bleeding time).

Some commonly used drugs have nutrition-related actions. For example, chronic phenytoin therapy is associated with folate deficiency and megaloblastic anemia. Folic acid and phenytoin are structurally similar and are thought to compete with each other for the same surface receptors. Diuretic drugs increase the excretion of nutrients by interfering with reabsorption in the renal tubules. Chronic use may result in depletion of potassium, magnesium, and zinc because renal excretion of these minerals is increased.

COMPLEMENTARY NUTRITIONAL THERAPIES

The use of nutritional supplements and herbal and botanical preparations is often considered an **alternative therapy** for health. Although these choices have been traditional in some non-Western cultures, they are now being used more frequently in Western cultures, where they have come to be viewed less as alternative practices to Western medicine and more as augmentations or supplements to health care. The term **complementary therapy** is now often used for these choices. Complementary nutritional therapies include supplements of basic food elements, vitamins, and minerals, as well as the use of herbs and botanicals.

Nutritional Supplements

If patients do not have enough of a nutrient, oral supplements of that nutrient may be prescribed as adjuncts to drug therapy.

Protein

Protein, which provides 4 kcal/g, is one of the most important and abundant substrates in the body. Generally, a patient requires 0.8 grams of protein per kilogram of body weight. The body may draw on dietary or tissue protein to obtain needed energy when the supply from carbohydrates and fats is inadequate. Proteins are polymers of essential amino acids, nonessential amino acids, or both. Although animal proteins generally contain sufficient essential amino acids, many plant proteins do not, and vegetarians may not eat a wide enough

variety of plants to ensure an adequate supply. Quality protein should provide approximately 10% to 15% of a healthy person's well-balanced diet.

People wishing to build muscle mass may take amino acid supplements and eat excess protein in the belief that increased protein intake facilitates the deposition of protein into muscles. However, ingested amounts exceeding those needed to replace body losses are simply converted into fat and stored. Some amino acids (e.g., L-carnitine) have gained popularity as preventive or therapeutic agents and are taken as dietary supplements. Their use may be hazardous in that there may be competition for transport with other amino acids into cells or the central nervous system (CNS). The research supporting their use is nonexistent or considered marginal by many nutritional experts. Supplements containing the essential amino acids lysine and arginine, promoted as regulators of body composition and muscle growth because these amino acids stimulate growth hormone secretion, have been proved clinically to lack these effects. Tryptophan has been used to enhance brain serotonin concentrations as a sleep inducer and in conjunction with weight-loss regimens.

Carbohydrates

Carbohydrates—especially sugars and starches—are the most common dietary component; they provide 4 kcal/g and constitute the body's primary source of fuel for heat and energy. A well-balanced diet for a healthy person supplies approximately 50% to 55% of the total kilocalories from carbohydrates. Carbohydrates are subdivided into simple or complex, depending on the size of the molecule. Simple sugars (e.g., fructose, sucrose) and refined sugars used primarily in soft drinks and baked goods are absorbed rapidly and quickly increase blood glucose. Conversely, starches are complex carbohydrates that must be digested; thus, absorption of glucose is slower, and serum levels of glucose, insulin, and triglycerides remain more stable.

The **glycemic index** represents how quickly the carbohydrate increases the blood glucose level. Simple carbohydrates have a high glycemic index while complex carbohydrates have a low glycemic index.

Some foods with a low glycemic index may actually be less healthy than some foods with a high glycemic index. For instance, potato chips have a lower glycemic index than brown rice. While the glycemic index is important, the glycemic load of a food is more important. The **glycemic load** includes both the glycemic index and the amount of carbohydrates in a particular food. For example, carrots have a high glycemic index but a limited amount of carbohydrates, thus it has a low glycemic load.

Fat

Dietary fats from animal and plant sources provide the body's alternate or storage form of heat and energy. Fat—a more concentrated fuel—supplies 9 kcal/g. Fat should supply no more than 30% of the total intake of a well-balanced diet in a healthy person (or fewer than 90 g/d). Triglycerides are the predominant dietary lipids. Other important natural and dietary lipids include cholesterol and its esters and phospholipids. Cholesterol is an important component of cell membranes and a precursor of steroid hormones. Phospholipids, like cholesterol, are important components of cellular membranes and intracellular organelles. Although the body is able to synthesize adequate amounts of phospholipids, phospholipid compounds are marketed as over-the-counter (OTC) health aids (e.g., lecithin) for treating or preventing aging, cancer, heart disease, obesity, and other conditions. Data to support these claims are limited or nonexistent.

Essential fatty acids—linolenic acids (omega-3; derived from corn, peanuts, soybeans) and linoleic acids (omega-6; derived from halibut, salmon)—must be supplied in the diet. Patients who are receiving all of their nutrition parenterally need to have fats administered to meet all their nutritional needs.

Dietary Fiber

Dietary fiber—a group of plant substances resistant to human digestion—is categorized by the food industry as soluble (dissolves in neutral or acid detergent) or insoluble (does not dissolve). Important characteristics of fiber are its water-retention ability, cation exchange properties, and antioxidant actions. Fiber added to the diet may be recommended to treat or prevent constipation, which can be an adverse effect of some drug therapies. If the patient cannot consume sufficient oral dietary fiber, drug therapies of bulk-producing laxatives, such as psyllium, may be prescribed.

Recommended Intake of Vitamin and Minerals

The Institute of Medicine (IOM) of the National Academy of Sciences is responsible for determining the recommended amount of vitamin and minerals required to keep a person healthy. Dietary Reference Intake (DRI) is the general term for a set of reference values used for planning and assessing nutrient intakes of healthy people. DRI is determined by evaluation of three important types of reference values: Recommended Dietary Allowances (RDA), Adequate Intakes (AI), and Tolerable Upper Intake Levels (UL). The RDA recommends the average daily intake that is sufficient to meet the nutrient requirements of nearly all (97% to 98%) healthy individuals in each age and gender group. An AI is set when there is insufficient scientific data available to establish a RDA. AIs meet or exceed the amount needed to maintain a nutritional state of adequacy in nearly all members of a specific age and gender group. The UL is the maximum daily intake that is unlikely to result in adverse effects.

Vitamins

Vitamins are a chemically diverse group of organic compounds needed by the body to maintain health by regulating metabolism and assisting in the biochemistry of food digestion as cofactors for enzymes. Small quantities of each necessary vitamin must be obtained exogenously, either because the vitamin cannot be synthesized in humans or because its rate of synthesis is too slow to produce sufficient quantities. The Food and Drug Administration considers nearly all vitamin products to be dietary supplements, and they are controlled by the Dietary Health and Supplement Education Act. Vitamins are generally classified as water soluble or lipid soluble. There are 13 vitamins—A, D, E, K (lipid soluble), vitamin C, and 8 B-complex vitamins (water soluble). Water-soluble vitamins are stored in the body only to a limited extent, and frequent consumption of these compounds is needed to maintain adequate body levels. Conversely, lipid-soluble vitamins are maintained in the body much longer, do not require such frequent ingestion, and have a greater potential for toxicity if taken in excess.

Vitamins may be prescribed when general nutritional status is poor, oral intake is insufficient, or the body has additional demands for a vitamin, such as vitamin C to promote wound healing. Vitamin supplements may also be prescribed to correct for general malnutrition to achieve optimal health or to maximize the therapeutic effects and minimize the adverse effects from drug therapy. When vitamins and minerals are taken in excess, potential adverse effects may occur. At the same time, many drugs can contribute to the deficiency of many vitamins.

Minerals

Major Mineral Cations

Major **mineral cations** include calcium, magnesium, potassium, and sodium. Their movement across cell membranes is highly regulated; they function in energy metabolism, membrane transport, and maintenance of membrane potential.

Potassium is the principal intracellular cation in body tissues. It has an important role in many physiologic processes, including transmission of nerve impulses; contraction of cardiac, skeletal, and smooth muscle; acid-base balance; and maintenance of normal renal function. Sodium functions to maintain the body's balance of calcium and potassium. It has an important effect in cardiac function, regulating osmotic pressure in the cells and fluids, acting as an ion balance in the tissues, producing a buffering action in the blood, and guarding against excessive loss of water from the tissues. No DRI for potassium and sodium has been established. Calcium is a critical component of the skeleton and is vital to neuromuscular transmission, cellular signaling, and blood clotting. The adult DRI is 1300 mg. Magnesium is involved in a great number of enzymatic reactions. Deficiency produces osteomalacia, neuromuscular disorders, seizures, and cardiac dysrhythmias. The adult DRI is 420 mg daily. Excess magnesium may cause CNS changes, hypotension, and cardiac toxicity including cardiac arrest.

If a patient is severely deficient in one or more of these electrolytes, intravenous (IV) replacement is used to prevent serious complications, and oral replacements may be ordered to treat less severe deficits. Electrolyte imbalances may increase the risk for adverse effects from some drug therapies. They may also occur as an adverse effect resulting from some drug therapies. Supplements are often used as adjuncts to drug therapy for these reasons.

Trace Elements

There are a number of essential **trace elements,** also known as microminerals. The most important of these include chromium, copper, iron, selenium, and zinc. Trace elements are present in minute amounts in body tissues and are essential to optimal growth, health, and development. Seafood is usually rich in nearly all micronutrients except manganese, which is readily available from plant sources.

Chromium improves insulin action, and a deficiency may cause elevated levels of blood sugar, cholesterol, and triglycerides. Copper is used in making blood cells and is active in the metabolism of iron. Copper-containing enzymes are involved in immune functions. Severe illness, high-dose zinc supplementation, and antacids can reduce absorption of copper. Supplementation may be necessary with zidovudine treatment (because zidovudine reduces copper levels) and with total parenteral nutrition.

Iron is an essential nutrient. It is needed to make red blood cells; deficiency results in anemia. Iron participates in oxidation and reduction reactions. It must be tightly bound to serum proteins to prevent potentially destructive oxidant effects. Bound to serum proteins, it is first stored and then distributed throughout the body.

Selenium is an especially important antioxidant. Its levels correlate with immune function—specifically, albumin levels, lean body mass, and total lymphocyte count. Deficiency occurs in infection and increased metabolic rates. Deficiency is also associated with heart disease and anemia.

Zinc is absorbed in the small intestine; high-fiber diets limit its absorption. Zinc promotes wound healing and functions in antibody production. Deficiency impairs protein metabolism and the immune response.

The trace minerals may be administered if dietary intake is low or the patient is malnourished. They are usually included in a multivitamin formula. Correction of generalized malnourishment is often an adjunct to drug therapy to achieve maximum therapeutic effect from the drug or to prevent adverse effects from drug therapy.

Herbal and Botanical Preparations

Herbal preparations and **botanical preparations** are those substances derived from a plant source and used as a dietary

supplement or as a medication. Although herbal and botanical preparations have been traditional in some non-Western cultures, they are now being used more frequently in Western cultures as augmentations or supplements to health care. To illustrate this point, United States sales of herbal supplements increased to over 4 billion dollars in 2007. This revival of interest in herbal, botanical, and dietary supplements in the United States during the past two decades can be attributed to an aging population with a large number of chronic diseases. Many of these diseases have no satisfactory conventional medical treatments, or the conventional treatment for them involves severely limiting adverse effects. Interest can also be attributed to a pervasive "back to nature" movement in a society increasingly attracted to good nutrition, exercise, and preventive health care as a means of remaining young and active.

Plants have historically been used for medicinal purposes. Many drugs used today are derived from plants. Therapeutic agents derived from plants or the preparations made from them are called **phytomedicinals**. Aspirin, for example, comes from the bark of the willow tree, and digoxin is derived from digitalis or purple foxglove. Today, many herbs and other plant substances are being sold as OTC preparations. Many of the most popular herbal, botanical, and dietary preparations are marketed as a means of preventing aging-associated disorders, providing energy enhancement and a feeling of well-being, and assisting with weight loss; they are also sold for more traditional therapeutic uses. Regulation of these products may be limited because they are considered food sources rather than drug therapies. The bioavailability, or activity, of a preparation may vary widely between manufacturers. Consumers tend to think of these substances as harmless because they are sold over the counter. In actuality, like prescription drugs, herbal preparations can cause substantial adverse effects (Table 10.1). Furthermore, herbs may interact with prescribed drugs in ways that affect their therapeutic response. Table 10.2 presents selected herbs and possible drug interactions.

Because of the increased OTC use of herbs and botanicals, Western medicine has recently examined many of these substances in clinical studies. Some findings support using these substances to treat or manage disease or altered physiology. For example, a health care provider may prescribe an herb such as St. John's wort for depression or saw palmetto for benign prostatic hypertrophy.

Nursing Management of the Patient With Dietary Considerations

Assessment of Relevant Core Patient Variables

Abnormal dietary intake and the use of herbs and nutritional supplements may have a bearing on drug therapy; therefore, question the patient during an initial drug assessment to uncover relevant information. If the assessment reveals an abnormal dietary intake, such as low protein or malnutrition, the deficiency must be corrected in some way. Determine why the patient is malnourished. Does the patient make poor choices as to what to eat, or is there a lack of money to buy food? Is there insufficient knowledge about what types of food should be in a balanced diet? Is the patient unable to feed himself because of muscle weakness? Is impaired cognition causing the patient to forget to eat? Does the patient have nausea or loss of appetite either from a disease process or as an adverse effect of drug therapy?

To assess the use of herbs and nutritional supplements, focus data collection on what substances the patient takes (e.g., drugs, nutritional supplements, herbs, and other preparations); why the patient takes them; which brands are used; and who recommended their use. This information is important and will help determine whether the desired effect of self-administered drug therapy is based on fact, fad, or tradition.

Also, document the patient's age and life span status, because many of these therapies are not recommended for use with children, during pregnancy, or during lactation. Carefully assess older adults, patients who are chronically ill, those with a history of marginal or inadequate nutritional intake, and anyone receiving multidrug therapy over an extended period, because such patients are likely to have drug-induced nutritional deficiencies. Because the effects of drug therapy can be altered by specific foods, the

time that a patient normally consumes food and beverages before self-administering drug therapy at home should be determined.

Nursing Diagnoses and Outcomes

Nursing diagnoses and outcomes related to nutritional considerations vary depending on the dietary factor and the drug therapy that the patient is receiving. Some potential general diagnoses include:

- Risk for Injury related to low protein levels and malnutrition
  Desired outcome: *Protein levels and malnutrition will be corrected to prevent adverse effects from drug therapy.*
- Risk for Injury related to adverse effects from excessive use of vitamins or herbs
  Desired outcome: *The patient will not develop any adverse effects while using nutritional supplements.*
- Risk for Injury related to drug interactions of vitamins, herbs, or food intake with prescribed drug therapy
  Desired outcome: *Drug interactions will be prevented while the patient is on drug therapy.*
- Deficient Knowledge related to interactions of vitamins or herbs with drug therapy
  Desired outcome: *The patient will obtain sufficient knowledge to make knowledgeable choices about the use of vitamins and herbs while on drug therapy.*
- Health-Seeking Behaviors related to the use of nutritional supplements
  Desired outcome: *The patient will effectively use nutritional supplements to complement drug therapy to increase health.*

Planning and Intervention

Maximizing Therapeutic Effects and Minimizing Adverse Effects

If the patient has been determined to have low protein levels, consult with the physician or nurse practitioner about protein replacement. Oral protein supplements or a high-protein diet may be ordered. If levels are substantially below normal, IV infusions of albumin may be indicated. If the patient is generally malnourished but eating, encourage him or her to eat a well-balanced diet. Verify that the patient is capable of feeding himself or herself and offer appropriate assistance if needed. Work with the physician or nurse practitioner to alleviate nausea, vomiting, or loss of appetite related to disease process or drug therapy that prevents sufficient oral intake.

If the patient cannot take in enough food orally, vitamins or other nutritional supplements may be ordered. In some cases, enteral nutrition (i.e., tube feedings) or total parenteral nutrition may be necessary to correct the imbalances.

If the assessment reveals that the patient is at risk for an interaction among a prescribed drug and foods, nutrients, herbs or nutritional supplements, discuss with the patient the many ways that these interactions affect nutritional status and drug therapy effectiveness. It may also be necessary to discuss these findings with the prescriber of drug therapy.

Many of the nurse's actions to maximize the therapeutic effect or minimize the adverse effects of drug therapy, in relation to dietary factors, are centered around patient education.

Providing Patient and Family Education

- Teach patients about the potential interactions of food, nutrients, and complementary nutritional therapies with prescribed drug therapy.
- Emphasize to patients and families the importance of being well nourished while receiving prescribed drug therapy.
- Teach patients when to take the prescribed drug in relation to meals if timing is relevant for the particular drug (e.g., should the drug be taken on an empty stomach to promote absorption?).
- Encourage patients to inform all their health care providers about all dietary supplements used.
- Teach patients that botanical supplements should be used as treatment for serious health conditions only with the advice and supervision of a qualified health practitioner.
- Instruct the parents of children and pregnant women or breast-feeding mothers not to use botanical products unless advised to do so by a qualified health practitioner, particularly if using these products is associated with toxicity or drug and food interactions.
- Counsel patients about the variable quality of nutritional products.
- Advise patients to watch for any unusual reactions to any medication and to report them to the health care provider.

Ongoing Assessment and Evaluation

Assess for potential drug interactions when a patient is taking any dietary supplement or herbal preparation in addition to prescribed drug therapy. These interactions may reduce the therapeutic effect of the prescribed drug, or cause adverse effects from either the prescribed drug or the supplemental therapy. Drug therapy can be evaluated as effective if dietary factors have not impaired drug action or produced adverse effects. Dietary treatments may be evaluated as effective if they return the patient to a normal physiologic status, or if they work efficiently as adjuncts to drug therapy.

CHAPTER SUMMARY

- Numerous medications and nutrients interact, which can lead to imbalances or interfere with drug effectiveness.
- Supplementary use of vitamins, herbals, and botanicals may be prescribed by a health care provider to meet normal nutritional needs or to treat diseases or pathologies. The use of these nutritional supplements may also be self-prescribed by the patient.
- Foods and nutrients can alter the absorption, distribution, metabolism, and excretion of medications.
- Adverse drug–nutrient interactions are most likely to occur with medications taken for chronic conditions, if several medications are taken, or if nutrition status is poor or deteriorating.
- When assessing for the extent of drug–nutrient interactions, it is important that the nurse consider the patient's age, drug dose, and duration of therapy with medications known to have an adverse effect on nutrients.
- The glycemic index and the glycemic load offer important information to guide the patient to a well-balanced, healthy diet.
- Dietary Reference Intake (DRI) is the general term for a set of reference values used for planning and assessing nutrient intakes of healthy people. DRI includes the Recommended Dietary Allowances (RDA), Adequate Intakes (AI), and Tolerable Upper Intake Levels (UL).
- Patients may not recognize the importance of mentioning their use of dietary supplements or their normal dietary patterns during a drug history. Nurses need to be aware of this lack of awareness and routinely ask patients about this information.

QUESTIONS FOR STUDY AND REVIEW

1. What factors in a patient's drug history suggest a likelihood of drug–nutrient interactions?
2. Describe how drugs and nutrients can interact and alter metabolism.
3. Describe how foods can alter drug absorption.
4. Why is it important for the nurse to routinely assess patients for their use of dietary supplements or herbal preparations?

Environment: Influences on Drug Therapy

Learning Objectives

At the completion of this chapter the student will:

1. Identify environmental settings appropriate for pharmacotherapy.
2. Identify limitations for drug therapy for each specific environmental setting.
3. Discuss the importance of medication reconciliation in relationship to patient safety.
4. Discuss environmental influences on drug stability and effectiveness.
5. Discuss environmental influences on adverse effects of drug therapy.
6. Identify the relationship between environment and occupation.
7. Identify the role of the nurse regarding environmental influences on drug therapy.

Key Terms

environment
hepatic drug-metabolizing enzymes
industrial chemicals
medication reconciliation
pollutants

The core patient variable of **environment** also is relevant to drug therapy. There are three aspects of environment related to drug administration. The first aspect of environment is the physical setting in which the drug is administered. The second aspect of environment is environmental influences that may affect the stability or efficacy of certain drugs or drug classes. The third aspect of environment is the factors that may increase the risk of adverse effects, injury, or toxicity from drug therapy (Figure 11.1).

These aspects of environment as well as the nurse's role regarding environment and pharmacotherapy are discussed in this chapter.

PHYSICAL SETTINGS FOR DRUG THERAPY

Drug therapy may be administered in a variety of settings. These settings include acute care hospitals, acute rehabilitative units, transitional care units, outpatient units, long-term care facilities, and the home or community environment. Many factors influence whether a particular drug or class of drugs may be administered safely in a specific physical setting.

Acute Care Hospitals

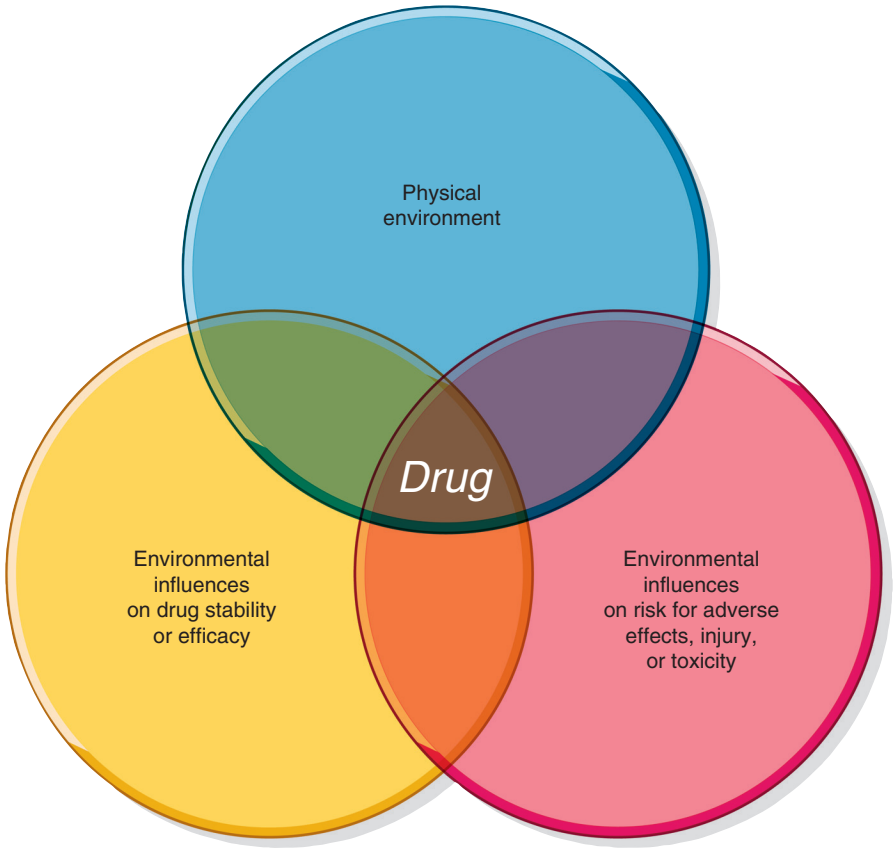
Although most types of drugs are administered in acute care hospitals, certain drugs or drug classes are given in specific areas of these hospitals. For instance, the patient receiving intravenous (IV) digoxin (Lanoxin) requires continuous heart monitoring. This requirement necessitates that the drug be administered in a critical care unit, step-down unit, or other specialized area that has both a specially trained nurse and the appropriate equipment, such as cardiac monitors, to assess the patient continuously.

Surgical patients receive inhaled anesthetics such as tubocurarine (Tubarine) only in the surgical suite, where the anesthesiologist or nurse anesthetist monitors the patient. Patients in active labor or immediately after delivery receive drugs such as oxytocin (Pitocin) in the delivery suite or postpartum unit. Alternatively, in an emergency, oxytocin may also be administered in the emergency department. Although these drugs are used for different medical problems, the common theme is that they require specialized nurses to administer them in a specialized unit of the acute care hospital.

Although most oncology drugs, such as 5-fluorouracil (5-FU), may be given on any medical unit, the administration of these agents is restricted to specially trained nurses. These nurses must understand specifics about handling chemotherapeutic drugs, recognizing and administering rapid treatment of severe adverse effects, and properly disposing of oncologic drugs (see Chapters 55 and 56).

Acute Rehabilitative Units

Acute rehabilitative units (ARUs) may be located in a portion of the acute care facility or another site off the main campus of the hospital. Although drugs given by most routes,



• FIGURE 11.1 The physical environment, environmental influences on drug stability or efficacy, and environmental influences that increase the patient's risk of adverse effects, injury, or toxicity intersect to affect the action of a drug.

including IV drugs, can be administered on these units, ARUs are developed to focus on the physical rehabilitation of the patient. Therefore, if the patient needs medication that requires close monitoring, or equipment such as cardiac monitors, the patient is moved back into the acute care hospital.

Transitional Care Units

Transitional care units (TCUs) have been developed to continue care of patients who are well enough to be discharged from the acute care facility but may not be eligible for a long-term facility because they need IV drug therapy or intense physical therapy. Like an ARU, these units may be in a portion of the acute care facility or in a different location. Because the patient-to-nurse ratio is higher in the TCU, drug therapy that requires close monitoring or equipment such as cardiac monitors limits the type of pharmacotherapy administered in this type of unit.

Outpatient Units

In the acute care facility, the term *outpatient* refers to the patient who arrives in the morning for a procedure with the expectation of returning home after the procedure is completed. Occasionally, the patient has a complication that requires that she or he be admitted to the acute care facility after the procedure.

In the community, *outpatient* refers to a patient who receives health care in an environment other than the acute care setting. These environments may include urgent care centers, physicians' offices, mental health clinics, or outpatient surgical suites.

Most pharmacotherapy may be administered in outpatient units as long as the particular site has the ability to monitor the patient closely and has life-saving equipment and drugs readily available. In some cases, on-site laboratory testing also may be required. For instance, before administering intramuscular gold salts, a complete blood count and urinalysis must be performed.

Outpatient chemotherapy is performed routinely. The limitation in the acute care setting—the need for specialized personnel—is also pertinent in the outpatient setting. Additionally, disposal of chemotherapeutic agents must be addressed carefully in this environment.

Long-Term Care Facilities

Long-term care facilities generally admit patients who do not require intense observation. These patients range from trauma patients to elderly people who will live out the remainder of their lives in the facility. The care in any given long-term care institution may be very limited or quite broad. The administration of certain drugs may necessitate the ability to intervene with life-saving equipment and other measures. While most facilities are capable of administering IV medications, they do not do so if the particular medication also requires special monitoring equipment. Some facilities, however, provide specific acute long-term care, such as the use of ventilators.

CRITICAL THINKING SCENARIO

Your patient has been involved in a major automobile accident and sustained a fracture of his femur. While talking with the patient, he remarks, "I feel like I am going to jump out of my skin. I haven't had my Ativan in 2 days." How would you respond?

Home Environment

Most drug routes are safe for administering medication in the home environment. Limiting factors include the need to monitor the patient closely and the need for special monitoring equipment. Although some patients receive pharmacotherapy from a home health nurse, many other patients are taught to self-administer medications, or family members and friends are taught to deliver the drugs safely.

The decision to teach the patient or family to administer drugs is made after a careful evaluation of the home environment by the home health nurse. Assessing the patient's environment may give important clues to its potential influence on therapeutic effectiveness, the patient's adherence to the drug regimen, and the potential risks from drug therapy itself. For example, if a patient is receiving a drug that causes dizziness as an adverse effect, stairs in the home may pose a risk for falls or injury. General factors to consider in the home include cleanliness; lighting; adequate heat, water, and refrigeration; and walkways in and around the house that are unobstructed and in good repair.

In addition, it is necessary to determine whether the patient lives alone or with other family members or caregivers who can help with the responsibilities of health care and assist with obtaining and administering drug therapy if needed. The hospital discharge planner assesses the patient's ability to monitor therapeutic effects and recognize any adverse drug effects, as well as whether the patient has the required financial resources, transportation, and knowledge to obtain the drugs.

MEDICATION RECONCILIATION

Errors in medication administration may occur in any of the previously described environments. The Institute for Healthcare Improvement (IHI) estimates that as many as 50% of all medication errors in hospitals occur because of poorly communicated medical information, which may occur during patient transfer from one location to another within the same health care facility or during transfer to a new health care environment. In 2001, the IHI launched its 100,000 Lives Campaign to improve patient outcomes. In 2006, the Joint Commission for accreditation of healthcare organizations set a goal requiring all accredited facilities to have protocols for documenting and reconciling medications across the environmental continuum.

Medication reconciliation is a systematic process in which the patient's medication history is compared to the current list of

prescribed medications. In most facilities, this process is done by the nurse, however, in some hospitals the process may be done by the pharmacist as well. Medication reconciliation also may be done in an outpatient setting, such as a provider's office. The goal of medication reconciliation is to improve patient outcomes by potentially preventing serious adverse effects.

The nurse is responsible for collecting the patient's medication history, including over-the-counter medications, vitamins, and herbs or other supplements, from the patient or patient's family. After that information is obtained, the nurse compares the medications ordered by the health care provider with the list of medications obtained from the patient or family. The nurse communicates any discrepancies between these lists to the health care provider, including any differences in the appropriate dose of medications. This process continues each time the patient is transferred from one setting to another, even within the same facility. When the patient is discharged, the nurse compares the medications administered in the hospital with the discharge medication orders and again discusses any discrepancies with the health care provider. Finally, the nurse teaches the patient, the patient's family, or the patient's caregiver the name, dose, and frequency of the medication to be taken at home, potential adverse effects, and what adverse effects necessitate contact with the health care provider.

ENVIRONMENTAL INFLUENCES ON DRUG STABILITY AND EFFECTS

Many drugs are sensitive to the physical environment. Excess heat, light, or moisture or sudden temperature changes can affect the stability of a drug, and many drugs lose their potency when exposed to these elements. For example, nitroglycerin, a drug used for acute anginal pain, is affected by air, light, and moisture. Because of these environmental interactions, the nurse is responsible for the safe storage of the drug away from elements that can decrease its effectiveness. In addition, patient education must include the importance of keeping the drug in its original container and the need to replace the patient's supply frequently.

The environment can also modify drug effects. For example, temperature affects drug activity. Heat relaxes peripheral vessels, accelerates the circulation, and thus intensifies the actions of some drugs such as vasodilators; cold has the opposite effect—it retards drug action by constricting the blood vessels and slowing circulation. High altitude puts the body under stress, and relative oxygen deprivation at high altitudes may make some drugs ineffective, whereas it increases the sensitivity to others, such as alcohol and central nervous system depressants.

Environmental influences can affect pharmacotherapy in any environmental setting, not just the home environment. For instance, some IV drugs that are administered in the acute hospital setting, such as nitroprusside and amphotericin B, must be covered in aluminum foil or with a brown bag during administration to avoid light sensitivity.

ENVIRONMENTAL INFLUENCES ON ADVERSE EFFECTS AND INJURY

Environmental chemicals are increasingly being recognized as agents that cause substantial drug interactions in some people. For example, polychlorinated biphenyls (found in industrial solvents or used as flame retardant), polycyclic aromatic hydrocarbons (caused by incomplete combustion of organic materials and found in cigarette smoke), chlorinated hydrocarbons (found in pesticides), and consumption of ethanol are active inducers of **hepatic drug-metabolizing enzymes.** People chronically exposed to these chemicals metabolize some drugs (e.g., cimetidine, theophylline) more rapidly than normal.

A patient's environment may also influence the relationship between physiologic function, drug effects, and adverse effects or injury. Alcohol, tobacco, or pesticides may alter the pharmacokinetics of certain drugs and increase the patient's risk for adverse drug effects. For example, benzodiazepines such as lorazepam (Ativan), in combination with alcohol, may increase the adverse effect of respiratory depression to such an extent that death may occur. Another example is heat and antihypertensive drugs. Almost all of the antihypertensive drugs may cause the adverse effect of orthostatic hypotension. The combination of pharmacotherapy for hypertension with soaking in a spa or hot tub may lead to syncope. Photosensitivity is another potentially adverse effect that is associated with many different types of drugs. When a patient is taking a drug that causes photosensitivity, the nurse assesses the patient's life style for potential exposure to sunlight and emphasizes ways to minimize this potential adverse effect. Appendix G lists common drugs that may induce photosensitivity.

The role of the home health nurse is to assess the physical environment of the patient to determine the limitations for home pharmacotherapy. That assessment should also extend to finding ways to decrease the potential for injury related to pharmacotherapy. For example, many patients receive narcotic analgesics to control pain when they return home. Some of the most frequent adverse effects to narcotic analgesics are sedation and dizziness. The home health nurse identifies potential hazards in the home environment, such as stairs and loose rugs, to teach the patient to avoid these potential hazards when feeling sedated or dizzy.

Simple daily activities also may be affected by environmental influences of pharmacotherapy. For instance, the patient who is a stay-at-home mother may not recognize that the heat of her home can increase the adverse effects of sedation and weakness when taking certain drugs. When she attempts to make dinner, a simple task such as cutting up vegetables may become hazardous.

In the broad context of environmental influences, the patient's occupation also must be considered. Certain types of adverse effects, such as sedation and dizziness, are enhanced by environmental influences and can lead to serious or deadly harm to patients with certain occupations. For instance, sedation or dizziness in a patient who works as a

taxicab driver may lead to accident and injury to the patient as well as others in his or her cab. Drugs that cause photosensitivity may actually cause partial-thickness burns in a patient who works as a lifeguard. Before the patient is discharged from the hospital, the nurse evaluates the patient's risk for adverse events based on his or her life style.

Patients who work in an environment that exposes them to **industrial chemicals** and pesticides have the highest risk for adverse effects and drug toxicity because these environmental **pollutants** affect drug biotransformation. These factors are thought to be responsible for decreased efficacy, prolonged pharmacologic effects, and increased toxicity.

A large number of drugs and chemicals, environmental pollutants, and endogenous substances are extensively metabolized in the liver before being excreted from the body. The environment can influence the metabolism of these substances. A variety of factors in the environment can influence the metabolism of chemicals by CYP450-dependent enzymes. These include concurrent drug treatment, cigarette smoking, and exposure to occupational and environmental pollutants.

THE NURSE'S ROLE

The nurse's role is extending more frequently beyond inpatient hospital settings to homes, schools, and industry. The nurse's role now includes the expanded range of health care concerns of health education, home health care, hospice, and public health because people are now being discharged from health care institutions at increasingly early stages in their treatment. Nurses monitor drug response and provide patient education about medication in a variety of patient care environments.

Nursing Management of the Patient with Environmental Considerations

Assessment

Drug action is not exclusively a biologic phenomenon. Environment is an important determinant of drug response. A number of components of the institutional environment are under the control of nursing. In the hospital, assess factors that influence drug outcome, such as a new or strange environment; unfamiliar people, noises, and equipment or procedures; and lack of physical activity. All of these factors may increase the need for some medications, such as analgesics, laxatives, and sedative-hypnotics. For example, providing a quiet, cool environment and reducing external stimuli to decrease tension and stimulation enhances the anxiolytic effects of sedative drugs.

Controlling the environment after discharge is a much more difficult task for the nurse. It is necessary to determine the environment in which the drug will be administered because drug therapies may occur in multiple environments. For example, patients may start chemotherapy or antidiabetic therapy in one environment, such as the acute care hospital, and continue therapy in the home environment.

People may not realize that environmental factors may affect their prescribed drug therapy. With that possibility in mind and to safeguard patients, conduct a complete drug assessment focusing on environmental and occupational influences.

Nursing Diagnoses and Outcomes

- Risk for Injury related to environmental hazards such as falls from stairs or loose rugs

Desired outcome: *The patient will remain without a fall.*

- Risk for Injury related to decreased drug stability stemming from environmental factors

Desired outcome: *The patient will store drugs as directed.*

- Impaired Skin Integrity related to environmental exposure to sunlight

Desired outcome: *The patient will take measures to control the amount of direct sunlight to exposed skin and use sunscreen at all times.*

Planning and Intervention

The planning and intervention phases of the nursing process contain short- and long-term goals. Often, these goals are modified as therapy proceeds. When working with patients to blend the element of environment into a regimen that promotes health maintenance and disease prevention, the nurse's role may be broad and include elements of advocacy, education, referral, consultation, clinical care, management, organization, research, and evaluation. However, at this stage of the nursing process, the nurse's primary role usually focuses on patient education.

The rapport established early in the nurse–patient relationship provides the basis for the trust that is needed as the nurse continues to collaborate with the patient. To maximize the benefits of drug therapy as it is affected or changed by environment, teach the patient about safe therapy and promote collaboration among health care providers and the patient. It may be necessary to teach patients how to evaluate their personal and occupational environments for hazardous chemicals and, if appropriate, suggest wearing or using protective equipment. Another aspect of patient education is teaching the patient about the proper way to discard medications. Therapeutic drugs can contaminate the environment through metabolic excretion, improper disposal, or industrial waste.

The extent of teaching varies, depending on the environment in which the patient will receive the drug (e.g., home, clinic, group home, hospice). Although some education is required whatever the setting, more information is necessary if the patient will be taking the drug at home than if the patient receives the drug in a rehabilitation center or other facility. The patient must be knowledgeable about all aspects of the drug regimen so that it can be self-administered safely and effectively. If another person—a family member or someone else—will be responsible for the patient's drug therapy at home, that person needs to be included in the educational process.

Ongoing Assessment and Evaluation

Evaluate the patient for increased or decreased drug effectiveness related to environmental stimuli. Assess the patient for signs of adverse effects that may have been induced by environmental factors. Review measures to control environmental factors with the patient at each clinic visit.

CHAPTER SUMMARY

- Environmental settings include acute care hospitals, acute rehabilitative units, transitional care units, outpatient units, home, and community.
- Limitations of pharmacotherapy for any setting include need for close monitoring of the patient, need for specialized equipment, need for life-saving equipment and drugs, and need for specialized personnel.
- Medication reconciliation must occur whenever a patient is admitted, transferred to a new environment, or discharged.
- The environment can affect the stability of a drug.
- The environment can affect the effectiveness of a drug.
- Environmental influences can increase the risk of adverse effects, toxicity, and patient injury.
- Environmental influences can increase the risk of injury in specific occupations.
- The nurse's role is to identify possible environmental influences on pharmacotherapy and institute appropriate patient education.

QUESTIONS FOR STUDY AND REVIEW

1. Identify elements of the environment essential for the nurse to assess regarding drug therapy.
2. How can smoking, alcohol, or environmental chemical exposures influence a patient's drug response?
3. What is the nurse's role in managing the patient with environmental considerations?
4. Explain the process of medication reconciliation.

Culture: Considerations in Drug Therapy

Learning Objectives

At the completion of this chapter the student will:

1. Identify the influences that culture and ethnicity have on health and illness.
2. Recognize similarities and differences among the five major ethnic groups in the United States.
3. Describe why it is important to assess a patient's culture and inherited traits when managing his or her drug therapy.
4. Describe techniques that can be used in nursing management in drug therapy when working with patients and families of different cultures and ethnicities.

North America has been called a "melting pot." A better expression might be "cultural mosaic," because this term signifies that people who emigrate to North America blend into society while retaining their individuality in terms of their culture. **Culture** is the shared customs and traditions, norms and values, institutions, arts, history, and folklore of a group. Similarly, **ethnicity** refers to a group that shares a common cultural heritage and that is linked by race, nationality, or language. An ethnic group is part of a larger social group.

The United States is becoming an increasingly multicultural society. In terms of nursing management and drug therapy, this diversity means that a patient's basic beliefs about health and disease may vary based on his or her cultural heritage. American society is primarily composed of five major ethnic population subgroups: white Americans, black Americans, Asian–Pacific Islander Americans, Hispanic Americans, and Native Americans. Each native and immigrant group has specific cultural attitudes about health, illness, and health care practices. Within each group, cultural attitudes, customs, and values may also vary widely (i.e., not all members of a culture have identical beliefs and practices). Members of minority cultures also tend to assume some or all of the practices and beliefs of the majority. Some aspects of minority cultures also become assimilated into the practices of the majority, producing a blend of cultural beliefs and attitudes.

Nurses today are being challenged to learn more about how cultural differences affect health, influence health-seeking behaviors, influence a patient's adherence or nonadherence to treatment regimens, and alter their responses to drug therapy. Nurses already realize that language and economics continue to be the main barriers to appropriate health care for many culturally diverse populations.

As patient populations become more culturally diverse, cultural competence becomes another feature of skillful nursing. **Cultural competence** requires maintaining awareness of one's own values and beliefs without letting them have undue influence on those of other backgrounds, demonstrating knowledge and understanding of another's culture, accepting and respecting cultural differences, and considering a patient's culture carefully.

Nurses must be aware that patients with various cultural and ethnic backgrounds may have beliefs and practices that differ from their own. These beliefs and practices are not wrong or inferior, merely different. Regardless of the patient's ethnicity or cultural background, nurses must be mindful of patients' beliefs and practices and consider them respectfully when managing drug therapy.

Ethnic groups share similarities in biologic and cultural characteristics. The term **biocultural ecology** (Purnell & Paulanka, 2003) refers to specific inherited physical, biologic, and psychological variations in ethnic and racial groups. These variations include skin color; physical body differences; genetic, endemic, and topographic diseases; individual psychological makeup; and biologic differences that affect the ways drugs are metabolized.

Recent pharmaceutical research has revealed that drug metabolism, dosing requirements, therapeutic response, and adverse effects differ among racial and ethnic groups. Additionally, research has found genetic variations within apparently homogeneous populations. For the purposes of this text, the core patient variable of culture and inherited traits is to be interpreted extremely broadly. In this text, the term *culture* refers to religious practices and beliefs, the use of medical or other health practices, and ethnicity—all of which may influence a patient's behavior in health and in illness. *Inherited traits,* or genetic variations, are also part of this core patient variable.

WORLD VIEW

Culture represents a way of perceiving, behaving in, and evaluating the world. A person's cultural identity influences his or her perception of the environment. Beliefs about the causes and effects of illness, health practices, and health-seeking behaviors are all influenced by a person's or group's perception of the environment—their world view. Three kinds of world-view health beliefs have been identified. These perspectives are known as biomedical health beliefs, magicoreligious health beliefs, and holistic health beliefs.

Biomedical Health Beliefs

In general, North Americans describe health from the scientific point of view. Scientific thinking underlies the biomedical view of health, in which life and life processes are controlled by physical and biochemical processes that can be manipulated by humans. For example, specific causes (bacteria, viruses) for an illness can be identified, and a specific treatment (drug therapy, surgery) can be developed to effect a cure.

Magicoreligious Health Beliefs

Predominant themes of magicoreligious health beliefs among some cultural groups focus on the concept of supernatural forces controlling health and illness and on the idea that illnesses are the result of "being bad" or "opposing God's will." Those who subscribe to these views perceive health as a gift from God and illness as an opportunity to realign with God. Prayer to God is used to cope with disease and to seek intervention for healing. Some cultures (e.g., West Indian) believe that magic, voodoo, or a hex or spell by a sorcerer or witch can cause illness. Some Mexican American and other Latin American groups believe that illness results from selection by the evil eye, or *mal ojo*. In these cases, the person seeks treatment from a traditional or folk healer, perhaps in addition to scientific therapies. The person's subscription to magicoreligious health beliefs influences his or her approach to health care.

Holistic Health Beliefs

A harmonious balance of the forces of nature is the basis of holistic health beliefs. According to this view, everything in the universe has a place and a function to perform according

to natural laws that maintain order. Disturbing these laws creates imbalance, chaos, and disease. Four facets of the person's nature—physical, mental, emotional, and spiritual—must be in balance and harmony for the person to be healthy.

Traditional Native American and Chinese American cultures have a holistic belief system. Disease occurs when an imbalance exists in the person's nature. An example of holistic health beliefs among Chinese American groups is the yin and yang theory of health and illness; among Mexican American and other Hispanic groups, it is the hot and cold theory of illness. Therapies that may be used to restore a state of balance may include exercise, herbal remedies, meditation, and nutritional or dietary changes.

For example, within the biomedical world view of health, tuberculosis is clearly defined as an infection caused by mycobacteria. However, according to a holistic world view, in which disease results from multiple environmental "hot" interactions, tuberculosis is caused by the interrelationships of poverty, malnutrition, overcrowding, and mycobacteria.

EFFECT OF CULTURAL DIVERSITY ON HEALTH CARE

Purnell's Model for Cultural Competence

To understand any culture thoroughly, examining it with the use of a conceptual framework is helpful. Purnell's model for cultural competence (Purnell, 2009) is an example of a conceptual framework that is geared specifically to health care providers. This model identifies 12 aspects (or domains) of every culture that health care providers should consider. The domains are:

1. Overview (heritage and residence)
2. Communication
3. Family roles and organization
4. Workforce issues
5. Biocultural ecology
6. High-risk health behaviors
7. Nutrition
8. Pregnancy and childbearing practices
9. Death rituals
10. Spirituality
11. Health care practices
12. Health care practitioners

This text does not present comprehensive descriptions of every culture in the United States, nor does it provide instructions for performing a comprehensive cultural assessment. The intention of this text is to provide general knowledge of cultural concerns relevant to nursing management in drug therapy, using a brief description of those factors in the five most common cultures in the United States. Although Purnell's model may continue to evolve, certain domains are easily applicable to nursing management in drug therapy. These aspects are overview (heritage and residence), communication, family roles and organization, spirituality, health care practices, and biocultural ecology.

According to Purnell's model, heritage describes where the people come from, and residence describes where they currently live. Heritage and residence are important factors to consider because they provide clues about potential illnesses or conditions that may be present in the patient and require drug therapy. For example, new immigrants to the United States who have lived in areas where malaria is prevalent (e.g., Egypt, Italy, Turkey, Vietnam) may need to be screened for malaria, and if they test positive, to receive drug treatment. Another example is patients who currently live in crowded, poor urban areas who may need to be screened for tuberculosis.

Communication is an important part of culture for the nurse to assess. Communication includes verbal language (including dominant language; dialects; contextual use of words; and paralanguage variations, such as voice volume, tone, and inflection) and nonverbal language (e.g., eye contact, facial expression, use of touch, and temporality of world view). Temporal relationships are defined according to whether a culture is oriented to the past, present, or future (Purnell, 2009). Past-oriented cultures (e.g., German) may value the importance of providing historical background before presenting new information. Present-oriented cultures (e.g., Chinese) place more importance on the "here and now" than on the past or future. Future- oriented cultures (e.g., white American, European) believe it is important to prepare for what lies ahead. Punctuality is also part of temporal relationships; some cultures see promptness as important for all aspects of life, whereas others may be more relaxed about time, especially in social situations. The nurse needs to be mindful of all of these issues when working with patients. The ability to communicate effectively with a patient has a major effect on assessment, teaching, and the entire nurse–patient relationship.

The domain of family roles and organization defines the relationships among those inside and outside the family. Family roles and organization include head of household and gender roles; family goals and priorities; developmental tasks of children and adolescents; roles of the aged and extended family; social status; and acceptance or non-acceptance of nontraditional lifestyles (e.g., divorce, single parenting, same-sex relationships). This information is important for the nurse to consider when providing teaching to the patient and family. For example, some Middle Eastern men may feel that the health care provider does not respect them as the head of the family if patient education is directed toward a female family member (even if the woman is the patient).

Spirituality includes all formal religious beliefs and the use of prayer. It also includes all behaviors that provide meaning to life and strength to the person. Spirituality may influence nutrition, health care practices, and the other cultural domains. Identifying sources of strength and comfort for patients is important because these resources assist in promoting health and high-level wellness. The nurse considers spirituality to treat the patient holistically.

Health care practices include the focus of typical care (acute or preventive); the basis for health care (traditional,

magicoreligious, or biomedical); beliefs about individual responsibility for health; self-medicating practices; views about mental illness, chronic illness, rehabilitation, organ donation, and transplantation; and responses to pain and the sick role. These practices influence not only how a patient responds to health and illness but also his or her acceptance of drug therapy. Drug interactions may occur from self-medication or the use of alternative therapies (e.g., herbs). The knowledge of health care practices not only assists the nurse in assessing the patient but also provides a basis for appropriate patient education.

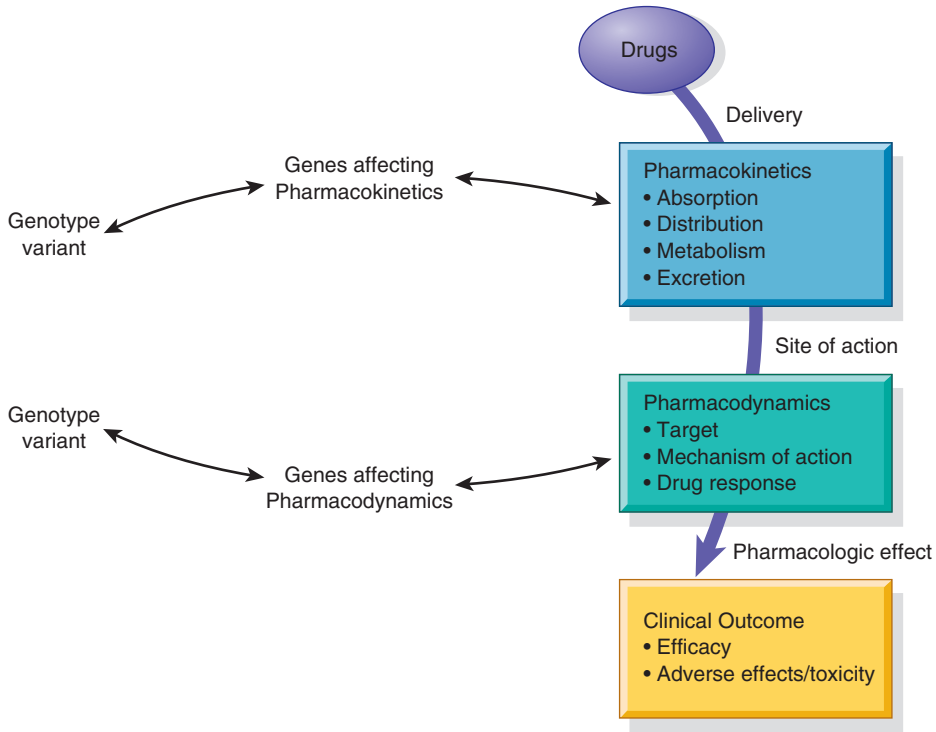
Biocultural ecology identifies specific physical, biologic, and physiologic variations that stem from ethnic and racial background. Some diseases have a genetic predisposition, placing certain ethnic groups at increased risk. These diseases may require drug therapy. For example, African Americans are more likely to develop hypertension than are white European Americans (Centers for Disease Control, 2009). Most important for nurses managing drug therapy, some racial and ethnic variations alter drug metabolism. Active pharmacokinetic processes (e.g., protein binding and metabolism) are more likely to be affected by ethnic differences than passive pharmacokinetic processes (e.g., absorption).

Although data in this field are limited, more studies are being done to examine drug therapy for interracial variations.

Pharmacogenetics, Pharmacogenomics, and Drug Therapy

That different people respond to a particular drug in different ways (e.g., some have little or no response to therapy, and others endure adverse effects) has long been a well-known, if puzzling, fact. As the study of genes and DNA has progressed, pharmacogenes, which are genes involved in the response to a drug, have been identified. There are 30,000 genes but an unknown number of pharmacogenes. Pharmacogenetics to Pharmacogenomics—the study of drug response in the context of the entire genome.

Pharmacogenetics is the study of inherited differences of a specific gene in response to clinical drug therapy (Pharmacogenetics and Pharmacogenomics Knowledge Base, 2011). People with some variations of genetically carried traits can have alterations in the following processes: drug metabolism, drug transportation, ion channels, or drug receptors. These alterations may increase or decrease drug levels that can be achieved from a dose, or increase or decrease the effectiveness of a drug's dose from that which normally occurs, placing these patients at risk for developing adverse effects or for clinical failure of drug therapy (even if they are taking a "standard" dose). These genetic factors therefore alter the dose necessary to be therapeutic but to avoid toxicity. This link between genetic makeup and drug response may be related to race or ethnicity; however, research increasingly shows individual variation within population groups that is not related to race or ethnicity. Understanding how different people respond to a particular drug and adjusting the drug dose to meet each person's unique needs is essentially the concept of "one drug for many people." The difficult challenges in analyzing and using pharmacogenetic data involve linking information about the variation in human genes to the variation in drug response, and determining if the cost of genetic testing is offset by savings from preventing serious drug adverse effects. Figure 12.1 is a visualization of the relationship between genes and drug therapy. Already there are over 50 drugs with pharmacogenetic discoveries listed



• FIGURE 12.1 Genotype and phenotype variations can alter a drug's effect from what is expected. Phenotype variations alter pharmacokinetics, pharmacodynamics and drug responses, clinical outcomes, and molecular and cellular functional assays. (©PharmGKB, 2006. Used with permission.)

in their drug label information (Shin, Kayser, & Langaee, 2009). The FDA lists pharmacogenetic information (which is termed "genomic biomarkers") that will help to: identify those patients likely to have a positive therapeutic response to a drug versus those likely to have a poor response; identify those patients likely to experience adverse effects (especially serious adverse effects); and determine the best dose to optimize the safe and effective treatment of a disease (FDA Table of Valid Genomic Biomarkers in the Context of Approved Drug Labels).

Pharmacogenomics is the study of drug response in the context of the entire genome. The genome of an organism contains all of its genetic information. In other words, it is the study of all genes in a group of individuals simultaneously to determine the basis for drug response variations (Pharmacogenetics and Pharmacogenomics Knowledge Base).

Pharmacogenomics entails the use of databases to identify disease-relevant drug targets in the human genome at the molecular level and to target drugs to clinical populations that share unique genetic profiles. This approach is essentially the concept of "many drugs for many people." With pharmacogenomics, researchers are able to look at variations in all the genes in a group of individuals simultaneously to determine the basis for variations in drug response. Ideally, those who prescribe drug therapy will use knowledge from pharmacogenomics as well as non-genetic factors (such as environment) to know how the patient is likely to react to a particular drug. They will therefore choose a drug that will achieve the maximum therapeutic effect but not produce adverse effects.

Pharmacogenomics, although still in its infancy, may become an important tool in developing new drugs in the future. Drugs with narrow therapeutic indexes (and therefore with high potential for serious adverse effects) are examples of drugs that might especially benefit from pharmacogenetic studies (Zhou, Di, Chan, et al., 2008). The challenge in analyzing data in pharmacogenomics lies in trying to understand how interacting systems of genes determine individual drug responses.

The observation that people metabolize drugs in different ways was the initial impetus for the study of pharmacogenetics. New knowledge is showing that genetic variations also occur in drug receptors or drug target systems, such as transport proteins or cell membrane enzymes. Genetic variations that have a low incidence in the population (<1%) are termed *mutations*. Genetic variations that have an incidence in the population of 1% or greater are called *polymorphisms,* which are variations in the DNA sequence. Most polymorphisms are a result of a change in a single nucleotide. Other possible polymorphisms involve inserting or deleting one or several hundred DNA bases, or inserting or deleting DNA repeating sequences. Genetic polymorphisms can account for 20% to 95% of variation in drug effects (Pierik, Rutgeerts, Vlietinck, et al., 2006).

Although many diseases are carried genetically, individual variation can still occur in a person's genetic makeup. Genotype is a person's specific gene composition; this composition reflects any variations unique to that person. Phenotype is the observable or measurable expression of a genotype. All people with a similar phenotype will experience a particular disease or disorder, but they will not necessarily have the identical genotype. These variations in genotype account for different responses to drug therapy. For example, a chromosomal variation known as the Philadelphia chromosome is present in most, but not all, patients with chronic myeloid leukemia. Chronic myeloid leukemia is a type of cancer in which large numbers of mature myeloid cells are found in the peripheral blood and in the bone marrow. The variation in genotype expressed as the Philadelphia chromosome produces a certain abnormal protein. Cells with this abnormal protein do not respond to drug therapy but continue to reproduce. Research that explained how this particular protein malfunctioned enabled creation of a specific drug, imatinib (Gleevec), with a mode of action aimed specifically at the dysfunctional protein. This drug is much more successful than others in treating chronic myeloid leukemia, but only if the genotype variation of the Philadelphia chromosome is present.

When there is variation in genotyping of a particular disease, the disease is sometimes referred to as a heterogenic disease. One example is inflammatory bowel disease. This variation in genotyping of a disease makes it difficult to predict how people with the same disease will react to drug therapy. Treatment responses in people with a heterogenic disease are influenced by many confounding factors, such as disease severity or duration, as well as polymorphisms (Pierik, Rutgeerts, Vlietinck, et al., 2006).

Because drug metabolism through the P-450 hepatic enzymes has been studied the longest, some conclusions about genetic variations in the enzymes responsible for drug metabolism are known. Some of these data show variation among races, although great individual variation exists within any population group (i.e., specific race). Nearly 80% of drugs currently in use are metabolized by CYP2D6, CYP2C19, and CYP2C9, therefore variations (polymorphisms) in these genes cause frequent variations in drug metabolism (Zhou, Di, Chan, et al., 2008). Approximately 5% of Europeans and 1% of Asians lack CYP2D6 activity and are therefore known as "poor metabolizers" (Zhou, Di, Chan, et al., 2008). For example, the isoenzyme CYP2D6 is known to be active in metabolism of approximately 20% drugs, including antidepressants, antipsychotics, beta blockers, and some chemotherapy drugs. Variations in the genes controlling this isoenzyme can cause metabolism of drugs to be either abnormally fast or abnormally slow. Human studies have revealed up to a 10-fold difference in the pharmacokinetics of various antidepressants, oral anticoagulants, nonsteroidal anti-inflammatories, and oral hypoglycemic drugs due to polymorphism of CYP2C9 (Kirchheiner & Seeringer, 2007).

Between 7% and 10% of white people lack an active CYP2D6 enzyme and therefore metabolize drugs poorly through this pathway. A small percentage of whites have a phenotype in which the CYP2D6 gene is duplicated, so

that they have two active genes, making them ultra-rapid metabolizers. Interethnic variability has been shown with Asian and black African/African American populations, who have reduced CYP2D6 activity compared with whites. Other unique ethnic groups are known to have variations of CYP2D6 that make them ultra-rapid metabolizers. One study of the isoenzyme CYP2C19 shows that 3% to 4% of whites and African Americans are poor metabolizers via this pathway, compared with 14% to 21% of Asians (Shilbayeh & Tutunji, 2006). A small recent study of Vietnamese found that they had similar variation in CYP2D6, CYP3A4, and CYP2C19 as other Asian populations (Veiga et al., 2009). One study examined the prevalence of the variation in CYP2C19 in Jordanian Arabs. It found that the majority of Jordanian Arabs are extensive metabolizers, although a subset are poor metabolizers (Shilbayeh & Tutunji, 2006).

Patients who respond to drugs differently based on their ethnic and genetic heritage may be at risk for a higher incidence of morbidity and mortality from a disease, because the prescribed therapy may not be as effective for them in controlling their disease. When one considers ethnic variation in drug activity, it is important to consider the route by which the drug is administered. Pharmacokinetic responses to drug therapy may be altered by different routes—for example, a drug that has a high first-pass effect when given orally does not exhibit this concern when given parenterally. Thus, if a patient had a racial genetic variation that altered their ability to metabolize (and have a first-pass effect), then giving the same drug by a different route may negate the ethnic genetic differences in drug metabolism (Chen, 2006). Given the multitude of factors that can influence a drug's dose will require long-term use of both knowledge of genetic factors as well as non-genetic factors that impact pharmacokinetics and pharmacodynamics (Shin, Kayser, & Langaee, 2009).

Although some genetic variation can be explained by race or ethnicity, these data cannot be solely relied on in cultures where genetic mixing of ethnic populations occurs. Interethnic mixing is becoming increasingly more common globally, which means that it is risky to apply knowledge that has been gleaned from pure ethnic groups to mixed populations. Ethnic subgroups of a larger ethnic group may also have unique genetic differences because they may have been geographically isolated in the past. For example, although Chinese, Malaysian, and Indian subgroups can all be considered Asians, one study found that genetic variations among them accounted for the fact that the Chinese and Malaysians required less warfarin (an oral anticoagulant) than Indians to achieve a therapeutic response without adverse effects. The authors believed that these differences reflected the ethnogeographic distinctions among the three groups (Lee et al., 2006).

Some data support individual genetic variation in CYP3A4 and CYP2C9 and the effects these variations have on drug interactions, drug metabolism, and drug dosing. Data are also being gathered on other isoenzymes in the P-450 family. (See also Chapters 4 and 5 for more information.) Identification of the genotype and/or the phenotype for these isoenzymes promises much therapeutic value, especially if the drug that is to be administered has a narrow therapeutic index (Zhou et al., 2008).

Genetic testing for some CYP alterations is available and is used increasingly at many clinical sites. Genetic variations which alter drug metabolism or drug effectiveness may exist, for which there is no created test yet. Thus patients may be at risk even if their genetic testing indicates that they are "normal" metabolizers. Other limitations on the tests include the cost of testing and the need for physician education related to ordering genetic testing as well as interpreting and utilizing the results. As more drugs become labeled with statements relevant to potential adverse effects or loss of effectiveness related to polymorphisms, with a recommendation to perform genetic testing prior to prescribing the drug, the testing for these genetic markers will become more common.

In addition to the P-450 family of isoenzymes, two other mechanisms of drug metabolism involve enzymes: *N*-acetyltransferases (NATs) and thiopurine methyltransferase (TPMT). NATs speed up the rate of the chemical reaction in which an acetyl group is transferred to a particular drug, increasing its water solubility and promoting renal excretion. Mutations or polymorphisms of NAT genes are responsible for slowing the metabolism of drugs such as isoniazid (an antitubercular agent) and some cardiovascular drugs, among others. Patients with genetic variations that affect these enzymes are at risk for higher circulating levels of drug and adverse effects. Tests to predict these variations are not currently part of routine clinical practice.

TPMT is necessary for the metabolism of certain types of drugs, known as thiopurine drugs. This chemical class of drugs is used for a variety of purposes, such as treating rheumatoid arthritis, preventing rejection of transplanted organs, treating pediatric acute lymphoblastic leukemia, and treating steroid-resistant inflammatory bowel disease. These drugs are highly toxic and have a narrow therapeutic index; thus, finding the proper dose for a patient is crucial to prevent adverse effects and injury. In some clinical areas, laboratory analysis for TPMT—rather than the conventional method of using the patient's weight—is considered the current standard for determining the proper dose of a thiopurine drug. Patients with an alteration in TPMT gene begin therapy at a much lower dose than the usual standard dose.

Another way that genetic variation can alter drug response is to alter the sensitivity of a target receptor to a specific drug molecule; if the receptor site is more or less sensitive to the drug then the therapeutic effectiveness may go down or the risk for adverse effects may go up. For example, the beta 2 receptor is one receptor target where genetic modification is clinically significant (Zhou et al., 2008).

Currently, pharmacogenetics is still a relatively new area of study; pharmacogenomics is even more in its infancy. Although these disciplines are actually two different fields of study, they can be considered interdependent and to have some outcomes in common. Indeed, the literature may use the terms almost interchangeably, causing potential problems

BOX 12.1 FOCUS ON RESEARCH

Cost Effectiveness of Warfarin Genotyping

Eckman, M.H., Rosand, J., Greenberg, S.M., & Gage, B.F. (2009). Cost-effectiveness of using pharmacogenetic information in warfarin dosing for patients with nonvalvular atrial fibrillation. *Annals of Internal Medicine*, 150(2), 73–83.

The Study

In order to determine the cost effectiveness of using pharmacogenetic testing before starting the anticoagulant warfarin in patients, a Markov state transition decision model was used by the researchers. They created an ideal "base case" of a 69-year-old man with newly diagnosed nonvalvular atrial fibrillation (these patients require long-term anticoagulation therapy) who has no contraindications to warfarin therapy. The effectiveness was measured in quality adjusted life years and costs were in 2007 U.S. dollars. They found that the patient had better outcomes if the genotype was assessed and dosing was based on the genotype. However, this increase in patient outcomes was expensive ($170,000 per quality adjusted life year). The researchers concluded that for 90% of patients with nonvalvular atrial fibrillation, it was not cost effective to perform genotyping to determine the dose of the warfarin. However, for patients with high risk of hemorrhage from the anticoagulant, which could lead to cerebral hemorrhage or other severe events, genotyping may be cost effective to determine the best dose of warfarin.

Nursing Implications

It has been long known that finding the correct therapeutic dose of the anticoagulant warfarin is difficult in some patients. They either have subtherapeutic levels of the drug or they have higher than normal levels and therefore bleed very easily. In 2007, the FDA revised the label for warfarin and suggested that genetic testing be considered before starting therapy to identify those patients who would be likely to have serious adverse effects from a "standard" dose of warfarin. This research brings up an important but not always considered point related to pharmacogenomics: the economic costs of testing may be too great to consider using the technology for everyone. In a time of economic difficulty and the need to constrain health care costs, the health care system cannot afford to increase the costs of drug therapy. Just because genetic testing of an individual (to find the best drug or the best dose before starting therapy) may be possible, does not necessarily mean it must be done. Nurses should be aware of the pros and cons related to pharmacogenetic testing. When patients would truly benefit (such as those at high risk for serious, life-threatening adverse events), nurses should consult with the prescriber about obtaining this testing before starting drug therapy.

when applying some of the pharmacogenetic/pharmacogenomic study findings. First, the findings may only relate to patients with one specific disease who have received a particular drug, and the data may not be applicable when the same drug is prescribed to patients with different diseases than the one originally studied. Second, therapeutic responses to a drug may vary among individuals because of variability of the disease (e.g., how long the patient has had the disease or the severity of the disease), or variability of drug response due to polymorphisms, or both. Third, many pharmacogenetic/ pharmacogenomic studies lack explicit statements concerning how to translate the study's findings into clinical practice (Pierik, Rutgeerts, Vlietinck, et al., 2006). As more information becomes available and technology develops to identify genetic variations easily and accurately, it is anticipated that drug therapy will be individualized to meet each patient's needs optimally while minimizing risks for adverse effects (Box 12.1).

Cultural Differences Among Major Ethnic Groups

The following sections describe some of the differences in the five predominant ethnic groups in the United States, using the parameters described in Purnell's model. Every culture includes variations; therefore, these are general characteristics. Any statement that describes a general characteristic of a culture risks being considered stereotypical. Therefore, these descriptions must not be considered applicable to every person in any given culture. Indeed, many aspects of the dominant culture are usually also present in the nondominant cultures of our society. Every patient needs to be assessed individually for beliefs and practices.

White Americans

The most prevalent culture in the United States is that of whites. The people in this cultural group trace their ancestors to various European countries. Although they exhibit differences, white Americans have many common cultural traits.

White Americans speak English; a few may also speak a second language. White Americans tend to be future oriented and encourage work and sacrifice today as an investment for the future. People in this cultural group expect to delay the purchase of nonessential items to provide for drug therapy, medical treatment, and other health care needs, in the belief that doing so will help ensure a healthier future. White Americans have a linear sense of time (e.g., this action or event happens at this time followed by another action or event at a particular time). Time is highly valued, and people in this cultural group tend to be punctual for meetings, appointments, and social gatherings (Purnell, 2009).

Married white Americans generally live in traditional nuclear families of a man and woman and their children. However, nontraditional, nonnuclear families are becoming more common. Although historically men worked and women stayed at home to care for children, this division of labor now occurs less frequently, and more households have two working spouses.

The predominant religious belief is Christianity, with multiple denominations represented (e.g., Protestant, Roman Catholic). However, some white Americans are Jewish. Some religious beliefs may affect a patient's acceptance of certain drug therapies. For example, Roman Catholicism does not support the use of birth control. This doctrine could alter a woman's acceptance of oral contraceptives, even when given for medical management of irregular menstrual periods.

Most white Americans share a bioscientific view of disease and health management, although nontraditional health care practices are becoming more accepted and common. Some white Americans hold strong religious views and rely on prayer to regain health. Many white Americans hold a combined belief in the abilities of science and prayer or faith to restore health. Health care practices are based primarily on traditional Western medicine, although alternative therapies are also used to some extent.

White Americans have been found to have more acid glycoproteins than other ethnic groups. Therefore, when they take drugs that bind to these proteins, they have lower amounts of free (or active) drug than when the same dose is given to someone of another ethnic group (Johnson, 2000). Most clinical drug studies have been performed on white men; therefore, the pharmacokinetic information from the study may or may not be applicable to white women or to other ethnic groups. More studies are now being done that include white women.

Black Americans

The largest group of black Americans is African American. This group will be discussed as illustrative of black Americans, although some differences exist among African-American and non–African-American blacks. African Americans trace their ancestors to Africans who were brought to North America as slaves. African Americans speak English and may also speak a black dialect of English. Generally, African Americans tend to be more present oriented than past or future oriented. Having a circular view of time, rather than a linear view, they are more relaxed about time than whites. It may be more important for some African Americans to have made an appointment than to be punctual. However, many African Americans share the dominant culture's belief in linear time (Purnell & Paulanka, 2003).

African Americans may have extended families, with the grandmother having an important role. Historically, the families tend to be matriarchal, although patriarchal families are not uncommon now.

Some African Americans tend to be very spiritual and actively practice their religions. Most African Americans are practicing Christians, with Baptist and Methodist being the most common denominations. However, several other Christian denominations are represented in African American culture, as are the Nation of Islam and other Islamic sects. Islamic lifestyle is strictly regulated, and important parts of this lifestyle include cleanliness pertaining to specific religious beliefs. During times of crisis (e.g., critical illness, imminent death), these patients and their families turn to religion. Because they believe that life is precious, they perceive almost any medical treatment (e.g., transfusion) needed to support survival as acceptable, unless it is contradicted by their religious beliefs.

Historically, access to traditional health care for African Americans was uncertain. As a result, folk medicine became a necessity for treating illness. Even today, some African Americans may turn to folk medicines and practices much as their ancestors did, viewing health as a state of harmony of body, mind, and spirit and illness as a state of disharmony resulting from natural causes, evil spirits, or divine punishment. Health-related folk practices are intended to restore harmony. The art of healing stems from a fundamental belief that healing power is a gift from God; prayer, rituals, or the laying on of hands often accompanies the use of home remedies. Certain people within the community may be identified as having this power to cure. The traditional healers of the African American community are usually women, who are proficient in using home remedies. Some African Americans may also seek advice from a voodoo practitioner. Additionally, African Americans use bioscientific medicine to treat disease and illness. Traditional or folk medicines may be used before, or concurrently, with Western medicine.

In general, African Americans respond to some drugs differently than whites. For example, they are less responsive to beta blockers (e.g., propranolol) and more responsive to monotherapy for hypertension than whites. The pathology of hypertension, a substantial health problem in this group, is caused by volume expansion, decreased levels of renin, and increased intracellular concentration of sodium and calcium. Because African Americans usually have dark eyes, their eyes dilate less than the eyes of people with light eyes in response to mydriatic drugs used during ophthalmologic procedures. Other biomedical differences include a higher incidence of extrapyramidal effects from tricyclic antidepressants and the antipsychotic haloperidol and greater susceptibility to tricyclic antidepressant delirium and other adverse effects of psychotropic drugs. These differences are based on pharmacogenetic differences in drug metabolism.

Asian and Pacific Islander Americans

Asian and Pacific Islander Americans have their ancestral origins in China, Japan, Korea, Vietnam, Cambodia, and other Asian countries and in the various Pacific Islands. Cultural differences among Asian–Pacific Islander Americans are many because of their diverse backgrounds. However, because the Chinese American population is the largest, it is discussed here.

Generally, Chinese Americans speak English. Older Chinese Americans may speak a Chinese dialect as their first language and may or may not speak English. Younger Chinese Americans speak predominantly English and may or may not also speak some Chinese.

The Chinese concept of time is related to the natural cycles of birth, life, and death. Therefore, time is to be integrated into life, rather than mastered (as whites attempt to do). Some Chinese Americans see little value in punctuality, whereas others, who view tardiness as a sign of disrespect and therefore as unharmonious, are prompt and expect the same promptness from others.

Traditional Chinese Americans place great significance on family and family roles. They emphasize the male relatives: fathers, sons, and uncles. Usually, the established head of

the household—a man—has great authority and assumes all major responsibilities for the family.

Many Chinese Americans consider formal religion to be superstition, whereas others practice Buddhism, Roman Catholicism, Protestantism, Taoism, or Islam. Religion is considered a personal expression, prayer is a source of comfort, and formal group services are minimal.

Chinese Americans believe that harmony with nature is essential for physical and spiritual well-being and that harmony comes from a balance among the cycles and elements of nature (fire, water, wood, earth, and metal) and the cycles of life. Traditional Chinese Americans view the body and spirit as a gift given to them by their parents and ancestors. Therefore, the body and spirit must be cared for and well maintained. Care and maintenance are accomplished through the powers that govern the universe: yin and yang. Although these forces are in opposition to one another, they function in unison. A person whose yin is flourishing and whose yang is steadily active or energized is considered to be healthy.

Yang represents the positive male energy that produces light, warmth, and fullness or satisfaction. Matters that are ascending, brilliant, dynamic, and external belong to yang. Yin, in contrast, represents the negative female energy of darkness, cold, and emptiness. Things that are descending, dull, internal, regressive, and static belong to yin. For example, the surface of the body and the back are yang; the inside of the body and the front are yin.

Yin also represents the five viscera of the five solid organs (heart, kidney, liver, lungs, and spleen; referred to as *ts'ang*), which collect and store secretions. Diseases of winter and spring are thought to be yin. Yang represents five hollow organs (bladder, gallbladder, large intestine, small intestine, and stomach), referred to as *fu,* and the diseases associated with the warmer seasons of summer and fall.

The pulses are controlled by both yin and yang. For example, if yin is too strong, the person is nervous, apprehensive, and catches colds easily. Disease is caused by an upset in the balance of yin and yang, and weather has an effect on the body's balance (e.g., heat is injurious to the heart; cold is injurious to the lungs). According to this culture, improper balance of yin and yang will shorten a person's life span.

Chinese American health care practices vary. Younger Chinese Americans usually seek Western medical care first and traditional Chinese treatment as a follow-up. Older Chinese Americans may seek health care in the reverse order. Traditional Chinese health care is based on the concept of harmonious yin and yang.

Herbal medicines and Western foods and drugs may affect some Chinese Americans in important ways. Chinese Americans are also more likely than most other Americans to have certain inherited conditions. For example, alpha thalassemia, an inherited disorder of hemoglobin metabolism, affects Chinese Americans with greater frequency than it affects other cultural groups (except those of Mediterranean origin), placing them at greater risk for anemia. In addition, a sex-linked genetic disease—a deficiency of glucose-6-phosphate dehydrogenase (G6PD)—is common in the Chinese American. This disease is characterized by a lack of the G6PD enzyme and results in anemia. Chinese American populations also have a relatively high incidence of lactose intolerance, which leads to gastric symptoms, such as diarrhea, when milk or other dairy products are consumed. Certain drugs are metabolized differently and have different effects in Chinese Americans. Among these drugs are mephenytoin (Mesantoin); diazepam (Valium; poorly metabolized in 15% to 20% of Chinese Americans); beta blockers, atropine (Sal-Tropine), and alcohol (increased sensitivity); antidepressants and neuroleptics (increased responses at lower doses); and analgesics (decreased sensitivity, but increased gastrointestinal [GI] adverse effects). Specific variations of drug metabolism among Chinese Americans are difficult to determine because most clinical drug studies have not differentiated them from other Asians.

Some variation of drug response among Chinese Americans is unrelated to differences in drug metabolism. Lithium carbonate (Eskalith), used in managing bipolar disorder, is a drug that is not metabolized, but it has a different effect in Chinese Americans than in Europeans and whites. Chinese Americans require lower levels of lithium to achieve a therapeutic response. Part of the explanation for the differences in drug responses lies in the number and type of drug receptors present. Just as different drugs can be metabolized only by specific liver enzymes, receptors are custom designed to accept only certain drug configurations. As with enzymes, the number and type of receptors are influenced by genetics. Chinese Americans, and other Chinese people, appear to have a greater number of lithium-activated receptors than other groups.

Hispanic Americans

Hispanic Americans are a large minority in the United States because of birth rates and immigration. Members of the Hispanic American community have their origins primarily in Puerto Rico, and in Mexico, Cuba, and other Latin American countries. The culture of Mexican Americans is described here.

Mexican Americans may speak either Spanish or English as their primary language. They may also be bilingual. Historically, Mexican Americans have been more present oriented than future oriented. Because time is viewed as relative, punctuality is relaxed, especially in social situations, although in modern society, the trend is toward greater punctuality. Mexican American families tend to be patriarchal, with the male head of the household as the primary decision maker. These roles too are changing, with greater responsibility being shared with female family members.

Although some Mexican Americans tend to view life as chance, believing that health is purely the result of good luck (if one's luck changes, so does one's health), others have a dominant fatalism and hold the opinion that God is responsible for delivering health or illness, and that good health should not be taken for granted. Still others are deeply involved in formal religions, primarily Catholicism, but some worship

with the Church of Jesus Christ of Latter Day Saints (LDS), Jehovah's Witnesses, Seventh Day Adventists, Presbyterians, and Baptists. In this context, appropriate ways of preventing ill health involve using herbs and spices, praying and wearing religious artifacts, and maintaining a balanced diet and physical activity. Socioeconomic and educational backgrounds influence the beliefs held by the individual Mexican American.

People are expected to maintain equilibrium by eating and working properly. Good health exists when the biologic, psychosocial, and spiritual natures are holistically balanced in relation to the environment. The more serious physical and mental-emotional illnesses are brought to the male *curandero* or female *curandera,* who is a holistic healer in the community. The use of herbs (commonly in the form of teas and poultices) is a popular treatment offered by folk healers. Western medicine is also used.

As with other cultural groups, Mexican Americans believe that disease occurs when there is an imbalance between opposing life forces. For Mexican Americans, these forces are perceived as hot, cold, wet, and dry. The body is composed of four kinds of fluids (also known as humors), which may vary in temperature and moisture content. They are blood (hot and wet), yellow bile (hot and dry), phlegm (cold and wet), and black bile (cold and dry). Imbalances may exist among these fluids, and these imbalances are manifested as illness. Maintaining a balance between these fluids is important to promote wellness. When the four humors are balanced, the body is healthy.

These concepts provide a way of determining the remedy for a particular illness. Illness is thought to be caused by prolonged exposure to hot or cold; to cure the illness, the opposite quality of the etiologic agent is applied to absorb the hot or cold. For example, a cold substance is used to treat a hot illness. Hot conditions include constipation, diarrhea, fever, infections, kidney problems, liver problems, rashes, skin ailments, sore throat, and ulcers. Cold foods include barley water, chicken, fish, dairy products, fresh vegetables, goat meat, honey, raisins, and tropical fruits. Cold herbs and medicines include linden, milk of magnesia, orange-flower water, sage, and sodium bicarbonate.

Conversely, hot substances are used to treat cold conditions. Cold conditions include cancer, colds, dysmenorrhea, earache, headache, joint pains, malaria, paralysis, pneumonia, rheumatism, stomach cramps, teething pain, and tuberculosis. Hot foods include aromatic beverages, beef, cheese, chili peppers, chocolate, eggs, pork, liquor, goat milk, onions, peas, temperate-zone fruits, and whole grains (except barley). Hot herbs and medicines include anise, aspirin, cinnamon, castor oil, cod-liver oil, iron preparations, garlic, ginger, penicillin, tobacco, and vitamin preparations.

Hot and cold do not refer to temperature but are descriptive of the nature of a particular substance. Food, beverages, animals, and people possess the characteristics of hot and cold in varying degrees. Other Hispanic groups also consider items as hot or cold, but different substances are classified into these categories.

Few clinical drug studies have separated Mexican Americans from other Hispanic groups, so that information about variations in drug metabolism must be generalized from findings in Hispanic groups. Some studies have shown that Hispanics may metabolize some drugs differently from other cultural groups. For example, studies indicate that Hispanics need lower doses of antidepressants than do other groups and experience greater adverse effects from these drugs. Further complicating the issue is the fact that many Mexican Americans have mixed heritage. Therefore, generalizations may not be accurate for all Mexican Americans.

Native Americans and Alaska Natives

The Native American and Alaska Native population in the United States consists of more than 500 tribes that are recognized by the federal government and many others that are not. Native Americans (or American Indians) and Alaska Natives are the original inhabitants of North America, and each tribal community is unique in its cultural beliefs. The Navajo Indians are the largest tribe. A person must have at least one quarter Navajo blood to be considered part of the tribe. The Navajo Indians are presented as the example of Native Americans and Alaska Natives.

The Navajo tribe lives in a large reservation that consists of portions of Arizona, Utah, and New Mexico. In New Mexico, the Navajo tribe is scattered and lives with Zuñi Indians and settlers from the LDS church. A nomadic people, the Navajo tribe travels great distances searching for adequate grazing grounds for their sheep. Navajo Indians speak Navajo, which until the 1970s was only a spoken language. A few older Navajo people speak some English or Spanish; younger Navajo people are usually bilingual and speak Navajo and English. The Navajo and Apache have similar languages, but their dialects are different. Minor variations in the pronunciation of Navajo words may change the meaning of the word or phrase spoken. Navajo Indians believe that silence is an appropriate way to communicate nonverbally, and feel comfortable even during long silences. Navajos, especially older people, take their time to respond carefully and thoughtfully to what is said to them.

In contrast to whites, who view time in a present–future–past sequence, Navajo Indians view time in a present–past–future sequence. This outlook means that Native Americans attach little value to planning for the future, often considering it foolish. Time has little meaning or importance. Activities begin when people or members of a group gather.

The Navajo, like most other Native Americans, are matrilineal. Men are important, but grandmothers and mothers are the center of society. No decisions are made unless the appropriate older woman is present.

Native American religion predominates among the Navajo, although some have been converted to Christian religions, such as the LDS church, Jehovah's Witnesses, and some evangelical groups. The Navajo view spirituality as being in a state of harmony with one's surroundings. Prayer is important. Spirituality cannot be separated from healing and is

CRITICAL THINKING SCENARIO

DIVERSITY, DRUG THERAPY, AND IMPLICATIONS FOR TEACHING

Forty-nine-year-old Maria Alvarez is a bilingual Mexican American for whom English is a second language. She is newly diagnosed with type 2 diabetes with prescribed "diabetic teaching" related to diet, exercise, and oral drug therapy. The nurse reviews cultural phenomena affecting health and health care among Mexican Americans and adult teaching-learning principles before working with Mrs. Alvarez.

1. What are some of the most significant considerations for the nurse to explore prior to teaching Mrs. Alvarez?
2. During one of the teaching sessions, the nurse plans to use pamphlets to teach Mrs. Alvarez about her disease and the prescribed drug therapy. What may be a limitation of printed material?

important in healing ceremonies. Illnesses result from not being in harmony with nature; from the spirits of an evil person, such as a witch; or from violating tribal taboos. Healing ceremonies restore mental, physical, and spiritual balance. The Navajo may use Western medicine in addition to healing from tribal ceremonies.

Type 2 diabetes is very common among Navajo people, as it is among all Native Americans and Alaska Natives. Other health problems common to the Navajo people are severe combined immunodeficiency syndrome (failure of antibody response and cell-mediated immunity, not related to acquired immunodeficiency syndrome [AIDS]), Navajo neuropathy (an inherited condition in which myelinated fibers are completely absent, and death occurs before the age of 24 years), albinism, and genetic blindness. Although little research has been conducted on variation in drug metabolism in Navajos, or other Native Americans and Alaska Natives, it is known that Navajo people can have increased adverse effects to some medications. For example, adverse reactions to lidocaine (Xylocaine), an anesthetic and antiarrhythmic, occur in 29% of Navajos but in only 11% to 15% of whites.

Nursing Management of Culturally Diverse Groups

In administering drug therapy to culturally diverse patient populations, it is necessary to respect each patient's cultural heritage, beliefs, and practices. A health care provider not fully aware of a patient's background may be unable to understand many of the patient's health beliefs and practices. Lack of knowledge or misunderstanding may unintentionally turn what should be a therapeutic experience into a degrading and humiliating experience for patients of other cultures. If possible, every effort should be made to accommodate the patient's traditional practices with standard drug therapy while providing nursing care to maximize therapeutic effects, minimize adverse effects, and promote health and safety for the patient and the family.

When caring for patients, be conscious of ethnocentrism, stereotyping, and cultural blindness. Because culture influences people so strongly in the way they feel, think, act, and judge the world, people often subconsciously restrict their view of the world to the point of being unable to accept other cultures. This inability is called **ethnocentrism.** Ethnocentrism inhibits acceptance of others and may lead to a clash of values and poor communication. Health care providers exhibit ethnocentricity when they act from the mistaken belief that only their own cultural and ethnic beliefs are normal, superior, or right. **Stereotyping** refers to the assumption that all patients of a particular culture or ethnic group will have the same response. Health care providers may exhibit **cultural blindness** if they proceed as if differences do not exist. Because the American health care system is based on the dominant pattern of Western scientific health beliefs and practices, it is not uncommon for health care providers to dismiss any deviations from the established pattern. The implication of all this is clear—throughout care, remember to be nonjudgmental and to convey respect.

Nursing Diagnoses and Outcomes

When developing nursing diagnoses, be aware of cultural beliefs, values, and behaviors that may influence the patient's situation. Although all nursing diagnoses may have related cultural factors, some can be specifically identified as having strong cultural implications. Patients with identified genetic polymorphisms are at risk for alterations in the effectiveness of the drug (either more than normal or less than anticipated) and increased risk of adverse effects from drug therapy. Box 12.2 presents nursing diagnoses and outcomes related to drug therapy, cultural diversity, and inherited traits.

Planning and Intervention

After the beliefs of the patient and family about health and disease, drugs and drug therapy, personal health habits, and chronic illness are assessed, planning and implementation may proceed.

Maximizing Therapeutic Effects

When drug therapy is recommended, make an effort to determine whether prescribed therapies are consistent with the patients' physical needs, cultural backgrounds, religious preferences, dietary preferences, and self-care practices. Then incorporate these aspects into nursing practice whenever possible and when not contraindicated for health reasons.

Minimizing Adverse Effects

Nurses and patients need to be aware that certain cultural practices (e.g., using herbal preparations in addition to conventional drug therapy) may create drug toxicity or herb–drug interactions. Conventional prescribed drugs may have actions similar or antagonistic to an herb or herbal product. For example, overmedication may result when ginseng (a tonic stimulant and an antihypertensive) is taken in combination with antihypertensive drugs. Some foods may also

Box 12.2 NURSING DIAGNOSES AND OUTCOMES RELATED TO DRUG THERAPY, CULTURAL DIVERSITY, AND INHERITED TRAITS

Impaired Verbal Communication

Desired outcome: Effective communication about drug therapy will be established among the patient, patient's family, and health care providers, despite possible language differences.

Anxiety related to new drug treatment

Desired outcome: Patient will recognize and express feelings of anxiety and will identify potential and actual sources of anxiety when health care practices during drug therapy interfere with cultural habits and health practices.

Fear of Health-Seeking Behaviors related to barriers to health care (e.g., caregiver's judgments of nonadherence or deviant behaviors) or fear of being criticized for traditional practices and inability to communicate these needs effectively in the English language

Desired outcome: Patient will recognize and express feelings of spiritual distress when health care practices, such as drug therapy, interfere with spiritual beliefs.

Ineffective Health Maintenance

Desired outcome: Patient (and family) will verbalize an understanding of beneficial, neutral, and harmful cultural health practices as they relate to drug therapy.

Ineffective Coping or Disabled Family Coping

Desired outcome: Individual (or family) will more effectively deal with stress after talking with a health care provider who explains the reason for, or expected outcome of, planned drug therapy as it relates to cultural beliefs and practices.

Spiritual Distress

Desired outcome: Patient will recognize feelings of spiritual distress when health care practices, such as drug therapy, interfere with traditional beliefs and habits.

Risk for Injury related to inherited altered response to drug therapy

Desired Outcome: Genetic variations that are known to be related to increased incidence of adverse effects of drug therapy or related to loss of effectiveness of drug therapy will be identified in the patient prior to the onset of such therapy to allow for its safe and effective use.

Box 12.3 COMMUNICATING WITH PATIENTS WHO SPEAK ANOTHER LANGUAGE

Use an interpreter (preferably) or a translator. Use dialect-specific interpreters (if possible) trained in health care. If possible, use an interpreter of the same age and same gender as the patient.

- Look at the patient when you speak, not at the interpreter.
- Speak slowly.
- Do not raise your voice or exaggerate your mouth movements.
- Provide time for interpretation or translation.
- Allow time for the patient to think before he or she responds.
- Avoid using relatives and children as interpreters; they may not be objective and the patient or relative may be embarrassed by the content of the discussion.
- Listen attentively.

If an interpreter or translator is not available:

- Remember that patients often understand more language than they can speak.
- Limit the number of words you use, and include as many words of the patient's language as possible.
- Speak slowly, but not loudly.
- Use nonverbal language.

interact with some drug therapies; normal dietary patterns must be assessed to help prevent food–drug interactions (see Chapter 10).

Providing Patient and Family Education

The communication style of the patient should be considered when preparing to provide patient education. The reasons for a treatment plan must be shared with patients and families and explained in language and at levels they can understand. When planning educational materials for patients whose primary language is not English, make every effort to obtain interpreters or translations of written materials. Interpreters are preferred to translators because an interpreter makes sure that the meaning behind the message is the same; translators merely change the words from one language to another. Box 12.3 provides guidelines for communicating with patients who speak another language. Pictures that reinforce the content of the verbal and written instructions are also helpful. Many computer systems are available that can automatically translate instructions into other languages (e.g., Spanish). Computer programs can also alter the level of language to make it appropriate for the patient's educational background. Compile and maintain a list of community resources that are available to assist patients of different cultures.

If the patient is present oriented, his or her understanding of acute and chronic illness may be affected by the perception of time. In such cases, teaching a patient about drugs for a chronic disease (e.g., hypertension) may be more successful if emphasis is placed on short-term problems (e.g., what may happen if the drug is not taken on time) than long-term problems, such as stroke and myocardial infarction.

In addition, consider gender roles and the importance of various family relationships to the patient when teaching about drug therapy. Ascertain that the appropriate person is present before beginning. For example, this person might be the grandmother of a Navajo Indian patient or the husband of a Mexican American woman.

Ongoing Assessment and Evaluation

To evaluate the effectiveness of nursing care for a patient of another culture, determine the extent to which the goals have been met by comparing the patient's current status with the identified outcome criteria.

CHAPTER SUMMARY

- Pharmacogenetics accounts for individual variation in the response to drug therapy. This variation is related to genetic alterations known as polymorphisms. Understanding the unique genetic makeup of an individual patient can ideally allow custom tailoring of the dose of a drug to promote therapeutic effect and prevent adverse effects.

  Pharmacogenetics is a new field, and knowledge about genetic variations affecting drug therapy is still somewhat limited, although it is rapidly growing. Some pharmacogenetic differences are inherited along ethnic or racial lines; other differences are unique to people and not inherited by ethnicity or race.
- Pharmacogenomics examines how all genes can affect drug therapy. The hope is that by understanding human genome variations, drugs can be developed that are more effective in different patient populations and predictions can be made concerning whether or not patients will have altered pharmacologic responses to a drug.
- Genetic variations of specific P-450 isoenzymes are known to influence drug metabolism. The variations include ultra-rapid metabolizers, extensive metabolizers, intermediate metabolizers, and poor metabolizers. Ultra-rapid metabolizers biotransform drugs using a particular isoenzyme more rapidly and thus may be at risk for subtherapeutic system levels of a prescribed drug. Poor metabolizers do not biotransform drugs using that isoenzyme, which means that systemic drug levels will rise higher than anticipated, producing more adverse effects.
- Genotype testing is now available for some of the P-450 isoenzymes and is used in clinical practice for some drugs.
- Many cultural groups in North America embrace both their original culture and the dominant North American culture.
- Although generalizations may be made about the beliefs of different cultural groups, these statements cannot be applied to all people sharing a cultural background. Every person must be assessed to determine his or her unique beliefs.
- Individual health-seeking behaviors and health practices exist and differ, sometimes markedly, among the major cultural groups in the United States.
- Medicinal plants and symbolic rituals play important roles in the health practices of many cultural groups.
- Patients should be advised of the potential for chemical interactions between folk medicine or herbal remedies and traditional (Western) drug therapy.
- Factors related to communication, time, and environmental control influence the relationship between the nurse and the patient whose backgrounds are culturally different.
- Individual variation in response to the effects of drugs and pharmacokinetic drug differences may occur because of biologic and genetic differences among people. For example, some patients may metabolize certain drugs more slowly because of a genetically induced enzyme deficiency.
- Nursing management emphasizes a thorough assessment of a patient's health beliefs, traditional practices, and cultural influences, so that the nurse and other health care providers may implement interventions that complement the patient's values. Therapeutic regimens that accommodate a patient's cultural values (and traditional rituals) are more likely to foster adherence to drug therapy and discourage alienation from the health care system.
- Cultural, ethnic, and environmental influences add complex issues to pharmacotherapy.

QUESTIONS FOR STUDY AND REVIEW

1. How does culture differ from ethnic group?
2. How is an awareness of cultural differences helpful when providing nursing management in drug therapy?
3. Describe strategies that can be used when your patient does not speak the same language as you.
4. Explain how an individual's concept of time will influence patient teaching about drug therapy.
5. Why are clinical drug studies that describe a drug's altered pharmacokinetic process in Hispanics not always applicable to Mexican Americans?
6. A patient is receiving a drug with a narrow therapeutic index that is highly metabolized by CYP2D6. Genetic testing has indicated that this patient is a poor metabolizer via CYP2D6. Is this patient more at risk for reduced therapeutic effects or increased adverse effects? What nursing actions would you use to either maximize the therapeutic effect or minimize adverse effects?

Drugs Affecting Adrenergic Function

Learning Objectives

At the completion of this chapter the student will:

1. State the neurotransmitters that stimulate the sympathetic nervous system
2. Understand how adrenergic drugs create their therapeutic effects in the sympathetic nervous system.
3. Differentiate adrenergic agonist from adrenergic antagonist drugs.
4. Identify core drug knowledge about drugs that act as adrenergic agonists or antagonists.
5. Identify core patient variables relevant to drugs that act as adrenergic agonists or antagonists.
6. Relate the interaction of core drug knowledge to core patient variables for drugs that act as adrenergic agonists or antagonists.
7. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that act as adrenergic agonists or antagonists.
8. Describe nursing interventions to maximize therapeutic effects and minimize adverse affects for drugs that act as adrenergic agonists or antagonists.
9. Determine key points for patient and family education for drugs that act as adrenergic agonists or antagonists.

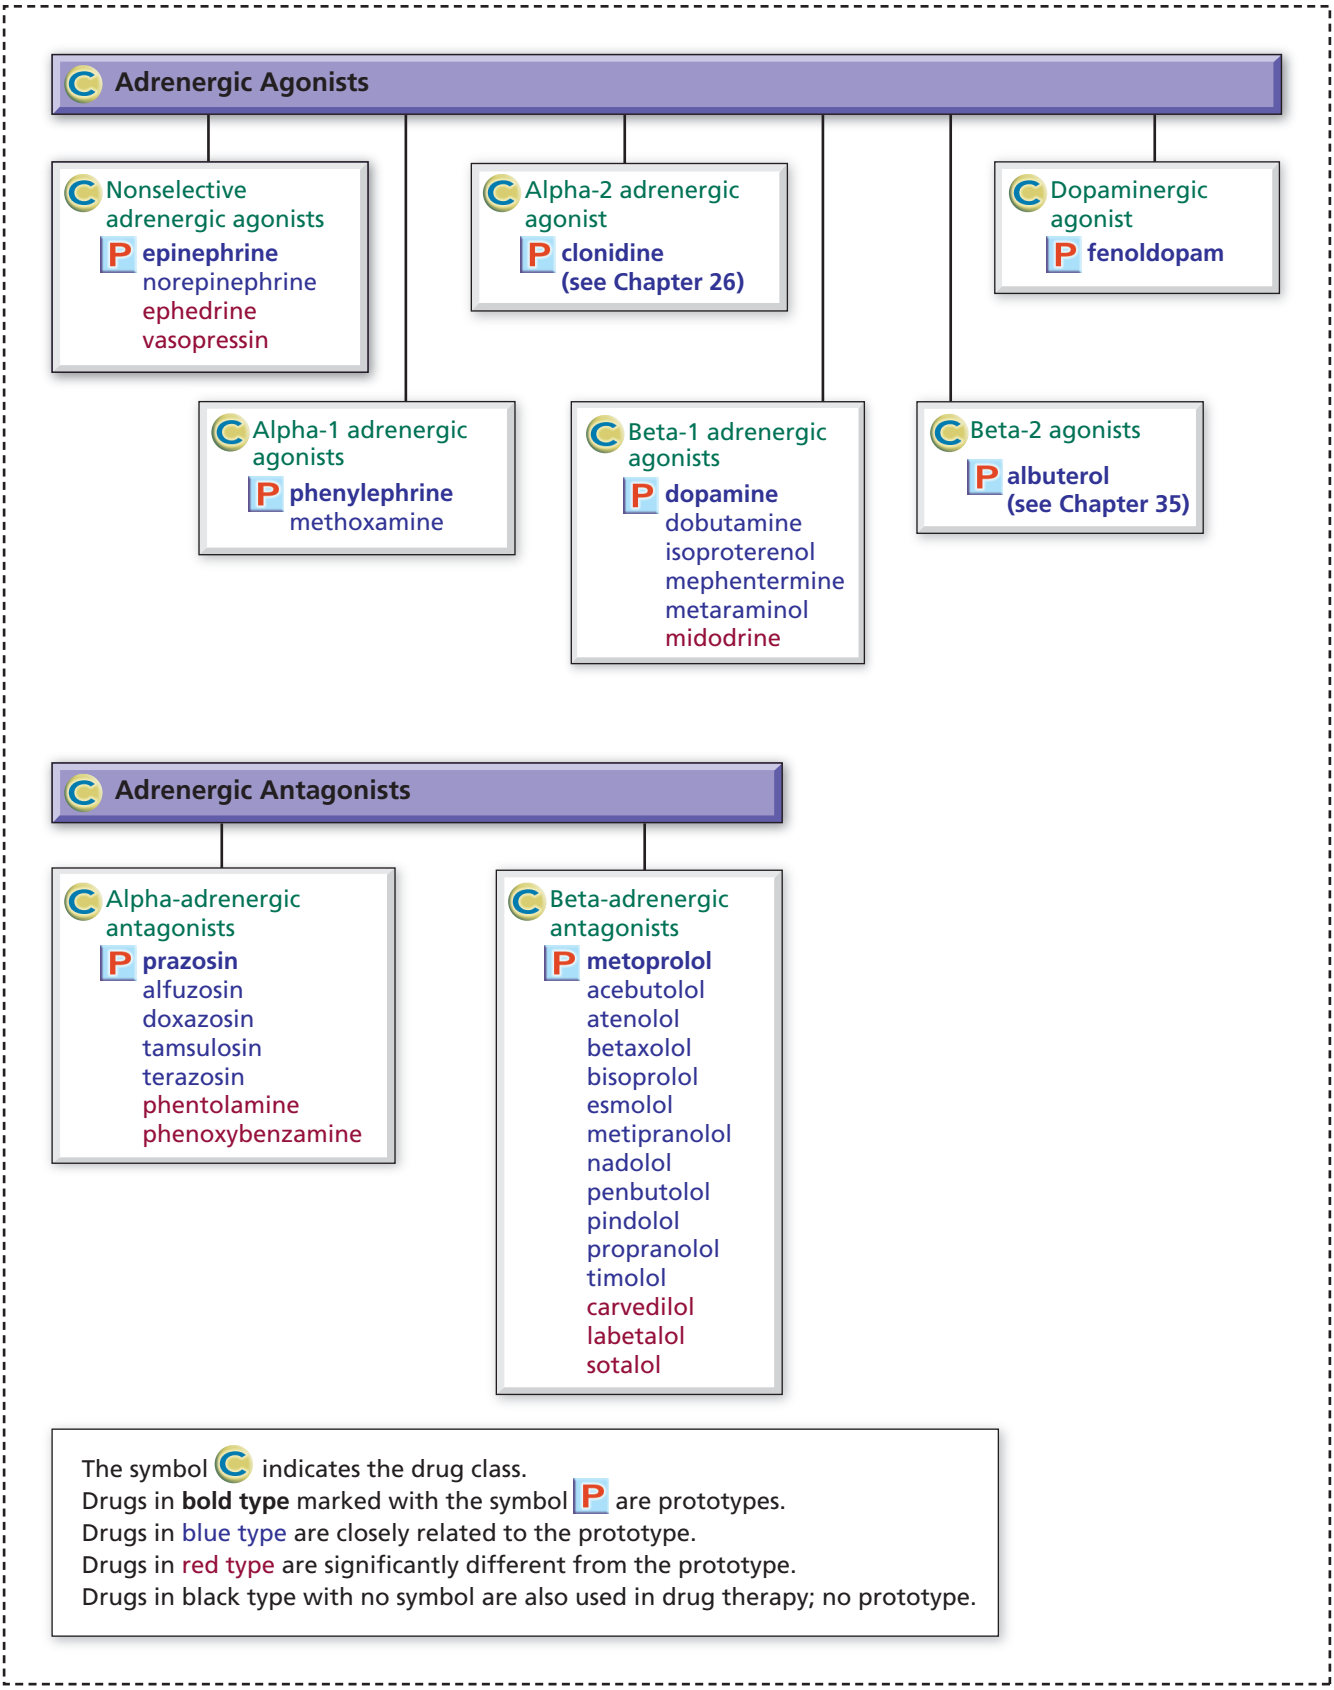
Drugs Affecting Adrenergic Function



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

The nervous system is a complex and amazing interconnected web that stimulates a physiological response and then curtails the same physiological response in the body to create just the right balance to support life. The normal function of the nervous system depends on the actions of neurotransmitters. Neurotransmitters are released from storage, stimulate particular receptors to cause an effect and then their effect is terminated as they are degraded or recycled and stored for future use.

The nervous system is responsible for maintaining our vital functions, such as breathing and keeping our hearts beating, while also allowing us to move voluntarily and to respond to environmental stimuli. It is easy to understand how important a properly functioning nervous system is to each individual. When the fine balance of stimulation and cessation of stimulation in the nervous system is disrupted, the individual can experience a wide variety of problems or pathologies. Many drug therapies work in the nervous system to either mimic the action of these neurotransmitters (when there is not enough intrinsic stimulation), or to block the receptor where the neurotransmitter attaches, thus preventing the effect from the neurotransmitter (when there is excessive stimulation from the neurotransmitter). Remember that drug therapy cannot produce any new effects in the body, it can only turn on or prevent effects for which the body is already capable.

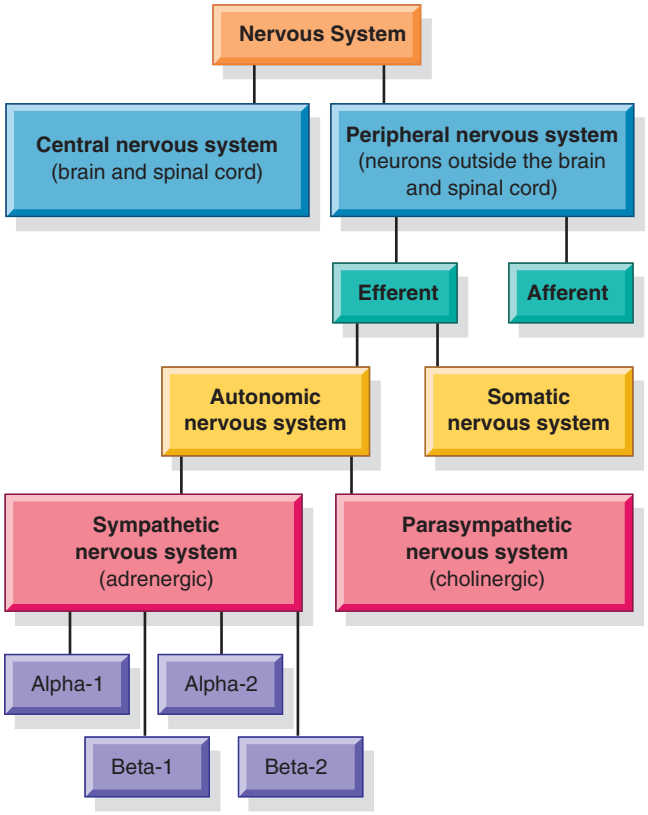
This chapter focuses on drugs that affect the sympathetic nervous system. These drugs either stimulate sympathetic receptors or they block these sympathetic receptors. Those that stimulate the receptors are referred to as adrenergic **agonists** (stimulators) and those that block are referred to as adrenergic **antagonists** (blockers). Prototypes have been selected that stimulate or block specific sympathtetic receptors. Some drugs are relatively specific for the receptor on which they act, while others affect more than one receptor. The prototype nonselective adrenergic agonist is epinephrine. The prototype alpha-1 adrenergic agonist is phenylephrine, and the prototype alpha-2 adrenergic agonist is clonidine. The prototype beta-adrenergic agonist is dopamine. The prototype beta-1 agonist is albuterol; it is discussed in Chapter 35. The prototype dopaminergic agonist is fenoldopam.

The adrenergic antagonists are categorized similarly. Prazosin is the prototype alpha antagonist, whereas the prototype beta-blocker is metoprolol.

PHYSIOLOGY

Function of the Autonomic Nervous System

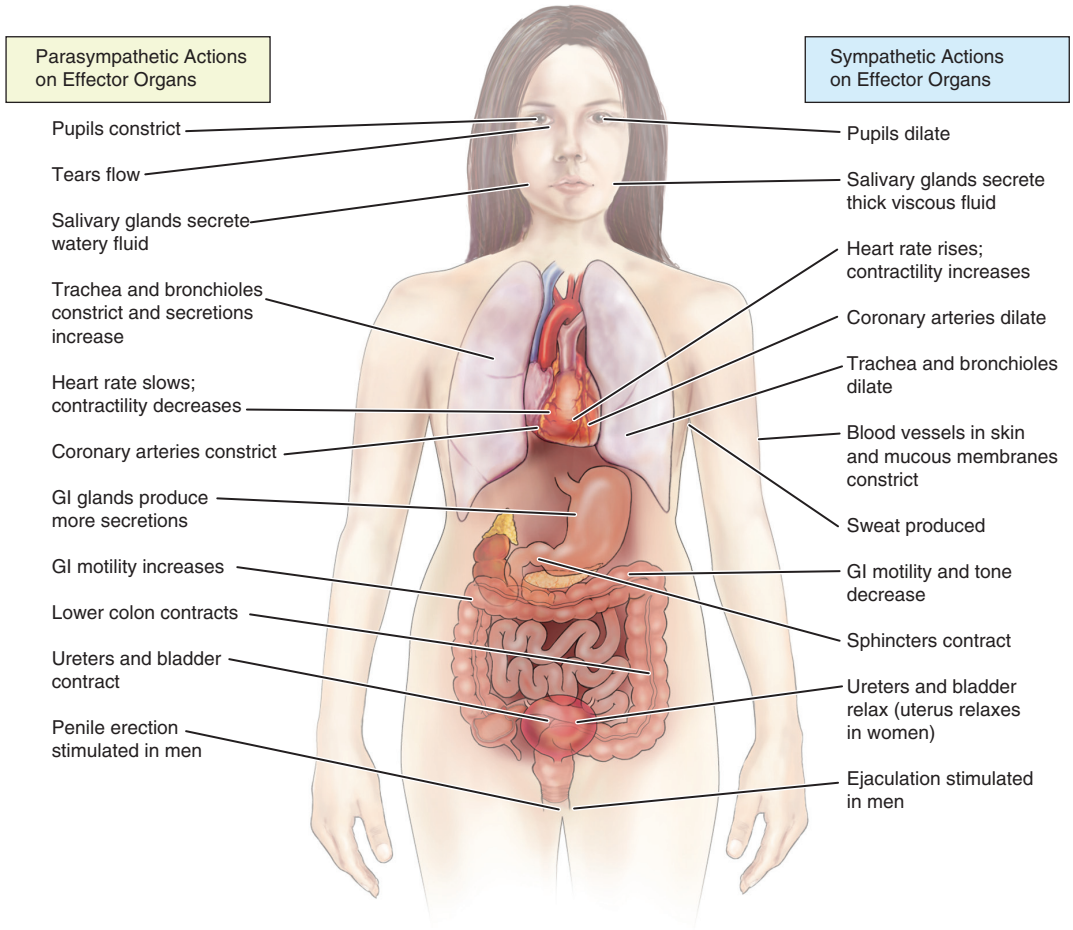
The nervous system is divided into two main branches: the **central nervous system** (CNS) and the **peripheral nervous system** (PNS) (Figure 13.1). The CNS is composed of the brain and spinal cord. The PNS consists of all neurons that are found outside the brain and spinal cord and is further subdivided into two major divisions: efferent and afferent. The efferent division has neurons that carry signals away from the brain and spinal cord to the periphery, whereas the afferent division contains neurons that carry impulses from the periphery to the CNS. The efferent division may be further subdivided into the somatic nervous system (which works on the skeletal muscles and is responsible for voluntary movement) and the **autonomic nervous system** (ANS) which is responsible for nonvoluntary nervous system control. The ANS is in turn subdivided into the **sympathetic nervous system** (SNS), also known as the **adrenergic nervous system**, and the **parasympathetic nervous system** (PSNS), also known as the cholinergic nervous system. See Figure 13.1 to help you visualize the branches of the nervous system.



• FIGURE 13.1 The human nervous system.

The ANS has been identified as an involuntary system responsible for the control of smooth muscle (e.g., in bronchi, blood vessels, and the gastrointestinal [GI] tract), cardiac muscle, and exocrine glands (e.g., gastric, sweat, and salivary glands). These regulatory functions of the body are monitored by both the sympathetic and parasympathetic branches of the ANS. Some organs and tissues are regulated by both systems. When both the SNS and PSNS stimulate a particular organ or tissue, the action may be oppositional or complementary. Figure 13.2 presents the major effects of the SNS and PSNS on the body. The cholinergic system and drugs which affect it are discussed in Chapter 14. The sympathetic system is responsible for the "fight or flight" response. In other words, it allows our bodies to be ready to act quickly to situations perceived as potential threats. Sympathetic stimulation will increase our heart rate, dilate our pupils, mobilize our energy, and redirect our blood flow from non-essential organs to our skeletal muscles.

PHYSIOLOGY



• FIGURE 13.2 Actions of the nervous system. Whereas the brain and spinal cord make up the central nervous system (CNS), the neurons found outside the CNS make up the peripheral nervous system, which carries nerve impulses to and from the CNS over afferent (to the brain and spinal cord) and efferent (from the brain and spinal cord) pathways. The efferent pathways, which make up the autonomic nervous system, regulate voluntary and involuntary activities of the smooth muscles and glands.

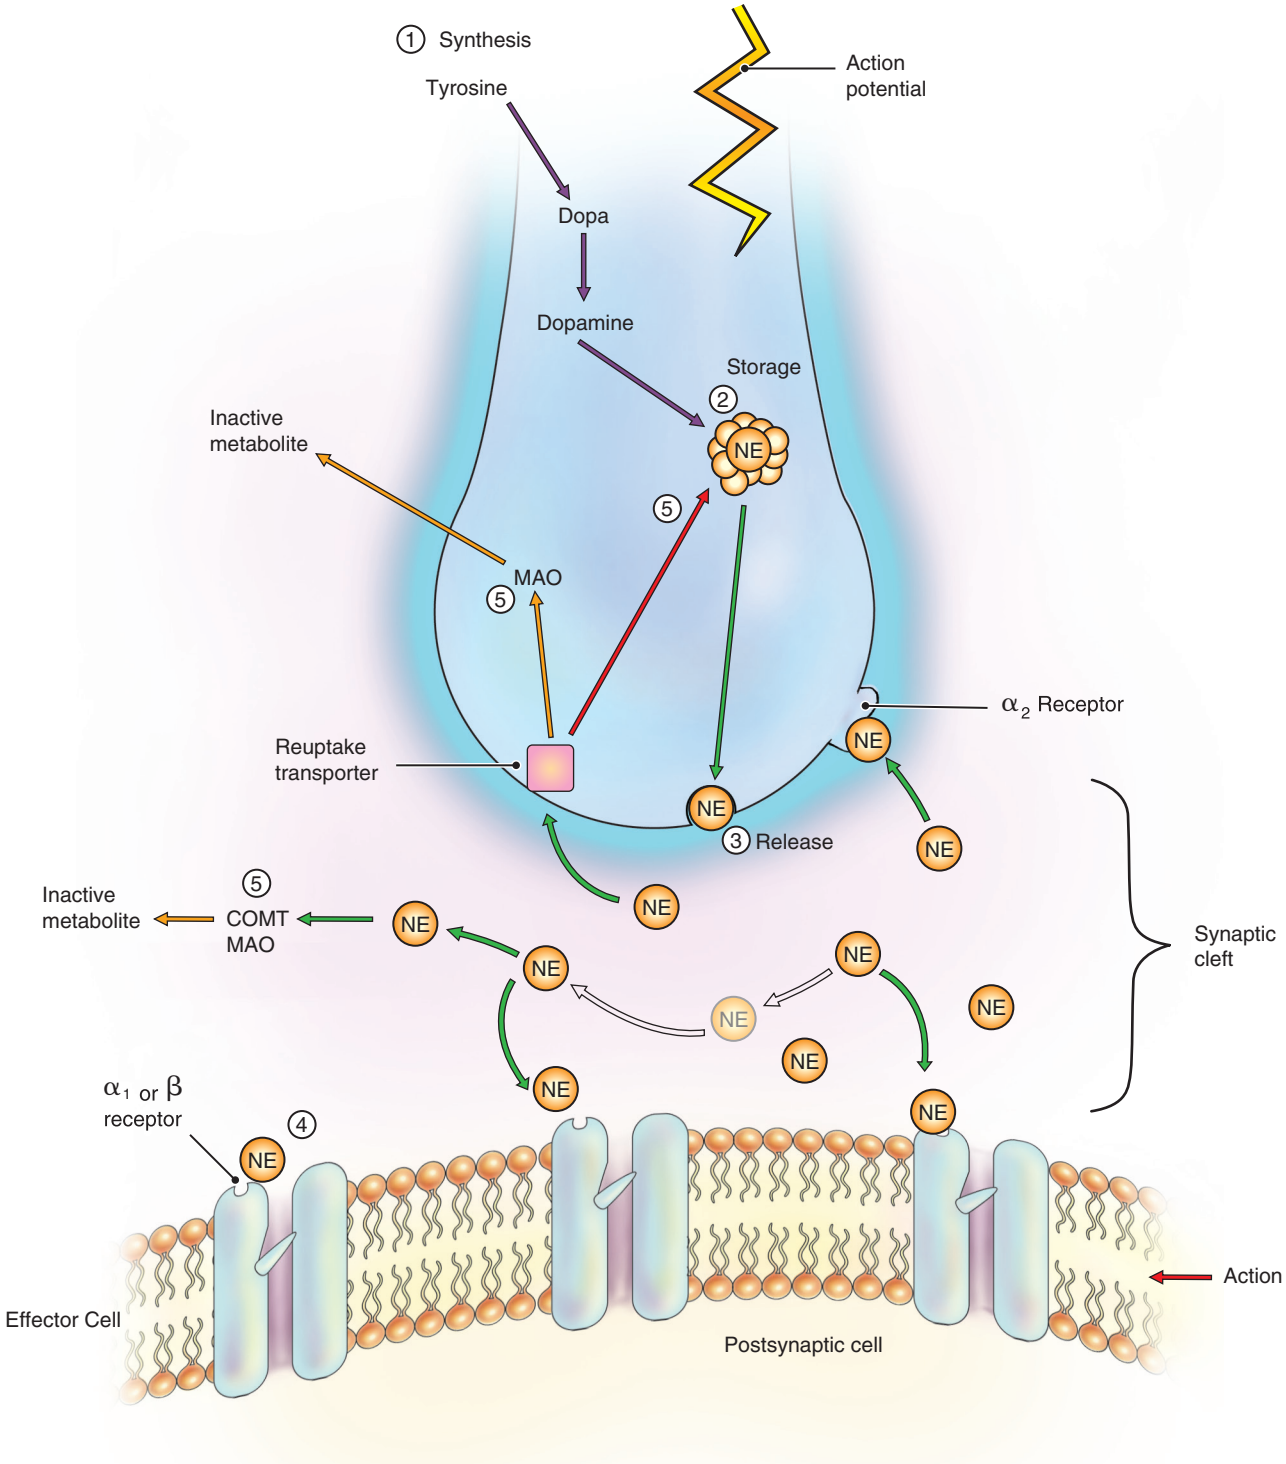
How does the body actually achieve stimulation of either the sympathetic or parasympathetic system? The actual connection between neurons and effector organs or tissues relies on **neurotransmitters** and **synaptic transmission**. The neurotransmitters in the ANS include acetylcholine (ACh), norepinephrine (NE), and epinephrine (Epi). Dopamine (DA) is the precursor to NE and is sometimes also considered in this group. Synaptic transmission initially involves the synthesis of neurotransmitters in the nerve terminal, with subsequent storage of the neurotransmitter awaiting an action potential that allows the neurotransmitter to be released. After release, the neurotransmitter diffuses across the synaptic gap and reversibly (i.e., not permanently) binds to a receptor on the postsynaptic cell. After binding and exerting an effect, the neurotransmitter is dissociated from its binding site by a variety of mechanisms that allow the neurotransmitter to be degraded or to undergo reuptake for reuse (Figure 13.3). To effect an action, the neurotransmitter needs to bind with an appropriate receptor site on the effector organ or tissue.

In the SNS, preganglionic transmission is mediated by ACh, whereas postganglionic transmission is mediated by NE. ACh also stimulates the adrenal medulla to release Epi. Once the postganglionic neurons are stimulated by neurotransmitters and transmit their impulse to the effector organs or tissues, several events may occur. For example, beta-1 stimulation by NE increases the heart rate, while at the same time beta-2 stimulation induces bronchodilation.

Neurotransmitters

Acetylcholine

Acetylcholine is the preganglionic neurotransmitter in the SNS and both the preganglionic and postganglionic



• FIGURE 13.3 Norepinephrine (NE) release and degradation. (1) NE is stored; (2) NE is released from the nerve terminal in response to an action potential and diffuses across the synaptic cleft; (3) NE binds to receptor site to stimulate an action; (4) NE is inactivated by COMT or (5) undergoes reuptake back to the nerve terminal for reuse or inactivation by MAO.

neurotransmitter in the PSNS (Figure 13.4). The precursors to ACh are choline and acetyl coenzyme A. After formation and storage, ACh is released in response to an action potential, and then binds to cholinergic receptors on the target organs or tissues. After dissociation, ACh is degraded by acetylcholinesterase (AchE) into two inactive products, acetate and choline, or it undergoes reuptake back to the nerve terminal, where it is re-stored for further use.

Norepinephrine

Norepinephrine is the postganglionic neurotransmitter in the SNS and thus is responsible for the stimulation of various organs under the control of the SNS. The precursors to NE include phenylalanine, tyrosine, dopa, and, as the final step, dopamine. NE is produced and stored in the presynaptic nerve terminals of the SNS. As with ACh, it responds to an action potential. NE is released and floods the synaptic cleft. NE can then bind to the postsynaptic receptors, which are called alpha-1, beta-1, and beta-2. As the amount of NE in the synaptic cleft increases, it will eventually bind to presynaptic alpha-2 receptors. Stimulation of these presynaptic receptors acts as a negative feedback loop to shut off the flow of NE into the synapse. The NE in the synaptic space either is transmitted back into the nerve terminal (called reuptake) where it can be restored for further use, or the NE can be degraded by one of two enzymes, either monoamine oxidase (MAO) in the nerve ending or catechol-O-methyltransferase (COMT) within the synaptic cleft (see Figure 13.3).

Epinephrine

Epinephrine is actually a hormone that is converted enzymatically from NE in the adrenal medulla. Epinephrine is also referred to as adrenalin. It is stored in the adrenal medulla and, like neurotransmitters, responds to an action potential. It then travels through the bloodstream throughout the body to target organs. Its termination occurs through hepatic metabolism. Epinephrine will stimulate all adrenergic receptors except dopaminergic. Alpha receptors are less sensitive to epinephrine, so the initial response will be to the beta stimulation. However, once there is significant stimulation of alpha receptors, these responses will override the effects of beta stimulation.

Dopamine

Dopamine is the precursor to NE. It is capable of stimulating all adrenergic receptors (alpha -1, alpha-2, beta-1, and beta-2 as well as specific dopamine receptors.

Adrenergic Receptors

Receptors are that are stimulated by NE are called adrenergic receptors; those that are stimulated by acetylcholine are called cholinergic. In the SNS, there are several types of adrenergic receptors, including alpha-adrenergic and beta-adrenergic receptors.

There are also subtypes of alpha- and beta-adrenergic receptors. The current pharmacologically significant adrenergic subtypes are alpha-1, alpha-2, beta-1, and beta-2 receptors

(there is also a beta-3 receptor). Alpha-1 and alpha-2 receptors also can be further divided into additional subtypes. Alpha-1 receptors are located in the eyes, blood vessels, bladder, male sex organs, and prostatic capsule. Alpha-2 receptors are located in presynaptic nerve terminals. Alpha-1 receptors are primarily responsible for vasoconstriction of coronary arteries and veins and decrease smooth muscle motility in the GI tract (to slow down digestion during flight or fight). Alpha-2 receptors are responsible for shutting off the release of NE. Beta-1 receptors are found primarily in the heart but also in the kidney. Beta-1 receptors are primarily responsible for increasing cardiac output by increasing the speed of conduction, increasing the force of contraction, and increasing the pulse rate. They also play a role in renin release from the kidney. Beta-2 receptors are located in the arterioles of the heart, lung, and skeletal muscles as well as in the bronchi, uterus, liver, and skeletal muscle. Beta-2 receptors are responsible for many effects: bronchial dilation (to promote breathing); creating energy from the breakdown of fats stored in fat tissue (lipolysis) or from providing glucose to the cells through new creation of glucose (gluconeogenesis) or the breaking down of glycogen into glucose (glycogenolysis) and promoting the release of insulin so that the new glucose can enter into cells to be used as energy; dilation of smaller coronary arteries, the hepatic artery, and arteries to skeletal muscle (to provide additional perfusion of the organs; contraction of skeletal muscle, relaxation of the uterus, relaxing the detrusor muscle of the bladder to allow urine storage in the bladder; to slow GI motility (to delay digestion) and contraction of GI tract sphincters to prevent defecation; increase renin release from the kidney; to thicken secretions of salivary glands; and inhibit the release of histamine from mast cells. Beta-3 receptors have also been identified. Beta-3 receptors help to break down fats in fat tissue for energy metabolism and for heat production; thus beta-3 has an active role in regulation of weight. It is hoped that this function could be tapped to create drugs for weight loss. Unfortunately, beta-3 receptors also cause tremors, and thus are not pharmacologically useful at this time.

The various adrenergic receptors respond to stimulation by one or more neurotransmitters. Alpha-1 and beta-1 receptors respond to all three sympathetic neurotransmitters (Epi, NE, and dopamine). Alpha-2 and beta-2 receptors respond to epinephrine and NE. The relative selectivity of various adrenergic agonists can be used to therapeutic benefit in determining which effector organs or tissues should be targeted (Table 13.1).

In addition to alpha-1 and beta-1 receptors, dopamine also affects dopaminergic receptors. As stated above, the dopaminergic receptor is related to adrenergic receptors in that dopamine is the precursor to NE. As such, it can activate both alpha- and beta-adrenergic receptors.

Stimulation of dopamine receptors in the brain controls both voluntary movement as well as neurocognitive functions. Although the number of dopamine receptors in the brain is limited, they are extremely important to normal brain function. Many dopamine receptors are located within the kidney In low amounts, dopamine binds with vascular and renal receptors, dilating blood vessels, increasing blood flow to renal, mesenteric, and coronary arteries, and increasing overall renal perfusion. As the presence of dopamine increases, beta-1 receptors are stimulated, increasing heart rate and strength of contraction. Dopamine in even higher concentrations acts on alpha-1 receptors, leading to vasoconstriction and elevated blood pressure. Dopaminergic receptors are known to exist as subtypes, and at least five have been identified. Dopaminergic receptors in the periphery are located primarily in the kidney.

PATHOPHYSIOLOGY

Diverse tissues and organs are innervated by the ANS, and few discrete disorders are directly related to compromise of the SNS. There are disorders or conditions that can benefit from additional stimulation of the adrenergic receptors (either in total or relatively selectively for one subtype of receptor) or the blockade of those receptors. Thus, the therapeutic uses of sympathetic drugs are related to providing extra-adrenergic stimulation or blockade of normal ANS functioning. Because adrenergic receptors are distributed throughout the body and because adrenergically innervated organs and tissues show a predominance of one type of receptor over another, it is important to examine the major effects mediated by the different types of receptors to understand the implications of drug treatment in differing pathologic states (see Table 13.1).

One of the most frequent indications for adrenergic agonist drugs is **shock.** Shock is the result of inadequate tissue perfusion, leaving the cells without the oxygen and nutrients they need to function normally and survive. When cell dysfunction is widespread, the patient can die. Shock has multiple causes. *Hypovolemic* shock results from a decrease in circulating blood volume from bleeding or hemorrhage. It occurs when intravascular volume decreases more than 15% and as much as 25%. *Cardiogenic* shock is the result of the heart's inability to pump enough blood to adequately perfuse the vital organs. This type of shock may be caused by myocardial infarction, ventricular arrhythmias, severe cardiomyopathy, or chronic heart failure. *Septic* shock occurs when a severe infection brings about circulatory insufficiency. *Obstructive* shock is caused by a massive blockage in blood flow that results in inadequate tissue perfusion. Obstructive shock can originate with a large pulmonary embolus, cardiac tamponade, restrictive pericarditis, or severe cardiac valve dysfunction. *Neurogenic* shock is uncommon. It occurs because of a blockade of neurohormonal outflow that may be induced by drugs (e.g., spinal anesthesia) or trauma to the spinal cord.

Shock has two phases—early (compensated) and late (noncompensated). In early shock, the body tries to compensate for the decreased perfusion. The heart and respiratory rates increase, and blood pressure is generally maintained, or it may be low-normal. The body begins to shunt some blood

flow away from the skin, although the skin is still perfused. Urine output decreases slightly as renal blood flow is reduced. Emotionally, the patient may be anxious or confused. When the body is no longer able to make up for changes brought on by shock, the patient develops late, or uncompensated, shock. Tachycardia persists, but the blood pressure falls dramatically, and the rate of respiration falls. Venous constriction occurs, and with the circulation shut off, the skin becomes cold and clammy. Urine output declines dramatically and may cease when the kidneys are no longer perfused. The patient becomes nonresponsive and unconscious.

Pharmacological Effects on the SNS

Understanding how the complex nervous system works can be overwhelming. Still, in consideration of pharmacology there is really only one question that students and nurses need to answer. And that is: How does drug therapy create a specific effect in the nervous system? And here, the answer is fairly direct. Drugs create their effect on the nervous system by either stimulating a neuroreceptor, or by blocking it to prevent the intrinsic neurotransmitter from attaching and creating an effect. So to understand drugs that affect the nervous system, we only need to concern ourselves with the receptors

on the postganglionic side. The physiology on the preganglionic side, while important, is not where drugs create their therapeutic effect. In this light, nurses need to know what happens when you stimulate or block alpha-1, alpha-2, beta-1, beta-2, and dopaminergic receptors to understand the pharmacodynamics of adrenergic drugs. Many drugs attach to these receptors, and they have many diverse uses in pharmacology. Because of the diversity of uses, students can find studying this content daunting. The facts appear random and include almost everything. It is recommended that students first memorize what occurs with receptor stimulation and blockade, then consider the given prototypes to be examples of stimulating and blocking those receptors. Throughout the rest of the text, there will be discussion of drugs that affect the nervous system. Thus it is important to gain a basis of what happens with stimulation and blockade of neuroreceptors to be a foundation of your knowledge for much of drug therapy. An additional point students should understand concerning drugs that act on the nervous system is that while you will learn what happens with each unique receptor when it is stimulated or blocked, drugs do not just affect one receptor. They may affect multiple receptors equally or they may be relatively selective in what they stimulate or block. This may account for a wide variety of actions and adverse effects from a particular drug. A final factor that makes studying nervous system drugs difficult is that multiple names seem to be used to mean the same thing. Students need to recognize these synonyms when they are used interchangeably. See Table 13.2 for this information.

C ADRENERGIC AGONISTS

Adrenergic agonists are drugs that mimic the action of the SNS; thus, they are also known as sympathomimetic agents. They exert their effects by direct or indirect stimulation of adrenergic receptors. Indirect mechanisms include increasing the transmission of NE, inhibiting NE reuptake, and inhibiting MAO or COMT. Inhibiting the reuptake of NE or inhibiting MAO or COMT is related to the dissociation and termination of NE binding to adrenergic receptors, which results in the continuation of the effects of NE.

These drugs are generally divided into two groups: catecholamines and noncatecholamines. Catecholamines are so named because of a chemical structure they have in common. Because of this chemical similarity, they also possess three similar characteristics. First, they have a short duration of action, resulting in their need to be administered in a continuous fashion (i.e., by intravenous [IV] infusion). Second, they cannot be given orally. As oral agents, they cannot be given continuously, and certain substances in the body (MAO and COMT) would degrade them before they reached systemic circulation. Third, because of their chemical structure, they do not cross the blood–brain barrier. Noncatecholamines have directly opposite characteristics. They have a longer duration of action, may be given orally, and do cross the blood–brain barrier.

Adrenergic agonists are also classified according to their selectivity. Drugs that stimulate multiple adrenergic subtype receptors are called **nonselective-acting drugs**. Nonselective adrenergic agonists stimulate both alpha and beta receptors. Drugs that target a specific subtype receptor are called **selective-acting drugs**. To maximize therapeutic effects and minimize adverse effects, selective-acting drugs are used more frequently than nonselective drugs. It is important to remember that selectivity is not absolute. Although a selective-acting drug is preferential to a given subtype receptor, when given in higher doses it may also stimulate other subtype receptors.

• C NONSELECTIVE ADRENERGIC AGONISTS

Nonselective adrenergic agonists stimulate most receptors; therefore, they have a multitude of uses. It is important to remember that these drugs stimulate all of the subtypes, regardless of which subtype would be most helpful for a specific pathology.

The prototype for nonselective adrenergic agonists is epinephrine. This drug stimulates alpha-1, alpha-2, beta-1, and beta-2 receptors. The only adrenergic receptor subtype it does not stimulate is the dopamine receptor.

Nursing Management of the Patient Receiving P Epinephrine

Core Drug Knowledge

Pharmacotherapeutics

Epinephrine has a wide variety of indications; some of the most common include: anaphylactic shock, hypersensitivity reaction; asthma, cardiopulmonary resuscitation, and ventricular fibrillation. Self-injectable epinephrine is prescribed in community settings for anaphylactic shock associated with allergies to foods, especially nuts, seafood, milk and eggs, as well as insect bites, bee stings, venom, and asthma.

Additionally, epinephrine can be used in the treatment of congestion of mucosa; blood coagulation disorder; excessive uterine contractions; syncope due to heart block or carotid sinus hypersensitivity; simple glaucoma; cataracts; chloroquine poisoning; cluster headaches; croup; GI hemorrhage; herpes simplex infection; hyperkalemia; hypothermia; mastocytosis; obstetric analgesia; priapism; septic shock; and wheezing in infants. It is also used in open heart surgery and as an adjunct in topical anesthesia (Table 13.3).

Pharmacokinetics

Epinephrine may be administered parenterally, topically, or by inhalation. Depending on the administration method, epinephrine exerts its effects very quickly and is metabolized rapidly. It is well absorbed after intramuscular (IM) or subcutaneous (SC) injection, and its duration of action ranges between 1 and 4 hours. It is metabolized in the liver and excreted through the kidneys.

Pharmacodynamics

Epinephrine is a potent sympathomimetic drug with profound effects on a variety of organ systems. It stimulates all adrenergic receptors and causes the greatest adverse effects in the cardiovascular system and CNS. It acts directly on the postsynaptic adrenergic receptors.

After activation of the receptor, epinephrine is terminated by reuptake into adrenergic nerves or inactivated by the enzymes COMT and MAO. Depending on the location and distribution of receptors, epinephrine exerts a variety of responses in different effector organs and tissues. In the cardiovascular system, epinephrine exerts positive (or increased) inotropic (force or energy of contraction) and chronotropic (heart rate) effects on the myocardium by stimulating beta-1 adrenergic receptors. Although it might seem that stimulation of beta-2 receptors (which cause vasodilation) and stimulation of alpha-1 receptors (which cause vasoconstriction) would cancel each other out and create no effect, this is not true. Initially the beta-2 receptor stimulation is prevalent in the body effects and there will be vasodilation in skeletal muscles as well as other organs. As the dose increases, then the alpha-1 effects are evident, and these override the beta-2. In the skin and viscera, epinephrine stimulates alpha-adrenergic receptors, causing vasoconstriction.The overall effect is to increase systolic pressure and slightly decrease diastolic pressure. In the respiratory system, epinephrine causes bronchodilation by stimulation of beta-2 adrenergic receptors and is used in this way to treat patients with asthma or to manage anaphylactic shock.

Contraindications and Precautions

Absolute contraindications to epinephrine include hypersensitivity, sulfite sensitivity, closed-angle glaucoma, and its use during labor. It is also absolutely contraindicated in patients with severe organic cardiac disease, and in patients receiving cyclopropane, chloroform, or trichloroethylene general anesthesia and in shock states other than anaphylactic shock. In septic shock, epinephrine should be reserved for only extreme cases of cardiac collapse if other catecholamines have failed, as it also impairs gastric blood flow and increases lactate (Coons & Seidl, 2007). The action of epinephrine can exacerbate the symptoms of closed-angle glaucoma. As a beta-2 agonist, epinephrine administered during labor can delay progression to the second stage. The cardiovascular effects of epinephrine, such as increased myocardial oxygen demand, increased heart rate, vasoactivity, and potential to induce arrhythmias, may be detrimental to patients with severe cardiac disorders. These same cardiovascular effects may worsen shock states, although epinephrine is used to manage anaphylactic shock and ventricular fibrillation. There are no absolute contraindications for patients requiring emergency therapy for anaphylactic reaction. In patients receiving general anesthetic agents, epinephrine may induce myocardial sensitization to catecholamines, resulting in cardiac irritability.

Relative contraindications include cerebrovascular disease, such as cerebral arteriosclerosis or organic brain syndrome. The alpha effects of epinephrine have the potential to induce cerebrovascular hemorrhage with these disease states, especially when epinephrine is administered intravenously. Another relative contraindication is hypertension because the vascular effects of epinephrine can worsen this condition. Patients with hyperthyroidism may become more sensitive to catecholamines, resulting in cardiotoxic symptoms. Epinephrine also increases glycogenolysis in the liver. Patients with diabetes mellitus are monitored for hyperglycemia. Use with caution in patients having long-standing asthma co-occurring with emphysema and degenerative heart disease, psychiatric conditions, preexisting seizures, difficulty urinating, and concurrent use of MAOI and tricyclic antidepressants or sympathomimetic drugs.

Adverse Effects

Adverse effects are frequent because of epinephrine's ability to stimulate the four major adrenergic subtypes. Potential severe adverse effects include hypertensive crisis, angina, cerebral hemorrhage, and cardiac arrhythmias. If extravasation occurs during parenteral administration, necrosis may result because of epinephrine's potent vasoconstrictive properties.

Patients with hyperthyroidism or hypertension are more susceptible to headaches, anxiety, fear, and palpitations after taking epinephrine. In others, the main adverse effects are tremor, weakness, dizziness, anxiety, pallor, palpitations, apprehensiveness, sweating, nausea, and vomiting. Because of the breakdown of glycogen that is stimulated in response to epinephrine's effect on beta-2 receptors in the liver and in skeletal muscle, epinephrine may increase blood glucose levels in patients with diabetes.

Drug Interactions

Epinephrine interacts with a variety of classes of compounds, including tricyclic antidepressants, oxytocics, halogenated anesthetics, and beta blockers (Table 13.4). In

addition, because epinephrine increases blood glucose levels and promotes hepatic glycogenolysis, it may interfere with blood glucose determinations.

Assessment of Relevant Core Patient Variables

Health Status

Document preadministration vital signs. If epinephrine is being given for respiratory distress, auscultate and document the patient's lung sounds. In patients with diabetes, obtain a baseline glucose level.

Before administering epinephrine in a nonemergency situation, evaluate for diseases, disorders, or medications that contraindicate the safe use of epinephrine or require special monitoring. If possible, assess the patient for a history of sulfite sensitivity because some epinephrine formulations contain sulfites that may induce a reaction (Box 13.1). It is also important to evaluate the use of over-the-counter (OTC) or herbal medications because these agents may contain sympathomimetic ingredients. However, when epinephrine is administered during an emergency, the potential benefits always outweigh the risks associated with it. If allergic anaphylaxis is suspected, assess to verify the triggers by obtaining a comprehensive history, investigating the circumstances of the episode, and perform allergen skin tests and measurement of allergen-specific IgE in serum (Simmons, 2006).

Life Span and Gender

Document the age and gender of the patient and assess women of childbearing age for pregnancy and lactation. Epinephrine is in the U.S. Food and Drug Administration (FDA) pregnancy risk category C, and its use should be avoided in pregnant or lactating women. It must be administered carefully to infants, small children, and very old patients because adverse drug effects may be more pronounced in these age groups. In children with asthma, epinephrine may produce hypotension and syncope.

Lifestyle, Diet, and Habits

Document the patient's occupation and daily activities. Patients treated for glaucoma with epinephrine may develop corneal pigmentation, which may impair their vision. This condition may have a significant impact on people working in transportation (e.g., airline flight crew, truck drivers) and those working at night in low-light conditions.

Patients with diabetes who receive epinephrine for chronic conditions (e.g., asthma) should monitor blood glucose closely. Insulin dosages may need to be adjusted.

Environment

Be aware of the environment in which the drug will be administered, and assess the home or other relevant setting if appropriate. When epinephrine is administered intravenously, it is given in a hospital setting or possibly by trained emergency personnel in the community. In community settings where no health care providers are available, individuals with allergies, asthma, or other conditions that put them at risk for anaphylactic shock must carry self-injectable epinephrine and know how to use it (Simmons, 2007). Patients with severe allergies also may carry self-injectable epinephrine for treatment prior to the arrival of emergency medical personnel. It may be administered by other routes in any setting.

BOX 13.1 COMMUNITY BASED CONCERNS

Teaching for Patients Prescribed Self-Injectable Epinephrine

Epinephrine is commonly prescribed in the community setting as an auto-injector for self-treatment of insect bites, stings, venom, and food allergies. All patients who have experienced anaphylaxis in the community should have access to epinephrine. Health care providers must teach patients how and when to use epinephrine and encourage its appropriate use by reassuring concerns about adverse effects. In most patients, adverse effects are minor and transient. They include tremor, dizziness, palpitations, anxiety, restlessness, and headache. Accidental self-injection, most frequently in the hand, typically does not have serious implications and resolves within 2 to 24 hours. Self-injectable epinephrine is marketed as EpiPen, EpiPen Jr and Twinject with premeasured doses for children and adults. Very large or obese individuals should have at least two doses. The number of auto-injectors dispensed should allow for a dose for every 10 to 20 minutes travel time to a medical facility.

Ensure that patients prescribed self-injectable epinephrine understand the following:

- Anaphylaxis is unpredictable. Subsequent exposures to an allergen can result in an increased reaction.
- Self-injectable epinephrine is the best treatment and will enable immediate relief.
- Carry the injector at all times. Risk for anaphylaxis occurs even outside of normal routines. Store in multiple settings or carry everywhere.
- Use the auto-injector without delay when exposed to an allergen at the first signs of trouble breathing, tightness in the throat or lightheadedness. Teach to distinguish exposures that are not likely to cause anaphylaxis, such as skin contact with a food allergen that is not ingested.
- Inject into the muscle of the outer thigh for more rapid systemic absorption.
- Antihistamines and inhalers are not sufficient treatment for anaphylaxis.
- Store at room temperature, do not refrigerate, and replace injectors yearly.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less Than Body Requirements, related to drug-induced anorexia or nausea
  Desired outcome: *The patient will maintain adequate nutrition by learning how to cope with adverse effects or use an antiemetic agent if recommended.*
- Disturbed Sleep Pattern, Insomnia, related to CNS excitation secondary to adrenergic drug therapy
  Desired outcome: *The patient will learn about and practice sleep hygiene or take bedtime sedatives as prescribed so that normal sleep patterns will be maintained.*
- Disturbed Sensory Perception related to impaired vision
  Desired outcome: *The patient will notify the provider if vision changes occur.*
- Ineffective Tissue Perfusion (Cardiopulmonary) related to cardiovascular effects of epinephrine
  Desired outcome: *The patient will notify the provider if tachycardia, chest pain, or palpitations occur.*

Planning and Intervention

Maximizing Therapeutic Effects

In addition to therapeutic monitoring, administering adrenergic agonists requires close monitoring of vital signs and careful monitoring for adverse effects. Physical measures to treat a stopped heart, such as chest compressions, are used before epinephrine. The IV route is preferred for treatment of cardiac arrest, although intramyocardial injection or insertion through an endotracheal tube may be done by trained personnel if IV access cannot be established. For treatment of respiratory problems, the SC or IV routes may be used. Encourage patients who receive epinephrine for other (nonemergency) uses to take the epinephrine exactly as prescribed and at the required dosage frequency to enhance therapeutic potential.

Minimizing Adverse Effects

When epinephrine is given to treat anaphylactic shock or cardiac arrest, monitor the patient's blood pressure carefully for hypertension. Monitor the patient's pulse and electrocardiogram (ECG) for changes in rhythm. If given intravenously, check the site frequently for patency to prevent extravasation. Should extravasation occur, infiltrate the region with phentolamine to minimize injury.

Patients receiving epinephrine for its cardiovascular effects are placed on continuous cardiac monitoring. Be prepared to intervene if adverse effects to epinephrine occur during therapy. For symptoms such as angina, tachycardia, or cardiac arrhythmias, be prepared to administer beta-adrenergic blocking agents. For hypertension, be prepared to administer alpha-adrenergic blocking agents.

Nursing strategies to minimize adverse effects include providing the patient with light, comfortable bedding, soothing baths, and optimal skin care. Patients receiving epinephrine for bronchodilation may experience restlessness and sweating. If the patient tires easily, you may need to help with self-care activities to minimize fatigue. In addition, promotion of sleep hygiene is important so that the patient can overcome the CNS stimulation that may occur with epinephrine.

Assisting the patient with menu planning may help to promote appetite and counteract the anorectic effect of epinephrine. Monitor the patient for signs of sulfite sensitivity. Finally, key interventions for patients with cardiovascular problems include monitoring for anginal pain and arrhythmias, whereas interventions for asthma patients include regular auscultation of lung sounds and assessment of respiratory functioning.

Epinephrine may be used for its vasoconstrictive properties in conjunction with local anesthetic agents to decrease bleeding during laceration repair. Read the label

carefully to avoid administering epinephrine to an area of the body where vasoconstriction may cause damage, such as the fingers, toes, nose, ears, or male genitalia.

Providing Patient and Family Education

- Many patients who take epinephrine are acutely ill; therefore, it is inappropriate to provide complex instructions. Teaching should be brief, simple, and supportive. Once the acute illness resolves, the patient and family members may realize a greater benefit from instruction, particularly if the patient will be discharged on epinephrine or a similar adrenergic drug.
- For patients taking epinephrine for bronchodilation, explain the proper use and care of a nebulizer or a metered-dose inhaler and advise patients and families about common adverse effects. Emphasize the timing of doses to prevent disrupting sleep.
- For patients at risk for anaphylactic shock in the community setting, teach the proper use of self-injectable epinephrine and emphasize the importance of wearing a Medic Alert bracelet.
- For patients taking epinephrine in ophthalmic form, teach how to instill topical eye drugs properly.
- Advise patients to avoid OTC drugs containing sympathomimetic ingredients, which may potentiate the effects of epinephrine.
- Remind patients with diabetes to monitor their blood glucose levels carefully.

Ongoing Assessment and Evaluation

Assess the patient for resolution of the presenting problem. For example, when epinephrine is administered for the management of bronchoconstriction, the effect of treatment is a decrease in wheezing. Regardless of the presenting problem, the patient is constantly monitored for adverse effects related to the action of epinephrine. It is important to remember that epinephrine is a nonselective adrenergic agonist. Therefore, all receptor subtypes (alpha-1, alpha-2, beta-1, and beta-2) are stimulated, and the potential for adverse reactions is high.

Drugs Closely Related to P Epinephrine

Norepinephrine (Levophed) is very similar to epinephrine. Like epinephrine, NE is a catecholamine and may not be administered orally. The major difference is that NE does not stimulate beta-2 receptors. Adverse effects and drug interactions are identical to those of epinephrine, with the exception that NE does not promote hyperglycemia. Clinically, NE is used in the management of hypotension and cardiac arrest.

Drugs Significantly Different From P Epinephrine

Ephedrine

Like epinephrine, ephedrine stimulates alpha-1, alpha-2, beta-1, and beta-2 receptors. Unlike epinephrine, it is not a catecholamine. Ephedrine, also known as *ma huang,* is derived from plants of the genus *Ephedra* and has been used in Chinese medicine for more than 5,000 years. Ephedrine is metabolized to norephedrine, which is responsible for the stimulating effects of the drug on the CNS.

In Western medicine, ephedrine is primarily used intravenously to prevent or treat hypotension associated with spinal anesthesia and topically for the treatment of sinus congestion. Ephedrine is used extensively in OTC medications because of its ability to stimulate multiple adrenergic receptors. It is a frequent ingredient in OTC bronchodilators as well as in many drugs used for colds and flu. Oral ephedrine and pseudoephedrine have been misused as an agent for weight loss and is often included in herbal products and dietary supplements that supposedly increase strength, decrease weight, and produce an "herbal high." One of its more recent uses is as a substrate for the illegal synthesis of amphetamine and methamphetamine. The U.S. Department of Justice, Drug Enforcement Agency has added both ephedrine and pseudoephedrine to the list of substances subject to the Controlled Substances Act (Drug Enforcement Agency, 2008). Consequently, as of 2008 commonly used OTC medications containing ephedrine or pseudoephedrine must be obtained behind the counter and quantities are limited for each transaction. When used inappropriately, potential severe adverse effects of ephedrine include heart attack, stroke, paranoid psychosis, vomiting, fever, palpitations, convulsions, and coma.

Vasopressin

Vasopressin, also known as antidiuretic hormone, is classified as an endocrine-metabolic or gastrointestinal agent as large doses will stimulate peristalsis. It is also used in the management of shock states due to ventricular fibrillation, hypovolemia, sepsis, and cardiopulmonary bypass. During these shock states, exogenous vasopressin increases blood flow to the heart and brain and reduces blood flow to the

skin, skeletal muscle, small bowel, and fat. According to the American Heart Association Advanced Cardiac Life Support Guidelines (AHA, 2005) a single dose of vasopressin (40 U IV) may be used to replace the first or second dose of epinephrine in the management of pulseless ventricular tachycardia (VT) or ventricular fibrillation (VF). However, recent studies have found that in the case of out-of-hospital cardiac arrest, vasopressin administered with epinephrine showed no improvement in outcomes over epinephrine alone (Gueugniaud et al., 2008). During in-hospital postresuscitation in refractory cardiac arrest, adding the glucocorticoids methylprednisolone and hydrocortisone to the combinations of vasopressin and epinephrine can improve survival (Mentzelopoulos et al., 2009).

• C Alpha-1 Adrenergic Agonists

The alpha-1 adrenergic agonists are drugs that stimulate the alpha-1 receptor directly. Phenylephrine (Allerest) is an ideal prototype for the alpha-1 adrenergic agonists.

Nursing Management of the Patient Receiving P Phenylephrine

Core Drug Knowledge

Pharmacotherapeutics

Phenylephrine may be used parenterally for treatment of vascular failure in shock, shock-like states, or drug-induced hypotension. Other parenteral uses include overcoming paroxysmal supraventricular tachycardia, prolonging spinal anesthesia, maintaining blood pressure during spinal and inhalation anesthesia, and vasoconstriction in regional anesthesia. Although approved for these uses, phenylephrine is generally not the drug of choice for management of these conditions. More commonly, phenylephrine is used topically for relief of nasal and nasopharyngeal mucosal congestion and to produce mydriasis (dilation of the pupil) for ophthalmologic procedures. Phenylephrine for nasal congestion is marketed as an OTC alternative to the now-regulated ephedrine and pseudoephedrine products, although its effectiveness at nonprescription doses has not been proven (Hatton et al., 2007).

Pharmacokinetics

Phenylephrine is poorly absorbed orally and is usually given parenterally or topically. Following IM administration, a vasopressor effect is apparent within 15 to 20 minutes and lasts for 1 to 2 hours (see Table 13.3). The drug is metabolized in the liver and excreted mainly in urine. It has an elimination half-life of 2 to 3 hours. Even if phenylephrine got into breast milk, it would probably be destroyed in the infant's intestines before absorption.

Pharmacodynamics

Phenylephrine is structurally similar to epinephrine and is a powerful alpha-1 adrenergic agonist with very little activity at beta-adrenergic receptors. The predominant actions of phenylephrine are in the vascular system, where it acts as a vasopressor by stimulating alpha-1 vascular receptors and thus causes vasoconstriction. As a result, renal perfusion and cardiac output are decreased, and blood pressure is increased by the heightened peripheral resistance. When used in nasal sprays or cold preparations, the vasoconstriction decreases nasal congestion temporarily.

Contraindications and Precautions

The main contraindications to phenylephrine are drug hypersensitivity, sulfite sensitivity, severe hypertension, ventricular tachycardia, and closed-angle glaucoma. Precautions need to be observed for hyperthyroid states and pregnancy and in patients who are elderly or have diabetes, myocardial disease, arteriosclerosis, uncorrected hypovolemia, or asthma.

Adverse Effects

The main adverse effects of phenylephrine are headache, restlessness, excitability, and reflex bradycardia following an increase in blood pressure. Restlessness and excitability are experienced by many people who take OTC nasal decongestants containing sympathomimetics, with effects similar to those of phenylephrine. Rebound nasal congestion is a common adverse effect.

Drug Interactions

Phenylephrine interacts with monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants, and oxytocics used in labor and delivery (Table 13.5).

Assessment of Relevant Core Patient Variables

Health Status

Assess for medical disorders such as diabetes, hyperthyroidism, heart disease, cerebral arteriosclerosis, bronchial asthma, idiopathic orthostatic hypotension, chronic bronchitis, and chronic obstructive pulmonary disease. Phenylephrine may increase airway resistance and bronchial smooth muscle tone and therefore should be given only if absolutely necessary. Also assess for a history of sulfite sensitivity because some formulations of phenylephrine contain sulfites that may induce a reaction. Finally, assess for recent use of prescription drugs (e.g., tricyclic antidepressants and MAOIs). Communicate positive findings to the health care provider in nonemergency situations before phenylephrine is administered.

Obtain pretreatment vital signs to establish a baseline for therapeutic monitoring and detection of potential adverse effects. During therapy, monitor therapeutic effects to evaluate the decrease in frequency or severity of target symptoms or the resumption of functions that were previously changed.

Life Span and Gender

Document the age and gender of the patient and assess women of childbearing age for pregnancy and lactation. Phenylephine is a pregnancy category C drug. During pregnancy, phenylephrine is used only if absolutely necessary because it is not known whether phenylephrine causes fetal

abnormalities. If the patient is breast-feeding, the infant is monitored for adrenergic stimulation. If such stimulation occurs, the drug may have to be discontinued.

Elderly patients may be at increased risk for blurring of vision from mydriasis. The topical 10% ophthalmic phenylephrine solution is avoided in infants and used cautiously with the elderly because there is an increased risk for systemic absorption.

Lifestyle, Diet, and Habits

Document the patient's occupation and activities of daily living. It is important to advise the patient to exercise caution when driving or operating machinery at night or under very bright light because mydriasis may cause temporary blindness. Additionally, ask the patient about his or her use of OTC cough, cold, or herbal remedies containing sympathomimetic ingredients, which intensify the effects of phenylephrine.

Environment

In the acute care hospital, phenylephrine is administered in a closely monitored area, such as the intensive care unit, for treatment of hypotension or shock. For other uses, it may be self-administered by the patient in any environment.

Nursing Diagnoses and Outcomes

- Impaired Gas Exchange related to bronchoconstriction or bronchospasm
  Desired outcome: *Gas exchange will remain unimpaired by coughing or drug-induced bronchoconstriction.*
- Imbalanced Nutrition: Less Than Body Requirements, related to anorexia or nausea secondary to use of an adrenergic drug
  Desired outcome: *The patient will take sufficient nourishment, manage diet adequately, and use antiemetics if necessary.*
- Disturbed Sleep Pattern, Insomnia, related to CNS excitation secondary to phenylephrine use
  Desired outcome: *The patient will maintain normal sleep patterns by practicing sleep hygiene measures and using a sedative at bedtime if necessary.*

Planning and Intervention

Maximizing Therapeutic Effects

Blood loss or volume deficits are corrected before IV phenylephrine is used to treat hypotension. Phenylephrine may be used concurrently with replacement therapy if necessary to prevent cerebral or coronary artery ischemia. For topical use, the following factors are considered:

- To produce optimal mydriasis, be careful to instill the ophthalmic form of phenylephrine into the conjunctival cul-de-sac.
- If the phenylephrine is in the form of a nasal spray, demonstrate the proper way to administer the spray. The patient can then perform a repeat demonstration.
- Encourage the patient to use phenylephrine exactly as prescribed and at the required dosage frequency to enhance therapeutic effects.

Minimizing Adverse Effects

When given to treat hypotension, IV phenylephrine is administered through a large vein, preferably in the antecubital space. This method will help prevent extravasation, which may cause necrosis as a result of vasoconstriction. Check the IV site frequently for patency. If extravasation does occur, the antidote is the potent alpha blocker phentolamine (Regitine), which is injected subcutaneously into the affected tissue with a fine-gauge needle. Also monitor for signs of sulfite sensitivity.

Teach the patient the following strategies to minimize adverse effects during topical drug therapy:

- Avoid driving at night because blurred vision can be hazardous. Wearing sunglasses, however, may relieve the glare of bright lights and reduce photophobia.
- Time doses to prevent disrupting sleep, and use effective sleep hygiene measures (dimmed lights, reduced noise, soothing music).
- Avoid OTC drugs that contain sympathomimetic ingredients that potentiate the effect of phenylephrine.

Providing Patient and Family Education

- Stress the hazards associated with driving and operating heavy or dangerous machinery until the effects of the drug on the individual are known.
- Teach the patient about drug interactions and advise not to use phenylephrine if he or she is taking MAOIs, tricyclic antidepressants, or drugs that treat glaucoma.
- Teach the patient to recognize and report signs and symptoms of adverse effects requiring medical attention, such as a fast, pounding, or irregular heartbeat; chest pain that lasts longer than 5 minutes; trouble breathing; or tingling in the hands or feet.
- Teach patients that prolonged use for nasal congestion for more than 3 to 5 days can cause rebound congestion.

Ongoing Assessment and Evaluation

Determining whether therapy is successful for patients taking phenylephrine and other adrenergic drugs is relatively straightforward. Because the contraindications and precautions for phenylephrine are many, it is important to assess lifestyle and occupation and be able to recognize and manage adverse effects. Completing a detailed and thorough history and physical examination on any patient anticipating long-term adrenergic drug therapy is essential.

Drug Closely Related to P Phenylephrine

Methoxamine (Vasoxyl) is a parenteral vasopressor agent used for blood pressure support during surgery and for terminating some supraventricular tachycardias. It increases blood pressure by increasing peripheral resistance through the alpha receptors.

Methoxamine is contraindicated for use in patients with sulfite sensitivity, severe hypertension, hyperthyroidism, bradycardia, partial atrioventricular block, myocardial disease, severe arteriosclerosis, or sulfite hypersensitivity.

MEMORY CHIP

P Phenylephrine

- Alpha-adrenergic agonist and vasopressor (constricts blood vessels, raises blood pressure)
- Treats hypotension, shock related to vascular failure, nasal congestion; also used during anesthesia
- Major contraindications: hypersensitivity, severe hypertension, ventricular tachycardia, and closed-angle glaucoma
- Most common adverse effects: hypertension, headache, sleep disturbances
- Most serious adverse effect: reflex bradycardia
- Important drug–drug interaction: possible life-threatening interaction with monoamine oxidase inhibitors
- Maximizing therapeutic effects: Instill eye drops in conjunctival cul-de-sac.
- Minimizing adverse effects: Avoid situations that increase blurred vision.
- Most important patient education: Stress safety related to blurred vision.

Like phenylephrine, methoxamine may interact with MAOIs, tricyclic antidepressants, and oxytocics. In addition, methoxamine may interact with bretylium, which results in arrhythmias. It may partially or fully reverse the antihypertensive effects of guanethidine. Lastly, use of methoxamine with halogenated hydrocarbon anesthetics can sensitize the myocardium to the effects of catecholamines.

Potential adverse effects include hypertension, ventricular ectopic beats, nausea and vomiting, headache, anxiety, sweating, pilomotor response, uterine hypertonus, fetal bradycardia, and urinary urgency.

• C Alpha-2 Adrenergic Agonists

As you recall from previous discussion, the alpha-2 receptors are located on the presynaptic side of the synapse. A significant release of NE is needed to flood the synapse and allow for stimulation on the presynaptic side. Stimulation of alpha-2 receptors act as a negative feedback loop for the release of the SNS neurotransmitter NE. In other words, stimulation of alpha-2 receptors in the SNS decreases sympathetic outflow by inhibiting the release of norepinephrine. The prototype alpha-2 adrenergic agonist is clonidine (Catapres), which has a narrow range of specific clinical indications and has fallen out of favor in many practice arenas. For this reason, although it can be considered a prototype, only a condensed discussion of it will appear in this text.

Clonidine

Clonidine's approved pharmacotherapeutic use is for the treatment of hypertension. Clonidine's alpha-2 stimulation results in decreased heart rate, decreased blood pressure, decreased vasoconstriction, and decreased renal vascular resistance. However, renal blood flow and glomerular filtration rate remain unchanged essentially. Clonidine is considered a secondary or supplemental antihypertensive; its antihypertensive uses are actually quite limited and are discussed in Chapter 26. Off-label uses are varied but mostly relate to its sympathetic inhibition effects from alpha-2 stimulation. They include preventing symptoms of alcohol, methadone, or opiate withdrawal during detoxification (perhaps the most common current use for the drug); reduction of allergen-induced inflammatory reactions in patients with extrinsic asthma; smoking cessation; and ulcerative colitis. Clonidine also can be administered via an epidural line to control pain; it appears to prevent pain transmission from the spinal cord to the brain.

Clonidine may be administered orally, parenterally, or, most frequently, transdermally. When administered transdermally, the drug is released at a constant rate for 7 days. Patients need to be taught how to apply the patch and how to safely dispose of it.

Some adverse effects of clonidine, such as dry mouth, drowsiness, dizziness, sedation, and constipation, are fairly common. Dry mouth and drowsiness also occur frequently when clonidine is administered transdermally. Rebound hypertension may occur if the drug is discontinued abruptly. Erythema is a common adverse effect.

Because clonidine can be used to prevent the symptoms of narcotic withdrawal, a black market exists for clonidine in some communities and the patient may be tempted to sell the prescription. Nurses and other health care providers should be alert to patients returning for a duplicate prescription of clonidine, claiming to have lost the original shortly after it was prescribed. This may indicate the patient has sold or stored the prescription. In such cases, the prescriber may be notified and consulted about a change in the prescription, particularly if it appears that the patient is not taking the clonidine.

• C Beta-Adrenergic Agonists

Beta-adrenergic agonists also mimic the action of the SNS; therefore, they are also known as sympathomimetic agents. They exert their effects by stimulation of one or both beta-adrenergic receptors. Like the alpha-adrenergic drugs, they are classified as either a catecholamine or noncatecholamine.

Beta-adrenergic agonists are also labeled according to their selectivity. Drugs that stimulate both beta-1 and beta-2 receptors are nonselective. Those that target either beta-1 or beta-2 are selective. To maximize therapeutic effects and minimize adverse effects, selective drugs are used most frequently. Again, as with alpha-adrenergic drugs, selectivity is preferential but not exclusive.

Beta-1 Agonists

The prototypical beta-1 agonist is dopamine (Intropin). Dopamine also can stimulate dopaminergic receptors, but it is chosen as the beta-1 agonist prototype as it clearly effects beta-1 receptors and is a drug widely used for cardiovascular problems.

Nursing Management of the Patient Receiving P Dopamine

Core Drug Knowledge

Pharmacotherapeutics

Dopamine is used to correct the hemodynamic imbalances present in shock due to myocardial infarction, trauma, endotoxic septicemia, open heart surgery, renal failure, and chronic cardiac decompensation (i.e., chronic heart failure) (see Table 13.3). For the treatment to be most effective, the patient should not be experiencing severe disruptions in urine production, myocardial function, and blood pressure. In other words, the earlier the signs of shock are recognized and treatment is started with fluids and dopamine, the more successful the therapy will be. There is debate that dopamine provides only transient improvements in renal perfusion in patients with renal failure, and low doses for nephroprotective purposes are discouraged (Drieghe et al., 2008). Dopamine is used off-label for cardiac catheterization, acute hypotension, and organ transplant.

Pharmacokinetics

The onset of dopamine's action is within 5 minutes. Duration of action is less than 10 minutes. The drug is distributed widely in the body but does not cross the blood–brain barrier. Dopamine is metabolized in the liver, kidneys, and plasma by MAO and COMT to inactive compounds. About one fourth of it is taken up into adrenergic nerve terminals that are specialized neurosecretory vesicles. There, through hydroxylation, it becomes norepinephrine. Dopamine is excreted mainly by the kidneys.

Pharmacodynamics

Dopamine is a naturally occurring catecholamine and a precursor to norepinephrine. It stimulates alpha-1 and beta-1 receptors through direct methods and indirectly through the release of stored epinephrine. It also has dopaminergic effects. Beta-1 stimulation produces increased cardiac output by increasing the force of contraction and heart rate. Although dopamine causes the oxygen needs of the myocardium to increase, this effect is less pronounced than when isoproterenol is administered. Tachyarrhythmias usually do not occur. Systolic blood pressure increases, whereas if any increases in diastolic pressure occur, they are usually minimal. Total peripheral resistance (from alpha effects) is not changed substantially if dopamine is given at low or intermediate levels. Although blood flow to the peripheral beds may decrease, blood flow to the mesenteric beds increases. Dopamine dilates renal and mesenteric vasculature as well as the cerebral and cardiac beds. This dilation, which is believed to arise from stimulation of dopaminergic receptors, produces an increase in renal blood flow, glomerular filtration rate, and urinary output. The dopaminergic zero effect in the peripheral resistance is lost as the dose becomes high because the alpha stimulation takes precedence. The alpha stimulation produces increased peripheral resistance, raising blood pressure as the dose of dopamine increases. The drug's dosage is titrated upward until adequate perfusion of vital organs is achieved.

Contraindications and Precautions

Dopamine is contraindicated in pheochromocytoma, uncorrected tachyarrhythmias, and ventricular fibrillation. Any underlying hypovolemia is corrected before therapy begins. Acidosis decreases the effectiveness of dopamine and other vasopressors. It is important to correct acidosis before starting therapy or as soon as it occurs. Dopamine must be administered in an environment where blood pressure, cardiac output, urinary flow, and pulmonary wedge pressure can be monitored closely.

Adverse Effects

The most frequent adverse effects from dopamine are ectopic beats, nausea and vomiting, tachycardia, angina, palpitations, dyspnea, headache, hypotension, and vasoconstriction. Infrequent effects are abnormal conduction, bradycardia, widened QRS complex, and piloerection. High

doses may cause ventricular arrhythmias and dilated pupils. High doses given over a long time have caused gangrene. Gangrene has also occurred in patients receiving low doses who had occlusive vascular disease.

Overdosage is evidenced by excessive hypertension. If overdosage occurs, reduce the rate or stop the infusion until the patient is stabilized.

Drug Interactions

A few drugs are known to interact with dopamine (Table 13.6).

Assessment of Relevant Core Patient Variables

Health Status

The absence of pheochromocytoma, uncorrected tachyarrhythmias, and ventricular fibrillation must be confirmed because these conditions are contraindications to the use of dopamine. Verify that existing volume deficits have been corrected. Also assess for drug use known to cause interaction, especially MAOIs. It is important to determine whether the patient has a history of occlusive vascular disease (such as arteriosclerosis, arterial embolism, Raynaud disease, or frostbite), because such a patient may be more likely to develop necrosis from vasoconstriction with dopamine. If possible, assess for a history of sulfite sensitivity, because some dopamine formulations contain sulfites.

Life Span and Gender

Assess for pregnancy because dopamine is a risk category C drug. Whether dopamine is excreted into breast milk is unknown. Also note the patient's age before administering dopamine. Dopamine's effect and safety in children has not been established, although it has been used in a limited number of pediatric cases.

Environment

Because dopamine is an IV drug, it is administered only in acute care settings, where continuous monitoring of the patient's cardiovascular status can occur.

Nursing Diagnoses and Outcomes

- Risk for Ineffective Tissue Perfusion to Vital Organs related to drug effect
  Desired outcome: *The patient will maintain sufficient perfusion of vital organs to prevent serious damage.*
- Risk for Injury related to adverse effects of drug therapy
  Desired outcome: *Adverse effects of drug therapy will not occur or will be minimized to prevent injury.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer IV dopamine using an infusion pump to regulate flow. It is important to start at low doses and titrate up until the desired renal or hemodynamic response is attained. Oxidizing agents, iron salts, or alkaline solutions such as 5% sodium bicarbonate are not added because these substances deactivate dopamine.

Minimizing Adverse Effects

If the drug is not prediluted, follow the manufacturer's instructions for dilution, because dopamine is a potent drug that may cause extravasation. It is imperative to use an infusion pump. Before treatment, correct hypovolemia

with whole blood or plasma as indicated. Monitor the blood pressure, urinary flow, cardiac output, and pulmonary wedge pressure closely throughout therapy.

Assess for a disproportionate rise in diastolic blood pressure, which may indicate predominant vasoconstriction. Patients with a history of occlusive vascular disease are monitored closely for changes in temperature or color of skin or extremities. If these changes occur, consult with the physician to determine the benefits of dopamine compared with the risk for developing necrosis.

Monitor the insertion site for patency, free flow, and signs of extravasation. Using a large vein such as the antecubital fossa decreases the potential for extravasation. Should extravasation occur, inject the affected area with phentolamine in the subcutaneous space to minimize the potential for necrosis or sloughing of tissues.

When discontinuing dopamine, gradually decrease the dose and then monitor the resulting effects. Sudden discontinuation of dopamine may induce hypotension.

Providing Patient and Family Education

- Dopamine is administered during an acute medical crisis. Patient education is therefore limited at that time.
- If the patient is awake and alert, inform the patient that his or her blood pressure is low and that the medication will raise blood pressure to a normal level.
- Instruct patient to report signs of chest pain, palpitations, rapid heart rate, and extravasation.
- Advise patient that this drug may cause headache, anxiety, nausea, vomiting, oliguria, and difficulty breathing.
- Reassure the patient and family that the patient will be monitored closely during administration of the drug.

MEMORY CHIP

P Dopamine

- Used to treat the hypotension resulting from shock because it stimulates alpha and beta receptors to increase cardiac output, blood pressure, and renal perfusion
- Correct hypovolemia before administering.
- Major contraindications: pheochromocytoma, uncorrected tachyarrhythmias, and ventricular fibrillation
- Most common adverse effects: ectopic beats, nausea and vomiting, tachycardia, angina, palpitations, dyspnea, headache, hypotension, and vasoconstriction
- Most serious adverse effect: ventricular arrhythmias
- Important drug–drug interaction: monoamine oxidase inhibitors
- Maximizing therapeutic effects: Use infusion pump, titrate drug until desired effect is obtained.
- Minimizing adverse effects: Monitor blood pressure, urinary output, cardiac output, and pulmonary wedge pressure throughout therapy.
- Most important patient education: Reassure patient that close monitoring will be maintained.

Ongoing Assessment and Evaluation

Dopamine therapy is effective if blood pressure stabilizes, urinary output returns to normal, cardiac output returns to normal, and the patient does not have serious adverse effects from the drug.

Drugs Closely Related to P Dopamine

Dobutamine

Dobutamine (Dobutrex) is chemically similar to dopamine. Like dopamine, its primary influence is on beta-1 receptors, with similar effects on the force of contraction. Dobutamine is somewhat less effective than dopamine at increasing the rate at the sinoatrial (SA) node. Also like dopamine, dobutamine's beta-2 effects on vasodilation are minimal. Unlike dopamine, dobutamine has almost no effect on alpha receptors to cause vasoconstriction. Although cardiac output and blood pressure are similarly increased with both drugs, dobutamine does not produce the increased renal output that dopamine does. Furthermore, dobutamine always increases peripheral resistance, whereas dopamine may increase or decrease peripheral resistance. Dobutamine does not cause the release of endogenous norepinephrine that dopamine causes.

The pharmacotherapeutic uses of dobutamine differ from those of dopamine. Dobutamine is indicated in the short-term treatment and support of patients experiencing cardiac decompression because of depressed contractility. The decreased contractility may be secondary to either organic heart disease or cardiac surgery. Patients with atrial fibrillation and a rapid ventricular rate are treated with digoxin before dobutamine treatment to protect the ventricles.

Dobutamine is metabolized by two methods: methylation of the catechol and conjugation. By-products are excreted in the urine. Onset of action is 1 to 2 minutes, but up to 10 minutes may be needed for the peak effect to occur. A contraindication unique to dobutamine is the presence of idiopathic hypertrophic subaortic stenosis. Although elevated pulse usually does not occur when using dobutamine, tachycardia can occur. Accompanying the tachycardia is a rapid and substantial increase in blood pressure, with the systolic pressure rising 50% or more. These adverse effects are usually dose related, and reducing the dose promptly corrects the problem. Interestingly, dobutamine also can cause significant hypotension if given in excessive amounts; again, decreasing the dose usually corrects the problem. Dobutamine may cause or exacerbate ventricular ectopic beats, although ventricular tachycardia is rare. Other rare adverse effects include nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath. Phlebitis and local inflammation at the IV site may occur; a large vein is chosen to minimize the patient's risk for developing these complications. Coons and Seidl (2007) identify a decreased responsiveness to dobutamine in elderly patients, and recommend that hemodynamic endpoints be targeted instead of using a specific dose. Doses of 2.5 to 10 mcg/kg per minute can increase cardiac output

without significantly increasing heart rate, but doses over 20 mcg/kg per minute increase the risk of tachycardia and hypotension in all patients.

As with dopamine, patients receiving dobutamine require continuous cardiac monitoring while receiving the drug. Blood pressure is checked frequently. Pulmonary wedge pressure and cardiac output (assessed on a cardiac monitor that reads the information from inside the heart via a catheter inserted into the pulmonary artery) are checked whenever possible.

Isoproterenol

Like dopamine, isoproterenol (Isuprel) has a strong effect on beta-1 receptors and produces similar increases in contractility. However, isoproterenol's effects on heart rate and vasodilation are much greater than those of dopamine. Isoproterenol does not stimulate the alpha receptors for vasoconstriction. Like dopamine, isoproterenol increases cardiac output. Renal perfusion is also affected, although unlike dopamine, isoproterenol can either increase or decrease it. Peripheral resistance always is decreased, but blood pressure may go up or down from isoproterenol. Although isoproterenol may be used to treat shock, the practice is uncommon because of the tachycardia that may occur. Isoproterenol is an ingredient in respiratory drugs used to manage asthma, bronchitis, and emphysema.

Mephentermine

Mephentermine (Wyamine) has a weaker effect than dopamine on the beta-1 receptors, causing less increase in contractility and heart rate. However, it has a stronger effect on the beta-2 receptors, producing moderate vasodilation. It has only a weak effect on alpha-1 receptors, causing a small increase in vasoconstriction. The pharmacodynamics of mephentermine, when compared with those of dopamine, are in some ways similar. It increases cardiac output and blood pressure. It may have no effect on peripheral resistance or it may increase it, and renal perfusion may increase or decrease. Mephentermine is used to treat hypotension from ganglionic blockade or spinal anesthesia. It can be used on an emergency basis to maintain blood pressure during hypovolemic shock, but only until blood or blood substitutes become available.

Metaraminol

Metaraminol (Aramine) is similar to mephentermine in that it has only minor effects on beta-1 receptors, creating mild increases in contractility and heart rate. It has more effect on vasoconstriction from alpha-1 stimulation than mephentermine, but less than dopamine has. It has no effect on vasodilation from beta-2 stimulation. It primarily increases blood pressure by increasing peripheral resistance. Unlike dopamine, it lowers cardiac output and renal perfusion. Although it stimulates the sinoatrial node somewhat (which theoretically should increase the heart rate), the net effect on the heart is bradycardia, resulting from a strong reflexive response to the significant vasoconstriction. Metaraminol is used in the prevention and treatment of acute hypotensive states occurring with spinal anesthesia. It is an adjunct treatment for hypotension due to hypovolemia, reactions to drug therapy, surgical complications, and shock associated with brain damage due to trauma or tumor. Unlike dopamine, it can be given by IM or SC injection, in addition to being given as an IV infusion.

Drugs Significantly Different From P Dopamine

Midodrine

Midodrine (ProAmatine) raises blood pressure, but it is not used as a vasopressor in shock. Instead, it is used in the symptomatic treatment of orthostatic hypotension in patients whose lives are impaired significantly despite standard clinical treatment. An unlabeled use is in the treatment of urinary incontinence. It is administered orally. Midodrine is a prodrug that becomes active when it changes into the metabolite desglymidodrine. The metabolite is an alpha-1 agonist that increases the tone of the arteriolar and venous vasculature, increasing peripheral resistance. It results in increased standing, sitting, and lying blood pressures in orthostatic hypotension. Because it increases supine blood pressure, midodrine is not given less than 4 hours before bedtime. Suggested dosing times are shortly before or just after rising in the morning, midday, and late afternoon. This dosing schedule helps the patient maintain his or her normal daytime activities and prevent supine hypertension during the night. If supine hypertension does occur, it may be controlled by preventing the patient from lying completely flat (e.g., by lying with the head of the bed elevated).

Beta-2 Agonists

Drugs that are selective for beta-2 stimulation are used in the management of chronic airway limitation (CAL) diseases such as asthma. They may be given orally, parenterally, by nebulizer, or by metered-dose inhalers. While historically nonselective beta-2 agonist drugs were used in these conditions, they produced significant cardiac adverse effects. To minimize adverse effects, use of beta-2 selective drugs has become the community standard. Beta-2 respiratory agonists differ from each other in the way they are delivered as well as in their onset and duration of action. The prototype respiratory beta-2 agonist is albuterol. Albuterol as well as other respiratory beta-2 agonist drugs are discussed in Chapter 35.

• C DOPAMINERGIC AGONISTS

Although there are five types of dopamine receptors, only dopamine-1 (DA1) and dopamine-2 (DA2) receptors mediate responses in the adrenergic nervous system. Stimulation of DA1 and DA2 receptors results in peripheral vasodilation; however, stimulating both receptors may have either complementary or opposing effects. Fenoldopam (Corlopam) is

a DA1 agonist and the prototype for dopaminergic agonist drugs. It was chosen as the prototype over dopamine as it only stimulates dopaminergic receptors.

Nursing Management of the Patient Receiving P Fenoldopam

Core Drug Knowledge

Pharmacotherapeutics

Fenoldopam is used for in-hospital, short-term (up to 48 hours) management of severe hypertension when rapid and selective but quickly reversible emergency reduction of blood pressure combined with renal vasodilation is necessary.

Pharmacokinetics

Fenoldopam is administered as a constant infusion. Steady-state concentrations are achieved within 20 minutes. There is a predictable relationship between the dose and the plasma concentration of fenoldopam. Metabolism of fenoldopam is by conjugation in the liver without involvement of the cytochrome P-450 enzymes. Ninety percent of infused fenoldopam is eliminated in urine and 10% in feces.

Pharmacodynamics

Fenoldopam is a selective peripheral DA1 agonist. Unlike dopamine, it does not bind with DA2, alpha, or beta receptors. It provides rapid vasodilation to the coronary, renal, mesenteric, and peripheral arteries. The pharmacokinetics of fenoldopam is not influenced by age, gender, or race in hypertensive emergency patients (see Table 13.3).

Contraindications and Precautions

Fenoldopam is contraindicated in patients with known hypersensitivity to sulfites because it is in a solution containing sodium metabisulfate (Varon, 2008). Patients with a history of glaucoma or intraocular hypertension are monitored closely because fenoldopam may increase intraocular pressure during infusion. Increases in intraocular pressure are dose-dependent (Varon, 2008). Patients with hypokalemia also require close monitoring because fenoldopam may reduce serum potassium when administered for more than 6 hours. Fenoldopam is given cautiously to patients with acute cerebral infarction or hemorrhage because it may cause hypotension.

Adverse Effects

Fenoldopam may induce symptomatic hypotension; therefore, close monitoring of blood pressure is essential. Fenoldopam may also cause dose-related tachycardia, especially with infusion rates greater than 0.1 mcg/kg/min. Tachycardia diminishes over time but remains elevated with higher doses. Patients may also experience flushing of the face, neck, or upper chest; headache; nausea; and vomiting. Less common adverse effects include abdominal or back pain, GI effects, sweating, and CNS effects such as insomnia, dizziness, nervousness, or anxiety.

Drug Interactions

No formal drug–drug interaction studies have been done with fenoldopam. Fenoldopam should be avoided with beta blockers and diuretics (Table 13.7). Theoretically, the potential exists for drug–drug interactions with the concomitant administration of antihypertensive agents such as alpha blockers, calcium-channel blockers, or angiotensin-converting enzyme (ACE) inhibitors.

Assessment of Relevant Core Patient Variables

Health Status

Assess for a history of sulfite sensitivity, because fenoldopam contains sulfites that may induce a reaction. Also assess for a history of glaucoma or intraocular hypertension and determine whether antihypertensive medications were used recently. Document preinfusion baseline vital signs, especially the blood pressure and heart rate. In a nonemergent situation, obtain a baseline serum potassium level.

Life Span and Gender

Fenoldopam is a pregnancy risk category B drug; however, because animal reproduction studies are not always predictive of human response, fenoldopam is used during pregnancy only if clearly needed. Whether fenoldopam is excreted in breast milk is unclear. Its safety and efficacy in pediatric use have not been established.

Environment

Fenoldopam is administered only in the acute care hospital setting. When used for antihypertensive emergent therapy, the drug is administered in a critical care environment.

Nursing Diagnoses and Outcomes

- Risk for Ineffective Tissue Perfusion related to hypotension, tachycardia, or increased intraocular pressure
  Desired Outcome: *The patient will maintain adequate tissue perfusion throughout therapy.*

TABLE 13.7 Agents That Interact with P Fenoldopam

Interactants	Effect and Significance	Nursing Management
Beta-adrenergic blocking agents	Potential inhibition of reflex tachycardia resulting in decreased cardiac output	Advise provider if patient has been on recent beta-blocker therapy. Avoid concomitant use.
Diuretics	The natriuretic and diuretic properties of fenoldopam could lead to worsening volume depletion.	Advise provider if patient has been on recent diuretic therapy. Avoid concomitant use.

- Risk for Injury related to hypokalemia
  Desired Outcome: *The patient will maintain a serum potassium level within normal limits throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Dilute the fenoldopam ampule concentrate with 0.9% sodium chloride or 5% dextrose. The drug is administered with an infusion pump to regulate flow. Fenoldopam is never administered as an IV push. The initial dose is titrated upward or downward, no more frequently than every 15 minutes and less frequently as goal blood pressure is approached. The recommended increments for titration are 0.05 to 0.1 mcg/kg/min to a maximum of 1.6 mcg/kg/min.

Minimizing Adverse Effects

Visually inspect the drug ampule. If particulate matter or cloudiness is observed, discard the medication. Start at low doses and titrate up to avoid reflex tachycardia. Monitor the heart rate and blood pressure continuously throughout the infusion. Fenoldopam may be abruptly discontinued in the presence of hypotension. In patients receiving fenoldopam for more than 6 hours, obtain baseline and periodic electrolyte levels, especially for potassium. Monitor intraocular pressure in patients with intraocular hypertension or glaucoma. Discard diluted solution that is not used within 24 hours of preparation.

Providing Patient and Family Education

- Explain to the patient and family the rationale for the use of fenoldopam.
- Emphasize the importance of reporting adverse effects, especially those associated with hypotension, during the infusion.
- Explain the necessity of frequent heart rate and blood pressure measurement.
- Reassure the patient that close monitoring will be maintained throughout drug therapy.

Ongoing Assessment and Evaluation

It is important to monitor vital signs throughout fenoldopam infusion. In the hypertensive patient, evaluate the efficacy of fenoldopam by monitoring the reduction in blood pressure.

Drugs Significantly Different from P Fenoldopam

Carbidopa-levodopa

Carbidopa-levodopa is also a dopaminergic drug but it works on the dopamine receptors in the brain, D_1, D_2, D_3. These dopamine receptors help to maintain a balance of stimulation versus non-stimulation of the basal ganglia in the brain. This balanced stimulation (with counter-balance from ACh stimulation) is required for normal, smooth, coordinated motor function. When there is a lack of this dopamine stimulation, the patient experiences Parkinson disease.

MEMORY CHIP

P Fenoldopam

- Used to treat severe hypertension by stimulating dopamine-1 receptors, resulting in peripheral vasodilation
- Major contraindications: sulfite hypersensitivity
- Most common adverse effects: hypotension, tachycardia, facial flushing, headache, nausea
- Most serious adverse effect: hypotension angina, cardiac dysrhythmia, heart failure
- Important drug–drug interaction: beta-blocking agents and diuretics
- Maximizing therapeutic effects: Titrate the drug slowly.
- Minimizing adverse effects: Continuously monitor heart rate and blood pressure; administer by continuous IV infusion (do not use bolus).
- Most important patient education: Reassure the patient that close monitoring will be maintained.

Carbidopa-levodopa is discussed as a prototype for treating Parkinson disease in Chapter 21.

C ADRENERGIC ANTAGONISTS

• C Alpha-Adrenergic Antagonists

Alpha-adrenergic antagonists block the stimulation of alpha receptors. Alpha-1 receptors have three distinct subtypes: alpha-1a, alpha-1b, and alpha-1d. Alpha-1a receptors mediate human prostatic smooth muscle contraction, whereas alpha-1b and alpha-1d receptors are involved in vascular smooth muscle contraction. Clinically relevant drugs in current use block alpha-1 receptors in the vasculature and the prostate. The prototype alpha-adrenergic antagonist is prazosin (Minipress).

Nursing Management of the Patient Receiving P Prazosin

Core Drug Knowledge

Pharmacotherapeutics

Prazosin is primarily used to treat hypertension as a second-line drug when combined with other drugs. It also may be used in the treatment of refractory chronic heart failure, Raynaud syndrome, post-traumatic stress disorder (PTSD), and benign prostatic hyperplasia (BPH).

Pharmacokinetics

Prazosin is given orally. It is metabolized in the liver without involvement of the P-450 enzymes and is excreted in the bile, feces, and urine. Prazosin is highly protein bound. It crosses the placenta and may enter breast milk. A single oral dose has a 10-hour duration of action and a half-life of 2 to 4 hours (Table 13.8).

Pharmacodynamics

Prazosin selectively and competitively blocks postsynaptic alpha-1 adrenergic receptors, decreasing sympathetic tone

Contraindications and Precautions

The main contraindication to prazosin use is hypersensitivity. Prazosin is used cautiously in patients with angina pectoris because severe hypotension may cause or worsen angina. Prazosin is also used cautiously in patients who are pregnant or who have chronic heart failure or renal failure.

Adverse Effects

The most common adverse effects of prazosin are lightheadedness, dizziness, headache, drowsiness, weakness, lethargy, nausea, and palpitations. These effects may spontaneously resolve or be alleviated with a decreased dosage. Other common adverse effects include reflex tachycardia, orthostatic hypotension, nasal congestion, and inhibition of ejaculation.

Prazosin is well known for causing "first-dose syncope." This adverse effect is more likely with higher doses and with patients who are volume-depleted (Sica, 2005) and may be avoided by administering a lower first dose with food. Prazosin-induced syncope is unpredictable and does not correlate with serum prazosin levels. Syncope may be preceded by tachycardia (120 to 160 bpm) and occurs more frequently with dosage increases alone or when increases are combined with the adjunctive use of other antihypertensive agents.

Prazosin may cause adverse effects in practically any body system. Adverse effects include edema, dyspnea, and angina. Prazosin therapy may also induce rash, pruritus, priapism, urinary frequency, incontinence, blurred vision, dry mouth, pancreatitis, liver function test abnormalities, diaphoresis, fever, arthralgia, and mental depression.

Drug Interactions

Prazosin has many potential drug interactions. Prazosin may interact with other antihypertensive medications, especially other alpha- or beta-blocking agents. It may also interact with drugs for erectile dysfunction, resulting in profound hypotension. Certain herbal supplements such as dong quai, ephedra, yohimbe, ginseng, saw palmetto, and garlic may also interact with prazosin. Alcohol should be avoided as well, as it may increase vasodilation.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient's history for diseases or disorders that may contraindicate the use of prazosin. Communicate positive findings to the provider before the drug is given. Before and throughout therapy, closely monitor the patient's heart rate and blood pressure and assist the patient with position changes and ambulation.

Life Span and Gender

Document the age and gender of the patient and assess women of childbearing age for pregnancy and lactation. If the patient is pregnant, prazosin must be used cautiously if at all because it is in FDA pregnancy risk category C. Safety and efficacy have not been established in pediatric patients. Elderly patients are more likely than other adults to be affected by postural hypotension and syncope.

Lifestyle, Diet, and Habits

Document the patient's occupation and daily activities. Patients should be cautious when operating machinery, exercising, driving, changing positions, or climbing stairs. Assess the patient for use of herbal supplements, which may interact with prazosin and for alcohol use, which may increase vasodilation.

Environment

Be aware of the environment in which the drug will be administered and assess the home or living environment, if appropriate. Prazosin may be administered in any setting, by health care providers, nurses, or the patients themselves.

Nursing Diagnoses and Outcomes

- Ineffective Tissue Perfusion related to prazosin-induced hypotension
  Desired outcome: *The patient will maintain adequate tissue perfusion.*
- Imbalanced Nutrition: Less Than Body Requirements, related to nausea secondary to prazosin use
  Desired outcome: *The patient will receive adequate nourishment by practicing appropriate dietary management.*
- Risk for Injury related to orthostatic hypotension
  Desired outcome: *The patient will remain free of injury.*

Planning and Intervention

Maximizing Therapeutic Effects

Emphasize the importance of taking the prescribed dose on a daily basis exactly as instructed. Explain the importance of refraining from OTC drug use because many OTC drugs contain ingredients that may decrease or dangerously enhance the effectiveness of prazosin.

Minimizing Adverse Effects

Nursing strategies to minimize adverse effects include having the patient take the first dose just before bedtime, having the patient lie down if syncope occurs, monitoring the patient's weight, and checking for edema. Explain the importance of changing position slowly to avoid orthostatic hypotension.

Providing Patient and Family Education

- Advise patients to take the drug as prescribed and to avoid operating machinery or driving for about 4 hours after the first dose.
- Teach the patient about additional adverse effects, such as dizziness and weakness (after changing position rapidly, in hot weather, after exercising, and after drinking

- Most serious adverse effect: "first dose syncope"
- Maximizing therapeutic effects: Refrain from administering any OTC drug in combination with prazosin.
- Minimizing adverse effects: Stress safety issues regarding CNS effects; check drug interactions.
- Most important patient education: safe ways to cope with postural hypotension; use caution driving or using heavy machinery.

alcohol). To avoid injury from these effects, the patient may need to avoid driving or engaging in tasks that require alertness until the body adjusts to the drug, to change positions slowly, to use caution when climbing stairs, to cool down when exercising, and to avoid consuming alcoholic beverages.

- Highlight the symptoms that should be reported to the provider if they occur. These symptoms include blurred vision, difficulty breathing, fainting spells, light-headedness, irregular heartbeat, palpitations or chest pain, mental depression, swelling of the legs and ankles, protracted vomiting, and prolonged, painful erections.

Ongoing Assessment and Evaluation

Monitoring of blood pressure, heart and lung sounds, and edema is important. To identify significant potential drug interactions, also determine whether any other drugs are being taken concurrently with prazosin.

Drugs Closely Related to P Prazosin

Alfuzosin (Uroxatral), doxazosin (Cardura), tamsulosin (Flomax), and terazosin (Hytrin) are also alpha-adrenergic antagonists. They differ from each other in pharmacokinetics and their specificity to alpha-1a subtype receptors. All of these drugs are used to manage benign prostatic hyperplasia (BPH). With the exception of alfuzosin, they all require dose titration when beginning therapy.

Alfuzosin is used primarily to treat symptoms of BPH. It is given cautiously to patients with hepatic dysfunction and is metabolized mainly by the P-450 system. It is also given cautiously to patients with pre-existing cardiac disorders because it may prolong the QT interval. Alfuzosin is the least likely of the alpha blockers to cause ejaculatory problems. It should be given with food. Doxazosin is also used in the management of hypertension as well as the treatment of BPH symptoms and CHF. Doxazosin, like prazosin, may also induce first-dose syncope. It is used cautiously in patients with hepatic dysfunction.

Tamsulosin is a once-a-day capsule that should be taken with a meal. The nurse teaches the patient not to open, crush, or chew the capsule, to maintain its prolonged action. Tamsulosin causes less hypotension than other alpha blockers and may be given concurrently with antihypertensive agents. Additionally, tamsulosin is the alpha blocker most likely to cause ejaculatory problems.

Terazosin is another alpha blocker that may cause first-dose syncope. It also alters lipid metabolism, decreasing the levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, and very-low-density lipoprotein (VLDL) cholesterol. Terazosin is also used in the management of hypertension.

Drugs Significantly Different From P Prazosin

Phentolamine

Unlike prazosin, phentolamine (Regitine, Oraverse) blocks both alpha-1 and alpha-2 receptors. It is used in the management of tissue necrosis caused by extravasation of parenterally administered alpha-adrenergic (e.g., epinephrine) drugs and in the management of symptoms from a pheochromocytoma, an adrenaline-secreting tumor of the adrenal gland that causes severe hypertension. Phentolamine may induce adverse effects similar to those of prazosin, but it is more likely to cause reflex tachycardia because of its ability to block alpha-2.

Phentolamine is contraindicated in patients with a known hypersensitivity or renal impairment. It is also contraindicated for use in patients with a history of acute myocardial infarction or any evidence of coronary artery disease because of its cardiac-stimulating effects and resultant increase in myocardial oxygen demand. Also, reflex tachycardia can exacerbate angina. Phentolamine is used with caution in patients with gastric and duodenal ulcers because the drug has a histamine-like effect. Phentolamine can stimulate secretion of gastric acid and pepsin in the stomach, which can aggravate peptic ulcer disease.

Phentolamine should not be used in conjunction with epinephrine. Phentolamine can antagonize epinephrine's alpha receptor–mediated actions and exaggerate its beta-adrenergic responses, resulting in hypotension, vasodilation, and tachycardia. Potential adverse reactions are similar to those of prazosin.

Phenoxybenzamine

Like phentolamine, phenoxybenzamine (Dibenzyline) blocks both alpha-1 and alpha-2 receptors. Its approved use is for the treatment of sweating and hypertension associated with pheochromocytoma. It has additional off-label uses for treatment of urinary symptoms associated with BPH, neurogenic bladder, and functional outlet obstruction and hypertensive crises brought on by sympathomimetic amines. The effects of phenoxybenzamine are similar to those of phentolamine. Phenoxybenzamine has a slower onset of action and a longer duration of action than phentolamine—its effects begin

several hours after administration, and the effects of a single dose may last 3 to 4 days.

• C Beta-Adrenergic Antagonists

Beta-adrenergic antagonists are frequently and more commonly called beta blockers. They comprise a significant group of drugs that can be grouped according to their specificity of action at the beta-1 and beta-2 receptors. If the predominant actions of stimulation of each of the two groups of beta-adrenergic receptors are considered, it follows that sometimes a therapeutic effect will require stimulation of beta-1 only (tachycardia, increased lipolysis, inotropy) or sometimes of both beta-1 and beta-2 receptors (vasodilation, decreased peripheral resistance, bronchodilation). Metoprolol (Lopressor, Toprol XL) is the prototype nonselective beta blocker.

Nursing Management of the Patient Receiving P Metoprolol

Core Drug Knowledge

Pharmacotherapeutics

Metoprolol is approved for the treatment of hypertension, angina, and controlled congestive heart failure. (For a complete discussion of beta-blocker therapy in heart failure, see Chapter 29). It is also used to treat irregular cardiac rhythms. It is used after myocardial infarction. It has been used to treat essential tremor when first-line medications are not effective (Lyons & Pahwa, 2008). Metoprolol also is used for the prevention of migraines (Schellenberg, Lichtenthal, Wohling, Graf, & Brixius, 2008),

Pharmacokinetics

Metoprolol is well absorbed following oral administration, and peak serum levels are observed within 1.5 to 4 hours of ingestion; however, hypotensive stability may not occur for 2 to 3 weeks. Beta blockade may occur within 1 to 2 hours. Parenteral dosing speeds the onset and lowers the duration. Much of an ingested dose is subjected to first-pass metabolism in the liver. Metabolites are excreted through urine. Metoprolol crosses the placenta and is excreted into breast milk. It has a half-life of 3 to 8 hours.

Pharmacodynamics

Metoprolol is a relatively selective beta-blocking drug that is selectively active on beta-1 (cardiac) receptors. It may also block beta-2 (bronchial, vascular smooth muscle) receptors at higher doses (greater than 100 mg). Some patients are more sensitive to these effects than other patients. Beta-1 blockade decreases heart rate and myocardial contractility during periods of high sympathetic activity (such as during physical exercise), which results in decreased cardiac output. As cardiac output decreases, so does blood pressure. In cardiac conduction tissue, beta blockade results in slowing of atrioventricular conduction and suppression of automaticity. These actions result in decreased oxygen demand, thus suggesting its use as an antianginal agent. As metoprolol decreases cardiac output, it may seem contradictory for it to be used in heart failure, where typically the left ventricle does not have the normal ejection fraction. However, the slower heart rate means that the heart does not have to work as hard, and this has benefits for an overstressed heart in heart failure.

Contraindications and Precautions

Metoprolol carries a black box warning that abrupt cessation of therapy will cause an exacerbation of angina and in some patients a myocardial infarction has occurred. This black box warning is similar to other beta blockers.

The main contraindications for metoprolol are related to pre-exisiting cardiac problems. These include severe bradycardia, complete heart block, cardiogenic shock, uncompensated cardiac failure, sick sinus syndrome (unless using a pacemaker), severe peripheral arterial disease, hypersensitivity, and pheochromocytoma. The action of metoprolol depresses conduction through the atrioventricular node and decreases contractility. These actions can exacerbate cardiac disorders. In Raynaud disease, symptoms can be exacerbated secondary to a reduced cardiac output and a relatively increased alpha stimulation. Beta blockers like metoprolol have been associated with major depression, although the mechanism is unclear. Abrupt discontinuation of metoprolol in patients with hyperthyroidism may induce a thyroid storm.

Metoprolol must be used cautiously if the patient has a history of narrowed airway or bronchospastic disease such as asthma as the beta-2 blockade (although limited) may exacerbate this problem. Caution is used in patients with pheochromocytoma and vasospastic angina because unopposed alpha stimulation may result in paradoxical hypertension. Metoprolol is used cautiously in patients with diabetes because beta blockade can mask the signs of hypoglycemia, especially palpitations, tachycardia, and tremors. Patients receiving metoprolol during surgery are monitored closely because of the cardiodepressant effects prevents the heart from responding to adrenergic stimulation from situations that require an increase in heart rate such as blood loss. Patients also require cautious use of metoprolol if they receive calcium channel blocking drugs. Patients with renal and hepatic diseases also require close monitoring to ensure clearance of the drug from the body.

Adverse Effects

If metoprolol or a similar beta blocker is withdrawn abruptly, severe hypertension, angina, myocardial ischemia, infarction, or ventricular arrhythmias may occur. Other common adverse effects are hypotension, bradycardia, heart block, pruritus, rash, diarrhea, dizziness, fatigue, headache, depression, and dyspnea. Major adverse effects include bronchospasm and cardiac complications. Respiratory complications are not as common with metoprolol as with nonspecific beta

blockers but are still possible. In the CNS, metoprolol may cause cognitive dysfunction or depression. Hallucinations and psychosis have been reported with high doses of the drug. These CNS effects are seen more frequently in elderly patients and resolve after discontinuation. The drug predisposes patients with type 1 diabetes to hypoglycemia and may trigger hyperthyroidism in susceptible individuals. In the GI system, diarrhea is common and may be severe enough to require discontinuation of the drug. Sexual dysfunction is possible but not as common in metoprolol as it is in non-selective beta blockers such as propranolol.

Drug Interactions

Beta antagonists have many interactions with other drugs. Some of the more significant interactions include those with clonidine, epinephrine, verapamil, aminophylline, barbiturates, phenothiazines, cimetidine, ergot derivatives, hydralazine, NSAIDs, insulin, lidocaine, prazosin, quinidine, and rifampin (Table 13.9).

Assessment of Relevant Core Patient Variables

Health Status

Assess for conditions for which the drug is contraindicated or for which special precautions might be necessary (e.g., uncontrolled asthma or chronic obstructive lung disease, severe sinus bradycardia, right ventricular hypertrophy or failure secondary to pulmonary hypertension, second- or third-degree atrioventricular block, cardiac failure, or cardiogenic shock). It is also important to determine whether any other drugs are being taken concurrently to identify significant potential drug interactions.

Because metoprolol is used mainly to treat angina, hypertension, CHF, cardiac arrhythmias, and migraine headaches, the physical assessment includes blood pressure, cardiovascular status, genitourinary function, and mental and neurologic status. Heart and lung sounds are auscultated as well.

Life Span and Gender

Document the age and gender of the patient and assess women of childbearing age for pregnancy and lactation. If the patient is pregnant, metoprolol is administered only if necessary. This drug is classified as FDA pregnancy risk category C, and the possibility of inducing fetal abnormalities is not established. Although metoprolol is excreted in breast milk, there have been no reports of adverse effects on infants; metoprolol is considered compatible with breast feeding. Elderly patients may be at risk for injury resulting from blurred vision related to metoprolol use.

Lifestyle, Diet, and Habits

Document the patient's occupation and daily activities. Advise patients, particularly those in hazardous occupations, to exercise caution when driving or operating machinery until the effects of the drug are known, as the drug may cause dizziness or drowsiness. Blurred vision also is possible.

Environment

Be aware of the environment in which the drug will be administered and assess the home or living environment, if appropriate. Metoprolol may be administered in any setting by health care providers, nurses, or patients themselves.

Nursing Diagnoses and Outcomes

- Risk for Ineffective Tissue Perfusion related to hypotension, bradycardia, or decreased cardiac output
  Desired Outcome: *The patient will maintain adequate tissue perfusion throughout therapy.*
- Risk for Injury related to dizziness secondary to beta blockade
  Desired outcome: *The patient will not sustain injury and will learn safe methods for dealing with dizziness and postural hypotension.*
- Disturbed Sleep Pattern, Insomnia and Drowsiness, secondary to beta blockade
  Desired outcome: *The patient will sleep normally and awaken rested.*
- Activity Intolerance related to lethargy and weakness secondary to beta blockade
  Desired outcome: *The patient will maintain a satisfactory activity level.*
- Risk for Fluid Volume excess related to decreased cardiac output
  Desired outcome: *The patient with chronic heart failure will not develop worsening of symptoms while on metoprolol.*

Planning and Intervention

Maximizing Therapeutic Effects

Instruct the patient to take metoprolol exactly as prescribed and at the required dosage frequency to enhance the therapeutic potential. Advise patients taking metoprolol in sustained-release form to swallow the whole drug and not to chew, crush, or break it. Patients may also take the drug with food to increase the drug's bioavailability and to avoid possible GI upset (e.g., diarrhea).

Inform patients about what to do if they miss a dose. If the next dose is more than 4 hours away (8 hours for sustained-release forms), the patient is advised to take the missed dose as soon as possible. If the next dose is scheduled to occur within the next 4 hours (8 hours for sustained-release forms), the patient should skip the missed dose and return to the regular schedule.

Minimizing Adverse Effects

- Metoprolol should not be used during acute exacerbation of CHF. Until the patient's heart failure is stabilized the drug should be withheld; contact the physician or nurse practitioner if a patient is admitted to the hospital with

TABLE 13.9 Agents That Interact with P Metoprolol

Interactants	Effect and Significance	Nursing Management
alcohol	Decreased absorption and increased elimination of metoprolol, resulting in tachycardia and possible increase in hypertension	Advise patient to avoid ethanol. Monitor blood pressure and heart rhythm.
aminophylline	Reduced elimination of theophylline	Monitor for signs and symptoms of theophylline toxicity.
barbiturates	Decreased metoprolol levels resulting from barbiturate induction	Monitor for increased blood pressure. Monitor respiration.
cimetidine	May increase metoprolol level twofold	Monitor cardiac function carefully (i.e., blood pressure, heart rate), and lower dosage of metoprolol as prescribed.
clonidine	Life-threatening increases in blood pressure after discontinuation of clonidine therapy	When clonidine is to be withdrawn from concomitant therapy with a beta blocker, discontinue the beta blocker first, and monitor blood pressure carefully.
epinephrine	Initial hypertension followed by bradycardia	Consult with prescriber: Labetalol (alpha/beta blocker) or alpha blockers (e.g., prazosin, doxazosin) may prevent rebound hypertension.
ergot derivatives	Peripheral ischemia and cold extremities	If used together, monitor for peripheral ischemic effects (i.e., cold extremities), and substitute a selective beta blocker (e.g., atenolol) if ischemia occurs.
hydralazine	Increased levels of both drugs	If concurrent therapy is required, administer with food or switch to a sustained-release beta blocker. Monitor blood pressure carefully.
insulin	Prolonged hypoglycemia with masking of symptoms	Monitor blood glucose level regularly. Anticipate adjustment in drug dosages. Consult prescriber about lowering metoprolol dosage, and monitor impact on blood glucose level.
lidocaine	Increased, potentially toxic lidocaine level	Consult prescriber about lower lidocaine dosage. Monitor for enhanced inotropic effect of metoprolol.
nonsteroidal anti-inflammatory drugs	Decreased metoprolol level	Monitor blood pressure.
phenothiazines	Increased levels of both drugs; phenothiazines inhibit first-pass metabolism of metoprolol	Administer concomitant therapy with caution. Monitor phenothiazine level, and decrease dosage if prescribed.
prazosin	Increased postural hypotension from prazosin	Monitor blood pressure. Caution patient to rise slowly from seated position and use hand railings, particularly on stairs.
quinidine	Moderate increase in drug levels	Use caution with concomitant administration. Monitor for hypotension, bradycardia, arrhythmias, and heart failure.
rifampin	Rifampin-induced enzymes that decrease beta blocker levels by increasing metabolism and clearance	If concurrent therapy is required, monitor blood pressure carefully. A higher dose of metoprolol may be required in patients receiving rifampin for longer than 1 to 2 wk. Or the prescriber may substitute atenolol or nadolol for metoprolol.
verapamil	Increased hypotensive effects of both drugs	Monitor blood pressure carefully for serious hypotension.

acute uncompensated CHF and the metoprolol is not temporarily stopped.
- Check the apical and peripheral pulses before giving metoprolol. If the pulse is irregular or if there is bradycardia, withhold the drug and notify the prescriber because signs may be early indications of adverse or cardiotoxic effects.
- Monitor for peripheral edema or weight gain as these may indicate worsening of heart failure from the metoprolol.
- Monitor blood pressure, pulmonary wedge pressure, and cardiac rhythm and conduction (by ECG), particularly when adrenergic antagonists such as metoprolol are administered intravenously, because altered cardiac output may result from adrenergic blockade.
- In patients with impaired renal or hepatic function, monitor for signs of drug accumulation and potential toxicity.

Providing Patient and Family Education

- Sympatholytic drugs interfere with compensatory and homeostatic mechanisms regulated by the normal functioning of the SNS, particularly in response to stress. Therefore, it is crucial to identify and monitor environmental stressors for patients receiving adrenergic antagonists, such as metoprolol.
- Careful teaching about adverse effects is important. This includes teaching patients how to take their own pulses and detect irregular rhythms or bradycardias, to monitor for worsening of CHF, and to monitor for depression.
- Promote therapeutic adherence by reminding patients and their family members that drug therapy is meant to control certain life-threatening or debilitating conditions and should be continued even when the patient is feeling well and has no symptoms.
- If drug therapy is being discontinued, stress tapering or gradual withdrawal to prevent rebound symptoms and to adjust the activity levels to suit the reduced blockade.
- As another safety factor, teach the patient to change position slowly to reduce dizziness and light-headedness and to avoid operating machinery or driving until full adaptation to side effects has occurred. Factors known to enhance postural hypotension (e.g., heat, exercise, and alcohol consumption) should be avoided.

Ongoing Assessment and Evaluation

The same assessment focus is used for adrenergic antagonists as for the adrenergic agonists. All patients with cardiovascular disorders are considered worthy of extra attention when taking an adrenergic antagonist such as metoprolol. When evaluating the success of nursing management in metoprolol therapy, anticipate the absence of signs and symptoms for the condition being treated, as well as minimal adverse effects.

If metoprolol is being given for angina or hypertension, blood pressure should be within normal limits, the frequency of anginal attacks should be reduced, and there should be tolerance to reasonable activity. Moreover, the patient should be free from injury resulting from postural hypotension or dizziness. If metoprolol is used in chronic heart failure then the patient should have a decrease in symptoms. For antiarrhythmic indications, no arrhythmias should be evident on ECG findings. The patient may report sexual adjustment. Ideally, the patient and family can understand, recognize, and cope with adverse effects.

Drugs Closely Related to P Metoprolol

Beta-1 selective drugs include acebutolol (Sectral), atenolol (Tenormin), betaxolol (Betoptic), bisoprolol (Zebeta), and esmolol (Brevibloc). These drugs are used to manage angina, hypertension, and chronic heart failure. Acebutolol and esmolol are also used in the management of cardiac arrhythmias. Esmolol is used post-acute MI and prior to rapid sequence intubation.

Nonselective beta-1 antagonists include propranolol (Inderal), metipranolol (OptiPranolol), nadolol (Corgard), penbutolol (Levator), pindolol (Visken), and timolol (Blocadren). These drugs have the same core drug knowledge and core patient variables as metoprolol. Pindolol is used in the management of hyperthyroidism. Nadolol is also used for GI hemorrhage, hyperthyroidism, migraine headaches, and cardiac arrhythmias. Metipranolol and timolol

MEMORY CHIP

P Metoprolol

- Selective Beta-2 blocker
- Treats hypertension, angina, chronic heart failure, cardiac arrhythmias, post-MI
- Decreases heart rate and contractility, slows conduction, suppresses automaticity
- Major contraindications: cardiovascular abnormalities (e.g., bradycardia, complete heart block, cardiogenic shock, uncompensated cardiac failure).
- Most common adverse effects: cardiac (hypotension, bradycardia, heart block, worsening of heart failure), depression
- Most serious adverse effect: heart block, bronchoconstriction/bronchospasm
- Maximizing therapeutic effects: Take the medication exactly as prescribed, never double a dose.
- Minimizing adverse effects: Assess pulse and blood pressure before giving a dose; assess for weight increases and fluid retention
- Most important patient education: to never abruptly stop taking the medication; how to check their own pulse and blood pressure; to monitor for weight gain or swelling in extremities, or worsening of CHF symptoms (if have CHF)
- **Black box warning: Suddenly stopping metaprolol can exacerbate angina and may lead to myocardial infarction.**

CRITICAL THINKING SCENARIO

THINKING CRITICALLY ABOUT BETA-BLOCKER THERAPY

Mr. DiGiovanni is a 65-year-old man with hypertension and angina. He was recently ill with a GI virus and had vomiting and diarrhea for 3 days. During this time he did not eat much and did not take his prescribed metoprolol as he could keep nothing down. He develops chest pain and is taken to the emergency room, where his vital signs are 98-118-22, 150/90.

1. What do you think has caused him to have chest pain, tachycardia, and hypertension?
2. Mr DiGiovanni is admitted, treated, and stabilized.What discharge teaching will he need related to his metoprolol therapy?

are used to manage ocular hypertension and glaucoma. Timolol is also used for post–myocardial infarction (MI) syndrome and supraventricular arrhythmias. Propranolol's uses are similar to metoprolol. These drugs also stimulate beta-2 receptors so there are respiratory effects which may be problematic for those with respiratory conditions such as asthma or COPD.

Drugs Significantly Different From P Metoprolol

Carvedilol

Carvedilol (Coreg) is a combined alpha selective and nonselective beta blocker. Although it has some pharmacologic similarities to labetalol, the ratio of beta-1 to alpha-1 effects is much greater for carvedilol than for labetalol. Carvedilol also possesses antioxidant properties (an effect not shared by other beta blockers). Carvedilol has multiple actions that make it a useful cardiovascular drug. Similarly to labetalol, carvedilol antagonizes both alpha-1 and beta receptors. However, the ratio of beta blockade to alpha-1 blockade for carvedilol is in the range of 10:1 to 100:1. The ratio for labetalol is 1.5:1. Carvedilol is indicated for the management of hypertension, heart failure, and stable angina and as post–myocardial infarction prophylaxis. It is frequently administered with other antihypertensive agents to gain additive therapeutic effects.

When carvedilol therapy is initiated, the patient should have a standing blood pressure measurement 1 hour after dosing. An initial dose of 6.25 mg should be maintained for 7 to 14 days; then, the patient should be evaluated for the effectiveness of the dose. If further control of diastolic blood pressure is needed, the dosage may be increased to 12.5 mg orally twice daily for an additional 7 to 14 days. If needed, the dosage may be further increased to the maximum recommended dosage of 25 mg orally twice daily if tolerated. If the pulse rate drops below 55 bpm, the dosage of carvedilol should be reduced. Doses should be taken with food to slow the rate of absorption and reduce the risk for orthostatic hypotension.

Labetalol

Labetalol (Normodyne) is a competitive nonselective beta-adrenergic and selective postsynaptic alpha-1 adrenergic receptor blocker that can be given orally and parenterally. Labetalol blocks beta-1 receptors in the heart, beta-2 receptors in bronchial and vascular smooth muscle, and alpha-1 receptors in vascular smooth muscle. The beta-blocking activity is three to seven times as potent as the alpha-blocking ability. The result of labetalol's actions at alpha and beta receptors leads to vasodilation and decreased total peripheral resistance, which results in decreased blood pressure without a substantial decrease in resting heart rate, cardiac output, or stroke volume.

Sotalol

Sotalol (Betapace) is an oral, nonselective beta-adrenergic blocking agent. Unlike other beta blockers, sotalol has no sympathomimetic activity or membrane-stabilizing effects but does possess class III antiarrhythmic properties similar to those of amiodarone. As a result, sotalol is used as an antiarrhythmic. It is primarily used in the management of atrial fibrillation or flutter, ventricular arrhythmias, and angina.

CHAPTER SUMMARY

- Regulation of physiologic processes in the autonomic nervous system (ANS) is managed by oppositional or complementary stimulation by the sympathetic (adrenergic) and parasympathetic (cholinergic) nervous systems.
- To effect an action, a neurotransmitter needs to bind with an appropriate receptor site on the effector organ or tissue.
- The primary neurotransmitter of the SNS is norepenephrine (NE). Additionally, epinephrine and dopamine stimulate adrenergic receptors.
- The sympathetic nervous system (SNS), commonly referred to as the fight-or-flight system, increases cardiovascular and respiratory function, increases metabolism, diverts blood to muscles, and decreases GI activity.
- SNS receptors with pharmacological relevance are subdivided into alpha-1, alpha-2, beta-1, and beta-2 subtypes. Alpha-1, beta-1, and beta-2 receptors are located on the post-synaptic side of the synapse, while alpha-2 receptors are located on the pre-synaptic side of the synapse. Stimulation of alpha-2 receptors acts as a negative feedback and shuts off the flow of NE, stopping sympathetic stimulation.
- Adrenergic agonists stimulate the adrenergic receptors, whereas adrenergic antagonists block adrenergic receptors within the SNS, preventing endogenous neurotransmitters from attaching to the receptor. There are multiple terms for these categories of drugs.
- Alpha-1 agonists, such as phenylephrine, stimulate alpha-1 receptors directly. They are most commonly used as nasal

decongestants and in ophthalmology to achieve mydriasis. They may also be used as vasopressors to treat vascular failure and related shock.

- Alpha-2 agonists such as clonidine shut off the sympathetic release of NE and sympathetic stimulation. They are used in the treatment of substance abuse to prevent withdrawal symptoms and have a minor use in the treatment of hypertension.
- Nonselective adrenergic agonists, such as epinephrine, are used to treat anaphylactic shock, asthma, hemorrhage, and ventricular fibrillation. The nonselective activity stimulates all four adrenergic subtypes.
- Dopamine, a vasopressor, is used to correct the hemodynamic imbalances present in shock. Dopamine is a naturally occurring catecholamine and a precursor to norepinephrine. It stimulates alpha and beta receptors directly and indirectly (by releasing the stored epinephrine). It also has dopaminergic effects, including increased renal perfusion, increased cardiac output, increased or decreased peripheral resistance (depending on the dose), and increased blood pressure.
- Drugs that are relatively selective for beta-2 stimulation are used to treat asthma.
- Fenoldopam, a dopamine-1 agonist, is used in the management of acute hypertension for rapid reduction of blood pressure.
- Alpha-1antagonists, such as prazosin, cause vasodilation and are used to treat hypertension and benign prostatic hyperplasia (BPH).
- Beta-blockers, such as metoprolol, are relatively selective for beta-1 receptors in the heart; in larger doses they also have effects on beta-2 receptors. They are used to treat hypertension, angina, controlled chronic heart failure, cardiac arrhythmias, hyperthyroidism, and migraine headache.

QUESTIONS FOR STUDY AND REVIEW

1. How do drugs that stimulate the SNS create their effect?
2. What happens when beta-1 receptors are blocked?
3. How is it possible that epinephrine creates both vasodilation and vasoconstriction?
4. Why is dopamine dosage determined by urinary output and cardiovascular response?
5. How does prazosin decrease blood pressure?
6. How does phenylephrine create its desired effects?

Drugs Affecting Cholinergic Function

Learning Objectives

At the completion of this chapter the student will:

1. State the neurotransmitter that stimulates the parasympathetic nervous system.
2. Understand how cholinergic drugs create their therapeutic effects in the parasympathetic nervous system.
3. Differentiate cholinergic agonist from anticholinergic drugs.
4. Identify core drug knowledge about drugs that act as cholinergic agonists or anticholinergics.
5. Identify core patient variables relevant to drugs that act as agonists or anticholinergics.
6. Relate the interaction of core drug knowledge to core patient variables for drugs that act as cholinergic agonists or anticholinergics.
7. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that act as cholinergic agonists or anticholinergics.
8. Describe nursing interventions to maximize therapeutic and minimize adverse affects for drugs that act as cholinergic agonists or anticholinergics.
9. Determine key points for patient and family education for drugs that act as cholinergic agonists or anticholinergics.

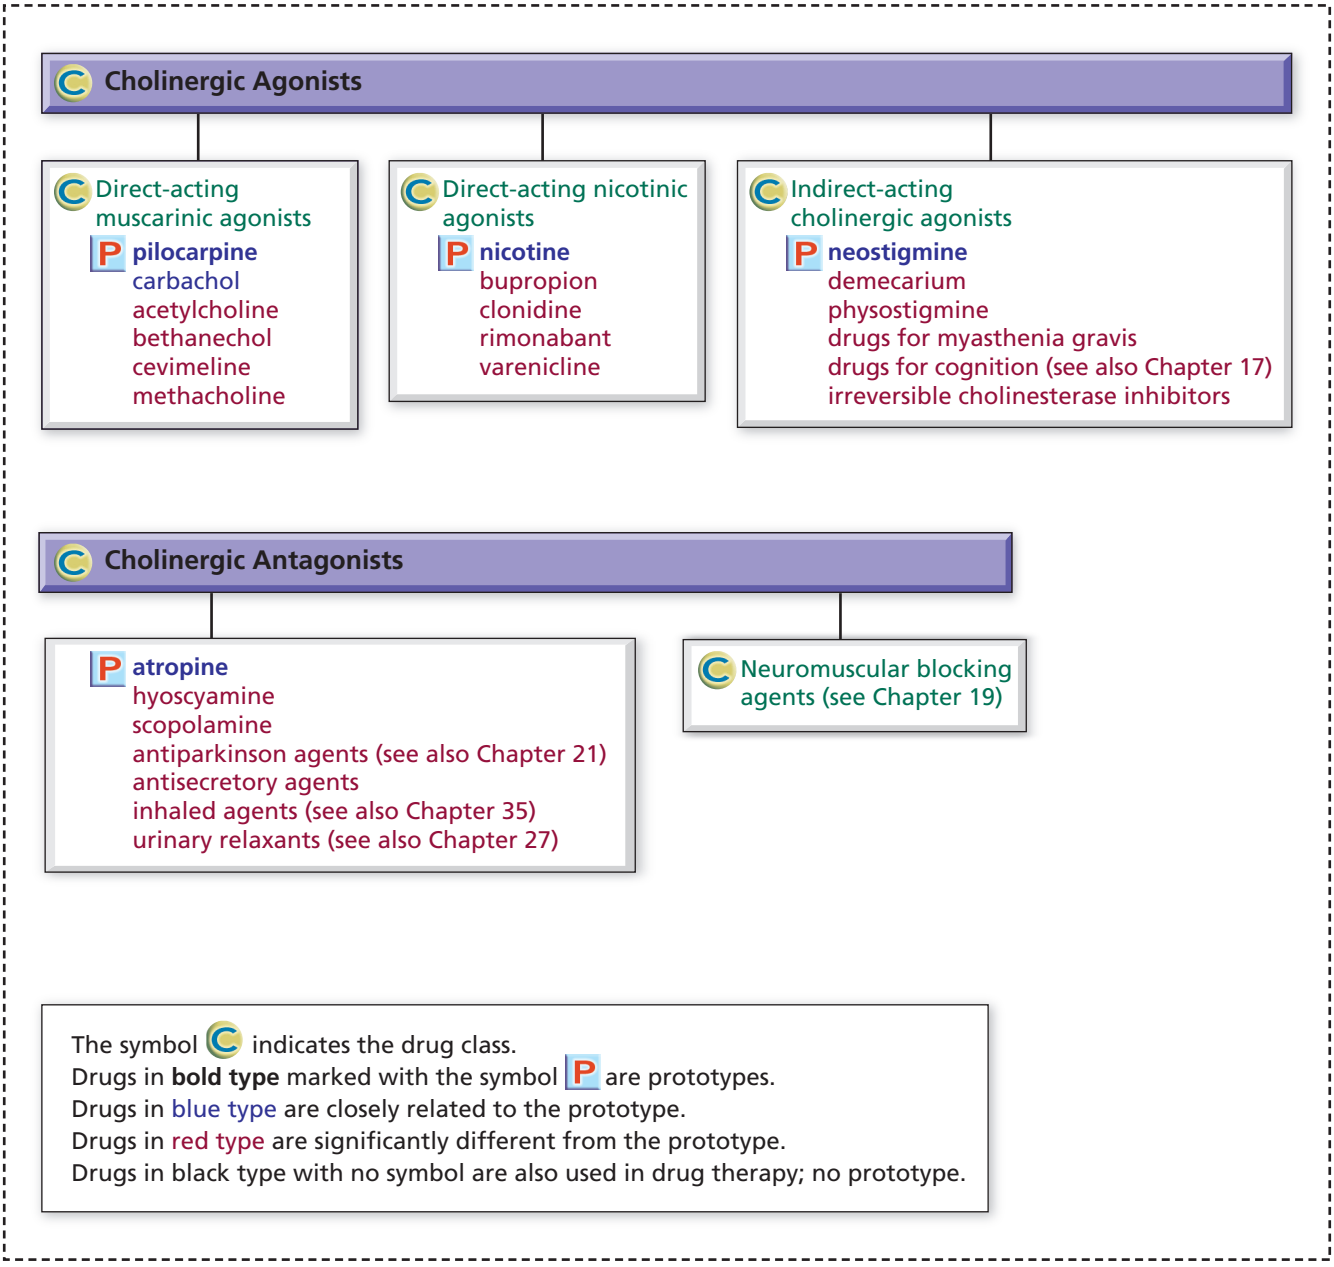
Drugs Affecting Cholinergic Function



As described in Chapter 13, the **autonomic nervous system** (ANS) is divided into the sympathetic (adrenergic) and parasympathetic (cholinergic) nervous systems. These systems work in combination or in opposition to maintain homeostasis within the body. As in the SNS, the PSNS effects occur in response to a neurotransmitter stimulating a receptor. Acetylcholine (ACh) is the neurotransmitter that produces parasympathetic effects. Because the receptor is stimulated by Ach, it is referred to as a cholinergic receptor. This chapter identifies drugs used to treat the major disorders that are affected by deficiencies or excesses in cholinergic neurotransmission. It also discusses the wide range of therapeutic uses of cholinergic drugs. This chapter presents the cholinergic drugs that are categorized into **cholinergic agonists** (i.e., they stimulate cholinergic receptors) and **cholinergic antagonists**, also known as anticholinergics (i.e., they block the cholinergic receptor and prevent ACh from attaching to the receptor).

The cholinergic drugs are also categorized by the type of cholinergic receptor they affect. For example, pilocarpine (Akarpine) is the prototype direct-acting muscarinic agonist, whereas nicotine (Nicotrol, ProStep) is the prototype direct-acting nicotinic agonist. Neostigmine (Prostigmin) is the prototype indirect-acting cholinergic agonist, also known as an anticholinesterase or cholinesterase inhibitor. The prototype representing the anticholinergics, is atropine (Atropine Sulfate).

PHYSIOLOGY

Function of the Autonomic Nervous System

As mentioned in Chapter 13, the autonomic nervous system is an involuntary system responsible for the control of smooth muscle, cardiac muscle, and exocrine glands. These regulatory functions of the body are monitored by both the **sympathetic nervous system** and the **parasympathetic nervous system.** The sympathetic and parasympathetic nervous systems work either as complementary or oppositional systems to maintain the involuntary functions of the body. Chapter 13 includes a discussion of synaptic transmission and regulation of physiologic processes; review that if necessary. The parasympathetic nervous system is sometimes referred to as the "rest and digest" system; it is responsible for normal physiological processes that are present when the SNS is not active. For example, stimulation of the PSNS receptors by ACh is responsible for increased salivation, increased GI tone and motility, and increased gastric secretions; all of these assist in the digestion of food. An acronym of SLUDD can be used help remember the functions of the PSNS (**S**alivation, **L**acrimation, **U**rination, **D**igestion, and **D**efecation). The PSNS regulates the body's visceral organs via the innervation of three kinds of tissues: smooth muscle, cardiac muscle, and glands. Although the stimulation of some of the muscarinic cholinergic receptors causes vasoconstriction, acetylcholine causes endothelial cells to produce nitric oxide, which diffuses to smooth muscle and results in vasodilation and perfusion of the organs.

Cholinergic Neurotransmitters

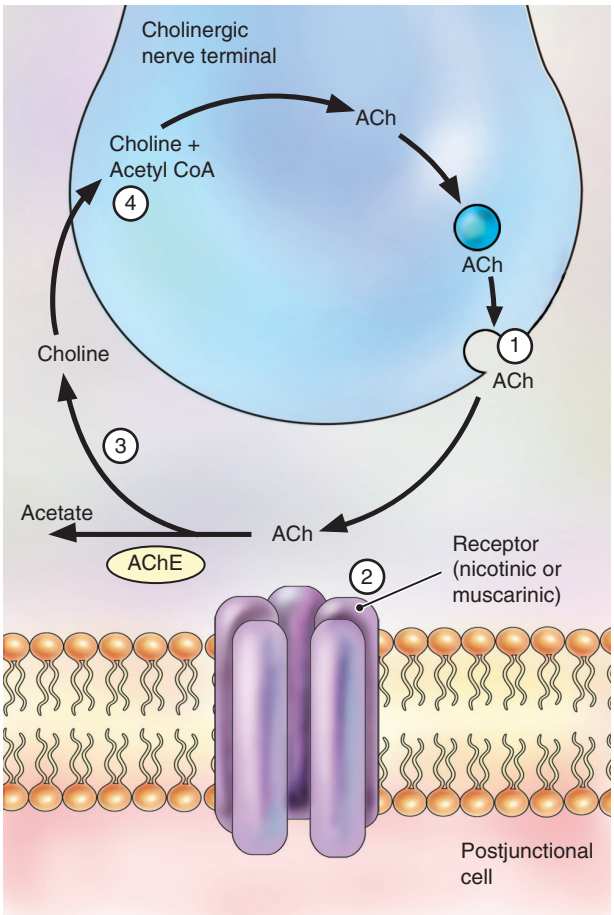
Cholinergic drugs act on the parasympathetic nervous system, one of the subdivisions of the ANS. Acetylcholine (ACh) is the presynaptic and postsynaptic neurotransmitter in the parasympathetic nervous system (see Figure 13.4). The precursors to ACh are choline and acetyl-coenzyme A. After formation and storage, ACh is released in response to an action potential, diffuses across the synaptic cleft, and binds to cholinergic receptors on the target organs or tissues. After dissociation, ACh is degraded into two inactive products, acetate and choline, by acetylcholinesterase (AChE) (Figure 14.1).

Cholinergic Receptors

There are three types of cholinergic receptors: nicotinic$_N$ (neuronal-type), nicotinic$_M$ (muscle-type), and muscarinic (Table 14.1).

Nicotinic Receptors

The **nicotinic receptors** (nicotinic$_N$ and nicotinic$_M$) are called *nicotinic* because they are stimulated primarily by nicotine, a plant alkaloid, but they will also respond to acetylcholine. They have a very low affinity for muscarine.



• FIGURE 14.1 Acetylcholine release and degradation. (1) Stored acetylcholine (ACh); (2) acetylcholine is released from the nerve terminal in response to an action potential and diffuses across the synaptic cleft; (3) binds to muscarinic or nicotinic receptor site to stimulate an action; and (4) is degraded by acetylcholinesterase into acetate and choline.

TABLE 14.1 Cholinergic Receptor Subtypes' Location and Action

Location	Response to Stimulation	Response to Blockade (all actions return the PSNS to baseline, they are NOT SNS effects)
Nicotinic$_N$		
All autonomic nervous system ganglia	Stimulation of sympathetic and parasympathetic *postganglionic* transmission	Prevents stimulation of sympathetic and parasympathetic *postganglionic* transmission
Adrenal medulla	Release of epinephrine	Prevents release of epinephrine
Nicotinic$_M$		
Neuromuscular junction	Contraction of skeletal muscle	Relaxation of skeletal muscle
Muscarinic		
Eye	Miosis (pupillary constriction)-poor night vision	Mydriasis (pupil dilation)-good night vision but decreased vision in daylight (photophobic)
	Improved accommodation	Decreased accommodation
Heart	Decreased rate	Increased rate
	Decreased force of contraction	Increased force of contraction
	Decreased speed of conduction	Increased speed of conduction
	All of these actions decrease cardiac output, contributing to a decrease in blood pressure	All of these lead to an increase in cardiac output and increase in blood pressure
Lung	Bronchoconstriction- difficulty breathing	Bronchodilation-improved ease of breathing
	Increased bronchial secretions	Decreased bronchial secretions
Blood vessels	Vasodilation to organs to improve perfusion and function	Vasodilation to peripheries and skin-causing flushed, red, warm skin
	Lowering of blood pressure, hypotension possible with excessive stimulation	Increase in blood pressure to baseline; hypertension possible with excessive blockade
GU system	Contraction of detrusor muscle of bladder and relaxation of internal sphincter to allow urination	Relaxation of detrusor muscle of bladder and Contraction of internal sphincter to prevent emptying the bladder Urinary retention
GI tract	Increased salivation	Dry mouth
	Increased gastric secretions to promote digestion	Decreased gastric secretions to prevent digestion
	Increased intestinal tone and motility (increased peristalsis), relaxation of internal sphincter to allow defecation	Decreased intestinal tone and motility leading to constipation
Sweat glands	Increased sweating	Decreased sweating
Sex organs	Erection (vasodilation)	Lack of erection, prevent sexual intercourse
CNS- brain	Dizziness, headache, nervousness, confusion, mental status changes, memory loss	Disorientation, agitation, anxiety, hallucination, delusions, delirium, psychosis, seizures, prolonged sedation, coma

Nicotinic$_N$ receptors are located on the cell bodies of all postganglionic neurons in both the sympathetic and parasympathetic nervous systems and in the adrenal medulla. Activation of nicotinic$_N$ receptors in the adrenal medulla results in the release of epinephrine.

Nicotinic$_M$ receptors are located at the neuromuscular junction of skeletal muscle. Stimulation of nicotinic$_M$ receptors results in skeletal muscle contraction.

Muscarinic Receptors

Muscarinic receptors respond to acetylcholine and also bind muscarine, an alkaloid substance isolated from mushrooms. There are five subtypes of muscarinic receptors (M_1–M_5). They are located on postsynaptic cells regulated by the PSNS and on sweat glands. Of interest is the presence of muscarinic receptors on blood vessels; however, these receptors are not associated with the nervous system. Although their physiologic activation is unclear, their pharmacologic response is vasodilation, resulting in decreased blood pressure.

PATHOPHYSIOLOGY

The tissues and organs that are innervated by the ANS are diverse, and few discrete disorders are directly related to

TABLE 14.2 Parasympathetic Nervous System Terminology Synonyms

compromise of the parasympathetic nervous system. Instead, the therapeutic uses of parasympathetic drugs are related to providing extra cholinergic stimulation or blockade of normal ANS functioning. Disorders of the bronchi, cardiovascular system, gastrointestinal or genitourinary tract, skeletal muscle, eyes, and various glands may respond to cholinergic stimulation through their muscarinic and nicotinic receptors.

Pharmacological Effects on the PSNS

How do drugs create their therapeutic effect in the PSNS? Similar to their action in the SNS, drugs create their therapeutic effects in the PSNS by stimulating cholinergic receptors or by blocking the receptor so that acetylcholine cannot attach to the receptor. So in order to understand how these drugs work, it is again necessary to first learn what happens when these receptors are stimulated or blocked. See Table 14.2 for help in learning these different effects. Students should then consider the prototype drugs listed in this chapter as examples of what happens with cholinergic stimulation or blockade. Cholinergic and anticholinergic drugs will be presented throughout the text, so understanding what happens at the receptor is crucial to building a knowledge of pharmacology. Students also should be aware that although the cholinergic receptors are technically divided into two subtypes, all of them will respond to ACh. Therefore, in practice these receptors often are just referred to as "cholinergic" and the drugs that effect them as "cholinergic" or "anticholinergic." As in the SNS, several words are used as synonyms related to the PSNS. For assistance in learning these terms, see Table 14.1. *Students must be careful not to think of drugs that produce PSNS blockade as being the same as drugs that cause SNS stimulation. Although there are similarities, this is not correct*. Instead, think of anticholinergic effects of drugs as returning the patient to the baseline so that the PSNS can be stimulated again.

Because the anticholinergic effects may be more familiar to students due to their presence in over-the-counter products, some students may wish to read this chapter "backwards," starting with the anticholinergics and then finishing with the cholinergics. However, conceptually for most students it is best to think of what happens with stimulation and then to consider blockade, so the drug prototypes are arranged in this manner.

CHOLINERGIC AGONISTS

Cholinergic agonists include direct-acting muscarinic agonists, direct-acting nicotinic agonists, and indirect-acting cholinergic agonists (Table 14.3).

• Direct-Acting Muscarinic Agonists

Direct-acting muscarinic agonists are drugs that bind to the muscarinic receptors located in various tissues and organs throughout the body. Their activation elicits a response that resembles the action of the parasympathetic nervous system; therefore, they are also called parasympathomimetic agents. Although pilocarpine (Akarpine) has limited therapeutic scope, it is the ideal prototype for the direct-acting muscarinic agonists.

Nursing Management of the Patient Receiving Pilocarpine

Core Drug Knowledge

Pharmacotherapeutics

Pilocarpine is a direct-acting cholinergic agonist with ophthalmic uses. The major indications for pilocarpine are open-angle glaucoma, acute treatment of angle-closure glaucoma, induction of **miosis** (pupillary constriction) to counteract mydriatic effects of sympathomimetics used in surgery, and miosis induction following ophthalmoscopy to counteract the effects of cycloplegics and mydriatics. Oral pilocarpine is used to treat xerostomia (dry mouth) caused by hypofunction of the salivary gland arising from radiotherapy for cancer of the head or neck.

Pharmacokinetics

Pilocarpine may be applied topically by solution or in an ocular system that allows sustained release over 7 days. With topical administration, miosis occurs within 10 to 30 minutes, and a maximal decrease in intraocular pressure occurs within 2 to 4 hours. When pilocarpine is given as an oral agent, peak effects are achieved in about 1 hour. Peak effects may take longer if the drug is taken with food. The mechanism for inactivation of pilocarpine is not clear but is thought to occur at the neuronal synapses and in plasma. Pilocarpine and its degradation products are excreted in the urine.

Pharmacodynamics

Pilocarpine directly stimulates cholinergic receptors. It produces miosis by contracting the iris sphincter. In open-angle glaucoma, pilocarpine contracts the ciliary muscle, increasing the outflow of aqueous humor, which reduces intraocular pressure. In closed-angle glaucoma, pilocarpine-induced miosis opens the angle of the anterior chamber of the eye, allowing the aqueous humor to exit. Pilocarpine also counteracts the mydriatic effects of sympathomimetic agents used in ophthalmologic examinations. When administered

orally, pilocarpine stimulates secretions of the exocrine glands. All secretory glands may be affected, with results including an increase in salivary flow.

Contraindications and Precautions

Some contraindications may not be applicable to ophthalmic use, and others are not applicable to oral use. Hypersensitivity is a contraindication regardless of the formulation utilized.

Ophthalmic pilocarpine is contraindicated for use in patients with a history of retinal detachment. Miotics can precipitate detachment of the retina, resulting in a sudden drop in intraocular pressure. Ophthalmic pilocarpine is also contraindicated for use in patients with acute iritis or other conditions that would be exacerbated by pupillary constriction.

Oral pilocarpine has more contraindications and precautions because of its systemic effects, specifically its ability to mimic the effects of the parasympathetic nervous system. For example, patients with asthma, chronic bronchitis, or chronic airway limitation may have exacerbations of these conditions because pilocarpine stimulates the mucous cells of the respiratory tract and increases bronchial smooth muscle tone and airway resistance. Pilocarpine causes contractions of the gallbladder or biliary smooth muscle, possibly resulting in biliary obstruction, cholangitis, or cholecystitis. Patients with cardiac disease may not be able to compensate for the transient changes in heart rhythm or hemodynamics caused by oral pilocarpine. Pilocarpine increases ureteral smooth muscle tone and may precipitate renal colic, especially in patients with nephrolithiasis. Oral pilocarpine may induce dose-related central nervous system (CNS) effects that could exacerbate conditions of psychiatric disturbances or cognitive disturbances.

Pilocarpine is classified as a pregnancy category C drug. The oral dosage form should only be used in pregnant women if the benefits outweigh the risks to the fetus.

Finally, patients using ophthalmic or oral preparations of pilocarpine should be cautioned about nighttime driving, particularly the elderly and those with opaque lenses. Loss of visual acuity and accommodation is greater in poor light.

Adverse Effects

The ophthalmic adverse effects of pilocarpine include transient stinging and burning, tearing, and ciliary spasm. The ocular system (Ocusert) may cause conjunctival irritation. Systemic adverse effects include hypertension, tachycardia, bronchiolar spasm, pulmonary edema, salivation and sweating, and nausea and vomiting. CNS effects include dizziness, headache, nervousness, memory loss, and exacerbation of a current psychosis. When systemic effects occur with other cholinergic agonists, a **cholinergic crisis** may arise. Cholinergic crisis must be recognized quickly and managed effectively. It is caused by cholinergic toxicity and results in medullary paralysis (central respiratory paralysis), peripheral respiratory paralysis, excessive tracheobronchial and salivary secretions, bronchospasm, and laryngospasm. These effects may cause respiratory failure,

which can be reversed with the maintenance of a patent airway. Muscle twitching, fasciculations, and paralysis may also occur. All symptoms of cholinergic crisis may be reversed with atropine, an anticholinergic drug.

Drug Interactions

There are no known important interactions between pilocarpine and other drugs, although other cholinergic agonists or blockers may enhance or antagonize its effects (Table 14.4).

Assessment of Relevant Core Patient Variables

Health Status

Cholinergic agonists such as pilocarpine do not have a wide range of therapeutic uses, but when they are used, they may cause systemic side effects and interact with preexisting disorders in life-threatening ways. A careful history and physical assessment will identify contraindications and precautions necessary for the person taking pilocarpine.

Determine whether the patient has uncontrolled asthma or acute iritis, which are contraindications to pilocarpine therapy. Assess patients for significant cardiovascular disease because they may be unable to compensate for transient changes in hemodynamics or rhythm induced by pilocarpine. Pilocarpine should be used cautiously in patients with chronic bronchitis or chronic airway limitation because it may increase airway resistance, bronchial smooth muscle tone, and bronchial secretions. Patients with a history of biliary disease or nephrolithiasis are also closely monitored.

Life Span and Gender

Document the age and gender of the patient and assess women of childbearing age for pregnancy and lactation. If the patient is pregnant, this drug should be used only if necessary because it is not known whether pilocarpine causes fetal abnormalities. If the patient is breast-feeding, the infant is monitored for cholinergic stimulation; if such stimulation occurs, the drug may need to be discontinued. Elderly patients may be at higher risk for injury because of blurred vision.

Lifestyle, Diet, and Habits

Document the patient's occupation and daily activities. Advise patients to exercise caution when driving or operating machinery at night or in low light because miosis compromises dark adaptation.

Environment

Be aware of the environment in which the drug will be administered and assess the home or living environment if appropriate. Pilocarpine may be administered in any setting by a health care provider, nurse, or the patient.

Nursing Diagnoses and Outcomes

- Risk for Injury related to blurred vision
  Desired outcome: *The patient will remain free of injury.*
- Disturbed Sensory Perception (Visual) secondary to instillation of topical miotic.
  Desired outcome: *The patient will adapt to blurring and adapt activity accordingly.*
- Acute Pain related to local corneal irritation by miotic instillate
  Desired outcome: *The patient will remain free from irritation.*

Planning and Intervention

Maximizing Therapeutic Effects

Because pilocarpine is usually instilled, demonstrate how to instill drops into the conjunctival sac. To obtain the optimal intraocular hypotensive effect using the Ocusert system, also demonstrate the placement and insertion of the system into the inferior conjunctival sac.

If both the solution and gel are used, the solution is applied first, and the gel is applied 5 minutes later. Following administration of the solution, finger pressure is applied on the lacrimal sac for 1 to 2 minutes.

Oral pilocarpine is administered at regular intervals throughout the day.

Minimizing Adverse Effects

As with all cholinergic agonists, the use of pilocarpine requires the availability of an antidote in case of systemic overdose or cholinergic crisis. Atropine is the usual agent for this purpose. For patients with known allergies or suspected hypersensitivity, life support measures must be available in case of bronchial spasm or allergic reactions. Systemic side effects include stimulation of sphincters, so that patients may need access to a bedpan or urinal.

Contact lenses should be removed before ophthalmic treatment. If pilocarpine drops are applied to the eyes when soft contact lenses are in place, the lenses can deteriorate or absorb the drug. It also is possible that hard contact lenses can cause corneal abrasion or roughening of the corneal

surface. Corneal abrasion can increase systemic absorption, possibly causing toxicity.

Providing Patient and Family Education

- Caution patients about blurred vision and its hazards.
- Teach patients to recognize systemic adverse effects and how to manage them.
- Instruct patients using the Ocusert system on inserting and removing the ocular device safely and antiseptically.

Ongoing Assessment and Evaluation

During therapy, monitoring of therapeutic effects should reveal the decrease in frequency or severity of target symptoms or the resumption of the problem for which pilocarpine was prescribed. Nurses familiar with ophthalmic surgery and conditions are adept at continuous assessment and evaluation of changes in intraocular pressure. Moreover, they can use a tonometer to gauge substantial changes in intraocular pressure. Other evaluations include whether adverse side effects are effectively minimized.

Drug Closely Related to P Pilocarpine

Carbachol (Isopto Carbachol) is another topical miotic agent used in the management of glaucoma. It is administered as an ophthalmologic solution up to three times daily. Like pilocarpine, it works by direct stimulation of the muscarinic cholinergic receptors in the eye. Contraindications and adverse effects are similar to pilocarpine.

Drugs Significantly Different From P Pilocarpine

Acetylcholine

Acetylcholine (Miochol-E) is a topical miotic agent. As a drug, acetylcholine is limited to use in the management of ophthalmologic surgery. It produces complete miosis in cataract surgery, keratoplasty, iridectomy, and other anterior segment surgery in which rapid miosis is required. Because it is given topically, systemic adverse effects rarely occur. However, it may cause problems for patients with acute cardiac failure, bronchial asthma, peptic ulcer, hyperthyroidism, gastrointestinal spasms (cramps), urinary tract obstruction, or Parkinson disease. It is contraindicated for use in patients with acute iritis and acute inflammatory disease of the anterior chamber of the eye.

MEMORY CHIP

P Pilocarpine

- A direct-acting muscarinic agonist used for simple and acute glaucoma, preoperative and postoperative intraocular tension, mydriasis, and xerostomia
- Major contraindications (ophthalmic): hypersensitivity, history of retinal detachment, and acute iritis
- Major contraindications (oral): hypersensitivity, severe respiratory diseases
- Most common adverse effects: blurred vision, myopia
- Most serious adverse effects: cholinergic crisis, bronchospasm
- Maximizing therapeutic effects: Administer ophthalmic solution into the conjunctival cul-de-sac.
- 6Minimizing adverse effects: availability of antidote, aseptic technique for ophthalmic administration
- Most important patient education: symptoms of cholinergic crisis and need for immediate medical attention

Bethanechol

Bethanechol (Urecholine) is an oral synthetic muscarinic stimulant with primary effects on the urinary and gastrointestinal tracts. Its effect on the bladder results from stimulation of muscarinic receptors in the detrusor muscle. As the detrusor contracts, the bladder capacity decreases, resulting in micturition. Bethanechol also stimulates ureteral peristalsis and relaxes the trigone and external sphincter. Because bethanechol is a direct-acting agonist, spinal cord injury does not compromise its actions. Stimulation of muscarinic receptors in the gastrointestinal tract restores peristalsis, increases motility, and increases the resting lower esophageal sphincter pressure. Bethanechol also stimulates the lower gastrointestinal tract, resulting in defecation. It is the preferred drug in the treatment of postpartum and postoperative nonobstructive urinary retention. It is also used in the management of urinary retention related to phenothiazine or tricyclic antidepressant therapy. Bethanechol may induce systemic adverse effects similar to those of pilocarpine. As with pilocarpine, drug interactions include other cholinergic or anticholinergic drugs. In addition, bethanechol in conjunction with ganglionic blocking agents may result in a critical decrease in blood pressure.

Cevimeline

Cevimeline (Evoxac) is a cholinergic agonist that is indicated for the treatment of symptoms of dry mouth in patients with Sjögren syndrome (Kruszka & O'Brian, 2009). It binds with muscarinic receptors and increases secretion of exocrine glands such as salivary and sweat glands. Cevimeline is contraindicated in patients with known hypersensitivity, uncontrolled asthma, acute iritis, or narrow-angle (angle-closure) glaucoma. It is used with caution in patients with cardiovascular or pulmonary diseases. Cevimeline can alter cardiac conduction or heart rate; therefore, patients with significant cardiovascular disease may be unable to compensate for transient changes in hemodynamics or rhythm. Also, cevimeline can increase airway resistance, bronchial smooth muscle tone, and bronchial secretions; hence, patients with asthma, chronic bronchitis, or chronic obstructive pulmonary disease should be closely monitored.

Methacholine

Methacholine (Provocholine) is a parasympathomimetic inhalation agent used to help diagnose bronchial airway hyperreactivity in patients who do not have clinically apparent

asthma. Methacholine induces bronchoconstriction in asthmatic patients more readily than in nonasthmatic patients.

Contraindications and precautions include hypersensitivity to parasympathomimetic agents, concurrent beta-antagonist therapy, epilepsy, cardiovascular disease characterized by bradycardia, peptic ulcer disease, thyroid disease, urinary tract obstruction, and clinically apparent asthma, wheezing, or very low baseline pulmonary function test results.

Prior to administering methacholine to women of childbearing age, determine the patient's pregnancy status. Methacholine testing should be done within 10 days of the first day of menses or within 2 weeks following a negative pregnancy test result. Methacholine should not be administered to women who breast-feed because it is unknown whether the drug is excreted in breast milk. When given to patients receiving beta blockers, the effects of methacholine can be exaggerated or prolonged. Common adverse effects include headache, throat irritation, light-headedness, and pruritus. Because acute respiratory distress may occur, emergency equipment and medications should be at the bedside during this diagnostic test.

• C Direct-Acting Nicotinic Agonists

The direct-acting nicotinic agonists are also called ganglionic stimulating agents. These drugs create their effect by attaching to the nicotinic receptor. The two significant classes of nicotinic stimulants are the ganglionic stimulants (e.g., nicotine) and the neuromuscular nicotinic stimulants that are discussed in Chapter 19.

Nicotine is the obvious selection as the direct-acting nicotinic receptor agonist prototype. Its pharmacological use is limited to products designed to help in the cessation of smoking tobacco. Non-pharmacologically it is used and abused in smoking and chewing tobacco.

Nursing Management of the Patient Receiving P Nicotine

Core Drug Knowledge

Pharmacotherapeutics

Nicotine replacement is used as an adjunct to smoking cessation programs. Various formulations are available, such as gum, transdermal patches, and nasal spray. The nicotine gum and transdermal patches are available over the counter (OTC) in the United States. The patches are preferred for maintenance therapy during smoking cessation programs, unless the patient is allergic to the patches. Gum, nasal spray, or lozenges may be useful for episodic or bolus effects of nicotine and in institutional settings in which smoking is not allowed (Frishman, 2007).

Pharmacokinetics

When delivered as a chewing gum, nicotine is readily absorbed through the buccal mucosa when the gum is chewed. However, the amount of nicotine absorbed depends on how long the saliva remains in the mouth and by the pH. "A low pH suppresses the buccal absorption of nicotine" (Frishman, 2007). Very little nicotine is absorbed from the gastrointestinal tract because of extensive first-pass metabolism through the liver. Regular use of the gum provides steady-state blood levels of nicotine similar to those achieved by smokers. However, peak plasma levels occur much more slowly than when tobacco smoke is inhaled. Nicotine levels reach the brain within 7 seconds of a single puff on a cigarette, but peak concentrations of the gum can take 14 to 20 minutes; the transdermal patch can require as long as 4 hours to reach peak concentrations.

Nicotine is widely distributed in the body tissues, particularly the CNS. It crosses the placenta and is secreted in milk. The concentrations of nicotine in amniotic fluid and fetal serum exceed those in maternal serum. Detectable amounts also appear in the serum and urine of infants of nursing mothers who smoke.

Nicotine is metabolized in the liver by oxidation and excreted by the kidneys as unchanged nicotine and metabolites.

Pharmacodynamics

Nicotine is a potent ganglionic and CNS stimulant, with actions that are mediated through specific nicotine receptors. In small doses, it stimulates all autonomic ganglia; in larger doses, initial stimulation is followed by blockade. The dependency potential of nicotine is based mostly on its CNS stimulant effects (Fant, 2009).

Contraindications and Precautions

Nicotine in any dosage form should not be used in patients immediately after myocardial infarction, or in those with life-threatening arrhythmias or severe or worsening angina pectoris. It should not be used in patients who have allergies to any of the components of the delivery system, including gum, nasal spray, and transdermal patches. Smoking should be avoided during nicotine therapy because of the potential for overdose and toxicity (with manifestations including dizziness, nausea, and headache).

Adverse Effects

The adverse effects of nicotine in the cardiovascular system include peripheral vasoconstriction and tachycardia. In the CNS, the effects may include headache, paresthesias, fatigue, insomnia, nervousness, nausea, hot flashes, and nightmares. Diarrhea, dry mouth, nausea, and dyspepsia are adverse effects on the gastrointestinal system. Use of Nicotrol spray may cause nasal irritation, lacrimation, throat irritation, sneezing, and coughing. The transdermal patches may cause erythema, pruritus, edema, or rash at the site of administration.

The nicotine transdermal system and nasal spray are classified as FDA pregnancy category D, although the benefits of nicotine replacement therapy during pregnancy appear to outweigh the risks of continued smoking during pregnancy.

TABLE 14.5 Agents That Interact with P Nicotine

Adenosine and lithium carbonate interact with nicotine (Table 14.5).

Assessment of Relevant Core Patient Variables

Health Status

A careful history and physical examination will identify contraindications and precautions pertaining to the person beginning nicotine replacement therapy. The patient's desire to cease smoking or the requirement not to smoke usually prompts nicotine replacement therapy. Before therapy begins, ensure that the patient has had neither a recent myocardial infarction nor symptoms of significant cardiovascular disease (e.g., arrhythmias and angina pectoris) because these conditions are contraindications to therapy. Before application of transdermal nicotine patches, skin test results should be reviewed to determine sensitivity to the drug.

Life Span and Gender

Document the age and gender of the patient and assess women of childbearing age for pregnancy and lactation. If the patient is pregnant, nicotine therapy should be used only if necessary—for example, in cases in which the benefits of smoking cessation are important. If the patient is breast-feeding, the infant should be monitored for respiratory or CNS stimulation. If such stimulation occurs, the timing of breast-feeding or the administration of the nicotine may need to be staggered to minimize adverse effects. Older adults undergoing nicotine therapy may be at increased risk for dizziness and sleep disturbances resulting from CNS stimulation.

Lifestyle, Diet, and Habits

Document the patient's occupation and daily activities. Advise patients not to smoke during nicotine therapy to avoid overdosage and adverse effects. Patients whose jobs require shift work should be aware that sleep disturbances may disrupt their rest. In addition, inspect the patient's oral cavity for dentures and other significant dental work. Nicotine gum is heavier and stickier than regular gum and may affect artificial teeth or other dental work.

Environment

Be aware of the environment in which the drug will be administered. Nicotine in any of its dosage forms may be administered in any setting by health care providers, nurses, or patients themselves.

Culture and Inherited Traits

Explore the patient's underlying cultural beliefs and values regarding smoking. In many cultural groups, such as Japanese American, Austrian, Polish immigrant, and highly acculturated Latino, smoking tobacco is popular and widely accepted. It is important to recognize that some patients may have more difficulty giving up smoking than others because of cultural influences.

Nursing Diagnoses and Outcomes

- Risk for Injury to mouth, teeth, or dental work related to gum viscosity, and sore throat or mouth related to use of the intranasal spray
  Desired outcome: *The patient will remain free of injury or problems related to adverse effects of therapy.*
- Disturbed Sleep Pattern related to drug-induced insomnia
  Desired outcome: *The patient will experience undisturbed sleep.*

Planning and Intervention

Maximizing Therapeutic Effects

The following nursing interventions may help to maximize the beneficial effects of nicotine therapy:

- Encourage the patient to adhere to the recommended dosage schedule because it is the one most likely to reduce craving.
- Encourage patients to avoid carbonated drinks, coffee, beer, wine, and other acidic drinks 15 minutes prior and during use of Nicorette gum or lozenge, as these may inhibit absorption (Frishman, 2007).
- Because nicotine replacement therapy is an adjunctive measure in smoking cessation programs, all other program measures are promoted and encouraged.
- Because craving is substantially increased when patients are exposed to others who smoke (promoting effects from secondary smoke inhalation, reinforcing old habits, and prompting recollection of pleasurable sociocultural influences), encourage the patient to minimize exposure to these influences initially.

Minimizing Adverse Effects

Overstimulation of the CNS may be counteracted by promoting good sleep hygiene and adjusting the dosage and timing

of the last nicotine dose of the day. Other adverse effects may require the episodic use of analgesics for headaches.

Avoiding gastrointestinal effects requires good mouth care (particularly for the patient using nicotine gum) and possibly the use of antiemetics (for nausea) or antidiarrheals, as needed. For patients using the transdermal nicotine patches, good skin care and rotation of patch sites will help to minimize skin reactions. Upper respiratory tract effects may be counteracted with a room humidifier. Adverse effects that cannot be managed and that may be specific to the delivery system warrant a change to a different system on a trial basis.

Clinical research trials are exploring whether a vaccine could decrease cardiovascular risks from smoking. See Focus on Research, Box 14.1.

Providing Patient and Family Education

- Caution patients receiving nicotine replacement therapy about adverse effects and the possibility of overdosing with concomitant use of tobacco smoking during therapy.
- Watch the patient demonstrate the correct use of sprays or transdermal patches to ensure safe, optimal self-dosing.
- Instruct the patient on how to manage adverse effects and encourage the patient to contact the health care provider if self-management is ineffective or if serious or persistent adverse effects continue.
- If toxicity or overdosing is suspected, the therapy must be discontinued until the effects abate and then a decreased dosage or frequency of dosing can be reintroduced.
- Encourage the patient to avoid other stimulants during nicotine therapy, including caffeine-containing beverages, because they may lead to exaggerated CNS stimulation experienced as irritability and nervousness.
- Encourage patients to avoid carbonated drinks, coffee, beer, wine, and other acidic drinks 15 minutes prior and during use of Nicorette gum or lozenge, as these may inhibit absorption.
- Caution the patient and family to keep nicotine out of the reach of children.
- Incorporate all other smoking cessation program measures in the educational effort because replacement therapy is only a short-term adjunct measure.

BOX 14.1 FOCUS ON RESEARCH

Wagena, E.J., Vos, A., Horwith, G., et al. (2008). Immunogenicity and safety of a nicotine vaccine in smokers and nonsmokers: results of a randomized, placebo-controlled phase 1 / 2 trial I. *Nicotine & tobacco research: official journal of the Society for Research on Nicotine and Tobacco,* 10 (1):213–218.

Background
The Study

Can you prevent the adverse effects from smoking by administering a vaccine? As smoking is responsible for much morbidity and mortality in this county, researchers are trying to find a new way to help patients who smoke and have been examining the possibility of a vaccine that could be used. The idea was that after receiving a nicotine vaccine, the nicotine would be targeted as an antigen by the immune system of the patient. After vaccination, any subsequent exposures to nicotine should result in an immunologic response where by the patient's antibodies will bind with the nicotine molecule. Binding the nicotine in this way will prevent its passage through the blood–brain barrier and any physiologic response (both pleasurable and harmful) to the nicotine from taking place.

This purpose of this early-phase clinical trial was to determine if the vaccine would indeed alter the immune system. Thirty subjects were chosen, 21 of whom smoked at least 15 cigarettes per day and admitted to having no desire to quit smoking during the study. Smoking status of these 21 was confirmed as nicotine was found in their urine upon initial screening. The other 9 subjects chosen were ex-or nonsmokers. The 30 study participants were randomly assigned to either the placebo or the active group. Smokers and nonsmokers were randomized separately. This study did not include women of childbearing potential.

A single dose of 100 mcg of active vaccine (NicVAX) or an identical placebo was injected by the study nurses into the deltoid muscle of the participants. All participants received four immunizations of either the active vaccine or the placebo on day 0, 14, 28, and 182. The participants were required to return after each injection for assessment of their antibody assay and smoking status. Smoking status was assessed by performing an alveolar carbon monoxide test and a urinary nicotine test.

All participants in the active group showed significant levels of nicotine-specific antibodies after receiving the fourth injection, most showed significant levels of antibodies after three rounds of injections. No nicotine-specific antibody was found to be present in the placebo group after all four injections. Results also showed that the immunogenicity of the vaccine was not affected by the presence of nicotine at the time of the injections. The adverse effects most frequently reported by both the active and placebo groups were bad taste, dry mouth, and tenderness at the injection site. Weight gain was also a frequent adverse effect, but only in the active group. In conclusion, the study found that the vaccine was safe and effective in generating an immune response to nicotine molecules in the blood in both smokers as well as nonsmokers.

Nursing Implications

While these early clinical trials are promising, there is a great deal of research that still needs to be done to develop a nicotine vaccine, As many people complain of weight gain when they stop smoking, the weight gain by the vaccinated group appears to support the hypothesis that by developing antibodies to nicotine the patient does not have their nicotinic receptors simulated, much as if they were stopping smoking. Nurses should stay abreast of these research trials and the development of a vaccine. If a vaccine could be developed, it would be very helpful in preventing the adverse effects of smoking even if patients did smoke. As pleasurable sensations from smoking should also be prohibited, people should be able to stop smoking easier if they received a vaccine. Until the development of a vaccine, patients should be encouraged to participate in smoking cessation counseling programs. Nurses should continue to educate their patients on the risk of nicotine during pregnancy. If a vaccine is developed, nurses should encourage their patients to maintain a healthy diet and exercise program in order to prevent weight gain after receiving the vaccine.

COMMUNITY BASED CONCERNS

How to Help Your Patient to QUIT SMOKING

Tobacco dependence is the most preventable cause of death (Fant, 2009). Research shows that nurses are an underutilized resource in helping to reduce smoking rates worldwide. One reason more nurses don't participate in this important patient education is a lack of nursing education about nicotine replacement therapy (NRT) and other smoking cessation techniques (Sarna, 2009). So, how should you plan and implement patient education for smoking cessation? Here are some tips:

ASSESSMENT

Assess patient's level of addiction by asking two important questions.

1. *How many cigarettes do you smoke a day?*
2. *How long after awakening do you have your first cigarette of the day?*

For patients that only smoke one to two cigarettes per day or who wait until the afternoon for their first cigarette, smoking should still be strongly discouraged, although NRT may not need to be used. Patients who smoke early in the day and who smoke several cigarettes throughout the day may need more than one kind of NRT (Tonstad, 2009).

Additional assessment questions include;

3. How do you feel about your smoking?
4. What do you like about it?
5. What are your concerns?"

These questions will help you determine how to tailor any smoking cessation program to the individual patient.

SET MUTUAL GOALS

1. Help the patient see their concerns about smoking as strengths. For example, if a patient says, "I don't want to be a bad example or my kids (or grandkids)." Then recognize, "It sounds like you want the best for your family. I can tell you about your options for reducing and eventually stopping your smoking."

INTERVENTIONS

1. Describe benefits of smoking cessation that are specific to that patient (Tonstad, 2009). For example:
   - If the patient has elevated lipid levels tell them these benefits of stopping smoking: HDL levels increase, even more than they would with moderate exercise and LDL levels decrease, decreasing the risk for sudden cardiac death
   - If the patient has a cardiovascular history tell them these benefits: Pulse decreases by an average of 7–8 beats/min when you stop smoking and pulse rate is inversely correlated with age of death; Even one cigarette a day can cause platelet aggregation, increasing risk for pulmonary embolism or other cardio-vascular events
   - If the patient is concerned about cancer tell them: Risks for cancer dramatically decrease with smoking cessation as damaged respiratory cells are able to recover
2. Provide information on therapies to stop smoking. The options are as follows:
   - Patch–21 mg/24 hours for 4 weeks, then 14 mg/24 hours for 2 weeks, then 7 mg/24 hours for 2 weeks, then 15 mg/24 hours for 8 weeks (Frishman, 2007).
   - Gum–9 to 12 pieces daily for 8 to 12 weeks or more. The gum should be chewed slowly and with periods of rest, to provide a steady absorption rate of the nicotine through the buccal mucosa (Tonstad, 2009).
   - Lozenge–Use up to 24 pieces per day for 6 weeks and then down-titrate. Use if gum is not tolerated because of taste or headache (Frishman, 2007).
   - Inhaler–Inhale deeply and frequently in order to achieve 30% blood level of nicotine as smoking. 80 puffs = 4 mg nicotine (Frishman, 2007).
   - Bupropion–150 mg two times a week, started one week before cessation and titrated up to desired dose. Schedule for 12 weeks or more (Tonstad, 2009).
   - Nortryptiline–a tricyclic anti-depressant that has beneficial impact on withdrawal symptoms. Not FDA approved for nicotine withdrawal, so should only be used as second-line treatment (Frishman, 2007).
   - Varenicline–Start 1 week before smoking cessation 0.5 mg/d for day 1 to 3, 0.5 mg two times per day for days 4 to 7, then up to 1 mg two times per day for 12 weeks. If the patient is successful after 12 weeks, continue for 12 more weeks to prevent risk of relapse (Frishman, 2007).
   - Clonidine–100 mcg twice a day, started a week before cessation and titrated up to 400 mcg twice a day according to tolerance. 3 to 4 weeks of therapy. Controls withdrawal symptoms (Frishman, 2007).
   - SSRIs (specific serotonin reuptake inhibitors)– for example, fleuxotrine, 60 mg/day may be helpful, although not as effective in smokers who are already depressed (Frishman, 2007).
   - MAOIs (monoamine oxidase inhibitors)—for example, moclobemide 400 mg/d for 2 months and then 200 mg/d for the third month of cessation (Frishman, 2007).
3. Encourage the patient to be seen by a certified counselor if possible. Combining a form of talk therapy with pharmacotherapy increases quit rates. If a counselor is not available, help the patient establish a support network that will encourage him/her to engage in some behavioral changes, such as avoiding second-hand smoke and drinking more than two alcoholic drinks at a time.

Evaluation

In order to establish further structure for a patient's cessation program, establish a quit date and *follow up*, especially if therapy is not an option for the patient (Tonstad, 2009).

MEMORY CHIP

P Nicotine

- A direct-acting nicotinic agonist used as an adjunct to smoking cessation programs
- Major contraindications: immediately post MI, life-threatening dysrhythmias, severe angina
- Most common adverse effects: erythema, pruritus, burning, headache, insomnia
- Most serious adverse effect: vasculitis
- Maximizing therapeutic effects: adherence to the recommended dosing
- Minimizing adverse effects: Limit timing of last dose to promote rest and sleep.
- Most important patient education: correct use of multiple administration routes, avoidance of other stimulants

Ongoing Assessment and Evaluation

During therapy, symptoms of tobacco craving should gradually subside. Throughout therapy, remain alert for signs and symptoms of overdosing, which indicate that the patient is "cheating" and smoking tobacco while taking the nicotine replacement. Dizziness, nausea, and headaches may result and promote nonadherence to the therapeutic use of nicotine. Other evaluative measures include assessing the quantitative decrease of adverse effects and promoting therapeutic adherence.

Drugs Significantly Different From P Nicotine

Bupropion

Bupropion (Zyban) is a lower dose of the antidepressant Wellbutrin. It is considered a first-line drug for smoking cessation. Bupropion is discussed in Chapter 16.

Clonidine

Clonidine (Catapres) is an alpha-2 agonist generally used for hypertension. It is considered a second line drug for smoking cessation. Clonidine is covered in depth in Chapter 28.

Rimonabant

Rimonabant (Zimulti, Acomplia) is a selective cannabinoid-1 receptor blockers used in the management of weight loss. During clinical trials for weight loss, it was found to be also helpful in smoking cessation as well as post-cessation weight loss (Fagerstrom, 2006). Rimonabant is also discussed in Chapter 22.

Varenicline

Varenicline (Chantix) is a partial agonist with high affinity and selectivity for alpha-4-beta-2 nicotinic acetylcholine receptor subtypes. Its binding produces agonist activity at a subtype of the nicotinic receptor, but at a significantly lower level than nicotine. Varenicline also prevents nicotine binding to alpha-4-beta-2 receptors, decreasing stimulation of the central nervous mesolimbic dopamine system, which is thought to be responsible for the reinforcement and reward experience associated with smoking. Varenicline is used in a 12-week pharmacologic intervention that may be extended an additional 12 weeks if the patient continues to abstain from smoking. Adverse effects include rash, gastrointestinal (GI) disturbances, headache, insomnia, dream disturbances, and lethargy. Varenicline is classified as a pregnancy category C drug and should not be taken when breast-feeding.

• C Indirect-Acting Cholinergic Agonists

Synaptic transmission of neurotransmitters was discussed in Chapter 13. To review, the final step of synaptic transmission is termination. After the neurotransmitter crosses the synaptic gap and binds to a receptor, the neurotransmitter is cleared from the synaptic gap by enzymatic degradation, reuptake, or diffusion. Acetylcholine, the neurotransmitter of the cholinergic nervous system, is cleared from the synaptic gap by acetylcholinesterase, also known as cholinesterase. Any drug that inhibits acetylcholinesterase (i.e., inhibits the breakdown of acetylcholine) will prolong the activity of acetylcholine at the synapse. Thus these drugs will indirectly increase the stimulation at the cholinergic receptor. For this reason, some indirect-acting cholinergic agonists are also known as *cholinesterase inhibitors* or *anticholinesterase agents*. It is important to remember that acetylcholine stimulates both nicotinic and muscarinic receptor sites; therefore, cholinesterase inhibitors prolong the action of acetylcholine throughout the body.

The two major groups of indirect-acting cholinergic receptor stimulants are the reversible and "irreversible" cholinesterase inhibitors. Neostigmine (Prostigmin) is the prototype for reversible cholinesterase inhibitors. As the "irreversible" cholinesterase inhibitors have minimal pharmacological properties, they are discussed under the section Drugs Significantly Different From Neostigmine below.

Nursing Management of the Patient Receiving P Neostigmine

Core Drug Knowledge

Pharmacotherapeutics

The most significant indication for neostigmine therapy is myasthenia gravis. In this disease, the neuromuscular junction is affected by an autoimmune process that diminishes the number of functional nicotinic receptors at the junction. The result is the characteristic weakness and fatigue that accompany exercise in people with this disease. The use of neostigmine effectively increases the amount of acetylcholine available at the myoneural junction, resulting in enhanced strength of muscle contraction.

Other clinical indications include urinary retention and paralytic ileus. Neostigmine is also used as an antidote for nondepolarizing neuromuscular blocking agents (Table 14.6).

TABLE 14.6 Agents That Interact with P Neostigmine

Interactants	Effect and Significance	Nursing Management
Aminoglycoside antibiotics (neomycin, streptomycin, kanamycin)	Mild nondepolarizing blocking action	Monitor for increased neuromuscular blockade.
Corticosteroids	Decreases effect of anticholinesterase therapy in myasthenia gravis	Ensure respiratory support if needed.
Depolarizing muscle relaxants (succinylcholine) and mivacurium	Increased, prolonged neuromuscular blockade	Avoid use if possible. If not, administer these drugs only as directed and only if indicated. Provide emergency respiratory support.
Magnesium	Antagonizes and counteracts beneficial effects of neostigmine	Avoid magnesium-containing drugs and foods.
Anticholinesterase drugs	Excessive GI stimulation and symptoms of cholinergic crisis or underdosage in patients with myasthenia gravis	Have antidote (atropine or belladonna) available to treat overdosage.

Pharmacokinetics

Neostigmine is administered both orally and parenterally. It is poorly absorbed when given orally. Onset of action occurs within 2 to 4 hours when taken orally, and within 10 to 30 minutes when given parenterally. The drug is metabolized by microsomal liver enzymes and hydrolyzed by cholinesterases. Duration of effect varies considerably among patients. Approximately 80% of neostigmine is excreted in the urine within 24 hours as unaltered drug and metabolites.

Pharmacodynamics

Neostigmine is a reversible inhibitor of postsynaptic cholinesterase and therefore acts as a cholinergic agent by increasing the synaptic presence of acetylcholine.

Contraindications and Precautions

Neostigmine is absolutely contraindicated in patients with gastrointestinal obstruction or ileus and urinary tract obstruction because it increases contractions of smooth muscle. It should not be used in patients with peritonitis because it increases gastrointestinal motility, which would exacerbate the disorder. Neostigmine should be used with caution in patients with peptic ulcer disease because it stimulates gastric acid secretion, again inducing an exacerbation of the disorder. The CNS stimulation induced by neostigmine may exacerbate hyperthyroidism or seizure disorders.

Neostigmine should be used cautiously in patients with hypotension and bradycardia because it can further decrease blood pressure and heart rate by increasing vagal tone. Neostigmine also has direct stimulatory effects on the myocardium, which can increase oxygen demand. This state can be dangerous for patients with cardiac disease, particularly coronary artery disease alone or in association with cardiac arrhythmias. In the respiratory system, neostigmine may induce bronchoconstriction; therefore, it should be used cautiously in patients with asthma, chronic bronchitis, or chronic airway limitation.

Adverse Effects

The most serious adverse effects result from overactity of the cholinergic system, which may be life threatening. This excessive cholinergic stimulation is termed cholinergic poisoning or cholinergic crisis. Think of this as "too much of a good thing," or more of the cholinergic effects than is normally desired from stimulation. Usually the cause is dose related; the dose of neostigmine is too high, leading to too much degradation of acetylcholinesterase, so excessive receptor stimulation results. Symptoms include nausea and vomiting, diarrhea, salivation, sweating, peripheral vasodilation, bronchial constriction, and respiratory arrest.

The most common unwanted effects of neostigmine's cholinergic stimulation of end organs are nausea and vomiting, diarrhea, abdominal pain, miosis, salivation, diaphoresis, sinus bradycardia, bronchospasm, and increased bronchial secretions.

Drug Interactions

Neostigmine and the anticholinesterase drugs in general interact with steroids, aminoglycoside antibiotics, depolarizing muscle relaxants, local anesthetics and some general anesthetics, and magnesium, all of which have an influence on the neuromuscular junction (Table 14.6). Steroids may decrease the anticholinesterase effects of neostigmine, with a resulting worsening of the myasthenic condition. This exacerbation may require an increased dose of neostigmine or alternate dosing of each class of agent. Some of the aminoglycosides cause a mild neuromuscular blockade, which may antagonize the effects of neostigmine. For the depolarizing muscle relaxants, such as succinylcholine, neostigmine may increase the time of neuromuscular blockade; thus, concurrent usage in people with myasthenia is contraindicated.

Assessment of Relevant Core Patient Variables

Health Status

Before administering the drug, perform a baseline physical assessment to document the current status of the patient,

especially respiratory status and muscle strength. Myasthenia affects the muscles of respiration and other muscle groups; therefore, respiratory function may be further compromised in the presence of upper respiratory tract infections or allergies. Undertreatment or overtreatment is of particular concern because it can lead to life-threatening crises.

Also assess for a history of diseases or disorders that contraindicate the use of neostigmine. Communicate positive findings to the health care provider before neostigmine is administered.

Life Span and Gender

Document the age and gender of the patient. Because they have lower body mass than other adults and decreased renal functioning, elderly patients may be more prone to the psychotogenic effects of cholinergic overdose, including restlessness, anxiety, and agitation. Also determine whether the patient is pregnant or breast-feeding because these patients should avoid neostigmine.

Lifestyle, Diet, and Habits

Document the patient's occupation, daily activities, and rest and exercise patterns. Patients taking neostigmine for myasthenia gravis may need to pace their daily activities to allow the peak and duration effects of neostigmine dosing to support their muscular and respiratory work.

Environment

Be aware of the environment in which the drug will be administered and assess the home or living environment, if appropriate. Neostigmine in its oral form may be administered in any setting by health care providers, nurses, the patient, or family members.

Nursing Diagnoses and Outcomes

- Impaired Gas Exchange related to drug-induced bronchospasm, increased secretions, or respiratory paralysis
  Desired outcome: *The patient will maintain effective gas exchange.*
- Ineffective Airway Clearance
  Desired outcome: *The patient will maintain effective airway clearance.*
- Ineffective Breathing Pattern related to drug dosage
  Desired outcome: *The patient will maintain effective breathing patterns.*
- Self-Care Deficit (Feeding, Bathing/Hygiene, Dressing/Grooming, Toileting) related to the impact of neuromuscular weakness secondary to overdose
  Desired outcome: *The patient will seek assistance in carrying out self-care as needed.*

Planning and Intervention

Maximizing Therapeutic Effects

Neostigmine is administered at regular intervals throughout the day to ensure effective blood levels. If the patient has difficulty swallowing or breathing, the parenteral form of neostigmine should be administered until oral therapy can be tolerated.

Minimizing Adverse Effects

As with other cholinergic stimulants, the use of neostigmine requires the availability of an antidote in case of systemic overdose or cholinergic crisis. Atropine, as an anticholinergic, is the usual antidote. In patients with myasthenia gravis, it is sometimes necessary to distinguish between a cholinergic crisis and a myasthenic crisis. In the case of a cholinergic crisis, it is likely that too much anticholinesterase has been given, whereas a myasthenic crisis may be the result of inadequate dosages failing to control myasthenic symptoms. A challenge IV dose of edrophonium (Tensilon), another anticholinesterease drug, will differentiate the two states. Edrophonium is used because it has a very quick onset (30 to 60 seconds) and the duration of action is only 10 minutes. If the symptoms of a patient with myasthenia gravis improve after the dose, it means they needed more cholinergic stimulation and their standing treatment for myasthenia gravis is inadequate; they can be considered to have been experiencing a myasthenic crisis. If there is no relief of symptoms or if an increase in muscle weakness follows (i.e., the patient gets worse), then the patient is receiving too much anticholinesterase and is experiencing a cholinergic crisis. In this case the antidote is necessary.

For patients with known allergies or suspected hypersensitivity, life-support measures must be available in case of bronchial spasm or hypersensitivity reactions. Because adverse systemic effects include stimulation of sphincters, patients may need access to a bedpan or urinal in case of rapid responses.

If the patient has a history of allergies or asthma or chronic obstructive lung disease, careful monitoring of the first few doses of neostigmine is required to ensure that respiratory difficulties do not occur.

Providing Patient and Family Education

The key considerations for patient and family education include managing serious adverse effects and recognizing crisis states that may require prompt and expert intervention:

- Explore aspects of long-term therapy that sometimes escape the attention or resources of acute care staff, such as decreased libido.

CRITICAL THINKING SCENARIO

NEOSTIGMINE THERAPY

Amy Rose, a 27-year-old legal assistant, has been admitted to your unit with a diagnosis of myasthenia gravis. She has been started on neostigmine therapy, and you are wondering how to differentiate between a myasthenic crisis and a cholinergic crisis.

1. Explain the key differences between the two situations, and propose a nursing management strategy that you could use for either situation.
2. Discuss the implications of a health care provider-ordered edrophonium test. Why do you think this test would be ordered?

MEMORY CHIP

P Neostigmine

- An indirect-acting cholinoceptor stimulant used in the management of myasthenia gravis
- Major contraindications: GI obstruction or ileus, urinary tract obstruction, peritonitis
- Most common adverse effects: nausea or vomiting, diarrhea, abdominal pain, miosis, salivation, diaphoresis, sinus bradycardia
- Most serious adverse effects: cholinergic crisis, cardiac arrest
- Maximizing therapeutic effects: Administer at regular intervals throughout the day to ensure adequate blood levels
- Minimizing adverse effects: availability of atropine, the antidote for cholinergic crisis
- Most significant nursing responsibility: Differentiate between cholinergic crisis and myasthenic crisis
- Most important patient education: symptoms of cholinergic crisis and need for immediate medical attention

- Assist patients and their families in understanding how to recognize myasthenic crisis (undermedication) and distinguish it from cholinergic crisis (overmedication), and in knowing how to respond to either situation. In myasthenic crisis caused by undermedication, muscle weakness becomes pronounced and may cause quadriparesis, quadriplegia, shortness of breath, respiratory insufficiency, and difficulty swallowing. Conversely, in a cholinergic crisis caused by overmedication, there is an increase in gastrointestinal motility with diarrhea and cramping, bradycardia, muscle fasciculation, pupillary constriction, and increased salivation and sweating. Advise the patient and family to seek immediate care if any of these symptoms occur.

Ongoing Assessment and Evaluation

Be familiar with procedures for detecting and managing myasthenic or cholinergic crises. Monitor changes in neuromuscular functioning, vital signs, respiratory rate and capacity, mobility, self-care levels, and self-esteem.

An important component of the ongoing assessment is the patient's neuromuscular status. The focus is on vital capacity (respiratory status), presence of ptosis, presence of diplopia, ability to chew and swallow, strength of hand grip bilaterally, and quality of gait if the patient is ambulatory. Acute care settings often provide a detailed assessment sheet designed specifically for the person with myasthenia gravis. Other data should include baseline and ongoing measurements of blood pressure and pulse and respiratory rates.

Drugs Significantly Different From P Neostigmine

Demecarium

Demecarium (Humorsol) is a long-acting cholinesterase inhibitor and potent miotic used in the management of glaucoma. It increases the amount of fluid that drains from the eye, resulting in reduced pressure in the eye. It also causes the pupil to become smaller and reduces its response to light or dark conditions.

Demecarium is a category X drug because it may cause fetal deformities. It is given cautiously to patients with cardiovascular disorders, asthma, seizure disorders, and hyperthyroidism.

Demecarium may cause local or systemic adverse effects. Local effects include burning, redness, stinging, or other irritation of the eyes. More serious local effects include eye pain and retinal detachment. Systemic effects are infrequent when demecarium is instilled carefully. Compression of the lacrimal duct for several seconds immediately following instillation minimizes drainage into the nasal chamber, where extensive absorption may occur.

Physostigmine

Physostigmine (Antilirium) is a parenteral and ophthalmic cholinesterase inhibitor. Physostigmine is most commonly used as an ophthalmic agent in the treatment of open-angle glaucoma. It is also used to counteract toxic anticholinergic effects (both central and peripheral) of other drugs, particularly in overdose situations. In the past it was used to treat tricyclic antidepressant overdose, but this use has lost favor because of physostigmine's own potentially harmful effects.

Drugs for Myasthenia Gravis

Ambenonium chloride (Mytelase), edrophonium (Tensilon), and pyridostigmine (Mestinon) are used to improve muscle strength in patients with myasthenia gravis and so also are indirect-acting cholinergic drugs. Ambenonium has a longer duration of action than neostigmine and is more potent. However, it is not used as frequently. Pyridostigmine is an analogue of neostigmine and is marketed in both regular and sustained-release tablets and is the most commonly used agent of the group for oral treatment of myasthenia gravis. It is also available in a form for intravenous administration. Other therapeutic uses are as prophylaxis in organophosphate poisoning and reversal of neuromuscular blockade. It is less potent than neostigmine. Edrophonium is the drug of choice for diagnosing myasthenia gravis because of its rapid onset (30 to 60 seconds) of action and short duration of action (about 10 minutes). It must be given IV. Because of the short duration of action and the need for IV therapy, it is not appropriate for long-term treatment of myasthenia gravis. It works by binding with acetylcholinesterase to prevent it from attaching to the cholinergic receptor. It is also used to differentiate cholinergic crisis from myasthenic crisis and to reverse the effects of nondepolarizing neuromuscular blockers after surgery. Contraindications, adverse effects, and drug interactions are similar to those of neostigmine.

Drugs for Cognition

Several indirect-acting cholinergic agonists are approved for improving cognitive symptoms, such as problems with memory, attention, reason, language, and ability to perform

simple tasks, associated with Alzheimer disease. Elevated levels of acetylcholine in the cerebral cortex are believed to be responsible for improvement in cognition; however, intact cholinergic neurons must be present. Currently, rivastigmine (Exelon), tacrine (Cognex), galantamine (Razadyne), donepezil (Aricept), and memantine (Namenda) are approved for the management of Alzheimer disease. These drugs work by enhancing cholinergic neurotransmission in relevant parts of the brain by the use of cholinesterase inhibitors to delay the breakdown of acetylcholine released into synaptic clefts (Birks et al., 2009). A full discussion of drugs used to treat Alzheimer disease is in Chapter 17. Neostigmine is not indicated for use in disorders of cognition, although the drugs used for cognition fall under the same class of drugs (Birks, 2006).

Irreversible Cholinesterase Inhibitors

Most of the irreversible cholinesterase inhibitors are in the organophosphate category. Because of the phosphate element of these drugs, they are highly lipid soluble and are easily absorbed from any administration site. Their ease of absorption, coupled with their potential toxicity, is the basis for their use as insecticides and chemical warfare agents.

There are a few therapeutically useful irreversible inhibitors, such as echothiophate and isoflurophate (Floropryl), which are used for glaucoma that is refractory to the usual miotics.

Overdose or accidental overexposure to irreversible anticholinesterase drugs is characterized by cholinergic crisis. The antidote of choice is pralidoxime (Protopam, PAM). Pralidoxime is not effective in reversing overdose of reversible anticholinesterase drugs. It works best when given immediately after the exposure. It does not cross the blood–brain barrier and, therefore, is ineffective in reversing anticholinesterase in the CNS.

CHOLINERGIC ANTAGONISTS

The cholinergic antagonists are drugs that antagonize, or block, muscarinic or nicotinic receptors directly. They are generally referred to as anticholinergics. They may be clustered into three categories: antimuscarinic drugs (the largest group), antinicotinic drugs (with two subcategories: ganglionic blockers and neuromuscular blockers), and cholinesterase regenerators.

Antinicotinic Ganglionic Blockers

The ganglionic blockers include mecamylamine (Inversine) and trimethaphan (Arfonad). Mecamylamine inhibits acetylcholine at the autonomic ganglia, causing a decrease in blood pressure. Mecamylamine is no longer recommended for treatment of hypertension as newer and more effective drugs have been created which have been found to decrease mortality from hypertension. Mecamylamine also blocks central nicotinic cholinergic receptors, which inhibits the effects of nicotine and may suppress the desire to smoke.

Trimethaphan blocks the ganglionic receptors so that acetylcholine cannot attach. It is used in treating hypertensive crisis and has been used in the emergency control of hypertension in patients with acute dissecting aortic aneurysm. It is discussed further in Chapter 26.

Neuromuscular Blockers

The neuromuscular blockers, which are covered in Chapter 19, include the prototype nondepolarizing agent tubocurarine, as well as cisatracurium, doxacurium, pancuronium, and vecuronium, as well as the prototype depolarizing agent succinylcholine. These drugs compete with acetylcholine for cholinergic receptors. They are used as adjuncts to anesthesia and assist in entubation.

Antimuscarinic/Anticholinergic Drugs

Atropine is an anticholinergic drug that specifically targets the muscarinic cholinergic receptors. Atropine is the ideal prototype for the antimuscarinic group of cholinergic antagonists.

Nursing Management of the Patient Receiving P Atropine

Core Drug Knowledge

Pharmacotherapeutics

Atropine has a multitude of therapeutic uses and a variety of preparations. It is used in emergency situations, such as symptomatic bradycardia, pulseless electrical activity, ventricular asystole, or cardiopulmonary resuscitation. Preoperatively, it is used to decrease respiratory secretions, and during surgery, it is used to block cardiovagal reflexes and succinylcholine-induced arrhythmias. Other uses include reversal of organophosphate insecticide toxicity or neuromuscular blockade, as well as the antidote to overdosage with a cholinergic drug or from eating poisonous mushrooms (which attach to muscarinic receptors). Ophthalmic solutions are used to change pupil size or activity of the ciliary muscle, and in the treatment of iritis or uveitis. Atropine-containing solutions are used to manage traveler's diarrhea or gastric spasms. Oral forms can also be used as treatment for ureteric colic. Off-label atropine might be used as an adjunct for treating asthma. Atropine is available as oral tablets and in oral solutions, as parenteral solutions for SC, IM, or IV administration, as an ophthalmic drop, and as a liquid for nebulization.

Pharmacokinetics

Following intramuscular administration, onset of effect is usually rapid, peaking at 30 minutes and lasting up to 5 hours (Table 14.7). Topical administration to the eyes may take 30 to 40 minutes to produce cycloplegia (paralysis of ciliary muscles), whereas intravenous (IV) administration produces rapid effects. Atropine is partially metabolized in the liver, with about 60% of a dose eliminated unchanged through the kidneys.

Pharmacodynamics

Atropine is a competitive inhibitor at autonomic postganglionic cholinergic receptors. Atropine attaches and blocks all cholinergic receptors throughout the entire body.

These receptors are found in gastrointestinal and pulmonary smooth muscle, exocrine glands, the heart, and the eye. The principal actions of atropine are: increase in heart rate; a reduction in salivary, bronchial, and sweat gland secretions; mydriasis (enlarged pupils); paralysis of the ciliary muscle; contraction of the bladder detrusor muscle and of the gastrointestinal smooth muscle; decreased gastric secretion; and decreased gastrointestinal motility.

The action of atropine on the heart rate is dose dependent. In doses of 0.4 to 0.6 mg, atropine causes a slight sinus bradycardia through vagal stimulation. In larger doses (1 to 2 mg), it causes sinus tachycardia secondary to inhibition of vagal control of the sinoatrial node in the heart. Atropine is mostly given for its ability to increase the heart rate.

Contraindications and Precautions

Contraindications to atropine use include hypersensitivity to anticholinergics or sulfites. Atropine is contraindicated in myasthenia gravis because the drug competes with the small amount of acetylcholine that has potential to act in the body. Atropine is relatively contraindicated in acute myocardial infarction because the drug can potentiate arrhythmias. In addition, the increase in heart rate caused by atropine increases the oxygen demand on the heart and can exacerbate myocardial ischemia. Precautions should be observed with patients who drive or perform hazardous tasks for a living (because of the adverse effects of drowsiness and blurred vision). Precautions are also needed for the elderly as well as those with glaucoma, severe forms of hepatic disease, ulcerative colitis, renal disease, prostatic hypertrophy, coronary artery disease, chronic heart failure, arrhythmias, tachycardia, hypertension, asthma, and allergies. Finally, precautions are needed for anyone with increased sensitivity (e.g., infants and small children) and for patients with brain damage, hyperthyroidism, and hyperthermia. All of these circumstances may be exacerbated with atropine and other anticholinergics.

Adverse Effects

The most common adverse effects of atropine are blurred vision, dry mouth, constipation, and urinary retention. The most serious potential adverse effect is an anticholinergic overdose. This overdose is characterized by the phrase "mad as a hatter (CNS psychotic effect), dry as a bone (salivary), red as a beet (peripheral vasodilation), and blind as a bat (mydriasis)."

In the CNS, the predominant effect is drowsiness, but more serious CNS effects are possible, especially in the elderly. These include: confusion, disorientation, delusions, hallucinations, and psychosis. Other potential adverse effects include elevation of intraocular pressure, decreased ability to sweat, and tachycardia. Although anticholinergic drugs are used in the management of asthma, the drying of respiratory secretions may result in mucus plugs that may actually induce bronchospasm and asthma attacks.

Atropine is a FDA pregnancy category C drug and should be avoided by pregnant and lactating women.

Drug Interactions

Atropine interacts with phenothiazine antipsychotics and with haloperidol (Table 14.8). Cardiac status, as measured by electrocardiography (ECG), may be affected by atropine. Atropine may interfere with ECG measurements through its cardiovascular effects and result in spurious cardiac findings. The ECG interpretation should note the atropine therapy.

Assessment of Relevant Core Patient Variables

Health Status

Because atropine has many actions on the body, carefully assess the patient for contraindications or precautions to its

TABLE 14.8 Agents That Interact with P Atropine

Interactants	Effect and Significance	Nursing Management
phenothiazines	Decreased antipsychotic efficacy of phenothiazines	Adjust phenothiazine dosage.
haloperidol	Decreased serum haloperidol levels, worsening of symptoms, onset of tardive dyskinesia	Avoid concurrent atropine or lower haloperidol dosage; monitor carefully.

use before administering the drug. It is important to determine whether the patient has acute angle-closure glaucoma, obstructive disease of the gastrointestinal tract, paralytic ileus, obstructive uropathy, intestinal atony (particularly in elderly or debilitated patients), megacolon complicating ulcerative colitis, unstable cardiovascular status in acute hemorrhage, tachycardia secondary to cardiac insufficiency of thyrotoxicosis, myasthenia gravis, toxemia of pregnancy, or previous exposure to high temperatures.

Communicate positive findings to the health care provider. Also determine whether the patient has chronic obstructive lung disease, severe heart disease, hypertension, ulcerative colitis, ileus, chronic lung disease, hyperthyroidism, autonomic neuropathy, hepatic or renal disease, prostatic hypertrophy, esophageal reflux, or hiatal hernia. Because these conditions may be exacerbated with atropine therapy, monitor these patients closely. Also assesses the patient's use of OTC or herbal medications. These drugs frequently contain atropine-like ingredients that may induce severe adverse effects.

Life Span and Gender

Document the age of the patient. Atropine must be used carefully with infants, young children, and anyone older than 40 years because the adverse effects may be more pronounced in these age groups.

Environment

Document the patient's occupation and daily activities. People treated with atropine may experience mydriasis and hence difficulties adjusting to changing light intensities. These effects may have considerable impact on people working in transportation (airline flight crew, drivers) and those working at night (because of photophobia and temporary blindness in response to bright lights).

Nursing Diagnoses and Outcomes

- Urinary Retention related to adverse effects of drug
  Desired outcome: *The patient will eliminate without difficulty.*
- Constipation related to adverse effects of drug
  Desired outcome: *The patient will continue baseline elimination pattern.*
- Risk for Injury related to drug-induced drowsiness and blurred vision
  Desired outcome: *The patient will understand adverse effects and develop a repertoire of strategies for their management.*
- Ineffective Sexuality Patterns or Sexual Dysfunction related to anticholinergic impact on erection and ejaculation in men and on vaginal secretions in women
  Desired outcome: *The patient and partner will adjust sexual functioning and develop a repertoire of strategies to maintain satisfaction.*

Planning and Intervention

Maximizing Therapeutic Effects

Two factors should be considered for the person receiving atropine, because they arise directly from the interactions between core drug knowledge and core patient variables. First, patients taking atropine for peptic ulcer disease should adhere to dietary restrictions established to prevent exacerbations of the disease, thereby allowing the therapeutic potential of the atropine to be achieved. Suggest administering the larger dose at bedtime to decrease sleep-disturbing pain. Second, patients need to be encouraged to take their atropine exactly as prescribed and at the required dosage frequency to enhance therapeutic potential.

Minimizing Adverse Effects

Because a prominent anticholinergic effect is dry mouth, good oral hygiene is important. Dryness may be relieved with hard candies, chewing gum, or lip balm. Blurred vision and mydriasis can be hazardous for drivers, particularly at night; therefore, driving is best avoided. Bright lights and photophobia may be counteracted with sunglasses. For patients with a complaint of dry eyes, artificial tears should be administered.

Atropine alters the body's ability to regulate temperature; therefore, minimize extremes of heat and strenuous exercise, and adequately and deliberately hydrate the patient. Constipation is a troubling adverse effect that may be managed by adding fiber to the diet, promoting hydration, and exercising moderately.

In longer-term therapy, stress the importance of mouth care and monitor the need for urinary catheterization or measures to relieve constipation and abdominal distention. A distressing adverse effect for many patients relates to their preferred modes of sexual expression, which may be dramatically changed with anticholinergic drugs. If appropriate, supportive counseling or directive teaching about alternatives to intercourse may be useful, although many of these issues are better managed by a sex therapist.

Providing Patient and Family Education

Important aspects of patient and family teaching include recognizing and managing adverse effects:

MEMORY CHIP

P Atropine

- An anticholinergic drug given in emergency situations such as severe bradycardia or during CPR. Used routinely as a preoperative medication to reduce intraoperative pulmonary secretions
- Major contraindications: hypersensitivity to sulfites, myasthenia gravis, acute myocardial infarction
- Most common adverse effects: blurred vision, constipation, dry mouth, urinary retention
- Most serious adverse effect: cardiac arrhythmias
- Maximizing therapeutic effects: Take the medication exactly as prescribed and at the required dosage
- Minimizing adverse effects: good oral hygiene, fluid replacement
- Most important patient education: safety issues for blurred vision; avoid OTC and herbal medications without the direct approval of the health care provider.

- Inform older men of the need to report any changes in urinary stream because it may be a prodromal symptom of prostatic hypertrophy.
- Suggest aids to elimination, including adequate exercise, added dietary fiber, and increased fluid intake.
- Stress the hazards associated with driving, especially at night, because night vision may be altered significantly by atropine.
- Remind the patient to avoid all OTC and herbal medications without the direct approval of the health care provider. As previously mentioned, these medications frequently contain atropine-like ingredients.

Ongoing Assessment and Evaluation

Assessment of goal attainment is relatively straightforward for patients receiving anticholinergic therapy with atropine. Ongoing assessment includes data about elimination patterns, sexual functioning and adjustment, and recognition and management of side effects. The ongoing assessments may be tailored to the clinical indications for which atropine or other anticholinergics are prescribed, but they should include any concurrent drug therapy to rule out the possibility of drug interactions. Vital signs measured at onset of therapy are compared with vital signs throughout therapy and are used to monitor and detect adverse effects.

Assess bowel and bladder function on an ongoing basis because of the profound impact that drug therapy may have on elimination. Because of the potential for confusion, anyone at risk for adverse CNS effects should have a mental status assessment.

Drugs Significantly Different From P Atropine

Hyoscyamine

Hyoscyamine (Cystospaz) relaxes smooth muscle spasm resulting from parasympathetic stimulation. It inhibits gastrointestinal propulsive motility and decreases gastric acid secretion. It also controls excessive pharyngeal, tracheal, and bronchial secretions. It requires only half the dose of atropine; therefore, it has a lower potential to induce adverse effects.

Scopolamine

Scopolamine (Isopto Hyoscine) is a naturally occurring anticholinergic agent found in belladonna leaf. Compared with atropine, scopolamine is more potent in its anticholinergic effects on the iris, ciliary body, and the salivary, bronchial, and sweat glands. It is less potent than atropine on the heart and on bronchial and gastrointestinal smooth muscle. In contrast to atropine, scopolamine at therapeutic doses produces CNS depression characterized by drowsiness, euphoria, amnesia, fatigue, and dreamless sleep resulting from decreased periods of rapid eye movement. Paradoxical CNS excitation manifested as restlessness, hallucinations, or delirium can occur, especially when the patient is experiencing severe pain. Scopolamine is very effective for the prevention of motion sickness, and this indication represents the most common clinical use. Other uses for scopolamine include treatment of iritis, uveitis, and Parkinson disease.

Antiparkinson Agents

Trihexyphenidyl (Artane) and benztropine (Cogentin) are centrally acting anticholinergics used adjunctively to treat all types of parkinsonian syndromes, including antipsychotic-induced extrapyramidal symptoms. In general, anticholinergic agents can help control tremors but are less effective for treating bradykinesia or rigidity.

Trihexyphenidyl (Artane) is effective in 50% to 75% of patients. Additionally, it can block dopamine reuptake, thereby prolonging dopamine's effects.

Benztropine (Cogentin) can be given both orally and parenterally. It produces less CNS stimulation than does trihexyphenidyl. Benztropine may be helpful in geriatric patients who cannot tolerate cerebral-stimulating agents. Antiparkinson drugs are discussed more in Chapter 21.

Antisecretory Anticholinergics

Glycopyrrolate (Robinul) and propantheline (Pro-Banthine) are oral agents used to decrease the secretion of gastric acid. Since the advent of histamine-2 blockers and proton pump inhibitors, these antisecretory anticholinergics have fallen out of favor because they induce myriad adverse effects. However, for patients unresponsive to histamine-2 blockers or proton pump inhibitors, these drugs may be effective.

Inhaled Agents

Ipratropium bromide (Atrovent) and tiotropium (Spiriva) are inhaled anticholinergic drugs that are structurally very similar to atropine. These drugs have greater antimuscarinic activity on the bronchial smooth muscle, and systemic effects are minimal. Compared with atropine, they are roughly twice as potent as a bronchodilator. Both drugs are used in the management of chronic obstructive pulmonary disorders such as chronic bronchitis, emphysema, and asthma.

Intranasal administration of ipratropium produces a localized parasympatholytic effect. This action reduces watery hypersecretion from mucosal glands of the nose, thereby relieving rhinorrhea associated with the common cold or allergic or nonallergic perennial rhinitis. These drugs are discussed more fully in Chapter 35.

Urinary Relaxants

In overactive bladder (OAB), the bladder or detrusor muscle contracts prior to the bladder being full, causing the patient to feel a sense of urgency to void. OAB can occur with or without urinary incontinence. Cholinergic antagonists such as darifenacin (Enablex), flavoxate hydrochloride (Urispas), oxybutynin, (Ditropan, Ditropan XL, or Oxytrol), solifenacin (Vesicare), tolterodine (Detrol, Detrol LA), and trospium (Sanctura) are used for OAB (Lam, 2007). These drugs are preferential to M_2 and M_3, but they may also stimulate the other muscarinic receptors, resulting in adverse effects. The most common adverse effect is dry mouth.

Oxybutynin is the only drug available in a generic formulation and as a transdermal patch. Its long-acting formulation causes dry mouth in approximately 60% of patients. For patients who cannot tolerate adverse effects of oxybutynin, trospium chloride is preferred (Biastre & Burnaski, 2009). The anticholinergics used in treating OAB are discussed further in Chapter 27.

CHAPTER SUMMARY

- The parasympathetic (cholinergic) nervous system stimulates the GI system and decreases metabolism and cardiovascular and respiratory function to preserve energy. It is considered the "rest and digest" system.
- In the parasympathetic system, the transmitter is acetylcholine, and the receptors are considered cholinergic. Cholinergic may be further divided into muscarinic or nicotinic.
- Parasympathetic or cholinergic drugs can be stimulating or blocking in their action. The cholinergic stimulating drugs are known as cholinergic agonists, and the cholinergic blocking agents are known as cholinergic anticholinergics. There are additional terms for these drugs (see Table 14.1).
- Acetylcholine is inactivated by acetylcholinesterase, which is sometimes referred to as cholinesterase.
- Drugs that interfere with acetylcholinesterase's breakdown of acetylcholine (i.e., they inhibit the action of acetylcholinesterase) are known as anticholinesterase agents.
- Therapeutic uses of cholinergic drugs are varied and related to providing extra cholinergic stimulation or blockage to normal autonomic nervous system functioning.
- Excessive stimulation of cholinergic receptors is known as cholinergic poisoning or cholinergic crisis. The symptoms of this overstimulation can be remembered by the saying: Red as a beet, dry as a bone, blind as a bat, and mad as a hatter. Overdosage with a cholinergic drug can produce this condition.
- A prototype of a direct-acting muscarinic agonist is pilocarpine, which is used for simple and acute glaucoma, preoperative and postoperative intraocular tension, and mydriasis.
- A prototype direct-acting nicotinic agonist is nicotine, which is used as an adjunct to smoking cessation programs.
- A prototype indirect-acting cholinergic receptor stimulant is neostigmine, which is used to control the symptoms of myasthenia gravis. It inhibits the action of acetylcholinesterase. As with any of the cholinergic drugs, adverse effects involve many of the major organ systems.
- Atropine is the prototype of the antimuscarinic anticholinergic drugs. It is most commonly used to raise heart rate in cardiac emergencies and preoperatively to dry oral secretions.

The most common adverse effects of anticholinergic drugs are blurred vision, dry mouth, constipation, and urinary retention.

QUESTIONS FOR STUDY AND REVIEW

1. What happens when you stimulate cholinergic receptors in the eye after administering pilocarpine eye drops?
2. What happens when you stimulate cholinergic receptors in the GI and GU tract?
3. If you administered a cholinergic drug, what adverse effects might occur in the cardiovascular system?
4. How does neostigmine create its therapeutic effect?
5. What signs and symptoms indicate a cholinergic crisis? What is the antidote?
6. You may have encountered a way of remembering excessive anticholinergic effects through the terms "mad as a hatter, blind as a bat, red as a beet, and dry as a bone." How does "dry as a bone" relate to adverse anticholinergic effects?
7. How does atropine cause both bradycardia and tachycardia? Which effect is the most common desired effect from the drug: raising the pulse rate or slowing it?

Drugs Relieving Anxiety and Promoting Sleep

Learning Objectives

At the completion of this chapter the student will:

1. Describe the varied therapeutic uses of benzodiazepines.
2. Identify core drug knowledge about drugs that relieve anxiety and promote sleep.
3. Identify core patient variables related to drugs that relieve anxiety and promote sleep.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that relieve anxiety and promote sleep.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that relieve anxiety and promote sleep.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that relieve anxiety and promote sleep.
7. Determine key points for patient and family education for drugs that relieve anxiety and promote sleep.

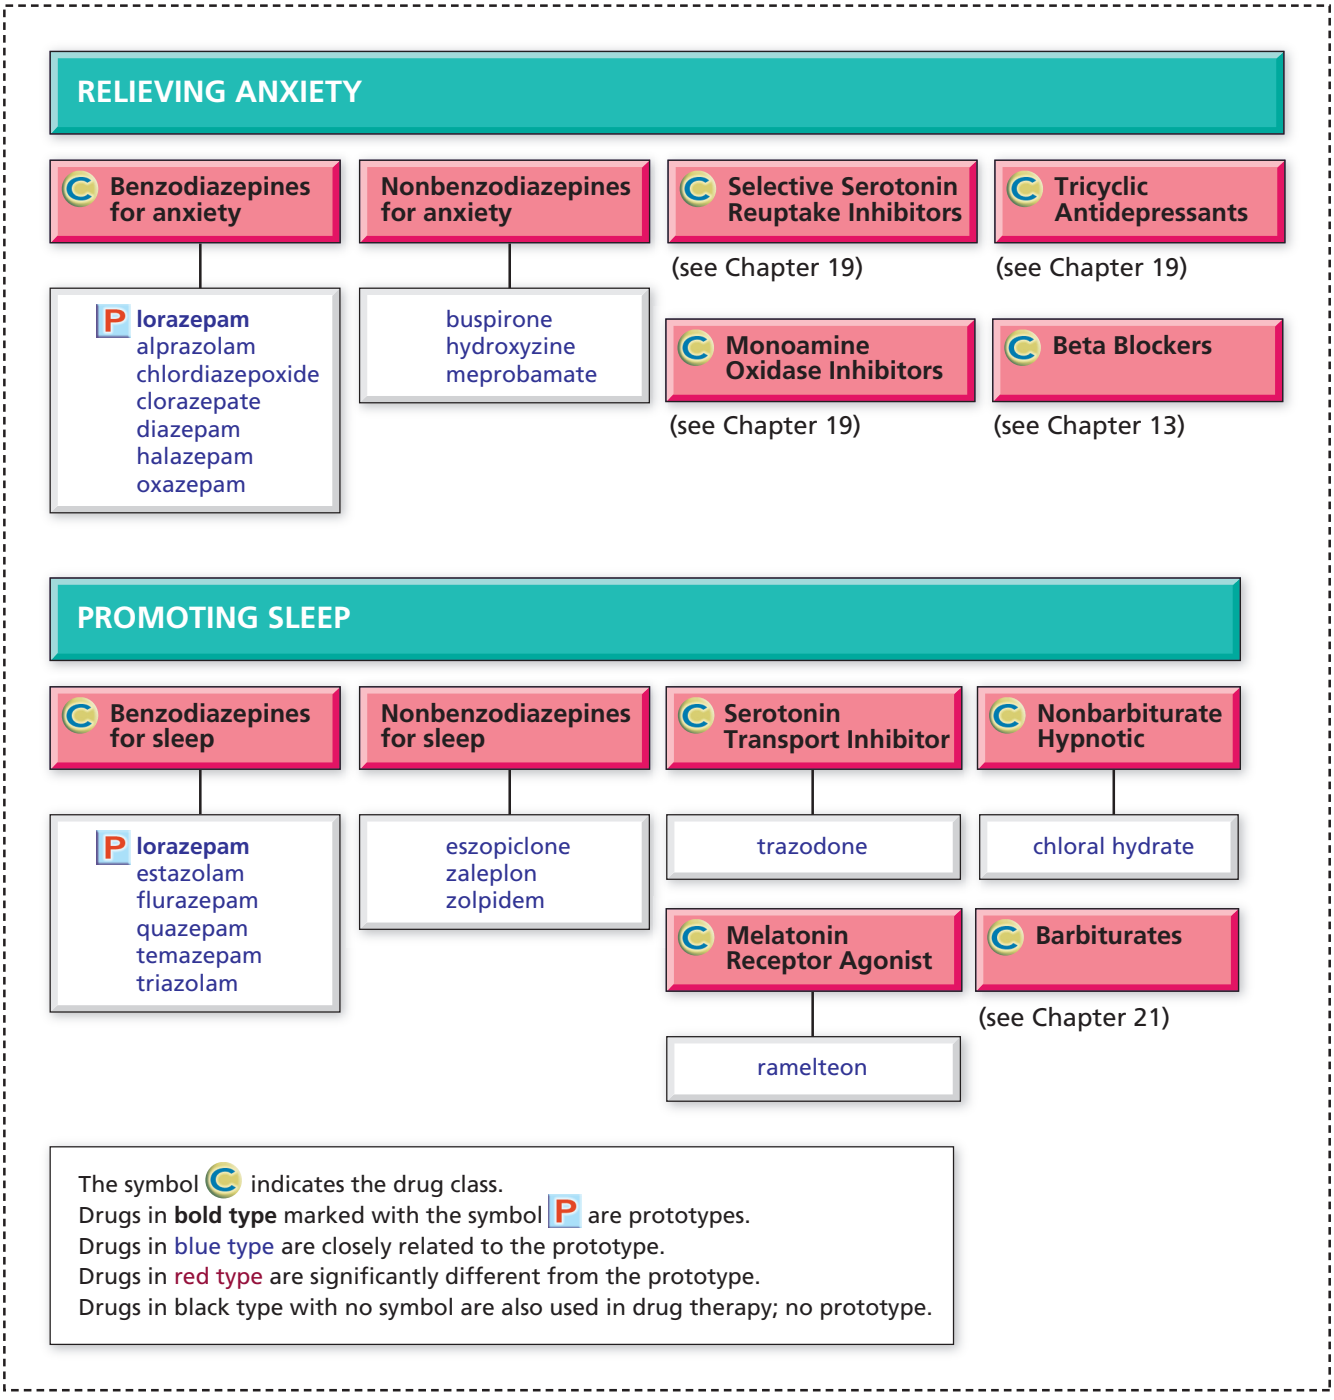
Drugs Relieving Anxiety and Promoting Sleep



Drugs that depress the central nervous system (CNS) cause a continuum of effects ranging from producing relaxation and relieving anxiety to producing anesthesia and loss of consciousness. Some drugs that depress the CNS, such as the benzodiazepines, can produce multiple effects depending on the dose and the route of administration. Two of those effects, relieving anxiety and promoting sleep, are discussed in this chapter. The prototype benzodiazepine for this chapter is lorazepam (Ativan). Lorazepam is primarily used to treat anxiety, although it may also be used to promote sleep and rest. This chapter also discusses drugs outside the benzodiazepine class that are used to relieve anxiety or induce sleep. Benzodiazepines used as muscle relaxants are mentioned in Chapter 20, and those used in seizure disorders are presented in Chapter 18.

PHYSIOLOGY

Emotions and Neurotransmitters

The brain governs all physiological and psychological functions of the body including cognition, thoughts, memory, motivation, and emotion. Human emotions, although universal, are not well understood. The limbic system in the brain is known to be primarily responsible for emotions, but why a particular situation might create a severe psychological response in one person but not in another is dependent on environmental and internals factors that are unique to the individual. Much of the neurophysiologic research that has been done on the emotions of fear and anxiety has centered on the amygdala, an almond-shaped structure, and on the hippocampus, both located within the brain. The amygdala receives incoming sensory signals and then communicates with the frontal lobes of the brain where information is interpreted. It is believed that the central part of the amygdala is the storage site for emotional memories. The amygdala can signal the brain that a threat is present and set off a fear response or anxiety. When a stimulus is interpreted as highly threatening, the amygdala floods the brain with danger messages, demanding immediate action and not allowing time for the rest of the brain to process the information with rational and systematic thought.

The systems of the brain do not operate in isolation and its structures undergo frequent refinement in response to the internal and external environment. This process is known as neuroplasticity. To illustrate the point of how functions of the brain adapt during its constant interaction with the environment, imagine what would happen if you were in the pathway of a falling tree. The cerebral cortex of your brain would interpret the sight, compare it to known past experiences, determine that the tree will hit you if you do not move out of the way, and send messages to various body systems to respond. In this case, the heart will beat faster to provide more blood supply to the muscles, and the muscles will contract to run. However, the amygdala determines that the tree is extremely dangerous to the body's well-being and demands that the body respond and *run now,* think later.

Another part of the brain, the hippocampus, is responsible for processing threatening or traumatic stimuli. The hippocampus helps encode information into memories. To continue with the above example, the next time you encounter a stimulus similar to the falling tree (such as the cracking noise the tree made before it began to fall), the hippocampus will remember this traumatic stimulus and send the message to the amygdala, which will then sense immediate danger and flood the brain with messages to flee for safety.

The brain sends its messages by a complex process in the nervous system that involves a release of neurotransmitters that assist in the movement of impulses along nerve pathways._. Neurotransmitters either inhibit or excite the receptor cell. One of those inhibitory neurotransmitters is gamma-aminobutyric acid, better known as **GABA.** The inhibitory action of GABA works in opposition to the excitatory neurotransmitter glutamate. GABA is released into the synapse, crosses the synapse, and then attaches to a postsynaptic receptor site. Once it is attached, an influx of negatively charged chloride ions enters the postsynaptic neuron. Hyperpolarization of the cell occurs, which in turn leads to an increase in the firing threshold. This produces an inhibitory effect on the nerve cell. A drug such as lorazepam acts by enhancing the actions of GABA (Mayers & Baldwin, 2006). Figure 15.1 depicts the action of GABA on the cell's receptors.

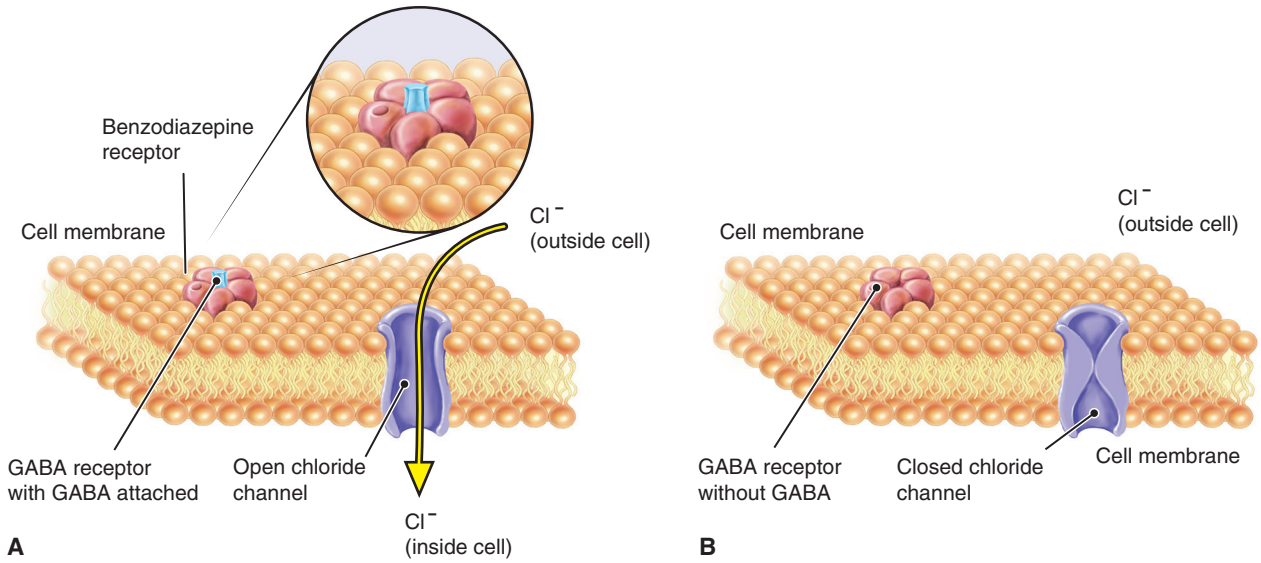
Sleep

Although sleep was once thought of as a time of inactivity, it is now known that the process of sleep involves active physiologic changes in which all major organs and regulatory systems continue to function. The activities that occur in the brain during sleep are essential for the maintenance of mental and physical health.. Circadian processes driven by the brain's biological clock cause sleep and wakefulness to occur at predictable times and are influenced by the physical environment such as light and darkness as well as social or work schedules. The sleep–wake cycle generally consists of eight hours of nocturnal sleep and sixteen hours of wakefulness in response to the release of the hormones melatonin and cortisol (National Sleep Foundation, 2006). While the eyes are closed during sleep, periodic rapid eye movements can be observed. Sleep, therefore, has two phases; the first has no rapid eye movements (**NREM**), and the second has rapid eye movements (**REM**)**.** NREM sleep is further sub-divided into four stages:

- Stage 1—light sleep; muscles relax; brain waves are irregular and rapid.
- Stage 2—brain waves are larger than in stage 1, with bursts of electrical activity.
- Stages 3 and 4—deep sleep, with even larger, slower brain waves called delta waves; this stage is often referred to as slow-wave sleep.

After stage 4 sleep, the body begins REM sleep. During REM sleep, brain waves are almost the same as they are during waking hours, and dreaming occurs. The body becomes essentially paralyzed during REM sleep, so that it cannot act out the dreams. After a period of REM sleep, the person cycles through the NREM stages before again returning to REM sleep. A complete sleep cycle consists of NREM and REM

PHYSIOLOGY



• FIGURE 15.1 Action of GABA on cell receptors. (**A**) When GABA attaches to the cell's receptors, it causes the chloride channel to open. The rush of chloride ions gives the inside of the cell a highly negative charge, which decreases the cell's ability to fire. GABA has an inhibitory action on the nervous system and has receptor sites on the cells. Benzodiazepines can occupy these receptor sites. When the receptor is occupied, it keeps the chloride channel open longer, thereby potentiating GABA's inhibitory effect. (**B**) When GABA is not attached to a receptor, the chloride channel closes. As the interior of the cell becomes more positive, it can fire.

cycles that alternate every 90 to 110 minutes and is repeated four to six times per night (National Sleep Foundation, 2006). Arousal from sleep is fairly easy when in REM but can be difficult from NREM. A person awakened from NREM sleep may be confused and disoriented until completely awake, a process that can take up to 5 minutes. Approximately 75% of sleep time is non-REM sleep, and 25% is REM sleep. REM periods generally become longer and more frequent during the later part of the sleep cycle.

A number of physiologic changes occur within the different stages of sleep. The low point of the 24-hour cycle for temperature occurs at night during sleep, although sleep does not cause the decrease. Urine secretion falls during sleep. The heart rate and respirations are slower and more regular during NREM sleep and then more rapid and less regular during REM sleep. Blood flow to the brain is increased during REM sleep. Autonomic nervous functions tend to be active during REM, with irregular breathing, variable pulse rate and blood pressure levels, and an increased metabolic rate. Hormones affecting growth, energy level, and metabolic function are secreted during sleep. Secretion of growth hormone increases during the first 2 hours, and surges of adrenocorticotropic hormone and cortisone secretion occur in the second half of the sleep period. Penile erections can occur during sleep and are more frequent during REM sleep. Luteinizing hormone secretion is increased for both boys and girls during puberty, and prolactin is secreted at an increased rate in both men and women, especially immediately after the onset of sleep.

The amount of sleep needed by a person varies throughout the life span, with infants requiring the most sleep and adults requiring the least. The time in each phase of the sleep cycle also varies throughout the life span. Although sleep requirements among people vary greatly, just as important as the quantity of sleep is getting the right mix of REM and NREM sleep (National Sleep Foundation, 2006).

PATHOPHYSIOLOGY

Anxiety

Anxiety is a universal experience among humans characterized by a feeling of unease that something bad or undesirable may happen. Anxiety functions as a protective mechanism that has evolved to help people recognize danger and take action for self-preservation. It has both physiological and emotional characteristics triggered by events that could be threatening, disruptive, or dangerous. Anxiety is considered to be pathologic however, if it develops when no actual threat exists, when it occurs chronically, and it interferes with the ability to function in daily life.

Anxiety disorders are differentiated by their own distinctive features, but they all share characteristics of excessive and irrational fear and dread. Anxiety is a serious illness that affects approximately 40 million American adults each year (National Institute of Mental Health, 2007), making it one of the most common mental conditions that often goes untreated.

Development of anxiety disorders is related to the combination of stressful life experiences, psychological characteristics, and/or genetic inherited traits (U.S. Public Health Service, 2009).

Anxiety disorders can occur with other physical and emotional problems and the symptoms of either can be difficult to differentiate. Depressive disorders, substance abuse disorders, and eating disorders are only of a few of the mental illnesses in which symptoms can be masked or exacerbated by anxiety disorders. People with anxiety disorders are two to three times more likely to have an alcohol or other substance abuse disorder at some point in their lives than the general population. Treatment may include psychosocial modalities such as cognitive behavioral therapies, exposure therapy, relaxation therapy, or psychotherapy, as well as drug therapy (Anxiety Disorders Association of America, 2009).

The following are some types of anxiety disorders:

- Panic disorder—sudden feelings of terror that come on suddenly and repeatedly without warning. Panic attacks are usually accompanied by physical changes such as heart pounding, sweating, weakness, faintness, or dizziness. A fear of impending doom, fear of losing control, and a loss of touch with reality are common in panic attacks. Because patients cannot understand or explain the physical changes that are occurring, they can have great concern about these symptoms, believing they are dying or losing their minds. Occurring at any time, even during sleep, the symptoms of a panic attack usually peak in 10 minutes but may continue for a while longer.

  Panic attacks often begin in adolescence or early adulthood, and panic disorder affects about 6 million American adults yearly. It is twice as common in women as in men. There appears to be a genetic predisposition to developing the condition, and comorbid disorders often include depression, drug abuse, or alcoholism, which need to be treated separately. People with panic disorder may develop phobias and avoid places or situations where a previous attack has occurred; some people may be so affected that they do not leave the house.

Phobic disorders are persistent, unrealistic fears of situations or objects that do not realistically pose a significant threat or danger. Phobias may be severe and incapacitating. Some specific phobias are further discussed in this chapter.

- Social phobia (also called social anxiety disorder)—overwhelming anxiety and excessive self-consciousness in everyday social situations. It is characterized by persistent, intense, and chronic fears of being watched and judged by others and by being embarrassed by one's own actions. Physical symptoms that often accompany social phobia include blushing, profuse sweating, trembling, nausea, and difficulty talking. Social phobia affects about 15 million adult American women and men. Onset usually occurs during childhood or early adolescence. Like other anxiety disorders, there is some evidence that genetic makeup may make a person more at risk of having social phobia. Comorbid conditions often include other anxiety disorders or depression. People with social phobia may resort to substance abuse in an effort to self-medicate their anxiety yet can respond successfully to psychotherapy and or medication.
- Specific phobia—an intense, irrational fear of a particular thing or situation that poses little or no actual danger. Common examples are fear of heights, elevators or enclosed spaces, or flying. The anxiety is not generalized to other situations. For example, a person who becomes extremely anxious if they are in a tall building may be able to climb a mountain without any anxiety.

  Specific phobias affect an estimated 19.2 million adult Americans and are twice as common in women as men. Onset of specific phobias is usually in childhood or adolescence, and the phobias persist into adulthood. The causes of specific phobias are not well understood, but there is some evidence that the tendency to develop them may run in families. If help is sought, specific phobias respond very well to carefully targeted psychotherapy.
- Obsessive-compulsive disorder (OCD)—recurrent, unwelcome thoughts with rituals attempting to control the anxiety resulting from these thoughts. For example, a patient may be filled with doubts and repeatedly check situations of concern (e.g., whether doors are locked). The recurring thoughts are obsessions; the behaviors that deal with those thoughts are compulsions. The compulsive behavior ends up taking over the person's life, providing little help in dealing with the anxiety from the obsessive thinking, and is distressing to the patient.

  OCD affects about 2.2 million American adults; men and women are equally affected. The disorder usually first appears in childhood, adolescence, or early adulthood. Comorbid conditions include eating disorders, other anxiety disorders, or depression. Research suggests that OCD may be inherited.

  OCD usually responds to pharmacologic treatment and/or psychotherapy that involve controlled exposure to the situation that produces fear or anxiety.
- Post-traumatic stress disorder (PTSD)—a debilitating condition that can develop following a terrifying event that involved physical harm or threat of physical harm to either oneself or to another. Events that can trigger PTSD include war experience, kidnapping, robbery, man-made disasters (e.g., bombings, fires), or natural disasters (e.g., hurricanes). A person experiences persistent frightening thoughts and memories of the ordeal, termed flashbacks. People with PTSD may feel emotionally numb and have difficulty relating to people they were once close to. They may startle easily, lose interest in things they used to enjoy, have trouble feeling affectionate, be irritable, become more aggressive, or even become violent. They avoid situations that remind them of the original incident, and anniversaries of the incident are often very difficult. PTSD symptoms seem to be worse if the event that triggered them was deliberately initiated by another person, such as in a mugging or a kidnapping.

PTSD affects about 7.7 million American adults, but it can occur at any age, including childhood. Women are more likely to develop PTSD than men, and there is some evidence that susceptibility to the disorder may run in families. Comorbidities that often accompany PTSD are depression, substance abuse, and one or more of the other anxiety disorders.

Psychotherapy and medication are usually effective in treating PTSD.

- Generalized anxiety disorder (GAD)—chronic anxiety that lasts more than 6 months and causes the person to have exaggerated worry and tension every day. In this disorder, the person always anticipates disaster and worries excessively over issues such as health, money, work, and family. Symptoms include inability to relax, startling easily, difficulty concentrating, and trouble falling asleep or staying asleep. Severe GAD can make it difficult to partake in ordinary daily activities.

  GAD affects about 6.8 million adult Americans. Women have a higher prevalence of GAD than men, and although it can begin anytime during life, it most frequently begins between childhood and middle age. Again, there is evidence that genes play a modest role in GAD. Comorbid conditions normally include other anxiety disorders, depression, and substance abuse.

  GAD is commonly treated with medication or cognitive-behavioral therapy, but comorbidities must also be treated appropriately.

The development of anxiety disorders may occur from a complex set of risk factors including genetics, brain chemistry, and life events. Neuroemotional memories stored in the amygdala are believed to play a role in disorders involving very distinct fears, such as phobias. Other parts of the brain may be involved with other types of anxiety. The hippocampus, for example, shrinks in people who have experienced severe stress because of child abuse or military combat, which may explain why people with PTSD have flashbacks, deficits in explicit memory, and fragmented memory of details of the traumatic event. Other research indicates that the basal ganglia and striatum in the brain are involved in obsessive-compulsive disorder (National Institute of Mental Health, 2006).

Neurotransmitters are known to play a role in anxiety, although exactly how they do so is not known. GABA has long been known to have a role in diminishing anxiety, and antianxiety drugs (**anxiolytics**) enhance the action of GABA. Serotonin and norepinephrine have also recently been discovered to function in anxiety, and other neurotransmitter systems, such as corticotropin-releasing factors and substance P, appear to be abnormally regulated in patients who have anxiety. More research is needed to determine whether drugs that are antagonists to these systems might be helpful in treating anxiety. Also, because GABA works to counteract glutamate, decreasing glutamate or diminishing its activity might decrease anxiety.

Sleep Disorders

It is estimated that between 50 and 70 million Americans are affected by chronic sleep disorders and intermittent sleep problems. Sleep deprivation has a profound impact on mental and physical health. Relationships have been shown between sleep disturbances and cardiovascular disease, obesity, diabetes, and a decreased immune response (National Sleep Foundation, 2006). Disordered sleep is not only a common symptom of many psychiatric illnesses, it can increase one's perception of stress, ability to manage stressors, and can dramatically influence one's quality of life (Leblanc, 2007). Sleep disorders are many and may include the following problems:

- Narcolepsy—sudden irresistible sleep attacks of unknown origin lasting from seconds to minutes, two to six times a day
- Sleep apnea—a group of disorders characterized by cessation of breathing during sleep, lasting 10 seconds or longer and occurring 30 or more times during a night's sleep
- Sleepwalking—getting up and walking about while still asleep, although the eyes are open; usually occurs in children
- Night terrors—occur only in children, with periods of fright, crying, moaning, or screaming after a brief time asleep; episodes usually do not last long and are not generally remembered in the morning
- Excessive daytime sedation
- Insomnia—problems with initiating and/or maintaining sleep

Across the lifespan, sleeplessness or lack of restful sleep has an effect on a person's ability to physically, cognitively, and emotionally function in the daytime. Sleep loss results in an accumulation of sleep debt that must eventually be repaid by either napping or sleeping longer in later cycles (National Sleep Foundation, 2006). In a large survey of adult Americans which focused on the sleep habits of working adults, 65% reported having at least one symptom of a sleep problem a few nights a week or more within the past month (National Sleep Foundation, 2008). The most common problems reported were frequent waking during the night and waking up feeling unrefreshed, followed by difficulty falling asleep and waking up early and being unable to return to sleep Within this survey, 44% reported one or more of these problems occurring almost every night, 26% reported high levels of daytime sleepiness, and 39% had driven while drowsy within the past year (National Sleep Foundation, 2008). Sleep problems also affect adolescents and children. Nearly half (45%) of adolescents surveyed reported a sleep problem at least one night a week (National Sleep Foundation, 2006). Parents surveyed about their infant to school-aged children reported that 69% had sleeping problems, including difficulty falling asleep and frequent awakening during the night (National Sleep Foundation, 2004). Sleeping difficulties are a common occurrence in the elderly. Aging is associated with a more fragmented sleep; waking more frequently during the night, going to sleep earlier in the evening, and awakening earlier in the morning (Wolkove, 2007).

Of these disorders, **insomnia** occurs most frequently. Insomnia is the perception or complaint of inadequate or poor-quality sleep. It has many presentations, which include:

- Difficulty falling asleep or staying asleep
- Waking up too early in the morning without being able to return to sleep
- Waking up frequently during the night with difficulty returning to sleep
- Not sleeping long enough
- Feeling that sleep was not restful
- Sleeping poorly

Because people vary greatly in their need for sleep and their satisfaction with sleep, insomnia cannot be defined merely by the number of hours a person sleeps or by how long it takes to fall asleep. Insomnia is instead classified by frequency of occurrence: acute (often due to a temporary situation such as jet lag or stress and lasting up to one month), or chronic (occurring for a month or longer).

Insomnia has many causes. Acute insomnia is often related to stress, environmental noise, extreme temperatures, change in the surrounding environment, sleep–wake schedule problems such as jet lag, or adverse effects of drug therapy. Chronic insomnia is more complex and often results from more than one cause, including underlying physical or mental disorders, as well as adverse effects of drug therapy. Not only is chronic insomnia a common cause of depression and a symptom of many mental illnesses, it is now thought that sleep problems increase the risk of developing depression (Mayers, Baldwin, 2006). Other underlying causes of insomnia include arthritis, kidney disease, heart failure, asthma, sleep apnea, narcolepsy, restless legs syndrome, Parkinson disease, hyperthyroidism, and hormonal changes during menopause. Insomnia tends to occur more often in women than men, especially after the women reach menopause.

In addition, chronic insomnia may be "primary," which means that it is not caused by other medical, psychiatric, sleep, or medication factors. Factors such as increased body temperature, metabolic rate, or brain metabolism may cause primary insomnia. Poor sleep habits may also contribute to primary and other forms of insomnia.

Chronic insomnia may also be related to the core patient variable of life span, diet, and habits. The following behaviors are associated with chronic insomnia: overuse of caffeine, misuse of alcohol or other substances, disrupted sleep–wake cycles such as from shift work, and chronic stress. Some people also have insomnia related to smoking cigarettes just before bedtime, excessive napping in the afternoon or evening, and expecting or worrying about sleep difficulties.

Although lifestyle changes can prevent insomnia in most people with acute insomnia, some patients need short-term drug therapy to help them sleep. Chronic insomnia can be treated by diagnosing and treating any underlying medical or psychological problems. Stopping behaviors that contribute to insomnia is also helpful. Patients may also need to apply behavioral techniques such as relaxation therapy, sleep restriction therapy, and reconditioning to overcome chronic insomnia. Relaxation techniques such as progressive relaxation and rhythmic breathing allow the muscles to relax and the mind to stop "racing," thereby allowing natural sleep to occur. Sleep restriction may be used when people spend too much time in bed trying to fall asleep. These patients are allowed only a few hours in bed at night for a while, and then the time in bed is gradually increased until a more normal night's sleep occurs. Reconditioning helps people reconnect being in bed and bedtime with sleeping. They need to avoid using their beds for any activity besides sleeping or sex. If they are unable to sleep, they are instructed to get out of bed and return to bed only once they are sleepy, so that eventually the body will associate the bed with sleeping. They are also coached to avoid naps and to continue going to bed and getting up in the morning at the same time every day. The use of drug therapy to treat chronic insomnia is very controversial. Generally, it is considered best to use drug therapy for the shortest duration possible.

DRUGS TO RELIEVE ANXIETY

Various drug therapies can be used in treating anxiety disorders. Treatment with drug therapy does not cure the anxiety but keeps it under control. The person with anxiety usually receives psychotherapy in addition to drug therapy. Many drugs that were originally designed to treat other conditions have been found to be helpful in treating some of the anxiety disorders, because they have an effect on the neurotransmitters involved in anxiety.

• Selective Serotonin Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) are a class of antidepressant drugs, some of which are now considered first-line therapy for anxiety disorders such as panic disorder, OCD, PTSD, GAD, and social phobia. Low serotonin levels are known to be present in severe stress and in many mood and anxiety-related disorders, and SSRIs indirectly increase the amount of the neurotransmitter serotonin available in the synapses. SSRIs that are prescribed for anxiety include citalopram (Celexa), fluvoxamine (Luvox), paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft). (Venlafaxine, a drug closely related to the SSRIs, is also used in treating GAD.) The prototype SSRI is sertraline (Zoloft), and it is discussed in Chapter 16.

SSRIs are generally well tolerated with few adverse effects. Unlike the benzodiazepines, they do not cause diminished alertness or ataxia. Although SSRIs can produce some nausea or jitteriness when first started, these adverse effects usually go away with continued use. However, SSRIs can also cause sexual dysfunction. Unlike the benzodiazepines, which can reduce anxiety from one dose, the SSRIs must be taken for several weeks for their full anxiety-relieving effect to be evident.

• Tricyclic Antidepressants

The tricyclic antidepressants (TCAs), another class of antidepressants, are not used as frequently as the SSRIs. Except for OCD, TCAs are as effective as the SSRIs in treating most anxiety disorders, most likely because they act similarly. TCAs work by affecting the regulation of serotonin or norepinephrine in the brain. The TCAs used to treat anxiety, panic disorder, and PTSD are doxepin (Adapin), nortriptyline (Aventyl), amitriptyline (Elavil), imipramine (Tofranil), maprotiline (Ludiomil), desipramine (Norpramin), trimipramine (Surmontil), and protriptyline (Vivactil). Clomipramine (Anafranil) is used to treat OCD. The tricyclics are discussed in Chapter 16. The prototype TCA is nortriptyline (Pamelor).

TCAs have a higher adverse effect profile than SSRIs, which limits their use as antidepressants. Adverse effects include dizziness, drowsiness, dry mouth, and weight gain. Overdosage with a TCA is much more likely to result in death than overdosage with an SSRI. As with the SSRIs, several weeks of therapy on TCAs are necessary before anxiety begins to diminish.

• Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors (MAOIs) are the oldest class of antidepressants. The MAOIs used to treat anxiety disorders are phenelzine (Nardil), tranylcypromine (Parnate), and isocarboxazid (Marplan). These drugs are occasionally prescribed for panic disorder and social phobia. Monoamine oxidase is the enzyme that degrades serotonin in the synapse. By inhibiting the enzyme, higher levels of serotonin can remain in the synapse and be active. The prototype MAOI is phenelzine (Nardil). Further information about MAOIs also appears in Chapter 16.

The MAOIs are associated with a significant risk of a serious drug–food interaction. If the patient taking an MAOI consumes food or drink that is high in tyramines, such as aged, cured meats, blue cheese, and Chianti wine, a hypertensive crisis (a potentially life-threatening condition) can develop. The newest MAOI is a transdermal patch (selegiline [Emsam]); the lowest available dose does not have the same risk of food–drug interactions, although higher doses may still have some risk.

• Beta Blockers

Beta blockers are adrenergic drugs most frequently used for a wide variety of cardiac conditions, such as angina, hypertension, and arrhythmias. Among other actions, they slow the heart rate. This helps patients with some types of anxiety who may be uncomfortable and highly aware of the tachycardia and palpitations that can occur in anxiety. Beta blockers are sometimes prescribed to control this symptom in social phobia. The prototype beta blocker propranolol is discussed in Chapter 13.

• C Benzodiazepines

Benzodiazepines are used for a number of therapeutic effects, including anxiety relief, sleep promotion, antiepileptic effects, muscle relaxation, treatment of acute alcohol withdrawal, induction of general anesthesia, preoperative sedation, and conscious sedation. Some of these drugs have other specific uses, many of them off label. As a class, benzodiazepines appear to potentiate the effects of GABA. Because GABA is an inhibitory neurotransmitter, this benzodiazepine-mediated intensification of the effects of GABA leads to more CNS depression than would normally be found.

Benzodiazepines bind to specific receptor sites to produce their effects. At least two types of these receptors are believed to exist: BZ_1 and BZ_2. Sleep mechanisms are thought to be related to BZ_1, and memory, motor, sensory, and cognitive functions related to BZ_2. Activity of the benzodiazepines may involve the following sites: spinal cord (muscle relaxation), brainstem (antiepileptic activity), cerebellum (ataxia effects), and the limbic and cortical areas (emotional behavior). The antianxiety effects of benzodiazepines are separate from those that nonspecifically depress the CNS (leading to sedation and motor impairment). Much larger doses of benzodiazepines are required to produce the effects of ataxia and sedation than to produce antianxiety effects.

As a drug class, benzodiazepines have a high margin of safety (i.e., a wide therapeutic index) and are therefore often the drug class of first choice to treat some types of anxiety, most commonly GAD. All of the benzodiazepines have similar efficacy; they differ by pharmacokinetics and cost. Lorazepam is the prototype benzodiazepine used to treat anxiety. Other drugs in this class represented by the prototype are alprazolam (Xanax), chlordiazepoxide (Librium), clorazepate (Tranxene), diazepam (Valium), halazepam (Paxipam), and oxazepam (Serax).

Nursing Management of the Patient Receiving P Lorazepam

Core Drug Knowledge

Pharmacotherapeutics

Lorazepam (Ativan) is used in treating anxiety disorders, most frequently in GAD, for short-term relief of anxiety that occurs with depression and for insomnia. Day-to-day stress and anxiety should not be treated with antianxiety drugs. Lorazepam, when given intramuscularly or intravenously preoperatively and before anesthesia, produces sedation, relieves anxiety, and decreases the patient's ability to recall events surrounding surgery. Off-label uses of lorazepam include treating status epilepticus, chemotherapy-induced nausea and vomiting, the symptoms of acute alcohol withdrawal, and psychogenic catatonia. Although there is no consensus for a benzodiazepine of choice for treatment of alcohol withdrawal, lorazepam can effectively be used to reduce the risk of seizures and decrease alcohol withdrawal symptoms (Vincent, et al., 2007). The use

CRITICAL THINKING SCENARIO

LORAZEPAM AND ANXIETY

Lena Hawthorne, 18 years old, was started on lorazepam for anxiety 3 days ago. She calls the clinic and tells you that the dosage must not be large enough because her symptoms of anxiety have increased. She complains of feeling so anxious that she feels she "might jump out of her skin." She also complains of having insomnia since she started taking lorazepam.

2. What interventions would you carry out or suggest at this time?

of benzodiazepines to treat seizures is further discussed in Chapter 18.

Pharmacokinetics

Lorazepam, like other benzodiazepines, is readily absorbed from the gastrointestinal (GI) tract. Unlike some of the other benzodiazepines, lorazepam is readily absorbed when it is given intramuscularly. Because of its high lipid solubility, lorazepam is widely distributed in the body tissues, and it is also highly protein-bound (85%). Compared to other benzodiazepines, lorazepam has an intermediate speed of onset when taken orally. Lorazepam is hepatically metabolized to an inactive substance, making it—along with oxazepam (Serax)—unusual among the drugs in the class, which are otherwise metabolized to active compounds. This easy inactivation is an advantage for patients with liver disease and for older adults. Lorazepam is eliminated through the urine.

Intravenous lorazepam is distributed quickly to the brain, which makes it effective in treating status epilepticus (discussed further in Chapter 18). Unlike diazepam, another benzodiazepine given for status epilepticus, lorazepam redistributes out of the brain slowly, providing prolonged protection against further seizures. Although the half-life of lorazepam in the blood is rather short, its effectiveness in controlling seizures is related to how long it is at the site of action—the brain, not the bloodstream. Lorazepam has been proven to be more effective than diazepam in controlling status epilepticus (Prasad, al-Roomi, Krishnan, et al., 2005). Table 15.1 provides a summary of selected benzodiazepines and a comparison of their pharmacokinetic properties.

Pharmacodynamics

Like all benzodiazepines, lorazepam increases the effects of GABA, which has an inhibitory effect on the CNS. However, none of the benzodiazepines act like GABA or increase the amount of GABA present. The intrinsic amount of GABA is limited; hence, the effects from benzodiazepines are also limited. Tolerance to lorazepam and the other benzodiazepines can occur if they are used long-term, requiring larger doses to achieve a therapeutic effect. Thus, it is recommended that they be limited to short-term use.

Contraindications and Precautions

Contraindications to administration of lorazepam, which apply to all the benzodiazepines, are hypersensitivity, psychoses, acute narrow-angle glaucoma, intra-arterial use, and use in children younger than 6 months. Prolonged administration of lorazepam or any other benzodiazepine produces physical dependence, and withdrawal symptoms occur if the drug is stopped suddenly. Like most other benzodiazepines, lorazepam is a pregnancy category D drug. Benzodiazepines, have been found in maternal and cord blood, indicating transfer to the fetus; therefore, they should not be used for obstetric uses during labor and delivery.

Paradoxical reactions have been reported with lorazepam and other benzodiazepines, evidenced by excitement, stimulation, and acute rage. These effects have been noted mostly in patients with psychiatric disorders and in hyperactive, aggressive children. But older adults are also at risk of paradoxical effects. Other symptoms that may occur are acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, and sleep disturbances. These effects usually occur within the first 2 weeks of therapy.

Adverse Effects

Lorazepam, like other benzodiazepines, is generally well tolerated, with few adverse effects. Mild drowsiness is common but transient, occurring in the first few days of therapy and then dissipating. Ataxia and confusion may also occur, especially in older adults and in debilitated patients. Dose adjustments should be made if these effects persist. Respiratory disturbances and partial airway obstruction may occur if excessive lorazepam is given intravenously before a procedure. A number of other adverse effects are possible, although they are rare. Many relate to the CNS depression that occurs with the drug therapy. These adverse effects are as follows:

- *Cardiovascular:* bradycardia, tachycardia, cardiovascular collapse, hypertension, hypotension, decreased systolic blood pressure, palpitations, edema, and phlebitis and thrombosis at intravenous (IV) sites
- *CNS:* problems with arousal and energy (sedation, sleepiness, depression, lethargy, apathy, fatigue, hypoactivity, restlessness, stupor, coma); balance and movement (light-headedness, syncope, rigidity, tremor, dystonia, vertigo, dizziness, unsteadiness, ataxia, impaired coordination, weakness, akathisia, hemiparesis, hypotonia, psychomotor retardation, seizures); mood and emotions (crying, sobbing, euphoria, nervousness, irritability, agitation); cognitive (memory impairment, disorientation, delirium, anterograde amnesia, confusion, difficulty in concentration, inability to perform complex mental functions); speech (slurred speech, aphonia, dysarthria); other (vivid dreams, "glassy eyed" appearance, headache, extrapyramidal symptoms, paradoxical reactions)
- *Dermatologic:* urticaria, pruritus, rash, dermatitis, hair loss, hirsutism, ankle and facial edema

P lorazepam (Ativan)	Anxiety, anesthetic premedication, status epilepticus, alcohol withdrawal, chronic insomnia	*Adult:* PO, 2–6 mg/d; IM, 0.05 mg/kg; IV, 2 mg *Child:* Not recommended; IV/IM, oral dose not established	*Onset:* PO, 1–3 h; IM, 15–30 min; IV, 1–5 min *Duration:* 12–24 h $t_{1/2}$: 10–20 h
alprazolam (Xanax)	Anxiety, panic disorder, agoraphobia	*Adult:* PO, 0.25–1.0 mg tid *Child:* Not established	*Onset:* 30 min *Duration:* 4–6 h $t_{1/2}$: 6.3–26.9 h
chlordiazepoxide (Librium)	Anxiety, alcohol withdrawal, anesthetic premedication	*Adult:* PO, 5–10 mg tid–qid (50–100 mg for alcohol withdrawal); IM/IV, 50–100 mg *Child* >6 y: PO, 5 mg bid–qid; IM/IV, 25–50 mg; not recommended under 6 y	*Onset:* PO, varies; IM, 10–15 min *Duration:* 48–72 h $t_{1/2}$: 5–30 h
diazepam (Valium);	Anxiety, status epilepticus, skeletal muscle relaxant	*Adult:* PO, IM, 2–10 mg/bid–qid; rectal, 0.2 mg/kg daily–bid; IV, 5–10 mg prn *Reduced dosage in geriatric or debilitated patients* *Child* >2 y: PO, 1–2.5 mg tid–qid; IM and IV, up to 0.25 mg/kg; Rectal, 0.5 mg/kg	*Onset:* PO, 30–60 min; IM, 15–30 min; rectal, rapid; IV, 1–5 min *Duration:* 3 h (1 h IV) $t_{1/2}$: 20–50 h
flurazepam (Dalmane);	Insomnia	*Adult:* 15–30 mg at bedtime *Child:* Not for use <15 y	*Onset:* 15–30 min *Duration:* 7–8 h $t_{1/2}$: 2–3 h; 47–100 h (active metabolite)
	Preoperative sedation, anxiolysis, amnesia Sedation Anesthesia	*Adult:* IM, IV: 1–5 mg *Child:* 0.025–0.15 mg/kg *Dose individualized/reduced in patients >60 y of age, debilitated, or chronically ill.*	*Onset:* IM, *Adult:* 15 min; *Child:* 5 min; IV, 1–3 min *Duration:* 6 h $t_{1/2}$: 1.8–6.4 h
C Benzodiazepine Antagonist			
flumazenil (Romazicon);	Benzodiazepine antagonist	*Adult:* IV, 0.2 mg q 60 s up to 1 mg (reversal of conscious sedation); 0.2 mg, then 0.3 mg q 30 sec up to 3 mg (management of benzodiazepine overdose).	*Onset:* 20–30 s *Duration:* 72 h $t_{1/2}$: 7–15 min; 41–79 min (repeated doses)

- *GI:* constipation, diarrhea, dry mouth, coated tongue, sore gums, nausea, anorexia, change in appetite, vomiting, difficulty swallowing, increased salivation, gastritis
- *GU:* incontinence, changes in libido, urinary retention, menstrual irregularities
- *Ophthalmic:* visual disturbances, diplopia, nystagmus
- *Psychiatric:* behavioral problems, hysteria, psychosis, suicidal tendencies
- *Hematologic:* elevated liver enzymes, leukopenia, blood dyscrasias, anemia, thrombocytopenia, eosinophilia
- *Miscellaneous:* decreased hearing, nasal congestion, auditory disturbances, hiccups, fever, diaphoresis, gynecomastia, changes in weight, dehydration, lymphedema, joint pain, and burning or pain at the intramuscular injection site

Drug Interactions

Several drug interactions are possible with lorazepam, the most important of which occur when lorazepam is coadministered with other drugs or substances that also depress the CNS. When lorazepam or other benzodiazepines are administered with alcohol, narcotics, barbiturates, or other CNS depressants, the effect on the CNS is additive. These combinations may depress respiratory drive, create severe hypotension or bradycardia, and substantially alter level of consciousness. Although lorazepam and other benzodiazepines are very safe when taken by themselves, even in large doses, the effects can be deadly when they are combined with other CNS depressants, especially in large quantities. Table 15.2 presents agents that interact with lorazepam.

TABLE 15.2 Agents That Interact with P Lorazepam

Interactants	Effect and Significance	Nursing Management
alcohol, CNS depressants (opioid narcotics, barbiturates)	Increased CNS effects of lorazepam	Evaluate patient for additive CNS-depressant effects. Monitor serum levels (if appropriate) for therapeutic levels. Avoid concomitant administration if possible.
antacids	Altered rate of absorption of lorazepam, but generally not the extent of absorption	Administer antacid 1 h before or 2 h after lorazepam.
digoxin	Increased serum concentration of digoxin and possible toxicity	Assess serum digoxin levels closely. Monitor the patient's cardiac status frequently for changes.
levodopa	Decreased control of parkinsonian symptoms	Administer lorazepam cautiously to patients receiving levodopa for Parkinson disease. Assess patient for increasing muscle rigidity, tremors, and drooling.
oral contraceptives	Increased clearance of lorazepam may affect symptom management	Change in lorazepam dosage may be needed.
phenytoin	Increased serum concentration of phenytoin leading to possible toxicity	Monitor serum phenytoin levels closely.
probenecid	Interference with hepatic conjugation leading to more rapid onset or prolonged effect of lorazepam	Assess patient for continued sedative effects. Assess for dosage change as indicated.
rifampin	Increased hepatic microsomal enzyme metabolism of lorazepam leading to decreased effectiveness of lorazepam	Assess for dosage change of lorazepam as indicated. Assess patient for changes in seizure control or decrease in sedative effect.
scopolamine	Increased sedation when administered with parenteral form of lorazepam	Institute safety measures. Assess patient for signs of increased drowsiness, dizziness, and ataxia.
theophylline	Possible antagonism of sedative effects of lorazepam	Assess for lorazepam dosage adjustment.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for any contraindications to using lorazepam before initiating therapy. Assess for renal and hepatic impairment, which may alter the circulating levels of the drug. In patients who have depression along with anxiety, assess for risk for suicide. Obtaining a baseline level of hepatic enzymes and a complete blood count provides a reference for comparison when these levels are checked throughout long-term therapy.

Life Span and Gender

Assess the patient's age. IV lorazepam is not recommended in children younger than 18 years of age because data regarding its effects are minimal. Similarly, the efficacy and safety of oral lorazepam have not been established for children younger than 12 years of age. When it is used in children, the initial dose should be small, and it should be increased in very small increments. Lorazepam is contraindicated in children younger than 6 months of age. Lorazepam and other benzodiazepines should be used with extreme caution in the elderly. Compared with younger adults, older adults taking lorazepam or other benzodiazepines are more likely to exhibit adverse effects than younger adults, therefore they are usually started at half the dose recommended for younger adults, titrated slowly, and used for only short periods (Wolkove, Elkholy, Baltzan, Palayew, 2007). According to the Beers Criteria for potentially inappropriate drugs in older adults, lorazepam and other benzodiazepines pose a high risk of severe adverse effects. Therefore, the dose of lorazepam should be limited to no more than 3 mg per day (Fick, Cooper, Wade, et al., 2003).

Specifically, lorazepam, like other benzodiazepines, may cause excessive ataxia or lethargy in older adults. In a systematic review medications as risk factors for fall, it was found that one of the main group of drugs associated with this risk were benzodiazepines (Hartikainen, Lonnroos, Louhivuori, 2007). Older adults taking benzodiazepines have been found to be at higher risk of developing impaired mobility or losing their ability to be independent in performing their activities of daily living than older adults who do not receive benzodiazepines (Gray, LaCroix, Hanlon,

et al., 2006). Risk factors must be carefully assessed when using benzodiazepines in older adults.

It is not clear from the literature whether benzodiazepines affect women differently than men. Some sources state that women metabolize all benzodiazepines differently, have a higher risk of developing physical dependency from benzodiazepines, and experience the desired and adverse effects of the drug differently. But other sources have not found any difference between men and women related to benzodiazepine use. Benzodiazepines, such as lorazepam, may be prescribed more for women than for men.

When lorazepam is prescribed to a woman, assess whether she is pregnant, because lorazepam is a pregnancy category D drug and should generally be avoided during pregnancy. It is not known whether lorazepam enters breast milk, although other benzodiazepines do. The post-partum period is a time of heightened risk for developing or relapse of mental illness (Menon, 2008), therefore more studies are indicated with use to determine the true of effect on the nursing infant.

Lifestyle, Diet, and Habits

Assess the patient for the use of alcohol, narcotics, and other CNS depressants, which have an additive effect with lorazepam. The patient who has a history of alcohol or substance abuse may be a poor candidate for lorazepam because of the likelihood of developing dependency on the drug. Studies have shown a higher rate of death from overdose when benzodiazepines are used with opiate abuse (Kenna et al., 2007). Determine whether the patient regularly drives, operates heavy machinery, or participates in other activities that require mental alertness. These activities may be dangerous during the initial period of drug use, because of drowsiness caused by the drug.

Environment

Oral lorazepam may be administered in any environment. IV infusions of lorazepam require that the patient be in a monitored environment. Equipment to maintain a patent airway should be at the bedside.

Culture and Inherited Traits

Studies have shown that some benzodiazepines have a longer half-life in Asians than in Caucasians due to differences in hepatic enzymes (Bray, et al., 2008). These results suggest that Asians should receive lower doses of the drug than whites, although no specific studies with lorazepam in Asians have been performed.

Nursing Diagnoses and Outcomes

- Risk for Injury related to drowsiness and other adverse effects
  Desired outcome: *The patient will not sustain an injury while on lorazepam.*
- Anxiety related to disease process
  Desired outcome: *The patient will achieve symptom control.*

MEMORY CHIP

Lorazepam

- Used to treat anxiety disorders
- Works by increasing the inhibitory effects of GABA
- Major contraindications: psychoses and acute narrow-angle glaucoma
- Most common adverse effects: mild drowsiness, ataxia, confusion
- Most serious adverse effects: paradoxical reactions
- **Life span alert: contraindicated in children under 6 months; pregnancy category D; older adults more likely to develop ataxia and confusion, so give smaller doses**
- Maximizing therapeutic effects: Daily dose should be split into two or three doses to give sustained daily therapeutic effect; counseling ("talk therapy") should be given while on drug therapy.
- Minimizing adverse effects: Assess for suicidal tendencies; discontinue long-term treatment by tapering dose slowly.
- Most important patient education: Avoid taking alcohol and other CNS depressants while on lorazepam to prevent additive CNS depression.

- Deficient Knowledge related to newly prescribed drug therapy
  Desired outcome: *The patient will learn the actions and adverse effects of lorazepam and how to safely self-administer the drug.*

Planning and Intervention

Maximizing Therapeutic Effects

Lorazepam has a fairly short duration of action; therefore, divide the daily dosage for treating anxiety into two or three doses and administer the drug throughout the day to achieve continued therapeutic effect. If one of the symptoms of anxiety experienced is difficulty sleeping, give the largest dose of the day at bedtime to promote sleep. If the drug is given solely as a sleep aid, give the entire dose at bedtime. Protect IV solutions of lorazepam from light and store them in the refrigerator to prevent loss of potency.

To help the patient learn coping skills and further decrease anxiety on a more permanent basis, talk therapy or counseling should accompany drug therapy with lorazepam.

Minimizing Adverse Effects

If GI distress occurs, administer lorazepam with food. Monitor for paradoxical reactions such as increased agitation or hallucinations and stop the drug if they occur. Hepatic function and blood cell counts should be assessed periodically during therapy to determine whether any adverse effects have occurred. To prevent undue adverse effects, older adults and children should be started on small doses of lorazepam, and the dose should then be increased slowly as necessary. Coadministration of lorazepam with other CNS depressants should be avoided if possible. If it is necessary to coadminister these agents, assess the patient carefully for signs of significant CNS depression.

BOX 15.1 FOCUS ON RESEARCH

Cost-Effectiveness of Benzodiazepine Tapering Methods

Oude Voshaar, R. C., Krabbe, P. F., Gorgels, W. J., et al. (2006). Tapering off benzodiazepines in long-term users: An economic evaluation. *Pharmacoeconomics*, 24(7):683–694.

The Study

The focus of this randomized, controlled study was to compare the relative costs and outcomes of tapering off long-term benzodiazepine use versus tapering off combined with cognitive behavioral therapy. Factors included in the cost analysis included the intervention treatment, prescribed drugs, health care services, productivity loss, and patient expenses. Patients (180) were divided between the two treatment groups and a control, in which benzodiazepine use continued. The findings showed a reduction in benzodiazepine costs in both treatment groups. Tapering off alone was slightly more cost-effective, but the difference was small. Addition of cognitive behavioral therapy to tapering did not appear to offer any clinical or economic advantages.

Nursing Implications

Long-term benzodiazepine use creates additional costs to the patient and to the health care system. Additionally, it places the patient at risk of adverse effects. Tapering off the dose of a benzodiazepine not only reduces the risk of withdrawal symptoms but also is a financial benefit to the patient. Commonly, cognitive behavior therapy accompanies this tapering. Although the study found that tapering off alone and tapering off with cognitive therapy were similarly effective clinically (stopping drug therapy led to no significant withdrawal complications), some patients may benefit from the support a group therapy session can offer. Therefore, nurses should assess patients' individual needs relative to using group therapy for benzodiazepine withdrawal.

Dilute injectable lorazepam with an equal volume of compatible solution, such as sterile water for injection, sodium chloride for injection, or 5% dextrose solution, and inject at a rate not to exceed 2 mg/min. Give IV lorazepam only in a monitored environment with equipment at the bedside to maintain a patent airway. Monitor patient closely during administration.

Carefully assess patients with depression and anxiety for suicidal tendencies. The number of pills dispensed to the patient should be the least amount feasible.

To prevent withdrawal symptoms when lorazepam is to be discontinued, the drug should be slowly tapered off if the patient has been on the drug for a long time or if a high dose of the drug was being taken. Withdrawal effects include insomnia, anxiety, loss of appetite, tremor, perspiration, tinnitus, and perceptual disturbances (Anwar, 2008). Craving for benzodiazepines will occur during the tapering-off period; however, the severity will decrease over time to negligible proportions (Mol, et al., 2006). See Focus on Research Box 15.1.

Providing Patient and Family Education

- To prevent additive CNS depression, teach patients to avoid taking alcohol and other CNS depressants while on lorazepam.
- Warn patients that drowsiness, sedation, and ataxia may occur when the drug is first started, but that these effects should disappear once they accommodate to the drug. Until the effects of the drug on a particular patient are known, the patient should avoid driving, operating machinery, or any other tasks that require mental alertness and concentration.
- If patients experience GI distress from lorazepam, instruct them to take the drug with food.
- Warn women of childbearing age to avoid becoming pregnant while on lorazepam because it is a pregnancy category D drug. Women should not breast-feed while on lorazepam because it is not known whether the drug distributes into breast milk, although other benzodiazepines do.
- Inform patients of the importance of returning for follow-up blood work if lorazepam therapy is to continue for an extended period.
- Teach patients and family what the paradoxical effects of lorazepam are and explain that if they occur, patients should stop taking the drug and immediately contact the prescriber.

Box 15.2 provides teaching guidelines for the patient who is prescribed benzodiazepines to be taken at home.

Ongoing Assessment and Evaluation

Lorazepam therapy is effective if the patient reports a reduction in feelings of anxiety and begins to develop other, more positive coping mechanisms for life problems. For lorazepam therapy to be effective, adverse effects either should not occur or should be tolerable and manageable so that the patient does not need to stop therapy. Throughout therapy, assess for therapeutic response and onset of adverse effects.

BOX 15.2 COMMUNITY BASED CONCERNS

Teaching for Patients Prescribed Home Benzodiazepine Therapy

Patients are often prescribed benzodiazepines, such as lorazepam, to be taken at home. In addition to the initial drowsiness that the drug can cause, CNS depression may also impair cognition and processing of information and may slow response time, all of which place these patients at considerable risk for having an accident while driving. This risk increases with the additive CNS depression that can occur if benzodiazepines are taken with alcohol and other CNS depressants, including prescription medications. Patients may forget about additive effects from alcohol use once they adapt to lorazepam therapy or if they do not experience drowsiness in the first place. Ensure that patients who are to start on lorazepam understand the following precautions:

- They should avoid driving until the effects of the drug on them are known.
- They should avoid drinking alcohol.
- If they ingest alcohol, they should have someone else (who has not been drinking) drive.
- If it is necessary to start another CNS depressant medication, they should again use extra caution driving until the combined effects of the drugs are known.

• Nonbenzodiazepines

Buspirone

Buspirone (BuSpar) is an azaspirodecanedione that is not chemically or pharmacologically related to the benzodiazepines or any other sedative or anxiolytic drug. It is used to treat symptoms of anxiety, although exactly how it works is unknown. In laboratory studies, it shows a high affinity for serotonin receptors, but it has no effect on GABA receptors. Buspirone also has moderate affinity for one type of brain dopamine receptor; it may act as a presynaptic dopamine agonist. It also increases norepinephrine metabolism in the locus ceruleus.

Optimum relief of anxiety usually occurs after 3 to 4 weeks of treatment, although some improvement is often seen within 7 to 10 days of starting therapy. Although buspirone is intended for short-term therapy, patients who have been treated with buspirone for up to 1 year have not required a dosage increase to maintain therapeutic effect, and withdrawal symptoms did not occur if the drug was stopped suddenly. This is an advantage over benzodiazepines, including the prototype, lorazepam. Buspirone produces much less sedation than lorazepam and does not produce substantial functional impairment. However, it can cause dizziness, nausea, headache, nervousness, light-headedness, or excitement as adverse effects. Because it is difficult to predict what effects any particular patient will experience, patients should be cautioned to avoid driving or operating machinery until the effects of the drug on them are known.

Hydroxyzine

Hydroxyzine (Vistaril) is a miscellaneous antianxiety drug that exerts CNS depressant activity in subcortical areas. It rapidly produces a feeling of calm and relieves anxiety without impairing mental alertness. Hydroxyzine also has bronchodilatory, antihistamine, analgesic, antispasmodic, and antiemetic effects. It can be administered intramuscularly or orally. It may be coadministered with a narcotic to control pain while minimizing the nausea that may be an adverse effect from the narcotic. Adverse effects of hydroxyzine include dry mouth, drowsiness (usually transient in continuous therapy), and involuntary motor activity (which usually occurs at higher-than-recommended doses).

Meprobamate

Meprobamate (Equanil) is also used for short-term management of anxiety symptoms. Meprobamate has selective effects at multiple sites within the CNS, including the thalamus and the limbic system. It may also inhibit multineuronal spinal reflexes. It has mild tranquilizing properties and some antiepileptic and muscle-relaxant properties.

Meprobamate can produce several CNS adverse effects, such as drowsiness, ataxia, dizziness, slurred speech, headache, vertigo, weakness, impaired visual accommodation, euphoria, overstimulation, paradoxical excitement, and fast electroencephalographic activity. Cardiovascular adverse effects include tachycardia, arrhythmias and palpitations, transient electrocardiographic changes, syncope, and hypotensive crisis. Nausea, vomiting, and diarrhea are possible, as are potentially severe allergic responses.

Meprobamate is a pregnancy category D drug that is associated with congenital malformations if taken in the first trimester. It is also excreted into breast milk at levels two to four times that found in the maternal plasma. It should therefore be avoided in pregnant women, women who might become pregnant, and breast-feeding women.

DRUGS TO PROMOTE SLEEP

Drugs to promote sleep come from several different classes. They include the benzodiazepines, nonbenzodiazepines that interact with the GABA-benzodiazepine receptor complex; melatonin receptor agonists; trazodone, an atypical antipsychotic; chloral hydrate, a nonbarbiturate hypnotic; and barbiturates. Although not discussed in this chapter, many over-the-counter sleep aids contain antihistamines such as diphenhydramine and doxylamine.

Benzodiazepines

In addition to their use in treating anxiety, benzodiazepines are used to treat insomnia or in situations in which a restful sleep is desired, such as the night before surgery. The benzodiazepine receptor subtype BZ_1 is thought to be associated with sleep mechanisms; BZ_1 receptors are specific GABA receptors located in the limbic, neocortical, and mesencephalic reticular systems in the brain. All of the benzodiazepines decrease the number of times the person awakens during the night. Stage 2 sleep is lengthened by all benzodiazepines. Most benzodiazepines shorten stages 3 and 4 (slow-wave sleep). Almost all benzodiazepines decrease the amount of time spent in REM sleep.

Five of the benzodiazepines have been approved for use as sleep aids (hypnotics). These are estazolam (ProSom), flurazepam (Dalmane), quazepam (Doral), temazepam (Restoril), and triazolam (Halcion). The major difference among these drugs is their half-life. Triazolam has the shortest half-life, at 1.5 to 5.5 hours, whereas quazepam has the longest half-life, at 41 hours. Table 15.3 presents the indications and half-lives for selected benzodiazepines. The drugs with shorter half-lives cause fewer problems with daytime sedation, although they may produce more early-morning insomnia.

The use of benzodiazepines as sleep aids should be short term. If benzodiazepines are used for as long as 3 or 4 weeks and then discontinued, REM rebound may occur (i.e., the REM sleep will occur more than usual in the sleep cycle). Abruptly discontinuing triazolam may produce rebound sleep disorder, in which the insomnia is worse than it was before treatment. The rebound effect is less likely to occur with estazolam, flurazepam, or quazepam, which have longer half-lives.

TABLE 15.3 Labeled Therapeutic Indications and Half-Lives of Benzodiazepines

Name	$t_{1/2}$ (h)	Anxiety	Insomnia	Seizures	Muscle Spasms	Alcohol Withdrawal	Anesthesia Induction
alprazolam	6.3–26.9						
chlordiazepoxide	5–30						
clonazepam	18–50						
Clorazepate	40–50						
diazepam	20–80						
estazolam	8–28						
flurazepam	2–3 (47–100 metabolites)						
Halazepam	14						
lorazepam	10–20						
midazolam	1.8–6.4						
oxazepam	5–20						
quazepam	41 (47–100 metabolites)						
temazepam	3.5–18.4 (9–15 metabolites)						
triazolam	1.5–5.5						

Anterograde amnesia (inability to remember events that occur after the drug is taken) is more likely to occur with high doses of triazolam, but it may also occur with lower doses of triazolam or with the other benzodiazepines. When patients with depression or other underlying psychiatric disorders take benzodiazepines for sleep, their conditions may worsen. Triazolam is especially likely to cause problems. Unusual or bizarre behavior has been noted in some patients who take benzodiazepines such as triazolam. These behaviors include loss of inhibition, aggressiveness, agitation, hallucinations, and depersonalization. Some European countries removed triazolam from the market in the early 1990s because of these adverse effects. Reducing the dose tends to limit the occurrence of these adverse effects.

Unlike lorazepam, benzodiazepines used to promote sleep are classified as pregnancy category X. These drugs are teratogenic when used during the first trimester, and if they are given to the mother during the last weeks of pregnancy, their distribution through the placenta results in neonatal CNS depression. Other adverse effects and characteristics of benzodiazepines are similar to those for lorazepam.

The use of benzodiazepines in older adults to treat insomnia, like their use in treating anxiety, places the older adult at increased risk for falls and other accidents. They have been associated with mobility problems and decreased ability to perform ADLs. Short-acting benzodiazepines do not appear to be any safer for older adults than longer-acting benzodiazepines (Gray, et al., 2006). Older patients taking benzodiazepines should be carefully monitored for daytime sedation and impaired motor coordination.

Nonbenzodiazepines

Eszopiclone

Eszopiclone (Lunesta) is a nonbenzodiazepine hypnotic. The drug induces sleep quickly, prevents waking during the night, and creates feelings of refreshment after a night's sleep; thus it is useful for a variety of insomnia problems. Eszopiclone is believed to achieve its therapeutic effect from interaction with GABA receptor–benzodiazepine receptor complexes. It is the only drug for insomnia that is approved for long-term use (up to 6 months of use). Unlike the benzodiazepines, eszopiclone does not seem to produce tolerance, even with long-term use. Withdrawal symptoms are possible after discontinuation, but they are mild. Caution should be used with individuals who have problems with drug addiction. Addicts report that ingesting zopiclone with alcohol heightens euphoria and in the United Kingdom, the street name for the drug is zim-zims (Cimolai, 2007).

Eszopiclone has a rapid onset (within 1 hour) and is metabolized in the liver and excreted in the urine. If taken with a high-fat or heavy meal the onset of action may be delayed. Because of its rapid onset, eszopiclone should be taken immediately before bedtime. Older adults are more sensitive to the effects of eszopiclone, as they are to other sedative/hypnotics; therefore, they should receive a lower dose than younger adults.

The most common adverse effects of eszopiclone after 6 weeks of use were headache, prolonged drowsiness, and an unpleasant taste. Eszopiclone is a pregnancy category C drug. It should not be used in labor and delivery, and whether it is known to cross into breast milk (Menon, 2008). Clinical trials have not been conducted in children under 18 years of age; effects in this age group have not been identified.

Zaleplon

Zaleplon (Sonata) is a sedative for short-term use (up to 28 days). Although a nonbenzodiazepine and not chemically related to the benzodiazepines, it does interact with the GABA-benzodiazepine complex. Zaleplon is prescribed to people who have trouble falling asleep. Because it has a fairly high first-pass effect, approximately 30% of an oral dose is metabolized prior to the drug's reaching the systemic circulation. Therefore, the half-life of zaleplon is short. Sedatives with short half-lives may be more likely to cause early morning waking, and zaleplon may do this, although there are not sufficient data to confirm this. However, if the patient has had problems with early morning waking or frequent waking prior to starting drug therapy, zaleplon will not decrease their occurrence; it should not be used if frequent waking is the presenting sleep problem. Additionally, zaleplon does not increase the total sleep time but only decreases the amount of time needed to fall asleep.

The most common adverse effects of zaleplon are drowsiness, dizziness, light-headedness, and difficulty with coordination. Zaleplon is a pregnancy category C drug.

As with other sleeping aids, zaleplon carries the warning that worsening of insomnia and emergence of new thinking or behavior abnormalities (starting as aggressiveness, agitation, hallucinations, and depersonalization) after starting treatment are possible and may be related to an unrecognized psychiatric or physical disorder. This adverse effect seems to be dose dependent, so the smallest effective dose possible should be used, especially in older adults and debilitated patients who may be more sensitive to these adverse effects. Additionally, next-day amnesia may occur. The risk of this adverse effect can be minimized if patients take the drug only when they know they will be able to sleep for at least 4 hours.

The effects of zaleplon may be reduced if it is taken with or immediately after a high-fat or heavy meal. Therefore the patient should be instructed to avoid taking this medication with meals. The circulating levels of the drug are increased with severe hepatic impairment. Affected patients should not receive zaleplon, and patients with minor hepatic impairment should receive a lower dose.

Like benzodiazepines, zaleplon may lead to dependency, and rebound insomnia is possible the first one or two nights after stopping the drug. Unlike the benzodiazepines, zaleplon is not known to cause withdrawal symptoms, although they are possible. Zaleplon has an abuse potential similar to benzodiazepines. Tolerance does not seem to develop when the drug is used for as long as 4 weeks, which is different from long-term use of benzodiazepines. Like other sleep-inducing drugs, zaleplon may have additive CNS depressant effects when coadministered with other CNS depressants. A smaller dose of zaleplon may be necessary when given with other CNS depressants. Alcohol should be avoided. Zaleplon contains FD&C Yellow No. 5 (tartrazine), which can cause allergic-type reactions (including bronchial asthma) in those susceptible; this sensitivity often occurs in those who also have aspirin hypersensitivity. Because a drug interaction occurs through the P-450 system, the dose of zaleplon should be reduced if the patient is receiving cimetidine (OTC Zantac). Cimetidine greatly increases the level of circulating zaleplon. It also is found to cross into breast milk (Menon, 2008).

Zolpidem

Zolpidem (Ambien) is used for short-term treatment of insomnia—generally not for more than 7 to 10 days. It induces sleep rapidly and should be taken immediately before going to bed and should not be given with meals. Although zolpidem is not chemically related to the benzodiazepines, it does interact selectively with the GABA-BZ receptor complex and shares some pharmacologic properties with the benzodiazepines. Zolpidem generally preserves all of the sleep stages and has only minor effects on REM sleep. Zolpidem is rapidly absorbed from the GI tract and has a short half-life. Hepatic dysfunction prolongs its half-life, but renal failure does not seem to increase the circulating level of zolpidem. The drug is available in both quick-onset and continuous-release oral forms. Two new forms of zolpidem have been recently made available, Edluar which is a sublingual form and Zolpimist which is an oral spray. Zolpidem does not seem to produce residual effects the next morning or cause a prolonged rebound effect when the drug is discontinued, although rebound insomnia is possible the first night after drug discontinuation. However, withdrawal symptoms can be seen if the drug is stopped abruptly, although this appears to be rare. Tolerance is possible.

The most common adverse effects from zolpidem are headache, prolonged drowsiness, and dizziness. Caution the patient that the drug may produce drowsiness and that he or she should take precautions until the effects of the drug are known. Zolpidem causes CNS depression, and as with all other CNS depressants, an additive effect is seen if zolpidem is combined with alcohol or other CNS-depressant drugs.

Zolpidem is a pregnancy category C drug. It is not recommended for use during labor and delivery or lactation. Clinical information is not available to determine the exact effect on children under 18 years of age. Older adults may be more susceptible to adverse effects, and their dose should be half of that given to younger adults (6.25 mg versus 12.5 mg). In addition, zolpidem, like other sedative/hypnotics, can produce visual or auditory hallucinations and behavior changes (including agitation or bizarre behavior) in certain patients. Patients who are known to have an underlying psychiatric illness as well as insomnia should take this drug cautiously, with the dosage kept as low as possible until the individual effects are known.

Melatonin Receptor Agonist

Melatonin is a hormone that is secreted by the pineal gland in a circadian cycle. Melatonin is released in response to

darkness and is believed to be involved in the maintenance of circadian rhythm underlying the normal sleep-wake cycle. During the daylight hours, secretion is low. Release of the hormone begins around 9 PM and peaks during the night hours (2 to 4 AM). Over-the-counter melatonin is not regulated by the Food and Drug Administration and may vary in its strength and purity. Over-the-counter melatonin is used to promote sleep and to re-establish normal sleep cycles when traveling (i.e., to prevent jet lag).

Ramelteon

Melatonin receptor agonists stimulate the same receptor sites as endogenous melatonin. The only prescription drug currently in this class is ramelteon. Ramelteon (Rozerem) is used in the treatment of insomnia when the patient has difficulty falling asleep. Unlike the benzodiazepines and other sleep aids, ramelteon has high affinity at two specific melatonin receptors, MT_1 and MT_2. Ramelteon's action at these receptors is therefore believed to be responsible for its ability to induce sleep. It does not have any significant affinity for GABA receptor complex or receptors that bind neuropeptides, cytokines, serotonin, dopamine, noradrenaline, acetylcholine, or opiates. Ramelteon has not been found to cause rebound insomnia or withdrawal symptoms, unlike benzodiazepines; neither does it seem to pose a risk for abuse or tolerance. Thus, unlike other hypnotics, ramelteon is not a controlled substance.

Ramelteon has a high first-pass effect and is absorbed rapidly, with a peak effect occurring usually in less than 1 hour. Because of its rapid onset, teach patients to take the drug no more than 30 minutes prior to going to bed. Ramelteon has a short half-life (2 to 5 hours). The isoenzyme CYP1A2 is most involved with its metabolism (the CYP2C and CYP3A4 subfamilies are also involved but only to a minor degree); drug molecules not metabolized are eliminated via the kidneys. Mild to moderate liver impairment increases the circulating level almost four-fold, and caution must be used if giving the drug to these patients.

Common adverse effects of ramelteon include headache, daytime sleepiness, dizziness, tiredness, nausea, worsening insomnia, and colds. Ramelteon may affect reproductive hormones by increasing prolactin, possibly decreasing testosterone levels. These changes may cause missed monthly periods, nipple drainage, decreased sex drive, or problems getting pregnant. If patients experience these problems, they should have blood tests to check their hormone levels. A high-fat meal significantly decreases the effectiveness of ramelteon; thus, it should not be taken either with or immediately after a high-fat meal. Ramelteon is a pregnancy category C drug.

Ramelteon may interact with other drugs. Fluvoxamine, which is a strong inhibitor of CYP1A2, increases the circulating levels of ramelteon so much that the two drugs should not be taken together. Other strong inhibitors of CYP1A2 should also be avoided, because they increase the risk of adverse effects; the effects of mild or moderate inhibitors have not been studied and are not known at this time. Other drug interactions via the P-450 system are possible.

Drugs From Other Classes

Trazodone

Trazodone (Desyrel) is an atypical antidepressant. This drug causes significant sedation as an adverse effect; thus, it is sometimes used as a sleep aid, unlike other atypical antidepressants. Trazodone is most commonly used to promote sleep if the patient is receiving an antidepressant that causes insomnia. See Chapter 16 for more discussion of trazodone.

Chloral Hydrate

Chloral hydrate is a nonbarbiturate hypnotic used to induce sleep and to cause preoperative sedation in order to lessen anxiety. It can be used as an adjunct to opiates and analgesics in pain control; it can also suppress or prevent alcohol withdrawal symptoms when given by rectal suppository. It is for short-term use only because it loses much of its effectiveness in producing and maintaining sleep after 2 weeks of use. Its exact mechanism of action is not known, although it is known to produce mild cerebral depression and quiet, deep sleep.

In therapeutic doses, chloral hydrate has little effect on respirations, blood pressure, or reflexes. It does produce numerous adverse effects in the CNS, including disorientation, incoherence, paranoid behavior, excitement, delirium, nightmares, and confusion, among others. Prolonged use may result in psychological and physical dependency and tolerance. Sudden withdrawal may cause CNS excitation with tremor, anxiety, hallucinations, or even delirium, and may be fatal. Chloral hydrate has largely been replaced by other drugs that promote sleep in a safer and more effective manner.

Barbiturates

Barbiturates such as phenobarbital (Bellatal), secobarbital (Seconal), and pentobarbital (Nembutal) were used to treat insomnia before the availability of the benzodiazepines. Although they are effective for short-term treatment of insomnia, they are also highly habit forming. Patients can develop tolerance and physical and psychological dependence on the drugs. Withdrawal symptoms can be severe and can lead to death. Patients who develop tolerance to a barbiturate are likely to overdose in an attempt to self-medicate and obtain therapeutic response. Overdosage results in severe respiratory depression as well as general CNS depression, likely followed by death. Because of these problems, barbiturates are not generally used to treat insomnia.

Phenobarbital is sometimes used as an adjunct for seizure disorders (see Chapter 18). Phenobarbital, as well as other barbiturates such as pentobarbital and secobarbital, is used parenterally as an adjunct to anesthesia.

CHAPTER SUMMARY

- Benzodiazepines, such as lorazepam, are used frequently to treat anxiety and sleep disorders. They work by intensifying the effects of GABA at specific receptors. They have fewer adverse effects and are generally better tolerated than older drug classes used for these conditions. They are generally very safe to use because they have a large therapeutic index.
- Benzodiazepines can also be used in treating seizures and muscle spasms, as adjuncts to anesthesia, and in managing acute alcohol withdrawal. They are currently the drug class of first choice in treating status epilepticus and treating or preventing seizures from alcohol withdrawal. Specific benzodiazepines are approved for different uses.
- Benzodiazepines differ mainly by their onset of action and half-life. They are generally recommended for short-term use in anxiety and insomnia, although their use in practice may vary. Only five benzodiazepines are specifically labeled to be used to treat insomnia: estazolam, flurazepam, quazepam, temazepam, and triazolam.
- Older adults are more sensitive to the adverse effects of benzodiazepines and should receive a smaller dose than younger adults. When benzodiazepines are used in older adults, drugs with shorter half-lives should be selected.
- Other drug classes used to treat anxiety are the selective serotonin reuptake inhibitors (SSRIs) and the tricyclics, both classes of antidepressants. Their effectiveness in anxiety treatment, irrespective of whether the patient has depression, is believed to be attributable to their effect on serotonin levels. For some anxiety disorders, SSRIs and tricyclics are now considered the first choice for treatment.
- Buspirone is another drug used to treat anxiety. It is not chemically related to the benzodiazepines. Tolerance and withdrawal do not occur with buspirone as they do with the benzodiazepines.
- Zolpidem and eszopiclone are newer agents used to treat insomnia. Zolpidem is for short-term use; tolerance may develop. Eszopiclone is unique in that it is labeled for long-term use up to 6 months, and tolerance does not develop even after long-term use. Both zolpidem and eszopiclone achieve their therapeutic effects by interacting selectively with some of the GABA-BZ receptor complexes and share some pharmacologic properties with the benzodiazepines, although they are not chemically related.
- Ramelteon is a hypnotic that works uniquely by stimulating melatonin receptors. It does not cause tolerance, dependency, or withdrawal and is not a controlled substance, unlike other hypnotics. It is approved for short-term use.
- The use of barbiturates and chloral hydrate for insomnia is now limited because other drugs depress the CNS more safely and effectively. Barbiturates are sometimes used for treating seizure disorders.

QUESTIONS FOR STUDY AND REVIEW

1. How does lorazepam, a benzodiazepine, decrease anxiety?
2. If a patient has been taking lorazepam regularly for several weeks, would the same dose continue to be effective? If the same patient suddenly stopped taking lorazepam, what physiologic effects might occur?
3. Why might lorazepam be the benzodiazepine of choice for a patient with anxiety and decreased liver function?
4. Why might an older adult be more at risk for falls than a younger adult when taking lorazepam at home?
5. Explain why triazolam, used to treat patients who have difficulty falling asleep, may also cause the adverse effect of early-morning insomnia.
6. Explain the advantages of eszopiclone over benzodiazepines used to promote sleep.

Drugs Treating Mood Disorders

Learning Objectives

At the completion of this chapter the student will:

1. Identify risk factors for the development of depression.
2. Identify the symptoms of major depression.
3. Identify the symptoms of dysthymic disorder
4. Identify the symptoms of bipolar disorder.
5. Identify the core drug knowledge of drugs used to treat mood disorders.
6. Relate the interaction of core drug knowledge to core patient variables for drugs used to treat mood disorders.
7. Generate a nursing plan of care from the interactions between core drug knowledge and the core patient variables for drugs used to treat mood disorders.
8. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect mood.
9. Determine key points for patient and family education for drugs that affect mood disorders.

Key Terms

antidepressants
bipolar disorder

Drugs in black type with no symbol are also used in drug therapy; no prototype.

Mood disorders are complex and serious biological illnesses that affect patterns of thinking, memory, energy levels, impulse control, sleep and appetite, and many other physiologic processes. This chapter reviews the common clinical manifestations of major depression, dysthymia, and bipolar disorder and the pharmacologic agents that are used to treat them. Feeling saddened is a common human experience in response to external events such as a loss, disappointment, or frustration. Mood disorders, however, are pervasive emotional states that have a neurobiological basis and can occur independently of environmental triggers. The prevalence of the use of the word *depression* to describe transient states of sadness has added to societal misconceptions that a person should be able to lift themselves out of depressive symptoms or that a mood disorder is caused by a weakness of character. Mood disorders are the oldest and most common psychiatric illnesses, manic depressive illness and melancholia were described by the ancient Greeks over 2000 years ago. The World Health Organization ranks depression as one of the leading causes of disability affecting 121 million people worldwide (WHO, 2009). The National Institute of Mental Health reports that depression affects almost 10% of Americans in a given year or nearly 21 million people (NIMH, 2009). The WHO supported Global Burden of Disease Study predicts that major depression will become second only to ischemic heart disease as the leading cause of disability worldwide by 2020 and will account for 15% of disease burden (WHO, 2009a). Without treatment, symptoms can last for weeks, months, or years to the point that some people recognize their persistently low mood state as what feels "normal" to them. Untreated depression robs the individual of the ability to fully experience joys in life, it limits one's ability to handle psychosocial stressors to the point that thoughts can become fatalistic, hopeless, and suicidal. Individuals with depression often do not talk about these thoughts to health care professionals because they themselves feel they should be able to manage better and fear judgment by others. Treatment of patients with mood disorders is far from limited to psychiatric treatment settings. It is not uncommon for a person with depression to have physiologic complaints and first seek treatment in general practice settings for problems such as GI disturbances, appetite disturbances, weight loss, sleep problems, headaches and other manifestations of pain. In addition, depression often co-occurs with other psychiatric illnesses and medical conditions. A convincing link that depression is one of the contributing variables in developing cardiovascular disease has been known for years and the presence of depression can also increase adverse cardiovascular events (Sansone, 2008). Associations with inflammatory illnesses such as rheumatoid arthritis have been made (Pav, 2008). In patients with diabetes the risk of depression appears to be higher (up to twice as much) than in those without diabetes (Williams, et. al, 2007). Studies have shown that people who have depression in addition to another serious medical illness tend to have more severe symptoms of both depression and the medical illness, more difficulty adapting to their medical condition, and more medical costs than those who do not have coexisting depression. Research has yielded increasing evidence that treating the depression can also help improve the outcome of treating the co-occurring illness (NIMH, 2007). Physicians in primary care settings must be ready to manage patients appropriately who are presenting with more covert symptoms of depression. For these reasons nurses must also be ready to provide safe and competent care by having adequate knowledge about assessment and management of mood disorders and a solid understanding of antidepressant and mood stabilizing medication.

Antidepressants are divided into several drug classes based on how they achieve their therapeutic effect. The three classes that are presented as prototypes are: selective serotonin reuptake inhibitors (SSRIs), the most widely prescribed drug class; tricyclic antidepressants; and monoamine oxidase inhibitors (MAOIs). Sertraline is the prototype SSRI discussed in this chapter; the prototype tricyclic antidepressant is nortriptyline; and the prototype MAOI is phenelzine.

The prototype mood stabilizer included in this chapter is lithium.

PHYSIOLOGY

The brain contains billions of specialized cells called neurons. Although neurons receive and release multiple types of molecular signals, they function as a cohesive system communicating with one another via neurotransmission of electrical signals. The action of neurons in the brain and the chemicals called neurotransmitters that are stored in and released by neurons is a complex process that plays a role in both normal and abnormal brain function. Some neurotransmitters are excitatory which speed the transmission, some are inhibitory thus delaying the signals. Receptors which are located either pre-synaptically or post-synaptically allow the neurotransmitter to act rapidly by direct effect on the ion channel or slowly through modulating the production of other signal transducing molecules called second messengers. The therapeutic action of psychotropic medication usually does not have an immediate effect within these systems therefore a noticeable clinical response to these medications may take several weeks.(Mohr, 2009; Pav, 2008) A more detailed description of neuroanatomy and neurotransmission can be found in Chapter 13.

What seems obvious, but is often forgotten, is that the mind and the brain are the same organ. Certain activities are often thought of as belonging to either the mind or the brain. In practical terms, critical thinking, emotions, and control of behavior are thought of as occurring in the mind, whereas activities such as controlling muscles of the body and regulating breathing, digestion, and body temperature are thought of as occurring in the brain. Conceptualizing the information in this way makes it easier to understand how illnesses in the brain can affect not only the emotions that a person experiences but also bodily functions such as movement and digestion.

PATHOPHYSIOLOGY

The National Institutes of Health declared the 1990s as the decade of the brain. During this time, unprecedented research about the brain and how it works improved the lives of people suffering with mood disorders. Research has been focused on creating medication that specifically targeted the neurotransmitters that are believed to affect mood. Illnesses resulting in mood disorders are associated with an imbalance or **dysregulation** of neurotransmitters, specifically, serotonin and norepinephrine. Improved techniques of brain imaging brought about greater understanding of the neurochemical processes at work as well as the structural changes that occur in the brain when a person experiences depression or stress. Research is also shedding light to the similar effects depression and stress share on immune and stress responses. Changes in the brain that are linked to these conditions include atrophy and structural remodeling in the limbic system, changes in the length and number of neuronal processes and a decline in neurogenesis (production of new neurons). Brain imaging studies show reductions of hippocampal volume with people who have been depressed most of their lives. This effect becomes more prominent when the depressive person was exposed to trauma during childhood (Pav, 2008). Antidepressant medications have been shown to target these abnormalities (Pav, 2008; Duman, 2002). The development of genetic studies has identified a specific gene that predisposes some people to develop depression when exposed to emotional stressor and it has been shown that all forms of mood disorders have genetic susceptibility and a hereditary component. There have been encouraging developments in resolving the problems in diagnosing and treating mood disorders but much remains to be discovered about the illness's exact etiology, its' prevention and treatment.

Major Depressive Disorder

Symptoms that characterize major depression are outlined by the American Psychiatric Association in the *Diagnostic and Statistical Manual for Mental Disorders,* fourth edition, text revision (DSM-IV-TR), which helps health care providers differentiate psychiatric illnesses.

Diagnosing major depression is partly a process of elimination. A patient's symptoms cannot be the result of a general medical condition such as cancer or hypothyroidism, nor can they be the result of drug abuse or an adverse effect of medication, although some drug classes are associated with depression. Box 16.1 lists these drug classes.

Box 16.1 DRUG CLASSES ASSOCIATED WITH DEPRESSION

- Alcohol
- Antiepileptics
- Antihypertensive agents
- Antiparkinsonian agents
- Antituberculosis agents
- H2 antagonists
- Narcotic analgesics
- Oral contraceptives
- Psychotropic agents
- Steroids

A pattern of other signs and symptoms must be present to complete an accurate diagnosis of major depression. Within a 2-week period, a person must manifest a depressed, even tearful mood or report or demonstrate to others a diminished interest or lack of pleasure in all activities most of the day. The symptoms must cause impairment at work or other social functions. Additionally, four other symptoms must be present from the following: changes in appetite, weight, sleep, or energy; a decrease in concentration; recurring death wishes; or thoughts of suicide. Thus, in addition to mood, major depression affects a person's body and ability to think. In cases of severe major depression, psychotic symptoms such as delusions may also occur.

Major depressive disorder affects approximately 14.8 million American adults, or about 6.7% of the U.S. population age 18 and older, in a given year (NIMH, 2008). Median age of onset of major depression is age 32 and the disorder is more prevalent in women than in men.

Risk factors for depression include:

- Having previously been depressed
- Having a first-degree relative diagnosed with depression
- Being a woman, an adolescent, or a young adult

Research indicates that alterations in neurotransmitters such as serotonin are associated not only with depression but also with the risk of suicide. Diminished levels of this brain chemical have been found in patients with depression, impulse control disorders, or a history of violent suicide attempts, and also in postmortem brains of suicide victims (NIMH, 2009a). In 2006, suicide was the 11th leading cause of death in the United States across all age groups. Depression accounts for about 60% of suicides of both youths and adults. Untreated depression is often associated with suicide. Less than 20% of depressed adults, and only about 2% of youths, are taking antidepressants at the time they commit suicide (Mann, Emslie, Baldessarini, et al., 2006). More than four times as many men as women die by suicide (CDC, 2009), although women report *attempting* suicide during their lifetime about three times as often as men (NIMH, 2008). Suicide attempts are an additional significant problem in depressed patients. In the population at large, it has been estimated that 12 to 25 attempted suicides may occur for every successful suicide (NIMH, 2008). It is also estimated that more than 90% of people who kill themselves have a diagnosable mental disorder, most commonly, a depressive or substance abuse disorder (NIMH, 2008).

Depression and suicide are problems across the lifespan. Depression affects about 3% to 5% of American youth annually. Suicide is the third leading cause of death among 15- to 24-year-olds, (CDC, 2009) about 0.01% of all youths will commit suicide per year. In 2005, one fifth of all high school students reported seriously thinking about committing suicide in the past 12 months, half of these attempted suicide. Although adolescent females were more likely to attempt suicide, the rate of completed suicides was higher in males (CDC, 2007). Suicide was also determined to be the second leading cause of death among 25 to 34 year olds (CDC, 2009).

Although depression frequently occurs in older adults, it should not be considered a normal part of aging. It is often a comorbidity with stroke, diabetes, cancer, and Parkinson disease, and older adults are more likely to experience these illnesses. Of the nearly 35 million Americans 65 years of age and older, an estimated 2 million have a depressive illness (including major depressive disorder, dysthymic disorder [mild, chronic depression], or bipolar disorder).

Older Americans are disproportionately likely to die from suicide. Comprising only 12% of the U.S. population, individuals 65 years of age and older accounted for 14% of all suicide deaths in 2006 (NIMH, 2009a). The highest suicide rates in the United States are found in white men older than 85 years of age followed by males aged 75 to 84 (CDC, 2009). Many studies have pointed to depression as the leading cause of suicide in the elderly (Garand, 2006). Frequently, polypharmacy confounds the diagnosis and treatment of mental disorders in the elderly (Crumpacker, 2008).

Dysthymic Disorder

Dysthymia and major depression have many common symptoms, including depressed mood, sleep disturbance, low energy, and poor concentration. Whereas in major depression the symptoms can be quite severe, the defining feature of dysthymia is the chronicity of symptoms. Depressive symptoms must persist for 2 years in adults and a minimum of 1 year in children and adolescents. From 3% to 6% of the U.S. population has suffered with this disorder at some time in their life, and the rate was found to be higher in primary care treatment settings (Sansone, 2009). Dysthymia is a serious disorder, it can be very disabling and often occurs with other psychiatric disorders such as major depression, anxiety, and substance abuse disorders (Sansone, 2009). Other symptoms that characterize dysthymia include low self-esteem, inability to make decisions, and feelings of hopelessness. The Greek word *dysthymia* means " bad state of mind." People with this disorder often see themselves as incapable, and their thoughts are filled with self-criticism and excessive guilt. Like *EEyore*, a character from "Winnie the Pooh," a person with dysthymia has a black rain cloud over them most of their days and aspects of their family and occupational life are profoundly affected. The long duration of these thoughts and feelings can result in the lack of clinical recognition of this type of depression; high rates of people with dysthymia go on to having a major depressive episode (Sansone, 2009).

Bipolar Disorder

Bipolar disorder is a brain disorder that not only causes unusual shifts between low and elevated mood but affects energy, activity levels, sleep, thought process, and judgment in extreme ways. Symptoms can occur on a spectrum from severe mania to hypomania to periods of being symptom free to mild to moderate depression and more severe depression (NIMH, 2009b). People with this disorder need to manage symptoms throughout their lives and if left untreated, bipolar disorder usually worsens in frequency and intensity of mood shifts and psychosocial consequences. There is a 90% recurrence rate with this disorder.

Mania, a characteristic symptom of bipolar disorder, is diagnosed when a person has an elevated or irritable mood lasting at least 1 week (or less if hospitalization is necessary) and at the same time has three or more of the following symptoms:

- Grandiosity
- Distractibility
- Decreased sleep
- More goal-directed activities or psychomotor agitation
- Rapid speech patterns
- Subjective expression of racing thoughts with changing topics or interjecting unrelated topics
- Excessive involvement in pleasurable activities that have a high potential for painful consequences (American Psychiatric Association, 2000)

In people diagnosed with bipolar disorder, depressive symptoms occur three times more frequently than manic symptoms (Noonan, 2007). This links the illness with a higher risk of suicide: 25% to 50% of people with this disorder attempt suicide at least once in their life time, and the majority of these suicide victims die by their first attempt (Foutoulakis, 2008). When a patient presents with symptoms of depression it is important to obtain a history back to school age to determine if there were previous episodes of mania. Persons often suffer for 10 to 12 years before a correct diagnosis and treatment for bipolar disorder begins (Noonan, 2007). The frequency of cycling between periods of mania and depression, along with the severity levels of each phase, differentiate between the subtypes of bipolar disorder.

This mood disorder affects approximately 5.7 million American adults in a given year, or about 2.6% of the U.S. population aged 18 and older (NIMH, 2008). Bipolar disorder runs in families and is inheritable. Close relatives of people suffering from this condition are 10 to 20 times more likely to develop either depression or manic-depressive illness than those in the general population. Because of this strong familial link, bipolar disorder is believed to have a genetic component; however, the exact gene or genes have not yet been identified.

Unlike major depression, with which women are diagnosed more frequently than men, bipolar disorder affects men and women equally. Most diagnoses are made in early adulthood. The median age of onset is 25 years.

It is not uncommon for bipolar disorder to occur with other psychiatric illnesses such as anxiety disorders, attention deficit disorder, and substance abuse disorders. Studies have also linked bipolar disorder with physical disorders such as diabetes, heart disease, migraines, and asthma (Schwartz, 2009). Throughout his or her lifetime, each person will establish a particular pattern of illness. Treatment usually takes a multifaceted approach with pharmacotherapy, symptoms management, and family therapy and education; with

treatment, 70% to 80% of people are able to live meaningful, productive lives.

ANTIDEPRESSANTS

Imagine going to a physician and explaining that you are experiencing a particular pain. The physician responds that he or she knows exactly what you are experiencing, can prescribe something to treat it, but will tell you it will be several weeks before the pain is gone. For patients experiencing emotional pain, such as depression, this is their very experience.

Most antidepressant drugs have a lag period of 10 days to 4 weeks before a therapeutic response is noted. Increasing the dose will not shorten this period but rather increases the incidence of adverse reactions Although antidepressants can bring about an immediate change at neuroreceptor sites, it is unclear why a corresponding immediate relief of depressive symptoms does not occur. A current hypothesis about antidepressant medication is that a correction of dysregulation of neurotransmitters occurs. Post-synaptic receptors, which participate in neurotransmission, may have as important a role as do the pre-synaptic receptors where regulation of neurotransmitter release and reuptake occur. Long-term antidepressant therapy produces changes in both pre- and post-synaptic neuroreceptors, which results in a higher level of available neurotransmitters. The decrease in sensitivity to the neurotransmitter at the pre-synaptic receptor sites is a process that takes days to achieve with antidepressant therapy. The effect of the antidepressant medication when administered for longer periods is a down-regulation, or decrease, in number of post-synaptic receptor sites, thus potentially explaining why the medication exerts a delayed response (Mohr, 2009; Pav, et al., 2008; Duman, 2002).

Research has demonstrated that the action of antidepressants may not wholly involve neurotransmitters. Antidepressants may also function to realign the connections between the cortical and limbic areas of the brain. One small study showed that depressed patients did not have normal connections between these two areas of the brain. Treatment with an antidepressant (specifically, sertraline) increases these connections and possibly increases the regulatory influence of the cortical mood-regulating regions over the limbic regions of the brain (Anand, Li, Wang, et al., 2005). This suggests the possible connection between depression and chronic stress responses. Antidepressant medication could be reversing the structural alterations in these regions of the brain affected by depression and stress. Recent studies have demonstrated an increase in neurogenesis in the hippocampal regions of the brain and the ability to refine genetic expression (Duman, 2002).

For the patient with an acute depressive disorder, this delay in the remission of depressive symptoms is difficult to accept. By the time a person seeks treatment for these illnesses, he or she wants immediate relief from pain. It is important to educate the patient to continue taking their medication despite the delay in symptom reduction or feeling completely recovered. Ongoing assessment of the patient should occur regularly while treated pharmacologically for depression as patients may only be achieving a reduction in their depressive symptoms. Only 30% of patients achieve a full remission of symptoms with an initial trial of antidepressant medication taken at adequate doses for a sufficient duration of time. This means a decision to either switch medications or to augment the treatment with another medication must be made by the treatment provider (Sussman, 2007; Rush, 2006).

Although the full therapeutic effect of mood lifting does not occur for up to 4 weeks, antidepressants begin to have some effect earlier in the course of treatment. Energy levels are likely to return to predepressive levels prior to a complete lifting of the depression. Suicidal patients are at great risk at this point because it is theorized that the medication gives the patient the energy to act on their suicidal thoughts and there are select patients who seem to be more vulnerable to this potential. Therefore it is essential for the patient to be reassessed at regular intervals for presence of suicidal thinking, intent, and plan, especially within the early stages of treatment (Crumpacker, 2008).

As discussed earlier, there are three main classes of antidepressants: SSRIs, tricyclics, and MAOIs. There are several other miscellaneous classes of antidepressant medication, such as the SNRIs (serotonin norepinephrine reuptake inhibitors). Each type of antidepressant works a little differently, but they all change the brain chemistry to improve neurotransmission. Table 16.1 presents a summary of selected drugs used to treat depression and other mood disorders.

All types of antidepressants are similarly effective in treating depression. However, if a patient does not demonstrate a therapeutic response to a particular drug, he or she may respond positively to another antidepressant, including another drug in the same pharmacologic class. Research has found that about one in four patients has remission of depressive symptoms after switching from one SSRI to another antidepressant (Rush, Trivedi, Wisniewski, et al., 2006). Alternately, similar positive response to drug therapy can be achieved by augmenting the original drug with a drug from a different class (Rush et al., 2006; Sussman, 2007).

Although antidepressants all act similarly, each type has unique adverse effects. The goal in antidepressant therapy is to bring about the greatest relief of symptoms while minimizing any unpleasant adverse effects as much as possible. Table 16.2 compares the adverse effects of selected antidepressant drugs, and Table 16.3 describes methods of managing these adverse effects.

• Selective Serotonin Reuptake Inhibitors

Currently, the selective serotonin reuptake inhibitors (SSRIs) are the first choice for treating depression. They are preferred over the tricyclics and the MAOIs because they can be less damaging to the heart and have minimal anticholinergic and hypotensive effects. Selection of one SSRI over another is based on individual patient response to a drug and prescriber

preference. It is important to note that if a medication from one class of antidepressants such as an SSRI is discontinued and switched to a different class of medication such as an MAOI, a washout period (waiting period) must occur. This period can vary between 7 and 14 days and will depend on the type of antidepressant being discontinued.

In 1987, fluoxetine (Prozac) became the first SSRI approved by the Food and Drug Administration (FDA) for use as an antidepressant in the United States. It immediately became popular because of its ease in dosing and few adverse effects. Its effectiveness, combined with the increasing social acceptance of antidepressant use, led many patients to ask their physicians for Prozac. Its great marketing success is thought to have stimulated widespread research and subsequent introduction of other, newer antidepressants. Fluoxetine has been around long enough that its patent has now expired, resulting in generic availability of this drug. But in the United States, the cultural impact is such that most people still think of Prozac when they think of antidepressants.

Currently, sertraline (Zoloft) is one of the most widely prescribed SSRIs in the United States. Because of its widespread use, sertraline has been chosen as the prototype SSRI.

Nursing Management of the Patient Receiving P Sertraline

Core Drug Knowledge

Pharmacotherapeutics

Sertraline was approved by the U.S. FDA in 1991 for treating depression in adults. Treating acute depressive disorder with sertraline requires several months or longer of drug therapy, just as it does with other antidepressants.

TABLE 16.3 Management of Adverse Effects of Antidepressants

Symptoms	Strategies for Management
Gastrointestinal	
Nausea, anorexia	Administer with food (or antacids) if drug absorption is unaffected.
Diarrhea	Use antidiarrheal medication (if not contraindicated).
Constipation	Diet change (increase fiber and fluids), exercise, stool softener (avoid laxatives); wait for tolerance to drug effects.
Sexual dysfunction	Discuss methods available for satisfactory sexual expression.
Anorgasmia	Encourage talk with health care provider regarding dosage reduction or drug holiday.
Erectile dysfunction	
Impaired ejaculation	
Orthostatic hypotension	Use calf exercises, wear support hose, increase fluid intake.
Anticholinergic effects (dry eyes and mouth)	Use artificial tears, frequent dental hygiene, sugar-free chewing gum; wait to develop tolerance to drug effects.
Tremor/"jitteriness"	Slow, gradual titration of increasing dosages; encourage discussion with health care provider regarding dosage reduction or drug holiday.
Insomnia	Take medication in the morning (exception is trazodone).
Sedation	Caffeine (if not contraindicated), take medication at bedtime (exception is bupropion in afternoon).
Headache	Evaluate diet, stress, other drugs used; suggest dosage reduction to health care provider.
Weight gain	Decrease carbohydrate intake; consume low-fat diet; exercise.

Additional approved uses for sertraline include obsessive-compulsive disorder (adults and children), panic disorder, and post-traumatic stress disorder.

Although sertraline is not approved by the FDA for treating depression in children at this time, the SSRI is widely used on an unlabeled basis to treat pediatric depression. Several studies have demonstrated that sertraline is safe and effective for treating major depressive disorder in children (Rynn, Wagner, Donnelly, et al., 2006; March, Klee, & Kremer, 2006).

Pharmacokinetics

Sertraline is well absorbed following oral administration, with peak plasma levels occurring within 4.5 to 8.4 hours. It has a 26- to 104-hour elimination half-life (with metabolites) and reaches a steady state within 7 days. SSRIs such as sertraline are extensively metabolized by the liver and should be used with caution in patients with severe liver impairment. Food may increase the onset of the peak effect from sertraline, but this result is not clinically significant, and no recommendations are made to take the drug with food.

Pharmacodynamics

Sertraline is a potent and selective inhibitor of neuronal serotonin (5-HT) reuptake and has a weak effect on norepinephrine (NE) and dopamine (DA) neuronal reuptake. Because the SSRIs do not have a high affinity for muscarinic (Ach), histaminergic (H_1), and alpha-adrenergic receptors, their capacity for causing anticholinergic, sedative, cardiac, and orthostatic hypotensive effects is considerably less than that of the tricyclics. Achieving antidepressant effects from sertraline, as with other antidepressants, can take anywhere from 10 days to 4 weeks. Some symptoms of depression, such as loss of energy, may be corrected before the mood is fully elevated.

Contraindications and Precautions

Sertraline should be administered with caution in patients with compromised liver function. Adjustments such as a lower or less-frequent dosing schedule may be made for these patients. Although no studies have been conducted specifically in patients with seizure disorders, the incidence of seizures in patients taking sertraline is 0.2%, which is similar to other antidepressant and placebo studies. A history of seizures therefore requires cautious use of sertraline

As previously mentioned, some concern exists that SSRI antidepressants such as sertraline, or other antidepressant drugs, may increase the risk of suicidal thinking or attempts at suicide in some children and adults. At this time, it is debatable whether sertraline or any other antidepressant actually induces suicidal ideation, or whether the drugs' ability to restore energy levels before elevating mood provides depressed patients with the ability to act on their depressed mood. The FDA has revised the warning labels of all antidepressant drugs with a standardized class warning to indicate that when taking sertraline as well as any other SSRI, both children adolescents and young adults ages (18 to 25) should be closely monitored for worsening of depression and the emergence of suicidal thoughts and tendencies. This warning is prominently displayed in a Black Box warning on the drug label (for more information on Black Box warnings, see Box 5.1 in Chapter 5). For many years, the SSRIs have carried on their label a precaution that close monitoring of

patients was necessary in the early stages of treatment. Only the significance of the warning has changed.

The issue of whether SSRIs and other antidepressants increase the risk of suicidality is still debated as some studies have shown that antidepressant medication may have a protective factor against suicide in adults—including young adults ages 18 to 25. The need for carefully designed research studies is imperative because it has been postulated that as a result of having the more significant FDA warning label, there has been a decrease in *treated* depression in some age groups. See Box 16.2 for a discussion of these current studies on the relationship between SSRI antidepressants and the risk of suicidal behavior. For the most recent labeling information on specific antidepressant medication, visit the FDA website: *http://www.fda.gov*.

Adverse Effects

Compared with the tricyclics, sertraline and other SSRIs have fewer adverse anticholinergic and cardiovascular effects and usually do not cause weight gain. Adverse effects, which are mild and brief, include gastrointestinal distress (anorexia, nausea, vomiting, and diarrhea), headache, fatigue, insomnia, and sexual dysfunction (delayed ejaculation, inability to achieve orgasm). Some of these adverse effects are transient, subsiding within the first 1 to 2 weeks of therapy. Other adverse effects may include hematologic problems, such as blood dyscrasias, leukopenia, and altered platelet function. Since serotonin is released by platelets to promote aggregation, use of SSRIs leads to depletion of serotonin in platelets which may result in decreased coagulation.

Syndrome of Inappropriate Anti-Diuretic Hormone Secretion or SIADH is another potential adverse side effect of sertraline or any SSRIs. The condition results in hyponatremia and it usually happens in the first week of SSRI treatment. A study of SSRI use in an elderly population found as many as 12% to 25% having hyponatremia and 12% having the syndrome. Symptoms of hyponatremia are nonspecific initially and could include malaise, nausea, headache, lethargy and myalgia, but could progress to loss of consciousness and convulsions. Age and female gender are possible risk factors for developing this complication (Looper, 2007).

For some patients, the most limiting adverse effects of SSRIs are the disturbances in sexual function. This effect may not be a concern to the depressed patient beginning therapy, but it may become a greater concern as the patient regains interest in sexual activity. The presence of this adverse effect is a frequent reason that patients consider stopping drug therapy. In clinical trials, only 10% to 15% of patients required discontinuation of treatment because of an adverse event. As noted earlier, sertraline and other SSRIs may increase the risk of suicide, although the incidence of suicide is extremely small. Suicidal thoughts or attempts that occur early in the course of therapy may be related to the drug's beginning to work; remember that the energy level of the patient increases before the depression is fully relieved.

Drug Interactions

Sertraline is highly bound (98%) to plasma protein. If it is administered with another drug that is highly protein bound, increased free concentrations of either drug may result. The activity of isoenzyme cytochrome P-450 2D6 may be substantially inhibited by sertraline. Any drug that is metabolized by this isoenzyme should therefore be administered with caution, because expected plasma levels will be altered. Consuming caffeinated beverages can increase the stimulant sensation experienced by the patient taking sertraline and other SSRIs. Nicotine intake from cigarette smoking may cause an increase in the metabolism of sertraline and other SSRIs. The FDA has issues a safety alter regarding the combined intake of sertraline and other drugs that enhances serotonergic neurotransmission and tryptans, medications used to treat migranes (FDA, 2009g). Even when prescribed on its own, a rare, life-threatening event called **serotonin syndrome** can occur as a result of overactivation of the central serotonin receptors. Symptoms to watch for are sweating, fever, increased blood pressure, tachycardia, abdominal pain, diarrhea, muscle spasm, increased motor activity, irritability, hostility, and altered mental state. In its most severe presentation, cardiovascular shock or even death may result This rare but serious side effect can occur with initiation or increase of dosage of any SSRI or SNRI (Looper, 2007). Table 16.4 summarizes potential drug interactions with sertraline.

Assessment of Relevant Core Patient Variables

Health Status

Review the patient's drug history for current drugs used, health history for any illnesses that may complicate therapy, and mental status. Assess for a history of seizures because SSRIs such as sertraline are used with caution in patients with such a history. The drug should be discontinued if seizures occur. Additionally, because anxiety, nervousness, and insomnia occur in 2% to 22% of patients treated with SSRIs, careful consideration should be given to the use of these antidepressants in patients who already exhibit one or more of these symptoms. SSRIs, such as sertraline, may not be the antidepressant drug class of choice for the extremely underweight depressed patient, because approximately 3% to 9% of patients treated with SSRIs experience substantial weight loss. However, only rarely has weight loss required patients to discontinue therapy.

Also, assess for the presence of suicidal ideation before starting therapy, and closely monitor the patient for evidence of worsening depression or onset of suicidal ideation while receiving sertraline or other SSRIs. The most critical time to closely monitor the patient for behavioral changes is during the first few weeks of drug therapy.

As previously mentioned, depression is commonly seen in patients with other medical conditions. The efficacy of antidepressant treatment with co-occurring disorders has yielded some interesting research which suggests that treatment of depression also can result in improvement of existing medical conditions. A finding from a study of diabetic

TABLE 16.4 Agents that Interact with P Sertraline

Interactants	Effect and Significance	Nursing Management
alcohol	Additive CNS depression may occur.	Monitor for adverse effects.
benzodiazepines	Decreased metabolism of benzodiazepines through hepatic oxidation route. Significance not known.	Monitor for adverse effects of benzodiazepines.
cimetidine	Increases half-life, AUC, and C_{max} of sertraline, but clinical significance is unknown.	Adjust sertraline doses as necessary.
clozapine	May elevate clozapine levels.	Monitor for adverse effects of clozapine.
cyproheptadine	May decrease or reverse pharmacologic effects of SSRIs.	Monitor for reduced efficacy of sertraline.
drugs metabolized by P-450 2D6	Sertraline or other SSRIs may substantially inhibit the activity of P-450 2D6 (especially during the beginning of therapy); metabolism of these other drugs may be reduced, potentially resulting in adverse effects.	Monitor for adverse effects. Lower doses of sertraline may be needed.
drugs that are highly protein bound	Because sertraline and other SSRIs are highly protein bound, sertraline may displace the other drug from the protein, causing increased circulating levels of the other drug and possibly adverse effects. If other drugs are started while the patient is on sertraline, the sertraline may be displaced from the protein, resulting in higher circulating levels of sertraline, and possibly adverse effects.	Monitor for adverse effects.
hydantoin	Sertraline may increase hydantoin levels.	Monitor for increased hydantoin levels.
MAOIs, St. John's wort	Serotonin syndrome, with serious, sometimes fatal, reactions such as hyperthermia, rigidity, vital sign changes, mental status changes, and autonomic nervous system instability.	Avoid sertraline and other SSRIs when MAOIs are used and within 14 days of stopping an MAOI. Teach patients not to self-medicate with St. John's wort if taking sertraline.
phenytoin	May increase phenytoin levels.	Monitor for adverse effects of phenytoin. Check blood phenytoin levels when starting therapy or changing dose of sertraline.
sumatriptan	Concurrent use increases serotonin levels, potentially leading to serotonin syndrome.	Avoid concurrent use.
sympathomimetic drugs	Increases sensitivity to the effects of sympathomimetics. Serotonin syndrome is more likely to occur.	Monitor for adverse effects.
tolbutamide	Coadministration has been shown to decrease the clearance of tolbutamide. Clinical significance unknown.	Monitor tolbutamide levels.
TCAs	May increase serum TCA levels.	Monitor for adverse effects. Monitor TCA blood levels. TCA dose may have to be reduced.
tryptophan	Concurrent use increases serotonin levels, potentially leading to serotonin syndrome.	Avoid concurrent use.
warfarin	Increases prothrombin time and may cause bleeding.	Monitor prothrombin time.

patients using sertraline for depression supported use of the medication following a remittance of depressive symptoms as it was found to delay the onset of another episode of depression and improve the interval of time before another episode of depression occurred. Recovery from depression also was associated with improved long-term glucose control, as measured by glycosylated hemoglobin levels (Lustman, Clouse, Nix, et al., 2006). Exactly how or why this occurs is not known at this time. Another study compared the use of sertraline in younger (below age 55) and older

(above age 55) diabetic patients and found that the younger group had a more positive response to sertraline in the prevention of recurrence of depression. The authors speculated that there were variables they did not account for in the older group; nonetheless, this study also correlated improved glycosylated hemoglobin levels during the depression-free intervals (Williams, et al., 2007). In addition, depression is associated with acute coronary syndrome (ACS). Sertraline has been the most studied medications used for the treatment of depressed patients with cardiac disease. The benefits demonstrated are that it is an antidepressant that is well tolerated in this group of patients and appears to improve the quality of life (Sansone, 2008). One study found that an episode of major depression associated with ACS is as likely to occur before the ACS as after it. Predictors of success in treating depressed patients with diabetes using sertraline were as follows: current episode of depression began before development of ACS; history of a previous depressive episode; or depression rated as severe. The likelihood of successful antidepressant effects from sertraline was increased if the patient had more than one of these three predictors (Glassman, Bigger, Gaffney, et al., 2006). More research is necessary in this area.

Life Span and Gender

Consider the patient's age. As previously discussed, although some research indicates that sertraline has been proved safe and effective for use in children, this drug is not approved for use in children to treat depression. When it is used in children, the pediatric dose is usually half that for adults because of children's smaller body size. Concern exists that sertraline, like all other antidepressants, may increase depression and risk of suicidal thinking or behaviors in children. Treatment with sertraline for depression appears to increase the risk of suicidality more in children than in adolescents (March, Klee, & Kremer, 2006). Clinical trials have not shown that the use of sertraline increases suicidality at all in children or adolescents treated for obsessive-compulsive disorder (March, Klee, & Kramer, 2006). See Box 16.2 for further discussion of the suicide risk with SSRI antidepressant medication.

The adverse effect profile in the elderly patient is similar to that in younger healthy adults. However, because of decreased clearance of the drug in the older patient, smaller doses and slower increases should be made when prescribing sertraline or other SSRIs. A pilot study of 37 mildly depressed elderly patients compared the use of sertraline with regular (facility-based, three times weekly for 60 minutes) exercise demonstrated that both were almost equally effective in decreasing symptoms of mild depression for this group of patients. The exercise group developed an improvement in physical strength and endurance not achieved by the group using only medication. Although this study used a small group of subjects, previous studies have suggested that combining exercise with antidepressant medication yields improved benefits in elderly patients (Brenes, 2007).

Ask female patients of childbearing age whether they are pregnant, intend to become pregnant, or are breast-feeding. The FDA classifies sertraline in pregnancy risk category C. Sertraline, however, is recommended as first-line treatment for breastfeeding woman in the United States because it exhibits undetectable levels in the breast fed infant (Menon, 2008; Field, 2008). Sertraline and two other SSRIs (Fluoxetine and Paroxetine) have been studied to determine if they can provide symptomatic relief in treating PMS and Premenstrual Dysphoric Disorder, the results show that these medications are most effective for ameliorating symptoms when the medication is used continuously rather than intermittently over the course of a woman's menstrual cycle (Shah, 2008).

Lifestyle, Diet, and Habits

The SSRIs can affect sexual functioning. Men may report delayed ejaculation or ejaculatory failure, whereas women may report the inability to achieve orgasm. However, sexual functioning can also be adversely affected by the very depression that the SSRI is prescribed to treat. Therefore, a baseline assessment of sexual functioning should be performed before starting treatment with sertraline.

Also, assess the normal use of caffeine in patients who will be starting sertraline, because caffeine interacts with sertraline. In addition, assess for alcohol use and determine whether the patient smokes cigarettes, because these agents also interact with sertraline. Alcohol abuse is a frequent co-occurring disorder with depression. Patients who stopped using alcohol and then began taking sertraline not only were less likely to be depressed but were less likely to relapse into drinking. Research indicated that if their depression was not controlled, they were much more likely to begin drinking again (Oslin, 2005).

Culture and Inherited Traits

Consider the patient's cultural background. Some people with a polymorphism in the P-450 isoenzyme 2D6 may lack this enzyme and therefore would be poor drug metabolizers, would have higher circulating drug doses, and could possibly experience adverse effects from the SSRIs, even at low doses. A range of 2D6 levels has been identified globally among various ethnic groups. Their findings suggest that poor metabolizing is least common in East Asians, followed by African Americans and then Hispanics, with whites exhibiting this condition most frequently. For this reason, an East Asian patient may respond more than an African American patient, a Hispanic patient, or even a white patient, even if they all receive the same dose of an SSRI. A small pharmacokinetic/pharmacodynamic study appears to support this finding. The researchers compared the dosage needed to achieve therapeutic effect in depressed Chinese and Caucasians treated with sertraline and the steady-state plasma concentrations of the two groups. The Caucasian patients required a higher dose of sertraline to achieve relief of depression and had a higher plasma level of sertraline than the Chinese patients (Hong,

BOX 16.2 COMMUNITY BASED CONCERNS

SUICIDALITY AND ANTIDEPRESSANT MEDICATION

Over the past years the possible relationship between the use of antidepressants and the increased risk of suicidality (defined as the combination of new suicide attempts, new onset of suicidal ideation, and worsening of pre-existing suicidal ideation) has been the topic of much debate. In 2003 and 2004 U.S. and European regulators issued public health warnings about this possible association. In the early 1990s, similar reports emerged of suicidal behavior in adults who received Prozac, the first SSRI, for depression. The belief was that Prozac had an early activating effect on depressed people and gave them enough energy to follow through on suicidal impulses before there was a mood elevating effect. In 1991, the US Food and Drug Administration had a psychopharmacologic drug advisory meeting and concluded there was no clear evidence of this risk. In 2003, anecdotal case reports of suicidality and suicide in adolescents receiving SSRIs (paroxetine) prompted the FDA to review 25 randomized controlled clinical trials involving SSRIs. The FDA's review reexamined the adverse effects reported from all pediatric clinical trials in which any SSRI was used. It is important to note that no pediatric suicides occurred in any of these trials and the definition of suicidality was not identical in all of the studies. The outcome of this review resulted in the addition of Black Box warnings to the labels of SSRIs (and other classes of antidepressants). This is the FDA's most serious drug label warning. Subsequent studies found the same risk with young adults population, ages 18 to 25 years. The current warning states: antidepressant medicine may increase suicidal thoughts or action in some children, teenagers and young adults within the first few months of treatment (Prescriber's Letter, 2008). There are many reports in the news that peak the public's concern and leads to fear of the use of antidepressant medication.

The scientific community is often split when interpreting findings of clinical research. Large scale reviews of data ensued to establish if these findings would be repeated in adult clinical trials. A review of 372 controlled trials of adults (nearly 100,000 subjects) using SSRI and non SSRI antidepressant medication concluded that antidepressant medication had a protective effect rather than causing an increase in suicidal ideation and behavior. There were eight suicides during the course of the reviewed trials involving almost 100,000 people. Data from this study did suggest there was a higher rate of suicide was found in adults under the age of 25 once antidepressant therapy had begun (Stone, 2009). Thus the FDA has since expanded the labeling of all antidepressants to include young adults under the age of 25 as well as adolescents and children in this Black Box warning.

Another analysis within the Veterans Health Administration looked at a cohort of about 226,866 veterans and compared suicide rates within the subjects before and after SSRI treatment. The results concluded that antidepressants may decrease the risk of suicide; they found no greater risk of suicide with use of SSRIs when compared to other antidepressants and there was no significant difference between adult age groups (Gibbons, 2007). Another study looking specifically at older patients and found that initiation of SSRI therapy is the most closely associated time period that could increase the risk of suicidal behavior when compared with other antidepressants (Juurlink, et al., 2006).

A recent large scale meta-analysis of 200,000 patients of all ages from eight observational studies had been analyzed to specifically look at the correlation between exposure to SSRI antidepressants and the increased rate in suicide completion or attempt. The findings of this study found that not only do SSRIs have a protective effect against suicide in patients age 65 and older, this is true in adults and even in young adults ages 18 to 25 years. This study did find a higher rate of suicide attempts and completions with the adolescent groups when SSRIs were used and supports the FDA's warning of use of antidepressant medications within this age group (Barbui, 2009).

A concern is that as a result of the FDA's antidepressant label warnings, depression is being undertreated in the pediatric community. There is another concern that this trend will be repeated in the young adult group as well. Rates of SSRI prescriptions and suicides were examined in the United States and in the Netherlands after the warnings were issued in 2003 and 2004. In the Netherlands, suicide rates increased by 49% between the years 2003 and 2005. In the United States, this rate increased by 14%. There was an inverse association between suicide rates with SSRI prescriptions. The conclusion that cannot be disputed is that suicide is more common in children with untreated major depression (Gibbons, 2007).

Any nurse involved with treating depressed patients in the community should reach one clear conclusion from these studies: **Safe and successful treatment of a depressed patient depends on much more than merely giving the correct dosage of an antidepressant.** It is not disputed that SSRIs can be physically activating in the initial stages of therapy, but the patient must be kept safe regardless of when the medication was initiated. To achieve this outcome in the community, it is essential to make critical interventions: the first is rooted in the development of a trusting therapeutic relationship with the patient with the goal of facilitating honest communication. This bond encourages the patient to take active responsibility for his or her own safety. Another is to conduct regular neuropsychiatric assessments of patients treated for depression. Can you imagine treating a patient for diabetes and not monitoring blood glucose levels, or giving electrolyte replacement therapy without looking at associated serum levels? Educating the patient and involving the family will play an integral role in providing a safe environment for the patient. Reports in the media may be misinterpreted and there may be a reluctance to seek treatment or take antidepressant medication if prescribed. Depressed patients are at risk of suicide and there seems to be select groups of patients that are more vulnerable to suicidal behavior at the initiation of antidepressant treatment. All precautions must be taken to maintain patient safety. There is much more to treating depressed patients than suggesting that they just take a pill a day and be on their way. Nurses working with patients who take antidepressant medication in the community or in any practice setting should assume that the assessment of the clinical response to antidepressant medication as well as the presence of suicidal thoughts or behavior is *their* responsibility.

Norman, Naing, et al., 2006). However, additional and larger research studies are still necessary to confirm these findings. Also, Native Americans must be included in further reports, because very few data exist for this group.

Other researchers have found that a polymorphism in a gene is linked with therapeutic response to SSRI treatment. Patients with a polymorphism that has the L (or long) allele have better response to an SSRI than patients who have the polymorphism of the S (or short) allele (Yu, Tsai, Chen, et al., 2002; Lotrich, Pollock, & Ferrell, 2003). The L allele is more highly prevalent in African Americans (77% to 87%) than in European Americans (56% to 60%) (Lotrich et al., 2003). Patients who have been identified as having the L allele should receive an SSRI,

such as sertraline, as a drug of first choice for treatment of depression, because they are likely to obtain therapeutic effects from this therapy. Some studies have shown that the outcome of antidepressant treatment runs in families but individual variation to treatment with antidepressant medication has been largely unpredictable. A search for a genetic predictor of response to treatment was reviewed in a prospective study of the 1,953 patients with major depessive disorder treated with the antidepressant citalopram in the Sequenced Treatment Alternatives for Depression Study (STAR D® study). A significant association was found between treatment outcomes with use of citalopram and the presence of the genetic markers which encode HTR2A (Serotonin 2A receptor). Serotonin 2A receptors downregulate with the SSRI medication citalopram and this study suggested this is a genetic variation that could help predict the effectiveness of an antidepressant medication (McMahon, 2006).

Nursing Diagnoses and Outcomes

- Risk for Suicide related to increased energy from sertraline without relief of suicidal ideations or low mood
  Desired outcome: *The patient will identify alternative coping mechanisms.*
- Restlessness related to psychomotor agitation secondary to sertraline use
  Desired outcome: *The patient will identify appropriate interventions to promote relaxation.*
- Sleep Pattern Disturbance: Less than Body Requirements, related to psychomotor agitation secondary to sertraline use
  Desired outcome: *The patient will identify appropriate interventions to promote sleep.*
- Nausea, Abdominal Pain, or both related to abnormal peristalsis secondary to sertraline use
  Desired outcome: *The patient will report a decrease of nausea.*
- Diarrhea and Loose Stools related to adverse effects of medication secondary to sertraline use
  Desired outcome: *The patient will re-establish and maintain normal pattern of bowel functioning.*
- Sexual Dysfunction related to disrupted sexual response pattern, such as impotence or anorgasmia, secondary to sertraline use
  Desired outcome: *The patient will identify satisfying and acceptable sexual practices and some alternative ways of dealing with sexual expression.*

Planning and Intervention

Maximizing Therapeutic Effects

By the time patients begin drug therapy, they may be at their most hopeless state. This state sometimes can even be compounded by their initial response to the medication. Equally important to remember is that the patient does not experience the maximum therapeutic effect for several weeks. Routine, consistent measurement of symptoms and adverse effects needs to occur at each treatment visit. The patient should be assessed using a standardized tool such as the Hamilton Rating Scale for Depression or the Quick Inventory of Depressive Symptomatology–Self Report (Rush et al., 2006). To maximize the therapeutic effect of antidepressant therapy, establish a therapeutic, trusting relationship with the patient by offering the hopeless patient hope for the future by being candid about the therapeutic effects and adverse effects of the medication. Properly administering the medication at regular times, without missing doses, is important as well.

Minimizing Adverse Effects

Remember that any possible adverse effects of sertraline often occur immediately or early in the treatment course. Restlessness or even insomnia may be reported by patients at the beginning of therapy. To minimize these effects, give the medication early in the day, when the patient is most active and least likely to be bothered by such effects. The adverse effects of nausea and diarrhea can be minimized as well by giving the medication with food or even by dividing the daily dose into more frequent, smaller doses. Carefully assess the patient on drug therapy for worsening of depression or signs of suicidal ideation. *Close monitoring of all patients, but especially children, teens and young adult, s is imperative to minimize the risk of suicide*. Closest monitoring needs to be done during the beginning of therapy and at each dose change. To further guard against suicide, sertraline and other SSRIs should be administered only in addition to counseling and therapy, not in its place.

To help the patient minimize any sexually related adverse effects, demonstrate a willingness to discuss these matters with the patient in an open and honest manner. Inquire about any changes in sexual functioning, because changes associated with medication use may lead to nonadherence to drug therapy. Patients should always be discouraged from consuming alcohol while undergoing sertraline therapy because increased central nervous system (CNS) depression may result. It is also important to protect the patient from ultraviolet light until his or her individual photos Sertraline can be associated with developing Serotonin Discontinuation Syndrome; you must consider the length of time the patient has been taking any SSRI, the dosage, and the half-life of the drug before stopping an SSRI. This can occur in 20% to 25% of patients stopping SSRIs abruptly and may last 1 to 2 weeks (Looper, 2007).

The symptoms of this syndrome can be remembered by using the mnemonic FLUSH:

Flu-like (e.g., fatigue, myalgia, loose stools, nausea)
Light-headedness, dizziness, or both
Uneasiness, restlessness, or both
Sleep and sensory disturbances
Headache

Symptoms of sertraline toxicity or overdose are dilated pupils, tachycardia, electrocardiographic (ECG) changes, anxiousness with decreased level of consciousness, and vomiting. No deaths have been reported by overdose involving sertraline alone. However, a few fatalities have occurred when sertraline was mixed with alcohol or other drugs in a deliberate overdose. Management of overdose should include treating presenting symptoms. There are no specific antidotes. Activated charcoal may be as effective as emesis or lavage.

Providing Patient and Family Education

- Educate patients and families about realistic expectations for antidepressant therapy. Include information about the delay in relief of symptoms and the necessity of continuing with the medication even after relief of symptoms is achieved.
- Educate patients and families about potential suicidal ideation. Families need special help to learn how to recognize behavioral changes that may indicate suicidal ideation, because patients may not recognize it in themselves.
- Teach the patient and family to read the Medication Guide that accompanies the filled prescription. They should read it each time they receive a refilled prescription because new information may be included (see Chapter 5, Box 5.2, What is an FDA Medication Guide?).
- Emphasize the risk for SSRI withdrawal syndrome if patients abruptly stop taking their medication.
- Inform patients about possible adverse effects (e.g., nausea, restlessness, insomnia, sexual dysfunction) and advise them on how to minimize disruption to their lifestyle. Emphasize that adverse effects may occur before therapeutic effects and that many of them are transient.
- Discuss the increased stimulant effect that results when sertraline and caffeine are combined and advise patients to modify their diet accordingly.
- Teach patients to avoid alcohol and other CNS depressant drugs to avoid any cumulative depressant effect.
- Caution patients about using heavy machinery or driving until individual response to the drug is known.

Ongoing Assessment and Evaluation

Continue to assess the patient's mood and observe any increase in anxiety, nervousness, restlessness, or insomnia. If the patient becomes physically energized yet experiences little improvement in mood, assess the patient especially closely for suicidal thoughts because he or she is at greater risk of acting on these thoughts under these conditions. Periodically monitor laboratory tests that assess liver function and measure total blood cholesterol and triglycerides to assess the patient for any possible changes. As sertraline therapy continues, expect patients to report an increased interest in their surroundings and more energy to participate in daily activities. Sertraline therapy is considered effective when depression is fully relieved and no serious adverse effects occur.

MEMORY CHIP

P Sertraline

- Selective serotonin reuptake inhibitor used to treat depression, obsessive-compulsive disorder, panic disorder, and post-traumatic stress disorder
- Major contraindications: Cautious use in patients with decreased liver function
- Most common adverse effects: gastrointestinal distress, headache, sleep disturbance, and abnormal ejaculation
- Most serious adverse effect: may possibly increase the risk for suicide, especially in pediatric populations
- **Life span alert: pregnancy category C, see black box warning**
- Maximizing therapeutic effects: Encourage patient to continue medicine, even though immediate response does not occur, and continue medication well after an improvement is experienced.
- Minimizing adverse effects: Give with food; avoid ultraviolet light.
- Most important patient education: Teach that a lag time occurs between beginning therapy and relief of symptoms; avoid alcohol and drugs.
- **Black box warning: may increase the risk of suicidal thoughts or behaviors in children, adolescents, and young adults**

Drugs Closely Related to P Sertraline

Other SSRIs closely related to sertraline include citalopram (Celexa), escitalopram (Lexapro), fluoxetine (Prozac), fluvoxamine (Luvox), and paroxetine (Paxil). Fluoxetine and escitalopram are the only SSRIs that are labeled for use in children, although they carry the same label warning about the potential for increasing suicidal ideation as the other SSRIs. (US FDA, 2009c) Fluoxetine has some unique pharmacokinetic properties. It has a much longer half-life than the other SSRIs. Unlike the others, which are excreted unchanged via the urine and feces, like sertraline, fluoxetine is metabolized in the liver.

Drugs Significantly Different From P Sertraline

Bupropion

Bupropion (Wellbutrin) is a weak blocker of neuronal uptake of norepinephrine and serotonin. It also inhibits, to some extent, neuronal reuptake of dopamine. Bupropion has the benefit of being somewhat energizing for patients with major depression. It also may be coadministered with other SSRIs to decrease the effect of the primary medication when sexual functioning is adversely affected. Research has found that bupropion is successful as a second-line drug when treatment with an SSRI alone has not been totally effective. Patients receive equal benefit from switching to bupropion or having the drug added to their regimen of an SSRI.

Bupropion should be administered with caution to any patient who has an increased seizure risk. Missed doses should never be doubled; seizure may result. Although the usual dose is 300 mg/d, the risk of seizure may be four times greater when bupropion is given at doses between 300 and 450 mg/d.

This risk further increases almost 10 times at doses of between 450 and 600 mg/d. A new salt form of buproprion called Aplenzin (buproprion hydrobromide) has recently been approved and is used in once-a-day dosing. Caution should be taken in patients with renal or hepatic impairment, and like other forms of bupropion, it is contraindicated for patients with any type of seizure disorder (FDA, 2009a).

A form of bupropion called Zyban has been available and is widely used for smoking cessation. Although not indicated for management of depression, it carries the same risks in taking bupropion as an antidepressant and prescribers should monitor patients for neuropsychiatric changes when taking this medication. Taking Zyban for smoking cessation with other forms of bupropion is contraindicated (US FDA, 2009b).

Trazodone

Trazodone (Desyrel) is a weak serotonin transport inhibitor as well as a serotonin receptor ($5\text{-}HT_2$) blocker. This combined action diminishes some of the troubling adverse effects associated with 5-HT transporter inhibitors, such as insomnia, jitteriness, and sexual dysfunction. Trazodone is also an adrenergic receptor blocker that affects both alpha-1 and alpha-2 receptors, so it can cause dizziness and orthostatic changes. It is not recommended for use by patients during the initial recovery phase of a heart attack. Patients with preexisting cardiac disease should also be monitored closely, particularly for cardiac arrhythmias.

Trazodone may cause priapism, a prolonged and often painful penile erection rarely associated with sexual arousal. Trazodone also causes sedation. For this reason it is often prescribed as a supplemental therapy to other antidepressants that cause insomnia as an adverse effect. Trazodone should be taken at bedtime to help promote sleep

Therapeutic response to trazodone usually occurs within 2 weeks. Administered orally, the drug is well absorbed; food enhances its absorption. Metabolism in the liver is extensive; none of its metabolites is believed to be pharmacologically active.

Serotonin and Norepinephrine Reuptake Inhibitors (SNRIs)

This is a class of medication that blocks the reuptake of both serotonin and norepinephrine with differing selectivity. It comprises several drugs: velafaxine (Effexor), duloxetine (Cymbalta), mirtazepine (Remeron), milnacipran (Savella), and desvenlafaxine (Pristiq). They have many similarities to the SSRIs therefore they carry the same risks, such the possibility of serotonin syndrome. These risk factors are described in detail under SSRIs and sertraline. Use of an SNRI or SSRI with an MAOI is strictly contraindicated and a washout period must occur between using these drugs.

Venlafaxine

Venlaflaxine (Effexor) is a mixed norepinephrine and serotonin reuptake inhibitor. It has no significant affinity for adrenergic receptor blockade (alpha-1 or alpha-2), H_1, or Ach receptors. Its pharmacologic effects are dose related, and it exhibits triphasic pharmacologic effects within its dosage range. At the lowest effective dose, venlafaxine primarily affects 5-HT reuptake. Its effects on NE and DA occur at higher concentrations (dosages of more than 300 mg/d). It may cause constipation, diaphoresis, dizziness, hypertension, nausea, nervousness, somnolence, and disturbance in sexual function.

When increasing the dosage, gradual titration is important to maximize venlafaxine's therapeutic effect. Minimizing adverse effects may be accomplished by giving an extended-release formulation of venlafaxine (Effexor XR), which provides more stable plasma and CNS drug levels than the rapidly absorbed and rapidly eliminated immediate-release drug formulation.

Venlafaxine is the most studied of all the SNRIs; many studies suggest that it is superior to SSRIs in treating the severely depressed because is exerts "dual action" inhibiting reuptake of serotonin and norepiphrine. However, when compared with other serotonin and norepinephrine reuptake inhibitors (SNRIs), such as duloxetine and milnacipran, venlafaxine seems to be the least well tolerated, causing serotonergic side effects of nausea, sexual dysfunction, withdrawal problems, and dose-dependent hypertension. It is also more cardiotoxic when compared with duloxetine and milnacipran (Stahl, 2005). Overdosage with venlafaxine has occurred, most commonly when it is used in combination with alcohol or other drugs. It can produce tachycardia, potentially life-threatening ECG changes, hypotension, changes in level of consciousness, mydriasis, seizures, rhabdomyolysis, liver necrosis, serotonin syndrome, vertigo, vomiting, and even death. Death from venlafaxine overdosage is more likely than from SSRIs but not as likely as from tricyclics. Patients should receive a small quantity of capsules when they are first started on drug therapy and are still depressed, in order to minimize the risk of intentional overdosage.

Duloxetine

This SNRI has been approved for treatment of major depression, generalized anxiety disorder, diabetic peripheral neuropathic pain and it has recently been approved for treatment of fibromyalgia. Typical dosing is 40–60 mg/d, in divided doses. It is not recommended for patients with severe hepatic or renal impairment. Common side effects include nausea, dry mouth, constipation, somnolence and decreased appetite (US FDA 2009d).

Desvenlafaxine

Desvenlafaxine (Pristiq) is an SNRI approved for treatment of major depression; it is available in 50 mg and 100 mg tablets. Common side effects are nausea, headache, dizziness, dry mouth, constipation, and decreased libido. Caution should be used in patients with hypertension or history of seizure (FDA, 2009e).

Milnacipran

Milnacipran (Savella) is an SNRI that has been approved for the management of fibromyalgia. All SNRIs show usefulness in relieving chronic pain, a condition that frequently co-occurs with depression (US FDA, 2009f).

Treatment Challenges

Symptoms of depression may not improve with initial treatment. When patients don't respond, there is a risk of stopping an antidepressant too soon or using a subclinical dose, thus preventing a sufficient trial of this medication. The results of a study called Sequenced Treatment Alternatives to Relieve Depression (STAR D*) helped develop treatment guidelines to manage patients with depressive symptoms that do not remit after initial therapy with an SSRI. It was found that two-thirds of the participants of this study did not achieve remission with initial treatment with an SSRI. The study examined the usefulness of switching to other antidepressants, using psychotherapy, or augmenting the original SSRI with medications from different classes: buspirone, bupropion, lithium, or triiodothyroxine were used. For patients who did not attain a full clinical response following these steps in treatment, a change to different antidepressant medication was tried: venlafaxine and mirtazepine (SNRIs), tricyclic antidepressants, or an MAO inhibitor.

To *not* experience improvement of symptoms is a very frustrating experience for patients. The lessons learned from the study help providers to use empirically based strategies to find pharmacologic solutions for patients with major depression that do not initially respond to an SSRI (Sussman, 2007). The addition of second generation antipsychotic medication to an SSRI can be used when psychotic features manifest during a major depressive episode. In cases of severe, chronic depression that does not respond well to medication, a biologic therapy, such as electroconvulsive therapy, is considered.

• C Tricyclic Antidepressants

The tricyclics were named for their molecular structure, which features a three-ring nucleus. They are generally categorized as secondary or tertiary amines. Most secondary amines (e.g., amoxapine, desipramine, maprotiline, mirtazapine, nortriptyline, and protriptyline) are better tolerated than tertiary amines (e.g., amitriptyline, clomipramine, doxepin, imipramine, and trimipramine). Although the tricyclics are similar in treating depression, they differ in potency and selectivity. Patients taking tertiary amines generally experience an increased incidence of anticholinergic effects, cardiovascular adverse effects, and impaired memory and cognition. The tertiary amines have a very narrow therapeutic index; even a moderate overdose, such as a dose greater than 1 g, is toxic and can be fatal. These are a few of the reasons secondary amine tricyclics are preferred over the tertiary amine tricyclics.

All tricyclics enhance the activity of norepinephrine and serotonin by blocking neuronal reuptake of these neurotransmitters. Their lack of specificity affects other receptor systems and is associated with anticholinergic, neurologic, and cardiovascular adverse effects.

The prototype tricyclic is nortriptyline (Pamelor), a secondary amine. Although secondary amines do not have as many of the adverse effects as the tertiary amines, they do share the same potential for cardiovascular toxicity. It is because of this risk that the tricyclics are not considered a first-choice treatment for depression.

Nursing Management of the Patient Receiving P Nortriptyline

Core Drug Knowledge

Pharmacotherapeutics

Nortriptyline is used to relieve the symptoms of depression. It is also used off-label at dosages of 75 to 300 mg/day as adjunctive analgesia for phantom limb pain and chronic pain (such as in migraine, chronic tension headache, diabetic neuropathy, trigeminal neuralgia, cancer pain, painful peripheral neuropathy, postherpetic neuralgia, and arthritic pain) and for cocaine withdrawal, panic disorder, bulimia nervosa, and premenstrual syndrome.

Pharmacokinetics

Nortriptyline is well absorbed from the gastrointestinal tract, achieving peak plasma concentrations in 2 to 4 hours. It undergoes a substantial first-pass effect and is highly bound (more than 90%) to plasma proteins, lipid soluble, and widely distributed in tissues, including the CNS. Wide individual variation occurs in steady-state plasma levels at a given dosage, primarily because of differences in the rate of metabolism or first-pass effect. Effective dosage levels vary greatly and must be individualized. Metabolism of nortriptyline and the other tricyclics occurs in the liver, through the P-450 enzyme system.

Pharmacodynamics

Nortriptyline specifically blocks reuptake of NE into nerve terminals, thereby allowing increased concentration at postsynaptic receptor sites. The chemical structure and pharmacologic activity of nortriptyline resemble those of the phenothiazine antipsychotics (see Chapter 17). Three major pharmacologic actions of nortriptyline are blocking of the amine pump, sedation, and peripheral and central anticholinergic action. Other pharmacologic and clinical effects include inhibition of histamine, sedation, and mild peripheral vasodilator effects.

Contraindications and Precautions

Nortriptyline should be used with extreme caution in patients with cardiovascular disorders because of the possibility of conduction defects, arrhythmias, chronic heart failure, sinus tachycardia, myocardial infarction, stroke, and tachycardia. These patients require cardiac surveillance at all dosage levels of the drug. In high doses, nortriptyline may produce arrhythmias, sinus tachycardia conduction defects, and prolonged conduction time. Elderly patients and patients with a history of cardiac disease are at special risk for developing cardiac abnormalities. Patients with hyperthyroidism or those receiving thyroid medications require close supervision because of the possibility of cardiovascular toxicity, including arrhythmias.

Nortriptyline can slow cardiac conduction and cause arrhythmias. It is possible that a patient will be sensitive to any of the tricyclics once he or she has developed sensitivity to one of them.

Because nortriptyline, like other tricyclics, lowers the seizure threshold, it should be used with caution in patients with a history of seizures or other predisposing factors (e.g., brain damage of varying etiology, alcoholism, concomitant drugs known to lower the seizure threshold). However, seizures have also occurred following administration of tricyclics to patients with no history of seizure disorders. Because of its anticholinergic effects, nortriptyline should be used with caution in patients with a history of urinary retention, glaucoma, or increased intraocular pressure because even an average dose may precipitate a recurrence. Human fetal risk has been demonstrated during clinical trials and postmarketing surveillance, which puts nortriptyline in FDA pregnancy category D. With other tricyclics such as amitriptyline and imipramine, there have been clinical reports of congenital malformations and limb-reduction anomalies.

Adverse Effects

Adverse effects are related to nortriptyline's effects on neurotransmitters. In comparison to drugs in this class that are tertiary amines, nortriptyline and other secondary-amine tricyclics have less effect on the histamine, cholinergic, and alpha-1 adrenergic receptor sites. At usual therapeutic concentrations, they block NE reuptake. Patients report sedation and anticholinergic effects most frequently, although they usually develop tolerance to these effects. Other adverse effects include disturbed concentration and confusion (especially in older adults), headache, tremors, nausea, vomiting, bone marrow depression, urinary retention, sexual function disturbances, skin rash, nasal congestion, and weight gain, which may be significant. In agitated patients, increased anxiety or agitation may occur. Schizophrenic or paranoid patients may exhibit a worsening of their psychoses. Because photosensitivity may occur, patients receiving nortriptyline should avoid sun exposure or use protective measures to prevent skin reactions.

Nortriptyline can cause skin rashes or "drug fever" in susceptible people. These allergic reactions are rarely severe. They are most likely during the first few days of treatment but may also occur later. If a patient develops rash or fever, the drug should be discontinued.

At the upper limit of the therapeutic range, serious and potentially life-threatening cardiac and CNS effects may begin to develop. Overdosage produces symptoms that are primarily an extension of the common adverse reactions. Cardiac irregularities, especially tachycardia and conduction disturbances, are common and create the most serious hazards. Fatal arrhythmias may occur as long as 56 hours after overdose. Other problems include metabolic acidosis, respiratory depression, seizures, and extremely high fever. Box 16.3 describes emergency measures for tricyclic overdose.

DRUG INTERACTIONS

Nortriptyline is associated with multiple drug interactions because it, like other tricyclics, is metabolized through the P-450 liver enzyme system. Drugs with potential for interaction with nortriptyline include sedative-hypnotics, alcohol, antihypertensives, antiarrhythmics, and anticholinergics. Nortriptyline and other highly protein-bound substances, such as aspirin, phenytoin, and phenothiazines, may compete for binding sites. Other drugs, such as methylphenidate, oral contraceptives, and antipsychotics, may interfere with the metabolism of nortriptyline. Nortriptyline may prevent the antihypertensive action of some drugs by their primary and secondary effects at the NE synapses. Administering nortriptyline with an MAOI may result in severe CNS toxicity. Nortriptyline potentiates the sedative effects of alcohol. Table 16.5 summarizes interactions that can occur with nortriptyline.

Box 16.3 EMERGENCY MEASURES FOR TCA OVERDOSE

- Provide symptomatic and supportive care.
- Monitor cardiac changes continually.
- Administer phenytoin, lidocaine, or propranolol as prescribed for life-threatening cardiac arrhythmias.
- Avoid giving drugs such as quinidine, procainamide, and disopyramide. These agents depress myocardial conductivity and contractility.
- Reserve administration of the cholinergic agonist physostigmine for life-threatening, refractory anticholinergic symptoms.

Assessment of Relevant Core Patient Variables

Health Status

Assess patients for pre-existing cardiovascular disease because these patients are especially sensitive to the potential cardiotoxicity of nortriptyline. Assess patients carefully for a history of seizure activity or organic brain disease because nortriptyline lowers the seizure threshold.

Life Span and Gender

Consider age-related factors associated with nortriptyline therapy. Lower dosages are recommended for adolescents and older adults. The dosage should be increased slowly depending on the clinical response and any evidence of intolerance.

Children are especially susceptible to the cardiotoxic and seizure-inducing effects of high doses of nortriptyline. Because of these safety issues and the uncertain benefit to children and adolescents, other types of antidepressants should be considered before nortriptyline or other tricyclics. Elderly patients may be especially sensitive to the anticholinergic adverse effects of nortriptyline, and this sensitivity can result in confusion, disorientation, delusions, and hallucinations. The combination of these symptoms can continue to worsen to the extent that the patient even becomes delirious. Older adults may be at an increased risk for falls during drug therapy with nortriptyline.

TABLE 16.5 Agents that Interact with P Nortriptyline

Interactants	Effect and Significance	Nursing Management
alcohol	Increased sedative effects	Avoid coadministration
anticholinergic agents	Increased anticholinergic effects	Assess patient for increasing tachycardia, dry mouth, blurred vision, constipation, and urinary retention. Coadminister with caution.
barbiturates	Decreased serum concentration of nortriptyline Potential additive CNS depression	Anticipate need for increase in nortriptyline dosage. Institute safety measures. Monitor neurologic status closely.
cimetidine, haloperidol, SSRIs	Increased plasma concentration of nortriptyline	Monitor serum levels as appropriate. Assess for signs of nortriptyline toxicity.
clonidine	Increased risk for hypertension and hypertensive crisis Increased anticoagulant effects	Monitor blood pressure closely. Avoid coadministration.
dicumarol		Assess for signs and symptoms of bleeding. Anticipate need for decreased dosage of dicumarol. Avoid coadministration.
guanethidine	Antagonism of guanethidine action	Monitor blood pressure closely.
disulfiram	Increased risk for organic brain syndrome Increased effect of nortriptyline	Avoid coadministration.
levodopa	Delayed levodopa absorption and decreased bioavailability	Assess for therapeutic effects of both drugs.
MAOIs	Hyperpyrexia, sweating, confusion, seizures, tachycardia, tachypnea, hypotension, coma, DIC, and death	Avoid coadministration. Discontinue MAOIs 7–10 days before starting nortriptyline.
oral contraceptives, phenothiazines	Inhibition of hepatic enzyme system metabolism of nortriptyline leading to increased plasma levels	Monitor for signs and symptoms of nortriptyline toxicity.

Assess women of childbearing age for pregnancy or intention to become pregnant, Neonatal toxicity in the forms of anticholinergic effects: urinary retention and bowel obstruction can develop with use of tricyclic antidepressants. Of all the tricyclic antidepressants, Desipramine is the preferred medication because of it relatively lower anticholingergic effects. Therefore, the drug should be used only when potential benefits to the mother outweigh potential hazards to the fetus. Also, ask if female patients are breast-feeding. Tricyclic antidepressants, with the exception of Doxepin, do not accumulate in breast-fed babies. Amitriptyline and imipramine appear to be the most appropriate drugs when needed during breast feeding (Menon, 2008).

Lifestyle, Diet, and Habits

Adverse effects of nortriptyline can be very similar to the symptoms of depression. For this reason, it is important to evaluate the patient's symptoms within the context of his or her lifestyle before starting nortriptyline therapy.

Ask the patient whether he or she performs activities that require mental alertness, manual dexterity, or motor coordination. Nortriptyline may impair concentration and coordination; hence, the patient receiving nortriptyline should perform such activities with caution until actual drug effects on the individual patient are known.

Photosensitivity may also develop as a result of nortriptyline therapy. Patients whose lifestyles expose them to the outdoors need to protect themselves from overexposure to sunlight.

Culture and Inherited Traits

Keep in mind inherited traits relevant to therapy with nortriptyline. Very little published information exists concerning differences in antidepressant pharmacology among African Americans, Hispanic Americans, and white Americans of European descent (Wood & Zhou, 1991); however, some studies have suggested that ethnicity influences the pharmacokinetics, pharmacotherapeutics, and pharmacodynamics of **psychotropic** drugs (agents that affect the mind,

emotions, or behavior). For example, results of one study showed that plasma nortriptyline levels were 50% higher in African American patients than in white Americans. Another reported that Hispanic American patients have greater sensitivity than others to the anticholinergic effects of tricyclics and therefore require a lower dosage. Collected survey data from multiple Asian countries indicated that imipramine and amitriptyline dosages were much lower than those customary in the United States, suggesting that Asians achieve significantly higher plasma concentrations of tricyclics and have lower clearance rates than whites. Although these studies have been criticized for improper control of independent variables, such as dosage for body weight or smoking and even diet or alcohol consumption, it is prudent to consider a patient's ethnic background, at least in part, until more conclusive studies prove otherwise.

As nortriptyline is metabolized by the P-450 system, it is helpful to identify inherited differences in these isoenzymes which can alter drug metabolism. Genotypes for two P-450 isoenzyme genes, P-450 2D6 and P-450 2C19, can be identified using the AmpliChip CYP450 laboratory test (de Leon, Susce, & Murray-Carmichael, 2006). This test classifies patients into two phenotypes for P-450 2C19 (extensive metabolizers and poor metabolizers). Three to four percent of Caucasians and African American are poor metabolizers of P-450 2C19, in comparison with 14% to 21% of Asians. Using the AmpliChip test, it is possible to identify four phenotypes of P-450 2D6: ultrarapid metabolizers, extensive metabolizers, intermediate metabolizers, and poor metabolizers. Ultrametabolizers have unusually high activity, extensive metabolizers are considered "normal," intermediate metabolizers have low activity of P-450 2D6, and poor metabolizers have no activity. For the isoenzyme P-450 2D6, 7% of Caucasians and 1% to 3% of other ethnic group are poor metabolizers. Downward adjustment in the dose of nortriptyline or other tricyclics is most likely needed by those who are poor metabolizers for each of these isoenzymes.

Nursing Diagnoses and Outcomes

Several nursing diagnoses may apply to the depressed patient receiving nortriptyline therapy. Examples include:

- Constipation or Diarrhea related to medication use
  Desired outcome: *The patient will establish normal bowel habits.*
  Disturbed Sleep Pattern related to medication-induced somnolence or insomnia
  Desired outcome: *The patient will report a satisfactory balance of rest and activity.*

In addition to these, selected nursing diagnoses for treatment with nortriptyline include the following:

- Risk for Poisoning related to TCA toxicity
  Desired outcome: *The patient will identify factors that increase the risk for and verbalize practices to prevent poisoning.*
- Risk for Injury related to adverse effects (e.g., blurred vision, drowsiness, and hypotension) secondary to nortriptyline use
  Desired outcome: *The patient will identify factors that increase the risk for and relate intent to practice safety measures to prevent injury.*
- Imbalanced Nutrition: More than Body Requirements, related to adverse effects of nortriptyline
  Desired outcome: *The patient will verbalize reasons for a risk for weight gain, identify normal nutritional needs, and discuss methods to control weight.*
- Disturbed Sensory Perception related to chemical alterations secondary to nortriptyline therapy
  Desired outcome: *The patient will experience normal sensory perception.*

Planning and Intervention

Maximizing Therapeutic Effects

Use therapeutic drug monitoring to monitor effective plasma drug levels to achieve the greatest likelihood of antidepressant response and the smallest risk of adverse effects. Optimal serum concentrations for nortriptyline are 50 to 150 ng/mL. For maintenance therapy, a single daily dose of nortriptyline may be used. A single daily dose at bedtime, if convenient, minimizes the daytime adverse effect of sedation. The sedative effect at bedtime may be beneficial in patients with concomitant sleep disorders.

Following remission, the patient may require maintenance medication for a longer time at the lowest dose that maintains remission. Maintenance therapy should continue for at least 3 months to decrease the possibility of relapse.

Minimizing Adverse Effects

Although the half-life of nortriptyline is long enough to permit single daily dosing, adverse reactions may require divided dosing schedules. Because older adults have an increased risk of adverse effects, they should receive initial doses equivalent to one half to one third of the dose administered to younger adults. Ultimately, elderly patients may benefit by receiving nortriptyline in split doses, because they may be unable to tolerate single daily doses. Regular ECG monitoring of cardiac rhythm is essential for any person taking nortriptyline. Therapy may also induce neutropenia; watch for clinical indicators such as fever or sore throat, which may signal serious neutrophil depression; therapy should be discontinued if such evidence of pathologic neutropenia occurs. In addition to serum levels of the drug, periodically monitor blood studies, including a complete blood count with differential, serum glucose level, and renal and hepatic function. Monitoring helps detect adverse effects so that intervention can occur before interrupted drug therapy or nonadherence compromises the therapeutic effect. Closely monitor patients with glaucoma during drug therapy, because nortriptyline may precipitate an acute episode of angle-closure glaucoma.

As with all antidepressant therapy, continue assessing the patient for low mood and suicidal thoughts. When a patient is most depressed, he or she may have thoughts of suicide but at the same time may not have enough energy or concentration to plan and follow through on these thoughts. However, the risk of suicide increases if the suicidal thoughts remain while the patient's concentration and energy improve to the point at which he or she can act on the suicidal thoughts. This fact is particularly important with the patient taking tricyclics because the very drug taken to treat the depression can also be taken in a lethal dose to commit suicide. Ensure patient safety by closely monitoring the number of pills that are accessible to him or her.

Providing Patient and Family Education

- Teach patients and families that the therapeutic response will not be immediate. Several weeks may pass before any measurable clinical effect is noted. The symptoms of depression may come and go during the earliest stages of treatment. If this possibility is not discussed, patients may become even more hopeless, thinking that they will never be symptom-free. Also, discuss the ongoing risk of suicide with patients and families.
- It is also important to teach patients about the need to continue with nortriptyline therapy even after initial relief of depressive symptoms. Inform them that stopping the medication at this time will most likely result in a relapse of the depressive symptoms.
- Stress the importance of taking the drug exactly as prescribed and of not stopping the drug abruptly or without consulting with the health care provider. Abrupt discontinuation may cause nausea, headache, and malaise.
- Help patients stay motivated to continue treatment. To promote adherence to the therapeutic regimen, educate patients and families about the medication effects—both therapeutic and adverse. Advise patients about adverse effects that, if unexplained, may contribute to nonadherence. These effects include sweating, weight gain, and sexual dysfunction.
- Warn patients of the possibility of photosensitivity reactions. Advise them to avoid prolonged exposure to sunlight or bright artificial light, to apply sunscreen before exposure, and to wear protective clothing.
- Emphasize the importance of keeping the drug safely stored and away from curious children. Children are very susceptible to nortriptyline-induced cardiotoxicity.
- Caution patients to avoid operating machinery, driving a vehicle, or engaging in activities that require focus and concentration until they are aware of their own individual response to the medication. Most antidepressants cause some degree of sedation and may impair mental alertness and physical coordination. Because certain drug combinations produce an additive CNS depressant effect, patients should not use antidepressants concurrently with alcohol or sleep-inducing drugs such as sedative-hypnotics.
- Advise patients to wear or carry medical identification, such as a Medic Alert tag, regarding antidepressant therapy because nortriptyline can interact with many other drugs.

Ongoing Assessment and Evaluation

Continually assess depressed patients for suicidal thoughts during nortriptyline therapy. As with all antidepressant therapy, the depressed patient with suicidal thoughts is at greatest risk for self-harm once he or she has become sufficiently energized to act on the thoughts. Because of the potential for drug-related toxicity to the heart, all patients, particularly those receiving higher than usual dosages of nortriptyline or other tricyclics, should have periodic ECG examinations regardless of normal cardiac functioning before treatment. Patients with pre-existing cardiovascular disease should be closely monitored, with ECG tracings performed routinely.

Patients taking multidrug therapies should be monitored for other effects as well because other drugs, such as antihypertensives, alcohol, and therapeutic hormones, may cause depression.

Obtain baseline and periodic laboratory blood tests to monitor leukocyte counts, differential blood cell counts, and liver function studies. Also, monitor drug serum levels to ensure that therapeutic levels are maintained. Nortriptyline therapy is considered effective when depression is relieved and adverse effects either do not occur or are minimal.

MEMORY CHIP

P Nortriptyline

- Tricyclic secondary amine antidepressant used to treat symptoms of depression
- Major contraindication: cautious use in patients with pre-existing cardiovascular disease
- Most common adverse effects: drowsiness, dry mouth, constipation, hypotension
- Most serious adverse effect: arrhythmias caused by changes in atrioventricular conduction
- **Life span alert: not recommended for children; decrease or divide the dosage for elderly patients, see black box warning**
- Maximizing therapeutic effects: Maintain a therapeutic serum plasma level; continue therapy at least 3 months to prevent relapse.
- Minimizing adverse effects: Give entire dose at bedtime to decrease drowsiness.
- Most important patient education: Symptom relief is not immediate and may take several weeks; when symptoms are relieved, medication must be continued.
- **Black box warning: may increase the risk of suicidal thoughts or behaviors in children, adolescents, and young adults**

BOX 16.4 FOCUS ON RESEARCH

Recovery from Major Depression in the Older Adult.

Dew, M., Whyte, E., Lenze, E., Houck, P., Mulsant, B., Polluck B., Stack, J., Bensasi S., Reynolds, C., (2007). Recovery from major depression in older adults receiving augmentation of antidepressant pharmacotherapy. *American Psychiatric Association*. 164(6):892–899.

This study used recommendations from the STAR D study (Rush, 2006) to examine if older adults could attain the same benefit of augmenting SSRI type antidepressant medication with an addition of another type of antidepressant if there was a poor initial clinical response. With this study, 195 older adults were treated for major depression disorder using paroxetine and psychotherapy. Subjects in the study were regularly evaluated, out of the 195 participants 105 were deemed to have an inadequate response to paroxetine and psychotherapy or had experienced a relapse after an initial promising response to these therapies. These 105 participants were offered a next step at treatment, some declined and fell out of the study and some could not continue with the study because of co-morbid illnesses. This left 69 participants to receive augmentation with either sustained released bupropion, notriptyline or lithium carbonate added to the participant's regime of paroxetine or psychotherapy.

The findings of this study were as follows:

- About 50% of these 69 participants experienced improvement in symptoms using the augmentation protocol outlined in the study.
- Poor sleep patterns at the beginning of the study was found to be the most significant variable associated with the participants who required augmentation.
- The recovery of the participants who did not respond to initial treatment with paroxetine and psychotherapy was much slower than the individuals who initially showed clinical remission of symptoms but then experienced a relapse.
- The recovery of participants with more medical complications and anxiety was also slower than other participants.
- The participants who required augmentation had a higher frequency of side effects with the addition of another antidepressant medication.

The authors of the study concluded that older adults can benefit from augmentation. They did concede however, that switching to a different antidepressant medication if the first one did not work (given at appropriate dosages and duration), may be just as effective a strategy for elderly patients; it is a simpler medication regime, it has less possibility of drug-drug interactions and would have lower economic costs.

Nursing implications

Although enormous gains have been made in understanding and treating major depressive disorder, this mental illness is typically very resistant to treatment. Confounding the diagnosis and treatment of major depression in the older adult are the physiologic complications of aging and co-morbid medical illnesses. Untreated depression results in poor quality of life, a higher incidence of co-morbid medical problems and ultimately higher rates of mortality. The conclusions of this study supported the practice of using an evidenced based protocol outlined by the STAR D* Study with elderly patients who do not respond to initial antidepressant and psychotherapy. The practice of adding additional medication however, is not without inherent risks to the elderly patient. Since poor sleep was a significant variable that correlated with the participant's lack of response to initial therapy, this should be a symptom that nurses listen to in all patients rather than dismissing it's significance. Additionally, a little prevention could go a very long way: patients with chronic medical illnesses are at risk for developing major depression, these patients should have regular screening before significant symptoms of major depression develop because of the high rates of resistance to treatment. Given our numbers in practice and exposure to the elderly in many practice settings, registered nurses are well poised at identifying patients who are at risk for depression and should have a watchful eye for potential complications in treatment.

• C Monoamine Oxidase Inhibitors

The monoamine oxidase (MAO) enzyme system is widely distributed throughout the body. This system is responsible for metabolizing amines such as dopamine, epinephrine, norepinephrine, and serotonin. Drugs described as MAOIs inhibit MAO enzymes, thereby increasing the concentration of those amines.

There are two subtypes of MAO. MAO A, found primarily in the gastrointestinal tract, liver, and peripheral adrenergic nerves, predominantly metabolizes norepinephrine, serotonin, and tyramine. MAO B, found in the brain, primarily metabolizes dopamine. Although the precise antidepressant mechanism of MAOIs is unclear, it is thought that the increases in norepinephrine and serotonin or changes in other amine concentrations in the CNS are responsible. MAOIs were initially used to manage tuberculosis. It was observed that patients taking these drugs often experienced an elevation in their mood and hypotension. Although they are effective as antidepressants and antihypertensives, their use is limited by their potential to cause intense adverse effects and potentially fatal interactions, such as hypertensive crisis. Potentially fatal pharmacodynamic drug–drug interactions can occur with MAOIs when they are combined with a variety of drugs that are norepinephrine or serotonin agonists or with foods rich in tyramine, such as air-dried, aged, and fermented meats, sausages, and salamis, aged cheeses, tap beers, and soy sauce. Because MAOIs are irreversible inhibitors of monoamine oxidase, up to 2 weeks may be required for normal amine metabolism to be restored once the drug is discontinued.

In general, nonselective MAOIs are indicated for patients who are unresponsive to other antidepressant pharmacotherapy. They are rarely first-choice drugs. The prototype MAOI is phenelzine (Nardil).

Nursing Management of the Patient Receiving P Phenelzine

Core Drug Knowledge

Pharmacotherapeutics

Phenelzine is used mainly to treat depression that is unresponsive to other drug therapy or treatments. Patients may have mixed anxiety and depression with phobic or hypochondriacal features. In some cases, phenelzine is used

to treat bulimia, cocaine addiction, and panic disorder associated with agoraphobia.

Pharmacokinetics

Phenelzine appears to be well absorbed following oral administration, and peak levels of phenelzine are reached in 2 to 4 hours. However, maximum inhibition of phenelzine does not occur for 5 to 10 days. Antidepressant action can take from 7 days to 8 weeks. Phenelzine is excreted in the urine, mostly as metabolites.

Half-life is fairly short and unrelated to the length of enzyme inhibition, which is prolonged: The clinical effects of phenelzine may continue for up to 2 weeks after therapy is discontinued.

Pharmacodynamics

Phenelzine increases the concentrations of DA, NE, and serotonin within the neuronal synapse because it inhibits the enzyme monoamine oxidase. Phenelzine, a hydrazine derivative, irreversibly inhibits both MAO A and MAO B.

Contraindications and Precautions

Poor liver function is a contraindication for using phenelzine because hydrazine compounds damage the functional tissues of the liver. Phenelzine is also contraindicated in patients with chronic heart failure. Cautious use is advised in patients with ischemic heart disease or a history of stroke or myocardial infarction because phenelzine may produce cardiovascular depressing effects, such as orthostatic hypotension, bradycardia, and decreased contractility of the heart muscle.

Adverse Effects

Toxic drug levels, which may damage the liver, can occur and appear to be unrelated to phenelzine dosage or treatment duration. Other adverse effects are anticholinergic, including blurred vision, constipation, and dry mouth. These effects are more pronounced at dosages above 45 mg/d. CNS-related adverse effects include akathisia, ataxia, dizziness, drowsiness, headache, insomnia, and nystagmus. Adverse effects related to other systems include agranulocytosis, anemia, leukopenia, thrombocytopenia, sexual function disturbances, and urinary retention.

The most serious adverse reactions involve changes in blood pressure and hypertensive crisis. Use of these drugs in elderly or debilitated patients or in patients with hypertension, cardiovascular problems, or cerebrovascular disease is inadvisable.

Drug Interactions

Pseudoephedrine and phenylpropanolamine, which are examples of mixed-acting sympathomimetics, are common ingredients in over-the-counter (OTC) decongestants, appetite suppressants, and weight-loss products. They release NE from adrenergic nerve endings. The indirect-acting sympathomimetics also trigger NE release. Acute, severe, and potentially fatal hypertensive crises are possible when combining phenelzine with drugs from either of these classes, tyramine, or tryptophan. Table 16.6 lists drugs that can interact with phenelzine.

These drug–drug or drug–food interactions occur because phenelzine and the other agents act in peripheral adrenergic nerve endings to increase the buildup of NE, although they prevent the release of NE in response to normal nerve activity. However, when phenelzine is combined with the mixed-acting and indirect-acting sympathomimetics, NE release is not inhibited. The result is an intense adrenergic response because of the extra supply of NE. Ingesting a tyramine-containing food or a sympathomimetic drug may precipitate a hypertensive crisis. Normally, MAO enzymes in the liver metabolize these substances rapidly. However, when MAO enzymes are inhibited, tyramine metabolism decreases and triggers the release of accumulated NE, triggering a hypertensive episode. The earliest symptom may be a severe headache. The necessity of avoiding these substances to prevent a life-threatening hypertensive crisis is the major limitation of MAOIs. Table 16.7 lists the tyramine-rich foods that should be avoided by patients taking MAOIs.

Assessment of Relevant Core Patient Variables

Health Status

Perform a baseline cardiovascular assessment and complete blood count and liver function tests for the patient taking phenelzine. Assess the patient's orientation, mood, and affect because phenelzine may cause memory and emotional changes, irritability, and nervousness.

Life Span and Gender

Consider the patient's age and its relation to phenelzine therapy. Phenelzine is not recommended for patients younger than 16 years. Because patients older than 60 years may be more prone to adverse drug effects, dosages (less than 60 mg/d) should be increased gradually and adjusted accordingly.

Ask women of childbearing age if they are pregnant, intend to become pregnant, or are breast-feeding. Phenelzine is in FDA pregnancy category C. It crosses the placenta and enters breast milk.

Lifestyle, Diet, and Habits

Assess the patient's lifestyle to determine whether he or she performs activities requiring alertness, physical coordination, or manual dexterity. Because of possible associated adverse effects such as ataxia, drowsiness, and blurred vision, patients need to exercise caution when driving or operating machinery. Also, evaluate the patient's nutritional status. Pyridoxine deficiency, frequently observed as numbness and swelling, is associated with phenelzine use. For this reason, the patient may need a pyridoxine (vitamin B_6) supplement. Ask the patient about his or her participation in outdoor activity, because phenelzine may cause photosensitivity. The patient should wear sunscreen and protective clothing in prolonged outdoor exposure, such as recreational or occupational pursuits.

TABLE 16.6 Agents That Interact with P Phenelzine

Interactants	Effect and Significance	Nursing Management
anesthetics	Adverse cardiovascular effects from sympathetic stimulation	Monitor heart rate, rhythm, and blood pressure for adverse effect from sympathetic stimulation.
antihypertensives (e.g., guanethidine, methyldopa)	Loss of antihypertensive effects	Monitor blood pressure for degree of control.
beta-adrenergic blockers	Bradycardia possible during concurrent use of MAOIs and beta-adrenergic blockers	Monitor heart rate, rhythm, and cardiac output for adverse effect from bradycardia.
dextromethorphan	Hyperpyrexia, hypotension, and death associated with this combination*	Caution patients taking MAOIs to avoid OTC cold and cough preparations.
levodopa	Hypertensive reactions with combinations of levodopa and MAOIs	Avoid concurrent administration. Monitor cardiovascular status for adverse effect.
L-tryptophan	Coadministration resulting in hyperreflexia, confusion, disorientation, amnesia, ataxia, and Babinski signs	Caution the patient taking MAOIs to avoid food supplements, herbal/homeopathic, or home remedies without approval from the health care provider.
meperidine	Coadministration may result in agitation, seizures, fever, apnea, and death with possible adverse reactions weeks after MAOI withdrawal	Avoid concomitant administration of MAOIs and meperidine. For analgesia, administer other narcotic analgesics with caution.
SSRI, TCA, or venlafaxine antidepressants	Potential serious (occasionally fatal) reactions, including hyperthermia, rigidity, autonomic instability with labile blood pressure, myoclonus, and extreme agitation	Monitor neurologic and cardiovascular status for adverse effect.
sulfonamide compounds	Coadministration may cause either sulfonamide or MAOI toxicity	Avoid concurrent administration.
sulfonylurea anti-diabetic agents	Possible potentiation of hypoglycemic response and delayed recovery from hypoglycemia	Monitor patients with diabetes for level of control and incidence of hypoglycemic episodes.
sumatriptan	Coadministration may cause sumatriptan toxicity	Avoid concurrent administration.
sympathomimetics (mixed acting or indirect acting, including anorexiants)	MAOI potentiation of sympathomimetic substances may cause severe headache, hypertension, hyperpyrexia possibly resulting in hypertensive crisis	Avoid concurrent administration.†
thiazide diuretics	Exaggerated hypotensive effects may result from concurrent use	Avoid concurrent administration. Monitor cardiovascular status and blood pressure for degree of control.

*Interaction inconclusive due to lack of adequate patient data.
†Direct-acting agents appear to interact minimally (if at all).

Assess the patient for willingness to adhere to the dietary restrictions required with phenelzine therapy. Assess for use of herbal preparations such as St. John's wort, L-tryptophan, and ginseng because they can interact with phenelzine.

Environment

Consider the environment in which phenelzine will be administered. The drug should be kept in a tightly closed container away from light and heat.

Culture and Inherited Traits

Consider the patient's ethnic background when beginning drug therapy with phenelzine. Acetylation inactivates phenelzine and its metabolites. About one half of Americans and Europeans (and more in Asia) are slow acetylators of hydrazine-type drugs, including phenelzine. This fact may contribute to the exaggerated effects observed in some patients who receive standard doses of phenelzine.

Nursing Diagnoses and Outcomes

- Risk for Injury related to drug–nutrient, drug–drug, or drug–environment interactions or hypertensive crisis secondary to phenelzine antidepressant therapy
  Desired outcome: *The patient will remain safe and injury-free during drug therapy.*
- Ineffective Therapeutic Regimen Management related to MAOI-required dietary restrictions
  Desired outcome: *The patient will acknowledge an understanding of the need to follow a low-tyramine diet and demonstrate appropriate dietary choices.*
- Imbalanced Nutrition: More than Body Requirements, related to adverse effect of phenelzine
  Desired outcome: *The patient will understand and acknowledge the risk for weight gain, identify normal nutritional needs, and discuss methods to control weight.*

Planning and Intervention

Maximizing Therapeutic Effects

Before phenelzine therapy is initiated, platelet MAO enzyme activity (mostly B subtype) is usually measured. After therapy is under way, an inhibition of more than 85% is associated with therapeutic response. However, platelet enzyme inhibition exceeding 95% increases the risk of serious drug and food interactions.

Minimizing Adverse Effects

The primary difficulties with phenelzine are the numerous dietary and medication restrictions that the patient must obey to avoid drug–food and drug–drug interactions. Taking phenelzine with foods high in tyramine or with certain drugs (e.g., ephedrine, dextromethorphan, cocaine, decongestants, appetite suppressants) increases the potential for a hypertensive crisis. The symptoms of hypertensive crisis include severe occipital headache, stiff neck, nausea, vomiting, diaphoresis, and extremely elevated systolic and diastolic blood pressure.

Advise the patient to avoid herbal preparations such as St. John's wort, L-tryptophan, and ginseng because they can interact with MAOIs. Encourage the patient to consult with the prescriber of the medication before using any OTC products. Alcohol (especially beer, ale, sherry, and Chianti wine), stimulants, and illicit drugs should never be used because they increase the likelihood of adverse effects or hypertensive crisis. Dosages exceeding 30 mg/d may result in postural hypotension, leading to syncope. If dosage increases are necessary, they should be made gradually. Other measures to minimize adverse effects include maintaining a tyramine-restricted diet during and for at least 2 weeks after phenelzine therapy and giving the drug with food or milk if gastrointestinal discomfort is problematic. If the patient has been on fluoxetine therapy, at least 6 weeks should elapse before phenelzine therapy begins.

Providing Patient and Family Education

- Warn all patients taking phenelzine against eating foods with high tyramine content or consuming alcohol during and for 2 weeks following phenelzine treatment. Ensure that the patient taking phenelzine understands and follows the special required dietary guidelines (see Table 16.7 for

a list of foods to avoid). Any aged food has the potential to produce a hypertensive crisis in patients taking phenelzine.
- Caution patients against self-medication with certain proprietary agents such as cold, hay fever, or weight-reduction preparations containing sympathomimetic amines while undergoing phenelzine therapy.
- Stress the importance of not discontinuing the phenelzine, adjusting the dosage, or ingesting any other medication, even OTC preparations, except on the advice of the prescriber. Alert patients that the medication may cause drowsiness or blurred vision and warn them to exercise caution when driving or performing other tasks that require alertness, coordination, or physical dexterity until effects of the drug are known.
- Alert patients to the possibility of dizziness, weakness, or fainting when arising from a sitting position.
- Emphasize to patients and families that antidepressant effects may be delayed a few weeks. Caution them to notify the health care provider if the patient develops severe headache, palpitations, tachycardia, a sense of constriction in the throat or chest, sweating, dizziness, neck stiffness, nausea, vomiting, or other unusual symptoms.

Ongoing Assessment and Evaluation

Observation of the patient is necessary to identify the therapeutic effects of phenelzine. These effects may occur within 7 days after therapy begins, although in some patients, a therapeutic response may not occur for up to 6 to 8 weeks. Effectiveness of phenelzine is demonstrated by improved mood and increased social activity in depressed patients. The patient's appetite, energy, and sleep pattern will improve as well.

During therapy, blood pressure should be monitored frequently to detect any abnormal response. Periodic liver function tests, such as aspartate transaminase, alanine transaminase, and bilirubin, should be performed. Phenelzine should be discontinued at the first sign of liver failure. Therapy should be discontinued immediately if the patient reports palpitations or frequent headaches, because these signs may signal a hypertensive crisis. Drug therapy with phenelzine is considered effective if depression is alleviated and serious adverse effects are avoided.

MEMORY CHIP

P Phenelzine

- Monoamine oxidase inhibitor used to treat depression unresponsive to other treatments or drug therapy
- Major contraindications: chronic heart failure, impaired liver or kidney function
- Most common adverse effects: restlessness, orthostatic hypotension, blurred vision
- Most serious adverse effect: hypertensive crisis
- **Life span alert: Avoid giving to children 16 and younger; reduce dosage for older adults, see black box warning**
- Maximizing therapeutic effects: Platelet monoamine oxidase inhibition activity should be monitored to achieve a goal between 85% and 95%.
- Minimizing adverse effects: Avoid tyramine-rich foods and over-the-counter cold remedies with dextromethorphan.
- Most important patient education: Adhere strictly to a tyramine-free diet (MAOI diet) during and 2 weeks after medication is stopped; antidepressant effect may take several weeks; take only as prescribed and do not stop abruptly.
- **Black box warning: may increase the risk of suicidal thoughts or behaviors in children, adolescents, and young adults**

Drugs Closely Related to P Phenelzine

Isocarboxazid and Tranylcypromine

Isocarboxazid (Marplan) and tranylcypromine (Parnate) are also MAOIs and are very similar to phenelzine. The differences of these drugs from the prototype are in two areas; neither is indicated for treating bulimia nervosa; and they have three serious, although rare, adverse effects not found with phenelzine: agranulocytosis, anemia, and thrombocytopenia.

Selegiline Transdermal

Selegiline transdermal (Emsam) is a new treatment for depression. It is effective in treating major depression as well as preventing relapses of depression. Like phenelzine, it is an irreversible MAO inhibitor, inhibiting both MAO A and MAO B, primarily MAO B. MAO A enzymes are distributed into the brain, gut, liver, placenta, and skin. MAO B enzymes are distributed in the brain, platelets, and lymphocytes. Oral selegiline is not approved as an antidepressant but is used in the treatment of Parkinson disease (see Chapter 17). Transdermal dosing of selegiline prevents the first-pass effect and thus produces higher systemic levels of the drug and fewer metabolites than the oral formulation. Selegiline transdermal systems are available in three sizes: 20 mg/20 cm^2, 30 mg/30 cm^2, and 40 mg/40 cm^2, which deliver 6, 9, or 12 mg, respectively, of selegiline over 24 hours.

Although selegiline remains active after 24 hours of wearing the transdermal patch, the absorption rate may become variable, so the patch should be changed daily. Increased drug absorption via the skin is possible based on individual factors; some patients may absorb up to one third more drug than is listed on the label. Absorption may potentially be increased with vasodilation, so patients should be instructed to avoid exposing the patch site to external sources of direct heat (such as a heating pad, electric blanket, heat lamp, saunas, hot tubs, heated water beds, or prolonged direct sunlight).

Like the prototype phenelzine, selegiline transdermal may cause serious drug interactions when used with other drugs that affect monoamine activity. Induction of serotonin syndrome may occur if the following drugs are used concomitantly with selegiline transdermal: SSRIs, dual serotonin and norepinephrine reuptake inhibitors, tricyclics, oral selegiline,

other MAOIs, mirtazapine, bupropion, some analgesics (meperidine, tramadol, methadone, propoxyphene, pentazocine), the antitussive dextromethorphan, cyclobenzaprine, buspirone, or the herbal supplement St. John's wort. Concomitant use with any of the following agents may cause hypertensive crisis: sympathomimetic amines (cold products, weight-loss preparations containing vasoconstrictors such as pseudoephedrine, phenylephrine, phenylpropanolamine, and ephedrine), general anesthetics, cocaine, and local anesthetics containing vasoconstrictors, or any herbal or dietary product containing tyramines. If a patient has been taking any of these drugs before they are to start therapy with selegiline transdermal, a wash-out period equal to 4 to 5 half-lives, approximately 1 week, should be allowed before starting treatment with selegiline transdermal. Fluoxetine, an SSRI with a longer half-life, should be stopped at least 5 weeks before starting selegiline transdermal therapy. If selegiline transdermal therapy is to be stopped, at least 2 weeks should be allowed before beginning treatment with any of the above-mentioned contraindicated drugs, because it creates a nonreversible effect on MAO enzymes; two weeks allows the body to produce new MAO so that there will not be a drug interaction.

A major advantage of selegiline transdermal over phenelzine is that this form of selegiline does not pose the risk of a drug–food interaction from dietary tyramine *when the 6 mg/24-hour dose is administered*. Because the MAO B enzymes do not appear in the gut, blocking them does not cause the typical drug–food interactions that can cause hypertensive crisis. Remember that selegiline transdermal blocks both MAO A and MAO B, but primarily B. There is a theoretical possibility that patients taking higher daily doses of selegiline transdermal can still experience hypertensive crisis if they consume dietary tyramines, so patients receiving these doses should still be advised to avoid dietary sources of tyramine. In clinical trials, no patients developed hypertensive crisis.

Adverse effects from selegiline transdermal include the risk of postural hypotension and skin reactions at the site of patch application. To minimize these effects, instruct patients to change positions gradually after lying down and to apply the patch to clean, dry, intact skin. Older adults are more at risk of orthostatic hypotension. Patches should be applied daily at approximately the same time but using a different location; upper chest or back (below the neck but above the waist), upper thigh, or outer upper arm are all appropriate sites. Only one patch at a time should be worn, and the patches should never be cut. Because active drug remains in the discarded patch, teach patients to fold the patch in half after removal and to dispose of it in a manner in which it is not accessible to children or pets.

MOOD STABILIZERS

When a person has been diagnosed with bipolar disorder and is experiencing a manic episode, he or she is treated with drugs that are categorized as mood stabilizers. Treatment with these drugs decreases the extreme range of mood experienced by the patient. In addition to mood, a manic episode also increases energy and disorganizes cognition.

Lithium carbonate (Eskalith), usually simply called lithium, is the prototype mood stabilizing or antimanic drug. Other drugs used to treat bipolar disorder and to stabilize mood include carbamazepine, gabapentin, and valproic acid. These drugs may be combined with lithium for a greater therapeutic effect.

Nursing Management of the Patient Receiving P Lithium

Core Drug Knowledge

Pharmacotherapeutics

Lithium is called a mood stabilizer because its primary action is to prevent extreme mood swings. Lithium is also thought to help control symptoms of mania and depression during periods of remission. Some studies have shown that lithium is efficacious in preventing suicide (Noonan, 2007). The therapeutic range for the drug is 0.6 to 1.2 mEq/L. The drug also has several unlabeled uses. It increases the neutrophil count in patients with cancer chemotherapy–induced neutropenia and in patients with acquired immunodeficiency syndrome (AIDS) who receive zidovudine therapy. It also is useful in preventing cluster headache and in treating bulimia, alcoholism, and postpartum-affective and corticosteroid-induced psychoses. Lithium has also been used as an adjunctive medication when there is limited response to antidepressant medication.

Pharmacokinetics

The intestinal tract provides nearly complete absorption of lithium within 6 hours. Food does not substantially slow absorption. Peak plasma levels occur in 0.5 to 3 hours, and plasma half-life is about 20 hours. Onset of action is slow (5 to 7 days, with full therapeutic effects established in 10 to 21 days). Lithium is not protein bound or biotransformed into metabolites. Excretion occurs almost entirely in the urine (95%) and varies with pregnancy, age, and renal status. Lithium and sodium compete for resorption in the proximal renal tubule, where 80% of lithium is reabsorbed. Many factors, such as sodium imbalance, dehydration, or diuretic use, can affect lithium clearance because of the competition between lithium and sodium for resorption. Dose-related adverse effects are not usually serious if serum levels are maintained below 1.5 mEq/L.

Distribution approximates total body water and is complete within 6 to 10 hours. Higher concentrations occur in the bones, thyroid gland, and portions of the brain than in the serum. Although distribution across the blood–brain barrier is slow, the cerebrospinal fluid level is 40% of the plasma concentration. Elimination half-life is 24 hours, with a range between 10 and 50 hours. A steady state is reached after 5 to 7 days without dose changes.

Pharmacodynamics

Lithium competes with calcium, magnesium, potassium, and sodium in body tissues and at binding sites. It alters sodium transport in nerve and muscle cells. It also affects the synthesis, storage, release, and reuptake of central monoamine neurotransmitters, including acetylcholine, DA, gamma-aminobutyric acid, NE, and 5-HT. Although the contributions of these effects are uncertain, its antimanic effects are thought to result from increases in NE reuptake and increased serotonin receptor sensitivity. Lithium has a very narrow therapeutic index

Contraindications and Precautions

Lithium is contraindicated in patients with severe cardiovascular or renal disease and in patients who are pregnant (category D) or breast-feeding.

Adverse Effects

The adverse effects of lithium can be classified as acute, chronic, and toxic. Acute effects include increased thirst, nausea, increased urination, and a fine hand tremor. Chronic adverse effects include increased urination, weight gain, hair loss, acne, and cognitive impairment. Low thyroid function and lack of kidney response to antidiuretic hormones may also occur in patients receiving long-term lithium therapy. However, discontinuing lithium treatment reverses these effects. Long-term lithium therapy (exceeding 10 years) commonly impairs the ability of the kidneys to concentrate urine, although this effect is not associated with a reduced glomerular filtration rate or with renal insufficiency. Lithium toxicity is dose related; the higher the circulating blood level of lithium, the more likely the patient will experience adverse effects and toxicity.

The most serious adverse effects associated with lithium occur when serum concentrations exceed 2 mEq/L, although some patients may experience toxicity even if their serum drug measurements are considered to be in the normal range (remember that the therapeutic range for the drug is 0.6 to 1.2 mEq/L).

Early symptoms include a coarse hand tremor, severe gastrointestinal upset (vomiting and diarrhea), blurred vision, drowsiness, mental dullness, slurred speech, confusion, muscle twitching, and a dizzy or spinning sensation. Serious, later symptoms include seizures, coma, arrhythmias, and permanent neurologic impairment. A serious lithium overdose can be life threatening.

Drug Interactions

Lithium interacts substantially with other drugs that deplete sodium. Examples of such drugs include thiazide diuretics and angiotensin-converting enzyme inhibitors. This interaction may lead to toxicity secondary to decreased renal elimination of lithium. Table 16.8 lists agents that can interact with lithium.

Assessment of Relevant Core Patient Variables

Health Status

Take a complete health history that includes a complete physical assessment and a complete drug history. Lithium's interaction with many other drugs makes this thoroughness essential. Health conditions that increase sodium resorption, such as chronic heart failure or cirrhosis of the liver, may also increase lithium resorption and lead to lithium toxicity. It is essential that patients who are taking lithium inform all health care providers, including dentists, that they are using this drug. Assess the patient's work history, because bipolar disorder can disrupt a person's ability to function at work or cause absenteeism

Life Span and Gender

Consider the patient's age, keeping in mind that lithium clearance in the kidneys decreases as a person ages. Elderly patients should use lithium cautiously because older adults experience more profound or toxic CNS effects. Older adults also are more likely to develop clinical hypothyroidism, lithium-induced goiter, and nephrogenic diabetes insipidus. Ask women of childbearing age whether they are pregnant, intend to become pregnant, or are breast-feeding. Lithium is classified in FDA pregnancy risk category D. It crosses the placenta, and serum concentration is equal in the mother and fetus. Lithium may cause fetal harm when given to a pregnant woman. Data from lithium birth registries suggest an increase in cardiac and other anomalies. Breast-feeding should be avoided by women taking lithium; valproic acid is better tolerated by breast-feeding infants (Menon, 2008).

Lifestyle, Diet, and Habits

Review the patient's diet because sudden changes in sodium intake may alter lithium resorption, changing the amount of drug that is available in the bloodstream. Assess the patient's use of alcohol and other drugs, including caffeine. Concurrent drug or alcohol abuse reduces responsiveness to drug therapy. Alcohol and caffeine-containing foods and beverages, such as coffee, tea, and some sodas, increase lithium excretion. Consider the patient's daily activities. Lithium therapy causes drowsiness and may impair activities that require alertness or physical coordination.

Environment

Be aware of the environments in which lithium may be administered. Lithium can be administered safely in acute care, chronic care, and home care settings.

Culture and Inherited Traits

Consider the patient's ethnic heritage. For example, in Japan, lower lithium doses result in the same serum blood lithium levels. This fact would support lower dosing of patients with Japanese heritage here as well.

  Desired outcome: *The patient will adopt strategies to restore and maintain proper fluid balance.*
- Risk for Poisoning related to effects of lithium toxicity
  Desired outcome: *The patient will comply with regular monitoring of blood lithium levels to maintain a therapeutic serum level.*

Planning and Intervention

Maximizing Therapeutic Effects

Continue to play an important role in helping patients with bipolar disorder remain in remission. Instruct the patient about early warning signs of a relapse, ways to manage psychosocial problems, and the importance of health-conscious behaviors. Patients may miss the highs of mania, considering life very flat while on lithium therapy. Offer emotional support to patients who feel this way and encourage them to continue with lithium therapy. If the patient cannot abstain from alcohol, advise moderate intake. Help the patient to arrange a work schedule that provides regular eating and sleeping schedules to minimize stress.

Minimizing Adverse Effects

Monitor the patient's blood level of lithium carefully when first starting therapy or whenever the dose is increased, to prevent toxicity from occurring. Patients' serum lithium levels should be monitored once or twice weekly during initiation of therapy and monthly thereafter to ensure dosage is within therapeutic ranges. Obtain a drug blood level at the first symptom of lithium toxicity. Blood specimens should be taken 8 to 12 hours after drug administration.

The risk of lithium toxicity is increased when the patient becomes hyponatremic (e.g., after diarrhea, with diuretic use, or with dehydration), so monitor these patients carefully. To maintain a therapeutic lithium level, patients should be encouraged not to make any major changes in their consumption of water or salt. Consuming lithium with food or dividing the dose minimizes gastrointestinal distress. Lithium is best taken with, or shortly after, meals. Administration should be accompanied by 10 to 12 glasses of water (8 oz) each day to prevent possible dehydration. Hemodialysis is effective in removing lithium from the body and may be indicated in cases of severe overdose or toxicity.

Providing Patient and Family Education

- Teach the symptoms of lithium toxicity and emphasize that patients must report any such symptoms to the prescriber at once.
- Stress the importance of adhering to a schedule of follow-up laboratory and medical appointments.
- Caution patients to avoid OTC products containing nonsteroidal anti-inflammatory drugs (NSAIDs), except for aspirin, because these products decrease renal clearance. Patients should not use NSAIDs without first consulting the health care provider.
- Caution patients against changing sodium intake, starting new drug therapy, or even using OTC drugs without first consulting the prescriber. Changes such as these may result in toxic lithium levels. In addition, explain the relationship between lithium activity and dietary sodium and teach patients how to maintain a constant level of sodium and fluid intake to avoid fluctuations in lithium level.
- Teach strategies to prevent dehydration during lithium therapy.

Ongoing Assessment and Evaluation

Monitor serum lithium levels throughout therapy as described above. Observe the patient's neurologic and psychiatric functioning and assess neuromuscular, gastrointestinal, cardiovascular, kidney, and thyroid function routinely. To evaluate emotional stability, contrast pretreatment behaviors and patient's report of mood state with current observations and patient report. It is equally important to observe the patient's adherence to the therapeutic regimen. Lithium therapy is considered effective when the bipolar disorder is controlled and the patient does not experience serious adverse effects.

MEMORY CHIP

P Lithium Carbonate

- Mood stabilizer for treating bipolar affective disorder, particularly manic episodes
- Changes in sodium or fluid intake will alter blood levels of lithium.
- Major contraindications: severe cardiovascular or kidney disease, pregnancy or lactation, sodium imbalance
- Most common adverse effects: increased thirst or urge to drink, frequent urination, nausea, fine hand tremor
- Most serious adverse effects: lithium toxicity (slurred speech, unsteady gait, weakness, drowsiness, diarrhea, vomiting, confusion, and irregular heartbeat, possibly even seizure)
- **Life span alert: Older adults are at greater risk for hypothyroidism, drug-induced goiter, and nephrogenic diabetes insipidus.**
- Maximizing therapeutic effects: Promote a healthy lifestyle (balanced diet and activity level); encourage adherence.
- Minimizing adverse effects: Monitor serum levels regularly.
- Most important patient education: Have serum lithium levels monitored, avoid major changes in sodium and fluid intake, consult with the prescriber before using any other drugs, even over-the-counter products (especially nonsteroidal anti-inflammatory drugs).

Drugs Significantly Different From P Lithium

Antiepileptics

Selective antiepileptic agents, such as carbamazepine, valproic acid, and lamotrigine, demonstrate antimanic effectiveness in patients who do not respond or are intolerant of lithium. The antiepileptics are discussed in more depth in Chapter 18.

Carbamazepine

Carbamazepine (Tegretol) is an alternative to lithium for managing acute mania and for maintenance therapy. The sustained-release form is used for these indications. It is thought to reduce the sensitization of the brain to repeated episodes of mood swing. Mood-stabilizing use of carbamazepine does not appear to cause the blood dyscrasias that

CRITICAL THINKING SCENARIO

BUG OR DRUG?

Your patient is a 55-year-old man with a diagnosis of bipolar disorder whose manic symptoms have recently been stabilized using lithium, 600 mg PO once in the morning and once in the evening. He comes to you asking for medicine to treat his diarrhea, stating that he has been experiencing this symptom for 2 days now, and it must be something going around or something he ate.

1. As his nurse, what are your concerns?
2. What further assessments and interventions should you take?

complicate its use as an antiepileptic. However, blood studies should be monitored to confirm that the patient is tolerating the medication without adverse effects.

Valproates

Valproic acid and divalproex sodium (Depakote) appear as effective as lithium in treating mania but are less effective in managing the depressive component of the disorder. Both these drugs are labeled for use in the treatment of acute manic episode or mixed manic-depressive episodes, with or without psychotic features. Long-term therapy appears to reduce the frequency and severity of bipolar episodes.

Valproic acid has been reported to cause serious or fatal hepatotoxicity within the first 6 months of therapy in some patients. Patients should be monitored very carefully for signs of liver damage, which may be rather nonspecific, such as malaise, weakness, lethargy, facial edema, anorexia, and vomiting. Liver function tests should be performed before starting therapy and then regularly throughout therapy, although serum levels will not always be altered even if hepatotoxicity is developing. The drug should be discontinued if there is significant hepatic dysfunction. Thrombocytopenia is also possible from valproic acid; this appears to be more probable if the dose is high. Because valproic acid can produce teratogenic effects (especially neural tube defects), it is an FDA pregnancy category D drug and should generally be avoided during pregnancy.

Lamotrigine

Lamotrigine (Lamictal) is used to prevent the reoccurrence of a mood disorder episode (depression, mania, hypomania, or mixed episode). It is considered maintenance therapy after acute episodes have been treated with other drugs. Lamotrigine has the potential to cause the life-threatening rash of Stevens-Johnson syndrome, although this is rare. Coadministration of lamotrigine with valproic acid may increase the risk of Stevens-Johnson syndrome. Administering too high an initial dose of lamotrigine or titrating the dose upward too quickly may also increase the risk.

Antipsychotics

Several atypical antipsychotics are also labeled for use in bipolar disorder. These drugs are discussed in Chapter 17. Olanzapine/fluoxetine (Symbyax) is used for depressive episodes. The drugs risperidone (Risperdal), quetiapine (Seroquel), aripiprazole (Abilify), and ziprasidone (Geodon) are used for acute mania.

CHAPTER SUMMARY

- Illnesses resulting in mood disorder are associated with an imbalance or dysregulation of neurotransmitters.
- Antidepressant therapy is used to treat depressive disorders. The three major classes of antidepressants are selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, and monoamine oxidase inhibitors (MAOIs). Several miscellaneous agents are also used as antidepressants.
- Antidepressants appear to relieve depression by creating changes in both presynaptic and postsynaptic neuroreceptors, correcting the neurotransmitter imbalance. The neuroreceptors affected by antidepressant therapy are the serotonin, norepinephrine, dopamine, acetylcholine, histamine, and alpha-1 adrenergic receptors. Antidepressants stimulate these receptors differently, depending on the drug class. The effects at serotonin, norepinephrine, and dopamine receptors are generally responsible for the therapeutic effects, whereas effects at the other receptor sites are generally responsible for adverse effects.
- All antidepressant therapy requires sustained use of the drug to achieve a therapeutic effect, sometime between 10 days and 4 weeks of therapy. Energy levels may return before the depressed mood is elevated, placing patients at great risk for suicide during this time, because they still have the mindset for suicide, but now they have the physical ability to act on their mood.
- No ideal antidepressant exists, because all produce adverse effects. Some adverse effects are mild and transient, whereas others may be serious. The nurse fulfills important functions, including teaching the patient and family safe and effective use of these agents, offering strategies to minimize adverse effects, and offering hope to patients that drug therapy will help lift their mood.
- Sertraline is the prototype SSRI; it is the most frequently prescribed antidepressant and is generally well tolerated by patients. Nortriptyline is the prototype TCA. Its adverse effect profile includes difficulty concentrating, cardiac irregularities, and seizures. Older adults are particularly prone to these adverse effects. Phenelzine is the prototype MAOI. It is the least used of the antidepressants because of its adverse effects. Hypertensive crisis is the most serious toxic effect of phenelzine and other oral MAOIs. It may occur after ingesting certain foods containing high amounts of tyramine or with concomitant use with several other drugs. The transdermal MAOI selegiline, in the lowest dose available, does not appear to carry the risk of tyramine interaction.
- Bipolar disorder is characterized by mood shifts that include mania and depression. The mood stabilizer lithium is considered the drug of choice for bipolar disorder.
- Lithium ions are managed in the body the same way that sodium ions are managed. Changes in either sodium or fluid intake therefore can affect how much lithium the kidney reabsorbs and changes the circulating level of lithium in the bloodstream.
- Lithium has a narrow therapeutic index. Serum drug levels of lithium must be monitored closely throughout therapy to prevent lithium toxicity.
- Some antiepileptic drugs have been approved for use as mood stabilizers. They are frequently better tolerated than lithium in some patients.

QUESTIONS FOR STUDY AND REVIEW

1. Identify the three main classifications of antidepressant drugs.
2. What is an additional assessment that you must make, in addition to medication efficacy, once the depressed patient has begun antidepressant therapy?
3. Identify an important point that you must teach the patient and his or her family to enhance adherence to antidepressant therapy.
4. What teaching can you give to a patient who complains of gastrointestinal distress associated with sertraline therapy?
5. What are common adverse effects produced by nortriptyline?
6. What are some dietary restrictions during phenelzine treatment?
7. What are the symptoms of an MAOI hypertensive crisis?
8. Identify the pharmacologic agents used to treat bipolar disorder.
9. What is the therapeutic range or level for lithium therapy?
10. What are the symptoms of lithium toxicity?

Drugs Treating Psychotic Disorders and Dementia

Learning Objectives

At the completion of this chapter the student will:

1. Identify diseases and disease processes in which psychotic disorders or dementia are present.
2. Identify the symptoms of psychotic disorders or dementia.
3. Identify the "positive and negative symptoms" of schizophrenia.
4. Identify core drug knowledge of drugs used to treat psychotic disorders or dementia.
5. Name the types of drugs that are used to treat psychotic disorders or dementia.
6. Identify core patient variables relevant to drugs that affect psychotic disorders or dementia.
7. Relate the interaction of core drug knowledge to core patient variables for drugs to treat psychotic disorders or dementia.
8. Generate a nursing plan of care from the interaction between core drug knowledge and the core patient variables for drugs to treat psychotic disorders or dementia.
9. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect psychotic disorders or dementia.
10. Identify the signs and symptoms of neuroleptic malignant syndrome.
11. Determine key points for patient and family education for drugs that affect psychotic disorders or dementia.

Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Although it is impossible to read a person's mind, much less to know precisely whether his or her thoughts are ordered or disordered, a person's thoughts influence his or her perception of reality, interpretation of the environment, speech, and behavior. **Psychosis** is the inability to perceive and interpret reality accurately, think clearly, respond correctly, and function in a socially appropriate manner. Disordered thoughts can produce speech and behavior patterns that are confusing and even frightening to the person and those around him. Psychosis is a symptom or syndrome that is associated with certain psychological illnesses (Stahl, 2008). The presence of these symptoms is used to make a diagnosis of a psychotic disorder, such as schizophrenia.

Historically, treating psychotic disorders involved containing the sick person and protecting society from what that person might do. The setting more closely resembled a jail than a hospital. The first drug therapy was aimed at sedating the patient in order to control behavior. It was not until the mid-1950s that drug therapy to control symptoms was devised. These drugs were very effective and constituted a major breakthrough in patient care. Unfortunately, these early drug therapies had many undesirable adverse effects, many of which were chronic, and some even permanent. The goal in creating new therapies has not necessarily been to create a more effective drug, but rather to create one with fewer adverse effects. Indeed, the original drugs are still considered the gold standard for effective symptom control. As brain imaging techniques advanced in the 1990s, it became possible to learn more about the sophisticated functioning of the brain; this new understanding enabled the development of drug therapies that worked at specific neuroreceptor sites in the brain and central nervous system (CNS). This targeted drug therapy not only was effective in relieving symptoms of psychotic disorders, such as delusions and hallucinations, but also minimized adverse effects by limiting the number of receptors that were stimulated by the drug. Recent research suggests that targeted therapy may improve adherence (Box 17.1).

Drugs that relieve symptoms of psychotic disorders are generally referred to as antipsychotics. They are also called neuroleptics, to reflect the fact that the drugs work in the nervous system at neuroreceptor sites. Both terms are currently used and are interchangeable. Table 17.1 presents a summary of selected antipsychotic drugs.

Antipsychotics are further divided into typical and atypical agents. The prototype typical antipsychotic is haloperidol, a high-potency typical antipsychotic. Low-potency antipsychotics are considered significantly different from haloperidol. The prototype atypical antipsychotic is olanzapine.

Drugs used in the treatment of Alzheimer type dementia are also discussed in this chapter. The prototype drug for Alzheimer disease is rivastigmine (Exelon).

PHYSIOLOGY

The cerebrum, the highest functional area of the brain, is concerned with activities such as creative thought, judgment, memory, and reason, and it is divided into two hemispheres. The frontal lobes control voluntary body movement, expression of feelings, perceptual interpretation of information, and thinking. The temporal lobes also play a role in the expression of emotions. Other major CNS functional systems include the extrapyramidal system, responsible for muscle coordination; the limbic system responsible for the emotions of anger, anxiety, fear, pleasure, sorrow, learning, and memory; and the reticular activating system, responsible for consciousness, filtering, and stimulus alert.

Within the nervous system, communication between neurons depends on neurotransmission. The movements of electrical impulses cause neurotransmitters to be released from the presynaptic cell (axon) into the synapse, where they are received by the postsynaptic cell (dendrite) of the next cell. The axons are insulated by a coating called myelin. The myelin sheath can be compared to the coating on an extension cord. It protects the internal wires from damage and prevents the electrical impulses from escaping into the surrounding area.

BOX 17.1 FOCUS ON RESEARCH

NEUROCOGNITIVE DEFICITS IN SCHIZOPHRENIA

Stahl, S. M. (2008) *Stahl's Essential Psychopharmacology*. Cambridge University Press. New York
Ventura, J., Thames, A. D., Wood, R. C., Guzik, L. H., Hellemann, G. S. (2010). Disorganization and reality distortion in schizophrenia: A meta-analysis of the relationship between positive symptoms and neurocognitive deficits. *Schizophrenia Research*. 121: 1–14.

There is a clear neurodegeneration that occurs in late stage schizophrenia, often referred to as stage IV (Stahl, 2008). Studies have been conducted to ascertain the relationship between certain prominent symptoms in schizophrenia and this decline in cognition. One hypothesis is that neurocognitive declines occur due to excitotoxicity and excessive action of the neurotransmitter glutamate (Stahl, 2008). This neurocognitive decline indeed has effects on the ability of schizophrenic individuals to live independently. Ventura et al (2010) conducted a meta-analysis looking at the relationship between positive symptoms and neurocognitive deficits. Specifically, the researchers analyzed the connection between reality distortion (delusions, hallucinations, suspiciousness) and disorganization (conceptual disorganization and bizarre behaviors) as they relate to cognitive decline. Their results demonstrated a moderate relationship between disorganization and neurocognitive decline, while the relationship between neurocognition and reality distortion was relatively weak. The strong relationship between disorganization suggests that improvements in community function could be improved with treatments that target disorganization symptoms (Ventura et al., 2010). As we look ahead, improvements in neurocognition as schizophrenics age could possibly reduce the need for premature long term care in this population, thus improving independence and quality of life.

Nursing implications

It is important for ongoing evaluation of symptomatology in schizophrenia, closer attention to target symptoms may indeed help aim treatments, both pharmacologic and non-pharmacologic. In patients with schizophrenia, it is appropriate to be aware of potential neurocognitive deficits for promoting independence. Often, as with dementias, early intervention may help promote executive functioning and independence.

TABLE 17.1 Summary of Selected C Antipsychotics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Typical Antipsychotics			
High Potency			
P haloperidol (Haldol)	Psychotic disorders, hyperexcitability in children	*Adult:* PO, 0.5–2 mg bid to tid; IM, 5–30 mg/d; IM deconate, 50-100 mg IM/mo *Child:* PO, 0.05–0.15 mg/d	*Onset:* PO, varies, IM, 15–30 min *Duration:* PO, 24–72 h; IM, 4–8 h $t_{1/2}$: 21–14 h
acetophenazine (Tindal)	Psychotic disorders	*Adult:* PO, 20–80 mg/d in divided doses *Child:* Not recommended	*Onset:* 2–3 h *Duration:* 36–48 h $t_{1/2}$: 10–20 h
fluphenazine enanthate (Prolixin)	Psychotic disorders	*Adult:* IM/SC, 12.5–25 mg *Child:* Not recommended	*Onset:* 24–72 h *Duration:* 1–3 wk $t_{1/2}$: 3.7 d

Thought, like mood, is controlled by neurotransmitters that stimulate neuroreceptors in the brain. The brain has unique receptors, unlike receptors elsewhere in the body. These receptors activate thought processes, and other unique receptors in the brain activate mood response. A combination of neurotransmitters is thought to play a role in the workings of the brain. The primary neurotransmitter related to thought processing is believed to be dopamine. Dopamine is secreted by neurons originating in the midbrain that function in coordination, emotion, and voluntary decision making.

Many areas of the brain secrete acetylcholine; reductions in the amount of this neurotransmitter cause cognitive changes. Acetylcholine has a number of functions, including arousal, coordination of movement, memory acquisition, and memory retention. Research is also being conducted on the extent to which norepinephrine and serotonin might be involved in thought processes. For a complete discussion of acetylcholine and norepinephrine, see Chapters 13 and 14.

PSYCHOTIC DISORDERS

In psychiatry, psychotic disorders are described by different diagnoses. Each diagnosis has its own etiology, symptoms, and treatments, although a given drug may be useful in more than one diagnosis.

Schizophrenia

Schizophrenia is a particular kind of psychosis that is characterized mainly by a clear sensorium but a marked disturbance in thinking. It is a complex illness with uncertain etiology. Schizophrenia interferes with a person's ability to think clearly, manage emotions, make decisions, and relate to others. According to the National Institute of Mental Health (2010), schizophrenia has a 1 year prevalence rate of 1.3 %. Schizophrenia is more likely to occur in men than women, and men tend to have an earlier onset of illness (Messias et al., 2007). The disease typically has an onset between the age of 15 to 24 years. The strongest risk factors appear to be lower social class and family history (Messias et al., 2007).

Schizophrenia is considered to have multiple causes. Current studies imply that one of the causes of schizophrenia is a strong genetic component. Recent research has discovered how two genes, considered schizophrenia risk genes, work at the molecular level to increase the risk of schizophrenia. The two genes are identified as disrupted-in-schizophrenia-1 (DISC1) and neuregulin 1:

- DISC1, which is involved in the development of the limbic system, has its peak effect in infancy; this suggests that the gene plays an important role in brain development. Three molecules that work in conjunction with DISC1 are reduced in people with schizophrenia. If DISC1 cannot bind to these molecules, this appears to trigger a series of events leading to schizophrenia (Lipska, Peters, Hyde, et al., 2006).
- Neuregulin 1 controls the construction and wiring of the brain during brain development; it also is responsible for communication between nerve cells and a person's ability to adapt to new situations. Genetic variations of neuregulin 1 appear likely to impair the gene from achieving its function and lead to the development of schizophrenia (Law, Lipska, Weickert, et al., 2006).

With a genetic predisposition, the various stressors that may occur in a person's life can trigger the disorder's symptoms. This effect could be compared to what can happen to a bridge made of wooden planks. The structure is strong enough to accommodate light loads safely, but if a heavy truck drove over the bridge, it would be likely to collapse. Other theories for the etiology of schizophrenia include the proposal that the illness is caused by neurodevelopmental changes during brain development. It is suggested that the disease is acquired from the fetal brain's environment. This theory is contradictory to the genetic theory, suggesting that it is not a genetic disease, but acquired (Stahl, 2008). (See Box 17.1 Focus on Research)

Other hypotheses exist for the pathogenesis of schizophrenia, especially with regard to changes in brain chemistry, because schizophrenia is associated with an unusual imbalance of neurotransmitters. The dopamine hypothesis is the most fully developed of these hypotheses. It is based on the unexpected discovery that agents that diminish dopaminergic activity have beneficial effects in reducing the acute symptoms and signs of psychosis, specifically, agitation, anxiety, and hallucinations. However, these agents reduce delusions and social withdrawal less dramatically. Imaging studies have lent credence to the belief that excessive dopamine activity is involved in schizophrenia, particularly on the left side, where the most recognizable "positive" symptoms (e.g., delusions or hallucinations) occur. This imbalance appears to

arise not from overproduction of dopamine, but rather from an increase in specific chemical receptors that attract dopamine. Moreover, there appears to be low activity of a subset of dopamine (D_1) receptors in the prefrontal cortex of the brain, where so-called negative symptoms originate. (Positive and negative symptoms are explained later in this chapter.)

The term *schizophrenia* is derived from the Greek words that indicate a broken or shattered personality, separating the cognitive and emotional aspects of the personality. Many people mistakenly believe that schizophrenia involves multiple personalities. People with schizophrenia do not have multiple personalities. Another common misconception is that affected people are prone to violence. Although patients with schizophrenia may sometimes become violent, they are far more likely to withdraw from society. In fact, these people are more often the victims rather than the perpetrators of violence. However, fears and misperceptions persist, and integrating patients with psychotic symptoms into society remains challenging (Box 17.2).

Schizophrenia is characterized by symptoms described as positive, negative, and disorganized. The positive symptoms are so named because they add a layer of something new to the person; they are an excess or a distortion of normal brain function. The positive symptoms of schizophrenia, and the most recognizable symptoms, include delusions (e.g., paranoia or distorted perceptions of other people's intentions) and hallucinations. For example, people with schizophrenia may have beliefs or thoughts that are fixed and false; these beliefs or thoughts are a type of delusion. Hallucinations, on the other hand, can affect any one of the five senses. Auditory hallucinations are the most common type of hallucination; a person with auditory hallucinations might hear voices talking to or about him or her. A person experiencing a visual hallucination may see persons or objects that are not there.

The negative symptoms of schizophrenia include flat or blunted emotions, lack of pleasure or interest in things (anhedonia), and limited speech. These symptoms take away from the person's personality and are thus considered "negative." They also represent a loss or diminishing of normal brain function. For example, people with schizophrenia may have difficulty understanding their feelings or expressing their emotions clearly. Furthermore, they view the world and society as uninteresting and not worth participating in, and they often may not say much or speak unless spoken to. Consequently, an affected person may have trouble relating to others, which in turn can lead to periods of intense withdrawal and profound isolation.

For people with schizophrenia, symptoms of disorganized thinking and speech may cause the following problems:

- Trouble thinking clearly and understanding what other people say
- Using words in a way that makes no sense to anyone else
- Inability to plan ahead
- Inability to solve relatively small problems

The disorganized behavior may make a person do things that do not make sense, such as repeated, rhythmic gestures or ritualistic movements.

Some symptoms of schizophrenia differ between men and women. For example, the negative symptoms are more often present in men; mood symptoms, especially depression, are more commonly seen in women. Additionally, delusions in women appear less bizarre, with more somatic and romantic preoccupation. Men are more concerned with political conspiracy and undercover activities and have more grandiose delusions of power, royalty, and divinity. Many people with schizophrenia have a combination of these symptoms.

Other Psychotic Disorders

Compared with schizophrenia, which is a permanent illness, other psychotic disorders may be short lived. As defined earlier, a psychotic episode is one in which a person loses touch with reality. In addition to being present in schizophrenia, psychosis can also be present in states of depression or mania. The causes of psychosis are varied and can include electrolyte imbalances, metabolic imbalances (e.g., diabetic ketoacidosis), drug abuse (either from drug intoxication or withdrawal), adverse effects from prescribed drug therapy, or hormonal shifts, such as those that occur during the postpartum period.

BOX 17.2 COMMUNITY BASED CONCERNS

Easing Fears About Mental Illness

It is an unfortunate reality that what little attention mental illness receives in the media mostly focuses on episodes of sensational violence, committed by people who are clearly psychotic. However, the overall number of people suffering from mental illnesses, particularly illnesses involving psychosis, is far greater than the number of those who behave violently. Psychotic people most often are the victims, rather than the perpetrators, of injury. Despite this reality, sensational stories of mental illness persist, and prisons fill with untreated mentally ill patients.

All nurses have a responsibility to continue to educate patients, their families, and all members of the community about the symptoms of various mental illnesses and about any resources available for treatment. Rallying the support of the community is crucial to increase the resources that will help patients receive appropriate treatment. More drugs for treating specific symptoms of mental illness are available today than ever before. These advances also mean that there is less need to fear the psychotic patient and more reason than ever before for the patient to be integrated as a functioning member of the community.

COGNITIVE DISORDERS

Dementia

Dementia is a clinical syndrome of progressive, degenerative loss of memory and of one or more of these abilities:

- Language skills
- Higher-level skills such as judgment, comprehension, and problem solving
- Ability to recognize or identify objects despite intact sensory function
- Ability to perform motor skills (American Psychiatric Association, 2007)

Mood and behavior may also be affected in dementia. Agitation or withdrawal, hallucinations, delusions, insomnia, emotional apathy, and loss of inhibitions are also common.

There are many types of dementia, including Alzheimer-type dementia, vascular dementia, and other dementia caused by diseases such as acquired immunodeficiency syndrome (AIDS). Dementia can also be a result of brain damage from substance abuse, such as alcoholism or inhalant use, or from exposure to environmental chemicals. In all of these circumstances, symptoms of dementia develop gradually, and although the deterioration is not necessarily diffuse or "global," it often affects some areas of intellectual functioning while sparing others. Early in the disease, the patient may be aware of changes in intellectual ability and become depressed or anxious and attempt to compensate by writing down information, attempting to structure routines, and simplifying responsibilities. These coping mechanisms may give patients the appearance of intact cognitive abilities for a while, even though they are actually in decline.

Alzheimer Disease

Alzheimer disease is one form of progressive dementia. Alzheimer disease, the most common cause of dementia among people 65 years of age and older, with nearly one in eight older adults affected by Alzheimer Disease. It is the fifth leading cause of death in older adults. An estimated 5.4 million American have Alzheimer Disease, of which 5.2 million are over 65 years of age. (Alzheimer Organization, 2011). The duration of illness, from onset of symptoms to death, averages 8 to 10 years.

At this time, there is no cure or way to prevent Alzheimer disease. As more and more Americans live longer, the number affected by Alzheimer disease will continue to grow, unless a cure or effective prevention is discovered. Alzheimer disease causes a gross, diffuse atrophy of the cerebral cortex. It is associated with extracellular plaques with beta-amyloid protein deposits and neurofibrillary tangles in the cortical neurons, with eventual loss of neurons. The earliest loss of neurons occurs in the nucleus basalis and the entorhinal cortex, where cholinergic neurons are preferentially affected. As the illness progresses, up to 90% of cholinergic neurons in the nucleus basalis baseline may be lost. Cholinergic deficiency in Alzheimer disease is most prominent at the more advanced stages.

Typically, Alzheimer disease begins insidiously with short-term memory loss, whereas long-term memory is initially spared. Eventually, long-term memory is also lost as the disease progresses. In addition to memory loss, other cognitive deficits also impair activities of daily living. People with Alzheimer disease frequently repeat questions, forget phone messages and appointments, do not pay bills, and get lost driving. They may lose weight because they no longer shop for food, cook, or eat. Furthermore, the cognitive deficits are relentlessly progressive; affective, behavioral, and motor signs become more common as the disease advances.

In addition to the cognitive deficits, behavioral and psychiatric symptoms (e.g., abnormal sleep, delusions, depression, hallucinations, mania, violent outbursts, and wandering) tend to occur at some point in most patients with Alzheimer-type dementia.

Vascular Dementia

Vascular dementia results from damage to brain tissue, caused by cerebrovascular events such as transient ischemic attacks or strokes. The areas that experience infarcts are associated with specific neurologic functions, so that an infarct in the cerebellum, for example, can produce problems with motor coordination or balance. Although vascular dementia and Alzheimer dementia differ in cause, many of the symptoms are similar.

Other Dementias

Dementia can also be caused by a variety of medical conditions. The primary mechanism of this diagnosis is the presence of or a noted history of a disease, such as AIDS, Parkinson disease, Huntington chorea, hypothyroidism, normal pressure hydrocephalus, brain tumor, or vitamin B_{12} deficiency. The symptoms caused by these conditions are also similar to those described earlier for Alzheimer disease. Box 17.3 presents risks for and causes of dementia, both irreversible and potentially reversible. Plassman et al. (2007) estimates that 30% of all dementias are caused by syndromes other than Alzheimer's disease.

Delirium

Delirium is a sudden disruption in cognitive functioning, most often caused by a physical change in the body, rather than by changes within the brain. This physical change prevents the

Box 17.3 RISK FACTORS AND POSSIBLE CAUSES OF DEMENTIA

Irreversible Risk Factors/Causes

- Age over 65 years
- Cerebral infarction or ischemia
- Diseases such as cardiovascular disorders, type 1 diabetes, degenerative (e.g., Parkinson disease), neoplasms
- Male gender
- Genetic factors such as apolipoprotein E gene on chromosome 19 and chromosome 10

Potentially Reversible Risk Factors/Causes

- Depression
- Diseases such as type 2 diabetes, hyperlipidemia, hypertension, infections
- Drugs with iatrogenic/idiosyncratic effect or polypharmacy
- Lifestyle habits such as excessive alcohol consumption, smoking, illicit drug use, among others
- Metabolic disorders
- Nutritional disorders
- Toxins
- Trauma

brain from receiving some critical element (e.g., blood or oxygen) that it needs to function effectively. This event can be conceptualized as "brain failure," just as any other organ fails as a result of physical impairment. A hallmark symptom of "brain failure" is a disturbance in the level of consciousness that comes and goes throughout the day or days when delirium is present. This disturbance can be either increases in activity (e.g., agitation, aggression, psychosis) or decreases in activity (e.g., somnolence, lethargy, apathy). This pattern is called waxing and waning. Another symptom of delirium, as with dementia, is that psychotic-like symptoms can occur in which the person loses touch with reality. Thus, the patient may experience hallucinations and delusions. Some causes of delirium include substance withdrawal, infection (e.g., septicemia and urinary tract infections), sensory deprivation, metabolic disturbances (arising from renal failure, diabetic ketoacidosis, hypoxia, and fluid or electrolyte imbalance), and adverse effects from some medications. One major difference between delirium and dementia is its onset. Unlike that of dementia, which is slow and gradual, the onset of delirium is rapid.

To treat delirium effectively, the underlying cause must first be identified. *Untreated delirium can be fatal because the underlying condition is not diagnosed and treated.* Although use of an antipsychotic or sedative calms the patient, it does not resolve the cause of the delirium.

C ANTIPSYCHOTICS

• C TYPICAL ANTIPSYCHOTICS

The typical antipsychotics were the first antipsychotic drugs created. They are sometimes referred to as the conventional antipsychotics. The use of the original drug in this class, chlorpromazine (Thorazine), has become limited because of its substantial adverse effects. Haloperidol (Haldol) is a commonly used typical antipsychotic and is the prototype for the class. No one drug or drug class is preferable for all patients with schizophrenia. The choice of the appropriate antipsychotic therapy, if the typicals and atypicals are equally effective and seem to have similar benefits, is related to the potential adverse effects that might occur. Some patients are willing to risk certain adverse effects but not others. So for some patients, especially those who would be at high risk of long-term cardiovascular impairment from metabolic syndrome, a typical antipsychotic may be the better drug, assuming prophylactic therapy is provided to minimize the risk of EPS. Other patients, who may be more sensitive to the EPS from a typical antipsychotic, may be better candidates for an atypical antipsychotic (Stahl, 2008).

Erik Johnsen and Hugo A. Jørgensen (2008) provide a review of sixteen randomized trials regarding the effectiveness of second generation antipsychotics. They found that olanzapine may have better drug adherence than other second generation antipsychotics, however olanzapine may also have an increase in metabolic side effects.

Nursing Management of the Patient Receiving P Haloperidol

Core Drug Knowledge

Pharmacotherapeutics

Haloperidol is used to treat psychotic disorders such as schizophrenia. It is also used to treat Tourette disorder, and it is indicated for pediatric patients with hyperactivity or severe behavioral problems. Off-label, it is used to treat nausea, vomiting, intractable hiccups, psychosis, delirium, and in phencyclidine (PCP)–induced psychosis. Haloperidol can be administered orally, intramuscularly, and intravenously.

Pharmacokinetics

Haloperidol is fairly well absorbed. Its bioavailability from oral doses is 60% to 65%. It is highly protein bound, at 92%. Its exact mechanism of metabolism is unknown, although almost all of it is eliminated by metabolism; about 1% is eliminated in the urine and stool. Research has found that ethnic background influences the pharmacokinetics of haloperidol. Asians achieved a 50% higher plasma concentration of haloperidol than whites who received the same dose. It is hypothesized that this difference is attributable to inherent differences in metabolism, but the precise reason is not known.

Pharmacodynamics

Haloperidol can take several days to reach its full therapeutic effect. The exact cause of this delay is unknown. The delay is frequently more frustrating to the nursing staff than to the patient. Haloperidol produces its effects by blocking dopamine (specifically, D_2), alpha, and serotonin receptors. It has minimal blocking effects at cholinergic and histamine receptors.

Blockade of dopaminergic receptors produces a decrease in movement disorders, relief of hallucinations and delusions, relief of psychosis, worsening of negative symptoms, and release of prolactin. Dopamine blockade also quiets the chemoreceptive trigger zone in the brain that produces nausea and vomiting, thereby relieving these symptoms. Blockade of dopamine receptors may actually create the net effect of too much cholinergic stimulation because the delicate balance between these two systems is altered. Many of the adverse effects from haloperidol are related to this relative imbalance between dopamine and cholinergic neurotransmitters.

Anticholinergic effects from haloperidol are modest but explain adverse effects such as dry mouth. How can haloperidol cause a relative excess of acetylcholine, but also anticholinergic effects? Remember that many drugs are only *relatively selective* for which receptors they stimulate or block. Here, the predominant effect is blockade of dopamine receptors, so the most common adverse effect will be not enough dopamine effects and too much acetylcholine effects. At the same time, *some* cholinergic receptors are also blocked by haloperidol, so there can be some symptoms related to cholinergic blockade (anticholinergic effects).

Other receptors affected by the nonselective actions of haloperidol are the alpha, serotonin, and histamine receptors. Blockade of alpha receptors produces many of the

cardiac adverse effects of haloperidol treatment. Other adverse effects, related to alterations in mood, are caused by the blockade of serotonin receptors. Blockade of histamine receptors produces adverse effects such as sedation.

Haloperidol may also decrease the seizure threshold in patients with seizure disorder. Haloperidol controls the positive symptoms of schizophrenia but has no effect on the negative symptoms. Occasionally, the negative symptoms may worsen with haloperidol therapy.

Contraindications and Precautions

Haloperidol is contraindicated if the patient has hypersensitivity to any of the drug's components. It is also contraindicated in Parkinson disease because cholinergic stimulation in that disorder is already excessive.

Haloperidol and other typical antipsychotics carry a black box warning that administration to elderly patients with dementia-related psychosis increases the risk of death in these patients. Deaths are mostly related to cardiovascular events (such as heart failure or sudden death) or infections (such as pneumonia). Haloperidol is not approved for use in patients with dementia related psychosis. This black box warning does not mean that these drugs cannot be used, just that the potential risks and benefits must be weighed. Under certain circumstances prescribers may use the antipsychotics in dementia related psychosis, especially when the psychosis produces aggressive or violent outbursts and other medications have failed (Meeks & Jeste, 2008).

Haloperidol should be administered with caution to patients who:

- Have been exposed to extreme heat or phosphorous insecticides
- Use atropine or other anticholinergic drugs
- Are currently withdrawing from alcohol
- Have any disorder of the skin (dermatosis) or other allergic reactions to phenothiazine derivatives (because of the risk for cross-sensitivity)
- Have experienced an idiosyncratic response to other centrally acting drugs
- Are pregnant, because it is a pregnancy category C drug

Adverse Effects

Adverse effects, which can be perceived as a substantial nuisance or a source of embarrassment to the patient, are the primary reason that patients stop taking haloperidol. Although many adverse effects can be managed or minimized pharmacologically, some patients need to accept that they will experience some adverse effects in order to have their psychotic symptoms controlled.

Adverse effects from haloperidol come from the blockade of various neurotransmitter receptors. The major risk to the patient receiving haloperidol comes from a group of symptoms called **extrapyramidal symptoms** (EPS). The cause of these symptoms is the relative lack of dopamine stimulation (i.e., excess dopamine blockade) and relative excess of cholinergic stimulation. EPS are the most common adverse effects of haloperidol. The risk of EPS increases if drug therapy is repeatedly and abruptly stopped and then restarted.

There are four major presentations of EPS. The first is Parkinson-like effects (also known as pseudoparkinsonism). With this adverse effect, the patient demonstrates symptoms that are typically seen in Parkinson disease, such as cog-wheeling muscle rigidity, fine tremor, slow motor responses, and a flat affect (a mask-like facial expression). It is important to distinguish this flat affect from the primary symptom of schizophrenia, which is flat affect without the mask-like features, combined with social withdrawal.

The second presentation of EPS is akathisia, a constant feeling of restlessness that the patient cannot control or explain. This presentation must be distinguished from signs of anxiety related to an identifiable source of worry.

The third presentation of EPS is acute dystonia, which involves prolonged muscular contractions and spasms. The spasms may present as arching and twisting of the neck, arching of the back, rolling of the eyes up toward the back of the head, or spasms of the laryngeal-pharyngeal muscles (which may occlude the airway, if the spasms are severe, and can be life-threatening). These symptoms cannot be controlled, occur suddenly, and may be frightening and painful.

The fourth presentation of EPS is called **tardive dyskinesia.** Tardive dyskinesia generally occurs late in haloperidol therapy and usually is irreversible. It is most commonly related to high doses and long-term use. Approximately 1 in 25 patients treated for a period of 1 year develops tardive dyskinesia. After treatment for 7 years, the incidence increases to one in four patients. Symptoms of tardive dyskinesia include involuntary lip smacking, chewing, mouth movements, tongue protrusion, blinking, grimacing, and involuntary muscle twitching of the limbs. Risk factors for developing tardive dyskinesia are listed in Box 17.4.

Other fairly common adverse effects of haloperidol include drowsiness, sedation, somnolence, lethargy, and dysphoria (a decline in mood). It has been hypothesized that the complaints of drowsiness and sedation may actually be signs of drug-induced depression that have been misinterpreted by the patient and the clinician. More research is needed to help devise antipsychotic drugs that do

Box 17.4 RISK FACTORS FOR TARDIVE DYSKINESIA (TD)

If the patient is receiving treatment with "typical" antipsychotics, additional factors that place the patient at risk for TD include:

- 6 months of antipsychotic therapy
- Increased length of antipsychotic therapy
- Antipsychotic dosage change—either increased or decreased
- Diagnosis of organic mental disorder or mood disorder
- Increased age
- Diabetes
- Genetic predisposition
- Race (African Americans may be twice as likely to develop TD than whites)

not produce these adverse effects, so that the quality of life can be improved for patients requiring long-term therapy.

Haloperidol used in higher than recommended doses and administration via the intravenous route (a non-approved route) has been associated with serious cardiovascular problems such as QT-prolongation, Torsades de Pointes (a form of ventricular tachycardia), and sudden death.

Use of typical antipsychotics such as haloperidol puts the patient at risk for developing a relatively rare, although potentially fatal, adverse effect called **neuroleptic malignant syndrome.** This syndrome is characterized by fever, sweating, tachycardia, muscle rigidity, tremor, incontinence, stupor, leukocytosis, elevated creatinine phosphokinase levels, and renal failure. Patients are more likely to develop neuroleptic malignant syndrome if they are dehydrated or taking large doses of haloperidol. Neuroleptic malignant syndrome can occur with use of any of the typical antipsychotics. In addition to having an underlying psychotic illness, the patient now also becomes delirious.

Leukopenia and neutropenia have been reported related to antipsychotic use, including haloperidol. This is usually a temporary effect. Another potentially fatal, although extremely rare, adverse effect of haloperidol is agranulocytosis. Although this adverse effect is possible, it is more common with the atypical antipsychotics.

A variety of other uncommon adverse effects can occur as a result of the use of haloperidol. They are categorized as:

- Cardiovascular (tachycardia, hypotension, hypertension)
- CNS (agitation, anxiety, catatonia-like state, confusion, convulsions, depression, euphoria, hallucinations, headache, insomnia, sedation, libido increases, transient dyskinetic signs, vertigo) (mostly from serotonin blockade and histamine blockade)
- Dermatologic (acne, alopecia, maculopapular skin reactions, photosensitivity)
- Gastrointestinal (anorexia, constipation, diarrhea, dry mouth, dyspepsia, nausea, salivation, vomiting) (from cholinergic blockade)
- Genitourinary (breast engorgement, galactorrhea, gynecomastia, impotence, breast pain, menstrual irregularities, priapism [prolonged erection], urinary retention)
- Hematologic and lymphatic (anemia, hyperglycemia, hypoglycemia, hyponatremia, leukocytosis, leukopenia, elevated blood ammonia levels, lymphomonocytosis)
- Hepatic (jaundice, impaired liver function)
- Musculoskeletal (severe spasms causing arching of the body from head to toe)
- Respiratory (bronchospasms, laryngospasm, increased depth of respiration)
- Special senses (cataracts, blurred vision, visual disturbances, retinopathy)
- Miscellaneous (sudden death, withdrawal syndrome, heat stroke, local tissue reactions from injection)

Drug Interactions

A few drug interactions are known to occur with haloperidol. Cigarette smoking has been linked with lower serum levels of haloperidol. Table 17.2 lists agents that interact with haloperidol.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient to determine whether he or she has an illness that is treated suitably with antipsychotics. Ensure that the patient does not have Parkinson disease, which is a contraindication for use of haloperidol. Also, assess for other conditions that require precautions for haloperidol use. Assess for a history of seizure disorder because haloperidol decreases the seizure threshold. Dehydration places patients at greater risk for developing neuroleptic malignant syndrome.

Life Span and Gender

Assess the patient's age. Determine whether the patient is pregnant or could become pregnant because haloperidol is a pregnancy category C drug. Safety and efficacy in children has not been assessed. Infants should not be breast-fed if the mother is receiving haloperidol. Oral haloperidol should not be used in children younger than 3 years. Young adult males, especially young black males, have the highest risk for the various dystonias. Older adult women have the highest risk of tardive dyskinesia. Older adults with dementia related psychosis are at higher risk of death from haloperidol and other typical antipsychotics.

TABLE 17.2 Agents That Interact with P Haloperido

Interactants	Effect and Significance	Nursing Management
anticholinergic agents	Decreased haloperidol serum concentrations	Coadminister with caution
azole antifungal agents	May elevate haloperidol serum concentrations	Adjust dose as needed
carbamazepine	Therapeutic effects of haloperidol may be decreased	Adjust dose as needed
charcoal	Charcoal can decrease absorption	Do not give together
lithium	Alterations in consciousness, encephalopathy, EPS, fever	Discontinue either drug if interaction is suspected
Maalox	Impairs absorption of typical (and possibly atypical) antipsychotics	Do not take within 1 h of taking haloperidol
rifamycins	May decrease haloperidol serum concentrations	Adjust dose as needed

CRITICAL THINKING SCENARIO

WHAT'S WRONG WITH THIS PATIENT?

Your patient, Mr. Jones, has schizophrenia and has been receiving haloperidol, 10 mg twice a day, and benztropine, 2 mg twice a day. His psychotic symptoms are usually well controlled. Today when he comes to the clinic for a checkup he tells you that "the voices" have been speaking to him again, warning him of a plot by terrorists to kill him. You ask to see all of the medications that he has brought with him. In addition to the haloperidol and the benztropine, you find a half-used package of over-the-counter diphenhydramine (Benadryl). He states he is having trouble with seasonal allergies.

1. As this patient's nurse, what do you think is happening to Mr. Jones?
2. As this patient's nurse, what actions should you take?

Lifestyle, Diet, and Habits

Assess the patient's typical daily fluid intake to determine whether the patient is sufficiently hydrated. Determine whether the patient smokes cigarettes, because smoking may decrease the effectiveness of haloperidol. Alcohol may have additive CNS effects with haloperidol, leading to profound CNS depression.

Environment

Assess the environment where the drug will be given. Intravenous (IV) administration is restricted to an inpatient setting and increases the risk of serious cardiovascular adverse effects. Intramuscular (IM) doses may be administered in an outpatient setting. Some formulations act as drug depots and slowly release the drug over several weeks. Other times, IM doses may be administered as an emergency treatment until the person can be admitted to an inpatient setting, or the acute symptoms are controlled. Oral haloperidol can be administered in any environmental setting. Because photosensitivity is a possible adverse effect, assess whether the person is outside frequently.

Culture and Inherited Traits

Assess the patient's ethnicity, because Asians have a 50% higher serum level of haloperidol than whites. This difference may affect the dose required to be effective.

Nursing Diagnoses and Outcome

- Risk for Injury related to EPS from haloperidol
  Desired outcome: *The patient will remain injury-free from haloperidol as EPS are prevented or minimized.*
- Altered Thought Processes related to hallucinations and delusion
  Desired outcome: *The patient's hallucinations and delusions will be controlled by haloperidol therapy.*
- Risk for Ineffective Management of Therapeutic Regimen, Individual, related to adverse effects of drug therapy or poor understanding of the need for drug therapy
  Desired outcome: *The patient will take haloperidol therapy as directed.*

Planning and Intervention

Maximizing Therapeutic Effects

Encourage the patient to take the drug routinely. Ensure that the patient has swallowed the medication when it is administered and that the patient has not kept the medication in his or her cheek (a practice referred to as "cheeking") in order to spit it out and avoid taking the medication. Depot or long-acting injections may be used to ensure medication adherence (Ascher-Svanum et al., 2009)

Minimizing Adverse Effects

Adverse effects are common and dose related. The goal of therapy is to find a dose that effectively controls the psychotic symptoms but produces minimal adverse effects.

Some of the adverse effects (e.g., sedation and drowsiness) are transient, but they can be distressing enough to cause the patient to stop therapy. Encourage patience and continued use of the drug until it can be determined whether the adverse effects dissipate with continued use of the drug. If adverse effects are distressing to the patient, modify the treatment plan to make the therapy more acceptable. For example, instead of giving two equal-sized doses daily to a patient, the larger dose or the entire daily dose could be given at bedtime if daytime sedation is a major problem. Additionally, encourage the patient to be as active as possible during the daytime hours to help ward off sedation.

Many of the adverse effects that are not transient can be minimized to some extent. For example, encourage the patient with akathisia to walk when he or she feels restless. Because many of the adverse effects are related to a relative excess of cholinergic stimulation, anticholinergic drugs—most commonly diphenhydramine, benztropine, *amantidine,* or trihexyphenidyl—may be administered to treat or minimize these effects. The choice of drug and the route of drug administration are dependent on the severity of the EPS present and the degree of patient distress. If the patient is experiencing acute dystonic symptoms, diphenhydramine (Benadryl) or benztropine may be used either intramuscularly or intravenously. Diphenhydramine works rapidly to alleviate acute dystonia, especially those forms that could be life threatening. Once a patient experiences acute EPS, the likelihood increases that acute EPS will recur. To prevent recurrence, benztropine or trihexyphenidyl is added to existing drug therapy on a continuing basis. Sometimes, these drugs are started prophylactically to prevent EPS. However, remember that these drugs have their own adverse effects (see Chapter 21 for more information). EPS are more likely to occur if the patient repeatedly stops and restarts therapy; thus, the patient should be encouraged to stay on drug therapy once started. Akathisia is sometimes difficult to differentiate from anxiety. If this difficulty arises, the prescriber may treat for one or the other, assess the effectiveness of therapy, and change the drugs if the patient does not respond positively to drug therapy.

If the patient develops neuromalignant syndrome, stop the antipsychotic immediately, as this is a potentially

life-threatening event. Notify the prescriber that the medication has been stopped for this reason, and obtain orders to treat the syndrome symptomatically. Infuse large volumes of normal saline as quickly as the patient can tolerate, which not only rehydrates the patient but also flushes the drug from the person's body. Antipyretics are also usually administered. Because of the delirium that can occur with neuromalignant syndrome, safety precautions may be required. If necessary, stay with the patient continuously, decrease environmental stimuli, or apply physical restraints (although restraints are usually used only as a last resort).

Providing Patient and Family Education

- Teach patients and families about realistic expectations of antipsychotic therapy. Include information about the delay before relief of symptoms and the necessity of continuing with the medication even after symptom relief is achieved.
- Inform patients and families about possible adverse effects. They need to understand that some adverse effects will have to be managed because it may not be possible to eliminate them completely.
- Encourage patients to report adverse effects so that these effects can be managed appropriately.
- Teach patients to avoid using alcohol and other CNS depressant drugs in order to avoid any additive effects that will produce CNS depression.
- Encourage patients to wear protective covering and sunscreen if they are outside a great deal. Advise them to balance the need to wear clothing to protect from photosensitivity with the need to choose clothing that is cool enough to prevent overheating and heat stroke. Remind patients to drink extra fluids when they are out in the heat in order to prevent dehydration that could lead to neuromalignant syndrome.
- Caution patients about use of heavy machinery or driving until individual response to the drug is known.

Ongoing Assessment and Evaluation

Treatment with haloperidol is considered effective if the psychotic symptoms are controlled or reduced and the patient does not develop serious adverse effects.

Drugs Closely Related to P Haloperidol

The other typical antipsychotics are closely related to haloperidol. Molindone (Moban), perphenazine, loxapine (Loxitane), trifluoperazine, fluphenazine (Prolixin), thiothixene (Navane), and pimozide are very similar to the prototype haloperidol in terms of therapeutic uses, pharmacokinetics, pharmacodynamics, and adverse effects. A few exceptions should be noted. The use of pimozide is restricted to treatment of Tourette syndrome. Thiothixene and pimozide have significantly longer half-lives than haloperidol. Unlike haloperidol, some of the typical antipsychotics are metabolized by the P-450 system: pimozide by CYP3A and CYP1A2 and perphenazine by CYP2D6. Molindone and perphenazine create more sedation than haloperidol.

MEMORY CHIP

P Haloperidol

- Typical antipsychotic used to treat schizophrenia and other psychotic illnesses
- Creates its effects by blocking dopamine (specifically D_2), alpha, serotonin, and histamine receptors; minimal blocking effects at cholinergic receptors
- Major contraindication: Parkinson disease
- Most common adverse effect: extrapyramidal symptoms (EPS) such as pseudoparkinsonism, akathisia, acute dystonia, and tardive dyskinesia
- EPS adverse effects are caused by relative lack of dopamine stimulation.
- Most serious adverse effect: neuromalignant syndrome
- **Life span alert: Young adult males, especially young black males, have the highest risk for dystonias. Older adult women have the highest risk for tardive dyskinesia.**
- Maximizing therapeutic effects: Encourage patient to take therapy; check that patient has swallowed drug.
- Minimizing adverse effects: Keep dose as low as possible; avoid going on and off the drug therapy because this behavior increases risk for EPS; administer anticholinergic drugs to treat or prevent EPS adverse effects.
- Most important patient education: importance of continued therapy; how to cope with transient adverse effects and minimize impact of chronic adverse effects
- **Black box warning: related to use in dementia related psychosis due to increased risk for mortality in elderly dementia patients.**

Drugs Significantly Different From P Haloperidol

Chlorpromazine (Thorazine), thioridazine (Mellaril), and mesoridazine (Serentil) are all considered low-potency antipsychotics compared with haloperidol, which is a high-potency antipsychotic. This distinction means that a higher dosage of the low-potency drug is necessary to achieve the same antipsychotic effect that is achieved with haloperidol. There is no difference in efficacy between the high-potency and low-potency antipsychotics in treating psychotic symptoms. Recall that the definition of potency is how many milligrams of drug are needed to achieve an effect, and that efficacy refers to how effective the drug is in achieving the therapeutic goal. See Chapter 4 for a complete discussion of these terms. These antipsychotic drugs differ distinctly, however, in their adverse effect profiles. High-potency antipsychotics such as haloperidol cause little sedation or anticholinergic adverse effects such as blurry vision, constipation, dry mouth, urinary hesitation, and delirium, whereas they have a very high likelihood of causing EPS such as dystonias, akathisia, and Parkinson-like effects. Low-potency antipsychotics such as chlorpromazine, on the other hand, tend to produce sedation and frequent anticholinergic adverse effects with a low probability of EPS. Table 17.3 presents a comparison of the risks of various adverse effects with high- and low-potency antipsychotic agents.

Because the high-potency and low-potency antipsychotics alleviate psychotic symptoms to a similar degree, most

Box 17.5 CLOZARIL TREATMENT/PATIENT MANAGEMENT SYSTEM

Results of early clinical studies with clozapine (Clorazil) indicated that it was associated with a 1% to 2% incidence of potentially lethal agranulocytosis. To minimize this risk, clozapine is available only through treatment systems that ensure a weekly or biweekly WBC testing prior to delivery of the next supply of medication. During the 5 years of WBC monitoring with the Clozaril National Registry, the risk for agranulocytosis was reduced to approximately 0.38%. Guidelines for the Clozaril treatment/patient management system include:

- Treatment systems may include facilities with on-site pharmacies, facilities without on-site pharmacies, and individual treating physicians.
- Patients taking clozapine are enrolled in the Clozaril National Registry.
- Clozaril is only available through weekly or biweekly distribution systems.
- WBC evaluation is required prior to initiation of therapy, weekly or biweekly during therapy, and for 4 weeks after discontinuation.
- All WBC evaluations (normal and abnormal results) must be promptly reported to the Clozaril National Registry within 7 days of collection.
- The Clozaril National Registry must be promptly notified of all patients who discontinue treatment.

prescribers consider which type has the least desirable adverse effect profile for each patient. A patient may also express a particular preference for one drug over another. The prescriber chooses the antipsychotic agent accordingly. For example, because an older adult is more sensitive to anticholinergic effects, a drug that produces little anticholinergic effect, such as haloperidol, may be used. Another example is a patient who has previously experienced an EPS such as akathisia from taking haloperidol, who may agree to try thioridazine, which, although more sedating, has much less likelihood of causing EPS.

• C Atypical Antipsychotics

Atypical antipsychotics differ from the typical antipsychotics in that they target only specific dopamine receptors, whereas the typical antipsychotics target all dopamine receptors. This specificity creates a much lower adverse effect profile. Another major advantage of the atypical antipsychotics is that they treat both the negative and positive symptoms of schizophrenia. The first atypical antipsychotic was clozapine. Because this drug causes a serious adverse effect, agranulocytosis, it is not often used in the United States. When it is used, strict guidelines must be followed (Box 17.5). Olanzapine (Zyprexa), which does not carry a risk for agranulocytosis, is the prototype atypical antipsychotic.

Conventional knowledge about typical antipsychotics and atypical antipsychotics is that the atypical agents are more effective, have fewer adverse effects, and are preferable to patients. These beliefs are based on short-term efficacy trials performed when the manufacturers were first developing atypical antipsychotics and seeking FDA approval. Because atypical antipsychotics generally cost more than typical antipsychotics, several recent studies have attempted to determine if the atypical agents are truly better and thus worth the additional cost. These research findings challenge the original assumption and indeed have set off great discussion among the psychiatric scientific community. In general, research has not found atypical antipsychotics to be more effective in managing symptoms than typical antipsychotics yet they are significantly more expensive. While atypical antipsychotics produce less tardive dyskinesia, and less akathisia, they increase the risk of hyperglycemia, hyperlipidemia, and weight gain. (Rosenheck, Perlick, Bingham, et al., 2003; Liebermann, Stroup, McEvoy, et al., 2005; Luft & Taylor, 2006). The impact on quality of life from atypical antipsychotics has not been clearly established as research is somewhat contradictory. Jones, Barnes, Davies, et al. (2006) found that patients who were randomly assigned to receive a typical antipsychotic actually had greater improvement in their quality of life and reduction in their symptoms after one year of treatment than those assigned to receive an atypical agent (other than clozapine). However, Lewis, Davies, Jones, et al. (2006) found atypical and typical antipsychotics to be similar in their effects on quality of life and symptoms in patients who had been previously unresponsive to drug therapy.

The decision to prescribe either a typical or an atypical antipsychotic will need to be based on individual basis for each patient as each can be considered to have benefits and risks.

Nursing Management of the Patient Receiving P Olanzapine

Core Drug Knowledge

Pharmacotherapeutics

Olanzapine is used to treat psychotic symptoms in schizophrenia and for short-term treatment of acute bipolar

disorder with either acute mixed or manic episodes. IM forms are used to treat the associated psychomotor agitation, such as threatening, urgently distressing, or self-exhausting behaviors. Olanzapine is also used in combination therapy with lithium or valproate for the treatment of acute manic episodes in bipolar disorder. In addition, it is useful as a maintenance drug for patients with bipolar disease who have responded to acute therapy.

Other off-label uses include Alzheimer-type dementia, other dementias, and obsessive-compulsive disorder that does not respond to selective serotonin reuptake inhibitors. Some research indicates that although olanzapine does have some efficacy in the treatment of Alzheimer disease, the adverse effects offset any therapeutic advantages so its use is not recommended (Schneider, Tariot, Dagerman, et al., 2006).

Pharmacokinetics

Olanzapine is moderately absorbed and achieves a bioavailability of 60%. The drug is highly protein bound, at 93%. It is metabolized by glucuronidation and oxidation through the cytochrome P-450 system, particularly CYP1A2 and CYP2D6. Elimination is through the urine and the feces, with about twice as much being eliminated in the urine. Half-life is between 21 and 54 hours. This long half-life allows the drug to be dosed once a day.

Pharmacodynamics

Olanzapine works by blocking several neuroreceptor sites, including serotonin, dopamine, muscarinic, histamine-1 (H_1), and alpha-1. Olanzapine has high affinity for these sites but lower affinity for gamma-aminobutyric acid (GABA), benzodiazepine, and beta receptor sites, although blockade at these receptor sites also occurs. Olanzapine, like other atypical antipsychotics, affects the negative symptoms as well as the positive symptoms of schizophrenia. (This is in contrast to typical antipsychotics, such as haloperidol, which affect only the positive symptoms.) Olanzapine, as well as other atypical antipsychotics, may elevate blood glucose levels, sometimes to extremely high levels, through an unknown mechanism. Recent research indicates one possibility. A particular brain enzyme from the hypothalamus, known as AMP-kinase, is known to stimulate appetite. What has recently been discovered is that the amount of this enzyme will increase in mice given an atypical antipsychotic. AMP-kinase levels have also been found to increase if histamine receptors (specifically, H_1 receptors) are stimulated. Therefore, blocking the H_1 receptor may prevent weight gain from atypical antipsychotics (Kim, Huang, Snowman, et al., 2007).

Contraindications and Precautions

The only labeled contraindication for olanzapine is known hypersensitivity. Like haloperidol and the typical antipsychotics, olanzapine and the other atypical antipsychotics also carries a black box warning that its use in older adults with dementia related psychosis increases the risk of death from cardiovascular events and infections. Olanzapine should be avoided in older adults with dementia-related psychosis, because of this increased risk (Salzman et al., 2008). If olanzapine or other atypical antipsychotics are used in treating dementia related psychosis, these drugs should be used for the shortest duration possible. Gradual dose reductions are recommended periodically to ensure that the lowest dosages are used. In the nursing home setting, guidelines require that these drugs are evaluated and gradual dose reductions are considered on an ongoing basis (Meeks & Jeste, 2008).

Olanzapine carries warnings for several other serious effects. Olanzapine, and all other atypical antipsychotics, may create hyperglycemia which may be severe enough to induce ketoacidosis or hyperosmolar coma, or death. Precautions should be taken if the patient has diabetes. Patients who are not diagnosed with diabetes at the start of therapy still remain at risk for developing significant hyperglycemia while taking olanzapine or other atypical antipsychotics. The risk appears to be highest in patients with multiple risk factors for diabetes. All patients should be monitored regularly for evidence of hyperglycemia. Antidiabetic therapy is frequently necessary.

Olanzapine and all other atypical antipsychotics may also induce significant hyperlipidemia and weight gain. The combination of elevated glucose levels, elevated lipid levels, and weight gain is described as metabolic syndrome and is considered a risk factor for serious cardiovascular effects, such as MI.

There is also a warning that olanzapine may induce seizures in patients with a history of seizures or with conditions that potentially lower the seizure threshold. Olanzapine should be used cautiously in patients with a history of seizure disorder because it is known to reduce the seizure threshold.

Olanzapine also carries several other precautions. Olanzapine is a pregnancy category C drug. It may cause hyperprolactinemai (elevated prolactin levels) (Lin, Poland, Lau, et al., 1988). Olanzapine may impair judgment, thinking, and motor skills, and ability to operate machinery.

Olanzapine can also induce orthostatic hypotension; additional precautions should be used if the patient receives other drugs that may cause orthostatic hypotension concurrently with olanzapine. Again, older adults are at increased risk. Caution should be used when treating patients who have hepatic impairment, in patients with pre-existing conditions that are associated with limited hepatic functional reserve, and in patients who are receiving other drugs that may cause hepatotoxicity, because clinically significant elevations of liver enzymes can occur. All antipsychotic drugs have been associated with esophageal dysmotility and aspiration; thus, olanzapine and other antipsychotics should be used cautiously in patients at risk for aspiration pneumonia.

Adverse Effects

In general, atypical antipsychotics are well tolerated and produce few adverse effects. In patients who do experience adverse effects, the most common are CNS related: drowsiness and sedation, insomnia, agitation, nervousness, hostility, and dizziness. The most serious adverse effects with olanzapine are tardive dyskinesia and neuroleptic malignant syndrome, although these effects occur very rarely.

Hyperglycemia can be common in patients with diabetes and may be pronounced enough to require insulin adjustments; diabetic ketoacidosis is possible. Patients without a history of diabetes risk developing diabetes from therapy; the more diabetic risk factors present, the more likely hyperglycemia may develop. In addition to elevated glucose levels, patients may gain weight (a significant number of patients gain more than 7% of their baseline weight), have decreased insulin sensitivity, have lipid elevations, and develop metabolic syndrome (increased visceral fat, as measured by waist circumference, hyperglycemia, hypertension, and dyslipidemia), placing the patient at increased risk for cardiovascular problems. Olanzapine has a higher risk for inducing metabolic disorders than some of the other atypical antipsychotics.

A wide variety of other adverse effects can potentially occur, including:

- Cardiovascular (hypotension, tachycardia, hypertension, bradycardia, cardiac arrest, cerebrovascular accident, chronic heart failure, palpitation, vasodilation, pulmonary embolus, and premature atrial fibrillation)
- CNS (asthenia, abnormal gate, akathisia, akinesia, tremor, amnesia, ataxia, delirium, dysarthria, hypesthesia, hypokinesia, incoordination, increased libido, vertigo, intense or abnormal dreams, euphoria, paresthesia, suicidal thoughts, neuroleptic malignant syndrome, and pseudoparkinsonism)
- Dermatologic (rash)
- Gastrointestinal (constipation, abdominal pain, weight gain, increased appetite, and dry mouth)
- Genitourinary (premenstrual syndrome)
- Musculoskeletal (arthralgia, neck rigidity, twitching, hypertonia, and tremor)
- Ocular (dimmed vision)
- Respiratory (rhinitis, cough, and pharyngitis)
- Metabolic (weight gain, increased glucose levels, increased lipid levels)

Drug Interactions

The risks of using olanzapine in combination with other drugs have not been extensively evaluated. Caution should be used when olanzapine is taken in combination with other centrally acting drugs or alcohol. Coadministering either ethanol or diazepam with olanzapine potentiates the orthostatic hypotension observed with olanzapine. Because of its potential for inducing hypotension, olanzapine may enhance the effects of certain antihypertensive agents. Olanzapine also may antagonize the effects of levodopa and dopamine agonists.

Agents that induce CYP1A2 or glucuronyl transferase enzymes, such as omeprazole and rifampin, may increase olanzapine clearance. Inhibitors of CYP1A2 could potentially inhibit olanzapine clearance. Although olanzapine is metabolized by multiple enzyme systems, induction or inhibition of a single enzyme may appreciably alter olanzapine clearance. Therefore, a dosage increase (for induction) or a dosage decrease (for inhibition) may have to be considered with specific drugs.

Carbamazepine therapy (200 mg twice daily) increases the clearance of olanzapine by approximately 50%, likely because carbamazepine is a potent inducer of CYP1A2 activity. Higher daily doses of carbamazepine may cause an even greater increase in olanzapine clearance. Fluoxetine, a CYP1A2 inhibitor, decreases the clearance of olanzapine, resulting in a mean increase in olanzapine maximum concentration (C_{max}) following fluoxetine of 54% in female nonsmokers and 77% in male smokers. Mean increases in olanzapine area under the curve (AUC) are 52% and 108%, respectively. Lower doses of olanzapine should be considered in patients receiving concomitant treatment with fluoxetine. The combination of olanzapine and the antidepressant fluoxetine increases the risk of suicide due to the increased availability of olanzapine. Table 17.4 lists potential drug interactions with olanzapine.

Assessment of Relevant Core Patient Variables

Health Status

Obtain the patient's baseline vital signs and other measurements, such as weight, serum glucose, triglyceride levels, and complete blood count, before olanzapine therapy begins. It is critical that a patient's serum glucose levels be monitored before and throughout any atypical antipsychotic therapy. Lipids levels should be monitored throughout therapy as well. Also, assess for various individual factors that

TABLE 17.4 Agents That Interact with P Olanzapine

Interactants	Effect and Significance	Nursing Management
carbamazepine	Therapeutic effects of olanzapine may be decreased	Adjust dose as needed
charcoal	Charcoal can decrease absorption	Do not give together
CYP1A2 inducers (e.g., carbamazepine, omeprazole, rifampin)	May decrease olanzapine serum concentrations	May need to increase olanzapine dose
CYP1A2 inhibitors (e.g., fluoxetine)	May increase olanzapine serum concentrations	May need to decrease dose
fluoxetine	Coadministration resulted in a small (16%) decrease in olanzapine clearance	May need to decrease olanzapine dose

can alter drug response, such as liver function and gastric absorption.

Life Span and Gender

Document the age and gender of the patient. Explore the sexual patterns and reproductive goals of the patient, because reproductive effects such as changes in libido, amenorrhea, irregular menses, impotence, and ejaculatory failure may occur. Consider whether the patient is pregnant or could become pregnant, because olanzapine is a pregnancy category C drug. The elderly patient receiving atypical antipsychotics should be considered at higher risk for adverse effects. Older adults with dementia related psychosis are at increased risk of death from infections and cardiovascular events if they receive olanzapine and other atypical antidepressants. This is an off label use of the drug.

Lifestyle, Diet, and Habits

Evaluate the patient's diet. Assess for high fat intake, high carbohydrate and sugar intake, and high overall calorie intake. Assess the baseline exercise level and throughout therapy.

Evaluate the patient's caffeine intake and diet because the efficacy of olanzapine may be affected by fluctuations in caffeine intake. Also assess for use of dong quai and St. John's wort (because these herbal medicines may cause photosensitization) and for the use of kava kava, gotu kola, valerian, St. John's wort, and ethanol (because these agents may increase CNS effects).

Assess the patient's occupational and recreational activities because orthostatic hypotension, drug-related dizziness, and blurred vision may impair coordination and dexterity, and hypotension may occur with hot tubs, hot showers, or tub baths.

Environment

Assess the climate in which the drug will be administered because drug-related heatstroke may occur in hot weather.

Nursing Diagnoses and Outcomes

Several nursing diagnoses may apply to the patient receiving atypical antipsychotics. Examples include:

- Imbalanced Nutrition: More than Body Requirements, related to increased appetite and secondary to olanzapine use
  Desired outcome: *The patient will state that there is a risk for weight gain and will identify the effects of a low-fat diet and exercise on weight control.*
- Risk for Injury related to drug-induced dizziness, blurred vision, and orthostatic hypotension
  Desired outcome: *The patient will identify factors that increase the risk for injury and will relate intent to use safety measures and practices to prevent injury.*
- Risk for Fluid and Electrolyte Imbalance and Hyperglycemia related to adverse effects of medication
  Desired outcome: *The patient will maintain appropriate fluid and electrolyte balance while receiving medication.*
- Risk for Sedation related to adverse effects of the medication
  Desired outcome: *The patient will maintain appropriate level of wakefulness while receiving medication.*

Planning and Intervention

Maximizing Therapeutic Effects

Maintaining adherence to any medication regimen once a patient experiences relief of symptoms is an ongoing challenge for all health care providers. With patients experiencing disturbances of their thoughts and perceptions, focus from the very start on developing a trusting therapeutic relationship. This trust frequently will be what enables the patient to develop the insight necessary to continue taking medication. This same trust can also form the basis on which you and the patient candidly discuss the many benefits of continuing with the medication, even if adverse effects occur. By focusing on the patient's own hopes and aspirations for the quality of life he or she wishes to have, you help contribute to adherence to the medication regimen.

Minimizing Adverse Effects

Assess fasting blood sugar before drug therapy is initiated. Fasting blood sugar must be monitored throughout therapy, especially if the patient has diabetes. Monitor all patients for signs of hyperglycemia throughout therapy. Diabetic therapy may be indicated. Lipid levels are also monitored during therapy due to the risk of metabolic syndrome related to the use of antipsychotics (Meyer et al., 2008). If older adults with dementia-related psychosis receive the drug off label, assess closely for cardiovascular complications by monitoring their EKG readings and use strict medical asepsis to minimize risk of infection and assess for indications of infection. Early assessment and treatment of these problems may minimize risk of deaths from these adverse effects. To minimize daytime drowsiness, you can give the entire daily dose at night. To prevent orthostatic hypotension, keep patients well hydrated and have them arise slowly from bed.

Providing Patient and Family Education

- Teach the signs of hyperglycemia; patients with diabetes may need to be taught to monitor blood sugar more frequently than before olanzapine therapy.
- Teach patients and families that the therapeutic response will not be immediate.
- Stress the importance of continuing drug therapy even in the absence of psychotic symptoms.
- Help patients stay motivated to continue treatment. To promote adherence to the therapeutic regimen, educate patients and families about the effects of medication—both therapeutic and adverse. Advise patients about adverse effects that, if unidentified, may contribute to nonadherence. An example of this kind of effect is sedation.
- Provide education on a low fat diet and calorie restricted diet (if indicated).
- Ensure that patients understand the importance of keeping the drug safely stored and away from curious children.

MEMORY CHIP

P Olanzapine

- Atypical antipsychotic used to treat schizophrenia and bipolar mania
- Olanzapine works by blocking serotonin, dopamine, muscarinic, H_1, and alpha-1 receptor sites
- Normally well tolerated
- Most common adverse effects: hyperglycemia (especially in diabetic patients), sedation, and drowsiness
- Most serious adverse effects: tardive dyskinesia and neuroleptic malignant syndrome (both rare)
- **Life span alert: Older adults are more at risk for adverse effects.**
- Maximizing therapeutic effects: Encourage patient to take medication regularly.
- Minimizing adverse effects: Monitor glucose levels throughout therapy for all patients; give daily dose at bedtime to decrease daytime sedation.
- Most important patient education: Full therapeutic effect will take time to achieve; patient may need to tolerate some adverse effects until they pass.
- **Black box warning: related to use in dementia related psychosis due to increased risk for mortality in elderly dementia patients.**

Ongoing Assessment and Evaluation

Treatment with an atypical antipsychotic such as olanzapine requires ongoing assessment and evaluation because of the ongoing, chronic nature of most illnesses in which they are used. For this reason, continue to assess the patient for the originally presenting symptoms for which the drug therapy was initiated. Also, evaluate the patient's ability to meet the therapeutic goals identified by the entire treatment team. Throughout this process, persist in monitoring for any adverse effects that the patient may develop, especially hyperglycemia and hyperlipidemia.

Drugs Closely Related to P Olanzapine

Drugs related to olanzapine include risperidone (Risperdal), ziprasidone (Geodon), aripiprazole (Abilify), paliperidone (Invega), clozapine (Clozaril), and quetiapine (Seroquel). Like olanzapine, these drugs are also approved for used in treating bipolar disorder and differ slightly from olanzapine in their adverse effects and half-lives. Risperidone, ziprasidone, and aripiprazole produce fewer anticholinergic effects. Quetiapine produces more sedation than olanzapine. Aripiprazole (Abilify) is a newer atypical antipsychotic and carries an indication for major depressive disorder as an adjunct treatment.

Compared with olanzapine, clozapine causes stronger anticholinergic effects and is more likely to produce sedation and orthostatic hypotension. Clozapine, too, produces significant weight gain; the other drugs closely related to olanzapine produce less weight gain. Clozapine has the unique adverse effect of increasing the risk for agranulocytosis, which can be fatal. Patients receiving clozapine require close watch of their white blood cell count. They are at most risk during the first 6 months of therapy. (See Box 17.5 for more information.)

Compared with olanzapine, aripiprazole has a longer half-life, and the other drugs have shorter half-lives.

DRUGS FOR ALZHEIMER-TYPE DEMENTIA

• C Acetylcholinesterase Enzyme Inhibitors

Acetylcholine is a neurotransmitter for several CNS circuits that are located in the basal forebrain, the hippocampus, and parts of the cerebral cortex. Agents that augment this system have been under investigation to treat Alzheimer disease for more than 20 years, and numerous types of drugs that augment levels of acetylcholine to compensate for losses of cholinergic function in the brain have been used in these patients. These drugs have included acetylcholine precursors, muscarinic agonists, nicotinic agonists, and acetylcholinesterase inhibitors. The only Food and Drug Administration–approved drugs to treat the symptoms of Alzheimer disease are the acetylcholinesterase inhibitors. Acetylcholinesterase (AChE) is the enzyme that breaks down acetylcholine. By inhibiting the action of AChE, acetylcholinesterase inhibitors (AChEIs) prolong the activity of acetylcholine on cortical cholinergic receptors and in the synapse. The mechanism of action of the three AChEIs—tacrine, donepezil, and rivastigmine—is essentially the same. These agents increase concentrations of the memory-regulating and cognition-regulating neurotransmitter acetylcholine by reversibly inhibiting the enzyme cholinesterase. Although these drugs have not been shown to alter the course of the dementing process, it is anticipated that disease effects will lessen as the disease process advances and fewer cholinergic neurons remain intact.

The prototype drug used to treat Alzheimer-type dementia is rivastigmine (Exelon). Table 17.5 summarizes selected Alzheimer drugs.

Nursing Management of the Patient Receiving P Rivastigmine

Core Drug Knowledge

Pharmacotherapeutics

Rivastigmine is indicated for treating mild to moderate dementia of the Alzheimer type. In clinical studies, it has been shown to enhance cognition (memory, language, orientation) and improve the ability to perform activities of daily living among patients with mild to moderate Alzheimer disease. Rivastigmine may also be effective in treating vascular dementia. More research is required to confirm this possibility.

Pharmacokinetics

Rivastigmine is rapidly and completely absorbed, with peak plasma concentrations reached in 1 hour. Administering

rivastigmine with food delays drug absorption (by about 1.5 hours) but does not impair it. Rivastigmine may be taken with food if gastrointestinal adverse effects are problematic. Rivastigmine also is formulated for topical use,administered in a daily patch; this formulation decreases the gastrointestinal adverse effects.

Rivastigmine is widely distributed throughout the body. It penetrates the blood–brain barrier, reaching peak concentrations in cerebrospinal fluid in 1.4 to 2.6 hours. Rivastigmine is 40% bound to plasma proteins.

Rivastigmine is rapidly and extensively metabolized by AChE; minimal metabolism occurs by the major CYP450 isozymes. Thus, no CYP450 drug interactions have been observed. It is about equally metabolized through the hepatic cytochrome P-450 enzyme system and excreted as unchanged drug in the urine. The elimination half-life is 1.5 hours, with most elimination as metabolites excreted from the kidneys. The oral solution and capsules may be interchanged at equal doses.

Pharmacodynamics

Rivastigmine is a carbamate derivative that is believed to exert its therapeutic effect by enhancing cholinergic function. This enhancement occurs by increasing the concentration of acetylcholine through reversible inhibition of acetylcholinesterase. Rivastigmine does not alter the course of the underlying dementing process.

Contraindications and Precautions

Rivastigmine is contraindicated in patients with hypersensitivity to carbamate derivatives. No adequate or well-controlled studies have been performed in children or in pregnant or lactating women; therefore, rivastigmine should be used cautiously in these patients. Rivastigmine is in pregnancy category B. It is not known whether rivastigmine is excreted in breast milk. Like other drugs that increase cholinergic activity, rivastigmine should be used with care in patients with a history of asthma or obstructive pulmonary disease.

Adverse Effects

Rivastigmine is associated with substantial gastrointestinal adverse reactions, including nausea and vomiting, anorexia, and weight loss. Other adverse effects include dizziness, headache, chest pain, peripheral edema, vertigo, joint pain, agitation, nervousness, delusion, paranoid reaction, coughing, generalized rash, and urinary incontinence. Rivastigmine may have vagotonic effects on heart rates (resulting in bradycardia) because the drug increases cholinergic activity. These vagotonic effects may be particularly important in patients with "sick sinus syndrome" or other supraventricular cardiac conduction conditions. Because it increases cholinergic activity, rivastigmine may cause urinary obstruction and may have some potential for causing seizures, although seizure activity also may be a manifestation of Alzheimer disease.

Drug Interactions

Pharmacokinetic drug interactions are not believed to occur with rivastigmine because only minimal metabolism of the drug occurs through the major CYP450 isozymes.

Synergistic effects can be expected when AChEIs are given with succinylcholine, similar neuromuscular blocking agents, or cholinergic agonists, such as bethanechol. Because of their mechanism of action, AChEIs have the potential to interfere with the activity of anticholinergic medications.

Assessment of Relevant Core Patient Variables

Health Status

Assess body systems thoroughly. The patient's cardiac status may be adversely affected by AChEIs because these drugs increase cholinergic activity and may cause bradycardia from vagal effects on heart rate. The cholinergic activity of the AChEIs may cause urinary retention or obstruction; men with benign prostatic hypertrophy may be especially at risk.

Evaluate the patient's renal and hepatic function. Dosage adjustments may be necessary in patients with renal

or hepatic function impairment. Review the patient's respiratory function because respiratory depression may occur. Carefully assess the patient's gastrointestinal status because AChEIs such as rivastigmine may increase gastric acid secretion, cause gastritis, and exacerbate peptic ulcer disease. Assess and closely monitor individuals with a history of ulcer disease or those receiving nonsteroidal anti-inflammatory drugs for symptoms of active or occult gastrointestinal bleeding.

Life Span and Gender

Assess the age of the patient. The mean oral clearance of rivastigmine is 30% lower in elderly people who take rivastigmine. Rivastigmine therapy is seldom indicated in women of childbearing years. If the drug is needed in a woman of childbearing age, assess for pregnancy and lactation. If appropriate, explore potential benefits of rivastigmine therapy compared with potential risks to the fetus or child.

Lifestyle, Diet, and Habits

Assess the patient for tobacco use because nicotine use moderately increases the oral clearance of rivastigmine (by 23%).

Environment

Be aware of the environment in which the drug will be administered. If appropriate, assess the patient's home or living environment. Secure all medication to avoid accidental inappropriate ingestion by the patient.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to decreased desire to eat secondary to nausea and vomiting from drug therapy
  Desired outcome: *The patient will ingest daily nutritional requirements in relation to activity level and metabolic needs.*
- Risk for Injury related to adverse effect of sedation
  Desired outcome: *The patient will establish appropriate sleep and rest patterns, participate in activities, and establish priorities for daily and weekly activities.*

Planning and Intervention

Maximizing Therapeutic Effects

It is important to detect and correct any treatable factors that can cause or contribute to cognitive impairment. Be aware that any cognitive impairment may be exacerbated by hearing or visual deficits, depression, delirium arising from a urinary tract infection, heart failure, electrolyte imbalance, or anemia. When the patch form is used, rotation of the site may be necessary to ensure adequate absorption. In patients with moderate dementia, it may be necessary to place the patch on the back where it cannot be removed by them.

Minimizing Adverse Effects

Offer small frequent meals or give the drug with food to offset gastrointestinal effects of nausea and vomiting. Monitor weight throughout therapy. If weight loss occurs, encourage intake of nutrient- and calorie-rich foods that are acceptable to the patient, such as Ensure or Boost beverages, milkshakes, or puddings. When the patch form is used, assess for dermatitis or rash at the site of the patch.

Providing Patient and Family Education

The irreversible nature of Alzheimer disease and its progressive, deteriorating course have devastating effects on affected individuals, their caregivers, and their families. Although drug therapy is directed toward enhancing cognitive and functional abilities, or at least slowing the cognitive decline, teaching considerations reflect more issues regarding the disease process and its progressive nature as well as the burdens facing the caregiver.

- Advise patients and families that nausea and vomiting are likely with rivastigmine use and that anorexia and weight loss may result. Encourage them to monitor for these adverse events and to inform the prescriber if they occur. Inform them that there is a patch form and this may decrease the gastrointestinal adverse effects, thus improving compliance.
- To increase the likelihood that patients will accept the medication from caregivers willingly, teach helpful communication techniques, such as using concrete language, maintaining social greetings and rituals, using a soft tone of voice, and simplifying and repeating instructions frequently.

Ongoing Assessment and Evaluation

Rivastigmine, as with other AChEIs, produces only modest improvement in some measures of cognitive functioning and in other areas of functioning in the patient with mild to moderate Alzheimer disease, apparently slowing the progression of the disease. However, advise patients and their families to maintain realistic expectations regarding what the drug can do.

MEMORY CHIP

P Rivastigmine

- Used in Alzheimer-type dementia
- Works by inhibiting acetylcholinesterase (the enzyme that breaks down acetylcholine), thus increasing the amount of active acetylcholine
- Most common adverse effects: gastrointestinal
- Most serious adverse effect: bradycardia
- Maximizing therapeutic effect: Assess for and correct any treatable factors that may impair cognition.
- Minimizing adverse effects: Offer small, frequent meals; monitor weight; offer nutritional supplements.
- Minimizing adverse effects: consider transdermal option to reduce the gastrointestinal adverse effects.
- Most important patient and family education: that drug therapy will not cure Alzheimer disease but will minimize symptoms; importance of monitoring weight; and techniques to gain patient acceptance of medication

Drugs Closely Related to P Rivastigmine

Donepezil (Aricept), galantamine hydrobromide (Razadyne), and tacrine (Cognex) all have similar pharmacotherapeutics and pharmacokinetics. Donepezil and galantamine are believed to be as effective as rivastigmine in the treatment of Alzheimer disease, although the therapeutic effect is very small. Tacrine may not be as effective as the other drugs. Like rivastigmine, these three drugs may also be effective in treating vascular dementia; more research is necessary to confirm this possibility. In contrast to rivastigmine, which is metabolized by cholinesterase, donepezil, galantamine, and tacrine are metabolized via the P-450 enzyme system. Donepezil seems to cause fewer gastrointestinal adverse effects than either rivastigmine or galantamine. Gradually slowing the titration of rivastigmine and galantamine over at least 3 months may minimize the gastrointestinal effects, making the GI adverse effects from the three drugs similar. The rivastigmine patch may be used to encourage compliance as it is dosed once daily and often reduces gastrointestinal side effects. Donepezil is dosed daily.

Drug Significantly Different From P Rivastigmine

Memantine (Namenda) is a drug for Alzheimer disease that works in a different way than the prototype rivastigmine. *N*-methyl-D-aspartate (NMDA) receptors are believed to be involved in learning and memory, and excessive stimulation of NMDA receptors by the neurotransmitter glutamate is believed to be involved in Alzheimer disease. Normally magnesium ions move away from the receptors, and glutamate then stimulates the receptors. Depolarization occurs at the time glutamate attaches, so calcium is allowed to flow into the calcium channels. Glutamate usually experiences reuptake in the synapse by the glia cell.

However, glutamate reuptake is prevented in Alzheimer disease, and thus glutamate remains in the synapse for a much longer time. Therefore, glutamate continues to stimulate the NMDA receptors, allowing excess calcium to flow into the cell. As the cell normally responds to changes in levels of calcium, this signal is muted with continuous infusion and function declines. Overactivation of glutamate receptors and continuous calcium influx ultimately cause damage to neurons and further decline of cognitive functions. This mechanism may be responsible for both cognitive deficits and neuronal loss in neurodegenerative dementia. Memantine blocks these NMDA receptor sites to prevent the glutamate from overstimulating the receptor. The synaptic level of glutamine does not decrease, but it is prevented from attaching to the NMDA receptor.

The benefits of memantine therapy are modest, and patients can experience a slowing of disease deterioration. Other patients may experience slight improvement in their symptoms. As the drug works in a different way than other drugs for Alzheimer disease, it can be used as combination therapy in disease management. Unlike the prototype rivastigmine, which is for mild to moderate Alzheimer disease, memantine is for moderate to severe disease.

Memantine is generally very well tolerated; in clinical trials the type and rate of adverse effects were similar to those associated with a placebo. Possible adverse effects include dizziness, constipation, headache, and confusion. In clinical trials during drug development, some patients with Alzheimer disease experienced a temporary period of confusion when starting drug therapy or when increasing the dose during the titration period. Memantine is administered orally twice a day.

CHAPTER SUMMARY

- Thought, like mood, is controlled by combinations of neurotransmitters that stimulate neuroreceptors in the brain. The primary neurotransmitter related to thought processing is believed to be dopamine.
- Another important neurotransmitter is acetylcholine. Many areas of the brain secrete acetylcholine; reduction in the amount of this neurotransmitter causes cognitive changes. Acetylcholine has a number of functions including arousal, coordination of movement, memory acquisition, and memory retention. Norepinephrine and serotonin are other neurotransmitters that are believed to be important to normal thought, but their exact mechanisms are not known yet.
- Schizophrenia, a psychotic disorder, has components termed positive and negative symptoms. The term "positive symptom" does not mean that the changes are beneficial to the patient. The positive symptoms of hallucinations and delusions add a layer of something new to the person. They are in excess of or are a distortion of normal brain function. The "negative symptoms" take away from the person's personality and represent a loss or a diminishing of normal brain function. Negative symptoms include flat or blunted emotions, lack of pleasure or interest in things (anhedonia), and limited speech.
- Haloperidol (Haldol) is the prototype typical antipsychotic. It is used to treat psychotic disorders, such as schizophrenia, and relieves primarily positive symptoms. The full therapeutic effect from haloperidol can require several days to develop. Haloperidol creates its effects by blocking dopamine (specifically, D_2), alpha, serotonin, and histamine receptors. It has minimal blocking effects on cholinergic receptors.
- Haloperidol's blockade of dopaminergic receptors produces decreased symptoms of movement disorders, relief of hallucinations and delusions, relief of psychosis, worsened negative symptoms, a release of prolactin, and a quieting of the chemoreceptive trigger zone in the brain. Its blockade of alpha, serotonin, histamine, and cholinergic receptors produces many of its adverse effects.
- The most common reason patients stop taking antipsychotic medications like haloperidol is the occurrence of adverse effects. The higher the dose of haloperidol, the more likely the patient will experience adverse effects. Stopping and starting therapy also increases the likelihood of developing extrapyramidal symptoms (EPS). Encourage the patient to stay with therapy, because some of the adverse effects are transient and can be managed.
- Chlorpromazine (Thorazine), thioridazine (Mellaril), and mesoridazine (Serentil) are all considered low-potency typical antipsychotics, compared with haloperidol, which is a high-potency antipsychotic. A higher dosage of these drugs is necessary to achieve the same antipsychotic affect as those achieved with haloperidol. Both types of typical antipsychotics have the same effectiveness, although they have different adverse effects. High-potency typical antipsychotics, such as haloperidol, have a very high likelihood of causing EPS (e.g., dystonias, akathisia, and Parkinson-like adverse effects). Low-potency typical antipsychotics are more likely to produce sedation and anticholinergic adverse effects but are unlikely to produce EPS.

- Atypical antipsychotics differ from the typical antipsychotics in that they target specific dopamine receptors instead of all of them and that they treat both the negative and positive symptoms of psychotic disorders.
- In general, atypical antipsychotics such as olanzapine are well tolerated and produce few adverse effects, although some patients experience sedation and dizziness. Elevated blood glucose levels can also be problematic, especially for patients with diabetes.
- Drugs that augment levels of acetylcholine, by preventing its breakdown by acetylcholinesterase, compensate for losses of cholinergic function in the brain and are used to treat Alzheimer-type dementia. Rivastigmine (Exelon) is the prototype acetylcholinesterase inhibitor (AChEI).
- Rivastigmine produces modest improvement in some measures of cognitive functioning and in other areas of functioning in the patient with mild to moderate Alzheimer disease, apparently slowing the progression of the disease. The most common adverse effects are gastrointestinal.
- Memantine is also used to treat patients with Alzheimer disease. It works in a unique way to prevent glutamine from overstimulating NMDA receptors. Its effect is also modest.

QUESTIONS FOR STUDY AND REVIEW

1. What are the major differences between high-potency and low-potency typical antipsychotic drugs?
2. Define EPS.
3. What are the differences between typical antipsychotics such as haloperidol and atypical antipsychotics such as olanzapine?
4. Why can acute dystonias be a medical emergency?
5. Describe some of the suggestions that you could offer to a patient to help him or her cope with sedation and drowsiness when haloperidol therapy is first initiated.
6. Describe how rivastigmine produces therapeutic effects in Alzheimer-type dementia.

Drugs Treating Seizure Disorders

Learning Objectives

At the completion of this chapter the student will:

1. Identify the three basic mechanisms of action of the antiepileptic drugs.
2. Identify common core drug knowledge about prototype drugs belonging to the major antiepileptic drug classifications.
3. Identify core patient variables of concern related to the major antiepileptic drugs.
4. Generate a nursing plan of care based on the interactions between core drug knowledge and core patient variables for the major antiepileptic drugs.
5. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for the major antiepileptic drugs.
6. Relate key points for patient and family education for the major antiepileptic drugs.

Drugs Treating Seizure Disorders

Antiepileptics

Antiepileptic drugs that decrease sodium influx

- **phenytoin** (P)
- ethotoin
- fosphenytoin
- carbamazepine
- felbamate
- lamotrigine
- levetiracetam
- oxcarbazepine
- topiramate
- valproic acid

Antiepileptic drugs that decrease calcium influx

- **ethosuximide** (P)
- methsuximide
- phensuximide
- zonisamide

Antiepileptic drugs that increase the effects of GABA

- **benzodiazepines**
- **lorazepam (see also Chapter 15)** (P)
- clonazepam
- clorazepate
- diazepam
- midazolam
- gabapentin
- phenobarbital
- pregabalin
- primidone
- tiagabine
- vigabatrin

Antiepileptic drugs used in seizures related to pre-eclampsia and eclampsia

- **Magnesium sulfate (see also Chapter 53)**

The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Epilepsy, a brain disorder, is not a single entity, but rather a group of neurologic disorders in which CNS neurons display hyperexcitability. This excessive neurologic activity produces a wide variety of effects, from loss of consciousness with generalized muscle twitching to mild alterations in consciousness such as confusion or a blank stare with repetitive blinking. All of these effects from altered neurologic activity are termed **seizures.** More than 2 million people in the United States have experienced an unprovoked seizure or have been diagnosed with epilepsy (National Institutes of Neurological Disorders and Stroke, website). Patients with patterns of seizures who are diagnosed with epilepsy are treated with antiepileptic drugs. Many of the antiepileptic drugs, especially the newer drugs, are not chemically related to each other and do not fit into a drug class with other drugs. The three main ways that antiepileptic drugs work are by decreasing the rate at which sodium flows into the cell, inhibiting calcium flow rate into the cell through specific channels, and increasing the effect of the neuroinhibitor gamma-aminobutyric acid (GABA). Some drugs work in more than one way. Three main classes of drugs used to treat seizures are discussed in this chapter: drugs that decrease sodium influx, represented by the prototype phenytoin; drugs that decrease calcium influx, represented by the prototype ethosuximide; and drugs that increase the effectiveness of GABA, represented by the benzodiazepines. The prototype benzodiazepine, lorazepam, is discussed at length in Chapter 15. Magnesium sulfate is a drug used specifically to treat seizures associated with preeclampsia and eclampsia that is significantly different from all of the prototypes. It is discussed at length in Chapter 53.

PHYSIOLOGY

Action potentials within neurons are initiated by an influx of sodium into the cell through special sodium channels in the cell membrane. For sodium to enter through the cell membrane, the channels have to be open and in an active state (also referred to as depolarization). An action potential follows, and neurons fire. As soon as sodium enters, the channels close and return to an inactive state (also known as a refractory period). When the voltage-dependent channel is inactive, sodium cannot enter through the cell membrane. Thus, the sodium channels cannot be further activated by depolarization, and no additional action potential or neuron firing can occur (UpToDate, 2010a).

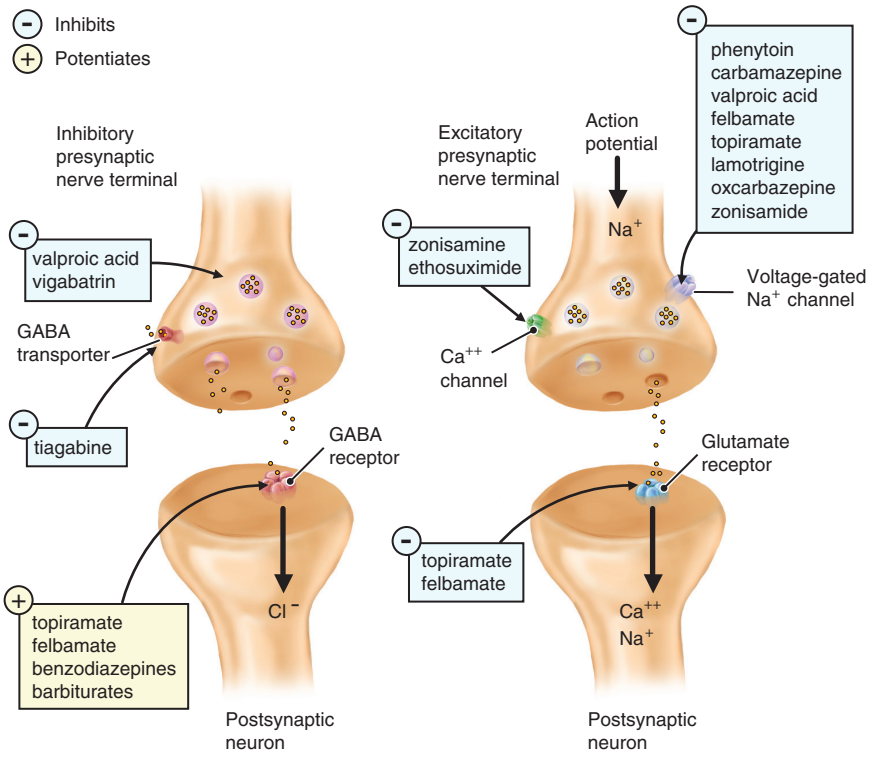
Influx of calcium through specialized voltage-dependent channels also plays a role in creating an action potential. Usually, this has a limited effect, except in the neurons of the hypothalamus. There are three types of calcium channels in neurons, which differ by their rate of reactivation and their voltage dependency. The movement of these two ions, sodium and calcium, into the cell is controlled by special mechanisms to maintain homeostasis and prevent excessive formation of action potentials. Neurons normally fire at about 80 times a second.

When the cell fires and the action potential spreads across the presynaptic terminal, release of neurotransmitters into the synaptic cleft occurs. Some of these neurotransmitters, such as **glutamate,** produce excitation, and others, such as GABA, inhibit the nervous system. **GABA** normally acts as a counterbalance to glutamate, preventing hyperexcitation, and works at specialized postsynaptic receptors; it is present throughout the brain. When GABA is attached at the receptor, it permits more chloride ions to flow across the cell membrane, inhibiting depolarization. After GABA is released into the synapse, it is taken back up by the nerve cell to be either degraded or re-released. Some GABA is taken up by glial cells, which are nonnerve cells in the supporting tissue around the brain and spinal column. GABA in glial cells is metabolized into the amino acid glutamine, which is used by nerve cells to create more GABA or glutamate (Figure 18.1).

PATHOPHYSIOLOGY

When a group of neurons exhibits coordinated, high-frequency discharge, it is termed a focus. The causes of a focus include head trauma, tumor growth, hypoxia, and inherited birth defects. When the activity from a focus spreads to other areas of the brain, causing other neurons to join in the hyperactivity, seizures result. Seizure may result from either high levels of glutamate or low levels of GABA, which allow the focus to take over in the brain. In epilepsy, the neurons may fire as many as 500 times a second, in great excess of the normal range. A genetic variation of the ion channels for sodium and calcium may allow excess ions to flow through these pathways, inducing seizures (National Institute of Neurologic Disorders and Stroke, website). The classifications of seizures are based on how widespread the neural hyperactivity is within the brain. The two basic types of seizures are partial (also known as focal) and generalized. Figure 18.2 presents the classifications of seizures. Table 18.1 shows which antiepileptic drugs are used for which seizure type. **Partial seizures** occur when focus activity is limited to an area of the brain, within one hemisphere. The hyperactive neurons are in the cerebral cortex, and the effect on the adjacent cortical areas is limited. When the focus activity is within both hemispheres, **generalized seizure** symptoms occur. The spread of focus activity can be compared to teenagers at a party. Although a few partygoers might get hyperactive and a little out of control, the parents in the house inhibit the spread of such behavior, and the party should stay on track. If no parents are present, no direct inhibition on the partygoers' actions occurs, and the hyperactive and wild behavior spreads to more and more people at the party, possibly resulting in a melee.

Partial seizures can be further divided into two main subgroups, simple and complex. The defining difference between them is the degree to which the level of consciousness is altered. Simple partial seizures may manifest as twitching in a particular muscle grouping, for example, in the right leg; no loss of consciousness occurs. Complex partial seizures likely involve some involuntary muscle twitching or movement also, but the patient seems confused or exhibits odd behavior, both of which are evidence of an impaired level of consciousness.



• FIGURE 18.1 Mechanisms of antiepileptic drugs.

Generalized seizures are divided into several subtypes: tonic-clonic (also referred to as grand mal), absence (also referred to as petit mal), atonic, myoclonic, status epilepticus, and febrile. A brief description of these generalized seizures follows:

- **Tonic-clonic seizure** (grand mal)—the entire cerebral cortex is altered by hyperexcited neurons. Initially, the

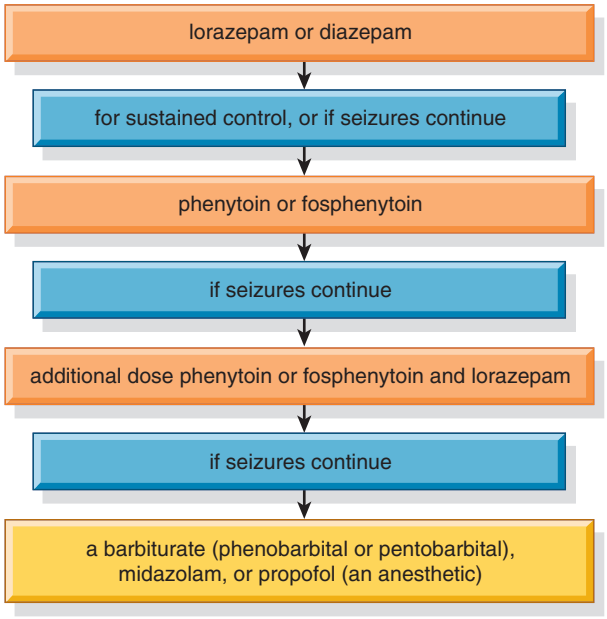
person experiences stiffness and rigidity (tonic phase) and falls to the ground. The person loses consciousness, and no movement follows for several seconds. Then, massive muscle spasms (**convulsions**) occur, with the muscles alternating between contracting and relaxing (clonic phase). Urinary or bowel incontinence and biting the tongue can occur during this phase. Premonitions or auras may occur before the onset of tonic-clonic seizures. Following the convulsions, the person gradually regains consciousness. The patient does not remember the events of the seizures and may not fully recover for up to several days. This post-seizure period is referred to as the **postictal** state.

- **Absence seizure** (petit mal)—very brief loss of consciousness, lasting several seconds but less than 1 minute, is characteristic. Some mild symmetric motor activity, such as eye blinking, often occurs. A blank stare and loss of attention may also be observed. Many times, the seizures are so brief that others do not notice them when they happen. These seizures usually occur in children. More than 100 absence seizures may occur in 1 day. The calcium channels that do not require a high voltage and which quickly become inactive are most likely an integral component of the thalamocortical circuits associated with absence seizures.
- Atonic seizure—a sudden loss of muscle tone occurs. If the muscles affected are just in the neck, "head drop" is observed. If the loss of tone is more widespread, the patient falls suddenly to the ground in a "drop attack."
- Myoclonic seizure—sudden rapid muscle contractions occur. The contractions can be limited to a body region, such as one limb, or can be generalized throughout the body.
- **Status epilepticus**—one seizure follows another without recovery of consciousness between events or return to baseline clinical state, or lasts longer than 5 minutes. All types of seizures in which consciousness is lost can progress to status epilepticus. The most common causes of status epilepticus are stopping antiepileptic drug therapy and alcohol withdrawal. Other causes include acute brain injury or infection and metabolic disorders. Status epilepticus affects about 195,000 people each year in the United States and results in about 42,000 deaths (National Institute of Neurological Disorders and Stroke, 2006). The longer the period of status epilepticus, the higher the mortality rate. The most life-threatening condition results from generalized tonic-clonic seizures, referred to as generalized convulsive status epilepticus.

Status epilepticus is a medical emergency, and intravenous (IV) drug intervention is needed immediately. Current clinical practice is to begin treatment when a patient has a single seizure lasting at least 5 minutes, or has two or more seizures without recovery. Figure 18.3 presents a treatment pathway for status epilepticus; see Table 18.1 for therapeutic drugs. Treatment failures are usually related to insufficient dosing. A patent open airway may be absent, cardiac function may be altered, and high fever (hyperthermia) can occur. Lactic acidosis and elevated blood levels of carbon dioxide may follow. Patients who remain comatose for more than 30 minutes after generalized clonic status epilepticus is controlled may be experiencing subtle status epilepticus. Generalized tonic-clonic motor activity is not associated with subtle status epilepticus; diagnosis is based on electroencephalogram (EEG) readings showing persistent ictal discharges.



• FIGURE 18.3 Treatment pathway for status epilepticus. The drugs shown in orange are first-line drugs. The drugs shown in yellow are second-line drugs. There is not consensus as to which of the second-line drugs should be used first.

- Febrile seizures—generalized seizures can also occur as a result of high fevers in infants and young children and are termed febrile generalized seizures. These types of seizures do not increase the risk of developing epilepsy as the child grows.

In addition to epilepsy, seizures may also occur from known and reversible causes—most commonly, metabolic abnormalities (e.g., hypoglycemia and electrolyte imbalance), meningitis, uremia, pre-eclampsia and toxemia of pregnancy, and drug and alcohol abuse.

C ANTIEPILEPTIC DRUGS

• ANTIEPILEPTIC DRUGS THAT DECREASE SODIUM INFLUX

Phenytoin (Dilantin) is the prototype drug that controls seizures by decreasing sodium influx into the cells. Remember that sodium influx produces an action potential, which then causes the neurons to fire. Phenytoin is representative of a class of drugs called the hydantoins.

Nursing Management of the Patient Receiving P Phenytoin

Core Drug Knowledge

Pharmacotherapeutics

Phenytoin is used to control partial and generalized (grand mal) and other psychomotor seizures. It is also used to prevent and treat seizures that occur either during or following

neurosurgery. Parenterally, it is used to treat status epilepticus after a benzodiazepine. Unlabeled uses of phenytoin include its common use as an antiarrhythmic drug, especially when the arrhythmia is induced by cardiac glycoside drugs, such as digoxin. Another off-label use of phenytoin is as an alternative to magnesium sulfate for treating severe pre-eclampsia during pregnancy. Other uses of phenytoin include treatment of trigeminal neuralgia (also called tic douloureux).

Therapeutic effects of phenytoin are closely related to the serum level of the drug. The therapeutic blood level of phenytoin is between 10 and 20 mcg/mL. However, it is possible for patients to achieve therapeutic effects (i.e., to have their seizures controlled) at levels below the standard therapeutic range, because great variability exists among people in how phenytoin is processed and how the body responds to the drug. Slight deviations from the therapeutic range may also produce nontherapeutic effects or adverse effects related to the unique pharmacokinetics of phenytoin. Therefore, determining an accurate and effective dose is somewhat difficult. For patients with low albumin levels or for those who are taking highly protein-bound drugs, "free" unbound serum phenytoin levels should be checked and multiplied by 10 to provide an approximation of the target total serum level (UpToDate, 2010b). Adjustments to the initial dose will most likely be needed when therapy is started. Be aware that dosing of phenytoin should be individualized to the patient's needs and that achieving the therapeutic range should be considered a guide but not an absolute rule. Patients who are to start phenytoin therapy orally should receive a loading dose (usually 15 mg/kg divided into three doses) and then a maintenance dose (usually 5 mg/kg/day, which may be given as one dose or divided into two doses) (UpToDate, 2010a).

Pharmacokinetics

Phenytoin is slowly absorbed when given orally. The rate and extent of absorption and bioavailability of phenytoin vary among individuals and also depend on the product formulation. Oral phenytoin reaches peak serum levels in 1.5 hours to 3 hours for prompt-onset preparations and within 12 hours for extended-release products. Intramuscularly administered phenytoin is very slowly and erratically absorbed because the drug precipitates at the injection site within the muscle. Absorption from the site may occur for 5 days or longer. Serum levels reached by intramuscular (IM) injection never equal those reached by oral dosing. Phenytoin is highly protein bound (about 90%). Phenytoin is metabolized in the liver to inactive metabolites, which can be excreted in the urine by tubular excretion. However, the biotransformation of phenytoin to the metabolite has a limit at any given time. In lower doses of phenytoin, complete metabolism occurs fairly easily. However, as the dose increases, not all of the drug can be metabolized at once, and the half-life of phenytoin will increase as the dose increases. At low dosage levels, which are frequently subtherapeutic, the half-life is 6 to 24 hours; as the dose is increased to achieve the therapeutic range, the half-life increases to between 20 and 60 hours.

Because of these pharmacokinetics, small changes in the dose of phenytoin may produce larger than expected changes in the serum concentration of the drug. This variability in the metabolism rate makes phenytoin different from most other drugs. To further complicate the process of metabolism, the rate of metabolism varies greatly among people. This limitation on rate of metabolism is an inherited trait. Table 18.2 summarizes the actions of selected antiepileptic drugs.

Pharmacodynamics

The primary site of action of phenytoin, and of other hydantoins, is believed to be the motor cortex. Phenytoin reversibly binds to sodium channels while they are in the inactive state. This binding delays the return of the channel to an active state. Because sodium can enter the cell to initiate an action potential only when the channels are active, the time between action potentials is greatly lengthened, the neurons cannot fire at an excessive rate, and excessive muscle contractions that occur in grand mal–type seizures are prevented. Phenytoin selectively binds to sites with hyperactive neurons; it does not alter the sodium movement into neurons that fire normally. This ability to selectively work at neurons that are firing abnormally explains why phenytoin is also effective in treating cardiac arrhythmias from ectopic foci.

Contraindications and Precautions

Because of its effects on ventricular automaticity has a black box warning that it must be given slowly intravenously. Phenytoin is contraindicated in patients with sinus bradycardia, sinoatrial block, second- and third-degree atrioventricular (AV) block, or Adams-Stokes syndrome. Phenytoin is also contraindicated if the patient is hypersensitive to hydantoins; phenytoin hypersensitivity reactions are not typical.

Phenytoin and other antiepileptic drugs now carry a warning that their use may increase the risk of suicidal ideation (thinking of suicide) or suicidality (attempting suicide). The Food and Drug Administration's 2008 meta analysis of clinical trials for antiepileptic drugs found that patients taking one or more of these drugs were almost twice as likely to have suicidal ideation or suicidality than those in the trials who received a placebo.

Because phenytoin may cause blood dyscrasias, it should not be administered with other drugs that also have this effect, if at all possible. If such drugs must be used, the patient should be monitored closely for blood dyscrasias. Other precautions include patients with acute intermittent porphyria (rare inherited metabolic disorder characterized by excessive excretion of porphyrins, acute abdominal pain, and neurologic disturbances), because phenytoin may precipitate a crisis. Use caution in diabetic patients because phenytoin may elevate blood glucose levels. Phenytoin use has been associated with osteomalacia, a softening and flexibility of the bones in adults.

Phenytoin should not be abruptly stopped because doing so can precipitate status epilepticus.

Phenytoin is a pregnancy category D drug, and use of the drug during pregnancy is a somewhat complicated and confusing issue. On the one hand, phenytoin, as well as other

antiepeleptic drugs, has been associated with an increased incidence of birth defects in infants whose mothers used the drug. These congenital malformations include cleft lip, cleft palate, and heart malformations. A fetal hydantoin syndrome has been identified that includes prenatal growth deficiency, microcephaly, and mental deficiency. However, these features of intrauterine growth retardation have all been associated with other causes as well as hydantoin use; therefore, phenytoin use may or may not be solely responsible for their onset. Most women taking phenytoin deliver normal, healthy infants. There have also been reports that maternal ingestion of phenytoin can produce bleeding in newborns, usually within 24 hours of birth. The defect is characterized by low levels of vitamin K–dependent clotting factors and by prolonged prothrombin times, partial thromboplastin times, or both. On the other hand, stopping the use of phenytoin and other antiepileptic drugs during pregnancy is likely to induce seizures, including status epilepticus, which places the fetus at risk for being without sufficient oxygen. Even minor seizures may pose a risk to the well-being of the developing fetus, although the exact effects are not known. No easy answer exists to the question of whether to use phenytoin during pregnancy. In general, it is now thought that phenytoin should not be discontinued if the nature, frequency, and severity of the seizures pose a serious threat to either the patient or the fetus. In other words, benefits should outweigh risks. Box 18.1 discusses antiepileptics and pregnancy.

Adverse Effects

The most frequent adverse effects of phenytoin occur in the central nervous system (CNS) and include nystagmus, ataxia, dysarthria, slurred speech, mental confusion, dizziness, insomnia, transient nervousness, numbness, tremor, and headache. Reducing the dose is often effective in eliminating these adverse effects. Other common adverse effects of phenytoin are nausea and gingival hyperplasia (overgrowth of the gums).

Rare but potentially life-threatening adverse effects of phenytoin are dermatologic reactions (Stevens-Johnson syndrome, lupus erythematosus syndrome, and bullous, exfoliative, or purpuric dermatitis), liver damage, and hematopoietic effects (blood dyscrasias). When given intravenously, phenytoin may

CRITICAL THINKING SCENARIO

WHAT HAPPENS WHEN ANTIEPILEPTIC THERAPY STOPS ABRUPTLY?

Rudy Hernandez, a 26-year-old man, is brought to the emergency room by ambulance, accompanied by his wife. He is currently unconscious, is having tonic-clonic convulsions, and has been incontinent of urine. He had two seizures at home without regaining consciousness before the ambulance arrived. His wife states that he was on phenytoin and valproic acid for seizure prevention and that he has been on medication since he was a teenager. She also reports he stopped his medication last week because he didn't like the adverse effects.

1. What type of seizure is Mr. Hernandez exhibiting? What is the likely cause of this seizure?
2. What nursing actions are indicated upon his arrival in the emergency room?
3. What drug therapy or therapies do you expect that he will receive?

Box 18.1 ANTIEPILEPTICS AND PREGNANCY

Teratogenic Effects

- Possible with all antiepileptic drugs
- Risk increases with first-trimester exposure and multidrug therapy
- Little data on new antiepileptic drugs because no studies; do not appear to cause malformation in monotherapy
- Innate ability to metabolize and eliminate antiepileptic drugs increases risk
- Metabolism of hormonal contraceptives is increased by antiepileptic drugs, decreasing their effectiveness, increasing risk for unplanned pregnancy

Competitive Inhibitors of Vitamin K

- Neonatal hemorrhage possible
- Phenytoin, carbamazepine, ethosuximide, phenobarbital, and primidone cause high mortality from hemorrhage
- Transferred in breast milk

Loss of Seizure Control

- Concentration of antiepileptic drugs decreases during pregnancy (even with steady or increasing dose)
- Concentration decreases differently for different antiepileptic drugs
- One fourth to one third of pregnant women will have increased incidence of seizures related to decreased drug concentration

TABLE 18.3 Agents That Interact with P Phenytoin

Interactants	Effect and Significance	Nursing Management
allopurinol, amiodarone, benzodiazepines, cimetidine, clonazepam, disulfiram, ethanol, fluconazole, ibuprofen, isoniazid, metronidazole, miconazole, omeprazole, phenothiazines, salicylates, succinimides, sulfonamides, tricyclic anti-depressants, trimethoprim, valproic acid	Increased pharmacologic effects of phenytoin from inhibition of its metabolism	Monitor patient for changes in seizure control. Monitor serum phenytoin levels. Assess for signs of phenytoin toxicity.
barbiturates, ethanol (chronic ingestion), rifampin, theophylline	Decreased pharmacologic effects of phenytoin due to its increased metabolism	Assess patient for increased seizure frequency and changed seizure control. Monitor serum phenytoin levels at regular intervals.
antacids, charcoal, sucralfate	Decreased phenytoin effects due to decreased absorption	Assess patient for increased seizure frequency and changed seizure control. Monitor serum phenytoin levels at regular intervals.
acetaminophen, carbamazepine, cardiac glycosides, corticosteroids, disopyramide, doxycycline, estrogens (and oral contraceptives), haloperidol, methadone, mexiletine, quinidine, theophylline	Decreased pharmacologic effects of interactants from increased metabolism by phenytoin Analgesic effects of acetaminophen may be reduced by concomitant phenytoin use; the potential hepatotoxicity of acetaminophen may be increased Corticosteroid use may mask systemic manifestations of phenytoin hypersensitivity reactions	Evaluate patient for changed seizure control. Assess patient for evidence of therapeutic effects of interacting drugs. Monitor patient for therapeutic serum levels (if applicable) of interacting drugs.

cause cardiovascular collapse (hypotension, cardiac arrhythmias) if it is administered too rapidly. Phenytoin may increase the risk of suicidal ideation or suicidality.

A number of other adverse effects are possible but not common; these include:

Dermatologic: rash, hirsutism, alopecia
Endocrine: diabetes insipidus, hyperglycemia
Gastrointestinal (GI): vomiting, diarrhea, constipation
Hepatic: hepatitis, jaundice
Respiratory: pneumonia, pharyngitis, sinusitis, hyperventilation, rhinitis, apnea, aspiration pneumonia, asthma, dyspnea, atelectasis, increased cough, epistaxis, hypoxia, pneumothorax, hemoptysis, bronchitis, chest pain, pulmonary fibrosis
Senses: tinnitus, diplopia, taste perversion, amblyopia, deafness, visual-field defect, eye pain, conjunctivitis, photophobia, hyperacusis, mydriasis, parosmia, ear pain, taste loss
Miscellaneous: polyarthropathy, weight gain, chest pain, edema, immunoglobulin A (IgA) depression, fever, photophobia, conjunctivitis, gynecomastia, periarteritis nodosa, pulmonary fibrosis, soft tissue injury at the injection site, lymph node hyperplasia (may represent a hypersensitivity reaction)

Drug Interactions

Numerous drugs interact with phenytoin. Be certain to check for drug interactions when patients are receiving phenytoin and any other drug. These interactions occur because of phenytoin-inducing effects on hepatic microsomal enzyme systems (also referred to as P-450). Pharmacologic induction of these enzymes enhances the metabolism of both endogenous and exogenous substances, including other antiepileptic drugs.

Drug interactions may increase or decrease the effect of phenytoin or the other drug (Table 18.3). Several enteral feeding preparations (tube feedings) may decrease phenytoin levels either by impairing absorption or through some other mechanism. Phenytoin, and other antiepileptic drugs that induce the P-450 system, increase the rate of metabolism of estrogen as well as increase the protein binding of progesterones in oral contraceptives. Both increasing estrogen metabolism and increasing protein binding of progesterone decrease the effectiveness of oral contraceptives, as there is less available estrogen and progesterone. Phenytoin and benzodiazepines precipitate if given via the same IV tubing. In addition, phenytoin may interfere with results of diagnostic endocrine tests that use dexamethasone.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient is hypersensitive to phenytoin or if he or she has any of the cardiac conditions that are contraindications for the use of the drug. Because phenytoin is highly protein bound, assess whether the patient has chronic conditions, such as liver failure, that alter the level of albumin protein. Check ordered blood work to determine whether albumin levels are abnormal.

Before starting therapy, also confirm that the patient has either grand mal or other psychomotor seizures that respond to phenytoin. See Box 18.2 for more information about core patient variables.

BOX 18.2 FOCUS ON RESEARCH

Core Patient Variables and Antiepileptic Drugs

Yeager, K. A., Dilorio, C., Osborne Shafer, P., McCarty, F., Letz, R., Henry, T., & Schomer, D.L. (2005). The complexity of treatments for persons with epilepsy. *Epilepsy & Behavior* 7(4):679–686.

The Study

Medication-management practices of people living with epilepsy were evaluated using data from the 2004 Project EASE (Epilepsy Awareness Support and Education). Data was obtained from self-reports of patients recruited at epilepsy clinics in Atlanta, Georgia, and Boston Massachusetts. Medication complexity was assessed using the Epilepsy Medication and Treatment Complexity Index (EMTCI). The level of complexity for specific medications was based on general medication information, frequency of administration, special instructions (different doses in the same day, changing dose due to menstrual cycle, etc.) and special actions (take with food, crush, must carry at all times, etc.). The medications ranked most complex were forms of carbamazepine and gabapentin. Evaluating the total regimen of all drugs for an individual, higher complexity was positively associated with seizures and hospitalization within the past year.

Nursing Implications

Medication regimens for managing epilepsy are complex and can require extensive memory recall and adjustments to daily routines. These factors certainly contribute to the very high level of medication nonadherence in these patients, which has been reported as high as 70% in some studies. Therefore, it is critical to consider individual patient's abilities and life routines when establishing treatment. Patient education and simplification of regimens is essential as they can influence comprehension of medication and ultimately adherence. Patients need to be involved in setting priorities and establishing a regimen that will work for them.

Life Span and Gender

Before phenytoin therapy begins, assess whether the patient is pregnant. The use of antiepileptic drugs such as phenytoin poses some risk to the developing fetus and, if possible, should not be started during a pregnancy. Women of childbearing age should use birth control to prevent unplanned pregnancy because of those risks, although antiepileptic drugs can reduce the effectiveness of oral hormonal contraceptives (World Health Organization, 2009). However, the effectiveness of oral hormonal contraceptives remains high and superior to intrauterine devices and barrier methods used alone. Exposure to phenytoin during the first trimester of pregnancy increases the risk of malformations in the child; taking multiple antiepileptic drugs increases the risk even more. Teratogenicity may be related to an individual woman's genetic makeup, which influences how well she metabolizes and eliminates antiepileptic drugs. When metabolism and elimination are slower than would normally be predicted, the risk of teratogenic effects increases. Phenytoin, like other antiepileptic drugs, is a competitive inhibitor of vitamin K; this action increases the risk of neonatal hemorrhage in the first 24 hours after birth. Phenytoin is associated with a high mortality rate in neonatal hemorrhage. Suddenly stopping phenytoin carries the risk of inducing seizures, as previously mentioned. This puts the fetus at risk of hypoxia during the mother's seizure. If possible, the woman should be weaned off phenytoin before becoming pregnant. Phenytoin is passed in breast milk, and so is the competitive inhibition of vitamin K; women taking phenytoin should not breast-feed.

Drug therapy with phenytoin, as with other antiepileptic drugs, need not be lifelong. Box 18.3 presents some guidelines for using and discontinuing antiepileptic drugs.

Older adults are more likely to experience hypotension and cardiac arrhythmias when phenytoin is given intravenously. Nonadherence to antiepileptic drug therapy is particularly high in the elderly, at more than 40% for those over 65 years old (Ettinger et al., 2009).

Lifestyle, Diet, and Habits

Assess for conditions that may make the patient more likely to have decreased blood protein levels. Does the patient have alcoholism? Is the patient malnourished? Is the patient's dietary protein intake severely limited? These conditions put the patient at greater risk for having greater amounts of free, active drug in the blood because less protein albumin is available for binding than would normally be expected. Therefore, the patient is more at risk for having adverse effects from the phenytoin. Chronic ingestion of alcohol also increases the metabolism of phenytoin and therefore alters blood drug levels.

Environment

Oral phenytoin can be administered in any setting. IV phenytoin should be given in a hospital setting, ideally with the patient in a bed with a cardiac monitor.

Nursing Diagnoses and Outcomes

Disturbed Sensory Perception related to adverse effects of drowsiness and sedation

Desired outcome: *The patient will not experience adverse effects to the degree that sensory perception is altered enough to impair quality of life.*

Risk for Injury related to the adverse effects of drowsiness and sedation

Desired outcome: *The patient will not sustain any injury while taking phenytoin.*

Altered Oral Mucous Membrane related to the adverse effect of gingival hyperplasia

Desired outcome: *The patient will demonstrate knowledge of optimal oral hygiene and experience no deterioration in dental health.*

Risk for Injury related to adverse effects of blood dyscrasias

Desired outcome: *The patient will return for follow-up blood work while taking phenytoin and will have no life-threatening blood disorders.*

Planning and Intervention

Maximizing Therapeutic Effects

Therapeutic effect of phenytoin is normally related to achieving a therapeutic blood level of the drug. Monitor blood levels to determine whether they are therapeutic. If the blood level is

BOX 18.3 COMMUNITY BASED CONCERNS

Starting and Stopping Antiepileptic Drug Therapy

Although antiepileptic drug therapy has often been considered lifelong, many patients can be successfully weaned off therapy. Antiepileptic drugs all produce adverse effects; about 1 in 30,000 patients taking an antiepileptic drug experiences a serious adverse effect, and 15% will need to have the drug discontinued because of adverse effects. Some of those adverse effects become more prevalent the longer the drug is taken. Generally, the second-generation antiepileptic drugs (gabapentin, lamotrigine, topiramate, levetiracetam, oxcarbazepine, and zonisamide) have a lower rate of adverse effects. In many patients, the risks of drug therapy may outweigh the risk of occasional seizure activity, and these patients should be considered for drug tapering. After antiepileptic drugs are withdrawn, almost 60% of patients remain seizure-free for 2 years. What follows are some current recommendations regarding the use and discontinuation of antiepileptic drugs.

When to Start Therapy

- After one seizure: usually not necessary, except if there is permanent injury to brain (e.g., cortical stroke, abscess, or tumor); a substantial risk of repeated seizures (abnormal EEG, especially if epileptiform discharges are present); a history of serious brain injury; a brain lesion identified on computed tomography (CT) or magnetic resonance imaging (MRI); focal abnormalities found on neurologic examination; mental retardation; or a first seizure that is a partial seizure.
- After two seizures: almost all patients, because the second seizure proves that patient has substantially increased risk of repeated seizures

When to Stop Therapy

The best time to stop is still somewhat unknown. There is no way to identify which patients will remain seizure-free. Generally, stopping therapy can be considered when the patient:

- Has been seizure-free for at least 2 years (about half of patients who are newly diagnosed with epilepsy become seizure-free after using the first drug prescribed)
- Receives single-drug therapy
- Is able to make individualized decisions
- Has a reasonable understanding of possible risks and benefits of stopping therapy

Withdrawal of drug therapy in some patients is likely to precipitate seizure activity.

Patients Are More Likely To Relapse If They Have:

- Identifiable brain disease
- Mental retardation
- Abnormal neurologic examination
- Seizure onset after age 10
- Multiple seizure types
- Poor initial response to treatment
- Been receiving combination drug therapy
- Some selected epilepsy syndromes, such as juvenile myoclonic epilepsy
- Abnormal EEG
- Family history of epilepsy
- Hippocampal atrophy or abnormal hippocampal signal on MRI

Withdrawal Schedule Recommendations:

- No known optimal tapering regimen
- Slower withdrawal (over 3 to 6 months) less likely to induce seizures; benzodiazepines and barbiturates should be over at least 6 months
- Taper one drug at a time if on combination therapy

not therapeutic, and the patient is still having seizures, notify the physician or other prescriber to inquire about increasing the dose. Remember that some patients achieve therapeutic results even when their blood levels of phenytoin are not in the ideal therapeutic range. The drug should be adjusted in very small increments because of the unusual pharmacokinetics of phenytoin. The risk is that a dosage change will move the blood phenytoin level from just marginally therapeutic to toxic. Titrating the dose upward gradually helps minimize this risk. Because of the long half-life, serum levels should be checked within 5 to 7 days after any change in the dose (increase or decrease) in order for the serum level to reflect steady-state levels (UpToDate, 2010a) accurately.

Phenytoin absorption is compromised when administered with enteral tube feedings. Check gastric residuals and refrain from administering the drug for 1 to 2 hours if the residual is greater than 100 mL. Continuous tube feedings should be held for 1 hour before and after administering the phenytoin.

Minimizing Adverse Effects

Adverse effects from phenytoin are frequently related to excessively high blood drug levels. It is important to monitor the patient's blood levels of phenytoin as well as the patient's physical response to drug therapy. Monitor drug levels most closely at the initiation of therapy or after every increase in the dose. If the patient is demonstrating adverse effects, the drug dosage may need to be decreased. Patients may demonstrate adverse effects even if the serum level of phenytoin is "normal"; it is important to adjust the dose to the clinical response of the patient, not the serum level. Dosage changes downward should also be done in small increments to avoid decreasing the blood level so much that it is below the therapeutic level. Monitor serum levels after any change in phenytoin preparation, because different brands or generic preparations of the drug may have different bioavailabilities that alter serum levels and seizure control. Be especially vigilant during this transitional period (UpToDate, 2010a).

It is important to analyze the patient's mental and neurologic function and behavior regularly for changes from baseline behavior to determine whether CNS adverse effects due to phenytoin are present. If the patient is having difficulty with dizziness, institute safety measures to prevent falls and injury. Assess the patient for depression or changes in mood or behavior which indicate suicidal ideation.

Administer phenytoin with meals if the patient is experiencing nausea and GI distress; avoid antacids because they may impair absorption. Patients with diabetes may experience elevated glucose levels; their glucose levels should be measured more frequently until the effects of phenytoin are determined.

Administer IV push phenytoin no faster than 50 mg/min in adults or 1 to 3 mg/kg/min in neonates; fast administration is associated with cardiovascular collapse. Careful monitoring of the pulse and blood pressure is essential during IV administration. Follow the administration of phenytoin with sterile saline through the same IV catheter to avoid local venous irritation from the alkalinity of the phenytoin. Phenytoin is not given as a continuous IV infusion. IM administration should be avoided because of irregular and delayed absorption. When phenytoin is given after a benzodiazepine to control status epilepticus, a separate IV insertion site and IV tubing must be used for each drug, because the two agents precipitate if they come into contact (UpToDate, 2010c).

Evaluate blood counts, bleeding tendencies, and white blood cell counts regularly to determine whether any hematologic adverse effects have occurred. Notify the prescriber if any abnormalities are detected to prevent serious adverse effects. Vitamin D and calcium supplements are recommended for patients showing symptoms of osteomalacia and also for those at high risk for developing osteomalacia. Report any signs and symptoms of skin rash. Although a rash is usually not serious, phenytoin may need to be discontinued to minimize the risk for severe reactions such as Stevens-Johnson syndrome. Patients of Asian descent should be screened for the HLA-B*1502 allele variant which can increase the risk of Stevens-Johnson syndrome and toxic epidermal necrolysis in those individuals.

Assess the age of a woman and her reproductive status. To offset the increased estrogen metabolism that occurs from phenytoin and other antiepileptic drugs that induce the hepatic enzyme system, women who are concurrently taking hormonal contraceptives may need to have the estrogen dose increased (Zupanc, 2006). To minimize the risk of neonatal hemorrhage, pregnant women taking phenytoin should receive 10 mg/d of vitamin K during the last week of pregnancy.

Providing Patient and Family Education

Much of the patient and family education regarding phenytoin is common to any antiepileptic drug that is prescribed. Box 18.4 contains guidelines for patient and family education common to antiepileptic drugs. Some educational points specific for phenytoin are:

Teach the importance of shaking suspension forms of phenytoin thoroughly before pouring and measuring the dose.

Teach patients and families the importance of good dental hygiene to prevent gingival hyperplasia and gum softening. Encourage patients to brush the teeth at least twice daily with a soft toothbrush and to floss daily.

Suggest that patients take phenytoin with food to minimize GI distress.

Teach patients with diabetes to check capillary blood glucose frequently.

Suggest bleaching or electrolysis if hirsutism is a problem for female patients, because shaving or depilatories often leave stubble.

Teach patients to notify the physician if they experience a change in mood or behaviors that indicate depression or suicidal thoughts or actions. They should also notify the physician if they experience: skin rash, severe nausea or vomiting, swollen glands, bleeding, swollen or tender gums, yellowish discoloration of the skin or eyes, joint pain, unexplained fever, sore throat, unusual bleeding or bruising, persistent headache, malaise, and any indication of an infection or bleeding tendency, which are signs of serious adverse effects. Female patients should also notify the physician if they become pregnant.

Teach women who have delivered an infant about the risks involved in breast-feeding.

Ongoing Assessment and Evaluation

Ongoing assessments include monitoring patients closely for therapeutic responses, seizure control, and adverse effects to drug therapy. Blood levels of the drug should be monitored whenever the dose is changed, or if the patient is having seizures. Because phenytoin interacts with so many drugs through its effect on the enzymes of hepatic metabolism, also determine the likelihood of drug interactions between phenytoin and other newly ordered drugs or newly discontinued drugs. Phenytoin therapy is effective if seizures can be controlled and the patient experiences no serious adverse effects.

MEMORY CHIP

P Phenytoin

- Used to treat generalized tonic-clonic (grand mal) and other psychomotor seizures; status epilepticus
- Binds to receptors on sodium channels, keeping the channels in a closed position longer, preventing influx of sodium ions and excessive firing of the cell
- Major contraindications: sinus bradycardia, sinoatrial block, second- and third-degree AV block, and Adams-Stokes syndrome
- Most common adverse effects: CNS (dizziness, ataxia, blurred vision), nausea, and gingival hyperplasia
- Most serious adverse effects: life-threatening dermatologic reactions, liver damage, and blood dyscrasias; cardiovascular collapse if given too rapidly by IV push
- **Life span alert: can cause fetal hydantoin syndrome, infant death from neonatal hemorrhage, and decreased effectiveness of hormonal contraceptives; circulating level will decrease during pregnancy, increasing risk for seizures**
- Maximizing therapeutic effect: Monitor for therapeutic blood level, avoid coadministration with enteral tube feedings
- Minimizing adverse effects: Change dose upward or downward in small increments; monitor blood levels when dosage is changed or if symptomatic of adverse effects; give IV push very slowly during status epilepticus; vitamin K before date of delivery; monitor mood
- Most important patient education: Be careful driving or operating machinery until effects of drug are known; potential risks to fetus if patient becomes pregnant; may increase suicidal thoughts
- **Black box warning: must be administered ver slowly IV**

Box 18.4 PATIENT AND FAMILY EDUCATION COMMON TO ALL ANTIEPILEPTIC DRUGS

Antiepileptic drugs require that much of the same information be shared with patient and family. The nurse providing education for the epileptic patient should include the following information:

- Antiepileptic drug therapy does not cure the seizure disorder; it suppresses seizure activity.
- When seizures recur so frequently that consciousness or normal function cannot be regained in the interval between seizures, the condition is known as status epilepticus; this is a medical emergency.
- Sudden withdrawal of the antiepileptic drug may cause a loss of epileptic control, and the patient may experience seizures or status epilepticus. Prescriptions should not be allowed to run out or expire.
- Failure to take prescribed drug therapy results in recurrent seizures, with increased emergency department and inpatient admissions. Stress the importance of taking drugs on schedule and recommend memory aides, such as written medication schedules and pillboxes, particularly for more complex drug regimens.
- Double dosing of an antiepileptic drug should be avoided. If a dose is missed, instruct the patient to take the dose as soon as it is remembered unless it is close to the time for the next dose.
- All antiepileptic drugs carry a warning that their use may increase thoughts of suicide or suicidal actions. Be alert for changes in behavior or mood that may indicate depression and report this at once to the prescriber. Read the Medication Guide that comes from the FDA with each prescription that is filled for the most up-to-date information on this and other potential adverse effects from drug therapy. Read the Medication Guide each time a prescription is filled as it will have the most up-to-date information contained within it.
- Follow-up appointments with the health care provider and periodic laboratory testing are important because they provide an ongoing record of response (both positive and negative) to antiepileptic drug therapy. Drug levels should be checked at least yearly in patients whose epilepsy is controlled on medication and whose drug dose remains constant. Drug levels need to be monitored more frequently if the patient continues to have seizures or if the dose is adjusted.
- A "seizure record" should be kept. This record can provide information about changes in the type or frequency of seizures over time, the effect of different medications on seizure control, adverse effects of medications, and seizure-provoking factors. This record should include the date and time, as well as the type, of seizure. If a precipitating factor is suspected (e.g., lack of sleep, missed medication, stress, menstrual period, alcohol use), the patient should write it down. For women, it may be helpful to keep track of the relationship between seizures and menstrual cycles. It is also helpful to record the medication, dosage, and blood drug levels (if known). Recommend that the patient and family (or caregiver) show this record to the health care provider during follow-up visits.
- A form of medical identification (e.g., MedicAlert) indicating the medical condition and the drugs prescribed for it, including dosage in case of an emergency, should be carried or worn by the patient.
- Use of OTC preparations, herbal preparations, and dietary supplements may interact with the effectiveness of antiepileptic drugs and should be avoided unless approved by the physician or nurse practitioner. Prescription medications may also interact with the antiepileptic drug, so all providers should be informed of the antiepileptic drug therapy.
- Transient mild drowsiness and dizziness are common in the first few days of therapy, until the patient becomes accustomed to the drug therapy. Observe caution while driving, operating machinery or performing other tasks requiring mental alertness and motor coordination until effects of the drug are known.
- Alcohol consumption should be avoided because it may increase the CNS-depressant effect of the antiepileptic; large amounts of alcohol (three or more drinks per day) are likely to increase the risk of seizures. Small amounts of alcohol (one or two drinks per day) do not usually affect seizure frequency once the patient's condition is well controlled.
- Environmental factors (e.g., flashing lights, alcohol) and physiologic factors (e.g., hypoglycemia, fatigue, stress) may increase the frequency of seizures. If stress aggravates seizure activity, teach the patient to develop effective stress management techniques.
- Antiepileptic drugs can have significant effects on hormonal homeostasis, although epilepsy itself may play a role in causing these problems. Men may experience reduced libido and sexual potency; women may experience sexual arousal disorders. Seizure frequency may increase during menses because of the increase in sex hormones that alter the excitability of cortical neurons.
- Certain P450 enzyme inducing antiepileptic drugs (phenytoin, carbazepine, barbiturates, primidone, topiramate, oxcarbazepine) reduce the effectiveness of oral contraceptives, increasing the risk of unintended pregnancy, and should be used with caution in women of childbearing age (World Health Organization, 2009). Even with changes in the rate of metabolism, oral hormonal contraceptives are still recommended as they offer comparable, if not superior, effectiveness in preventing pregnancy compared to other contraceptive methods, such as intrauterine devices or barrier methods, which are more effective when used in conjunction with oral contraceptives. While oral contraceptives generally do not affect antiepileptic drug activity, studies have shown that serum levels of laotrigine decrease significantly and seizure activity increases with the use of combined oral contraceptives that include estrogen.
- The risk of having a child with a congenital defect may be two to three times greater in epileptic women who received antiepileptic drugs in the early stages of pregnancy. Most antiepileptic drugs are not recommended during pregnancy and lactation. However, the majority of women receiving antiepileptics deliver healthy infants.

Drugs Closely Related to P Phenytoin

Ethotoin

Ethotoin (Peganone) is a hydantoin like phenytoin, with similar pharmacodynamics and pharmacokinetics. It is used in the treatment of tonic-clonic and complex partial seizures. Unlike phenytoin, ethotoin is available only as an oral tablet. Although all hydantoins may cause gingival hyperplasia, the severity of the hyperplasia may be decreased if the patient is switched to ethotoin. Like phenytoin, ethotoin carries the warning that it may increase suicidal thoughts or actions.

Fosphenytoin

Fosphenytoin (Cerebyx) is actually a prodrug of phenytoin; that is, it is converted to phenytoin. Thus, the actions of the drug are the same as phenytoin. Fosphenytoin creates two unique metabolites when converting into phenytoin: phosphate and formaldehyde. These metabolites are

excreted without problems when fosphenytoin is given in recommended amounts. Fosphenytoin is given as doses of phenytoin equivalents. It is administered only as a short-term therapy when other means of IV phenytoin administration are unavailable, inappropriate, or deemed less advantageous. It can also be substituted, short-term, for oral phenytoin. The safety and effectiveness of fosphenytoin sodium when given for more than 5 days are not known. The drug is administered parenterally. Like phenytoin, it carries the warning that it may increase suicidal thoughts or actions.

Drugs Significantly Different From Phenytoin

Carbamazepine

Carbamazepine (Tegretol) is used to treat partial seizures with complex symptoms. It can also be used in treating generalized tonic-clonic seizures, mixed seizure patterns, or other partial or generalized seizures. Although effective in all of these types of seizures, carbamazepine seems to produce the most effect in treating partial seizures with complex symptoms. Carbamazepine is also used to treat trigeminal neuralgia. Off-label uses for carbamazepine include its common use in treating several psychiatric disorders (bipolar disorder, depression, schizoaffective illness, schizophrenia resistant to other drug therapies, dyscontrol syndrome associated with limbic system dysfunction, intermittent explosion disorder, post-traumatic stress disorder, and atypical psychosis). Other off-label uses are management of alcohol, cocaine, and benzodiazepine withdrawal; restless legs syndrome; nonneuritic pain syndromes, painful neuromas, or phantom limb pain; neurogenic or central diabetes insipidus; and hereditary or nonhereditary chorea in children. Therapeutic blood level for controlling seizures is 2 to 4 mcg/mL.

Carbamazepine is chemically related to the tricyclic antidepressants. Its mode of action is similar to that of phenytoin; it is believed to suppress the inflow of sodium into the cell, thereby decreasing frequency of action potentials and controlling seizures. It is generally well absorbed. Bioavailability of the drug is essentially the same for conventional tablets, extended-release tablets, and oral suspension. However, peak times differ among these routes, with the quickest peak (about 1.5 hours) from the suspension and the slowest peak (3 to 12 hours) from the extended-release format. Therapeutic blood level for the drug ranges from 4 to 12 mcg/mL for an adult. Carbamazepine is less protein bound than phenytoin, at 76%. Although carbamazepine, like phenytoin, is metabolized by the liver, the characteristics of metabolism are different. The metabolite formed also has antiepileptic activity; its half-life is shorter than that of carbamazepine. The half-life of carbamazepine is initially 25 to 65 hours; with repeated doses of the drug, the half-life decreases to 12 to 17 hours. Excretion of the drug and metabolite are primarily through the urine, but some is also excreted through the feces.

Like phenytoin, carbamazepine is a pregnancy category D drug, and the same concerns exist about its use in pregnancy and sudden discontinuation of the drug during pregnancy.

The most common adverse effects from carbamazepine are similar to those from phenytoin: dizziness, drowsiness, unsteadiness, nausea, vomiting, and diarrhea. A major difference in the adverse effects of these two drugs is the Black Box warning carried by carbamazepine in regard to its potential to cause three fatal blood dyscrasias. These are aplastic anemia (lack of red blood cells caused by disorders of bone marrow), thrombocytopenia (lack of platelets), and agranulocytosis (complete lack of white blood cells). Carbamazepine has been found to increase the risk of developing these fatal disorders; patients taking the drug are between five and eight times more likely to develop these hematologic problems than the general population not taking the drug. Still, even with this increased risk, the likelihood that aplastic anemia, thrombocytopenia, or agranulocytosis will develop is very low. Many patients have transient or persistent decreased red blood cell, platelet, or white blood cell counts and do not develop the more serious conditions. However, patients receiving carbamazepine need to be monitored for these conditions, even more carefully if any changes occur in the blood cell counts. Drug therapy should be discontinued if considerable depression of bone marrow function is apparent. Patients who have hematologic abnormalities should not receive carbamazepine, and those of Asian descent should be screened for the HLA-B*1502 allele variant which can increase the risk of Stevens-Johnson syndrome and toxic epidermal necrolysis in those individuals. Like phenytoin it carries the warning that it may increase suicidal thoughts or actions.

Valproic Acid

Valproic acid (Depakote), also called valproate, is a broad-spectrum antiepileptic drug that is effective against all types of seizures. It is the most widely prescribed antiepileptic drug worldwide. In the United States, the only Food and Drug Administration (FDA)–approved use is for absence seizures, although in practice it is used for tonic-clonic, atonic, myoclonic, and partial seizures. Additionally, valproic acid is approved to treat mania and migraine headaches. Recent randomized experimental trials with valproic acid indicate that it is as effective as phenytoin in treating status epilepticus (Agarwal et al., 2007). The therapeutic blood level for seizure control is 50 to 150 mcg/mL. Valproic acid is available as several formulations, some quick release, some delayed release, and some extended release.

Valproic acid works through a number of different mechanisms. Like phenytoin, it blocks the voltage-gated sodium channels but at different sites than phenytoin or carbamazepine. Unlike phenytoin, it also increases GABA release and concentration. Valproate does not seem to have any direct effect on the GABA receptor. Valproate also inhibits nerve terminal GABA transaminase, which raises presynaptic GABA levels. Valproate may also increase GABA synthesis. Like ethosuximide (to be discussed), valproate acts against special calcium channels to block calcium influx, but has a less favorable adverse event profile (UpToDate, 2010a).

Oral absorption of valproic acid is rapid, and all oral formulations have almost 100% bioavailability. Like phenytoin, valproic acid is highly protein bound, although as the dosage of valproic acid increases, the percentage of drug that is bound decreases. Valproic acid is metabolized through the liver, but, unlike phenytoin, it does not induce hepatic enzymes and does not affect oral hormonal contraceptives. However, it can potentially inhibit the drug metabolism of some drugs. The half-life of valproic acid is between 9 and 18 hours; shorter half-lives of 5 to 12 hours can occur in patients also being medicated with enzyme-inducing agents such as phenytoin, carbamazepine, or barbiturates.

The most common adverse effects of valproic acid are GI problems, tremor, and weight gain. Adverse effects, which are not common but very serious and potentially lethal, are elevated blood ammonia levels (hyperammonemia), possibly with encephalopathy symptoms; platelet disorders; pancreatitis (life threatening); and liver toxicity (including liver failure and death). Liver toxicity, although rare, appears to be more of a risk in children younger than 2 years who are on multiple–antiepileptic drug therapy. Liver function tests should be periodically monitored for patients receiving valproic acid. Other adverse effects that can occur include CNS effects (sedation, ataxia, confusion); dermatologic effects (transient hair loss, skin rash, photosensitivity, Stevens-Johnson syndrome); endocrine effects (irregular menses, breast enlargement); psychiatric effects (depression, psychosis, aggression); and miscellaneous effects (weakness, fever, hearing loss, otitis media).

Valproic acid is a pregnancy category D drug. Case reports in the literature indicate an increased risk of neural tube defects (such as spina bifida) when the drug is used during pregnancy, with about 1% to 2% of births having neural tube defects. This adverse effect is usually associated with the use of higher doses. Compared with phenytoin, carbamazepine, and lamotrigine, valproic acid poses the highest risk of serious fetal adverse effects (Meador et al., 2006).

Valproic acid may cause falsely elevated urine ketone tests when used in patients with diabetes and altered thyroid tests. Like phenytoin, it carries the warning that it may increase suicidal thoughts or actions.

Lamotrigine

Lamotrigine (Lamictal) is approved as an adjunct therapy for treating partial seizures in adults and generalized seizures of Lennox-Gastaut syndrome (the most severe form of childhood epilepsy, characterized by very frequent seizures of several different types; it is usually nonresponsive to other antiepileptic drug therapy) in pediatric and adult patients. This drug has been found effective as adjunct therapy in primary generalized tonic-clonic seizures. In addition, clinical studies have shown that lamotrigine is effective as monotherapy for adolescents and adults with newly diagnosed partial or mixed seizure disorders. It *is* effective in treating children with newly diagnosed absence seizures, the most common pediatric epilepsy syndrome, but less so than ethosuximide and valproic acid (Glauser et al., 2010).

Lamotrigine is not chemically related to other antiepileptic drugs. It appears to act by decreasing the sodium influx into the cells. A standardized serum blood level has not been determined.

Lamotrigine is easily absorbed from the GI tract and has about 98% bioavailability, which is not affected by food. Peak serum levels are reached in 1.4 to 4.8 hours. Lamotrigine is much less protein bound than phenytoin, at about 55%. Lamotrigine does not displace other protein-bound antiepileptic drugs. An unusual feature of lamotrigine is its ability to bind in melanin-containing skin (e.g., in eyes and pigmented skin). Lamotrigine is metabolized by hepatic enzymes and is capable of inducing its own metabolism with repeated administration. When administered with other antiepileptic drugs that induce hepatic enzymes, its elimination is increased. The exception to this effect is when lamotrigine is administered along with valproic acid. Valproic acid more than doubles the half-life of lamotrigine, requiring dose adjustments of lamotrigine.

The most common adverse effects of lamotrigine are CNS effects (dizziness, double vision, ataxia, blurred vision, somnolence, and headache), GI effects (nausea and vomiting, which are dose related), and rash. Although rashes can be common, serious life-threatening rashes, including Stevens-Johnson syndrome, can occur. Life-threatening rashes are more common in children treated with lamotrigine. For this reason, children younger than 16 years should not be treated with lamotrigine unless they have Lennox-Gastaut syndrome that is resistant to other drugs. Administering lamotrigine with valproic acid also appears to increase the incidence of rash. Because it is not possible to distinguish which rashes will become serious, drug therapy should be stopped at the first sign of a rash. Unfortunately, even stopping drug therapy immediately may not prevent a rash from becoming life-threatening or permanently disfiguring. Like phenytoin, it carries the warning that it may increase suicidal thoughts or actions.

Lamotrigine is a pregnancy category C drug. Animal studies have shown maternal and fetal toxicity, but teratogenic effects have not been determined, although lamotrigine is known to decrease the fetal folate concentrations in animals.

Topiramate

Topiramate (Topamax) is used to treat partial-onset seizures and tonic-clonic seizures. There is evidence that topiramate is effective monotherapy in adolescents and adults with newly diagnosed partial or mixed seizure disorders (French et al., 2004). Off-label uses include cluster headaches, infantile spasms, and Lennox-Gastaut syndrome (a severe form of epilepsy). Like phenytoin, topiramate has an effect on the sodium influx into cells, blocking formation of action potentials. Unlike phenytoin, topiramate has two other methods of action. Topiramate enhances the effectiveness of GABA, increasing the inhibitory effects of the neurotransmitter. Topiramate also blocks the receptors for glutamate, a stimulating neurotransmitter. Therapeutic serum levels have not been determined.

Topiramate is easily absorbed when taken orally. Bioavailability of tablets is about 80%; it is not altered by food intake. Peak levels occur in about 2 hours. The half-life of topiramate is 18.7 to 23 hours. Steady state is reached in about 4 days in patients with normal renal function. Unlike phenytoin, topiramate has low protein binding, about 13% to 17%. Also unlike phenytoin, topiramate is mostly excreted unchanged in the urine. Only a small percentage of the drug is metabolized. A drug interaction related to the P-450 system occurs when topiramate is taken with other drugs that induce these enzymes, such as phenytoin. While phenytoin may increase the metabolism of topiramate, topiramate may decrease the metabolism of phenytoin (UpToDate, 2010d. Enzyme induction will also reduce the effectiveness of oral hormonal contraceptives, which may still be the most effective form of contraception and can be augmented with intrauterine devices or barrier methods.

Topiramate is a weak carbonic anhydrase inhibitor and, like other carbonic anhydrase inhibitors (e.g., acetazolamide and dichlorphenamide), it promotes kidney stone formation by reducing urinary citrate excretion and increasing the urinary pH. The concurrent use of topiramate and other carbonic anhydrase inhibitors increases the risk of kidney stone formation. The renal bicarbonate loss that results from inhibition of carbonic anhydrase can produce metabolic acidosis. Larger doses of topiramate are more likely to result in metabolic acidosis. Baseline and periodic evaluation of serum bicarbonate are recommended for those receiving topiramate (UpToDate, 2010d).

Topiramate carries a warning that oligohidrosis (decreased sweating) and hyperthermia, with potentially serious sequelae, may occur. These adverse effects have infrequently required hospitalization. This warning is based on postmarketing reports that have been received. Most cases have been associated with high environmental temperatures or vigorous exercise. Caution needs to be used if topiramate is prescribed with other drugs that can predispose the patient to heat-related disorders, such as other carbonic anhydrase inhibitors or drugs with anticholinergic effects. Teach all patients, especially parents of children prescribed topiramate, to monitor for decreased sweating and elevated temperature and to seek medical help if these occur. Proper hydration in hot weather, especially before and during exercise or activity, is helpful to decrease the effects from oligohidrosis and hyperthermia.

Topiramate is ranked as a pregnancy category C drug. Animal studies have found that teratogenic effects can occur if given during the time of organ development. No studies have been done with humans.

The most common adverse effects with topiramate are weight loss and the CNS effects (psychomotor slowing; cognitive impairment such as difficulty with concentration, speech or language problems, especially word-finding difficulties; somnolence and fatigue). Other CNS effects are also possible, but not as common. However, generally, the drug is well tolerated.

Topiramate is available in tablets and in sprinkle capsules. Tablets should be swallowed whole because they have a bitter taste if broken. Instruct patients to open the sprinkle capsules and to sprinkle the entire contents onto a teaspoon of soft food, such as applesauce, and swallow (not chew) it immediately. Follow with water to guarantee that all the drug is swallowed.

Oxcarbazepine

Oxcarbazepine (Trileptal) is chemically similar to the metabolite of carbamazepine; it was designed to mimic its efficacy while minimizing adverse effects and risks of drug interactions. Oxcarbazepine is used as either monotherapy or adjunctive therapy in adults with partial seizures and as adjunctive therapy for children 4 to 16 years of age with partial seizures. In addition, there is evidence that oxcarbazepine is effective monotherapy in adolescents and adults with newly diagnosed partial or mixed seizure disorders (French et al., 2004). Although the precise mechanism of action of oxcarbazepine is not known, it is believed to block voltage-sensitive sodium channels, similar to phenytoin. Its effects on increasing potassium conduction and suppressing high-voltage calcium channels may also contribute to the antiepileptic properties of oxcarbazepine. The drug is rapidly absorbed. It has moderate–low protein binding, at 40%. The drug is rapidly converted to its active metabolite; all of the drug's effects are achieved through the metabolite. The metabolites are excreted through the urine.

There seems to be some cross-hypersensitivity between oxcarbazepine and carbamazepine. Between 25% and 30% of patients who have exhibited hypersensitivity to carbamazepine also have hypersensitivity to oxcarbazepine. Oxcarbazepine is a pregnancy category C drug. Although no human studies exist to confirm the drug's teratogenicity in humans, its similar chemical structure to carbamazepine, a known teratogen, makes it likely that oxcarbazepine also causes human teratogenic effects.

The most common adverse effects of oxcarbazepine are related to the CNS (dizziness, somnolence, diplopia, abnormal vision, fatigue, ataxia, abnormal gait, and tremor) and the GI system (nausea, vomiting, abdominal pain, and dyspepsia). Hyponatremia can also occur with oxcarbazepine use; clinically important hyponatremia generally occurs within the first 3 months of treatment. Routine assessment of sodium levels in patients taking oxcarbazepine is necessary.

Oxcarbazepine is a CYP3A4/5 inducer and can cause substantial drug interactions with some other antiepileptic drugs that are also inducers of this pathway. The circulating levels of oxcarbazepine decrease when it is given with carbamazepine, phenytoin, valproic acid, or phenobarbital. Coadministering these drugs causes only phenytoin and phenobarbital levels to rise. Verapamil, a calcium channel blocker used in several cardiac conditions, causes oxcarbazepine levels to decrease substantially. Oxcarbazepine causes the circulating levels of oral contraceptives to decrease by up to half. Teach women taking oral contraceptives that they need to use an additional form of birth control while taking oxcarbazepine.

Levetiracetam

Levetiracetam (Keppra) is an adjunct antiepileptic drug used to treat partial-onset seizures in adults and children as well as generalized myoclonic seizures in adults and adolescents. Research has shown that levetiracetam monotherapy is as effective as phenytoin, with less undesirable adverse effects and better long-term outcomes, although it is labeled only as an adjuvant therapy (Szaflarski et al., 2010). Levetiracetam is chemically unrelated to other antiepileptic drugs. Unlike phenytoin, its exact mechanism of action is not known, although it does *not* inhibit seizures by any mechanism related to inhibitory or excitatory neurohormones. Levetiracetam may prevent hypersynchronization of epileptiform burst firings and propagation of seizure activity from the hippocampus.

Levetiracetam is rapidly absorbed, and food does not affect the extent of absorption. Two thirds of the drug is renally excreted unchanged. The one third that is metabolized is not metabolized through any of the P-450 isoenzymes, and it does not induce any of the P-450 isoenzymes. An advantage of levetiracetam is that it does not require titration when therapy is started; patients can be started on the maintenance dose. Dosing needs to be decreased if renal impairment develops.

Generally, levetiracetam is well tolerated. The most common adverse effects are usually mild to moderate in intensity, and they are transient, disappearing after initial titration. These effects include fatigue, somnolence, dizziness, upper respiratory infection, and asthenia (weakness). Somnolence can occur in nearly 50% of patients unless the dose is slowly increased upward to the desired dose. Like phenytoin, it carries the warning that it may increase suicidal thoughts or actions.

Unlike phenytoin and other antiepileptic drugs, levetiracetam has no known drug interactions. It is a pregnancy category C drug.

Felbamate

Felbamate (Felbatol) is not a first-line antiepileptic drug. It is approved to treat partial seizures, either with or without generalization in adults, and Lennox-Gastaut syndrome in children, but it is used only if other therapies have not been effective and the epilepsy is considered severe. This restriction is attributable to the fact that felbamate greatly increases the risk of aplastic anemia (lack of red blood cells from bone marrow damage). The incidence of aplastic anemia among patients who are taking felbamate may be more than 100 times the incidence found in the general population. Death occurs in 20% to 70% of the patients who develop aplastic anemia, depending on the severity of the disorder. Aplastic anemia usually occurs as a full-blown syndrome; thus, there are no clinical warning signs or indications, and laboratory work does not indicate early signs of problems. However, monitoring laboratory studies does indicate full-blown aplastic anemia. Felbamate also greatly increases the risk of liver failure. Liver function tests must be monitored during therapy. Because of these serious consequences, felbamate is used only if other therapies have failed and the benefit to the patient outweighs these considerable risks. Therapeutic blood levels have not been determined.

The exact manner in which felbamate decreases seizure activity is unknown, which is a significant difference from phenytoin.

Felbamate is well absorbed from the GI tract. About half of the drug is metabolized to several metabolites, and the other half is excreted in the urine unchanged. Terminal half-life of felbamate is 20 to 23 hours.

In addition to the serious adverse effects listed previously, felbamate can produce photosensitivity as well as many other adverse effects, all of which are not common. Felbamate is a pregnancy category C drug. Like phenytoin, it carries the warning that it may increase suicidal thoughts or actions.

• Antiepileptic Drugs That Decrease Calcium Influx

The prototype antiepileptic drug that inhibits influx of calcium is ethosuximide (Zarontin).

Nursing Management of the Patient Receiving P Ethosuximide

Core Drug Knowledge

Pharmacotherapeutics

Ethosuximide is used to treat absence (petit mal) seizures. A therapeutic serum level is 40 to 100 mcg/mL. It is available as capsules and as a syrup.

Pharmacokinetics

Readily absorbed from the GI tract, ethosuximide can reach a peak serum level in 3 to 7 hours. Ethosuximide is extensively metabolized to inactive metabolites, and 20% is excreted unchanged by the kidneys. The plasma half-life is 30 hours in children and 60 hours in adults.

Pharmacodynamics

Ethosuximide, one of the succinimides, works by inhibiting the influx of calcium ions when they travel through a special set of channels, known as T-type calcium channels. Although an electric current is generated when the calcium moves through the T-type channels, in most neurons, this current has only a minimal role in creating an action potential. However, in the hypothalamus neurons, this electric current does play an important role in creating an action potential. Because hypothalamic neurons are responsible for absence seizures, control of action potentials in this location reduces the incidence of absence seizures.

Contraindications and Precautions

Hypersensitivity to succinimides is the only contraindication for ethosuximide. Caution should be used if ethosuximide is used as monotherapy in mixed types of epilepsy because it may increase the frequency of tonic-clonic (grand mal) seizures in some patients. Caution should be used if the

patient has pre-existing renal or liver disease. Ethosuximide is a pregnancy class C drug. Like phenytoin, ethosuximide carries the warning that it may increase suicidal thoughts or actions.

Adverse Effects

Common adverse effects of ethosuximide are drowsiness, dizziness, and lethargy. The patient usually accommodates to these adverse effects. Nausea and vomiting are also common. Other CNS and GI effects are possible but not common. Serious adverse effects include blood dyscrasias, with and without bone marrow suppression. Some of the cases of blood dyscrasias have been fatal. Another serious adverse effect is the development of systemic lupus erythematosus. Liver or renal function may also be impaired.

Adverse effects, which are uncommon, include:

- *Dermatologic:* pruritus, urticaria, Stevens-Johnson syndrome, pruritic erythematous rashes, skin eruptions, erythema multiforme, alopecia, hirsutism
- *Genitourinary:* urinary frequency, renal damage, vaginal bleeding, microscopic hematuria
- *Psychiatric:* confusion, instability, mental slowness, depression, hypochondriacal behavior, sleep disturbances, night terrors, aggressiveness, inability to concentrate (these are most often in patients who have previously had psychological disorders)
- *Miscellaneous:* periorbital edema, hyperemia, muscle weakness, swollen tongue, gum hypertrophy

Drug Interactions

Ethosuximide is known to interact with some of the other antiepileptic drugs. Table 18.4 describes these interactions, effects and significance, and nursing management.

Assessment of Relevant Core Patient Variables

Health Status

Patients should have absence seizures in order to receive ethosuximide. Confirm that the patient does not have a hypersensitivity to the drug before starting therapy. Determine whether the patient has pre-existing renal or hepatic disease, both of which indicate caution with ethosuximide use.

Life Span and Gender

Like all antiepileptic drugs, ethosuximide may cause teratogenic effects if given during pregnancy. However, as with other antiepileptic drugs, suddenly discontinuing ethosuximide may cause an increase in seizures. Women of childbearing age should be aware of the risks related to pregnancy. Assess whether a woman is pregnant before starting drug therapy.

Environment

Ethosuximide can be administered in all environmental settings.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to adverse GI drug effects of anorexia, abdominal complaints, nausea, and vomiting
  Desired outcome: *The patient will not experience major nutritional imbalances while receiving ethosuximide.*
- Risk for Injury from falls related to CNS adverse effects of ethosuximide
  Desired outcome: *The patient will not sustain an injury while receiving ethosuximide.*
- Risk for Injury from blood dyscrasias related to adverse effects of ethosuximide
  Desired outcome: *The patient will not experience major changes in his or her complete blood cell counts.*

Planning and Intervention

Maximizing Therapeutic Effects

When initiating therapy or changing a dose, monitor the drug serum level to determine whether a therapeutic range has been obtained.

Minimizing Adverse Effects

Assess complete blood counts regularly to determine whether any low blood cell counts are present. If patients develop signs of infection (sore throat, fever), the blood

TABLE 18.4 Agents That Interact with P Ethosuximide

Interactants	Effect and Significance	Nursing Management
valproic acid	Increased pharmacologic effects of ethosuximide Both increases and decreases in ethosuximide levels have occurred	Monitor patient for changes in seizure control. Assess patient for evidence of therapeutic effects of interacting drugs.
phenytoin	Serum hydantoin levels may increase	Evaluate patient for changed seizure control. Assess patient for evidence of therapeutic effects of interacting drugs. Check for therapeutic serum levels of interacting drugs.
primidone	Lower primidone and phenobarbital levels may occur	Evaluate patient for changed seizure control. Assess patient for evidence of therapeutic effects of interacting drugs. Check for therapeutic serum levels of interacting drugs.

cell counts should also be checked at that time. Periodic urinalysis and liver function studies help identify early any complications that might be from ethosuximide therapy. Like all antiepileptic drugs, taper the dose gradually if it is necessary to discontinue the drug to minimize the risk for seizures, including absence status.

Providing Patient and Family Education

Much of the teaching for ethosuximide is similar to that for phenytoin and other antiepileptic drugs. Specific teaching includes the following:

- Teach patients to take the drug with milk or food if GI upset occurs.
- Teach patients to notify the physician if any of the following occurs: changes in mood or behavior that indicate depression or suicidal thinking, skin rash, joint pain, unexplained fever, sore throat, unusual bleeding or bruising, severe drowsiness, severe dizziness, blurred vision, or pregnancy.
- Teach women of childbearing age to use birth control, because drug therapy carries some risks if they become pregnant. Women who wish to become pregnant while taking this drug need to be counseled about the importance of discussing their options with their physicians first.

Ongoing Assessment and Evaluation

Ongoing assessments include monitoring patients closely for therapeutic responses, seizure control, and adverse effects of drug therapy. Blood levels of the drug should be monitored whenever the dose is changed or if the patient is having seizures. Ethosuximide therapy is effective if seizures can be controlled and the patient experiences no serious adverse effects.

Drugs Closely Related to P Ethosuximide

Methsuximide (Celontin) has similar actions and adverse effects as ethosuximide. Unlike ethosuximide, it is available only as capsules. Peak concentration levels are reached somewhat more rapidly than for methsuximide—in 1 to 4 hours instead of in 3 to 7 hours.

Phensuximide (Milontin) is very similar to the prototype ethosuximide, with a few exceptions. Like methsuximide, it also peaks in 1 to 4 hours instead of in 3 to 7. Unlike ethosuximide, which is extensively metabolized, phensuximide is excreted in urine and bile, and less than 20% is excreted via the kidneys unchanged. Phensuximide may discolor the urine pink, red, or red-brown. This is not harmful. It may also cause some hematuria. Phensuximide carries an additional warning that when given to patients with acute intermittent porphyria, caution should be used. Like ethosuximide, it carries the warning that it may increase suicidal thoughts or actions.

Drug Significantly Different From P Ethosuximide

Zonisamide (Zonegran) is used as an adjunct drug in treating partial seizures, as well as generalized seizures, in adults. Its therapeutic level has not been determined.

Zonisamide is a sulfonamide drug. Although the exact mechanism of action is not known, it is believed to block calcium flow through T-type calcium channels, like ethosuximide. Additionally, zonisamide appears to alter sodium influx, like phenytoin. Zonisamide also facilitates dopamine and serotonin transmission. It has *not* been shown to increase the effectiveness of GABA.

Absorption of zonisamide is fairly slow with oral administration, and peak levels occur within 2 to 6 hours. If food is present when the drug is administered, the peak does not occur until 4 to 6 hours; however, the bioavailability is not changed with the presence of food. Zonisamide has fairly low protein binding at 40%. Zonisamide binds extensively in erythrocytes as opposed to the plasma. Eight times as much drug is in red blood cells compared with the plasma. The half-life of zonisamide varies; it is 63 hours from the plasma and 105 hours from the red blood cells. A steady state occurs in 14 days. Metabolism occurs in the liver, but most of the drug is eliminated in the urine unchanged. If zonisamide is taken with other drugs that induce hepatic enzymes, its rate of metabolism is increased.

Hypersensitivity to zonisamide or to sulfonamides is a contraindication. Death can occur, although rarely, related to a hypersensitivity reaction to sulfonamides. Zonisamide is a pregnancy category C drug. Like ethosuximide, it carries the warning that it may increase suicidal thoughts or actions.

Common adverse effects of zonisamide include dizziness, somnolence, fatigue, ataxia, decreased mental functioning, nausea, headache, irritability, and renal calculi. Serious adverse effects include Stevens-Johnson syndrome, aplastic anemia, and agranulocytosis. Lack of sweating and elevated temperatures in children were noted during clinical testing. The drug is not approved for use in children.

Zonisamide is known to increase the levels of the following laboratory tests: serum creatinine, blood urea nitrogen, and serum alkaline phosphatase.

MEMORY CHIP

P Ethosuximide

- Used to treat absence (petit mal) seizures
- Works by inhibiting the influx of calcium ions through T-type calcium channels
- Most common adverse effects: drowsiness, dizziness, lethargy, nausea and vomiting
- Most serious adverse effects: blood dyscrasias, systemic lupus erythematosus
- Maximizing therapeutic effect: Monitor serum levels.
- Minimizing adverse effects: Monitor serum levels and complete blood counts; assess mood
- Most important patient education: Notify the physician of skin rash, joint pain, signs of infection, unusual bleeding or bruising, or pregnancy; may increase suicidal thoughts

• Antiepileptic Drugs That Increase the Effects of GABA

Antiepileptic drugs that affect GABA are designed to increase the supply of GABA by lowering GABA metabolism, reducing reuptake of GABA into the neurons and glia, or increasing the production of GABA. Other antiepileptic drugs imitate the action GABA or improve GABA's inhibition of the nervous system.

Benzodiazepines

Benzodiazepines produce their many effects by potentiating the effects of the neurotransmitter, GABA, which is an inhibitory neurotransmitter. The GABA receptor complex has binding sites for GABA as well as for benzodiazepines and phenobarbital. Certain benzodiazepines are approved for different therapeutic uses, although all of the drugs in the class share many similarities. The prototype benzodiazepine is lorazepam and is discussed in Chapter 15. This chapter highlights diazepam, clonazepam, and clorazepate as antiepileptic drugs. Benzodiazepines are the drugs of first choice in treating status epilepticus. Because benzodiazepines as a class have been associated with the development of tolerance, their usefulness in chronic treatment for epilepsy is limited.

Diazepam

Diazepam is used as an adjunct to other antiepileptic drug therapy in convulsive disorders. It has historically been the drug of first choice to treat status epilepticus, although lorazepam is now often used and has some advantages over diazepam. In fact, research has shown that lorazepam is more effective than diazepam or phenytoin used alone for cessation of seizures and has an effective duration of up to 6 hours compared to 20 minutes for diazepam (Prasad et al., 2007). Both diazepam and lorazepam are an effective adjunctive therapy for myoclonic and atonic seizures, as well as partial and generalized tonic-clonic seizures (UpToDate, 2010a). Diazepam is also used to treat anxiety, as a muscle relaxant, in the treatment of acute alcohol withdrawal, and as a preoperative medication to reduce anxiety, tension, and recall of events. An off-label use is for treatment of panic attacks. The therapeutic blood level of diazepam has not been determined. Diazepam works like all benzodiazepines by increasing the effectiveness of GABA.

Onset of action when taken orally is very rapid for diazepam, and peak plasma levels are reached in 30 minutes to 2 hours. Diazepam is highly lipid soluble, so it rapidly crosses the blood–brain barrier. The drug is very highly protein bound, higher than lorazepam, at 98%. Like lorazepam, diazepam is metabolized through the liver; unlike lorazepam, it is metabolized to an active metabolite. Elimination half-life is 20 to 80 hours; this time is lengthened in obese patients. Like other benzodiazepines, diazepam is excreted in the urine.

Unique pharmacokinetic differences exist between diazepam and lorazepam, which are relevant when the drugs are used to treat status epilepticus. Although both drugs achieve therapeutic effects within a few minutes of IV administration, the onset of action of diazepam is more rapid, with an effect on seizure activity noticeable in as little as 10 to 20 seconds after administration. The onset of action of lorazepam is two minutes or less. The antiepileptic effect of the two drugs differs also; the duration of action of diazepam is short, with seizures often reoccurring 30 to 60 minutes after disruption of status epilepticus, whereas that of lorazepam is long—four to six hours. This phenomenon occurs because diazepam is distributed quickly to the brain, where it creates its effect, but then is rapidly redistributed out of the brain to other body tissues, specifically adipose tissues. On the other hand, lorazepam has a much slower redistribution out of the brain and therefore a longer duration of action in status epilepticus—that is, more than 12 hours (see Chapter 15 for more information).

Diazepam is similar to lorazepam and other benzodiazepines in terms of contraindications, precautions, adverse effects, and drug interactions. Because diazepam is used as an adjunct therapy and coadministered with other antiepileptic drugs, additional CNS depression may occur, and patients need to be cautioned when the drug is added to their therapy. Like the other antiepileptic drugs, diazepam carries the warning that it may increase suicidal thoughts or actions.

Diazepam is administered intravenously during status epilepticus; the small veins in the dorsum of the hand or the wrist should be avoided. It should be injected very slowly, no faster than 5 mg in 1 minute. Diazepam should not be mixed or diluted with other solutions or drugs, either in the syringe or in IV bags of fluid. A separate IV line should be placed to deliver phenytoin after diazepam or other benzodiazepine, because these precipitate if given via the same IV tubing. Diazepam interacts with plastic containers and administration sets, substantially decreasing the availability of drug delivered. If it is not possible to give diazepam directly into the vein, it can be administered through the IV infusion tubing as close to the insertion site into the vein as possible. Although a deep IM route could be used if absolutely necessary, IM injections produce low or erratic plasma levels and may not control status epilepticus easily. For this reason, the IM route is normally avoided.

After status epilepticus is treated with a benzodiazepine such as diazepam or lorazepam, IV phenytoin should be administered.

Clonazepam

Clonazepam is used alone or as adjunctive treatment for Lennox-Gastaut syndrome (absence variety) and atonic and myoclonic seizures. It may be useful in patients with absence seizures who have failed to respond to succinimides, such as ethosuximide. Unlabeled uses include periodic leg movements during sleep, parkinsonian (hypokinetic) dysarthria, acute manic episodes of bipolar disorders, multifocal tic disorders, adjunct treatment for schizophrenia, and neuralgias. Therapeutic serum levels are 20 to 80 mg/mL.

Like other benzodiazepines, clonazepam increases the effectiveness of GABA. Clonazepam suppresses the spike

and wave discharge that occurs with absence seizures and decreases the frequency, amplitude, duration, and spread of neuronal discharge in motor seizures. The onset of action of clonazepam is intermediate, with peak plasma level being reached in 1 to 2 hours. Clonazepam is highly protein bound, at 97%. It is metabolized through the liver to five metabolites. The elimination half-life is 18 to 50 hours.

Tolerance to the antiseizure effects of clonazepam can occur within months. Abrupt withdrawal of the drug induces seizures, including status epilepticus.

Clonazepam can produce an increase in salivation as an adverse effect. It should be used with caution in patients for whom increased salivation causes respiratory difficulty. Like diazepam, when given with other antiepileptic drug therapy, clonazepam causes additive CNS depression. Like the other antiepileptics, it carries the warning that it may increase suicidal thoughts or actions.

Other adverse effects, precautions, and drug interactions are similar to the prototype, lorazepam.

Clorazepate

Clorazepate is used as adjunctive treatment for partial and generalized tonic-clonic seizures; it is also used to treat anxiety disorders and for symptom management in acute alcohol withdrawal. The therapeutic blood level for clorazepate has not been determined. It has a fast onset of action, reaches a peak in 1 to 2 hours, and has an elimination half-life of 40 to 50 hours. Clorazepate is highly protein bound at 97% to 98%. It is metabolized in the liver by the same pathway as diazepam. Like all benzodiazepines, it achieves its effects by enhancing the effects of GABA. Additional core drug knowledge about clorazepate is similar to the prototype, lorazepam.

Midazolam

Unlike diazepam, midazolam is primarily used as an anesthetic. Like diazepam, midazolam can stop seizures in status epilepticus quickly (frequently less than one minute); however, because of its short half-life, it needs to be administered as a continuous infusion to maintain an antiseizure effect. It is used in treatment of refractory status epilepticus in which other drug treatment has been unsuccessful, and nasal and buccal administration is useful when IV access is not possible (UpToDate, 2010c).

Drugs Significantly Different From the Benzodiazepines

Gabapentin

Gabapentin (Neurontin) is an adjunct antiepileptic drug used in treating partial seizures, with or without secondary generalization, in patients older than 12 years. Evidence indicates that gabapentin is effective monotherapy in adolescents and adults with newly diagnosed partial or mixed seizure disorders (French et al., 2004). It is also used in treating partial seizures in children 3 to 12 years of age. Off-label uses include multiple sclerosis, amyotrophic lateral sclerosis, neuropathic pain, bipolar disorder, and prophylaxis for migraine headaches. A therapeutic blood level of gabapentin has not been established.

Gabapentin is structurally related to the neurotransmitter GABA, but it does not interact at GABA receptors. It is believed to promote the release of GABA. It is absorbed through the GI tract, and food does not affect its absorption. It is almost entirely free from protein binding, with only 3% bound. Gabapentin is excreted renally, without undergoing metabolism. Elimination half-life is 5 to 7 hours. Patients with renal failure or renal disease may have additional risks of adverse effects from the drug.

Gabapentin is a pregnancy category C drug. It is secreted into breast milk and should generally be avoided during nursing because the safety and efficacy in children younger than 3 years is not known. The most common adverse effects of gabapentin for patients older than 12 years of age are CNS effects: somnolence, dizziness, ataxia, fatigue, and nystagmus. In children between 3 and 12 years of age, the most common adverse effects of gabapentin are viral infection, fever, nausea and vomiting, somnolence, and hostility. Children younger than 12 years of age could have other neuropsychiatric adverse effects such as behavior problems, aggressive behavior, thought disorders with trouble concentrating or changes in school performance, restlessness, and hyperactivity. Usually, the occurrence of these effects is mild to moderate in intensity.

Because gabapentin does not affect hepatic enzymes responsible for metabolism of other drugs, it is free of drug interactions. This advantage makes it ideal to combine with other antiepileptic drugs for seizure treatment. The only important drug interaction is with antacids, which reduce the bioavailability of gabapentin by 20%; to avoid this interaction, gabapentin should be administered at least 2 hours after antacids are given.

The dose of gabapentin should be increased gradually in older adults, because they may have age-related kidney function deterioration. As with all antiepileptic drugs, gabapentin should be withdrawn slowly and gradually to prevent the onset of seizures. Like other antiepileptic drugs, it carries the warning that it may increase suicidal thoughts or actions.

Pregabalin

Pregabalin (Lyrica) is chemically related to gabapentin. It is used as adjunct therapy to treat partial seizures in adults. It is also used to treat neuropathic pain associated with diabetic peripheral neuropathy and postherpetic neuralgia. Pregabalin modulates the release of several neurotransmitters, including glutamate, noradrenaline, and substance P (which is involved in pain perception). Pregabalin also decreases the influx of calcium into the cell. All of these actions inhibit neuronal excitability.

Pregabalin is taken orally. Steady state is achieved within 24 to 48 hours. Although the plasma half-life is six hours, the effect of pregabalin appears to be much longer. Pregabalin is excreted unchanged; it is not metabolized. The drug has no effect on the P-450 system. Pregabalin does not bind to

plasma proteins, so it does not have significant drug interactions with other antiepileptic drugs or other drugs.

The most common adverse effects of pregabalin are CNS effects: dizziness, somnolence, and ataxia. Less common adverse effects include weight gain, peripheral edema, blurred or double vision (which is normally transient), weakness, and impaired concentration. Because pregabalin also may cause euphoria, it is classified as a schedule V controlled substance. Like other antiepileptics, it carries the warning that it may increase suicidal thoughts or actions.

Pregabalin is a pregnancy category C drug.

Phenobarbital

Phenobarbital is used to treat generalized tonic-clonic and cortical focal seizures. Phenobarbital is also used to treat acute convulsive episodes that require emergency intervention (e.g., status epilepticus, eclampsia, cholera, meningitis, tetanus, and toxic reactions to strychnine or local anesthetics), as a preanesthetic, and to induce sleep (see Chapter 15). Phenobarbital is a general CNS depressant that suppresses the sensory cortex; decreases motor activity; alters cerebellar function; and produces drowsiness, sedation, and hypnosis. Phenobarbital's antiepileptic activities are relatively nonselective. Like the benzodiazepines, phenobarbital stimulates GABA receptors, thereby elevating the seizure threshold and limiting the spread of seizure activity by affecting the CNS neuronal pathway neurotransmitters. Tolerance does not occur to the antiepileptic effects of phenobarbital, as it does to the sedative effects. The therapeutic blood level of phenobarbital is 10 to 40 mcg/mL.

Phenobarbital is absorbed through the GI tract; time to reach a peak plasma level varies from 30 minutes to more than 1 hour. It is only moderately protein bound, at 40% to 60%. It is metabolized in the liver and induces the hepatic enzyme system. It can induce its own metabolism. Its half-life is long, 53 to 143 hours. One fourth of phenobarbital is excreted in the urine unchanged.

Phenobarbital is classified as a pregnancy category D drug, and fetal abnormalities are possible if it is used during pregnancy.

Adverse effects are related to CNS depression, and respiratory depression is the most serious. The degree of respiratory depression is dose dependent. The dosage used to control seizures is rarely involved with substantial respiratory depression. Drowsiness occurs commonly with phenobarbital use in the treatment of seizures; however, tolerance to this effect develops with chronic use. Other CNS effects may occur. In some instances, phenobarbital produces CNS effects that are the opposite of what would normally be expected. Therefore, agitation, hyperactivity, insomnia, irritability, and CNS stimulation may occur. Children and older adults are particularly prone to these paradoxical effects. Adverse cognitive effects in children may also include impaired short-term memory and deficits on neuropsychological tests and memory concentration tasks. Fever may occur with chronic use. As with other antiepileptic drugs, status epilepticus may occur if phenobarbital is stopped suddenly after chronic use. In addition, additive CNS depression occurs if phenobarbital is taken with other CNS depressants. Like other antiepileptic drugs, it carries the warning that it may increase suicidal thoughts or actions.

Because phenobarbital induces the hepatic enzyme system and alters the metabolism of a large number of other drugs, it is characterized by many drug–drug interactions. Enzyme induction will also reduce the effectiveness of oral hormonal contraceptives, which may still be the most effective form of contraception and can be augmented with intrauterine devices or barrier methods.

The drug's many adverse effects, drug interactions, and slow administration mean that its use has greatly decreased since the creation of the newer antiepileptic drugs and it is generally not used a first-line therapy for status epilepticus (UpToDate, 2010c). The reasons phenobarbital is not the best drug for status epilepticus are as follows: When given for emergency use, phenobarbital is administered intravenously and may require at least 15 minutes before peak concentration is reached in the brain to control the seizure. Because of phenobarbital's long half-life, if it is administered continuously until the seizure activity ceases, severe barbiturate-induced CNS depression, including respiratory depression and excessive hypotension, can occur. Because of the length of time needed to reach a therapeutic effect and control status epilepticus, more rapidly acting drugs, such as diazepam or lorazepam, are normally used to treat status epilepticus initially. Phenobarbital is used as a second-line drug after interventions with a benzodiazepine and phenytoin have failed.

Primidone

Primidone (Mysoline) is used to control grand mal, psychomotor, or focal epileptic seizures, either alone or used in combination with other antiepileptic drug therapy. An unlabeled use of primidone is benign familial tremor. Although primidone is actually considered to be an adjuvant antiepileptic drug, one of the active metabolites of primidone is phenobarbital. The other active metabolite is phenylethylmalonamide (PEMA). Although primidone has antiepileptic properties of its own, much of its effect comes from the antiepileptic properties of phenobarbital and PEMA. Animal studies have shown that PEMA also potentiates the effects of phenobarbital. Phenobarbital accounts for between 15% and 25% of the metabolites formed by primidone.

Primidone has a half-life of 5 to 15 hours. PEMA and phenobarbital have longer half-lives (10 to 18 hours and 53 to 140 hours, respectively) and accumulate with chronic use. About 40% of primidone is excreted unchanged in the urine. The remainder of the drug is excreted as unconjugated PEMA and as phenobarbital and its metabolites.

The therapeutic effects and adverse effects of primidone are similar to those of phenobarbital and other antiepileptic drugs. Nursing management of the patient is also similar. It is a potent P450 inducer and will have many drug interactions, including oral hormonal contraceptives.

Tiagabine

Tiagabine (Gabitril) is used as an adjunct therapy in treating partial seizures; thus it is never used as monotherapy. Like the benzodiazepines, it is believed to enhance the effectiveness of GABA. Unlike the benzodiazepines, tiagabine binds to the sites associated with GABA reuptake. By binding to these sites, it inhibits GABA reuptake by presynaptic neurons and glia cells, and the neurotransmitter can further stimulate the receptors on the postsynaptic cells. Tiagabine is sometimes referred to as a GABAergic drug.

Tiagabine is absorbed rapidly and almost completely from the GI tract and peaks in about 45 minutes if taken on an empty stomach; a high-fat meal slows the rate but not the extent of absorption. Tiagabine is highly protein bound, at 96%. Metabolism of tiagabine is in the liver through hepatic enzymatic pathways, mostly CYP3A, although other isoenzymes may also be involved. Although half-life is 7 to 9 hours in healthy adults, it can be decreased considerably (up to 65%) when taken with other antiepileptic drugs that induce hepatic isoenzymes, such as phenytoin, carbamazepine, primidone, or phenobarbital. An unusual feature of the pharmacokinetics of tiagabine is that it exhibits a diurnal effect; steady-state values are 15% lower after the evening dose than after the morning dose. A therapeutic drug level for tiagabine has not been established.

Like all other antiepileptic drugs, tiagabine is not recommended to be used during pregnancy or breast-feeding. It is classified as a pregnancy category C drug because animal studies have indicated teratogenic effects. However, no related controlled studies have been done in women. Tiagabine is excreted in breast milk.

Although tiagabine is usually well tolerated, the most common adverse effects are related to the CNS system. These include dizziness, muscle weakness, somnolence, nervousness, tremor, insomnia, difficulty with concentration or attention, ataxia, and confusion. GI problems of nausea, diarrhea, or vomiting are also common. Although animal studies indicate a risk for visual-field impairment from tiagabine, clinical research has not supported this (see Box 18.4).

Tiagabine is used to prevent seizures, but it now has a warning on its label stating that it may cause seizures if used in patients who do not have epilepsy (FDA, 2005). The FDA lists 59 reports of induced seizures, including seven cases of status epilepticus, which were associated with unlabeled use of tiagabine in patients without epilepsy. Off-label uses include treatment of various psychiatric diseases and chronic pain management. Exactly why tiagabine may induce seizures in such patients is not known, although there are two theories. First, patients who take tiagabine as an antiepileptic are taking it as an adjunct to other antiepileptic drugs, which frequently induce hepatic enzymes that would metabolize tiagabine. Second, it is possible that patients who use tiagabine for an off-label indication are also taking some other medication that may lower the seizure threshold. A drug interaction between these two drugs then results in seizure activity (UpToDate, 2010a). Like the other antiepiletics, it carries the warning that it may increase suicidal thoughts or actions.

Vigabatrin

Vigabatrin (Sabril) is used to treat refractory partial seizures in cases in which other drug therapy has failed to control seizures. The drug has been marketed in Canada and in many European and Asian countries for years, and was approved in 2009 by the U.S. Food and Drug Administration for infantile spasms in children 1 month to 2 years and in combination therapy for refractory complex partial seizures in adults (Food and Drug Administration, 2009). Like tiagabine, vigabatrin is a GABAergic drug. Unlike tiagabine, tiagabine is an irreversible inhibitor of GABA-transaminase (responsible for the metabolism of GABA). Also unlike tiagabine, vigabatrin has been found to significantly increase the risk of visual-field impairment (see Box 18.4). About one third to one half of the patients receiving long-term treatment with vigabatrin develop visual field defects characterized by a bilateral, absolute concentric constriction of the visual field; the severity of the impairment can be mild or severe. Sometimes, the damage to the retina is permanent. Adults seem to be at higher risk for developing the adverse effect (although more research is needed with pediatric populations), and men have about twice the risk of women for developing these problems. Because of these serious adverse effects, patients should receive vigabatrin only if all other combinations of antiepileptic drug therapy have been tried and were unsuccessful. Patients receiving vigabatrin should regularly have their vision tested. As for all other antiepileptic drugs, assess the patient receiving vagabatrin for changes in mood and behavior that may indicate depression or suicidal thoughts.

DRUGS USED IN SEIZURES RELATED TO PRE-ECLAMPSIA AND ECLAMPSIA

Magnesium sulfate is a drug that is completely different from all of the other antiepileptic drugs. Magnesium sulfate is used in treating seizures related to severe pre-eclampsia or eclampsia in pregnant women. It is also used to control preterm labor. Magnesium has a depressive effect on the CNS. It prevents or controls seizures by blocking the neuromuscular transmission of acetylcholine and decreasing the amount of this neurotransmitter liberated at the end plate by motor nerve impulses. This drug is discussed in more detail in Chapter 53.

CHAPTER SUMMARY

- Antiepileptic drugs work by inhibiting influx of sodium ions through sodium channels into the cell, inhibiting calcium ion influx into special calcium channels, or altering the effectiveness of GABA.
- All antiepileptic drugs carry risks for teratogenicity. Stopping drug therapy also carries the risk for inducing seizures, which is risky to the mother and the fetus. Most babies born to epileptic mothers on drug therapy are normal.

- Status epilepticus is a medical emergency and requires IV drug therapy. The first line of treatment is a benzodiazepine, either diazepam or lorazepam. Phenytoin is used next. Phenobarbital is a third-line drug used if neither the benzodiazepine nor the phenytoin is effective.
- Antiepileptic drug therapy can be successfully discontinued in about 70% of people once they are seizure-free for 2 years.
- Nursing management procedures for the antiepileptic drugs are similar in many respects. Patients need to understand the disease process, how the disease and drug therapy may affect their lives, and possible adverse effects of drug therapy.

QUESTIONS FOR STUDY AND REVIEW

1. What is the difference between a seizure and a convulsion?
2. Why is phenytoin useful in treating both seizures and some cardiac arrhythmias?
3. What is the first-line drug of choice in treating status epilepticus?
4. Why should dosage changes of phenytoin be made in small increments?
5. Why would patients with low serum albumin levels be more at risk for adverse effects from phenytoin?
6. How does ethosuximide reduce absence seizures?
7. How do benzodiazepines suppress seizure activity?

Drugs Producing Anesthesia and Neuromuscular Blocking

Learning Objectives

At the completion of this chapter the student will:

1. Describe the physiology of the central nervous system as it relates to anesthesia and neuromuscular blocking.
2. Identify observable changes in stages of anesthesia and neuromuscular blockade.
3. Identify risk and disease factors that may influence a patient's response to anesthetics and neuromuscular blocking agents.
4. Identify core drug knowledge about anesthetic and neuromuscular blocking agents.
5. Identify core patient variables related to anesthetic and neuromuscular blocking agents.
6. Relate the interaction of core drug knowledge and core patient variables for anesthetic and neuromuscular blocking agents.
7. Generate a nursing plan of care based on the interactions between core drug knowledge and core patient variables for anesthetic and neuromuscular blocking agents.
8. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for anesthetic and neuromuscular blocking agents.
9. Determine key points for patient and family education about anesthetic and neuromuscular blocking agents.

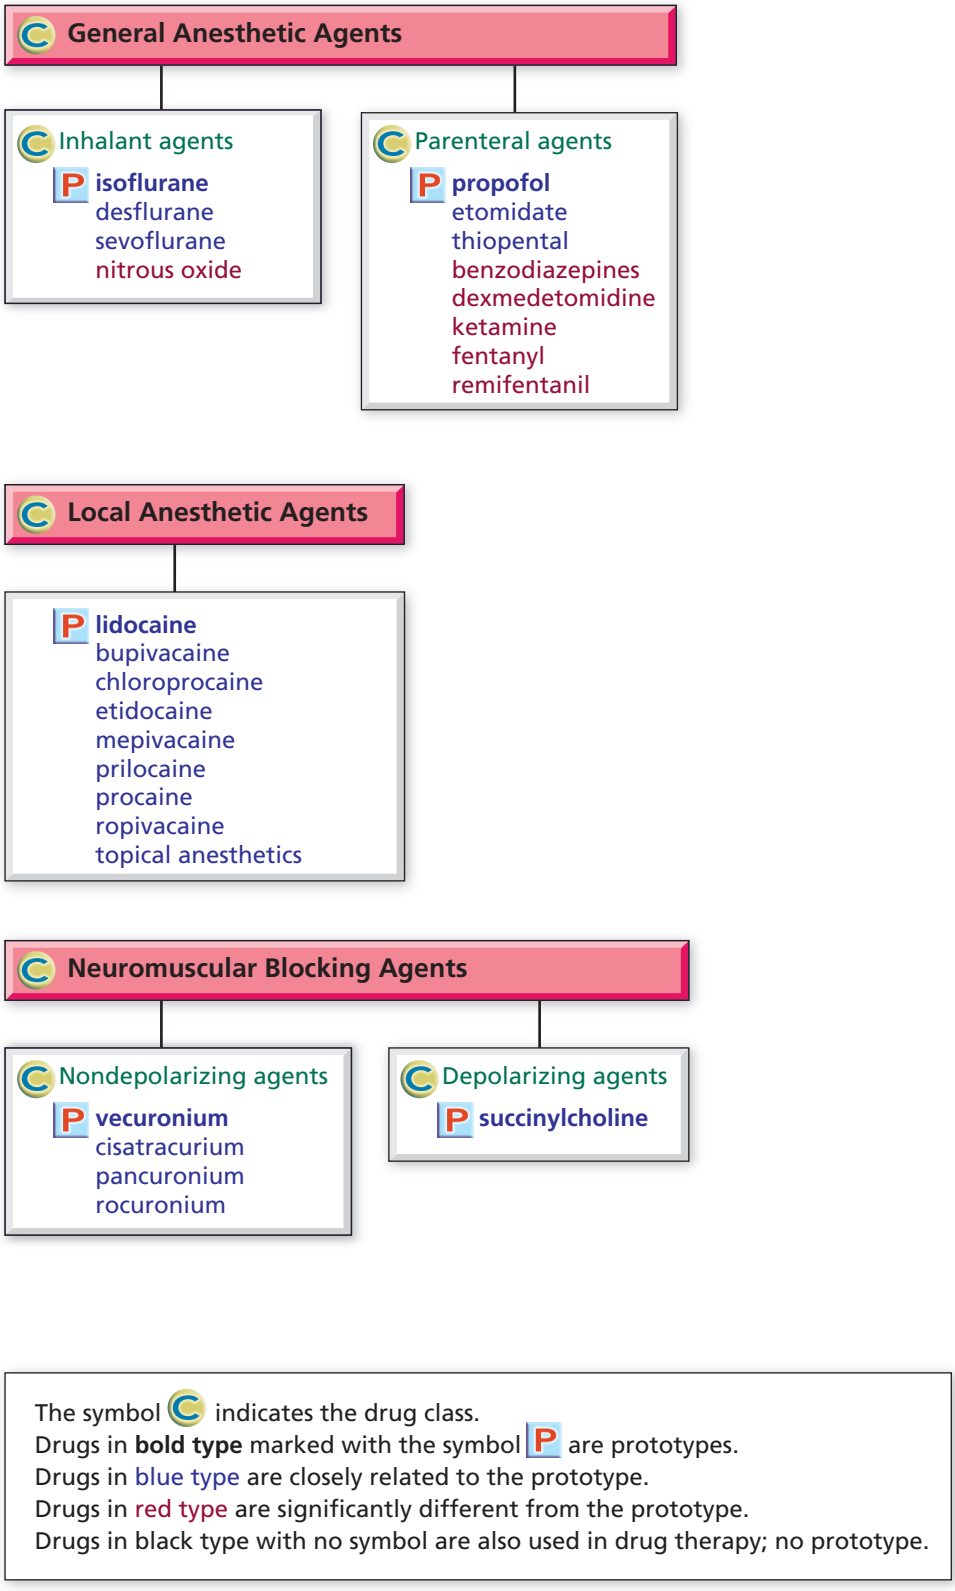
Drugs Producing Anesthesia and Neuromuscular Blocking



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Anesthesia produces a loss of feeling or sensation through administration of a drug or drugs. It is used to avoid sensations (especially pain) and memories associated with surgery and diagnostic procedures. Anesthesia can be classified into two categories: general and regional. **General anesthesia** is characterized by a state of unconsciousness, analgesia, and amnesia. All three states must be present. General anesthetic drugs are subdivided into inhaled agents and intravenous agents. **Regional anesthesia** occurs when sensory transmission from a specific area or region of the body to the central nervous system (CNS) is blocked. This is accomplished through local anesthetic drugs administered in an epidural block, a spinal block, or peripheral nerve blocks. Regional anesthesia is utilized to perform minor surgical procedures for a conscious patient or as an adjunct for general anesthesia. This type of anesthesia is frequently used in ambulatory surgical centers. Local anesthesia is similar to regional anesthesia, but employs its effect on a smaller area of the body. Neuromuscular blocking agents are used to cause **paralysis** (loss of motor function) for surgical procedures or to facilitate mechanical ventilation. These agents are subdivided based on their mechanism of action into **nondepolarizing drugs** (which bind to acetylcholine receptors and function as a competitive antagonist) and **depolarizing drugs** (which closely resemble acetylcholine, binding to the receptor and functioning as an agonist).

This chapter discusses drugs used to induce anesthesia and skeletal muscle paralysis. The focus is not to present the specific anesthetic considerations on how to deliver anesthesia, but rather provide a basic overview of the drugs and their effects on a patient who is recovering from anesthesia in a post-anesthesia care unit (PACU) or on a surgical unit. Inhaled anesthetics are represented by the prototype drug isoflurane (Forane). Intravenous anesthetics are represented by the prototype drug propofol (Diprivan). Local anesthetics, used for regional anesthesia, are represented by the prototype drug lidocaine (Xylocaine). Nondepolarizing neuromuscular junction (NMJ) blockers are represented by the prototype drug vecuronium (Norcuron). Depolarizing NMJ blockers are represented by the prototype drug succinylcholine (Anectine).

PHYSIOLOGY

Central Nervous System Anesthesia

Researchers have yet to identify specifically the mechanism of action of anesthetic drugs. There is simply not one "switch" that anesthetics can turn off and produce amnesia, analgesia, and unconsciousness. However, through different pathways, anesthesia can be accomplished by interrupting the nervous system activity in the CNS. The CNS includes the spinal cord, brain stem, and cerebral cortex—all sites of action in which anesthesia drugs produce their effects. The spinal cord is speculated to be where purposeful responses to painful stimuli are inhibited; the brainstem (specifically the reticular activating system) is probably where consciousness is interrupted; and the cerebral cortex (the site of complex brain functions) is where interference of memory, attention, and awareness probably occur.

At the synaptic level in the CNS, normal arousal mechanisms are affected through presynaptic release of neurotransmitters, such as norepinephrine, serotonin, and dopamine. As described in Chapter 13, these transmitters diffuse across the synaptic cleft to the postsynaptic effector membrane, which is usually another neuron. The postsynaptic membrane contains receptors for the transmitters. The transient combination of the transmitter with the receptor causes membrane changes, leading to propagation of the action potential. An action potential is the brief reversal of electrical polarization of a nerve or muscle cell membrane. In the neuron, the action potential constitutes the nerve impulse. The transmitter can be metabolized by postsynaptic enzymes (such as monoamine oxidase) or removed from further activity through reuptake into the presynaptic storage vesicles. Anesthetics may provoke a decreased release of neurotransmitters or an increased reuptake and inhibition of the postsynaptic enzymes. The result is a diminished postsynaptic response, leading to decreased arousal, decreased sensation (including pain), and loss of consciousness.

Local Anesthetics

Nerve impulses depend on the flow of ion currents through channels in the cell membrane. Nerve cells are negatively polarized at rest, a state that is maintained by active Na^+/K^+ exchange. When a cell is stimulated, it becomes depolarized, and an action potential occurs. Local anesthetics reversibly block all nerve impulses by disrupting membrane permeability to sodium during an action potential. These drugs therefore stop the generation and propagation of the nerve impulse.

Neuromuscular Blockade

Muscle relaxation and paralysis can take place at a variety of sites, including the CNS, somatic nerves, motor nerve terminals, acetylcholine receptor sites, the **motor end plate** (the terminal branch of a motor nerve, which forms part of the NMJ), the muscle membrane, or the internal contractile units of muscle. Normal muscle function involves the arrival of a nerve impulse at the motor nerve terminal, followed by the release of the neurotransmitter acetylcholine into the synaptic cleft. Neuromuscular blockade occurs at acetylcholine receptor sites, where acetylcholine reacts with the muscle cell membrane, causing depolarization and subsequent muscle relaxation.

Nondepolarizing drugs are competitive antagonists preventing the binding of acetylcholine to the receptor; therefore the end plate is unable to depolarize. After administration, muscle fasciculation will not be present, unlike with depolarizing drugs. Depolarizing drugs, structurally similar to acetylcholine, cause continuous muscle depolarization and prevent repolarization. The muscle is unable to repolarize as long as the drug continues to bind to the acetylcholine receptor.

PATHOPHYSIOLOGY

Anesthetics are called functional drugs because they are not used to treat a pathologic disease or disorder. Instead, their effects allow the patient to undergo procedures that either treat or improve a specific disease state. These drugs are utilized in different combinations to achieve the appropriate point along the sedation and anesthesia continuum for a specific procedure. Examples of procedures that anesthetic drugs are used for include general surgery, pediatric dental procedures, electroconvulsive therapy, CT scans, MRI, endoscopy, bronchoscopy, heart catheterization, and complicated dressing changes.

The Joint Commission has identified four levels of sedation and anesthesia on a continuum. These include minimal sedation (anxiolysis), moderate sedation and analgesia (**conscious sedation**), deep sedation and analgesia, and anesthesia. Under conscious sedation, patients respond purposefully to verbal commands alone or with light tactile stimulation and are able to maintain their own airway and breathe spontaneously.

C GENERAL ANESTHETIC AGENTS

The goal of a general anesthetic is to achieve akinesia, analgesia, and amnesia. After administration of a general anesthetic, loss of consciousness and sensation usually follows increasing levels, or stages, of CNS depression. Classic studies with early anesthetics indicate the presence of four stages, which are differentiated through increasing influence on reflex activity, muscle tone, and respiration. Stages I and II constitute anesthetic induction; keeping the patient at stage III is anesthetic maintenance. Reversal of the stages to the conscious state is the process of recovery. The four stages of anesthesia are as follows:

- Stage I, analgesia: From the induction of anesthesia to loss of consciousness. The patient experiences a loss of pain sensation but still remains responsive until the end of the stage.
- Stage II, delirium/excitement: Systolic pressure rises, and the patient may experience excitation, agitation, and restlessness, along with an increased respiratory rate and disconjugate gaze. Potentially dangerous responses can occur during this stage including vomiting, laryngospasm, tachycardia, and uncontrolled movement.
- Stage III, surgical anesthesia: Stage III may have four planes, or levels, characterized by differential responses of the ocular muscles, eye reflexes, and pupils. It begins in plane I with the resumption of regular respiration and the beginning of muscle relaxation. By plane IV, spontaneous respiration ceases. Most surgery occurs when the patient is in planes II or III.
- Stage IV, medullary depression: The respiratory and vasomotor centers are depressed, spontaneous respiration has ceased, and marked hypotension with weak and irregular pulse can occur. Unless rapid intervention and support occur, coma and death follow.

General anesthesia is produced for the most part by a combination of drugs rather than one single agent. This process, called **balanced anesthesia,** is a highly variable technique of general anesthesia using narcotics, analgesics, muscle relaxants, and inhalational agents to produce and maintain the appropriate stage of anesthesia. Constant patient assessment and re-evaluation along with sensitive titration of drugs ensures delivery of an adequate and safe anesthetic.

• C INHALED ANESTHETIC AGENTS

The inhalant anesthetics are typified by isoflurane (Forane), a halogenated ether that is the prototype for this group.

Nursing Management of the Patient Receiving P Isoflurane

Core Drug Knowledge

Pharmacotherapeutics

Isoflurane is used to maintain anesthesia and is one of the main components of balanced anesthesia in the operating room for procedures that require amnesia and immobility. It is rarely used for inhalation induction of anesthesia because of its pungency and irritability to the patient.

Pharmacokinetics

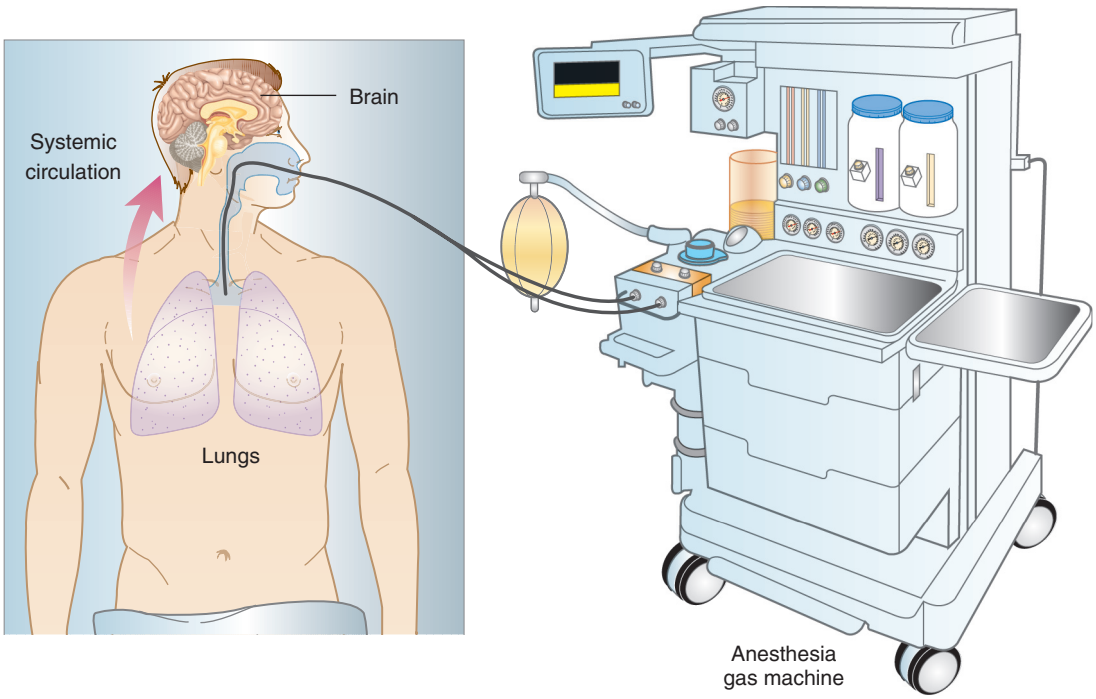
The uptake and distribution of isoflurane and all of the volatile anesthetics are influenced by several factors starting with the delivery of the agent from the anesthesia gas machine (Figure 19.1). The gas machine vaporizes the liquid volatile and delivers it at a desired concentration to the patient via the breathing circuit. The agent is absorbed from the alveoli in the lungs into the systemic circulation. The brain (site of action) and other tissues equilibrate with the partial pressure of the volatile delivered to them by the blood.

A tiny fraction of the inhaled dose (<1%) is metabolized and does not result in any end-metabolite toxicities. Alveolar ventilation is responsible for the excretion of isoflurane. Table 19.1 provides a comparison of the pharmacokinetic properties of halogenated general anesthetic agents. However, it is important to recognize that volatile agent pharmacokinetics are more frequently and accurately described by their blood and tissue solubilities than simply by their onset, duration, and half-life times. In addition, other factors, such as the patient's total body fat composition, ventilation, circulation, and the length of anesthesia time, all influence the onset and recovery of the anesthetic.

Pharmacodynamics

The exact mechanism of action of isoflurane—and for the inhaled anesthetics altogether—is unknown. Several theories have been postulated. It is likely that the effects are mediated through physicochemical properties of the gases (lipid solubility, oil-gas, and blood-gas partition coefficients), rather than through specific binding with receptors or through potentiation or inhibition of specific neurotransmitters.

The minimum alveolar concentration (MAC) is a measure of potency. It is the concentration of anesthetic gas required to eliminate movement in 50% of patients challenged by a



• FIGURE 19.1 Volatile anesthetics are delivered to the patient from the anesthesia gas machine through the breathing circuit. The gas is absorbed by the lungs into the systemic circulation and causes dose-dependent central nervous system depression.

standardized skin incision. The smaller the MAC, the more potent the agent. The concept of MAC can be viewed as a general guide to the overall depth of anesthesia. The MAC of isoflurane is 1.17% for adults when it is administered alone, but it decreases when administered with nitrous oxide.

Contraindications and Precautions

The main contraindications to isoflurane are hypersensitivity to halogenated compounds and predisposition to malignant hyperthermia, which is often determined from the individual or family history (see Chapter 20). Isoflurane and the other volatile agents cause an increase in cerebral blood flow due to their vasodilation effects and therefore increase intracranial pressure (ICP). This is insignificant if the patient has a normal ICP; however, it should be used with caution in patients with an increased ICP (for example brain mass or hematoma).

Isoflurane is assigned to pregnancy category C and should be used in pregnant women only when the benefits outweigh the risks.

Adverse Effects

Isoflurane along with all of the inhalational agents have adverse effects that are dose dependent and related to their pharmacologic properties. With many anesthetics, blood pressure drops secondary to vasodilation, during induction and returns following surgical stimulation. Like other anesthetics, isoflurane depresses renal function (renal blood flow, glomerular filtration rate, and urine output). However, it is not generally nephrotoxic, and this depressed function can

CRITICAL THINKING SCENARIO

POST-ANESTHETIC COMPLICATIONS IN THE PACU

Mona B., is a 55-year-old female with a past medical history of hypertension, high cholesterol, renal insufficiency, breast cancer, and a history of post-operative nausea and vomiting who arrives to your slot in the PACU after a right mastectomy. In report form the anesthesia provider, you are told this patient had a general anesthetic and was paralyzed throughout the case. The patient received fentanyl and hydromorphone during the case and the vital signs were stable. The patient is drowsy but arousable to voice and appears comfortable and pain free. Ten minutes after report has been received, the patient has a decreased respiratory rate, complains of shortness of breath and her O2 saturation decreases to 88% on room air (patient has taken her oxygen mask off).

1. What are the possible causes of this respiratory depression?
2. What are the important questions to ask or get clarification when receiving report?

be avoided with adequate hydration preoperatively. Dose-dependent respiratory depression occurs with all inhaled anesthetics, sometimes resulting in the need for mechanical ventilation throughout surgery. Tremor and shivering may occur in response to a decreased body temperature, but these adverse effects are generally self-limiting. Nausea and vomiting may also occur. If vomiting occurs after surgery in the PACU, the patient is at risk for aspiration pneumonia. Volatile anesthetics produce a dose-dependent decrease in uterine smooth muscle contractility and blood flow.

Isoflurane has been observed to react with carbon dioxide dry adsorbents in anesthetic circle systems to form carbon monoxide and cause carboxyhemoglobinemia. To avoid this adverse effect, carbon dioxide adsorbents in the anesthesia gas machine are changed frequently.

Drug Interactions

Isoflurane potentiates the effects of nondepolarizing muscle relaxants and prolongs the blockade. Additional interactions are identified in Table 19.2.

Assessment of Relevant Core Patient Variables

Health Status

Take a careful health history. Many factors influence the process of anesthetic induction, maintenance, and recovery, including lung conditions, cardiovascular status, obesity, previous drug history, and comorbidity. Inhalation anesthetics are administered through the lungs and absorbed across alveolar surfaces. Therefore, a lung condition may have a profound impact on the efficacy and nature of anesthesia. Patients with chronic obstructive lung disease, asthma, or a history of cigarette smoking present potential problems in anesthesia based on changes in lung compliance, bronchoconstriction, and ventilation-to-perfusion ratios. Patients with compromised pulmonary function have a substantially increased rate of postoperative complications. Similar issues arise for patients with cardiovascular compromise or disease because absorption, distribution, metabolism, and excretion of inhalant anesthetics are all affected by blood flow through the lungs and the rest of the body.

Life Span and Gender

Document the age of the patient. Challenges with isoflurane administration differ by age group.

In older adults, especially those with failing organ systems, difficulties may occur in detoxification and excretion of administered anesthetic agents, which may lead to increased intensity and duration of drug effects, including toxic effects.

BOX 19.1 FOCUS ON RESEARCH

Post-operative Nausea and Vomiting Prevention

White, P., O'Hara, J., Roberson, C., et al. (2008). The Impact of Current Antiemetic Practices on Patient Outcomes : A Prospective Study on High-Risk Patients. *Anesthesia & Analgesia*, 107(2): 452–458.

Background Information

Post-operative nausea and vomiting (PONV) is a common complication to anesthesia that can contribute delays in discharge time from the hospital and a full recovery back to activities of daily living. Studies suggest 25% to 30% of patients will experience PONV during their recovery and in those with risk factors, the incidence increases to 60% to 80%.

Risk factors for PONV are patient-, surgical- and anesthesia-related. These factors include female gender, nonsmoking status, history of PONV or motion sickness, and opioid administration during surgery. Laparoscopic procedures and plastic surgery have a higher incidence of PONV.

The Study

This is a multicenter, prospective, observational study designed to estimate the effectiveness of common antiemetic therapies for prevention and treatment of PONV. There were 376 patients at 11 different sites. Patients had at least two major risk factors (see above) and underwent either a laparoscopic or plastic surgery. Ninety-two percent of the patients received a prophylactic antiemetic. Thirty-four percent of the patients received a single antiemetic, most often a 5-HT3 receptor antagonist (ondansetron or granisetron), while 35% of the patients received a two-drug antiemetic regimen (5-HT3 and dexamethasone). A 5HT3 receptor antagonist, dexamethasone, and droperidol were administered in combination in 23% of the patients. Emesis rates were lower (18%) when 3 or more antiemetic agents were administered when compared to just one agent (40%). It was demonstrated that the patients who received three or more antiemetics had significantly lower rates of emesis after they were discharged from the PACU.

Nursing Implications

This research study demonstrates the importance of administering an antiemetic for PONV prophylaxis. It also demonstrated that there is a significant difference in the effectiveness of prophylaxis when using more than one antiemetic drug. With this knowledge, nurses can advocate for appropriate PONV prophylaxis and educate patients about the risk of PONV and the medications that can prevent it and improve recovery time and outcomes.

TABLE 19.2 Agents That Interact with P Isoflurane

Interactants	Effect and Significance	Nursing Management
nondepolarizing muscle relaxants, such as pancuronium, vecuronium	Potentiates effects of neuromuscular blockers and prolongs blockade	Monitor respiratory function (dosage may need to be reduced). Prepare to provide ventilatory support.
alfentanil	Prolongs respiratory depression and increases incidence of bradycardia	Monitor respiratory and cardiac function. Provide ventilatory support.
labetalol	Additive hypotensive effects and decreased cardiac output	Monitor cardiac function. Use extra caution if interaction is anticipated.
herbal drugs • St. John's wort • *Hypericum perforatum*	Herbal drugs may intensify or prolong the effects of isoflurane.	Advise patient to stop herbal medications 2–3 wk before surgery.
hepatic inducers • alcohol • barbiturates • carbamazepine • INH • phenytoin • rifampin	Chronic use of agents that induce hepatic enzymes can increase isoflurane metabolism, thus increasing the risk for hepatic injury.	Document the use of these agents in the medical record. Advise the anesthesia provider of the use of these drugs.

Assess women of childbearing age for pregnancy. Isoflurane has a low pregnancy safety rating (category C). In animal studies, isoflurane showed the potential for fetotoxicity; however, no human studies have been performed. Its use during pregnancy is determined by the balance between potential benefit and harm to both the woman and the fetus.

Lifestyle, Diet, and Habits

Measure the patient's height and weight. The patient with morbid obesity who requires anesthesia may experience problems with isoflurane administration. The obese patient may be particularly prone to longer recovery times and a greater incidence of adverse effects with fat-soluble anesthetics such as isoflurane and methoxyflurane. Other comorbid conditions, such as hypertension, cardiac insufficiency, respiratory difficulties, and diabetes, all of which can generate their own special anesthetic challenges, often occur in obese patients, compounding these difficulties.

One other important category of anesthetic challenge is substance abusers; substance abuse often coexists with disease states that require special attention during anesthesia. For example, alcohol abuse is often associated with an elevated level of hepatic enzymes, which may increase the requirement for anesthetic drugs. In addition, liver dysfunction may lead to changes in the metabolism of such agents. With drug dependency, the postanesthetic period may require more careful monitoring than usual, in case abstinence syndromes develop (see Chapter 9). Take a careful drug history to reveal previous use or abuse of drugs that have the potential to cause severe interactions with isoflurane and other anesthetic agents.

Environment

Isoflurane and other general anesthetics may be administered in special settings by anesthesiologists (a type of specialist physician) and nurse anesthetists (advanced practice nurses trained in anesthesia). Administration usually occurs only in settings that allow for postanesthetic recovery and full life support.

Nursing Diagnoses and Outcomes

- Ineffective Airway Clearance related to suppressed cough reflex and the presence of secretions
  Desired outcome: *The patient will maintain effective airway clearance by being suctioned as necessary and by performing deep breathing and coughing exercises.*
- Ineffective Breathing Pattern related to respiratory depression secondary to drugs used during anesthesia
  Desired outcome: *The patient will maintain effective breathing despite respiratory depression by administration of oxygen as appropriate.*
- Risk for Aspiration related to drug-induced nausea and vomiting, gastrointestinal (GI) distention, hypoxia, and stimulation of the vomiting center
  Desired outcome: *The patient's nausea and vomiting will be minimized by preanesthetic administration of antiemetics to reduce the risk for aspiration and nausea.*
- Ineffective Thermoregulation related to CNS depression secondary to drugs used during anesthesia
  Desired outcome: *The patient will be warmed as necessary during the postanesthetic disturbance of thermoregulation.*
- Disturbed Sensory Perception, varied, related to CNS depression secondary to drugs used during anesthesia

Desired outcome: *The patient will remain free of sensory or perceptual alterations through careful reorientation, repeated as necessary.*

Planning and Intervention

Maximizing Therapeutic Effects

Preinduction and induction should be carried out in a place where environmental stimuli, particularly noise, are kept to a minimum. Inform the patient about induction procedures and describe measures that are useful for promoting uncomplicated recovery. Also, give preoperative support and reasonable reassurance to concerns voiced by the patient.

Minimizing Adverse Effects

After anesthesia, monitor blood pressure and temperature to detect residual hypotension. Because gaseous or volatile inhalational agents (such as isoflurane) are expired quickly through the lungs, the recovery phase is often short. Manage shivering and tremors, which are common following surgery, with blankets. Until normal respiration resumes, adequate respiratory support must be maintained; take steps such as administering oxygen and asking the patient to cough, to perform deep-breathing exercises, or to change position. After the patient awakens, assess the need for postoperative analgesia.

Recovering patients need to be in a room in which the air supply is continually replaced and exhaled gases are carried out through exhaust vents. Prevent aspiration by helping the patient into a side-lying position and by administering antiemetic drugs. Monitor vital signs frequently to prevent complications such as shock. When the patient returns to the room or unit from the postanesthesia care unit (PACU), continue monitoring vital signs, bowel sounds, and urine output because these signs are directly affected by isoflurane.

Providing Patient and Family Education

Family and patient education falls into preoperative and postoperative categories:

- Provide preoperative teaching to help patients anticipate the surgery and anesthesia without excessive fear and assimilate routines that will aid postoperative recovery.
- Postoperatively, instruct patients to avoid nonprescribed CNS depressants or herbal agents unless approved by the prescriber.
- For outpatient surgery, discharge patients into the care of a responsible adult and instruct patients not to drive or engage in any hazardous activities requiring full alertness or coordination.

Ongoing Assessment and Evaluation

The evaluation of progress in the recovery phase is often carried out in two stages. Initially, the unconscious patient may be transferred to a postanesthesia recovery area. The patient should regain consciousness, orientation, some stability of vital signs, and an ability to cooperate with instructions during this stage. After the immediate postsurgery, and postanesthesia goals have been reached in the PACU, the patient can be transferred back to a room or unit, and a less stringent postoperative protocol may be followed. Other assessments specifically related to the procedure or surgery are distinct from those required for the postanesthesia state. When the patient returns to the room or unit, continue to monitor vital signs, bowel sounds, and urine output, as was done in the PACU.

Drugs Closely Related to P Isoflurane

Desflurane

Desflurane (Suprane) is similar in molecular structure to isoflurane yet has some distinct advantages to its use. This

BOX 19.2 COMMUNITY BASED CONCERNS

Discharge Criteria After Surgery

Whether the patient is being discharged from the post-anesthesia care unit (PACU) to go home or to be admitted to the hospital, discharge criteria must be met. There are two scoring systems (Aldrete and PADSS) that are commonly used in the PACU to assess the patient and determine if the patient is safe for discharge.

The Aldrete Score was developed in 1970 by Dr. Aldrete and is still widely used today. He revised it in 1995 and the modified Aldrete Scoring System is below: (A score ≥ 9 is required for discharge).

Respiration

2= Able to take deep breath and cough
1=Dyspnea/shallow breathing
0= Apnea

O_2 saturation

2= Maintain Sp O_2 > 92% on room air
1= Needs O_2 inhalation to maintain O_2 saturation >90%
0= O_2 saturation, 90% even with supplemental oxygen

Consciousness

2= Fully awake
1= Arousable on calling
0= Not responding

Circulation (BP= blood pressure)

2= BP+/– 20 mmHg preop
1= BP+/– 20-50 mmHg preop
0= BP+/– 50 mmHg preop

Activity

2=Able to move four extremities voluntary or on command
1= Able to move two extremities
0= Unable to move extremities

It is important for the PACU nurse to be able to appropriately assess for adequate ventilation and oxygenation, vital signs, pain control, nausea and vomiting, and surgical bleeding.

MEMORY CHIP

P Isoflurane

- A potent inhalation anesthetic
- Major contraindications: hypersensitivity to halogenated compounds, predisposition to malignant hyperthermia
- Most common adverse effects: hypotension, hypothermia, nausea, or vomiting
- Most serious adverse effect: respiratory depression
- Maximizing therapeutic effects: low-stimulus environment, preoperative teaching regarding anesthetic induction
- Minimizing adverse effects: Monitor need for respiratory support.
- Most important patient education: preoperative teaching regarding anesthesia and surgical procedures

volatile has low blood-gas and lipid solubility; therefore, once the gas is discontinued at the end of the case, emergence is rapid because of the decreased saturation in the blood and tissue. Desflurane has a MAC of 6.6%. Desflurane is very pungent and is associated with coughing, increased secretions, and laryngospasm; therefore, it is not used for inhalation induction of anesthesia. At high inspired concentrations, tachycardia and hypertension can occur and for this reason should be avoided in patients that have coronary vascular disease.

Sevoflurane

Sevoflurane (Ultane) offers advantages beyond others in its class. It has a MAC of 1.8%. Induction of and recovery from anesthesia are rapid, and cardiorespiratory depression is minimal, which makes sevoflurane generally safe in patients with coronary artery disease. Additionally, because of its low tissue solubility and nonirritating odor, sevoflurane is an appropriate agent for inhalation induction of anesthesia in the pediatric and adult populations.

Sevoflurane metabolizes to inorganic fluoride and is degraded in soda lime (carbon dioxide absorbents in the anesthesia gas machine) to potentially toxic metabolites, which can be nephrotoxic and hepatotoxic. However, the anesthesia provider can prevent this by delivering the inhaled gas in a specific way.

Drug Significantly Different From P Isoflurane

Nitrous oxide is a colorless, odorless, tasteless, nonflammable, nonirritating, inorganic gas rather than a halogenated ether. It is used commonly as an adjunct in balanced anesthesia to decrease the MAC of halogenated agents. Nitrous oxide is also used for a process called the second gas effect: when two gases (either isoflurane or sevoflurane both slower agents) and nitrous oxide (a faster agent) are administered together, it speeds up the onset time of the slower agent. Nitrous oxide is a powerful analgesic but a relatively weak inhaled anesthetic.

Nitrous oxide is readily absorbed into the blood through the pulmonary capillary system. It has a relatively low solubility in blood and a MAC of 104%. Nitrous oxide is rapidly eliminated in the expired breath, essentially unchanged, with minimal diffusion through the skin. However, nitrous oxide can leave the blood easily and enter an air-filled cavity, causing it to rapidly expand. This chemical property adds limitation to the use of nitrous oxide in specific surgical cases (middle ear, bowel, and intraocular surgeries) or patient disease (pneumothorax). Nitrous oxide can also expand air-filled cuffs of pulmonary artery catheters and endotracheal tubes.

The benefit versus risk ratio should be considered when administering nitrous oxide in pregnant patients undergoing anesthesia, as animal studies show that it can cause fetal death, growth retardation, and skeletal anomalies. Prolonged administration of nitrous oxide can cause inactivation of methionine synthase, a vitamin B_{12}-dependent enzyme, which is necessary for the synthesis of DNA. In the absence of methionine synthase, interference with myelin formation can have significant effects on the rapidly growing fetus.

This effect does not occur within the time frame of clinical surgery, but it poses a potential problem for providers who are chronically exposed to nitrous oxide.

Controversy also exists if nitrous oxide contributes to postoperative nausea and vomiting.

• C Intravenous Anesthetic Agents

Intravenous (IV) anesthetics are also known as induction agents. Several classes of drugs are used as IV anesthetics in balanced anesthesia and total intravenous anesthesia (TIVA) including barbiturates, benzodiazepines, opioid analgesics, and nonbarbiturate hypnotic agents.

Propofol (Diprivan), a nonbarbiturate hypnotic agent, is the prototype for IV anesthetics (Table 19.3). Often nicknamed "the milk of anesthesia," propofol appears as a milky white solution because it is formulated in a solution with soybean oil, glycerol, and egg phospholipids.

Nursing Management of the Patient Receiving P Propofol

Core Drug Knowledge

Pharmacotherapeutics

Propofol is used for induction and maintenance of general anesthesia and maintenance of sedation in the ICU.

Pharmacokinetics

Propofol is administered intravenously and is rapidly distributed to all tissues in the body. Loss of consciousness usually occurs within 40 seconds and continues for 3 to 5 minutes after a bolus injection. The drug rapidly redistributes throughout the body leading to the advantage of propofol use: the rapid return of consciousness with minimal psychomotor impairment.

Because the metabolic clearance of propofol exceeds hepatic blood flow, it is metabolized through both hepatic and extrahepatic (lung) routes. Continuous infusion of propofol can be administered without a cumulative effect because of its rapid clearance. The kinetics of propofol do not appear to be affected by chronic hepatic or renal disease.

Pharmacodynamics

The cellular mechanism of action of propofol is unknown, but it is thought to mediate activity of the inhibitory gamma-aminobutyric acid (GABA) receptors. However, the clinical response is clear: anesthesia is immediate and short-lived. Respiratory effects of propofol include dose-dependant respiratory depression (with apnea occurring after induction doses) and a relative bronchodilating effect. Propofol produces cardiac depression and its effects result in hypotension, decreased cardiac output, and systemic vascular resistance. Administration of propofol also produces a decrease in cerebral metabolism, cerebral blood flow, and a decrease in intraocular pressure. Propofol is a weak analgesic agent; therefore, it is generally administered with other analgesics. It also has some anti-emetic properties.

When high-dose propofol is used for long-term (>24 hours) maintenance of sedation as in an ICU, propofol infusion syndrome has been described, yet the incidence is 1% in both pediatric and adult populations. Propofol infusion syndrome is characterized by marked bradycardia (resistant to treatment), combined with fatty liver enlargement, metabolic acidosis, rhabdomyolysis, or myoglobinuria. The syndrome usually leads to fatal cardiac and renal failure.

Contraindications and Precautions

Propofol is contraindicated for patients with a hypersensitivity to propofol or any of the ingredients of its emulsion vehicle. Propofol is relatively contraindicated in patients with a seizure disorder because they are at an increased risk of developing convulsions during the recovery phase.

Propofol should be used with caution in patients with cardiac or peripheral vascular disease because the cardiovascular depressive and hypotensive effects of the anesthetic can aggravate these conditions. In addition, propofol should be used cautiously in patients with cerebrovascular disease, impaired cerebral blood flow, or increased ICP because it can cause a substantial reduction in mean arterial pressure and cerebral perfusion.

Adverse Effects

The most common adverse effect of propofol is pain on injection usually seen when administered in small veins. Preceding the injection it is a common practice to administer lidocaine. The solution in which propofol is prepared can support bacterial growth so it is recommended that aseptic technique is used when administering the drug.

Drug Interactions

Propofol may interact with benzodiazepines and CNS depressants (Table 19.4).

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for a history of hypersensitivity to propofol, soybean oil, glycerol, or egg phospholipids. Also, assess the

TABLE 19.4 Agents That Interact with P Propofol

Interactants	Effect and Significance	Nursing Management
CNS depressants • Alcohol • Anesthetics • Benzodiazepines • Barbiturates • Histamine-1 blockers • Opioids • Phenothiazines • Tricyclic antidepressants	The pharmacologic effects of propofol may be enhanced, resulting in increased sedation and respiratory depression.	Provide continuous patient assessment. Monitor sedation. Monitor respiratory status. Provide supportive therapy as needed.
carbidopa-levodopa	When levodopa is abruptly withdrawn, a symptom complex resembling neuroleptic malignant syndrome may occur.	Administer levodopa as soon as patient is able to resume PO medications. Monitor for muscular rigidity, hyperthermia, mental changes, increased creatine phosphokinase concentration, diaphoresis, and tachycardia.
catecholamines	Propofol and catecholamines may drive each other in a progressively myocardial depressive loop, which could lead to cardiac arrhythmias or cardiac failure.	Monitor cardiovascular status. Follow standing protocols for titrating these drugs.
herbal medications • St. John's wort • *Hypericum perforatum*	Coadministration of propofol with herbal medications may intensify or prolong the effects of propofol.	Advise the patient to discontinue herbal medication 2–3 wk before surgery.

patient for diseases or disorders that contraindicate the use of propofol and for concomitant use of drugs that may interact with propofol. Positive responses should be communicated to the anesthesiologist or nurse anesthetist before surgery.

Life Span and Gender

Document the age of the patient. Elderly, debilitated, and dehydrated patients are typically more sensitive to the effects of propofol than younger patients. In addition, elderly patients typically have reduced total-body clearance of propofol and should be given lower induction doses and slower infusion rates for anesthesia maintenance.

Environment

Propofol must be given in a controlled environment, such as an operating room or ICU. A cardiac monitor, blood pressure monitor, and ventilator generally are required during administration.

Nursing Diagnoses and Outcomes

- Ineffective Breathing Pattern related to respiratory depression secondary to drugs used during anesthesia
  Desired outcome: *The patient will maintain effective breathing despite respiratory depression by administration of oxygen as appropriate.*
- Disturbed Sensory Perception, varied, related to CNS depression secondary to drugs used during anesthesia
  Desired outcome: *The patient will remain free from sensory or perceptual alterations through careful reorientation, repeated as necessary.*

Planning and Intervention

Maximizing Therapeutic Effects

For the surgical patient, preinduction and induction should be done in a low-stimulus environment, as with isoflurane. It is imperative to educate patients preoperatively to minimize their anxiety, which, in turn, helps maximize the therapeutic effects of propofol.

In the critical care setting, a low-stimulus environment is also important. To avoid overstimulation, interact with the patient only when necessary. Evaluate the depth of analgesia and adjust the infusion of propofol according to the health facility's standing orders.

Minimizing Adverse Effects

Visually inspect the propofol preparation for particulate matter and discoloration before administration. If the emulsion appears to be separated, do not use it. Because the propofol emulsion does not contain preservatives, it is important to limit its duration of administration to avoid bacterial growth. When propofol is used for critical care sedation, it should be discarded after 12 hours if administered directly from the container provided from the pharmacy or within 6 hours if transferred to a syringe or other container.

Providing Patient and Family Education

- Provide preoperative patient education about the induction process to minimize fears of anesthesia.
- In the critical care unit, explain the purpose of the light anesthesia state and reassure patients that they are being constantly monitored.
- For outpatient surgery, discharge patients to the care of a responsible adult and instruct patients not to drive or engage in any activity that requires full alertness or coordination.

Ongoing Assessment and Evaluation

Monitor patients receiving propofol as an induction agent for balanced anesthesia in the postanesthesia recovery room until they are awake and have stable vital signs.

MEMORY CHIP

P Propofol

- A parenteral anesthetic used in the management of general anesthesia, sedation induction or maintenance, and status epilepticus
- Major contraindications: hypersensitivity to soybean oil, glycerol, or egg phosphatide
- Most common adverse effects: nausea, vomiting, involuntary movements
- Most serious adverse effects: apnea and anaphylaxis
- Maximizing therapeutic effects: low-stimulus environment
- Minimizing adverse effects: Time the administration to avoid potential bacterial growth.
- Most important patient education: Reassure the patient that he or she is being constantly monitored.

When propofol is used to maintain light anesthesia in the critical care unit, continuously monitor blood pressure, cardiac output, and pulmonary capillary wedge pressure. Assess the patient's lung sounds frequently for respiratory depression. Because the patient remains motionless, turn the patient every 2 hours and assess for skin breakdown. Constantly monitor the level of sedation and titrate propofol to maximize sedation. Serum triglycerides should be monitored every 3 to 7 days.

Drugs Closely Related to P Propofol

Etomidate

Etomidate (Amidate) is a nonbarbiturate, nonanalgesic anesthetic used primarily for induction, but it can be used for IV anesthesia when supplemented by an opioid analgesic. Induction is rapid, and recovery from a single dose takes only a few minutes (7 to 14 minutes) because of rapid redistribution of drug to other tissues. Etomidate is metabolized by the liver and plasma esterases and has a much shorter elimination time than propofol. There appears to be less respiratory and cardiovascular depression than with barbiturates and propofol. Additionally, etomidate does not release histamine.

The popularity of etomidate has diminished because of its adverse effects, including involuntary movements (myoclonia) during induction, a high incidence of nausea and vomiting during recovery, and adrenocortical suppression. However, it is still utilized in trauma or critically ill patients because of its lack of cumulative response, hemodynamic stability, hypnosis, and lack of histamine release.

Thiopental

Thiopental (Pentothal) is a barbiturate anesthetic agent. Its rapid onset and short duration of action are ideal for an induction agent. Its onset of action after IV administration is less than 1 minute, and the hypnotic action lasts only a few minutes. Metabolism of thiopental takes place in the liver slowly, and the drug accumulates to a toxic level in the tissues after repeated administrations. Thiopental is contraindicated in patients with certain types of porphyria. Thiopental differs from propofol in that it is not used for the duration of anesthesia by continuous infusion, does not provide any analgesia, and can cause an increase in heart rate.

Drugs Significantly Different From P Propofol

Benzodiazepines

Benzodiazepines (e.g., diazepam, lorazepam, midazolam) have been used as parenteral agents in balanced anesthesia. Midazolam is water soluble at low pH and has been reported to cause less pain on injection and a lower incidence of venous thrombosis than diazepam. Additionally, midazolam can be administered intramuscularly. Chapter 15 discusses benzodiazepines in depth.

Dexmedetomidine

Dexmedetomidine (Precedex) is an α_2-receptor agonist that produces analgesia, anxiolysis, and sedation without respiratory depression. It is used as an adjuvant in balanced anesthesia, for sedation for procedures other than surgical and for short-term (<24 hours) sedation in the ICU. The use of dexmedetomidine can lead to intraoperative hypotension and bradycardia but it also has been reported to improve hemodynamic stability and post-operative pain control.

Fentanyl

Fentanyl (Sublimaze) is an opioid analgesic used in general anesthesia and conscious sedation (often co-administered with midazolam). Fentanyl produces dose-dependent analgesia, sedation, and respiratory depression with a rapid onset time. The duration of action is short and is eliminated by redistribution when given in a single dose. Chapter 24 discusses opioid agents in depth.

Ketamine

Both chemically and pharmacologically, ketamine (Ketalar) closely resembles phencyclidine, which is a street drug with a pronounced effect on sensory perception. Different from other IV anesthetics, ketamine produces **dissociative anesthesia** characterized by catatonia, amnesia, analgesia yet maintains consciousness and protective reflexes (laryngeal and pharyngeal reflexes). The patient may appear awake and reactive, but under ketamine anesthesia the higher centers of the brain do not perceive auditory, visual, or painful stimuli. Because of the high incidence of postoperative psychological phenomena (sensory and perceptual illusions and vivid dreams) associated with its use, benzodiazepines, barbiturates, or propofol are co-administered with ketamine to decrease these reactions.

Ketamine binds to *N*-methyl-D-aspartate (NMDA) receptors, in addition to opioid and non-opioid receptors. Also different than propofol, ketamine has analgesic and bronchodilatory properties. It also increases cerebral metabolism, cerebral blood flow, ICP, heart rate, and arterial blood pressure. Because of these unique characteristics of ketamine, it

offers an alternative induction agent or as an adjuvant when trying to limit opioid use or when inducing a hemodynamically unstable shock patient or a patient with acute bronchospasm. Ketamine IM can be used for anesthesia induction if obtaining IV access is problematic.

After IV administration, ketamine has an initial half-life of 10 to 15 minutes, which subsequently changes to a longer half-life of 2.5 hours, corresponding with redistribution from the CNS and hepatic biotransformation. The metabolites of ketamine are excreted in the urine. Cardiovascular and respiratory stimulation occurs shortly after injection, peaks after a few minutes, and subsides within 15 minutes.

Ketamine is contraindicated in patients for whom a substantial increase in blood pressure would be hazardous. It is not used for patients with psychiatric disorders, because of the potential for a reaction during emergence from anesthesia, which may include hallucinations and agitation. It also should be avoided in cases of known hypersensitivity. Caution is advised for using ketamine in cases involving mild to moderate hypertension, pregnancy or lactation, alcohol abuse, acute intermittent porphyria, elevated intraocular pressure or ICP, and hyperthyroidism.

Ketamine may enhance the actions of the nondepolarizing neuromuscular blockers (discussed later in this chapter) and prolong respiratory depression. Theophylline should not be coadministered with ketamine because the two interact and may cause unpredictable seizures. Patients on thyroid enhancement therapy may experience hypertension and tachycardia when taking ketamine.

Nursing care of the patient under ketamine anesthesia is largely protective because of the dissociative state that it causes and the likelihood of emergence reactions. Take vital signs and a brief mental status examination as a pretreatment assessment.

The expected outcomes for ketamine anesthesia are effective and safe anesthesia, adequate airway maintenance, and minimal emergence reaction. Emergence reactions may be avoided or diminished if care is taken to reduce external stimuli during the recovery phase and to allow the patient to wake up spontaneously. Frightening emergence symptoms can be stopped with a benzodiazepine such as diazepam. Because emergence reactions may occur up to 24 hours after anesthesia, instruct the patient to avoid hazardous activities, including driving, for at least that long. Ambulatory patients must be discharged into the care of a responsible adult. Instruct the patient to avoid alcohol and other CNS depressants for 24 hours. The nurse in the PACU and the nurse in charge of the patient on his or her return to the unit should evaluate outcomes achieved and compare them with what would be expected under normal conditions.

Remifentanil

Remifentanil (Ultiva) is an ultra-short-acting, selective mu-opioid analgesic, which is used as an adjunctive medication during general anesthesia in both the inpatient and outpatient setting. It has a rapid onset and short half-life even when given as a continuous infusion. It is quickly metabolized by hydrolysis by plasma esterases. Remifentanil is extremely useful during balanced anesthesia because it works rapidly, is titratable, and has a rapid and predictable recovery period.

• C LOCAL ANESTHETIC AGENTS

Local anesthetic agents are divided into esters and amides based on their chemical structure. Important practical differences exist between these two groups. Esters are rapidly hydrolyzed in the body by plasma cholinesterase and other esterases. One of the main breakdown products is para-aminobenzoic acid, which is associated with allergic phenomena and hypersensitivity reactions. In contrast, amides are slowly degraded in the liver by P-450 enzymes and hypersensitivity reactions are extremely rare.

Local anesthetics produce local or regional anesthesia and analgesia by blocking electrical transmission of pain along nerve fibers (specifically voltage-gated sodium channels) and abolishing sensations in a limited and well-defined area of the body without loss of consciousness (Figure 19.2). The blockade affects all nerve fibers sequentially: autonomic, then sensory, then motor, with effects diminishing in reverse order. Clinically, the loss of nerve function affects temperature first; then pain, touch, and proprioception; and finally, skeletal muscle tone.

Local anesthetics share the same mechanism of action, but they differ in their potency, onset of action, and duration (Table 19.5). Local anesthetic agents include lidocaine, bupivacaine, etidocaine, mepivacaine, ropivicaine, prilocaine, procaine, and chloroprocaine. The prototype discussed in this chapter is lidocaine (Xylocaine), an amide local anesthetic agent.

Nursing Management of the Patient Receiving P Lidocaine

Core Drug Knowledge

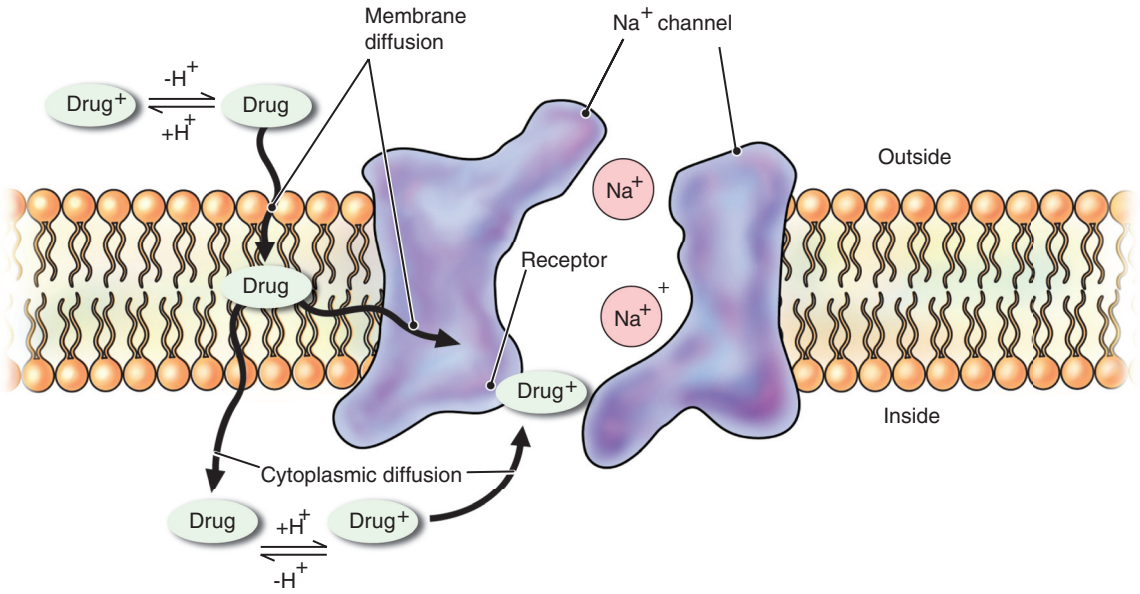
Pharmacotherapeutics

Lidocaine is used as a local anesthetic in a variety of situations, including regional blocks, peripheral nerve blocks, ophthalmic anesthesia, dental anesthesia, and infiltration anesthesia. It can be applied topically for dental pain, neuropathic pain, and skin disorders that cause inflammation and irritation. When administered intranasally, it is also effective for migraine headaches.

In addition to its uses as a local anesthetic, lidocaine is also used intravenously for ventricular tachycardia and ventricular fibrillation. See Chapter 31 for a discussion of lidocaine as an antiarrhythmic agent.

Pharmacokinetics

Lidocaine may be administered topically, orally, subcutaneously, intradermally, submucosally, and intravenously. Only minimal amounts of lidocaine enter the circulation following subcutaneous injection. The duration of action of subcutaneously administered lidocaine is 1 to 3 hours, depending



• FIGURE 19.2 Local anesthetics' mechanism of action.

on the strength of the lidocaine preparation used. Adding epinephrine to lidocaine in proportions of 1:200,000 to 1:100,000 slows the vascular absorption of lidocaine and prolongs its effects.

Lidocaine is nearly completely absorbed following oral administration but undergoes extensive first-pass metabolism in the liver, resulting in a systemic bioavailability of only 35%. Some systemic absorption is possible when using oral viscous solutions.

Transdermal absorption of lidocaine is related to the duration of application and the surface area over which the patch is applied. When the lidocaine patch is used as directed, very little systemic absorption occurs. After topical administration of viscous solutions or jelly to mucous membranes, the duration of action is 30 to 60 minutes, with peak effects occurring within 2 to 5 minutes.

Pharmacodynamics

Lidocaine produces its analgesic effects through a reversible nerve conduction blockade, which diminishes the nerve membrane's permeability to sodium. This action decreases the rate of membrane depolarization, thereby increasing the threshold for electrical excitability. Direct penetration of the nerve membrane is necessary for effective anesthesia, which is achieved by applying the anesthetic topically or injecting it subcutaneously, intradermally, or submucosally around the nerve trunks or ganglia supplying the area to be anesthetized.

Contraindications and Precautions

Lidocaine is contraindicated in patients with hypersensitivity to amide local anesthetics and in patients with hypersensitivity to sulfites or the preservative methylparaben. To avoid systemic absorption of lidocaine, its administration as a nerve block or as epidural, local, or spinal anesthesia is contraindicated in patients with infection or inflammation at the injection site.

Applying lidocaine preparations to severely traumatized mucosa (large skin abrasions, eczema, burns) can increase its absorption, which in turn increases the risk of systemic toxicity. Application to the oral mucosa can interfere with swallowing and increase the risk of aspiration. Lumbar and caudal epidural anesthesia should be used with extreme caution in patients with existing neurologic disease, spinal deformities, sepsis, and severe hypertension, because the risk of adverse effects increases.

Adverse Effects

Allergic reactions such as urticaria, angioedema, bronchospasm, and anaphylactic shock may occur with lidocaine administration. Some preparations contain sulfites and methylparaben, which can cause severe allergic reactions, including status asthmaticus, in susceptible patients.

Local anesthetic agents are relatively free from adverse effects if they are administered in an appropriate dosage and in the correct anatomic location. However, systemic and localized toxic reactions may occur, usually from accidental intravascular or intrathecal injection, or from an excessive dose of the local anesthetic agent. Systemic reactions to local anesthetics are dose dependent and primarily involve the CNS and the cardiovascular system. Initial symptoms include light headedness, tinnitus, and tongue numbness. Signs of toxicity due to higher doses of absorption progress to patient symptoms of visual disturbances, muscle twitching, seizures, unconsciousness, coma, respiratory arrest, and cardiovascular depression.

Transoral or transdermal application of lidocaine is unlikely to cause systemic adverse reactions because of

the small amount of lidocaine absorbed. Potential local reactions include erythema, edema, and dysesthesia (abnormal sensations including numbness, tingling, prickling, or burning). These reactions are usually mild and transient, resolving within a few minutes to a few hours.

Drug Interactions

Drug interactions occur most frequently with IV administration of lidocaine. Subcutaneous administration rarely causes drug interactions unless lidocaine is inadvertently administered into an artery or vein.

Local anesthetics can interact with antihypertensive agents, cholinesterase inhibitors, monoamine oxidase inhibitors, and opiate agonists (Table 19.6). These interacting drugs will be discussed in more detail in subsequent chapters.

Assessment of Relevant Core Patient Variables

Health Status

Assess for hypersensitivity to lidocaine or any other drug with "caine" in the name. Communicate positive findings to the provider before administering lidocaine.

Before using topical anesthesia, inspect the area. Do not apply topical anesthesia to abraded or denuded skin. For viscous lidocaine, assess for the patient's ability to swallow before using the drug.

TABLE 19.6 Agents that Interact with P Lidocaine

Interactants	Effect and Significance	Nursing Management
antihypertensive agents	Epidural administration of local anesthetics with antihypertensive agents may result in additive hypotensive effects due to loss of sympathetic tone.	Monitor vital signs.
cholinesterase inhibitors	Local anesthetics can antagonize the effects of cholinesterase inhibitors by inhibiting neuronal transmission in skeletal muscle.	Dosage adjustment of the cholinesterase inhibitor may be necessary to control the symptoms of myasthenia gravis.
monoamine oxidase inhibitors (MAOIs)	Concomitant administration of MAOIs and local anesthetics increases the risk of hypotension.	MAOIs should be discontinued 10 days before surgery requiring a regional block.
opiate agonists alfentanil fentanyl morphine sufentanil	Concomitant use of low-dose local anesthetics with opiate agonists may increase analgesia and decrease opiate dosage requirements.	Monitor for analgesic efficacy. Monitor CNS depression.

Life Span and Gender

Lidocaine should be used with caution in patients who are pregnant or breast-feeding. Although lidocaine is a pregnancy category B drug, local anesthetics can cross the placenta rapidly when administered for epidural, paracervical, pudendal, or caudal block anesthesia, resulting in fetal bradycardia. The frequency and extent of toxicity are dependent on the procedure performed. Maternal hypotension can result from regional anesthesia; to alleviate this problem, elevate the feet and position the patient on her left side. When lidocaine is used as epidural anesthesia during labor and delivery, it may prolong the second stage of labor. Monitor for cardiovascular and CNS depression in the fetus or neonate.

Lifestyle, Diet, and Habits

Viscous lidocaine may be provided for patients with stomatitis or chronic ulceration in the mouth. It is important that patients assess their ability to swallow before eating or drinking to avoid biting the interior of the mouth or aspirating foods or fluids.

Environment

Lidocaine is used in a variety of settings, including hospitals, outpatient surgical settings, clinics, private physician's offices, and dental offices. Topical or viscous lidocaine may be administered in the home environment.

Nursing Diagnoses and Outcomes

- Fear related to traumatic injury and concern about pain during the surgical procedure
  Desired outcome: *The patient will be assured that pain will not occur during the procedure.*
- Risk for Peripheral Neurovascular Dysfunction related to action of drug
  Desired outcome: *The patient will refrain from activities that may induce injury while area is numb.*
- Impaired Swallowing related to administration of viscous lidocaine
  Desired outcome: *The patient will refrain from eating or drinking for 1 hour after swallowing viscous lidocaine.*

Planning and Intervention

Maximizing Therapeutic Effects

Assist with the administration of lidocaine after the patient is informed about the process. Use a calm, reassuring approach and allow the patient to voice concerns before the procedure begins.

Minimizing Adverse Effects

Read the drug label carefully before helping the provider administer lidocaine. Preparations containing preservatives should not be used for spinal or epidural anesthesia. Preparations with epinephrine should not be administered in areas such as fingers, toes, nose, or penis because prolonged vasoconstriction may damage these areas of the body. Restrict food and fluids for 1 hour after viscous lidocaine is swallowed.

Providing Patient and Family Education

- Tell patients and families how local anesthetics such as lidocaine work. Assure patients that the area will be numb before the procedure begins. Encourage patients to verbalize any discomfort during the procedure.
- Advise patients receiving topical anesthesia at home to place the anesthetic on the dressing first and then to place the dressing on the site. Remind patients receiving viscous lidocaine that it causes numbness of the tongue, cheeks, and throat. Patients should not eat or drink for 1 hour to keep from biting the cheeks or tongue and to avoid aspiration.
- Advise patients of the expected duration of lidocaine's effects. Patients should contact the provider if sensation does not return.

Ongoing Assessment and Evaluation

Evaluate for the lack of sensation before starting a procedure and remind patients to assess for sensation before resuming food or fluid intake.

MEMORY CHIP

P Lidocaine

- Used for infiltration anesthesia, regional blocks, nerve blocks, ophthalmic anesthesia, obstetric anesthesia, or dental anesthesia
- Major contraindications: hypersensitivity to amide local anesthetics, sulfites, or methyl paraben; infection or inflammation at the site of administration
- Most common adverse effects: minimal adverse reactions unless accidental intravascular or intrathecal injection occurs
- Most serious adverse effect: allergic reactions
- Maximizing therapeutic effects: calm reassurance by staff
- Minimizing adverse effects: Read labels carefully. Be sure to use the right preparation for the right procedure.
- Most important patient education: safety due to lack of sensation

Drugs Closely Related to P Lidocaine

Bupivacaine, chloroprocaine, etidocaine, mepivacaine, ropivicaine, prilocaine, and procaine have the same mechanism of action but differ in potency, duration and onset of action (see Table 19.5). The potency is based on the lipid solubility of the local anesthetics (the more lipid soluble the more potent the drug). The duration of action is influenced by protein binding and lipid solubility of the drug (increased protein binding and lipid solubility provides a longer blockade time).

Bupivacaine

Bupivacaine (Marcaine) is recommended for local or regional anesthesia. It has the ability to separate sensory and motor blockade because its effect on motor function varies with concentration. With bupivacaine administration, analgesia persists longer than anesthesia, which postpones the need for postoperative narcotics. In combination with narcotics, bupivacaine is also used in epidural patient-controlled analgesia. Bupivicaine is the most cardiotoxic local anesthetic. If systemically absorbed at high doses, it will cause sudden cardiac collapse with ventricular dysrhythmias that are resistant to resuscitation.

Chloroprocaine

Chloroprocaine (Nesacaine) is chemically similar to procaine except for an additional chloride atom which increases the rate of hydrolysis by plasma cholinesterase. Chloroprocaine is a low-potency ester-type local anesthetic that has a rapid onset and a short duration of action.

Etidocaine

Etidocaine (Duranest) is used for epidural, local, and retrobulbar (eye block) anesthesia in surgical and dental procedures. Like lidocaine, etidocaine has a rapid onset of sensory and motor blockade, but the duration of analgesia is 1.5 to 2 times longer. Its profound motor blockade may last up to 9 hours when dosed in an epidural.

Mepivacaine

Mepivacaine (Carbocaine, Polocaine) has an intermediate duration of action. Compared with lidocaine, it produces less vasodilation and has a more rapid onset and longer duration of action. Mepivacaine is indicated for infiltration (administration of a local anesthetic into the area to be numbed) and transtracheal anesthesia and for peripheral, sympathetic, regional, and epidural nerve blocks in surgical and dental procedures.

Ropivicaine

Ropivicaine (Naropin) is a newer local anesthetic that causes less cardiovascular and CNS side effects than bupivacaine. It has an longer duration of action that is used in regional anesthesia. Unlike the other local anesthetics it causes vasoconstriction instead of vasodilation.

Prilocaine

Prilocaine (Citanest) is used primarily for dental anesthesia. It has an intermediate duration of action and is longer acting than lidocaine. Prilocaine causes the least systemic toxicity of the amides but at high doses may cause methemoglobinemia, a condition marked by high levels of a hemoglobin compound that does not carry oxygen.

Procaine

Procaine hydrochloride (Novocain) is a short-acting local anesthetic of the ester type used for local or regional anesthesia and dental applications. It has no topical anesthetic activity. Procaine is more likely to cause a hypersensitivity reaction and vasodilation than amide-type local anesthetics.

Topical Anesthetics

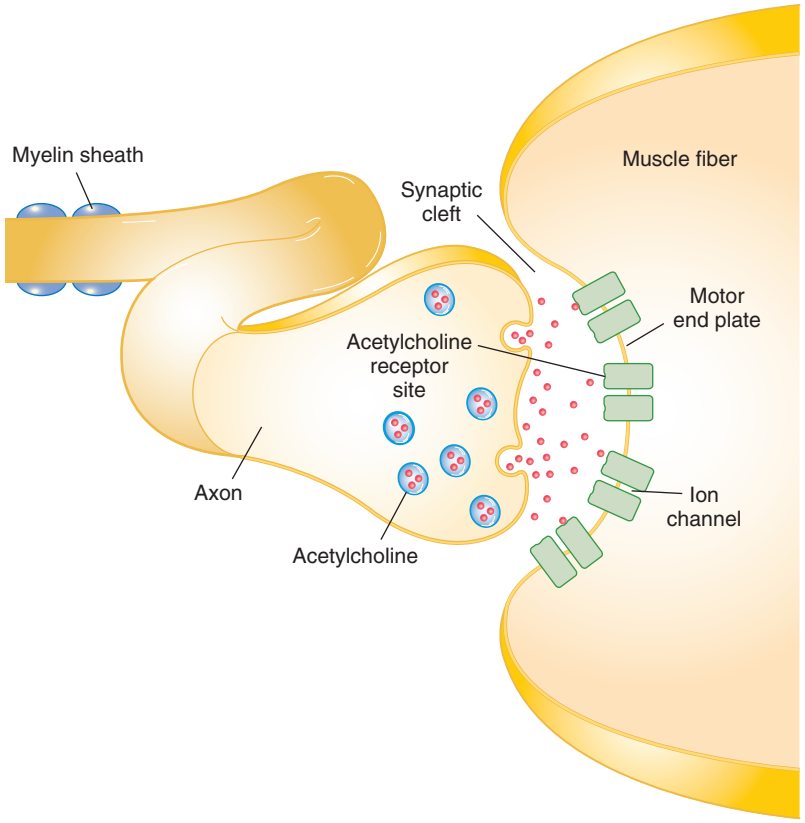
Local anesthetics may be applied to the skin, the eyes, the ears, the nose, and the mouth, as well as to other mucous membranes. In general, cocaine, lidocaine, and prilocaine are the most useful and effective local anesthetics for topical administration, and when used for that purpose, they usually have a rapid onset of action (5 to 10 minutes) and a moderate duration of action (30 to 60 minutes). In addition to its use as a topical anesthetic, cocaine is a potent vasoconstrictor.

Absorption of local anesthetics through intact skin is usually slow and unreliable, and high concentrations are required. EMLA cream is a mixture of local anesthetics (lidocaine and prilocaine in an emulsion) that may be used to provide surface anesthesia of the skin, particularly for children. Cutaneous contact (usually under an occlusive dressing) should be maintained for at least 60 minutes before venipuncture.

C NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking agents interrupt transmission of nerve impulses at the neuromuscular junction causing paralysis. Neuromuscular blocking agents are divided into two categories: non-depolarizing and depolarizing drugs.

Nondepolarizing drugs are competitive antagonists preventing the binding of acetylcholine to the receptor; therefore the



• FIGURE 19.3 The neuromuscular junction consists of a prejunctional motor nerve ending (axon), synaptic cleft and the motor end plate. The motor end plates are the terminal branches of motor nerves found on the skeletal muscle. Normally, the neurotransmitter acetylcholine is released from the axon and diffuses toward the receptor site through the synaptic cleft. Muscle contraction occurs when the acetylcholine binds to the receptor. Neuromuscular blockers compete with acetylcholine, not allowing acetylcholine to bind and therefore preventing muscle contraction.

end plate is unable to depolarize. After administration, muscle fasciculation will not be present, unlike depolarizing drugs. Depolarizing drugs, structurally similar to acetylcholine, cause continuous muscle depolarization and prevents repolarization. The muscle is unable to repolarize as long as the drug continues to bind to the acetylcholine receptor. In both categories of drugs, neuromuscular blockade occurs at acetylcholine receptor sites on the motor end plate (Figure 19.3). Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response and may vary with the procedure, the other drugs given, and the state of the patient.

• C Nondepolarizing Neuromuscular Blocking Agents

Nondepolarizing neuromuscular blocking agents include vecuronium, rocuronium, pancuronium, and cisatracurium (Table 19.7). The prototype drug is vecuronium (Norcuron).

Nursing Management of the Patient Receiving P Vecuronium

Core Drug Knowledge

Pharmacotherapeutics

Vecuronium, a nondepolarizing muscle relaxant, is an anesthesia adjunct used to provide skeletal muscle relaxation to facilitate intubation and mechanical ventilation and to improve surgical conditions during surgical procedures. Vecuronium also may be used in the ICU setting to assist with mechanical ventilation.

Pharmacokinetics

Vecuronium, only available for IV use, has an intermediate duration of action (30 to 60 minutes) when compared to other nondepolarizing neuromuscular blocking agents. With an intubating dose of 0.1 mg/kg, onset of muscle paralysis occurs within 2 to 4 minutes. Clinically, the speed of onset and duration of blockage are monitored by using a peripheral nerve stimulator on the facial or ulnar nerve to assess the effect of the neuromuscular blocking agent.

Vecuronium is excreted by the kidney; therefore drug kinetics will be altered with patients who have kidney disease. In addition, a majority of the drug is eliminated in the liver and excreted in the bile. Hypothermia inhibits the means of elimination and alters the pharmacokinetics; keeping the patient normothermic is extremely important.

Pharmacodynamics

As previously discussed, nondepolarizing neuromuscular blocking agents are antagonists of acetylcholine; they compete with the neurotransmitter for the cholinergic receptor sites at the motor end plate. The neuromuscular blocking actions of vecuronium may be reversed with anticholinesterases such as neostigmine, pyridostigmine, and edrophonium. These drugs block the normal breakdown of acetylcholine at the motor end plate, causing the neurotransmitter to accumulate and returning muscle stimulation.

Vecuronium does not induce histamine release and is considered cardiovascular stable. There have been some reports of bradycardia. Vecuronium does not easily cross the blood–brain barrier or the GI epithelium; hence it does not produce CNS effects, and oral absorption is ineffective. It cannot be stressed enough that neuromuscular blocking agents do not affect consciousness or produce sedation. Patients must be provided adequate anesthesia or sedation before administering muscle skeletal relaxants. Because patients will be paralyzed, they will be unable to spontaneous ventilate and must be mechanically assisted.

Contraindications and Precautions

Vecuronium is contraindicated in patients who have ever shown hypersensitivity to the drug or to any other nondepolarizing blocker. It is classified as a pregnancy category C drug, and is only given if the benefit justifies the risk.

Vecuronium is used with caution in patients with myasthenia gravis or Eaton-Lambert syndrome as small doses have profound effects. Vecuronium should be used with caution in patients with hepatic disease and decreased renal function because the drug is eliminated in the urine and bile. In addition, patients with an electrolyte imbalance may experience altered drug affects.

Adverse Effects

The principal adverse effects of vecuronium result from its blockade of neuromuscular activity at all neuromuscular end plates. Prolonged paralysis can cause immobility that leads to pressure sores (decubitus ulcer formation). Prolonged apnea can result from the paralysis of the respiratory muscles. Therefore, assisted ventilation is needed until the drug's effects resolve or anticholinesterase administration is successful.

Drug Interactions

Drugs that potentiate the action of vecuronium tubocurarine include antibiotics (aminoglycosides, tetracyclines, polymyxin B), inhalation anesthetics, magnesium salts, quinine derivatives, and verapamil. Table 19.8 illustrates these potential drug interactions.

TABLE 19.8 Agents That Interact with P Vecuronium

Interactants	Effect and Significance	Nursing Management
antibiotics aminoglycosides lincosamide polymyxin B polypeptides tetracycline	Potentiate the action of vecuronium, resulting in profound and severe respiratory depression	Avoid combination. Provide life support as needed. Provide anticholinesterases as indicated.
antiepileptics carbamazepine	In combination, may decrease the duration or efficacy of vecuronium	Monitor for decreased muscle relaxant effectiveness. Titrate drug as necessary.
inhalation anesthetics	Potentiate the actions of vecuronium	Monitor respiratory function. Titrate drug as necessary. Provide life support as needed.
magnesium salts	May enhance the actions of vecuronium, resulting in profound and severe respiratory depression	Monitor respiratory function. Titrate drug as necessary. Provide life support as needed.
quinine derivatives	Have a synergistic action with vecuronium, resulting in profound and severe respiratory depression	Monitor neuromuscular function. Titrate drug as necessary. Provide life support as needed.
verapamil	May enhance the action of vecuronium because of its blockage of calcium channels in skeletal muscle	Avoid combination if possible. Monitor respiratory function. Titrate drug as necessary. Provide life support as needed.

Assessment of Relevant Core Patient Variables

Health Status

Evaluate the patient for a history of hypersensitivity to any NMJ blocker or for any renal or hepatic disease. For patients with a history of any of these disorders, place a note on the chart and the drug administration record (Kardex) identifying the need to monitor them closely.

Before administration, perform a physical assessment. The physical examination should include body weight, temperature, state of hydration (skin turgor, pulses), reflexes and muscle tone, pulse, blood pressure, respiratory rate, and adventitious breath sounds. Assess laboratory tests to establish baseline electrolyte values and renal and hepatic status.

Life Span and Gender

Assess women of childbearing age for pregnancy. Vecuronium is pregnancy category C and should be given only if the potential benefit justifies the risk to the fetus. However, it can be used safely as an adjunct to anesthesia in cesarean deliveries. After birth, closely observe the infant for any signs of respiratory depression, because the drug crosses the placenta.

Environment

Be aware of the environment in which the drug will be administered. As with all neuromuscular blocking agents, vecuronium causes respiratory impairment and reversible paralysis. It should be administered only by a person skilled in airway management.

Necessary equipment for intubation, controlled ventilation, and administration of oxygen must be immediately available.

Nursing Diagnoses and Outcomes

- Impaired Spontaneous Ventilation related to respiratory paralysis
  Desired outcome: *The patient will be maintained with artificial ventilation until the ability to sustain spontaneous respirations returns.*
- Impaired Skin Integrity related to paralysis
  Desired outcome: *The patient will remain free of skin breakdown.*
- Fear related to paralysis and helplessness
  Desired outcome: *The patient will be reassured and comforted to prevent fear and sympathetic effects of fear during paralysis.*

Planning and Intervention

Maximizing Therapeutic Effects

Maximize the therapeutic effects of vecuronium by helping patients understand the reason for the therapy and by helping to decrease their fear and anxiety. Anxiety can be alleviated by reassuring the patient that they will be sedated during the time period in which they are chemically paralyzed with a neuromuscular blocking agent. Monitor patients carefully for pain or distress; responses of the pupils, blood pressure,

and heart rate, although not foolproof, are probably the most reliable guide to their condition. Also, frequently reassure patients that the staff is aware of their feeling of helplessness. The hearing of these patients is not impaired; therefore, explain procedures and interventions.

Minimizing Adverse Effects

Have resuscitation equipment and drugs at the bedside throughout therapy. Evaluate the depth of paralysis by use of a stimulator and use cholinesterase inhibitors to overcome excessive or prolonged neuromuscular blockade.

If paralysis is prolonged, change the patient's position frequently to prevent venous stasis or decubitus ulcer formation and provide frequent skin care to prevent skin breakdown.

Providing Patient and Family Education

- Before administration, explain to patients and families that the drug will paralyze muscles and the patient will be unable to speak, move, or breathe unassisted. It is important to explain that these effects should subside a short time after the drug is discontinued and that the patient will be provided with hypnotic and amnestic drugs as an adjunct.
- Advise patients that adverse effects may occur after administration. These effects include sore muscles, constipation, difficulty voiding, and dizziness on arising. Explain the importance of reporting these symptoms to avoid potential injury.

Ongoing Assessment and Evaluation

Monitor the respiratory and cardiac status of the patient frequently. For patients with prolonged paralysis, monitor skin status frequently. Conscious patients should be monitored for any sign of distress, which is especially important because they are unable to talk or move. However, keep in mind that patients can still hear if inadequately sedated. For patients with prolonged paralysis, turn the patient every 2 hours and monitor for skin breakdown. Provide protection to the corneas by taping eye pads in place and by using artificial tears. Continue use of benzodiazepines and analgesic agents to provide a calm environment for these patients.

Drugs Closely Related to P Vecuronium

Other non-depolarizing intermediate-acting neuromuscular blocking agents include cisatracurium and rocuronium. Pancuronium is structurally similar to vecuronium, however it has a longer duration of action.

Cisatracurium

Cisatracurium besylate (Nimbex) has an intermediate onset and duration of action. It has a unique way of elimination that is different than the other non-depolarizing muscular blocking agents. It undergoes Hoffman elimination, which is pH and temperature dependent. Cisatracurium is very effective and safe for patients who have liver disease and renal failure. Cisatracurium does not cause dose-related increases in histamine release and can be used safely in patients with cardiovascular disease.

Pancuronium

Pancuronium (Pavulon) has a longer duration of action. It is a vagolytic drug and is therefore associated with increases of heart rate, blood pressure and cardiac output. This drug characteristic can be useful in some patients that are bradycardiac and hypotensive as a result of narcotics. Pancuronium produces little histamine release. Pancuronium is contraindicated for use in neonates.

Rocuronium

Rocuronium (Zemuron) has an onset of action is comparable with that of succinylcholine, but its duration of action is considerably longer. Because of its rapid onset, rocuronium may be a useful alternative to succinylcholine for rapid-sequence induction. In addition to its therapeutic actions, rocuronium can cause an increase in heart rate, but this side effect is minimal at normal doses. Rocuronium produces little histamine release and no ganglionic blockade; thus, hypotension and bronchospasm are not associated with its use. Children generally require larger doses per kilogram than adults do to achieve muscle relaxation.

• C Depolarizing Neuromuscular Junction Blockers

Depolarizing NMJ blockers work by causing the muscle cell membrane to depolarize or become excited, which causes muscle contraction. This action leads to paralysis of the muscle after repeated excitation. This mechanism differs from that of nondepolarizing NMJ blockers, which prevent excitation. Succinylcholine (Anectine) is the prototype depolarizing NMJ blocker (Table 19.8).

Nursing Management of the Patient Receiving P Succinylcholine

Core Drug Knowledge

Pharmacotherapeutics

Succinylcholine is used primarily for rapid endotracheal intubation and other procedures which need a very short-acting paralytic. It is also of value in modifying muscle contractions and preventing fractures during electroconvulsive

therapy because it produces a complete neuromuscular blockade within 1 minute that lasts for a few minutes, allowing sufficient time to complete the therapy. The use of succinylcholine as an adjunct to anesthesia or to facilitate prolonged mechanical ventilation has been largely replaced by the use of more effective and less toxic NMJ blockers. However, succinylcholine still plays an important role and is widely used but not without controversy.

Pharmacokinetics

Succinylcholine is administered intravenously and intramuscularly. It has a rapid onset and a short duration of action. Following IV administration, complete muscle relaxation occurs in 30 seconds to 1 minute, lasts for 2 to 3 minutes, and then dissipates within 10 minutes. After intramuscular (IM) injection, muscle relaxation occurs in 2 to 3 minutes and lasts 10 to 30 minutes.

Succinylcholine is distributed in the extracellular fluid but does not readily cross the placental barrier. Succinylcholine has a complex excretion pattern. Approximately 10% of the dose is excreted unchanged in the urine. Succinylcholine is mostly hydrolyzed by plasma pseudocholinesterase to metabolites. One of the metabolites, succinylmonocholine, has nondepolarizing muscle relaxation properties. It is excreted partly in urine, and the remainder is broken down into inactive metabolites. Succinylmonocholine is hydrolyzed slowly.

Pharmacodynamics

Succinylcholine acts as an agonist at the cholinergic nicotinic receptors of the motor end plate. Like the usual neurotransmitter acetylcholine, it depolarizes the postsynaptic membrane, producing repetitive excitation of the motor end plate. Muscular fasciculations (rapid contractions) result, followed by flaccid paralysis. Because of this effect, patients often experience postoperative muscle pain. The ensuing paralysis is short lived because the succinylcholine is hydrolyzed by plasma pseudocholinesterase.

Contraindications and Precautions

Succinylcholine is contraindicated in any patient with a known hypersensitivity to the drug. Because it can induce malignant hyperthermia, it is also contraindicated in any patient with a personal or family history of the disorder. Succinylcholine may interact with acetylcholine to produce prolonged apnea; thus, this agent is contraindicated in patients with familial plasma pseudocholinesterase disorders. In addition, succinylcholine is contraindicated in patients with an open eye injury or acute narrow-angle glaucoma because it causes a transient elevation in intraocular pressure immediately after injection (Box 19.3). Succinylcholine may also increase cerebral blood flow and intracranial pressure as fasciculations stimulate muscle fibers and therefore increase cerebral activity. It should be used cautiously in patients with head injuries or pre-existing increased intracranial pressure.

Succinylcholine should be used with caution in patients prone to low pseudocholinesterase levels. Decreased concentrations of serum pseudocholinesterase, the major enzyme that degrades succinylcholine, can lead to very high levels of the drug and prolonged action.

Succinylcholine should also be used with caution in patients who have or are at risk for hyperkalemia. Intense muscle contraction and potassium release from succinylcholine may induce hyperkalemia and provoke complications of hyperkalemia, such as cardiac arrhythmias. Caution is advised especially with children and adults who have compromised cardiac function, degenerative or dystrophic neuromuscular disease, or paraplegia. These patients tend to become severely hyperkalemic when succinylcholine is administered.

Adverse Effects

The principal adverse effects of succinylcholine are associated with muscle paralysis caused by the drug. Prolonged apnea can result from the paralysis of the respiratory muscles, and assisted ventilation is needed until the drug's effects are known. Increased intraocular pressure can aggravate or precipitate glaucoma.

A mild histamine release associated with succinylcholine may result in respiratory difficulty, including wheezing and bronchospasm, cardiac arrhythmias, hypotension, and even cardiac arrest in susceptible patients. Malignant hyperthermia has been reported infrequently. Other metabolic effects include hyperkalemia, with its resultant muscular and cardiac effects, and myoglobinemia and myoglobinuria, which are associated with extreme muscle contraction. Patients may complain of intense muscle pain that may persist for several days after they have received the drug.

Drug Interactions

Succinylcholine interacts with aminoglycosides, anticholinesterases, procaine, and trimethaphan (Table 19.9). It also interacts with drugs that decrease plasma cholinesterase, such as cyclophosphamide, echothiophate, lidocaine infusion, metoclopramide, and quinine derivatives.

Interactants	Effect and Significance	Nursing Management
aminoglycosides	Potentiate neuromuscular effects of succinylcholine	Use combination with caution. Delay administration of aminoglycosides as long as possible after recovery of spontaneous respirations. Monitor for respiratory depression. Have mechanical ventilation available.
anticholinesterases	Inhibition of plasma cholinesterase by anticholinesterases may delay hydrolysis of succinylcholine	Use this combination with caution. Monitor patients' spontaneous muscle activity, which must continue for 5 min before longer-acting agents are administered.
plasma cholinesterase inhibitors cyclophosphamide echothiophate lidocaine infusion metoclopramide quinine derivatives oral contraceptives	Plasma cholinesterase (pseudocholinesterase) necessary to hydrolyze succinylcholine; decreased plasma cholinesterase interferes with the inactivation of succinylcholine, may prolong neuromuscular blockade	Measure serum cholinesterase levels for patients who have been receiving drugs that inhibit plasma cholinesterase. Reduce succinylcholine dosage if plasma cholinesterase levels are decreased. Monitor for respiratory depression. Have mechanical ventilation available.
procaine	Procaine and succinylcholine both hydrolyzed by plasma cholinesterase; competition for the enzyme possibly resulting in prolonged effects of succinylcholine	Monitor for respiratory depression. Have mechanical ventilation available.
trimethaphan	Potent noncompetitive inhibitor of plasma cholinesterase; directly decreases the sensitivity of the respiratory center, increasing risk for respiratory depression	Avoid this combination. Substitute nitroprusside for trimethaphan.

pseudocholinesterase levels include those with severe burns, malnutrition, dehydration, severe hepatic disease, cancer, severe anemia, or myxedema. Also, assess for a history of slow recovery from anesthesia or difficulty during anesthesia.

Before administering succinylcholine, perform a physical assessment. The physical examination should include body weight and temperature, state of hydration (skin turgor, pulses), reflexes and muscle tone, pulse rate, blood pressure, respiratory rate, and adventitious breath sounds.

Life Span and Gender

Document the age and gender of the patient and assesses women of childbearing age for pregnancy. Succinylcholine is used cautiously in children because it can cause severe bradycardia or cardiac arrest. The drug is in pregnancy category C. Although it is uncertain whether it causes fetal harm, it should be used cautiously during pregnancy because the drug places the patient at risk for increased drug effects, such as prolonged apnea. Succinylcholine is commonly used during cesarean section. If repeated dosing is required during delivery, the neonate should be monitored closely for apnea and flaccidity.

Environment

Be aware of the environment in which the drug will be administered. Like vecuronium, succinylcholine causes respiratory impairment and paralysis. It should be administered only by a qualified clinician. Necessary equipment for intubation, controlled ventilation, and administration of oxygen must be immediately available.

Nursing Diagnoses and Outcomes

- Impaired Spontaneous Ventilation related to respiratory paralysis
  Desired outcome: *The patient's breathing will be maintained with artificial ventilation until the ability to sustain spontaneous respiration returns.*
- Impaired Physical Mobility related to drug-induced paralysis
  Desired outcome: *The patient will remain free from disorders related to immobility, such as skin breakdown.*
- Fear related to paralysis and helplessness
  Desired outcome: *The patient will be reassured and comforted to prevent fear and sympathetic effects of fear during paralysis.*

Planning and Intervention

Maximizing Therapeutic Effects

Maximize the therapeutic effects of succinylcholine by helping the patient understand the rationale for the therapy and by helping decrease fear and anxiety.

Minimizing Adverse Effects

To decrease muscle fasciculations, the patient should receive a small dose of a nondepolarizing NMJ blocker before

MEMORY CHIP

Succinylcholine

- A depolarizing neuromuscular junction blocking agent used to facilitate endotracheal intubation and short procedures such as endoscopy or electroconvulsive therapy
- Major contraindications: hypersensitivity, history of malignant hyperthermia, familial plasma pseudocholinesterase disorders, and narrow-angle glaucoma
- Most common adverse effects: increased ocular pressure, histamine release, muscle pain
- Most serious adverse effects: prolonged paralysis and apnea
- Maximizing therapeutic effects: Decrease anxiety and fear.
- Minimizing adverse effects: Have resuscitation equipment at the bedside.
- Most important patient education: Reassure the patient that he or she is being constantly monitored.

succinylcholine is given. This step is especially important when succinylcholine is used in children.

Providing Patient and Family Education

- Before administration, explain to patients and families that the drug will paralyze muscles and that patients will be unable to speak, move, or breathe unassisted. It is important to explain that these effects should subside soon after the drug is discontinued.
- Because this drug may be used in an emergency situation, explain the effects of the drug to patients even if they appear to be unconscious.

Ongoing Assessment and Evaluation

Monitor for symptoms of malignant hyperthermia, such as muscle rigidity (especially the jaw), tachycardia, tachypnea, and elevated body temperature. Have dantrolene on standby in case malignant hyperthermia occurs. Also, monitor the cardiac and respiratory status of the patient while succinylcholine is being administered.

CHAPTER SUMMARY

- Anesthesia is a loss of feeling or sensation.
- Balanced anesthesia is a combination of anesthetic agents used to decrease the depth of anesthesia and keep the patient safe.
- Anesthetic agents are divided into inhaled and intravenous agents.
- Isoflurane (Forane) is a halogenated inhaled anesthetic. Nursing management of patients recovering from isoflurane anesthesia includes carefully monitoring residual CNS depression, manifested as respiratory depression.
- Nitrous oxide is an inflammable gas used to increase the effectiveness of halogenated agents without severely depressing the depth of coma.
- Propofol (Diprivan) is the prototype intravenous anesthetic. It has a quick onset and short duration of action.
- Ketamine (Ketalar) causes dissociative anesthesia.
- Local anesthetics such as lidocaine produce local or regional anesthesia by blocking nerve conduction. They are used to facilitate various types of procedures.
- Nondepolarizing NMJ blockers, such as tubocurarine, prevent nerve impulses from exciting muscle; paralysis ensues because the muscle is unable to respond.
- Depolarizing NMJ blockers, such as succinylcholine, cause muscle paralysis by overexcitement (depolarization) and subsequent exhaustion of the muscle.
- The NMJ blockers are primarily used as adjuncts to general anesthesia, to facilitate endotracheal intubation, or to facilitate mechanical ventilation.

QUESTIONS FOR STUDY AND REVIEW

1. What is balanced anesthesia?
2. What environmental safeguards are needed for patients receiving anesthesia?
3. Propofol is administered in a special emulsion vehicle. What problems does this vehicle pose?
4. Describe the potential systemic adverse effects of locally administered lidocaine (Xylocaine).
5. What is the difference in the mechanism of action between non-depolarizing NMJ blockers and depolarizing NMJ blockers?
6. Mrs. Smith has just returned to the intensive care unit after surgery. She is being maintained on pancuronium bromide. The charge nurse comes into the room and starts to discuss Mrs. Smith's prognosis. What should you do?
7. Your patient is scheduled to receive succinylcholine for a surgical procedure. What teaching points would you need to include in a plan for this patient to prepare him or her for the postoperative experience?

Drugs Affecting Muscle Spasm and Spasticity

Learning Objectives

At the completion of this chapter the student will:

1. Correlate the pathophysiology of muscle spasm and spasticity with appropriate pharmacotherapy.
2. Identify core drug knowledge about pharmacologic therapies that affect muscle spasm and spasticity.
3. Identify core patient variables related to drugs that affect muscle spasm and spasticity.
4. Relate the interaction of core drug knowledge with core patient variables for pharmacologic therapies that affect muscle spasm and spasticity.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for pharmacologic therapies that affect muscle spasm and spasticity.
6. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect muscle spasm and spasticity.
7. Determine key points for patient and family education about drugs that affect muscle spasm and spasticity.

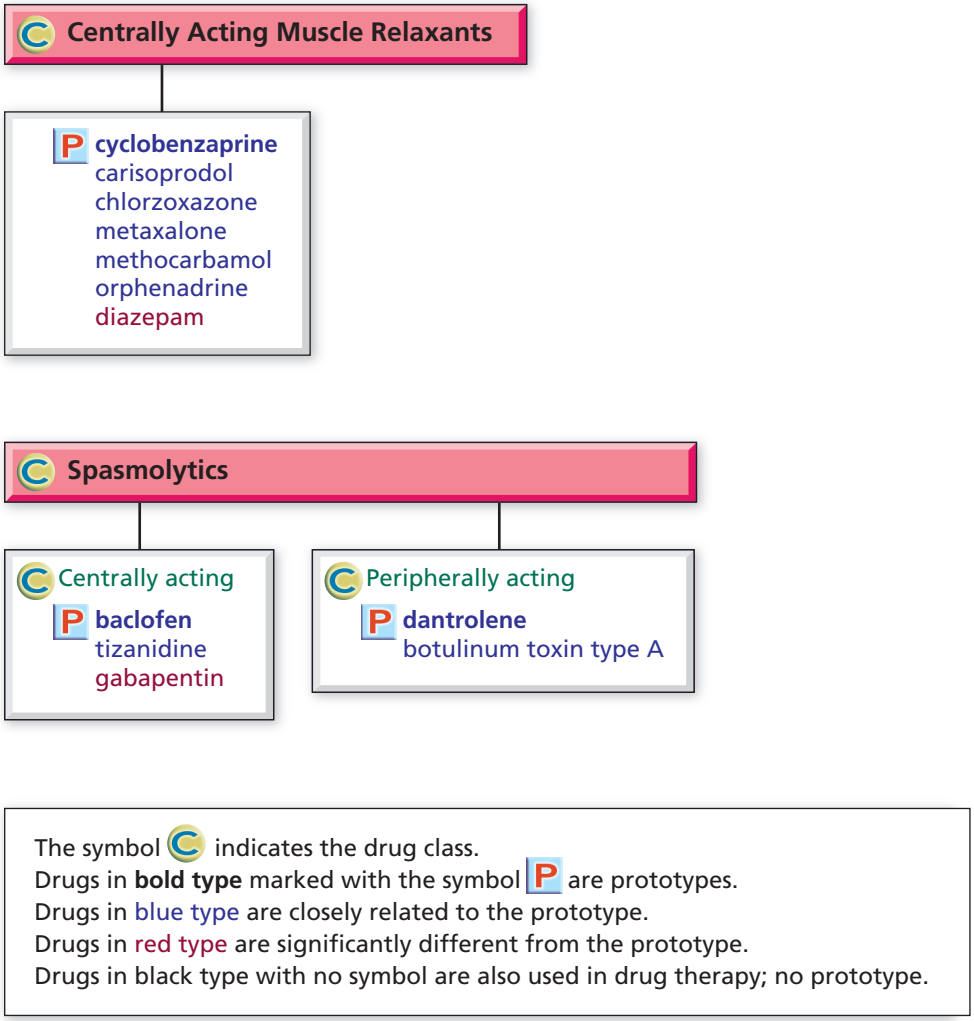
Drugs Affecting Muscle Spasm and Spasticity



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Drugs used to manage muscle spasm and spasticity can be divided into two major therapeutic groups: skeletal muscle relaxants and **spasmolytics.** Skeletal muscle relaxants are used in combination with physical therapy and anti-inflammatory agents (see Chapter 24) to treat muscle spasms (involuntary contraction of a muscle from a peripheral musculoskeletal condition). Spasticity, an involuntary muscle contraction that is not coordinated with other muscles and is associated with upper motor neuron syndromes, is treated with physical therapy and drugs called spasmolytics. Spasmolytics are categorized as **centrally acting** or **peripherally acting.** As their names imply, these agents act in the brain or in the peripheral muscles.

This chapter discusses the centrally acting muscle relaxant cyclobenzaprine (Flexeril), the centrally acting spasmolytic baclofen (Lioresal), and the peripherally acting spasmolytic dantrolene sodium (Dantrium). Table 20.1 presents a summary of these drugs. In addition, this chapter addresses core drug knowledge, core patient variables, nursing management practices, potential nursing diagnoses, and patient education guidelines related to the use of these drugs. For discussion of physical methods for managing spasm and spasticity, refer to an appropriate medical-surgical textbook.

PHYSIOLOGY

The human body contains approximately 600 skeletal muscles. Skeletal muscle is voluntary, meaning a person can contract it at will. Seen under a microscope, skeletal muscle fibers show a pattern of cross-banding, which gives rise to its other name: striated muscle. The striations are caused by the alignment of bands, the most prominent of which are the A bands, I bands, and Z lines. The unit between two Z lines is called the sarcomere (Figure 20.1).

Striated muscle is composed of two contractile proteins: actin and myosin. The thin filaments are made of actin, which is attached to the Z lines and is found in both A bands and I bands. The thick filaments, found in A bands, are made of myosin. In the process set forth in the sliding filament theory, the sarcomere shortens, and the Z lines move closer together when muscle contracts. The filaments slide together because myosin attaches to, and pulls on, actin. The myosin head attaches to the actin filament, forming a crossbridge. After formation of the crossbridge, the myosin head bends, pulling on the actin filaments and causing them to slide. The result is that the Z lines move closer together, the I band becomes shorter, and the A band stays the same (see Figure 20.1). Muscle contraction is like climbing a rope. The crossbridge cycle is one of grabbing, pulling, and releasing, repeated over and over.

Muscle contraction is triggered by a sudden inflow of calcium ion (Ca^{2+}). In the resting state, the protein tropomyosin winds around actin and covers the myosin-binding sites. The Ca^{2+} binds to a second protein, troponin; this action causes the tropomyosin to be pulled to the side, exposing the myosin-binding sites. With the sites exposed, muscle contracts in the presence of adenosine triphosphate (ATP). Muscle contraction stops when Ca^{2+} is removed from the immediate environment of the myofilaments.

PATHOPHYSIOLOGY

Muscle Spasm

A muscle **spasm** is a sudden violent involuntary contraction of a muscle or group of muscles resulting from an imbalance of excitatory and inhibitory input from descending motor pathways from the brain and spinal cord. Spasm is usually related to a localized skeletal muscle injury from acute trauma. Spasms may also stem from disorders such as hypocalcemia, hypokalemia or hyperkalemia, chronic pain syndromes, or epilepsy. Pain and interference with function attend muscle spasm, producing involuntary movement and distortion. When a muscle goes into spasm, it freezes in contraction and becomes a hard knotty mass, rather than normally contracting and relaxing in quick succession. During spasm, the blood vessels that normally feed the muscles and supply oxygen constrict, further compounding the problem.

Tonic spasm, or cramp, is characterized by an unusually prolonged and strong muscular contraction, with relaxation occurring slowly. In the other form of spasm, called **clonic** spasm, contractions of the affected muscles occur repeatedly, forcibly, and in quick succession, with equally sudden and frequent relaxations.

Spasticity

Spasticity is a motor disorder that comprises involuntary, velocity-dependent increased muscle tone that is associated with neurologic conditions or trauma to the central nervous system. This contraction causes stiffness or tightness of the muscles and may interfere with gait, movement, or speech. Damage to the portion of the brain or spinal cord that controls voluntary movement usually causes spasticity. Spasticity may be associated with spinal cord injury, multiple sclerosis (MS), cerebral palsy, anoxic brain damage such as a cerebrovascular accident (CVA), brain trauma, severe head injury, and some metabolic diseases, such as adrenoleukodystrophy and phenylketonuria. Symptoms may include hypertonicity (increased muscle tone), clonus (a series of rapid muscle contractions), exaggerated deep tendon reflexes, muscle spasms, scissoring (involuntary crossing of the legs), and fixed joints. The degree of spasticity varies from mild muscle stiffness to severe, painful, and uncontrollable muscle spasms. The condition can interfere with daily activities and with rehabilitation in patients with certain disorders. Goals for treating individuals with spasticity include improving functional activity and mobility, reducing the risk of avoidable complications such as pressure sores and orthopedic deformity, to allow stretching and strengthening of muscles, and alleviating pain.

The removal of calcium ions restores the inhibitory action of troponin-tropomyosin; crossbridge action is impossible in this state.

C CENTRALLY ACTING MUSCLE RELAXANTS

The centrally acting muscle relaxants are a group of drugs with similar pharmacologic properties. They act in the central nervous system (CNS). The prototype for centrally acting muscle relaxants is cyclobenzaprine (Flexeril), because evidence indicates that it is the most efficacious (Table 20.1). Diazepam (Valium), a benzodiazepine, is mentioned because it is used in managing both muscle spasms and spasticity. Benzodiazepines are discussed in depth in Chapter 15.

Nursing Management of the Patient Receiving P Cyclobenzaprine

Core Drug Knowledge

Pharmacotherapeutics

Cyclobenzaprine is used to manage muscle spasms associated with acute musculoskeletal disorders, such as low back strain, muscle tenderness, or movement restriction due to musculoskeletal conditions. It is also used as supportive therapy in patients with tetanus or fibromyalgia.

Pharmacokinetics

Cyclobenzaprine is administered orally. It is well absorbed from the gastrointestinal (GI) tract and probably undergoes first-pass metabolism because plasma levels vary considerably among patients. Onset of skeletal muscle relaxation occurs in about 1 hour, and duration of action ranges from 12 to 24 hours. Optimal effects may take 1 to 2 days to fully develop. Cyclobenzaprine undergoes extensive metabolism and is excreted mainly as conjugated inactive metabolites in the urine and as unchanged drug through bile in the feces. Its half-life ranges from 1 to 3 days.

Pharmacodynamics

Cyclobenzaprine relieves muscle spasms through a central action, possibly at the level of the brain stem, with no direct action on the neuromuscular junction or the muscle involved. It reduces pain and tenderness and improves mobility. Because of its structural similarity to the tricyclic antidepressants (TCAs), cyclobenzaprine may reduce tonic somatic motor activity by influencing both alpha and gamma motor neurons. Cyclobenzaprine is ineffective for treating spasticity associated with cerebral or spinal cord disease or in children with cerebral palsy.

Contraindications and Precautions

Cyclobenzaprine is contraindicated for patients with hyperthyroidism because of a possible increased risk of arrhythmias or an exacerbation of tachycardia. Because of its similarity to the TCAs, cyclobenzaprine is also contraindicated for use within 14 days of administration of monoamine oxidase inhibitors (MAOIs).

In overdoses, TCAs cause conduction disturbances and have been associated with torsades de pointes (an atypical tachycardia) and death. Because it is closely related to the TCA amitriptyline, cyclobenzaprine should be used cautiously in patients with heart failure, cardiac arrhythmias, or atrioventricular block or other conduction disturbances, and in those who are in the acute recovery phase following myocardial infarction (MI).

Cyclobenzaprine possesses anticholinergic activity. Patients with increased intraocular pressure, angle-closure glaucoma, or urinary retention require careful monitoring. In addition, cyclobenzaprine should be used with caution in pregnant or breast-feeding women. Studies for determining safe use during pregnancy have not been performed.

Adverse Effects

The common adverse effects of cyclobenzaprine are related to its CNS depression and anticholinergic activity. The most common adverse effects are drowsiness, dizziness, and dry mouth. Other frequent adverse effects include fatigue, asthenia (loss of strength and energy), nausea and vomiting, constipation, dyspepsia, dysgeusia (unpleasant taste), blurred vision, headache, nervousness, and confusion.

TABLE 20.2 Agents That Interact with P Cyclobenzaprine

Interactants	Effect and Significance	Nursing Management
CNS depressants • sedatives • tranquilizers • alcohol • opioids	Cyclobenzaprine, in combination with other CNS depressants, may induce additive effects, resulting in increased CNS depression.	Avoid this combination. Monitor for sedation and dizziness. Provide ambulatory assistance. Ensure patient's safety.
Tramadol	Cyclobenzaprine may react with tramadol, resulting in seizure activity.	Use of tramadol with cyclobenzaprine is not recommended. Monitor for seizure activity.
Guanethidine	Cyclobenzaprine may react with guanethidine, decreasing guanethidine's antihypertensive effect.	Use of guanethidine with cyclobenzaprine is not recommended. Monitor blood pressure. Discuss possible increased dosage of guanethidine with health care provider.
MAOIs	Although the mechanism of action is unknown, it is likely that concurrent administration of cyclobenzaprine and MAOIs enhances adrenergic activity, increasing the likelihood of oretic (hydrochlorothiazide) crisis, severe seizures, and death.	A minimum of 14 days should elapse between the discontinuance of MAOIs and the initiation of cyclobenzaprine therapy. Monitor for elevated temperature, confusion, or seizure activity.
Phytomedicinal herbs • Valerian • *Valeriana officinalis* • Kava kava • St. John's wort • gotu kola	Combination therapy can cause additive effects of sedation and dizziness, which can impair the patient's ability to undertake tasks that require mental alertness.	Monitor for sedation and dizziness. Provide ambulatory assistance. Ensure patient's safety. Dosage adjustments of either or both medications may be necessary.
Tricyclic antidepressants	Cyclobenzaprine is structurally similar to tricyclic antidepressants. When given concurrently, some of the more serious CNS reactions noted with the tricyclic antidepressants may occur.	Monitor for seizure activity. Monitor for arrhythmias.

Serious adverse effects, including arrhythmias, seizures, and MIs, can occur because of cyclobenzaprine's similarity to the TCAs.

Drug Interactions

Interactions between cyclobenzaprine and CNS depressants or antimuscarinic drugs may be extensive. Cyclobenzaprine may also interact with tramadol, guanethidine, MAOIs, histamine-1 blocking agents, and various herbal remedies. These interactions are highlighted in Table 20.2.

CRITICAL THINKING SCENARIO

CYCLOBENZAPRINE IN THE COLLEGE ENVIRONMENT

Katie C., a senior in college is seen at the student health center during finals week, complaining of severe neck spasms. Despite warm compresses and ibuprofen, the spasms have not resolved. She is prescribed cyclobenzaprine.

1. Given the college environment and lifestyle, what information would you include in your patient teaching session about this medication?
2. What in her medical history would be important to identify that could contraindicate being given this prescription?

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for a history of cyclobenzaprine hypersensitivity or pre-existing diseases such as hyperthyroidism, cardiac dysfunction, recent MI, urinary hesitation/retention, and glaucoma. Caution should be used in patients with mild hepatic impairment. Also, assess for use of medications that may interact with cyclobenzaprine, such as MAOIs. Communicate positive findings to the prescriber before administering the drug. Also, assess for over-the-counter (OTC) drugs used for allergies or hay fever, because these drugs usually have an anticholinergic effect, and additive effects occur when anticholinergic drugs are given concurrently with cyclobenzaprine.

Life Span and Gender

Assess older adult patients for the anticholinergic and CNS depressant effects of cyclobenzaprine, as susceptibility increases with increased age. Safety and efficacy have not been established in patients less than 15 years old.

In addition, it is important to evaluate the female patient's pregnancy and lactation status. Safety during pregnancy has not been documented, although cyclobenzaprine is a

pregnancy category B drug. Distribution of the drug into breast milk has not been established, but TCAs are found in breast milk. Because of its structural similarity to the TCAs, cyclobenzaprine may also distribute into breast milk.

Lifestyle, Diet, and Habits

Assess for use of alcohol or any other CNS depressant, which increases the sedating effects of cyclobenzaprine. Advise the patient to assess the depth of sedation related to cyclobenzaprine use before driving a vehicle or attempting activities that require mental alertness or motor coordination. Long-term use of cyclobenzaprine may result in physical dependence. Assess for potential abuse of this drug.

Environment

Cyclobenzaprine may be administered in any environment, but it is most often given on an outpatient basis. Because it can cause sedation, discuss with the patient possible hazards in the home environment.

Nursing Diagnosis and Outcome

- Risk for Injury related to CNS depressant effects and potential cardiovascular effects.
  Desired outcome: *The patient will remain free from injury throughout therapy*.

Planning and Intervention

Maximizing Therapeutic Effects

Have the patient take cyclobenzaprine with a full glass of water at evenly spaced intervals. Coordinate physical modalities such as physical therapy, whirlpool, and cold or hot compresses to the affected area.

Minimizing Adverse Effects

While the patient is hospitalized, ensure the patient's safety by keeping the bed in the lowest position with the side rails up. Accompany the patient during ambulation until the degree of sedation is ascertained. Also, caution the patient about the potential for orthostatic hypotension resulting in dizziness and teach the patient to change positions slowly. Finally, remind the patient of the potential for synergistic effects when cyclobenzaprine is taken with other CNS depressants, especially alcohol. Because cyclobenzaprine can cause physical dependence with long-term use, slowly withdrawing the drug over 1 to 2 weeks is important to prevent abstinence syndrome (see Chapter 9).

Providing Patient and Family Education

- Instruct patients to take cyclobenzaprine exactly as prescribed. If patients miss a dose, they should take it as soon as they remember but should never double the dose.
- Explain that adverse effects such as mild drowsiness, dizziness, or clumsiness may accompany cyclobenzaprine therapy. Although these symptoms will often improve with time, patients must refrain from driving or performing hazardous tasks until their level of sedation is ascertained. Advise patients to contact the prescriber if sedation persists or is bothersome. Also, emphasize the need to refrain from alcohol, which may exacerbate these adverse effects.
- Advise patients to contact the prescriber immediately if they experience severe headache, confusion, hallucinations, or sudden or increased weakness. Female patients should contact the prescriber immediately if they suspect they may be pregnant.
- Instruct patients to avoid using any OTC or prescription drugs without first consulting the prescriber. Many of these drugs can cause dangerous adverse effects when taken with cyclobenzaprine.
- Finally, instruct patients never to abruptly cease cyclobenzaprine if therapy has been with high doses or over a prolonged period; rather, they should decrease the dosage gradually over 2 weeks.

Ongoing Assessment and Evaluation

Constantly evaluate the patient's safety. Monitor the level of sedation and report to the prescriber if it is severe. In addition to CNS symptoms, monitor for GI symptoms, such as gastric distress or constipation. Provide analgesics for headache, offer small and frequent meals to decrease GI upset, and establish a bowel program if constipation becomes a problem. Successful cyclobenzaprine therapy is marked by decreased muscle spasms and no injury to the patient related to adverse effects.

MEMORY CHIP

P Cyclobenzaprine

- Centrally acting muscle relaxant is used for muscle spasms; ineffective for spasticity
- Most common adverse effect: sedation; safety is a nursing priority
- Most serious adverse effects: occur with abrupt withdrawal and include agitation, auditory or visual hallucinations, seizures, or psychotic symptoms
- **Life span alert: Older adult patients are more prone to sedation and anticholinergic effects.**
- Maximizing therapeutic effects: Take medication exactly as prescribed.
- Minimizing adverse effects: Avoid use of other CNS depressants.
- Most important patient education: Never abruptly stop medication; withdraw medication over a 2-week period.

Drugs Closely Related to P Cyclobenzaprine

Drugs that are similar to cyclobenzaprine include carisoprodol, chlorzoxazone, metaxalone, methocarbamol, and orphenadrine. Like cyclobenzaprine, they all work by affecting the CNS rather than the muscle itself. Thus, patient safety is a priority with all of these drugs.

Carisoprodol

Carisoprodol (Soma) is given orally. Although carisoprodol is itself a nonscheduled drug, it can be very addictive because it is metabolized into meprobamate, a Schedule IV controlled

substance. Tolerance and physical dependence may occur with prolonged use; therefore limit use to 2 to 3 weeks. Significant adverse effects include hypomania at higher than recommended doses, withdrawal syndrome, and hypersensitivity. Patients taking carisoprodol may also experience an idiosyncratic reaction inducing weakness, visual or motor disturbances, confusion, or euphoria. Hypersensitivity or idiosyncratic reactions generally occur within administration of the first four doses. Two factors have led to the diminished use of carisoprodol: its ability to produce dependence and the availability of newer agents.

Chlorzoxazone

Chlorzoxazone (Paraflex, Parafon Forte) has been used for many years. It is metabolized in the liver; therefore, it should be used with caution in patients with hepatic disease, because it may cause hepatotoxicity ranging from a mild elevation in hepatic enzymes to hepatic necrosis. In addition, a metabolite of chlorzoxazone is rapidly excreted in the urine, and the drug should be used with caution in patients with renal impairment because it may alter excretion and possibly cause toxicity. Chlorzoxazone requires multiple daily doses and is more expensive than cyclobenzaprine.

Metaxalone

Metaxalone (Skelaxin) is another oral muscle relaxant. It produces less sedation than cyclobenzaprine but requires 4 times a day dosing and is more expensive. Metaxalone is contraindicated in patients with severe renal and hepatic impairment. Before administration, baseline renal and hepatic function should be evaluated, especially if the patient will have long-term therapy. Periodic liver function tests (LFTs) should be performed throughout therapy.

Patients taking metaxalone may experience paradoxical muscle cramps or a mild withdrawal syndrome if the drug is discontinued abruptly.

Methocarbamol

Methocarbamol (Robaxin) may be administered by oral, intramuscular (IM), and intravenous (IV) routes. In addition to its use for muscle spasm, methocarbamol is used in managing tetanus. Methocarbamol may cause brown, brown-black, or green urine. Like chlorzoxazone, it causes less sedation than cyclobenzaprine. Contraindications to methocarbamol include hepatic or renal disorders, age younger than 12 years or older than 60 years, and pregnancy. It is used with caution in patients with seizure disorders because it may exacerbate seizure activity.

When methocarbamol is given intravenously, the rate should not exceed 300 mg/min (3 mL of 10% injection). Because the solution is hypertonic, extravasation may occur, resulting in thrombophlebitis, sloughing, and pain at the injection site.

Orphenadrine

Orphenadrine (Norflex) is another centrally acting muscle relaxant. Administration is oral or parenteral. In addition to having CNS effects similar to those of other centrally acting skeletal muscle relaxants, orphenadrine may induce, although rarely, aplastic anemia or anaphylactic reaction. When given intravenously, it should not be diluted and should be given slowly over 5 minutes.

Orphenadrine should be used with caution in conditions that are affected by its anticholinergic and antihistaminic effects, which include bladder obstruction, prostatic hypertrophy, GI obstruction, peptic ulcer disease, gastroesophageal reflux disease, asthma, glaucoma, and myasthenia gravis. Orphenadrine should also be used with caution in older patients who do not tolerate anticholinergics well. Additionally, caution should be taken when administering to patients with cardiac insufficiency or thyrotoxicosis. The safety of orphenadrine in children or pregnant or breast-feeding women has not been established.

Orphenadrine interacts with haloperidol, worsening schizophrenic symptoms and possibly contributing to the development of tardive dyskinesia. It also interacts with amantadine, with resultant additive anticholinergic effects. Orphenadrine decreases the action of phenothiazines when given concurrently.

Drug Significantly Different From P Cyclobenzaprine

Diazepam (Valium) is a benzodiazepine that can produce any level of CNS depression required, including sedation, hypnosis, skeletal muscle relaxation, antiepileptic activity, or coma. Diazepam and baclofen are the only two centrally acting drugs that are used for spasticity as well as muscle spasm. Although diazepam is an extremely effective muscle relaxant, its use as a maintenance drug for spasms is limited because of its potential for physical and psychological dependence. Additionally, withdrawing diazepam abruptly may induce seizure activity. For further information on benzodiazepines, see Chapter 15.

C CENTRALLY ACTING SPASMOLYTICS

The centrally acting spasmolytics work in the CNS to reduce excessive reflex activity and to allow muscle relaxation. They are used to alleviate musculoskeletal pain and spasms and reduce spasticity in a variety of neurologic disorders. The prototype for the centrally acting spasmolytics is baclofen (Lioresal), which is very effective and inexpensive.

Nursing Management of the Patient Receiving P Baclofen

Core Drug Knowledge

Pharmacotherapeutics

Baclofen relieves some components of spinal spasticity—involuntary flexor and extensor spasms and resistance to passive movements. It is useful in the treatment of spasticity and myoclonus resulting from disorders such as MS,

cerebral palsy, and traumatic injury to the spinal cord. Baclofen is not useful in treating spasms that follow a CVA, or those that occur in Parkinson disease or Huntington chorea. Surgically implanted pumps are used to deliver intrathecal baclofen to patients who have long-term needs or poor control with oral medications. Baclofen has been used in patients with focal dystonic movements, including torticollis (wry neck). It has been used with some success in Meige syndrome (blepharospasm-oromandibular dystonia) and stiff-man syndrome, also known as Moersch-Woltmann syndrome. Stiff-man syndrome occurs primarily in men. It is characterized by muscular rigidity accompanied by paroxysmal painful spasms precipitated by physical or emotional stimuli.

Baclofen has been effective in treating intractable hiccups. It may also be used to manage trigeminal neuralgia and various types of neuropathic pain, including migraine headaches. Neuropathic cancer pain also responds to baclofen therapy.

Pharmacokinetics

Baclofen may be administered orally or intrathecally. It is absolutely contraindicated for intravenous, intramuscular, subcutaneous, or epidural administration. When administered orally, baclofen is rapidly absorbed with peak blood concentrations seen in 2 to 3 hours. It is distributed throughout the body and minimally crosses the blood–brain barrier. Baclofen also crosses the placenta and passes into breast milk. Serum half-life ranges from 2 to 4 hours. The kidneys excrete 70% to 85% of a dose as unchanged drug and active and inactive metabolites. The liver metabolizes the remainder, which is excreted through the feces. Hemodialysis and hemoperfusion have successfully eliminated baclofen from the blood in cases of drug-induced intoxication.

When introduced into the intrathecal space, effective CSF concentrations are reached with plasma concentrations 100 times less than seen following oral administration of baclofen. Though there is considerable interpatient variability, onset of action following intrathecal administration occurs within 1 hour, with peak antispasmodic effect seen at 4 hours. Intrathecal baclofen is cleared by CSF uptake in the CNS.

Pharmacodynamics

Baclofen is a derivative of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) and acts specifically at the spinal end of the upper motor neurons at $GABA_B$ receptors to inhibit transmission of impulses and cause hyperpolarization. This action reduces excessive reflex activity underlying muscle hypertonia, spasms, and spasticity and allows muscle relaxation. The mechanism of action explains why baclofen is not used for spasticity resulting from CVA or Parkinson disease, because these disorders involve lesional or functional impairment of basal ganglia coordination, in an area of the CNS above the spinal motor neurons.

Contraindications and Precautions

Baclofen is contraindicated in anyone who has demonstrated previous hypersensitivity to it. It is also contraindicated for spasticity of cerebral origin or for reducing the rigidity of parkinsonism or Huntington chorea because it is ineffective in these disorders.

Abrupt discontinuation of baclofen should be avoided, as it may result in severe side effects. Gradual reduction of dosage is recommended. Abrupt withdrawal from oral baclofen may induce confusion, seizures, exacerbation of severe spasticity, hallucinations, and other psychiatric disorders. Abrupt discontinuation of intrathecal baclofen may result in high fevers, hypotension, dysphoria, altered mental status, seizures, rebound spasticity, and muscle rigidity that may advance to rhabdomyolysis, disseminated intravascular coagulation, multi-system organ failure, and death. Withdrawal from intrathecal baclofen may mimic sepsis, autonomic dysreflexia, serotonin syndrome, neuroleptic malignant syndrome, status epilepticus, and toxic or metabolic disorders.

Baclofen is used with caution in patients who have seizure disorders. It has caused deterioration in seizure control and electroencephalographic changes in patients with epilepsy. When given to patients with CNS disorders, such as cerebral hemorrhage or a prior CVA, baclofen may increase the risk for developing CNS, respiratory, or cardiovascular depression and ataxia. Baclofen can increase blood glucose concentrations and should therefore be used cautiously in patients with diabetes mellitus. Patients with pre-existing psychiatric disorders are more likely to develop baclofen-induced psychiatric disturbances. Baclofen should also be used with caution in patients who have renal impairment, because most of the drug is excreted unchanged in the urine.

Baclofen is classified as a pregnancy category C drug and should be used during pregnancy only when the benefits to the pregnant woman outweigh the risks to the fetus. Baclofen appears in small amounts in breast milk; therefore, caution should be used in administering it to breastfeeding women. Baclofen has not been approved for use in children younger than 12 years.

Adverse Effects

The most common adverse effects of baclofen therapy include drowsiness, weakness, dizziness and lightheadedness, headache, nausea and vomiting, hypotension, constipation, lethargy and fatigue, confusion, insomnia, and increased urinary frequency. Other effects in the CNS include euphoria, excitement, depression, and hallucinations. Baclofen may also cause paresthesias, myalgias, or tinnitus. The patient may experience difficulty with coordination, tremors, rigidity, or ataxia. The patient may also experience vision disturbances such as nystagmus, strabismus, miosis, mydriasis, or diplopia. Adverse effects in the GI system include xerostomia, anorexia, dysgeusia, abdominal pain, and diarrhea. Cardiovascular adverse effects, such

as palpitations, angina, excessive diaphoresis, and syncope, are possible. Genitourinary (GU) effects may include urinary incontinence or retention, dysuria, erectile dysfunction, ejaculation dysfunction, and nocturia. Integumentary adverse effects may include rash and pruritus.

Drug Interactions

Teach the patient that baclofen may impair his/her ability to perform tasks that require mental alertness or physical coordination. CNS depression may occur when baclofen is administered concurrently with other CNS depressants. Concurrent use with monoamine oxidase inhibitors may increase CNS depression and cause hypotension. Concomitant use of baclofen with other antihypertensive agents may result in hypotension. Baclofen has also been reported to cause false-positive results on tests for occult blood in the stool. Additionally, baclofen may induce elevations in levels of aspartate aminotransferase (AST), alkaline phosphatase, or serum glucose (Table 20.3).

Assessment of Relevant Core Patient Variables

Health Status

Assess for a history of baclofen hypersensitivity or preexisting disorders that contraindicate the use of baclofen. Also assess for muscle spasms and their causes. Baclofen therapy does not affect skeletal muscle spasms resulting from CVA or parkinsonism.

Perform a physical examination that includes baseline assessments of neurologic function, cardiac function, kidney function, and muscle strength and spasticity. Laboratory assessments should include baseline liver and kidney function values and blood glucose level.

Life Span and Gender

Older patients are more susceptible to baclofen-induced sedation and psychiatric disturbances, including hallucinations, excitation, and confusion. Therefore, continually assess older patients taking baclofen for such adverse effects. Evaluate the patient for pregnancy. Baclofen may be used during pregnancy when the benefits to the pregnant woman outweigh the risks to the fetus. Baclofen should not be used in children younger than 12 years.

Lifestyle, Diet, and Habits

Caution the patient about the concurrent use of alcohol and baclofen. Alcohol may increase the risk for CNS depression and other CNS adverse effects. Also, caution patients to assess their level of alertness (which may be affected by CNS depression) before attempting to drive, use machinery, or perform activities that require concentration.

Environment

Oral baclofen can be given in any environment and is generally self-administered in the home. Intrathecal baclofen administration requires a surgical procedure to implant the device. The prescriber refills the reservoir every 4 to 12 weeks, depending on the daily dose.

Nursing Diagnoses and Outcomes

- Acute Pain related to headache, muscle pain, GI disturbances, or rash

  Desired outcome: *The patient will be provided with measures to decrease the discomfort of drug therapy and the possibility of nonadherence.*

- Risk for Disturbed Sensory Perception related to visual changes, vestibular dysfunction, and somatosensory changes
  Desired outcome: *The patient will be protected from injury if dizziness, weakness, visual changes, or perceptual changes occur.*

Planning and Intervention

Maximizing Therapeutic Effects

Have the patient take baclofen with a full glass of water at evenly spaced intervals. For the patient with GI distress, coordinate small, frequent meals.

Minimizing Adverse Effects

Ensure the patient's safety by keeping the bed in the lowest position with the side rails up. Assist ambulatory patients with locomotion because sedation and muscle weakness may increase. Advise the patient to change positions slowly to prevent dizziness. Remind the patient to assess his or her sedation level prior to driving or performing tasks that require concentration.

Providing Patient and Family Education

- Education for patients receiving baclofen is similar to that for patients receiving cyclobenzaprine. As with cyclobenzaprine, caution patients to avoid sudden cessation of the drug; instead, patients should taper doses of the drug over 2 weeks.
- Emphasize the importance of safety related to sedation. Be sure patients understand to avoid any activity that requires concentration, especially driving, until their level of sedation is established.
- Remind patients to refrain from alcohol or any other CNS depressant agents.
- Advise patients that it may take up to 1 month to experience the full benefit of baclofen therapy.
- Advise patients of the importance of contacting the prescriber should they experience severe headaches, confusion, hallucinations, or sudden or increased weakness. Advise all female patients to contact the prescriber immediately if they become pregnant.
- Instruct patients with diabetes to use capillary blood glucose monitoring because baclofen may cause blood and urine glucose levels to rise. These patients should notify their prescribers if serum glucose level elevations persist.
- For patients receiving intrathecal baclofen, teach the patient and family aseptic technique and how to assess the integrity of the catheter and infusion system.

Ongoing Assessment and Evaluation

To ensure safety, assess the patient for the CNS effects of baclofen throughout therapy. Monitor for the emergence of hallucinations or psychotic episodes and consult with the prescriber immediately about the possibility of reducing the dose or discontinuing the drug. Also, monitor the patient for integumentary, GI, or GU system complaints. Suggest approaches for dealing with minor symptoms, such as analgesics for headache or small, frequent meals for GI upset. Help establish a bowel program if constipation occurs. For GU effects such as erectile dysfunction, refer the patient to the prescriber and ensure that the patient does not abruptly stop the medication.

Therapeutic monitoring during baclofen therapy will show improvement in symptoms of spasticity and a decrease in resistance to passive movement of limb joints.

MEMORY CHIP

P Baclofen

- Centrally acting spasmolytic is used for muscle spasms or spasticity
- Major contraindication: patients who use spasticity to maintain posture or balance
- Most common adverse effect: sedation; safety is a nursing priority
- Most serious adverse effects: occur with abrupt withdrawal and include agitation, auditory or visual hallucinations, seizures, or psychotic symptoms
- **Life span alert: Older patients are more prone to sedation and other effects on the central nervous system.**
- Maximizing therapeutic effects: Administer at evenly spaced intervals.
- Minimizing adverse effects: Assist in changing positions slowly; withdraw medication over a 2-week period.
- Most important patient education: Never abruptly stop medication.

Drug Closely Related to P Baclofen

Tizanidine (Zanaflex) is an oral agent used to reduce muscle tone and treat spasticity related to cerebral or spinal cord pathology and MS. It is structurally and pharmacologically similar to clonidine and other alpha-2 adrenergic agonists and works at both the spinal and supraspinal levels. Although tizanidine and baclofen are equally effective in treating spasticity, tizanidine is much more expensive. Tizanidine also is effective in reducing the perception of neuropathic, trigeminal, and musculoskeletal pain by regulating central afferent nociceptive signals.

Tizanidine is used cautiously in patients with hypotension, hepatic disease, psychosis, or renal impairment. An important potentiating interaction with tizanidine occurs with oral contraceptives, fluvoxamine, and ciprofloxacin because they are CYP1A2 inhibitors. Tizanidine also has additive effects when given with other antihypertensive agents, alpha-2 agonists, or ethanol. Adverse effects parallel those of other alpha-2 adrenergic agonists, including dry mouth, drowsiness, dizziness, GI disturbances, and liver function abnormalities. Because of its adrenergic action, hypotension and orthostatic hypotension may also occur. Bradycardia may

also be seen as well as prolongation of the QT interval on the ECG. Tizanidine produces greater drowsiness and sedation than baclofen but is not associated with the muscle weakness that may occur with baclofen therapy. Slow upward titration of the dose can minimize adverse effects. Patients on long-term therapy should have baseline LFTs performed prior to starting therapy and repeated at 3 and 6 months, and then periodically thereafter.

Drug Significantly Different From P Baclofen

Gabapentin (Neurontin) is a miscellaneous antiepileptic drug that has demonstrated efficacy in the management of neuropathic pain and spasticity. It is useful in managing spasticity associated with MS; this is an off-label indication. It may also be used to treat neuropathic pain associated with postherpetic neuralgia and peripheral diabetic neuropathy. Although its exact mechanism of action is not known, it is thought to interact with voltage-gated calcium channels to decrease pain and spasticity. Gabapentin is orally administered and rapidly absorbed. It is highly lipid soluble, crosses the blood–brain barrier, and is widely distributed in the CNS. Gabapentin is not metabolized and is excreted unchanged in the urine; therefore, monitoring renal function is important. Gabapentin is unusual in that it does not interact with other drugs and does not alter the serum concentrations of other anticonvulsants. Common adverse effects include drowsiness, somnolence, blurred vision, nausea, and fatigue. For additional information regarding gabapentin, see Chapter 18.

C PERIPHERALLY ACTING SPASMOLYTICS

Peripherally acting spasmolytics relax muscles through direct action on the skeletal muscle fibers. They neither interfere with neuromuscular communication nor have CNS effects. Dantrolene (Dantrium) is the most frequently used peripheral agent and the prototype for the peripherally acting spasmolytics

Nursing Management of the Patient Receiving P Dantrolene

Core Drug Knowledge

Pharmacotherapeutics

Dantrolene is an oral and intravenous skeletal muscle relaxant. IV dantrolene is the drug of choice, when accompanied by supportive measures, for acute treatment of malignant hyperthermia, a life-threatening complication of general anesthesia (Box 20.1). Preoperatively, it can be used orally or intravenously to prevent malignant hyperthermia in patients considered at risk.

Dantrolene has several other pharmacotherapeutic uses. It has been used for the treatment of neuroleptic malignant syndrome, though the response to dantrolene in this condition is not always successful. It has been effective in treating upper motor neuron disorders, such as hereditary spastic paraplegia. It has also been used to treat heatstroke and to prevent and treat the rigors associated with amphotericin B. It is useful in managing spasticity resulting from spinal cord and cerebral injuries, MS, cerebral palsy, and possibly CVA. Dantrolene is not effective in treating acute muscle weakness of local origin or muscle weakness resulting from rheumatoid spondylitis, arthritis, or bursitis. Dantrolene use has found favor in the neurologic intensive care unit as an agent to provide neuroprotection by inhibiting serotonin-induced vasoconstriction. This effect is favorable in cerebral vasoconstriction syndromes such as vasospasm after subarachnoid hemorrhage or trauma.

Pharmacokinetics

Approximately 35% of an oral dose of dantrolene is absorbed; peak plasma concentrations are reached in approximately 5 hours. The liver metabolizes dantrolene to

BOX 20.1 COMMUNITY BASED CONCERNS

Dantrolene Therapy and Malignant Hyperthermia

Malignant hyperthermia (MH) is a rare myopathy that is characterized by an acute hypermetabolic state within muscle tissue. It is an autosomal dominant inherited disorder with an incidence of approximately 1:15,000 pediatric patients and 1:40,000 adults. MH is triggered by certain drugs used during general anesthesia and presents with signs including masseter muscle rigidity, tachycardia, hypercarbia due to increased body metabolism, and fever that may exceed 110° F. Severe complications of MH include cardiac arrest, brain damage, internal bleeding, and organ failure. Death can result from these complications.

In order to achieve a successful outcome, an MH crisis must be promptly identified and treated early in the course of the crisis. Treatment strategies aim to terminate the episode and treat complications such as acidosis and hyperkalemia. Intravenous dantrolene is the mainstay of therapy for an MH crisis. Dantrolene directly interferes with muscle contraction by binding the RYR1 receptor calcium channel and inhibiting calcium release from the sarcoplasmic reticulum. The dose of dantrolene administered for an MH crisis is 2.5 mg/kg repeated every 5 minutes until the episode is terminated, up to 10 mg/kg.

Dantrolene may also be given prophylactically to prevent an MH episode in the perioperative period. However, this is not generally recommended as it may worsen muscle weakness in a patient that is already susceptible to muscular disease. Providing a non-triggering anesthetic to patients with a personal or family history of MH is key in prevention of an MH crisis.

The perioperative nurse can assist in preventing an MH episode by obtaining a detailed personal and family history from the patient, inquiring about adverse reactions to anesthesia. Any suspicious findings during the detailed history should be immediately communicated to the rest of the perioperative team including the surgeon and the anesthesia care team. Additionally, the perioperative nurse must be knowledgeable about the protocol for treatment of an acute MH crisis as he or she will frequently be called upon to assist in the treatment of this life-threatening crisis.

weakly active metabolites which are excreted in the urine. The elimination half-life is reported to be about 9 hours in healthy adults and 7.3 hours in children. Therapeutic effects in patients being treated for upper motor neuron disorders may not appear for 1 week or more. Dantrolene crosses the placenta and enters breast milk.

Pharmacodynamics

Dantrolene's mechanism of action differs from that of other oral skeletal muscle relaxants. Dantrolene reduces the force of contraction of skeletal muscle inhibiting the RYR receptor, which in turn reduces the amount of Ca^{2+} released from the sarcoplasmic reticulum, thereby uncoupling (relaxing) muscle contraction from excitation. Interference with the release of Ca^{2+} from the sarcoplasmic reticulum may prevent the increase in intracellular Ca^{2+}, which activates the acute catabolic events of malignant hyperthermia. Dantrolene has little or no effect on contraction of cardiac or intestinal smooth muscle. It may decrease hyperreflexia, muscle stiffness, and spasticity in patients with upper motor neuron disorders.

Contraindications and Precautions

Dantrolene is contraindicated in patients with active liver disease because of its associated liver toxicity. Dantrolene causes weakness because of its generalized reduction of muscle contraction. Thus, it is given very cautiously in patients who rely on spasticity to maintain an upright posture and balance, such as patients with cerebral palsy. Additionally, each vial of IV dantrolene contains 3 g of mannitol. Therefore, IV dantrolene may be inappropriate for patients with mannitol hypersensitivity.

No contraindications apply to IV administration of dantrolene to prevent or acutely treat malignant hyperthermia crisis in the perioperative period. Dantrolene should be used with caution in patients with pre-existing myopathy or neuromuscular disease with respiratory depression. The risk of perioperative complications is increased in patients with these conditions who receive dantrolene for prevention of malignant hyperthermia.

Dantrolene should also be used with caution in patients with cardiac disease and pulmonary dysfunction, particularly chronic obstructive pulmonary disease. For patients with cardiac disease, dantrolene can precipitate pleural effusions or pericarditis. In patients with pulmonary dysfunction, dantrolene can precipitate respiratory depression. Dantrolene is classified as a pregnancy category C drug; therefore, pregnant or lactating women should avoid its use.

Adverse Effects

The most common adverse effect of dantrolene therapy is muscle weakness. Manifestations of such muscle weakness may include drooling, dysphagia, slurred speech, drowsiness, dizziness, malaise, and fatigue. Serious adverse effects seen with dantrolene therapy include potentially fatal hepatitis, seizures, and pleural effusion with pericarditis. There are also rare reports of pulmonary edema following IV dantrolene administrations in which the diluent volume and mannitol needed to deliver the dantrolene may be the contributing factor.

In the GI system, symptoms include diarrhea, constipation, GI bleeding, anorexia, difficulty swallowing, abdominal cramps, and nausea and vomiting. Diarrhea is usually dose-dependent and transient, but in some cases it can be severe, and the drug may have to be withheld. Hematologic adverse reactions with dantrolene therapy include aplastic anemia, leukopenia, and lymphocytic lymphoma.

Rash, acne, abnormal hair growth, and photosensitivity are possible integumentary effects. IV dantrolene may cause edema and thrombophlebitis. Rarely, IV administration may cause erythema and urticaria.

Drug Interactions

Because dantrolene is metabolized by the liver, it is possible that metabolism may be enhanced by drugs that are known to induce hepatic enzymes. Drugs that interact with dantrolene include CNS depressants, clofibrate, estrogens, verapamil, methotrexate, and warfarin. Table 20.4 discusses these potential interactions.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a comprehensive health history, including any history of active hepatitis, estrogen use in women older than 35 years, impaired cardiac or pulmonary function, any liver disease, or spasticity used to sustain upright posture and balance in locomotion or to obtain or maintain increased function. Communicate positive findings for any of these factors to the prescriber.

Perform a physical examination before initiating therapy. Assessment of the musculoskeletal system should include the patient's posture, ability to walk, reflexes, and muscle tone. Document the amount and location of spasticity. Other assessments should include the CNS and GI systems. Laboratory tests should include a complete blood count (CBC) and AST, alanine aminotransferase, alkaline phosphatase, and total bilirubin levels.

Life Span and Gender

Consider the patient's age relative to dantrolene therapy. Hepatotoxicity occurs most commonly in patients older than 30 years of age, especially women older than age 35 who are taking estrogens. It generally occurs 3 to 12 months after starting dantrolene therapy. Children younger than 5 years should not receive dantrolene. Older patients are more vulnerable to the adverse effects of dantrolene. Before giving dantrolene, assess the patient for pregnancy and breast-feeding, because the safety of dantrolene therapy has not been established for pregnant or lactating women.

TABLE 20.4 Agents That Interact with P Dantrolene

Interactants	Effect and Significance	Nursing Management
Calcium channel blockers • diltiazem • verapamil	In combination with dantrolene, calcium channel blockers may increase hyperkalemia and myocardial depression.	Avoid coadministration, if possible. Monitor cardiac function. Monitor potassium levels.
Clindamycin	In combination with dantrolene, clindamycin may increase neuromuscular blockade.	Monitor for increased effects of dantrolene.
Clofibrate	Clofibrate may decrease plasma protein binding of dantrolene, resulting in decreased effects of dantrolene.	Monitor for efficacy of dantrolene therapy.
CNS depressant drugs • alcohol • benzodiazepines • barbiturates • opioids	In combination with dantrolene, CNS depressant drugs may have additive effects, increasing CNS depression.	Monitor for increased sedation. Institute safety measures, especially with ambulation.
Estrogens	Mechanism of interaction is unknown; women older than 35 y are at risk for hepatotoxicity when estrogens and dantrolene are coadministered.	Monitor for signs of hepatotoxicity. Coordinate periodic liver function tests for long-term therapy.
Nondepolarizing Neuromuscular blocking drugs • Rocuronium • Vecuronium • Cisatracurium • Pancuronium	Nondepolarizing neuromuscular blocking drugs are potentiated by dantrolene	Monitor for signs of neuromuscular weakness or incomplete reversal of blockade following general anesthesia. Signs may include respiratory impairment and muscle weakness
Phytomedicinals • *Valeriana officinalis* • kava kava • *Piper methysticum* • gotu kola	In combination with dantrolene, phytomedicinals may have additive effects, increasing CNS depression.	Monitor for increased sedation. Institute safety measures, especially with ambulation.
Psychotropic drugs • MAOIs • phenothiazines	In combination with dantrolene, psychotropic drugs may increase neuromuscular blockade.	Monitor for increased effects of dantrolene.
Methotrexate	The combination of dantrolene and methotrexate may increase methotrexate concentrations. Clearance of methotrexate is impaired by dantrolene or its metabolite 5-hydroxydantrolene	Monitor for increased effects of methotrexate.
warfarin	Warfarin may decrease plasma protein binding of dantrolene, resulting in decreased effects of dantrolene.	Monitor for efficacy of dantrolene therapy.

Lifestyle, Diet, and Habits

Dantrolene capsules contain lactulose. Therefore, assess the patient for lactose intolerance before the drug is given. Assess for alcohol consumption because alcohol increases the sedative properties of dantrolene.

Environment

Caution the patient about the potential for photosensitivity and advise wearing appropriate clothing and sunscreen whenever in direct sunlight. Because dantrolene causes muscle weakness, also discuss with the patient any barriers in the home (such as stairs) that may be affected by dantrolene therapy. In addition, caution the patient to assess the drug's effects before attempting to ambulate without assistance.

Nursing Diagnoses and Outcomes

- Risk for Injury related to muscular weakness
  Desired outcome: *The patient will be injury free despite muscular weakness.*

FOCUS ON RESEARCH

Potential Abuse of Muscle Relaxants

Owens, C., Pagmire, B., Salness, T., et al. (2007). Abuse potential of carisoprodol: a retrospective review of idaho medicaid pharmacy and medical claims data. *Clinical Therapuetics, 29*(10): 2222–2225.

The Study

Carisoprodol is a frequently prescribed muscle relaxant to treat acute painful musculoskeletal conditions. This retrospective review of claims data looks at potential indicators of abuse in long-term users of carisoprodol vs. other skeletal muscle relaxants. Patients in both groups were similar in age, gender, and skeletal muscle relaxant-related indications. Researchers identified that patients taking carisoprodol used concomitant opioids more frequently, more commonly had a previous drug abuse diagnosis, and continued to pay out of pocket when insurance coverage was discontinued as compared to those patients taking other skeletal muscle relaxants. Collectively these factors suggest the abuse potential of carisoprodol.

Nursing Implications

This research study demonstrates the potential for patients to abuse carisoprodol over other skeletal muscle relaxants. It is important for the nurse to recognize this possible drug characteristic and assess for indications of abuse. Likewise, educating patients of the potential to abuse this drug and the risk of becoming physically dependent is important. Addiction has psychosocial, environmental, and behavioral dimensions that the nurse must be able to assess and easily recognize.

- Diarrhea or Constipation related to drug effects
  Desired outcome: *The patient will maintain baseline bowel habits.*
- Risk for Disturbed Sensory Perception: Kinesthetic, related to dizziness, malaise, and fatigue
  Desired outcome: *The patient will remain free of injury from adverse effects.*
- Disturbed Body Image related to drug-related dermatologic effects
  Desired outcome: *Any adverse effects will be resolved by the end of therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer dantrolene with food or milk to avoid gastric distress. For patients with difficulty swallowing, mix the contents of the capsule with fruit juice and administer immediately. If extended-release capsules or tablets are prescribed, do not open or crush them.

Minimizing Adverse Effects

To avoid injury, supervise the transfer or ambulation of patients taking dantrolene. Also, provide frequent skin care and hygiene measures to prevent skin breakdown and request treatment for acne if appropriate. Protecting the patient from exposure to ultraviolet light is important, as is providing sunscreen if exposure is inevitable.

Therapy is initiated at low doses and gradually increased to minimize dose-related side effects. This practice also determines the minimum effective dose and allows a smooth induction of antispastic effects.

Providing Patient and Family Education

- Before the drug is given, explain to patients and family that the drug is being used to relieve spasticity and that muscle weakness may occur. Family members should be instructed to assist patients with ambulation and ensure safety precautions.
- Inform patients that one of the most dangerous adverse effects of dantrolene therapy is hepatitis. Write down a list of symptoms for patients to report to the prescriber immediately, including loss of appetite, nausea, vomiting, yellowed skin or eyes, and changes in color of urine or stool. Also, explain that regular follow-up medical care, including blood tests, is necessary to monitor the effects of the drug on the body.
- Advise patients that other adverse effects may occur, such as drowsiness, dizziness, GI upset, diarrhea or constipation, or rash. Discuss self-care measures to alleviate common symptoms and urge patients to contact the prescriber if the symptoms do not abate. To avoid photosensitivity, advise patients to wear appropriate clothing and use sunscreen when in direct sunlight.

Ongoing Assessment and Evaluation

Monitor for improvement in symptoms of spasticity and decrease in resistance to passive movement of the limb joint. Beneficial effects in spasticity may take 1 week or more to appear. Assist ambulatory patients with locomotion, because muscle weakness may increase.

Monitor for signs of adverse effects, especially hepatitis and hematologic effects. Coordinate periodic laboratory tests to evaluate liver function and the CBC. Withhold dantrolene and contact the prescriber if clinical signs of hepatitis appear.

Drug Closely Related to P Dantrolene

Botulinum toxin type A (Botox) is a neurotoxin used for its muscle-relaxing properties. It is a protein that is produced by the anaerobic bacterium *Clostridium botulinum*. As many as seven serotypes of botulinum neurotoxin exist, but only types A and B are in clinical use at this time. Botulinum toxin type B (Myobloc) is less potent and shorter-acting than botulinum toxin type A.

Botulinum toxin type A is produced under controlled laboratory conditions and is given in extremely small therapeutic doses (0.05 to 0.1 mL per injection site). It blocks neuromuscular conduction by binding to receptor sites

P Dantrolene

- Peripherally acting spasmolytic is used for muscle spasms or spasticity.
- Drug of choice for preventing or treating malignant hyperthermia
- Major contraindications: patients who use spasticity to maintain posture or balance (such as patients with cerebral palsy) or who have active hepatic disorders
- Most common adverse effect: muscle weakness; safety is a nursing priority
- Most serious adverse effect: fatal hepatitis, especially in women older than 35 years who are taking estrogens
- Maximizing therapeutic effects: Give with food or milk to decrease GI distress.
- Minimizing adverse effects: Assist with ambulation.
- Most important patient education: Advise patients of symptoms of hepatitis and the importance of notifying the prescriber should any occur.

on motor nerve terminals, entering nerve terminals, and inhibiting the release of acetylcholine. Conditions that are treated with botulinum toxin injections include muscle contraction, headaches, chronic muscle spasms in the neck and back, torticollis (severe neck muscle spasms), myofascial pain syndrome, and spasticity from MS or CVA. Botulinum toxin type A is given as an IM injection. Gradual relaxation of muscle spasm develops 1 to 2 weeks after the injection. The reduction of muscle spasm lasts for 3 to 4 months, and pain relief can last even longer. Potential adverse effects from the injection may include temporary increase in pain, weakness in the muscles injected, body aches, dry mouth, hoarseness, and flu-like symptoms. It is contraindicated in the presence of infection at the proposed injection site.

Additionally, botulinum toxin type A reduces contractions associated with blepharospasms and corrects eye alignment in patients with strabismus. It may also treat primary axillary hyperhidrosis (severe underarm sweating), excessive drooling associated with neurologic disorders, and is considered the second-line therapy for neurogenic bladder.

In 2002, the FDA approved botulinum toxin type A (Botox Cosmetic) for cosmetic use. It has been successfully used to treat severe glabellar (frown) lines and is approved for use in adult patients up to 65 years of age. When botulinum toxin type A is injected into the muscles in a particular area of the face, those muscles cannot "scrunch up" for a period of time because they are paralyzed. The effect lasts for 3 to 6 months. Teach your patient the importance of receiving this type of treatment in a medical facility rather than at a "Botox party."

Formation of antibodies to botulinum toxin type A may reduce the effectiveness of the toxin by inactivating its biologic activity. This can be minimized by injecting with the lowest possible dose and allowing for longer intervals between injections.

CHAPTER SUMMARY

- Drugs used to manage muscle spasm and spasticity are divided into muscle relaxants and spasmolytics. Muscle spasm is a sudden, violent, involuntary contraction of a muscle or group of muscles.
- Cyclobenzaprine (Flexeril) is the prototype for centrally acting muscle relaxants.
- Centrally acting muscle relaxants do not act directly on painful muscles; rather, they work by their CNS depressant activity.
- Most centrally acting muscle relaxants are not effective in treating spasticity.
- In addition to their CNS depressant effects, centrally acting muscle relaxants have anticholinergic and antihistaminic effects.
- Safety is a primary concern for patients receiving centrally acting muscle relaxants and spasmolytics.
- Centrally acting muscle relaxants should be given with caution to older adults. They are not indicated for use in children.
- Spasticity is a prolonged increased tone in muscles that may lead to contraction.
- Baclofen (Lioresal) is the prototype centrally acting spasmolytic drug.
- Gabapentin (Neurontin) is a miscellaneous antiepileptic drug that also has spasmolytic properties.
- Dantrolene (Dantrium) is a peripherally acting spasmolytic that affects spasticity within the muscle fibers.
- Botulinum toxin type A (Botox) is used to manage chronic muscle spasms that do not respond to other treatment methods. It may also be used for cosmetic purposes.
- Spasmolytics should be used cautiously in patients who require spasticity to remain upright.

QUESTIONS FOR STUDY AND REVIEW

1. What is the difference between muscle spasm and muscle spasticity?
2. Your patient, who has a history of depression, rammed his car into a light pole, sustaining multiple contusions and abrasions. The patient is taking amitriptyline (Elavil) four times a day and diazepam (Valium) as needed. The patient is placed on cyclobenzaprine for muscle spasms of the neck and back. What precautions would you take with this patient?
3. Which drugs are effective in managing both muscle spasm and muscle spasticity?
4. Why is baclofen ineffective for spasms from CVA or Parkinson disease?
5. What symptoms suggest hepatitis in the patient who is on long-term dantrolene therapy?
6. Your patient was injured in a motor vehicle crash yesterday. The patient has severe musculoskeletal pain in the upper back. Is botulinum toxin a good choice for the management of this patient?

Drugs Treating Parkinson Disease and Other Movement Disorders

Learning Objectives

At the completion of this chapter the student will:

1. Correlate the pathophysiology of movement disorders with appropriate pharmacotherapy.
2. Identify core drug knowledge about drug therapies that affect movement disorders.
3. Identify core patient variables related to drugs that affect movement disorders.
4. Relate the interaction of core drug knowledge to core patient variables for therapies that affect movement disorders.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for therapies that affect movement disorders.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect movement disorders.
7. Determine key points for patient and family education for drugs that affect movement disorders.

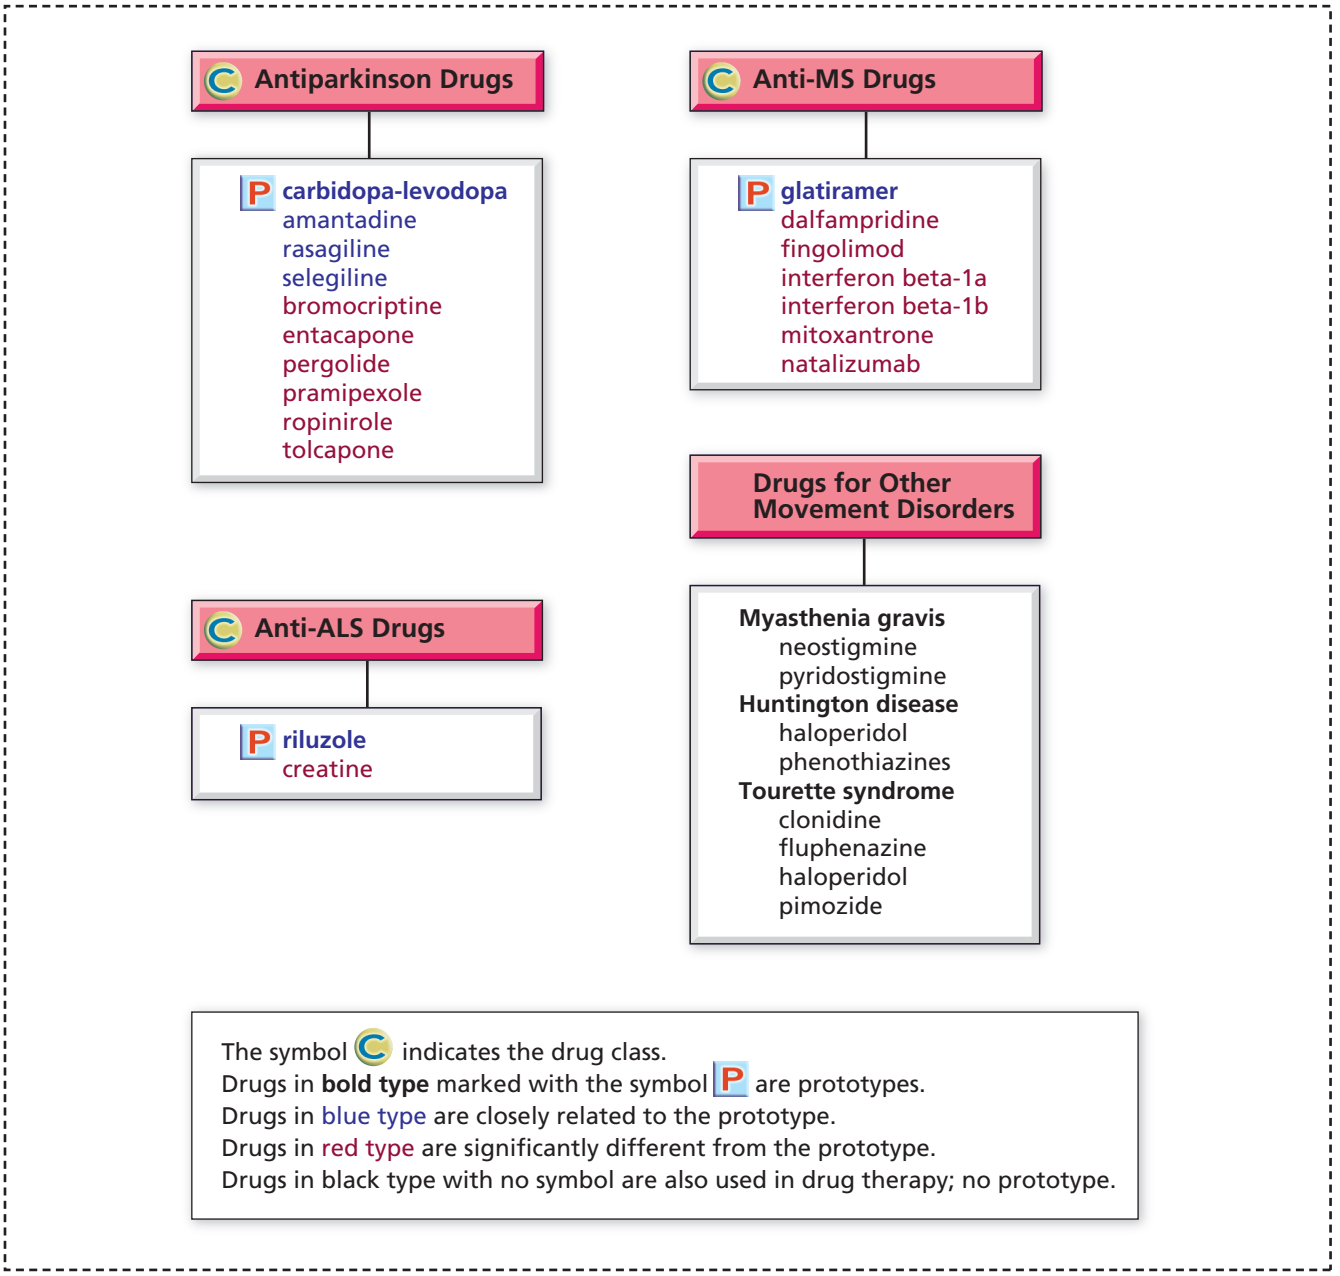
Drugs Treating Parkinson Disease and Other Movement Disorders



Movement disorders can be chronic, severe, and debilitating. These disorders are incurable, and patients with them have various responses to treatment. As a result of a disorder's progression, patients may become socially isolated and depressed. As patients become increasingly disabled and the drugs become minimally effective, your primary role shifts from one of medical intervention to psychosocial and functional care, with the aim of helping the patient maximize remaining capacities. This chapter limits the discussion to the nurse's pharmacologic role. Information on the nonpharmacologic role of the nurse can be found in a medical-surgical textbook or subject-specific website.

This chapter discusses three major movement disorders—Parkinson disease, amyotrophic lateral sclerosis (ALS), and multiple sclerosis (MS)—focusing on drugs used to inhibit the symptoms associated with these diseases. In addition, it discusses core drug knowledge, core patient variables, nursing management, potential nursing diagnoses, and patient education related to the use of these drugs.

PHYSIOLOGY

The extrapyramidal system is responsible for coarse control of voluntary muscles. This "system" is composed of basal ganglia, cortical areas of the brain that project to the basal ganglia, cerebellar areas of the brain that project to the basal ganglia, and parts of the reticular formation and thalamic nuclei that connect to the basal ganglia. Motor activity requires integration of the actions of the cerebral cortex, basal ganglia, and cerebellum.

The basal ganglia are a group of functionally related nuclei located in paired groups in each cerebral hemisphere. Two primary nuclei are the corpus striatum, located deep within the cerebrum, and the substantia nigra, a group of darkly pigmented cells located in the midbrain. When the basal ganglia are stimulated, muscle tone in the body is inhibited, and voluntary movements are refined.

The regulatory neurotransmitter *dopamine* is produced in the substantia nigra and adrenal glands, and then transmitted to the basal ganglia along a neural pathway for secretion when needed. Recently, five dopamine receptors have been identified in the brain. Three of these receptors (dopamine-1, dopamine-2, and dopamine-3—usually called D_1, D_2, and D_3, respectively) appear to play important roles in properly balancing the stimulation of the basal ganglia involved in normal motor function. Acetylcholine, an excitatory neurotransmitter, is produced by the basal ganglia and in the nerve endings in the periphery of the body. When the body wants to make a movement (e.g., walking or picking up a cup of coffee), the striatum releases dopamine and acetylcholine through the nervous system to the appropriate muscles, which enables initiation, modulation, and completion of smooth, coordinated movement within a fraction of a second.

PATHOPHYSIOLOGY

Parkinson Disease

Parkinson disease occurs with death of the neurons that produce dopamine, a neurotransmitter in the brain. Parkinson disease generally afflicts patients aged 60 years and older, is more apt to affect men than women and progresses slowly to neuromuscular debilitation. Researchers have found that a mutated gene, called a parkin gene, may trigger the disease at an earlier age. Although 13 genes have been linked with Parkinson disease, genetics seems to play only a small role in the development of the disease. Other risk factors associated with Parkinson disease include head trauma, well water consumption and environmental toxins such as herbicides and pesticides. No conclusive evidence exists designating the cause of Parkinson disease; yet scientists believe that the disease occurs due to an interaction of genetics and environment. In Parkinson disease, degeneration of the neurons that supply dopamine to the striatum occurs, resulting in reduced dopamine in the nerve terminals of the nigrostriatal tract. Consequently, an imbalance exists between dopamine inhibition and acetylcholine excitation (Figure 21.1). Additionally, unopposed acetylcholine stimulates the release of gamma-aminobutyric acid (GABA). The combination of excessive acetylcholine and GABA is the basis for most symptoms of Parkinson disease, such as muscle rigidity, tremor at rest, **akinesia** (loss of voluntary movement) or **bradykinesia** (abnormal slowness of movement), and postural instability.

Dopamine is the neurotransmitter that sends information to the parts of the brain that control movement and coordination. As the disease progresses, messages from the brain telling the body how and when to move are delivered more slowly, leaving the patient incapable of initiating or controlling normal movements. Patients may also experience depression, emotional changes, and sleep problems. Memory loss and slow thinking may develop, although the ability to reason usually remains intact.

Parkinsonism is a syndrome with characteristics similar to Parkinson disease that are secondary to other conditions that structurally damage the dopaminergic pathway or interfere with dopamine's action within the basal ganglia. Well-known precipitants of parkinsonism are drugs such as the phenothiazines, metoclopramide, and reserpine. Drug-induced parkinsonism is usually reversible when the drugs are discontinued.

Amyotrophic Lateral Sclerosis

ALS is a progressive neurologic disorder related to degeneration of nerve cells responsible for controlling voluntary movement. It is also known as Lou Gehrig disease, after the famous baseball player who succumbed to the disorder. The etiology of ALS is unknown. It presents in adulthood, usually between ages 40 and 60 years, and affects men two to three times more often than women. ALS affects both the upper

• FIGURE 21.1 (**A**) Normal balance. This figure depicts the body at rest when the dopamine and acetylcholine systems are balanced. When the body moves, the brain understands the movement the body wants to make and it sends out a balance of dopamine and acetylcholine messages to keep that movement smooth. This figure represents Parkinson disease, in which the normal levels of acetylcholine and dopamine are imbalanced and abnormal movement affects the body until chemical balance can be restored, to a degree.

motor neurons in the cerebral cortex and the lower motor neurons in the brain stem and spinal cord. Although this disorder is neurologic, one of its classic features is that it spares the entire sensory system and the intellect. Additionally, it spares the cranial nerves that innervate movement of the eye (cranial nerves III, IV, and VI).

The disease begins in the distal neurons and then progresses in a centripetal but asymmetric fashion. The loss of upper motor neurons results in spastic paralysis and hyperreflexia. The loss of lower motor neurons results in decreased muscle tone and reflexes and flaccid paralysis. Ultimately, neuronal cell death leads to muscular weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Although periods of remission may occur, ALS typically progresses rapidly, and death occurs within 5 years for 50% of patients diagnosed with the disease.

Multiple Sclerosis

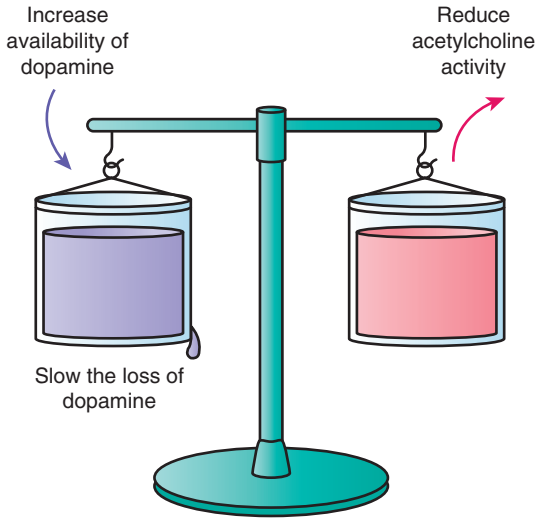
Multiple sclerosis is an automimmune disease where the body attacks the myelin sheath resulting in neuromuscular debilitation. MS is a major cause of neurologic disability among young and middle-aged adults. There are four disease courses of MS: relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing.

At the time of diagnosis, 85% of patients have relapsing-remitting MS, which is characterized by clearly defined relapses (also called exacerbations, flare-ups, or attacks). The relapse is followed by partial or complete recovery periods (remissions). Approximately 10% of MS patients have primary progressive MS. This form of MS is characterized by a slow but nearly continuous worsening of the disease from the onset of MS, without distinct relapses or remissions. There may be a variation in the rate of progression, an occasional plateau, or a temporary minor improvement. Before the use of disease-modifying drugs, 50% of patients with relapsing-remitting MS developed secondary progressive MS within 10 years of diagnosis. In this subtype, the symptoms of MS change from those of relapsing-remitting MS to a steady progression of the disease with or without intermittent relapse and remission. It is unclear whether the use of disease-modifying drugs will alter the timing of this subtype. Progressive-relapsing MS, which affects only 5% of patients, is rare. This type of MS is characterized by a steady progression of disease, but the patient also has clear acute relapses with or without recovery. This differs from relapsing-remitting MS because of the steady progression of the disease between relapses and remissions.

In MS, more than one area of inflammation and scarring of the myelin in the brain and spinal cord occurs. When myelin is damaged, messages between the brain and other parts of the body are affected. The most common symptoms of MS include fatigue, weakness, spasticity, balance problems, bladder and bowel problems, numbness, vision loss, tremor, and vertigo. The signs and symptoms reflect the location of the lesions; therefore, not every patient experiences every symptom of MS.

ANTIPARKINSON DRUGS

The relative lack of dopamine, combined with the relative excess of excitatory acetylcholine, causes the symptoms of Parkinson disease. The goal of therapy is to restore the balance between dopamine and acetylcholine, which can



• FIGURE 21.2 The goal of pharmacologic treatment for Parkinson disease is to restore the homeostatic balance between acetylcholine and dopamine, which can be accomplished by increasing the amount or availability of dopamine, slowing the loss of dopamine, or blocking the activity of acetylcholine.

be accomplished by increasing the activity of dopamine or blocking the action of acetylcholine (Figure 21.2).

Drugs used to treat Parkinson disease increase dopamine levels **(dopaminergics)**, stimulate dopamine receptors (dopamine agonists), extend the action of dopamine in the brain (dopa decarboxylase [DDC] or catecholamine O-methyl transferase [COMT] inhibitors), or prevent the activation of cholinergic receptors (anticholinergics). Anticholinergics are discussed in depth in Chapter 14; thus they are only briefly summarized in this chapter. Information about antiparkinson agents is given in Table 21.1.

• C Dopaminergics

The combination drug carbidopa-levodopa (Sinemet, Parcopa) is the prototype for the dopaminergics.

The logical solution to the imbalance in Parkinson disease is to administer dopamine to the patient; however, dopamine does not cross the blood–brain barrier. Therefore, levodopa, the precursor to dopamine, is the drug of choice, because it does cross the blood-brain barrier and will be converted into dopamine in the brain. Unfortunately, levodopa is largely deactivated in the periphery of the body by two enzymes: dopamine decarboxylase(DDC) and catechol-*O*-methyl transferase (COMT).

When levodopa is administered as a single drug, approximately 2% actually crosses the blood–brain barrier. To increase the amount of levodopa available to cross the blood–brain barrier, it is combined with the drug carbidopa, a DDC inhibitor. Carbidopa does not cross the blood–brain barrier, but it decreases peripheral destruction of levodopa, allowing 10% of levodopa to reach the brain.

Nursing Management of the Patient Receiving P Carbidopa-Levodopa

Core Drug Knowledge

Pharmacotherapeutics

Carbidopa-levodopa (Sinemet, Parcopa) is a combination drug used in treating Parkinson disease. It is also used to treat restless-leg syndrome.

Pharmacokinetics

With oral administration, carbidopa-levodopa may begin to take effect after 1 to 2 months, although some patients require up to 6 months of therapy before noting an effect. The plasma half-life of both carbidopa-levodopa and carbidopa alone is roughly 1 to 2 hours, and the duration of action of a dose is 5 hours. Most carbidopa-levodopa is metabolized into dopamine in the periphery of the body, whereas carbidopa itself is minimally metabolized. Carbidopa-levodopa is eliminated renally as dopamine metabolites and in small amounts as unchanged drug. In addition, carbidopa-levodopa crosses the placenta and is present in breast milk.

Pharmacodynamics

Carbidopa-levodopa diffuses levodopa into the central nervous system (CNS), where it is converted to dopamine. The resulting change in dopamine–acetylcholine balance is believed to improve nerve impulse control and to form the basis of the drug's antiparkinsonian activity. Carbidopa does not cross the blood–brain barrier.

When carbidopa is administered in combination with levodopa, it inhibits the conversion of levodopa to dopamine in the periphery of the body, thereby increasing the amount of levodopa available to diffuse into the CNS. Because the bioavailability of dopamine increases in the CNS, the dosage of levodopa can be reduced. This reduction minimizes the potential for nausea/vomiting adverse reactions from levodopa. The carbidopa-levodopa combination also enables more rapid and even titration of effect.

Contraindications and Precautions

Patients with hypersensitivity to carbidopa-levodopa should not take the drug. Carbidopa-levodopa can activate malignant melanoma; thus, the drug is contraindicated in patients with undiagnosed pigmented lesions or a history of melanoma. Although carbidopa-levodopa may not be used in patients with closed-angle glaucoma, it may be used in patients with open-angle glaucoma if intraocular pressure is closely monitored and controlled. Simultaneous administration of carbidopa-levodopa with monoamine oxidase inhibitors (MAOIs) can result in hypertensive crisis. Therefore, MAOIs should be discontinued 2 to 4 weeks before therapy with carbidopa-levodopa begins.

Precautions to carbidopa-levodopa therapy include cardiac disease (especially arrhythmias or past myocardial infarction [MI]), pulmonary disease, peptic ulcer disease,

and diabetes mellitus. Carbidopa-levodopa may exacerbate symptoms in patients with these disorders.

Additionally, carbidopa-levodopa may cause mental status changes and should be used with caution in patients with a history of psychiatric disorders. All patients receiving carbidopa-levodopa should be monitored closely for signs of mental disturbances, including depression or suicidal thoughts.

Adverse Effects

Adverse gastrointestinal (GI) effects are common in patients receiving carbidopa-levodopa and include nausea and vomiting, anorexia, and weight loss. Another common adverse effect to carbidopa-levodopa therapy is orthostatic hypotension.

Of the more serious adverse effects of carbidopa-levodopa therapy, abnormal movements are the most common. These abnormal movements result from the increased dopamine in the brain. Abnormal and involuntary movements include the following:

- Continuous rapid jerky involuntary movements resembling a grotesque dance (**chorieform** movements)
- Jerking, twisting movements distinguished by prolonged rhythmic muscle contractions (**dystonic** movements)
- Difficulty executing voluntary movements resulting in tic-like behavior (**dyskinetic** movements)
- Clenching the teeth, associated with forceful lateral or protrusive jaw movements, resulting in rubbing, gritting, or grinding the teeth (**bruxism**)
- Jerking, flinging movements of an extremity (**ballismus**)
- Protrusion of the tongue
- Opening and closing of the mouth
- Bobbing of the head
- Rhythmic movements of the feet or hands
- Quick movements of the shoulder

Abnormal movements are usually dose related and may resolve with a reduction in dose. Unfortunately, with a dose reduction, the symptoms of Parkinson disease may recur.

Psychiatric disturbances may develop with the administration of carbidopa-levodopa. Symptoms include memory loss, anxiety, nervousness, agitation, restlessness, confusion, insomnia, nightmares, daytime somnolence, euphoria, malaise, and fatigue. Patients taking carbidopa-levodopa are also at risk for developing severe mental depression, suicidal tendencies, dementia, hallucinations, paranoid delusion, psychoses, and hypomania.

Cardiac arrhythmias can occur during carbidopa-levodopa therapy because conversion of levodopa to dopamine in the periphery can activate beta-1 receptors. This occurs most frequently in patients with a history of heart disease. Other cardiovascular symptoms include flushing and hypertension.

For patients taking carbidopa-levodopa for a prolonged period, **bradykinetic episodes,** also known as the "**on–off syndrome,**" may occur. Characteristics of this syndrome include akinesia, a sudden return of the effectiveness of the drug, and akinesia paradoxica (an abrupt hypotonic reaction in which the patient usually falls as he or she begins to walk). The akinetic episode can last from minutes to hours. A sudden return of effectiveness may follow, and the cycle can recur many times each day. Recently, the Food and Drug Administration (FDA) approved a new drug to treat these episodes in patients with Parkinson disease (Box 21.1). Loss of response to levodopa may also occur as a more gradual process, usually before the next dose of medication.

Neuroleptic malignant syndrome (NMS, also called parkinsonian crisis) is characterized by an abrupt onset of marked rigidity, akinesia, tremor, and hyperpyrexia. It can follow abrupt discontinuation of carbidopa-levodopa

BOX 21.1 COMMUNITY BASED CONCERNS

Treating Hypomobility in Parkinson Disease

Patients with advanced Parkinson disease who are taking levodopa may experience bradykinetic episodes, also known as "on–off syndrome." These episodes are characterized by a shift from the ability to be mobile (on) to an unpredictable period of immobility (off). The intensity, duration, and frequency of "off" periods vary from patient to patient. Intensity ranges from partial loss of movement to total immobility. On–off syndrome is thought to be related to an increased sensitivity in the brain to small changes in serum levels of dopamine.

Apomorphine hydrochloride (Apokyn) has been approved by the Food and Drug Administration (FDA) as an orphan drug for treating acute, intermittent episodes of hypomobility. Apomorphine hydrochloride helps the patient walk, talk, or move more easily, but it does not prevent hypomobility, nor does it replace the patient's drugs for Parkinson disease.

Apomorphine hydrochloride is given as a subcutaneous injection. Symptoms improve within 15 minutes, and the effect lasts for approximately 2 hours. The drug must be given with an antiemetic, because it can induce nausea and vomiting. It should not be given concurrently with antiemetic agents classified as 5-HT_3 antagonists, because this type of antiemetic drug can induce hypotension or loss of consciousness. Examples of these drugs include ondansetron, granisetron, dolasetron, palonosetron, and alosetron. Common adverse effects associated with apomorphine hydrochloride include yawning, dyskinesias, nausea and vomiting, sedation or sleepiness, dizziness, runny nose, hallucinations, edema, chest pain, increased sweating, flushing, and pallor. Apomorphine hydrochloride is an FDA pregnancy category C drug. It is unknown whether it enters breast milk.

When educating patients about apomorphine hydrochloride, you must emphasize the importance of continuing all drugs prescribed for Parkinson disease, despite symptom relief with apomorphine hydrochloride. In addition, emphasize the importance of taking the drug with certain antiemetic drugs. Monitor the first injection to evaluate the patient's or caregiver's ability to administer a subcutaneous injection correctly; emphasize the importance of aspirating before injecting to avoid intravenous (IV) administration.

TABLE 21.2 Agents That Interact with P Carbidopa-Levodopa

Interactants	Effect and Significance	Nursing Management
Hydantoins	Mechanism of action unknown, but decrease effectiveness of carbidopa-levodopa	Monitor for decreased therapeutic effects. Consider alternative antiepileptic therapy.
iron salts	May form chelates that decreases carbidopa- levodopa absorption	Separate administration of these two drugs as much as possible. Monitor for decreased therapeutic effects.
MAOIs	Inhibit peripheral metabolism of carbidopa- levodopa, resulting in increased levels of dopamine; may result in hypertensive crisis	Do not co-administer these drugs. If accidental administration occurs, phentolamine is the antidote.
phenothiazines	May inhibit dopamine receptors in the CNS	Monitor for decreased therapeutic effects.
tricyclic antidepressants	Delay the absorption of carbidopa-levodopa and may decrease its bioavailability	Monitor for decreased therapeutic effects.

therapy, and it occurs most frequently in patients who are also receiving antipsychotic drugs.

Other adverse effects associated with carbidopa-levodopa include episodic hyperventilation, bizarre breathing patterns, hoarseness, and increased nasal secretions. Urinary retention, polyuria, and urinary incontinence may also occur. Rarely, leukopenia may occur, necessitating discontinuing the drug temporarily.

When levodopa (Dopar) is given alone, it may induce dark-colored sweat or urine.

Drug Interactions

Carbidopa-levodopa can interact substantially with hydantoins, MAOIs, phenothiazines, or tricyclic antidepressants (TCAs). Levodopa alone interacts with pyridoxine. Table 21.2 presents a list of agents that interact with carbidopa-levodopa.

Carbidopa-levodopa administration may cause abnormalities in laboratory tests. Elevations of liver function test values such as alkaline phosphatase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactic dehydrogenase (LDH), and bilirubin may occur. Commonly, levels of blood urea nitrogen, creatinine, and uric acid are lower during administration of carbidopa-levodopa. Carbidopa-levodopa may cause a false-positive reaction for urinary ketone bodies when a test tape is used for determination of ketonuria. False-negative tests may result with the use of glucose-oxidase methods of testing for glucosuria.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for tartrazine allergy, melanoma, and closed-angle glaucoma. Assess also for a history of psychiatric disorders that necessitate administration of MAOIs. If the patient has any of these disorders, notify the prescriber before administering carbidopa-levodopa.

Assess for previous levodopa or carbidopa-levodopa therapy. After 2 to 5 years of continuous therapy, these drugs lose their overall effectiveness in controlling symptoms of Parkinson disease. Administering a higher dose may affect symptoms but also increases the patient's risk of adverse effects.

Perform a complete physical examination, including mental status. Carbidopa-levodopa can exacerbate diseases or disorders in every body system; therefore, evaluate baseline functioning. Appropriate laboratory or diagnostic tests are determined in part by the patient's pre-existing conditions. Patients with cardiovascular disorders require a baseline electrocardiogram. Patients with pulmonary disorders should have baseline pulmonary function tests. Patients with glaucoma should have intraocular pressure measured at baseline. For patients with diabetes, a glycosylated hemoglobin (HbA_{1C}) level should be obtained. Baseline hepatic function or renal function tests are included for patients with disorders in those body systems.

Throughout the physical examination, document the signs and symptoms of Parkinson disease, such as abnormal posture and gait, muscle rigidity, and tremors. Assess the patient's ability to perform activities of daily living such as dressing, eating, and walking. This baseline information is used to assess the efficacy of carbidopa-levodopa therapy and progression of the disease.

Some patients receiving carbidopa-levodopa have experienced postoperative bleeding episodes; therefore, hematologic studies are recommended for all patients who undergo surgery while receiving the drug (Box 21.2).

Life Span and Gender

Carbidopa-levodopa is a Food and Drug Administration (FDA) pregnancy category C drug and therefore should be used with caution during pregnancy. It should not be given to breast-feeding women because carbidopa-levodopa enters breast milk and may inhibit lactation. Therefore, assess all female patients for pregnancy or breast-feeding. In addition, carbidopa-levodopa should not be administered

BOX 21.2 FOCUS ON RESEARCH

Cohen, J. A., et al. (2010). Oral fingolimod or intramuscular interferon for relapsing multiple sclerosis. *The New England Journal of Medicine,* 362(5), 402–415.

Rationale

Presently, glatiramer acetate and beta interferon are FDA-approved drugs for use in relapse remitting MS and have been shown to reduce relapse rates by approximately 30%; yet both drugs are associated with systemic reactions in up to 60% of patients and need to be given parenterally. Oral fingolimod has been shown to decrease the number of lymphocytes circulating within the body and the lymphocytes ability to initiate an autoimmune reaction on the axons in the myelin sheath. Previous studies on fingolimod have been smaller scale and shorter term investigations.

The Study

A double-blind, double-dummy study comparing fingolimod to interferon beta-1a was conducted on randomly assigned 1,153 relapsing remitting multiple sclerosis patients to determine fingolimod's impact on the relapse rate over one year. This phase 3 clinical trial demonstrated a significantly decreased annualized relapse rate and a decrease in new or enlarged lesions on MRI with 1 year's use of fingolimod versus the use of interferon. No significant findings were obtained related to sustained progressive disability. Adverse effects included hypertension, bradycardia/AV block, increased liver enzymes, macular edema, skin cancer, and two fatal infections from either herpes simplex encephalitis or disseminated primary varicella zoster. Studies transcending longer periods of time are necessary to establish safety and efficacy of this drug in MS patients.

Nursing Implications

The study is a phase 3 clinical trial meaning that the drug is being investigated on large groups of patients using randomized controlled methods at multi-centered sites to compare the 'gold standard' to the experimental drug. The keys for nurses are to become familiar with the process of clinical trials used before the drug is launched on the market, consider the nursing role in clinical trials and to increase nursing knowledge of drugs on the horizon as the drug nears appropriate regulatory agency approval for use by the public.

to children younger than 18 years of age, so confirm that the patient is 18 years or older.

Lifestyle, Diet, and Habits

Coordinate a consultation with a nutritionist for patients taking carbidopa-levodopa. Patients should attempt weight control because increased body weight increases the work of the body, especially the muscles. A high-protein diet can slow or prevent absorption of carbidopa-levodopa. Therefore, moderate amounts of protein should be divided equally for consumption throughout the entire day. Pyridoxine (vitamin B_6) increases the action of decarboxylases that destroy levodopa in the periphery of the body, resulting in reduced effects of levodopa. Accordingly when taking levodopa alone, patients should avoid foods containing large amounts of pyridoxine, such as avocados, bananas, beef liver, oatmeal, halibut, chicken, pork, mashed potatoes, wheat germ, and sunflower seeds. Because carbidopa inhibits the action of the pyridoxine, patients taking carbidopa-levodopa (Sinemet) may eat foods high in pyridoxine or take pyridoxine supplements. Patients should also increase dietary fiber and fluids to offset the potential for constipation.

Environment

Carbidopa-levodopa is usually administered in the home environment. Assess patients for their ability to understand the prescriber's directions and to physically self-administer drugs. A new formulation of the combination drug (Parcopa), which dissolves rapidly on the tongue, may improve patients' ability to self-medicate. Home care referrals are necessary for patients who cannot self-medicate. Because carbidopa- levodopa does not affect the progression of the disease, coordinate counseling and physical and occupational therapies for the patient to optimize therapeutic outcome.

Culture and Inherited Traits

In decarboxylation, carbidopa-levodopa is metabolized by COMT, which antagonizes the therapeutic effects of carbidopa-levodopa. COMT activity destroys levodopa in the periphery of the body and is found in higher amounts in people of Chinese, Filipino, or Thai descent. Therefore, ask patients about their ethnic heritage as part of the assessment.

Nursing Diagnoses and Outcomes

- Disturbed Thought Processes related to adverse CNS effects
  Desired outcome: *The patient will remain oriented and communicate effectively.*
- Disturbed Sleep Pattern related to drug therapy
  Desired outcome: *The patient will report alterations in sleep patterns affecting activities of daily living.*
- Impaired Physical Mobility related to on–off effect
  Desired outcome: *The patient will immediately report incidents of the on–off syndrome to the prescriber.*
- Risk for Injury related to drug-induced orthostatic hypotension
  Desired outcome: *The patient will learn to change position slowly, carefully, and safely to minimize effects of orthostatic hypotension.*

Planning and Intervention

Maximizing Therapeutic Effects

Have patients take carbidopa-levodopa on an empty stomach to facilitate absorption of the drug. If the patient has trouble swallowing pills, the rapid-dissolving formulation should be used. Monitor the patient's diet to limit foods high in protein. If the drug causes severe nausea, give the patient a small amount of food 15 to 30 minutes after administering drug therapy.

Minimizing Adverse Effects

Administer carbidopa-levodopa at evenly spaced intervals, and always titrate the dose. Slowly increase the dose to prevent nausea, vomiting, or orthostatic hypotension, and slowly decrease it to prevent NMS (parkinsonian crisis).

Providing Patient and Family Education

- Advise patients that carbidopa-levodopa therapy is palliative and will not cure the disease. Patients must understand that it takes weeks to months to notice benefits from therapy. Caution patients that they should neither change the drug dosage in an attempt to hasten the therapeutic benefits nor discontinue the drug abruptly because they think treatment has failed.
- Advise patients to notify the prescriber about any of the following adverse reactions: uncontrollable movements of the face, eyelids, mouth, tongue, neck, arms, hands, or legs; mood or mental changes; irregular heartbeat or palpitations; difficult urination; severe or persistent nausea or vomiting; appetite loss; difficulty swallowing; or distorted taste.
- Demonstrate how to change positions slowly to avoid dizziness or fainting. Advise patients to assess how the drug affects them before driving, using machinery, or performing tasks that require mental alertness.
- Discuss the potential for "on–off syndrome" described in the section on Adverse Reactions. Ensure that patients understand that they are at risk for injury from falls during the "off" periods. Convey the importance of contacting the prescriber immediately if patients experience an akinetic episode. Advise the patient to report gradual "off" periods before the next dose. Adjustment of medications may decrease this occurrence.
- Include necessary dietary changes in patient education. Patients should avoid high-protein foods when the drug is ingested, and alcohol.
- Caution patients with pre-existing disorders such as arrhythmias, pulmonary diseases, or peptic ulcer disease that carbidopa-levodopa may exacerbate their condition. Patients must contact their prescriber if their symptoms increase in frequency or intensity. Caution patients with diabetes to monitor their glucose by capillary blood testing because carbidopa-levodopa may induce false-positive urinary glucose results. Finally, carbidopa- levodopa sometimes darkens urine and sweat. Assure patients that this effect is no cause for concern.

Ongoing Assessment and Evaluation

Monitor for improvement in the patient's ability to perform daily activities and for decreased muscle rigidity and tremors. During periods of dose adjustment, monitor blood pressure every 4 hours. When dose adjustment is done in the home, teach a family member how to monitor blood pressure.

Monitor for signs of adverse effects from carbidopa-levodopa therapy. Dosage changes may increase adverse effects; thus, notifying the prescriber if these signs occur is important. Monitor for signs of personality, behavioral, or mental changes. Eliciting information regarding these potential changes from the family and patient is important. Patients should also receive a periodic eye examination because carbidopa-levodopa may affect intraocular pressure.

Monitor for signs or symptoms of NMS. If signs or symptoms of NMS develop, assess for adherence to drug therapy to ensure proper dosing. Report any signs of NMS to the prescriber immediately, and instruct the patient and family members that they should report any signs of NMS to the prescriber immediately.

With successful therapy, decreased muscular rigidity, bradykinesias, and tremors, as well as improved mobility, should be observed. The patient should be able to verbalize the importance of contacting the prescriber immediately if any adverse reactions occur and the need for periodic re-evaluation by the prescriber.

Drugs Closely Related to P Carbidopa-Levodopa

Amantadine, selegiline, and rasagiline are also dopaminergic agents.

Amantadine

Amantadine (Symmetrel) is an oral antiviral drug that has been found to be effective in treating Parkinson disease. However, this efficacy diminishes within a short time. Amantadine's effects may decrease within as little as 3 to 6 months. Little is known about the precise mechanism of action of this drug in the brain.

Adverse effects of amantadine include insomnia as well as daytime fatigue. Other adverse effects are swollen feet, anxiety, dizziness, urinary retention, depression and hallucinations. The patient may also experience effects similar to those of anticholinergic drugs, such as blurred vision, constipation, urinary retention, and xerostomia (dry mouth). These effects may be enhanced when amantadine is given concurrently with other drugs that have anticholinergic effects. An adverse effect specific to amantadine is "livedo reticularis," a reddish-blue netlike mottling of the skin. Fortunately, this condition is benign and disappears when amantadine therapy is stopped.

Selegiline

Selegiline (Eldepryl) is an MAOI that is selective to monoamine oxidase type–B (MAO-B), a chemical that breaks down dopamine. Selegiline decreases the destruction of dopamine, whether the dopamine is extrinsic, such as the dopamine produced from carbidopa-levodopa, or intrinsic. It is thought to slow the progression of Parkinson disease. Selegiline delays the need for carbidopa-levodopa and effectively prolongs the efficacy of pharmacotherapy. As with amantadine, its action diminishes rapidly; the therapy is viable for only 12 to 24 months.

Selegiline is metabolized in the liver into two metabolites: amphetamine and methamphetamine. These metabolites may be responsible for the most common adverse effect of selegiline, which is insomnia. Concurrent administration of selegiline with carbidopa-levodopa may enhance adverse effects such as orthostatic hypotension, dyskinesias, nausea, and psychological disturbances.

MEMORY CHIP

P Carbidopa-Levodopa

- Used as dopaminergic agent to treat Parkinson disease
- Most contraindications: known hypersensitivity, allergy to tartrazine, melanoma, closed-angle glaucoma, or breast-feeding
- Most common adverse effects: abnormal movements, orthostatic hypotension, GI effects,
- Most serious adverse effects: neuroleptic malignant syndrome—common with abrupt cessation of drug; precautions with cardiac, pulmonary, and peptic ulcer diseases, diabetes mellitus, psychosis and pregnancy
- Maximizing therapeutic effects: take drug on empty stomach, reduce protein in diet
- Minimizing adverse effects: titrate drug upward to avoid GI effects, titrate drug downward to avoid neuroleptic malignant syndrome
- Most important patient education: caution about hypotension and "on-off syndrome"

Selegiline (Zelapar) is a new orally disintegrating tablet for Parkinson disease for patients with difficulty swallowing. Selegiline (Emsam) is a transdermal system for the treatment of depression (Chapter 19). The transdermal system is ineffective in treating Parkinson disease.

Rasagiline

Rasagiline (Azilect) is the newest FDA-approved drug for symptomatic treatment of Parkinson disease and in non-human subjects has been shown to slow Parkinson disease progression. Like selegiline, it inhibits MAO-B. It is approved for use as an initial single-drug therapy in early Parkinson disease, and as an addition to carbidopa-levodopa in more advanced disease. Rasagiline may interact with tyramine-rich foods or beverages such as cheese and red wine. Drug–drug interactions may also occur with dietary supplements or amines contained in many cough or cold medications. Patients need to avoid these sources of tyramine and amines when taking rasagiline. Like other Parkinson medications, this drug may cause dyskinesias, hallucinations, and hypotension.

Drugs Significantly Different From P Carbidopa-Levodopa

Dopamine Agonists

The various dopamine agonists differ in chemical structure, duration of action, and side effects. The response to a particular dopamine agonist varies considerably between individuals, so that if one dopamine agonist does not offer benefit or causes adverse effects, another agonist may be tried.

Bromocriptine

The pharmacologic action of a dopamine agonist differs from that of carbidopa-levodopa. Bromocriptine (Parlodel), a dopamine agonist, is an oral synthetic agent that has been used to treat Parkinson disease for many years. Its other indications include acromegaly, amenorrhea, galactorrhea, infertility, and prolactin-secreting pituitary adenomas. It is being investigated for use in treating insulin resistance in patients with type 2 diabetes mellitus.

Bromocriptine works by stimulating D_2 receptors and antagonizing D_1 receptors in the hypothalamus and striatum. For treating Parkinson disease, the effect is to increase the availability of dopamine. Additionally, bromocriptine suppresses prolactin secretion from the anterior pituitary gland, enabling ovulation and ovarian function in amenorrheic patients and suppressing lactation in women with normal ovarian activity.

The adverse effects of bromocriptine therapy limit its use. Symptoms such as psychiatric disturbances, nausea, and orthostatic hypotension are very common. Bromocriptine exacerbates pre-existing conditions such as psychiatric illness, peripheral vascular disease, and peptic ulcer disease. In addition, bromocriptine may cause patients with a history of MI to experience serious cardiac problems.

Bromocriptine should not be administered with drugs that antagonize its actions. Such drugs include those that increase the concentration of prolactin, such as haloperidol (Haldol), loxapine (Loxitane), molindone (Moban), MAOIs, imipramine (Tofranil), amitriptyline (Elavil), methyldopa (Aldomet), phenothiazines, and reserpine (Serpalan). Estrogens or progestins can produce amenorrhea or galactorrhea and should not be given concurrently.

Pergolide

Pergolide (Permax), is another ergot-derived dopamine agonist that is similar to bromocriptine in action, with 10 times the potency of bromocriptine at the D_2 receptors. It has two actions that are different than bromocriptine. It also stimulates D_1 receptors and it affects 5-HT_{2B} receptors on heart valves. Pergolide directly activates dopamine receptors in the striatum and on heart valves, inhibits the secretion of prolactin, and decreases luteinizing hormone. The effects on prolactin secretion persist much longer than the antiparkinsonian action.

Because pergolide is a potent dopamine receptor agonist, it should not be administered with dopamine receptor antagonists (i.e., neuroleptics such as phenothiazines, haloperidol, and thiothixene). Dopamine receptor antagonists can antagonize the effects of pergolide.

Adverse effects of pergolide are nausea, vomiting, confusion, hallucinations, lightheadedness, and fainting. A rare side effect known as fibrosis (thickening or scarring of the membrane lining of body organs) has also been reported. Like cabergoline, it may increase the risk for newly diagnosed cardiac valve regurgitation.

In 2007, pergolide in its brand-name and generic forms was withdrawn from the U.S. market because of studies that implicated the drug in causing serious heart-valve damage. Pergolide may still be available in markets outside of the United States.

Pramipexole

Pramipexole (Mirapex) is the third dopamine agonist used to treat Parkinson disease. Carbidopa-levodopa is converted in the brain into dopamine. In contrast, dopamine agonists such as pramipexole help alleviate the symptoms of Parkinson

disease by acting directly on dopamine receptors in the brain. Pramipexole is a selective agonist at D_2 and D_3 receptors in the brain. It is more selective for these receptors than either bromocriptine or pergolide.

Pramipexole has been approved for treating both early and late stages of Parkinson disease. With early-stage monotherapy, pramipexole (like selegiline) delays the need for carbidopa-levodopa, thus extending the pharmacotherapeutic benefits of carbidopa-levodopa when it is used to treat more advanced stages of Parkinson disease. Additionally, in later stages of Parkinson disease, co-administering pramipexole and carbidopa-levodopa can decrease the dosage of carbidopa-levodopa by 25%. This reduction decreases the potential for carbidopa-levodopa's adverse effects.

In the early stages of Parkinson disease, the most frequent adverse effects of pramipexole are nausea, dizziness, drowsiness, insomnia, and postural hypotension. In advanced stages of Parkinson disease, additional adverse effects include dyskinesias, extrapyramidal syndromes (abnormal involuntary movements), and hallucinations. Inform patients that postural hypotension may occur more frequently during initial treatment and that hallucinations can occur at any time during the course of treatment. Pramipexole may cause sleep attacks. Should this occur, the patient should notify the provider and refrain from activities that require mental alertness. Monitor patients with pre-existing renal dysfunction carefully.

Ropinirole

Ropinirole (Requip), the last dopamine agonist, is similar to pramipexole. Like pramipexole, ropinirole may be used in early Parkinson disease or in later stages in conjunction with carbidopa-levodopa. In addition, ropinirole is FDA approved for the treatment of restless legs syndrome. With ropinirole, the dose of carbidopa-levodopa may be reduced, which may in turn help decrease the on–off fluctuations that affect some patients who have been on carbidopa-levodopa for many years.

Administering ropinirole as monotherapy can induce adverse effects in every system of the body. In the autonomic nervous system, the most common adverse effects include diaphoresis, flushing, and dry mouth. In the overall body, the most common adverse effects include weakness, chest pain, dependent edema, fatigue, malaise, pain, and peripheral edema. Cardiovascular adverse reactions include atrial fibrillation, extrasystoles, hypertension, hypotension, orthostatic hypotension, palpitations, sinus tachycardia, and syncope (sometimes with sinus bradycardia). Most cases of syncope occurring with ropinirole therapy are reported more than 4 weeks after initiation and are usually associated with a recent increase in dosage. In the GI system, common adverse effects include abdominal pain, anorexia, dyspepsia, flatulence, and nausea and vomiting. The most common adverse reactions affecting the CNS and peripheral nervous system include dizziness, hyperesthesia, restlessness, and vertigo. The metabolic and nutritional adverse effect is weight loss, whereas respiratory adverse effects include bronchitis, dyspnea, pharyngitis, rhinitis, sinusitis, visual impairment, and xerophthalmia (conjunctival dryness).

Psychiatric adverse reactions include amnesia, impaired concentration, confusion, hallucinations, drowsiness, and yawning. There have been many reports of patients who have fallen asleep while driving or performing other normal daytime activities while taking ropinirole. The episodes have occurred as late as 1 year after initiating treatment. Some patients have reported feeling completely alert before these events. It is not clear whether the medication, the sleep status of the patient, or the Parkinson disease itself contributed to these episodes.

In addition to the above adverse effects, ropinirole in combination with carbidopa-levodopa may induce additional effects, including dyskinesia, falls, headache, hypokinesia, paresis, paresthesias, tremor, constipation, diarrhea, dysphagia, flatulence, hypersalivation, anemia, upper respiratory infections, pyuria, urinary incontinence, and diplopia. Furthermore, anxiety, abnormal dreaming, hallucinations, nervousness, and somnolence (drowsiness) may also occur. The potential advantage of ropinirole over carbidopa-levodopa is a lower incidence of dyskinesia and lower propensity to induce adverse psychiatric effects. Like pramipexole, ropinirole may also cause sleep attacks. Ropinirole is contraindicated during pregnancy because it may cause fetal harm.

Catecholamine O-Methyl Transferase Inhibitors

Tolcapone

Tolcapone (Tasmar) inhibits the enzyme COMT, which degrades dopamine in the periphery of the body. The higher and more sustained plasma concentrations of levodopa that result translate into more constant dopaminergic stimulation in the brain, which in turn leads to greater effects on the signs and symptoms of Parkinson disease. The decreased destruction of levodopa allows a decrease in the daily dosage of carbidopa-levodopa. Tolcapone is indicated for treating Parkinson disease in patients who are experiencing fluctuations in symptoms and are not responding to or are not appropriate candidates for other adjunctive therapies.

COMT also metabolizes medications other than levodopa, including dopamine, dobutamine, epinephrine, norepinephrine, isoproterenol, methyldopa, and bitolterol. The dosage of these agents may have to be reduced in patients who are treated with tolcapone. Because COMT and MAO are the two major enzyme systems involved in the metabolism of catecholamines, the possibility exists that the combined use of tolcapone and a nonselective MAOI such as phenelzine or tranylcypromine would inhibit most pathways involved in normal catecholamine metabolism. Therefore, the concurrent use of these agents should be avoided. However, tolcapone can be used with the selective MAO-B inhibitors selegiline or rasagiline, because these agents have been used together in antiparkinsonian regimens without difficulty.

The most frequent adverse effects of tolcapone are dyskinesia, nausea, increased daytime sleepiness, dystonia, orthostatic hypotension, diarrhea, dizziness, and hallucinations. Tolcapone may elevate liver transaminase concentrations in the blood. Because of reports of fatal liver injury, the manufacturers of tolcapone advise that its use should be reserved for patients who do not respond to or are not appropriate candidates for other available treatments. Extensive liver function testing is required for all patients before and during therapy.

Entacapone

Entacapone (Comtan) is the second COMT inhibitor to be approved and is indicated as an adjunct to carbidopa- levodopa in treating patients with idiopathic Parkinson disease who experience the signs and symptoms of end-of-dose "wearing-off." This agent has no antiparkinsonian effect of its own, and it must be administered with carbidopa-levodopa. Like tolcapone, adding entacapone to a carbidopa-levodopa regimen increases the bioavailability of levodopa. Entacapone is also available as a fixed-dose combination pill with carbidopa-levodopa (Stalevo).

Entacapone has the same adverse effect profile as tolcapone, with the exception that entacapone is not associated with hepatotoxicity or clinically important elevations of liver enzymes. This exception represents an important advantage over tolcapone. Potential drug–drug interactions with entacapone are similar to those for tolcapone.

Centrally Acting Anticholinergic Drugs

The centrally acting anticholinergic drugs work by blocking the access of acetylcholine to cholinergic receptors in the striatum. Centrally acting anticholinergic drugs are less effective than carbidopa-levodopa. They can be used to decrease tremors and rigidity as a monotherapy approach in early Parkinson disease or in combination with dopaminergic drugs in later stages. They are used with caution in older patients because of the potential for severe CNS effects. The anticholinergics used most frequently in treating Parkinson disease are benztropine (Cogentin), diphenhydramine (Benadryl), and trihexyphenidyl (Artane). For additional information concerning anticholinergic drugs, see Chapter 14.

C ANTI-AMYOTROPHIC LATERAL SCLEROSIS DRUGS

Historically, there has not been specific pharmacotherapy for treating ALS. In December 1995, the FDA approved riluzole (Rilutek), the first drug for treatment of ALS (Table 21.3). Riluzole, the prototype anti-ALS drug, does not cure ALS. Rather, it is used to delay the need for tracheostomy or mechanical ventilation in patients who have ALS. Research for additional ALS medications is ongoing.

Nursing Management of the Patient Receiving P Riluzole

Core Drug Knowledge

Pharmacotherapeutics

Riluzole is indicated for treating ALS because it slows down the disease's progression by delaying for several months the loss of muscle strength and limb function. The drug is given to extend survival time before tracheostomy is necessary; it is not a cure.

Pharmacokinetics

Riluzole is administered orally in 50-mg doses every 12 hours. Its onset of action is slow, and its duration of action is 3 to 5 days. Well absorbed from the GI tract, riluzole has a half-life of 12 hours. Low protein diets may extend the length of time required to reach stable serum drug levels. Hepatic metabolism of riluzole is extensive, producing six major and several minor metabolites. The cytochrome P-450 enzyme system is involved in hydroxylation and glucuronidation. The main isozyme involved in hydroxylation is CYP1A2. Riluzole crosses the placenta and enters breast milk.

Excretion of riluzole is mainly renal and 5% fecal. Riluzole is largely excreted as metabolites, with about 2% excreted as unchanged drug. Renal clearance of riluzole is individualized, possibly because of the variability of CYP1A2 (see Table 21.3).

Pharmacodynamics

The etiology of ALS is unknown. One of the leading theories of its pathogenesis is that motor neurons are injured by glutamate, a major excitatory brain neurotransmitter.

TABLE 21.3 Summary of Selected Drugs for the Management of Amyotrophic Lateral Sclerosis

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Anti-ALS Agents			
P riluzole (Rilutek)	ALS	*Adult:* PO, 50 mg q 12 h *Child:* Not recommended	*Onset:* Slow *Duration:* 3–5 d $t_{1/2}$: 12 h
creatine	ALS	*Adult:* PO, 1 packet dissolved 1 fruit juice daily	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown

Although the mode of action of riluzole in treating ALS is also unknown, it may work by inhibiting glutamate release and inactivating sodium channels found in damaged neurons which indirectly reduces glutamate receptor stimulation.,

Contraindications and Precautions

The only contraindication to riluzole therapy is a hypersensitivity to any of its components. However, many precautions are issued.

Riluzole has affected fetal development and viability in animal studies; however, adequate studies on human pregnancy have not been completed. It is assigned to FDA pregnancy category C and should be administered only when the benefits to the mother outweigh the risks to the fetus throughout pregnancy. Nursing women need to be advised to avoid breast feeding due to excretion in human breast milk.

Hepatic disease, renal disease, or renal impairment can affect the clearance of riluzole, which is extensively metabolized in the liver and excreted in the urine. Patients with pre-existing hepatic or renal disease should be given riluzole with caution.

Adverse Effects

Evaluating adverse effects caused by riluzole can be difficult because ALS has several manifestations that may be mistaken for adverse effects. In reviewing the adverse effects for patients taking riluzole, consider natural disease progression.

Potential side effects are muscle fatigue, nausea, dizziness, diarrhea, anorexia, vertigo, and somnolence. When these symptoms become troublesome, treatment should be discontinued. Riluzole increases levels of hepatic enzymes in 50% of patients. This increase occurs in patients with no history of hepatic injury. Rarely, jaundice may also occur.

Many potentially adverse reactions have been reported with riluzole therapy, involving every system of the body. However, these adverse reactions have occurred in less than 1% of patients receiving riluzole. One of the most serious potential adverse effects is neutropenia. Although such reactions are rare, a complete blood count (CBC) should be monitored for the patient's safety.

Drug Interactions

As previously mentioned, riluzole may cause hepatic injury. The potential exists for increased risk for hepatic injury when riluzole is used concurrently with potentially hepatotoxic drugs. Additionally, drugs that induce the hepatic enzyme system may also increase the risk for hepatic injury.

The principal isoenzyme involved in the metabolism of riluzole is CYP1A2. Inhibitors or inducers of this enzyme may change plasma concentrations, resulting in toxic or subtherapeutic concentrations of the drug. Table 21.4 presents agents that may interact with riluzole.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a careful history, including any pre-existing hepatic or renal dysfunction. Assess also for a history of cigarette smoking. Communicate any positive findings to the prescriber.

It is important to complete a physical examination of the patient before initiating therapy. Riluzole can induce

TABLE 21.4 Agents That Interact with P Riluzole

Interactants	Effect and Significance	Nursing Management
CYP1A2 inhibitors • amitriptyline • caffeine • quinolones • theophylline	Administering riluzole with drugs that inhibit CYP1A2 has the potential to increase plasma concentrations of riluzole by decreasing the rate of clearance.	Monitor for toxicity. Monitor serum plasma levels.
CYP1A2 inducers • cigarette smoke • charcoal-broiled foods • omeprazole • rifampin	Administering riluzole with substances that induce CYP1A2 has the potential to increase plasma concentrations of riluzole by increasing the rate of clearance. adverse effects in every body system. With the exception of hepatic injury, the chance of these adverse reactions is less than 1%. Baseline data are helpful if any of the reactions should occur. Document baseline CBC and renal and hepatic function tests for all patients.

Life Span and Gender

Older patients are more likely to have age-related hepatic and/or renal function changes. Although no specific recommendations for dosage in older adults have been made, older patients need to be more closely monitored for adverse effects.

The metabolism of riluzole depends largely on the activity of a specific isozyme, CYP1A2. This isozyme reportedly is more active in men than women. Higher blood concentrations of riluzole and its metabolites may be present in women, which may increase the risk for adverse effects in women. Continually assess female patients for these effects.

Lifestyle, Diet, and Habits

Evaluate the patient's diet for high fat content, use of caffeine products, and high intake of charcoal-broiled foods, and determine whether the patient is a smoker. The absorption of riluzole may be diminished by up to 20% in patients who consume a high-fat diet. Caffeine products can inhibit CYP1A2, resulting in increased serum concentration of riluzole. Conversely, charcoal-broiled foods and tobacco smoking can induce CYP1A2, which may increase the elimination of riluzole from the body.

Environment

Riluzole is usually administered in the home environment. Assess patients for their ability to understand the prescriber's directions and to physically self-administer drugs. Appropriate home care referrals are necessary for patients unable to self-medicate. Riluzole is extremely expensive. Evaluate patients' financial circumstances and refer patients and families for social services as appropriate.

Culture and Inherited Traits

Determine whether the patient is of Japanese descent. Riluzole clearance in ethnic Japanese patients is 50% less efficient than in whites. It is uncertain whether this effect is related to a difference in metabolic function in ethnic Japanese or to environmental factors such as smoking, alcohol or coffee intake, or diet.

Nursing Diagnoses and Outcomes

- Risk for Injury related to hepatic dysfunction, anemia, and CNS and cardiovascular effects of riluzole therapy
  Desired outcome: *The patient will immediately report any signs of hepatic dysfunction (fatigue, rash, jaundice), anemia (fatigue, sore throat, easy bruising), or CNS or cardiovascular effects to the prescriber.*
- Disturbed Thought Processes related to adverse CNS effects
  Desired outcome: *The patient will remain oriented and able to communicate effectively.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer riluzole with a full glass of water. To increase bioavailability, it is best for riluzole to be taken on an empty stomach, at least 1 hour before or 2 hours after meals. For patients who will be self-medicating, explain the importance of correct administration.

Minimizing Adverse Effects

At the beginning of therapy, riluzole may cause dizziness or sedation. Caution the patient to refrain from driving, using machinery, or performing tasks that require mental alertness until the effects of riluzole have been established.

Providing Patient and Family Education

- It is most important to explain to patients and their families that riluzole will not change the course of the disorder. At best, riluzole will delay the need for tracheostomy and mechanical ventilation. Patients must understand what the eventual sequelae of ALS are and have a legal document in place if they choose to refuse life-sustaining measures.
- Advise patients to take riluzole on an empty stomach at 12-hour intervals. Teach patients to eat a low-protein diet. Also, advise patients to refrain from caffeine, alcohol, and charcoal-broiled foods.
- Advise patients of the potential adverse effects of riluzole. Because progression of the disease may mimic common adverse effects, patients should always contact the prescriber if any symptoms should occur.
- Advise patients about the importance of regular follow-up and the need for periodic blood testing. Present symptoms of hepatic dysfunction and emphasize the importance of contacting the prescriber if any appear.

Ongoing Assessment and Evaluation

Coordinate regular follow-up evaluations of the patient. At each visit, evaluate the patient for the onset of adverse effects and complete a physical examination. CBC and ALT levels should be taken monthly during the first 3 months of treatment, then every 3 months for the remainder of the first year. After the first year, ALT levels should be monitored periodically. Patients with elevated ALT levels require more frequent monitoring. Discontinuation of

CRITICAL THINKING SCENARIO

RILUZOLE AND REALITY

Mrs. Baxter has been diagnosed with ALS. She has moderate weakness in her extremities and uses a walker to ambulate. During your home visit, Mr. Baxter tells you, "I'm so glad they have started my wife on riluzole. I was thinking of having our attorney come over and do all that paperwork about the will because I was so scared. Now I don't have to."

1. How would you respond to Mr. Baxter?
2. What specific topics would you cover with him?

riluzole therapy should be considered when ALT levels become five times the normal range. During each encounter with the patient, reinforce the necessity of dietary and smoking restrictions.

Effective therapy should delay deterioration of the respiratory muscles. The patient should acknowledge the importance of contacting the prescriber immediately if any adverse reactions occur. The patient should also acknowledge the importance of periodic re-evaluation by the prescriber.

Drugs Significantly Different From P Riluzole

Creatine

Creatine monophosphate is a dietary supplement granted FDA orphan drug status for use in patients with ALS. It is similar to the natural compound creatine phosphate, which is an essential component of the energy-converting system in muscle cells. Creatine's primary function is to maintain adenosine triphosphate (ATP) levels within muscle. Muscles use the energy supplied by ATP during anaerobic activity, such as lifting weights. Creatine also promotes an anabolic environment in the muscle, which promotes protein synthesis that is important for muscle growth and repair. Creatine may also be combined with the antibiotic minocycline for managing ALS. Two clinical studies have shown no significant differences in respiratory, motor or functional capacity in ALS populations; although both studies showed an improved survival trend (Shefner, 2004; Rosenfeld, 2009).

Creatine should be used cautiously in people with pre-existing renal disease that produces renal impairment or renal failure. Creatine generates an increased amount of creatinine that must be eliminated by the kidneys. Studies have not been done to show the safety of creatine in children or during pregnancy.

Drugs for Symptom Abatement

Patients with ALS are affected by diverse symptoms, including spasticity, muscle cramping, depression, gastric reflux, excessive salivation, viscous phlegm, pain, constipation, urinary urgency, and in the final stages of the disease, breathing difficulty. Drugs used to decrease spasticity include baclofen, tizanidine, and diazepam (see Chapter 16). For muscle cramps, patients may be prescribed quinine, baclofen, or clonazepam (see Chapters 16 and 18). Gastric reflux is managed with use of histamine-2 blocking agents or proton pump inhibitors (see Chapter 51). For excessive salivation, patients are prescribed anticholinergics or antihistamines (see Chapters 14 and 48). Viscous phlegm can be decreased with guaifenesin (see Chapter 48). Pain is managed initially with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen (see Chapter 24). As the disease progresses, pain management may require narcotic administration (see Chapter 23).

Constipation is a major problem and may be treated with laxatives, prune juice, enemas, or a bowel program (see Chapter 51). Urinary urgency is controlled with tolterodine (see Chapters 14 and 55). Because many of these drugs can be purchased on an over-the-counter basis, educate the patient to consult with the prescriber before using these drugs in an effort to avoid drug–drug interactions.

MEMORY CHIP

P Riluzole

- Used to manage ALS delaying need for a ventilator
- Most contraindications: hypersensitivity to riluzole components
- Most comman adverse effects: neutropenia, multiple system impact
- Maximizing therapeutic effects: decrease protein intake; avoid caffeine, charcoal-broiled foods, tobacco, and alcohol
- Minimizing adverse effects: avoid tasks requiring mental alertness until riluzole effects known
- Most important patient education: teach to obtain CBC and ALT levels monthly times 3, then every 3 months

C ANTI-MULTIPLE SCLEROSIS DRUGS

Although there is no cure for MS, various drugs are available to modify the disease course, treat exacerbations, and manage symptoms (Table 21.5). Pharmacotherapy for MS uses a multilayered approach. Drugs used to affect the progress of the disease are called "ABC therapy." These drugs are interferon beta-1a (Avonex), interferon beta-1b (Betaseron), and glatiramer (Copaxone). The interferons are also used in managing hepatitis C and other disorders and are discussed in Chapter 54. Glatiramer is the prototype drug for managing MS.

Nursing Management of the Patient Receiving P Glatiramer

Core Drug Knowledge

Pharmacotherapeutics

Glatiramer is used to reduce the frequency of attacks in patients with relapsing-remitting MS, It slows the development of new lesions on the myelin sheath and reduces disability. Advantage of glatiramer acetate over interferon beta drugs is the absence of flu-like symptoms.

Pharmacokinetics

The pharmacokinetics of glatiramer in humans has not been studied, and no direct and sensitive analytical method exists for measuring glatiramer in serum. In animal studies, it is readily absorbed after subcutaneous injection, and no evidence exists of any tissue accumulation of glatiramer (see Table 21.5).

Pharmacodynamics

Glatiramer acetate is a synthetic chemical that is similar in structure to myelin basic protein. Its action is unclear; however, the drug is thought to modify immune processes that cause MS by acting as a decoy to locally generated autoantibodies. This effect results in decreased tissue destruction.

Contraindications and Precautions

Absolute contraindications include intravenous (IV) administration and hypersensitivity to mannitol. It should be used with caution in already immunocompromised patients and in patients receiving vaccinations, because the action of glatiramer is to modulate the immune response.

Adverse Effects

Glatiramer may induce chest pain or tightness, breathing difficulties, hives or severe rash, pounding heartbeat, and unusual muscle weakness or tiredness. Patients should be instructed to report these symptoms to the provider immediately.

The most common adverse effects include lumps, pain, and redness at the site of injection. Other common adverse effects include anxiety, bleeding, inflammation, itching, dizziness, flushing, joint aches, muscle stiffness, nausea or vomiting, tremor, and weakness. These symptoms may become quite bothersome, and the patient should contact the provider if they do not subside.

Drug Interactions

Although no known drug–drug interactions occur, glatiramer can alter the results of a Papanicolaou test (Pap smear); therefore, women should tell their obstetrician-gynecologist if they are taking glatiramer.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a patient history, especially questioning hypersensitivity to mannitol or pre-existing immunocompromise. Document patient limitations related to MS to serve as a baseline for evaluating the effectiveness of glatiramer therapy.

Life Span and Gender

Glatiramer is an FDA pregnancy category B drug. It is not known whether glatiramer is excreted into breast milk. Glatiramer has not been studied in patients younger than 18 years.

Lifestyle, Diet, and Habits

Glatiramer has no known interactions with lifestyle, diet, or habits. Much literature has been published on the appropriate diet for a patient with MS, but diet does not affect the use of glatiramer.

Environment

Glatiramer may be used in any environment and is most frequently self-administered at home. It should be kept in the refrigerator before use and should not be exposed to high temperature or intense light. Emphasize the need to place used syringes in a puncture-resistant container and then return the container to the prescriber for proper disposal.

Nursing Diagnoses and Outcomes

- Weakness related to glatiramer injection
  Desired outcome: *The patient will recognize weakness and take measures to decrease its impact on activities of daily living.*
- Skin Integrity, Impaired, related to injection site reactions
  Desired outcome: *The patient will employ strategies to minimize injection site reactions.*
- Disturbed Sensory Perception related to anxiety and dizziness
  Desired outcome: *The patient will notify the provider if these adverse effects occur.*

Planning and Intervention

Maximizing Therapeutic Effects

Explain that glatiramer should be kept in the refrigerator until it is used. Teach the patient and family how to transfer sterile water into the glatiramer using aseptic technique, gently swirl the vial, and then allow the mixture to stand at room temperature until all of the powder is dissolved. Advise the patient and family using glatiramer from prefilled glass syringes to allow the syringe to sit at room temperature approximately 20 minutes before injection.

Minimizing Adverse Effects

Teach the patient and family to administer the subcutaneous injection correctly. It is important to deliver the medication into the subcutaneous tissues and avoid either intradermal or IV administration. Explain the importance of rotating the injection site so that no one spot is used more than once a week.

Providing Patient and Family Education

- Review the potential adverse effects of glatiramer, focusing on how common adverse effects differ from serious effects that should be reported to the provider.
- Review location of subcutaneous injection sites. Subcutaneous sites include the thigh, back of the hip, stomach, and upper arm.
- Review reconstitution procedure of glatiramer powder.
- Review aseptic technique for subcutaneous administration.
- Review appropriate disposal of syringes.

Ongoing Assessment and Evaluation

Elicit a history from the patient at each subsequent visit, focusing on improvement of baseline symptoms or acquisition of new symptoms. Question the patient about adverse effects and document them in the medical record.

Effective therapy should decrease the intensity of baseline symptoms and prolong the intervals between acute exacerbations of MS. The patient should recognize important adverse effects that require contact with the provider.

Drugs Significantly Different From P Glatiramer

Interferons

Interferon beta is also used in treating MS. Interferon beta is available as interferon beta-1a (Avonex, Rebif) and interferon beta-1b (Betaseron). Interferon beta works by decreasing interferon gamma and other proinflammatory cytokines. Interferon gamma is believed to be one of the major factors responsible for triggering the autoimmune reaction resulting in MS. In MS, T cells migrate across the blood–brain barrier in response to interferon gamma and attack antigens on nervous system tissues. By reducing interferon gamma, T-cell migration is reduced, resulting in less tissue damage. Another action of interferon beta is an increased production of nerve growth factor, which may have a favorable effect of remyelination.

A recombinant process produces both drugs, but in other respects, they differ greatly. In therapy, 1-mg interferon beta-1a represents 200 million units of activity, whereas 1 mg of interferon beta-1b represents 32 million units of activity. Interferon beta-1a shows a reduction in relapse rate and slows disease progression. Interferon beta-1b shows a very substantial clinical benefit in decreasing relapse but has not been shown to slow disease progression. Interferon beta-1a (Avonex) is administered by intramuscular injection, whereas interferon beta-1a (Rebif) and interferon beta-1b (Betaseron) is administered by subcutaneous injection. Interferon beta-1a has not been associated with injection-site necrosis, whereas interferon beta-1b is associated with an injection-site reaction in roughly 85% of patients. Administration of acetaminophen or ibuprofen prior to and 24 hours after interferon beta injections helps to decrease injection-site reactions. Interferon beta should not be administered to patients with hypersensitivity to interferon beta or albumin. It is an FDA pregnancy category C drug and should be avoided during pregnancy because of the risk of spontaneous abortion. It should also be avoided during breast-feeding because serious adverse reactions may occur in the infant. Interferon beta is also used with caution in patients who have a history of cardiac arrhythmias, heart failure, or MI. Suicidal ideation has occurred in patients on interferon beta therapy. It is unclear whether this ideation is related to the drug or to the disease process of MS.

Mitoxantrone

Mitoxantrone (Novantrone) is a chemotherapeutic drug initially developed for certain forms of cancer. An immune system suppressor, it is delivered intravenously in a medical setting. Mitoxantrone is contraindicated for patients with heart disease, liver disease, or certain blood disorders because

MEMORY CHIP

- Most common adverse effects: chest pain/tightness, difficulty breathing, hives/severe rash

- Minimizing adverse effects: correct procedure to administer subcutaneous injections
- Most important patient education: avoid accidental IV administration

it may make these problems worse. It is also contraindicated during pregnancy because it may cause birth defects. Mitoxantrone is withheld in patients with hepatic impairment and elevated liver enzymes as no tests exist to predict drug clearance rates to determine dosage adjustments.

Mitoxantrone may cause serious, even fatal, heart damage. To avoid potential heart damage, the drug is typically limited to 12 doses over a period of 2 to 3 years. It may also suppress neutrophils and platelets, increasing the patient's risk of infection or bleeding. Frequent tests are needed to monitor heart function and hematopoietic status while taking mitoxantrone.

Common but less serious side effects of mitoxantrone include nausea, hair loss, increased risk of infections, especially urinary tract infections, menstrual cycle changes, mouth sores, and diarrhea or constipation. Mitoxantrone causes the urine to become blue-green for 24 to 48 hours after each treatment. Although this color change is harmless, the patient should be informed prior to treatment.

The patient taking mitoxantrone should not receive any immunizations without the physician's approval.

Natalizumab

Natalizumab (Tysabri), a monoclonal antibody, is an alpha-4 integrin antagonist in a class known as selective adhesion molecule inhibitors. It is FDA approved to treat patients with relapsing forms of MS to reduce the frequency of symptom flare-ups or exacerbations of the disease. Natalizumab is recommended for patients who have had inadequate response to, or are unable to tolerate, other approved MS therapies.

Natalizumab works by blocking the ability of $\alpha_4\beta_1$ integrin and $\alpha_4\beta_7$ integrin to bind to their receptive vascular-cell adhesion molecules. Binding to adhesion molecules is an important step in white cells crossing arterial blood vessels and entering into the brain to attack myelin in MS. Because of its different mechanism of action, natalizumab is expected to be an important therapeutic option in the management of MS.

Natalizumab was previously taken off the market because some patients developed progressive multifocal leukoencephalopathy (PML). PML, which is caused by a common virus called the JC virus, is characterized by demyelination or destruction of the myelin sheath. Symptoms include speech disturbances, ataxia, vision loss, mental deterioration, paralysis, and, ultimately, coma. Natalizumab is now available under a restricted distribution program called TOUCH, and prescribing physicians and patients must enroll in a mandatory registry program. The drug is given intravenously every 4 weeks at registered infusion centers. The risk of PML rises as the number of natalizumab infusions administered increases. In addition, immune reconstitution inflammatory syndrome (IRIS) has been noted in patients with PML after natalizumab has been discontinued. IRIS is a rare and severe inflammatory problem that results in deteriorating patient status after the immune system has been restored (U.S. Department of Health & Human Services, 2010).

Natalizumab is contraindicated for patients with a compromised immune system and patients taking other drugs that suppress the immune system. Common adverse effects include headache, fatigue, infections, depression, joint pain, and menstrual disorders.

Dalfampridine

Dalfampridine (Ampyra) is one of the newer drugs on the market to treat MS. Indication for the use of dalfampridine is to improve speed of ambulation in patients experiencing any of the four major forms: relapsing-remitting, primary progressive, secondary progressive, and progressive-relapsing. Over 85% of MS patients suffer difficulties with ambulation and perceive this symptom to be one of the most challenging issues of their disease. Dalfampridine may be used as a monotherapy or as an adjunct with above noted MS pharmacotherapeutic therapies.

The demyelinzation of nerves in MS results in potassium channels on nerve surfaces becoming exposed and potassium leaking from the channels resulting in disrupted electrical current. The mechanism of action of dalfampridine is to block the potassium channels on nerve surfaces, which improves nerve impulse conduction leading to improved speed of ambulation.

Common adverse effects of dalfampridine are urinary tract infections, insomnia, headache, and dizziness. The two most serious adverse effects are seizures and hypersensitivity reactions. Due to the risks of seizures, a risk evaluation and mitigation strategy was created to clearly communicate to patients the likelihood of seizures related to the consumption of higher than recommended dosages of the medication.

No drug interactions were identified in clinical trials; yet not all drug interactions have been studied at this time. Complete medication lists need to be obtained from all patients being prescribed this product. Contraindications to the use of dalfampridine include a history of seizures and renal failure. The drug is excreted via the kidneys and renal impairment may lead to toxic levels of the medication within the bloodstream, resulting in an increased risk of seizures. Dalfampridine is a Class C Pregnancy medication, indicating insufficient evidence support for use in humans with potential benefits possibly outweighing the risks. No information is currently available related to the transmission of the drug via breast milk for lactating mothers. Consequently, lactating mothers are advised to discontinue use of dalfampridine when breastfeeding. Safety has not been established in patients less than 18 years of age (Bastings, 2010). An annual expense of greater than $10,000. to the insurer could restrict the use of this medication.

Fingolimod

Fingolimod (Gilena) is a new oral treatment for relapsing remitting MS, which was approved by the US FDA Advisory Council in June 2010 and which it is anticipated will have full FDA approval for use in September 2010. Fingolimod is from a new group of disease-modifying agents from the class of sphingosine 1 phosphate-receptor modulators and is indicated to decrease the number of MS exacerbations and

impede the development of physical disabilities. Fingolimod acts on the sphingosine 1 phosphate receptor sites found on thymocytes and lymphocyte surfaces, leading to the impounding of lymphocytes into secondary lymph organs. The reduction of lymphocytes circulating within the body reduces the possibility of autoimmune reactions on the myelin sheath.

Common adverse effects of fingolimod are headache, nasopharyngitis, fatigue, and upper respiratory infections. The more serious adverse effects include bradycardia, AV heart blocks, liver enzyme elevation, and macular edema. As a result of the incidence of the more serious adverse effects, recommendations for use are expected to include first-time dosing in monitored situations, where ECG may be performed to assess for bradycardia and AV heart blocks for six hours after dosing, with atropine/isopreterenol available for treatment as needed. Subsequent monitoring of liver enzymes, ophthalmic assessments, and pulmonary function tests are advised related to the incidence of liver enzyme elevation, macular edema, MS relapse, and risk for decreased pulmonary function. Because of the immunosuppressive effect of fingolimod, more research is needed to more thoroughly determine the risk for malignancies and infections. Further studies are expected to determine the lowest effective dose as current studies have investigated the effects of 0.5 mg and 1.25 mg, with determination that 0.5 mg would be permitted for prescriptive dosing at this time due to the risk for toxicity. Studies have not been conducted on patients with dysrhythmias or diabetes; therefore, the drug should be contraindicated in these populations. Other anticipated contraindicated populations include patients with histories of seizures, malignancies, or cardiac/pulmonary disorders. Pregnancy classification of the drug has yet to be determined. No information is currently available related to use in lactating mothers or children less than 18 years old. Few drug interactions were identified in clinical trials; yet not all drug interactions have been studied at this time. Complete medication lists need to be obtained from all patients being prescribed this product. Drug interactions to be considered include a rise in fingolimod levels with concomitant administration of ketoconazole due to CYP4F2 inhibition. An additional potential drug interaction is the simultaneous administration of beta blockers or calcium channel blockers with fingolimod, which could increase the risk of AV heart blocks and bradycardia.

Drugs for Symptom Abatement

As in ALS, many other classes of drugs are used to manage the symptoms that accompany MS. Pharmacotherapy for symptoms of MS may include glucocorticoids to shorten the duration of an acute attack or delay the progression of optic neuritis. Other drugs useful in managing symptoms include tolterodine for bladder incontinence; carbamazepine or gabapentin for shooting sensory pain; baclofen, carisoprodol, or benzodiazepines for muscle spasticity; and tizanidine for low back pain.

OTHER MOVEMENT DISORDERS AND RELATED DRUG THERAPY

The following disorders and the drugs used to treat them are important to include in any discussion of drugs used to treat movement disorders. The drugs commonly used to treat these disorders are covered in depth in other chapters in this textbook. Therefore, the disorders and drugs commonly used to treat them are discussed briefly in this chapter. For more detailed information about the specific drugs, refer to the appropriate chapter in this textbook.

Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder that impairs the receptors for acetylcholine at the myoneural junction. It occurs more frequently in young women and men over 50 years of age. In this disease, immunoglobulin G (IgG) antibodies to acetylcholine receptors are formed, then block and ultimately destroy the receptors so that the muscle cannot be stimulated. The patient experiences skeletal muscle weakness and rapid fatigue of the affected muscles. Proximal muscles are affected rather than distal muscles.

The first symptoms of MG are usually weakness of the eye muscles and ptosis. Oropharyngeal muscle weakness and difficulty with chewing, swallowing, or talking may also be the presenting symptoms. The severity of weakness fluctuates throughout the day, generally increasing in the afternoon or as the environmental temperature rises. The course of the disease is usually progressive; however, in some cases, weakness is restricted to the ocular muscles. Spontaneous improvement may occur, but symptoms generally recur as the disease progresses.

Diagnosis of MG is based on the edrophonium (Tensilon) test. In this test, the patient is induced into weakness by being required to maintain a position. Edrophonium, a short-acting acetylcholinesterase inhibitor, is administered intravenously. Intramuscular neostigmine may also be used. With either drug, the patient should have an increase in muscle strength that dissipates after the duration of action of the drug. The most sensitive test for MG is a single-fiber electromyelogram (SFEMG), which measures "jitter" in the involved muscle(s).

As with other movement disorders, MG has no cure. The drugs of choice for MG are cholinesterase inhibitors such as neostigmine (Prostigmin) or pyridostigmine (Mestinon) and are discussed in Chapter 14. Although corticosteroids (Chapter 48), cyclophosphamide (Chapter 57), and immunosuppressants (Chapter 54) such as azathioprine (Imuran) and cyclosporine (Sandimmune) may be used for MG treatment, all of them are used off label except for prednisone.

Huntington Disease

Huntington disease (chorea) is an inherited disorder that remains undiagnosed until midlife, when symptoms first occur. The two main symptoms of the disease are progressive mental status changes leading to dementia and choreiform (rapid, jerky) movements. The inhibitory neurotransmitter GABA is depleted in the basal nuclei and substantia nigra.

Levels of acetylcholine in the brain also appear to be reduced. However, dopamine is unaffected.

Early symptoms of Huntington disease include mood swings; depression; irritability or trouble driving; and difficulty learning new things, remembering facts, or making decisions. As the disease progresses, personality changes, moodiness, and behavior disturbances occur. The dementia, which accompanies progressive disease, may be related to excessive amounts of dopamine. As atrophy of the brain continues, rigidity and akinesia develop.

There is currently no effective treatment to prevent or delay the progression of Huntington disease, and death usually occurs within 10 to 20 years after the appearance of the first clinical symptoms. Treatment of choreiform movements have traditionally included antipsychotic drugs such as haloperidol (Haldol) or phenothiazines, which block dopamine receptors. These drugs are discussed in depth in Chapter 17. In 2008, the FDA approved the first drug in the United States called xenazine (tertrabenazine) for treatment of Huntington Chorea symptoms. Xenazine's mechanism of action is unknown, but believed to reversibly deplete dopamine, serotonin, norepinephrine and histamine from nerve terminals leading to a decrease in chorea or involuntary jerky movements. Adverse effects observed include increasing cognitive impairment, Parkinsonism, rigidity, depression/suicide, sedation and disability. Genotyping for CYP2D6 is necessary for higher dosages to determine the patient's metabolizer status. Poor metabolizers need to have their dose reduced particularly if receiving a strong CYP2D6 inhibitor such as paroxetine (Paxil). Dosing is titrated slowly up with careful assessment for depression, sedation and dysphagia. Xenazine may interfere with their ability to perform complex motor/mental skills leading to difficulty driving a car or operating machinery. Alcohol and CNS depressants may interact with xenazine potentiating sedation. Xenazine is contraindicated in impaired hepatic function, suicidal patients, untreated depression, and patients receiving MOA inhibitors or reserpine and is a category C for pregnancy (Yero & Rey, 2008). Research to find other agents that are useful in treating this disorder is ongoing.

Gilles de la Tourette Disease

Gilles de la Tourette disease (Tourette syndrome, [TS]) is an autosomal dominant inherited tic disorder appearing in childhood and characterized by multiple motor or vocal tics lasting more than 1 year. Patients may also have obsessive-compulsive behavior, attention deficit hyperactivity disorder, or other psychiatric disorders. Coprolalia (involuntary utterances of vulgar or obscene words) and echolalia (involuntary parrot-like repetition of a word or sentence just spoken by another person) can occur but are rare.

Motor and vocal tics from this disease may respond to haloperidol (Haldol) and similar D_2 receptor blockers (see Chapter 17). Up to 80% of patients with TS initially benefit from haloperidol, sometimes dramatically; however, only approximately 20% of patients continue haloperidol for an extended period. Patients often discontinue the drug because of the emergence of side effects such as excessive fatigue, weight gain, dysphoria (affective disorder characterized by anxiety and depression), parkinsonian symptoms, intellectual dulling, memory problems, personality changes, feeling "zombie-like," akathisia (inner restlessness observed with fidgeting and rocking actions), school or social phobias, loss of libido, sexual dysfunction, and, especially after chronic use of high doses, tardive dyskinesia.

Pimozide (Orap) is another drug used for TS. It is chemically distinctive from haloperidol and phenothiazines, with potent dopamine-blocking properties. Its side effects are similar to those of haloperidol but may be less severe and appear in fewer patients. Routine electrocardiographic studies before and periodically during treatment are advised because of potential cardiotoxicity.

Another drug useful in treating TS is clonidine (Catapres), an imidazoline compound with alpha-adrenergic agonist activity. In low doses, clonidine decreases the release of central norepinephrine, resulting in decreased motor tics and improving attention problems. Clonidine has a low incidence of associated side effects, but most important, it does not have the potential to cause tardive dyskinesia. Clonidine is covered in depth in Chapter 28.

CHAPTER SUMMARY

- Movement disorders are chronic, severe, and debilitating.
- Parkinson disease is a naturally occurring disorder characterized by rigidity, rest tremor, bradykinesia or akinesia, and postural instability.
- Parkinsonism is a syndrome of symptoms resembling Parkinson disease but caused by trauma, drugs, or infection.
- Amyotrophic lateral sclerosis (ALS) is a neuromuscular degenerative disease that progresses quickly until the patient experiences respiratory compromise and ultimately death.
- Drugs used to treat movement disorders are not curative.
- Dopaminergic drugs are used to treat Parkinson disease by increasing the action of dopamine in the CNS. The prototype dopaminergic drug is carbidopa-levodopa (Sinemet, Parcopa).
- Dopamine agonists are drugs that stimulate dopamine receptors in the brain. They do not need to be converted into dopamine in order to achieve their effect.
- Drugs that decrease the action of acetylcholine (anticholinergic drugs) are also used to treat Parkinson disease.
- The only FDA-approved anti-ALS drug is the prototype riluzole (Rilutek).
- Riluzole delays the need for tracheostomy and mechanical ventilation.
- Multiple classes of medications are used to manage the symptoms of ALS.
- Multiple sclerosis is generally treated with the "ABC" approach. This term is derived from the names of the drugs interferon beta-1a (Avonex), interferon beta-1b (Betaseron), and glatiramer (Copaxone).

- Other movement disorders and the drugs used to treat them include myasthenia gravis, neostigmine; Huntington disease (chorea), xenazine; haloperidol or phenothiazines; Tourette syndrome, haloperidol, clonidine, and fluphenazine.

QUESTIONS FOR STUDY AND REVIEW

1. How do dopaminergic and anticholinergic drugs work to decrease the symptoms of Parkinson disease?
2. Why is carbidopa-levodopa considered more efficient than levodopa alone?
3. What is neuroleptic malignant syndrome? When is it most likely to occur?
4. What is a bradykinetic episode?
5. What diet restrictions should be discussed when a patient starts carbidopa-levodopa therapy?
6. What assessments should you make throughout carbidopa-levodopa therapy?
7. What is the goal of riluzole therapy?
8. For patients taking riluzole, why is assessing adverse effects difficult?
9. What dietary restrictions should you discuss with the patient starting riluzole therapy?
10. How does glatiramer differ from the interferons in managing multiple sclerosis?
11. What pharmacodynamic similarities of glatiramer and interferon beta may affect patient adherence to therapy?

Drugs Stimulating the Central Nervous System

Learning Objectives

At the completion of this chapter the student will:

1. Describe the physiology of the central nervous system (CNS) as related to arousal and stimulation.
2. Describe the various therapeutic uses of CNS stimulants.
3. Identify core drug knowledge about pharmacotherapies that stimulate the CNS.
4. Identify core patient variables relevant to drugs that stimulate the CNS.
5. Relate the interaction of core drug knowledge to core patient variables for therapies that stimulate the CNS.
6. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for therapies that stimulate the CNS.
7. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that stimulate the CNS.
8. Determine key points for patient and family education for drugs that stimulate the CNS.

Key Terms

analeptics
anorectic
attention deficit hyperactivity disorder
cataplexy

Drugs Stimulating the Central Nervous System

Many substances are used to stimulate the central nervous system (CNS). These substances, sometimes called **analeptics,** include drugs that are used for therapeutic effects and nontherapeutic effects, both legal and illegal. Substances with therapeutic effects are categorized as central, anorectic, or respiratory stimulants. Central and respiratory stimulants are generally used to stimulate the CNS, whereas **anorectic** agents depress the appetite. The central stimulants are used to treat narcolepsy and as adjuncts in treating attention deficit hyperactivity disorder (ADHD). The anorectic agents suppress appetite or the sensation of hunger, mainly through serotonergic activity or central sympathomimetic effects. They are used as adjuncts to diet and exercise in the short-term management of moderate to severe obesity. The respiratory stimulants are rarely used, but as analeptics, they are representative of drugs that affect the brain stem and respiratory centers.

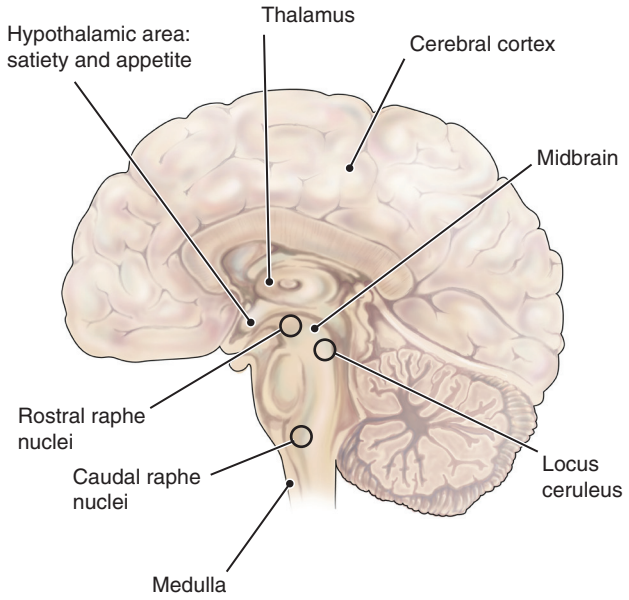
This chapter presents dextroamphetamine (Dexedrine), the prototype for centrally acting CNS stimulant drugs; phentermine (Adipex-P), the prototype anorectic agent; and caffeine, the prototype respiratory stimulant. In addition, this chapter discusses core drug knowledge, core patient variables, nursing management, potential nursing diagnoses, and patient education related to the use of these drugs.

PHYSIOLOGY

The CNS is responsible for providing control systems and surveillance for many vegetative and conscious functions, including appetite, satiety, attention, arousal, activity, and respiration. The hypothalamus mediates appetite and satiety. Various sleep and arousal mechanisms are linked to the raphe nuclei and locus ceruleus in the pons and other parts of the reticular activating system (RAS).

The control of respiration occurs in the pons and medulla. Functional, structural, or lesional disorders may lead to disruptions in the usually smooth regulation of appetite, arousal, and activity. Figure 22.1 is a schema of the brain that shows the location of some regulatory centers involved in appetite, arousal, activity, and respiration.

At a synaptic level in the CNS, normal arousal mechanisms are affected through presynaptic release of neurotransmitters, such as norepinephrine, serotonin, and dopamine (Figure 22.2). These transmitters diffuse across the synaptic cleft to the postsynaptic effector cell, which is usually another neuron. The postsynaptic membrane contains receptors for the transmitters. In normal arousal, the transient combination of the transmitter with the receptor causes membrane changes that lead to propagation of the action potential. The transmitter can be metabolized by postsynaptic enzymes such as monoamine oxidase or removed from further activity through reuptake into the presynaptic storage vesicles. CNS stimulants may provoke an increased release



• FIGURE 22.1 Regulatory centers of the brain.

of neurotransmitters, a decreased reuptake of neurotransmitters, or inhibition of postsynaptic enzymes. The result is a heightened postsynaptic response, leading to increased arousal. Similar mechanisms occur in the sympathetic nervous system, where drugs such as the amphetamines act as indirect adrenergic agonists.

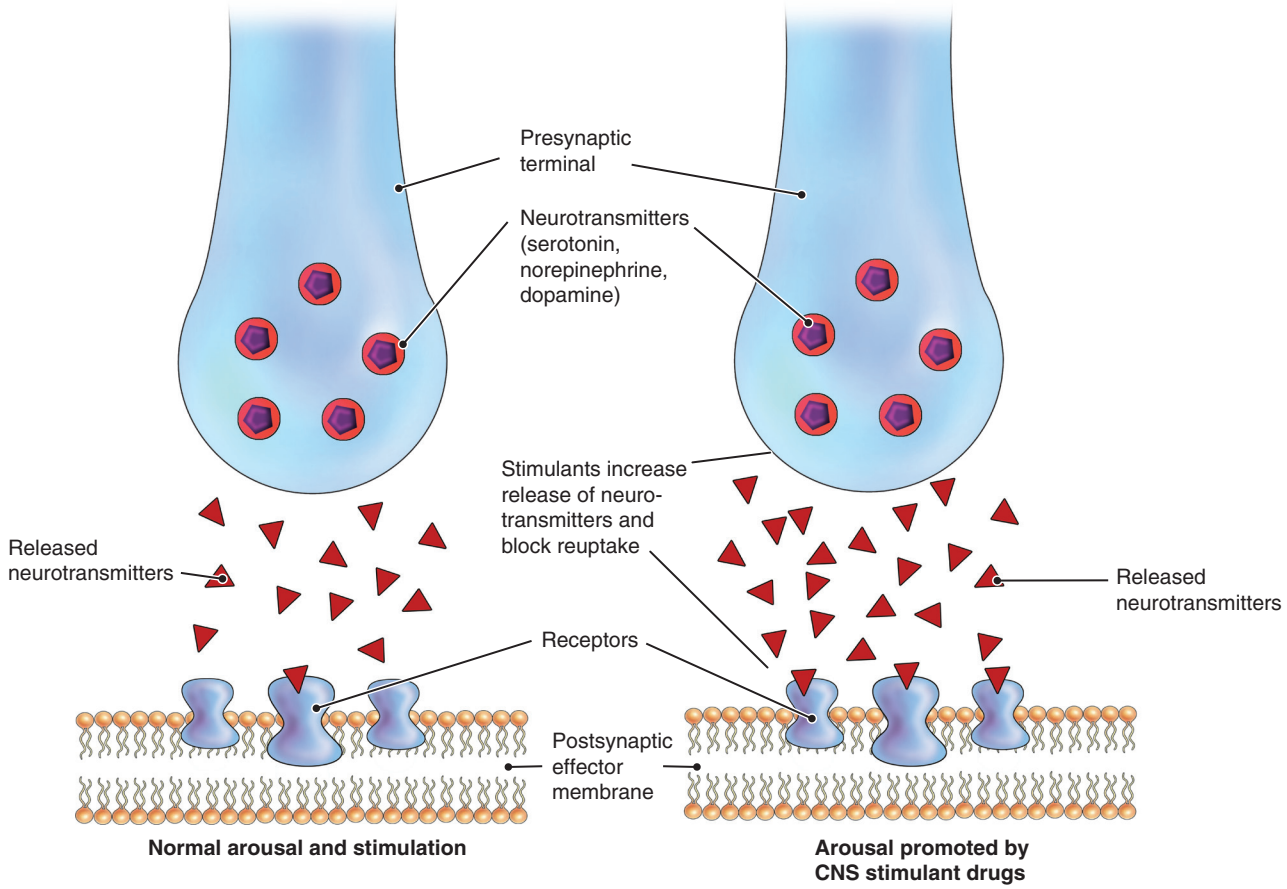
PATHOPHYSIOLOGY

The CNS stimulants are indicated in various disorders and conditions, including narcolepsy, ADHD, obesity, and respiratory stimulation.

Narcolepsy

Narcolepsy, a neurologic condition that affects approximately 1 of every 1,000 people, is characterized by irresistible bouts of rapid-eye-movement (REM) sleep during nonsleep cycles. Associated features include disturbed nocturnal sleep and REM sleep disturbances such as cataplexy, sleep paralysis, hypnagogic hallucinations, and abnormal sleep-onset REM periods. **Cataplexy** is a brief, sudden loss of motor control. In the person with narcolepsy, cataplexy usually manifests itself as a postural collapse to the ground, even though the person maintains full consciousness. **Sleep paralysis** usually precedes the onset of sleep and involves being unable to speak or move, even though awareness of external events remains intact. The elapsed time is usually brief but may seem inordinately long to the person who experiences it.

Hypnagogic hallucinations are auditory, visual, or kinesthetic sensations without stimuli, appearing in the transition period between wakefulness and sleep. For example, the waking person may sense another person in the room but



• FIGURE 22.2 CNS arousal.

when fully awake recognizes that he or she is alone. Most people notice such hypnagogic hallucinations occasionally; however, they occur with greater intensity and frequency in patients with narcolepsy. Restoration of more normal physiologic arousal leads to the return of more normal sleep-activity cycles and forms the basis of CNS stimulant pharmacotherapy for narcolepsy.

Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is the most prevalent chronic health issue affecting school-aged children. It is characterized by a persistent pattern of inattentiveness, hyperactivity, and impulsivity that is more frequent and severe than typically observed in people of a comparable developmental level (Box 22.1). In the United States, data from the Centers for Disease Control and Prevention indicate that in 2006, about 7.4% of children between 4 and 18 years of age were reported to have a history of ADHD (Bloom, 2007). The prevalence of ADHD in adults is estimated to be 4.4% (Antai-Otong, 2008). Comorbid states that may accompany ADHD include learning disabilities, conduct disorder, oppositional defiant disorder, depression or anxiety, bipolar disorder, and Tourette syndrome.

Current research suggests that ADHD has a biologic basis. Studies involving twins have demonstrated mean hereditability to be 77% (Spencer, 2007). Genetic studies have shown alterations in several genes that affect the levels or functioning of the neurotransmitters dopamine, norepinephrine, or serotonin at nerve synapses in the brain. Stimulant drugs that are effective against ADHD are thought to work by altering the levels of dopamine and norepinephrine at the synapse. In addition to genetic influences, prenatal factors such as pregnancy or delivery complications, prematurity, and fetal exposure to alcohol or tobacco also increase the risk of ADHD.

The management of ADHD is complex but usually involves pharmacotherapy with one or more of the CNS stimulants, combined with behavior modification.

Overweight and Obesity

Obesity has become one of the major health issues in the United States. The increased number of patients with obesity threatens to overburden our health care system because it is closely associated with comorbid states such as hypertension, coronary artery disease, diabetes mellitus, and osteoporosis. According to the National Health and Nutrition Examination Survey (NHANES), an estimated one-third of adults, or 72 million people, in the United States are obese (NHANES, 2007). The latest reports from NHANES, the show a dramatic increase in obesity in the last 25 years,

Box22.1 DIAGNOSTIC CRITERIA FOR ADHD

A. Either 1 or 2 applies.
   1. Six (or more) of the following symptoms of **inattention** have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:
      Inattention
      a) Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
      b) Often has difficulty sustaining attention in tasks or play activities
      c) Often does not seem to listen when spoken to directly
      d) Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
      e) Often has difficulty organizing tasks and activities
      f) Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
      g) Often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
      h) Is often easily distracted by extraneous stimuli
      i) Is often forgetful in daily activities
   2. Six (or more) of the following symptoms of **hyperactivity-impulsivity** have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:
      Hyperactivity
      a) Often fidgets with hands or feet or squirms in seat
      b) Often leaves seat in classroom or in other situations in which remaining seated is expected
      c) Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
      d) Often has difficulty playing or engaging in leisure activities quietly
      e) Is often "on the go" or often acts as if "driven by a motor"
      f) Often talks excessively
      Impulsivity
      g) Often blurts out answers before questions have been completed
      h) Often has difficulty awaiting turn
      i) Often interrupts or intrudes on others (e.g., butts into conversations or games)

B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before 7 years of age.

C. Some impairment from the symptoms is present in two or more settings (e.g., at school [or work] or at home).

D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.

E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, or personality disorder).

but with little change between 2003–2004 and 2005–2006. Healthy People 2010 target obesity goal is a rate is 15%, which was last reached in 1980 and is far from the 2005 rate of 34.3% (Table 22.1).

Overweight refers to an excess of body weight compared to set standards. The excess weight may come from muscle, bone, fat, or body water. **Obesity** refers specifically to having an abnormally high proportion of body fat. One can be overweight without being obese, as in the example of a bodybuilder or other athlete who has a lot of muscle. However, many people who are overweight are also obese.

To determine obesity, the measurement of choice for researchers and health care providers is body mass index (BMI). BMI is a direct calculation based on height and weight and is not gender specific. To determine BMI, divide a person's weight in kilograms by height in meters squared (weight [kg]/height squared [m^2]). Although BMI does not directly measure percentage of body fat, it provides a more accurate measure of overweight and obesity than weight alone. Box 22.2 lists BMI index categories.

In addition to BMI, health professionals may rely on a person's waist measurement to determine the location of excess body fat and the corresponding health risks. Health risks increase as waist circumference increases. A woman whose waist measures more than 35 inches and a man whose waist measures more than 40 inches may be at particular

SOURCE: CDC/NCHS, National Health and Nutrition Examination Survey.

Obesity rates have increased dramatically in the last 25 years and among men, there was an increase in obesity prevalence between 1999 and 2006. There was no siginficant change in obesity prevalence, however, between 2003-2004 and 2005-2006 for men or women.

Box22.2 BODY MASS INDEX (BMI) CATEGORIES

- Normal weight: 18.5–24.9
- Overweight: 25–29.9
- Extremely obese: >40
- Children: >95th percentile for age and sex

risk for developing health problems. An increased percentage of abdominal or upper-body fat is related to the risk for developing heart disease, diabetes, high blood pressure, gallbladder disease, stroke, and certain cancers. Body fat concentrated in the lower body (e.g., around the hips) may be less harmful in terms of mortality and morbidity, with the exception of varicose veins and orthopedic problems.

Weight regulation is multifactorial. Key endocrine systems involved in weight regulation include the hypothalamic–pituitary axis, the leptin system, insulin, neuropeptide Y, leptin-regulated hormones, and the autonomic nervous system. Although major endocrine dysfunction may cause obesity, by far the most common causes are overeating and a sedentary lifestyle.

Treating obesity involves a combination of different methods, including modifying eating behavior, implementing and maintaining an exercise program, and using adjunctive pharmacologic therapy to reduce appetite (Box 22.3). Drugs used to manage appetite include serotonin agonists such as phentermine, stimulants such as methylphenidate, lipase inhibitors such as orlistat, and selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine.. In morbidly obese patients, surgical intervention called bariatric surgery has been found to be most effective for long-term weight loss.

Respiratory Stimulation

In patients at risk for postoperative pulmonary complications, respiratory depression may be a complication arising from chronic obstructive lung disease and frequent hypercapnia.

Hypercapnia is a buildup of carbon dioxide levels that may result from pulmonary compromise, frank lung disease, or changes in ventilatory efficacy. The increased levels of carbon dioxide depress the CNS, including the respiratory center, and further compound the problem.

Preterm infants may experience hypercapnia because of their immature respiratory systems. They are prone to postoperative respiratory depression and apnea severe enough to warrant pharmacologic respiratory stimulation. Pharmacologic management of respiratory depression includes administering CNS stimulants such as caffeine and doxapram that act directly on the respiratory center to stimulate effective ventilation and reverse hypercapnia.

C CENTRALLY ACTING CNS STIMULANTS

The centrally acting CNS stimulants are drugs that stimulate the CNS directly or indirectly. This group of drugs includes the amphetamines, methylphenidate, pemoline, and cocaine. The ideal and most widely used CNS stimulant is dextroamphetamine (Dexedrine), an amphetamine. This drug is the prototype for the purposes of discussing the central CNS stimulants. Table 22.2 presents a summary of selected CNS stimulants.

Nursing Management of the Patient Receiving P Dextroamphetamine

Core Drug Knowledge

Pharmacotherapeutics

The major therapeutic uses of dextroamphetamine include treatment of narcolepsy and ADHD and anorectic adjunct therapy in obesity. Dextroamphetamine is occasionally used to treat refractory depression, which is an unlabeled use. As a stimulant, dextroamphetamine is classified as a Drug Enforcement Administration (DEA) Schedule II drug, which means its use is tightly controlled.

BOX 22.3 FOCUS ON RESEARCH

Limitation of Pharmacotherapy for Weight Loss

Woo, J., Sea, M., Tong, P., Ko, G., Lee, Z., Chan, J., et al. (2007, December). Effectiveness of a lifestyle modification programme in weight maintenance in obese subjects after cessation of treatment with Orlistat. *Journal of Evaluation in Clinical Practice, 13*(6), 853–859. Retrieved September 14, 2009, from CINAHL Plus with Full Text database.

The Study

In this study, 55 patients were treated with Orlistat for 6 months following which Orlistat treatment was terminated and patients were divided into two groups: those in the intervention group who began a 6-month lifestyle modification program with monthly follow-up and those in the non-intervention group with follow-up every 3 months who did not participate in the lifestyle modification program. The lifestyle modification program consisted of monthly group sessions with discussion on dietary management, physical activity, and exercise management, also providing group support. Patients were given tailored menu plans based on their calculated BMR (basal metabolic rate) at the end of Orlistat treatment and daily food and activity diaries were collected. At the end of the 6-month period, patients from each group were measured. All patients in the non-intervention group had an increase in weight, BMI, waist and hip circumference, and percentage of body fat comparable to the magnitude of reduction obtained during the previous Orlistat treatment, where the intervention group maintained their weight loss.

Nursing Implications

Losing weight and keeping it off is a difficult task. The nurse needs to be a patient advocate. Review the importance of diet and exercise in combination with pharmacotherapy at each visit. Encourage the patient to keep a food and exercise diary and become involved in peer support groups to increase compliance. Be supportive—even if there is only a minimal weight loss.

Pharmacokinetics

Following oral ingestion, dextroamphetamine has an onset of 20 to 60 minutes and a duration of 5 hours. The sustained-release form of the drug has an onset of 60 to 90 minutes and lasts 6 to 10 hours. The half-life ranges between 10 and 30 hours. Dextroamphetamine is metabolized by the liver and is excreted, partly unchanged and partly in the form of inactive metabolites, in the urine. This process peaks at 12 to 24 hours.

Pharmacodynamics

The exact mechanism of action of dextroamphetamine is unknown, although it is likely that indirect alpha- and beta-adrenergic activity mediates both central and peripheral effects. Dextroamphetamine causes the release of norepinephrine and, in higher doses, dopamine in adrenergic nerve terminals. It also interferes with the reuptake of dopamine. The sites of action in the CNS are the cerebral cortex and the RAS. The drug's anorectic effects are likely secondary to CNS stimulation in the hypothalamic satiety-feeding center.

Contraindications and Precautions

Dextroamphetamine is contraindicated in patients with advanced arteriosclerosis, symptomatic cardiovascular disease, moderate to severe hypertension, hyperthyroidism, known hypersensitivity or idiosyncratic reactions to other sympathomimetic drugs, glaucoma, or a history of drug abuse. Dextroamphetamine use in patients with these disorders places them at risk for hypertension, increased intraocular pressure, or abuse of the drug. Caution is warranted in older adults with even mild hypertension because the adrenergic stimulation of the amphetamines increases blood pressure.

Because of its pressor effects, dextroamphetamine is contraindicated during the first 14 days after discontinuing monoamine oxidase inhibitor (MAOI) therapy, because

MAOI therapy itself may predispose the patient toward elevated blood pressure. Therefore, this 14-day washout period for MAOIs must be observed to prevent hypertensive crisis.

Dextroamphetamine should be given very cautiously to children and adolescents with structural cardiac abnormalities or other serious heart problems. Sudden death and serious cardiac events have occurred in these patients, even with normal doses. Monitoring the growth and development of all children is important because amphetamines have been associated with growth suppression. Stimulant drugs should not be used in children with ADHD and concomitant Tourette syndrome or tics because stimulants exacerbate these motor disorders.

Dextroamphetamine is assigned to pregnancy category C, and women should not use it during the first trimester of pregnancy or during lactation. If its use is required during such periods, the prescriber should monitor treatment carefully to prevent fetal growth abnormalities or irritability in the breast-fed infant.

Some formulations of dextroamphetamine contain yellow dye No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible people. This sensitivity is rare, although it is frequently seen in patients who also have aspirin hypersensitivity.

Dextroamphetamine should be used with caution to avoid overdose or drug abuse. The least amount feasible should be prescribed or dispensed at any one time to minimize the possibility of overdosage. Patients should be advised not to discontinue therapy abruptly because rebound symptoms may occur. As tolerance develops, particularly to the anorectic effects of the drug, the recommended dose should not be exceeded in an attempt to increase the effect. Instead, the drug should be discontinued. Patients who have recently ceased smoking cigarettes or using other products that contain nicotine may show hypertensive sensitivity to dextroamphetamine, partly because of the absence of the vasoconstrictive toning effects of nicotine.

Adverse Effects

The most serious potential adverse effects for dextroamphetamine are sudden death, stroke, and MI, which may occur in patients with underlying serious cardiovascular disorders or structural abnormalities. Psychiatric adverse effects such as hearing voices, becoming suspicious for no reason, or becoming manic, even in patients who did not have previous psychiatric problems, have also occurred.

Dextroamphetamine may produce the prototypical effects of all CNS stimulants: decreased appetite, rebound irritability and depression, headache, jittery feeling, gastrointestinal (GI) upset, sleep difficulties, anxiety, and increased blood pressure or heart rate. Blood glucose may also elevate; therefore, patients with diabetes need to monitor their blood glucose closely. Ocular irritation, resulting from decreased lacrimation, and mydriasis are two visual adverse effects that may interfere with activities such as driving. Occasionally, patients with allergic tendencies may experience urticaria when taking dextroamphetamine. Finally, the pronounced sympathomimetic action of dextroamphetamine may lead to an inability to ejaculate and either increased or decreased libido. The FDA has issued a black box warning for dextroamphetamine, as well as other stimulant drugs used for ADHD. There is a high risk for dependency, nontherapeutic use, and the potential to distribute to others.

Drug Interactions

Considerable care must be exercised when administering dextroamphetamine with many other classes of drugs. One noteworthy feature of anorectic drugs is their ability to cause rapid change in nutritional status, which may lead to cachexia and hypoproteinemia and thus possibly alter the pharmacokinetics of other drugs. CNS depressants, if administered with CNS stimulants, counteract each other and leave only residual adverse effects. Table 22.3 lists agents that interact with dextroamphetamine.

Dextroamphetamine may cause elevations in plasma corticosteroid levels beyond normal diurnal variations, which may interfere with serum or urinary steroid determinations.

Maximal absorption of dextroamphetamine occurs in the alkaline environment of the small intestine. Therefore, acidic juices and fruits may impair GI absorption. In addition, foods that acidify urine increase the renal clearance of dextroamphetamine and may lower serum levels. This effect is seen with the anorectic influence of dextroamphetamine, which prompts a form of fasting ketoacidosis and leads to enhanced excretion.

Assessment of Relevant Core Patient Variables

Health Status

Evaluate the patient for pre-existing medical or mental health problems that may exacerbate the symptoms of ADHD. It is important to check the patient's history to rule out any contraindications to the pharmacotherapy, including other drug therapies and drug and alcohol abuse. If the patient is a child or adolescent, ask the parents whether there is a history of cardiac disease or cardiac structural abnormalities. Question the patient regarding the use of nonprescription drugs, particularly those with sympathomimetic effects, because patients often do not report the occasional use of over-the-counter (OTC) drugs unless asked.

Evaluate the patient for advanced arteriosclerosis, symptomatic cardiovascular disease, moderate to severe hypertension, hyperthyroidism, glaucoma, agitated states, a history of drug abuse, a recent history of MAOI use, or known hypersensitivity or idiosyncrasy to the sympathomimetic amines, all of which are contraindications for the use of dextroamphetamine.

Document baseline physical assessment data, including height, weight, and vital signs. In addition, an electrocardiogram (ECG) is important for ruling out any cardiovascular abnormalities that CNS stimulants might exacerbate, especially in children and adolescents.

TABLE 22.3 Agents That Interact with P Dextroamphetamine

Interactants	Effect and Significance	Nursing Management
Acidifying agents: GI acidifying agents (guanethidine, reserpine, glutamic acid HCl, ascorbic acid, fruit juices) Urinary acidifying agents (ammonium chloride, sodium acid phosphate)	Decreased absorption of dextroamphetamine; lowered blood levels of dextroamphetamine	Instruct patient to avoid acidic foods. Inform patient of possibly reduced effect of medication (especially of the antihypertensive guanethidine).
Alkalinizing agents: Urinary alkalinizing agents (sodium bicarbonate, acetazolamide) GI alkalinizing agents (sodium bicarbonate)	Increase blood levels of dextroamphetamine, potentiating actions	Avoid administering alkaline agents or increase dosing interval.
Antidepressants, tricyclic; SSRIs	Increased sensitivity to the effects of tricyclics and sympathomimetics; increased risk of serotonin syndrome	Avoid combination; monitor for increased CNS effect.
MAO inhibitors	Exacerbation of dextroamphetamine effects, hypertensive crisis, cerebral bleeding	Avoid; allow proper MAOI washout period.
Chlorpromazine	Diminished effects of dextroamphetamine; may increase psychosis	Avoid; may be of therapeutic use in overdose.
Calamus	Reduced amphetamine effects	Inform patient of possibly reduced effect of medication.

Life Span and Gender

Ask whether the patient is pregnant. If the patient is pregnant, dextroamphetamine should be used only if absolutely necessary because it is not known whether dextroamphetamine causes fetal abnormalities (pregnancy category C). If the patient is breast-feeding, monitoring the infant for CNS stimulation is important. In the event of CNS stimulation in the infant, the mother may need to discontinue the drug. Very young and very old patients may be at higher risk for injury because of CNS adverse effects of agitation and restlessness. Monitoring children's growth is important because dextroamphetamine may cause growth suppression.

Lifestyle, Diet, and Habits

Ask the patient about his or her regular consumption of caffeine-containing drinks such as tea, coffee, and cola because they may increase the adverse effects associated with dextroamphetamine.

Support adherence to the drug regimen to enhance the patient's quality of life. People involved in shift work need to adjust the timing of their doses to avoid sleep disturbances and allow for normal appetite. Be mindful of the high abuse potential for dextroamphetamine and assess patients carefully for a history of drug or alcohol abuse.

Environment

Dextroamphetamine may be administered in any setting by physicians, nurses, or patients. Therefore, assess the safety of the patient's environment. When the patient is a child, it is advisable for parents to store and monitor the drugs.

Culture and Inherited Traits

In some immigrant populations, alternative therapies and drug use are a part of religious or cultural practice. Therefore, it is important to determine the nature and type of alternative therapy or ritual drug use to avoid drug–drug interactions and to maximize the therapeutic effects of dextroamphetamine.

Nursing Diagnoses and Outcomes

- Disturbed Sleep Pattern related to drug effects or caffeine use
  Desired outcome: *The patient maintains normal sleep patterns through proper use of sleep hygiene measures and bedtime (hour of sleep [HS]) sedation.*
- Delayed Growth and Development related to drug effects
  Desired outcome: *The patient maintains a normal growth and development profile.*
- Disturbed Sensory Perception related to drug response
  Desired outcome: *The patient remains free from sensory and perceptual disturbances.*
- Imbalanced Nutrition: Less than Body Requirements, related to amphetamine abuse and anorexia
  Desired outcome: *The patient maintains adequate nutrition.*
- Nonadherence to Therapeutic Regimen related to lack of motivation, poor self-image, or negative effects of prescribed drug
  Desired outcome: *The patient adheres to the drug regimen.*

Planning and Intervention

Maximizing Therapeutic Effects

It is important to administer dextroamphetamine with food in the morning and no fewer than 6 hours before bedtime, preferably longer for the sustained-release formulations. Inform patients and family members that improvements may not be seen until several weeks after the treatment is initiated. Provide emotional and psychological support during this period: a great deal is necessary, particularly because families often feel guilty about the disorders being treated. It is important to explain to the obese person that anorectic agents are used only to supplement a combined program of calorie reduction, nutritional counseling and adjustment, and systematic exercise of large muscle groups. Enhance support by encouraging the person to attend self-support groups and psychotherapy. Explain that people suffering from narcolepsy, ADHD, or obesity usually benefit from programs designed to foster and enhance self-esteem.

Minimizing Adverse Effects

Monitor for adverse effects of dextroamphetamine and intervene if they occur. In patients experiencing decreased appetite, administer the morning dose of medication before or with breakfast to ensure a good caloric intake at the beginning of the day. Monitor for rebound irritability and depression as the stimulant wears off. Consult with the prescriber to change the time or frequency of dosing if these symptoms are intolerable. Monitor also for headache. Intermittent headaches may be treated with acetaminophen; however, if frequent headaches occur, contact the prescriber to decrease the dose of stimulant or possibly change to a different formulation. To minimize GI distress, administer the medication with meals.

In the event of toxicity or overdose, it is necessary to monitor vital signs and anticipate use of antiepileptics and antipsychotics. Patients who are experiencing drug toxicity or overdose are vulnerable, and they must be placed in a nonstimulating yet supportive environment where they are protected from hurting themselves and kept from injuring others. Reassure the patient with drug toxicity or overdose, particularly because profound depression of systems initially stimulated by the drug may occur.

Providing Patient and Family Education

An important component of health promotion is the encouragement and support of patients taking dextroamphetamine and their families. Ensure that patient and family education includes explaining the importance of adhering to dosing instructions and dosage scheduling, and understanding recommendations regarding possible adverse effects, other drugs to avoid, drug storage, missed doses, abuse potential, and monitoring the effects of therapy.

- It is important to caution all patients treated with dextroamphetamine therapy about adverse effects and the possibility of overdosing. Advise patients and their families about managing adverse effects and about when to consult with their caregivers if self-management is ineffective or if serious and persistent adverse effects continue. If toxicity or overdosing is suspected, it is important to decrease frequency of dosing.
- Provide the patient or the patients' family with a Patient Medication Guide that explains the risk of cardiovascular or psychiatric adverse effects.
- Encourage patients to avoid other stimulants during dextroamphetamine therapy, including caffeinated beverages, because these may lead to exaggerated CNS stimulation, irritability, and nervousness.
- Alert patients and parents or caregivers to keep dextroamphetamine in safe storage, out of children's reach.
- Advise patients to take dextroamphetamine early in the day, unless otherwise instructed, to avoid nighttime insomnia. If the tablets are sustained release or long acting, advise patients not to crush or chew them. Tell patients to notify their prescriber if they experience nervousness, restlessness, insomnia, dizziness, dry mouth, diarrhea, constipation, or an unpleasant taste; a dosage adjustment may be necessary. It is also important to tell patients to avoid all other drugs (including OTC drugs) while taking dextroamphetamine, unless the prescriber recommends them.
- Tell patients and family members what to do if they miss a dose of dextroamphetamine. When patients miss one dose, it is important for them to take that dose as soon as possible to prevent trouble sleeping. However, the dose should be taken no later than 6 hours before bedtime for the short-acting form, and no later than 10 to 14 hours before bedtime for the long-acting form. If patients do not remember the missed dose until the next day, they should skip the missed dose and return to the normal dosing schedule. Patients must never take double doses of the drug.
- Advise patients that dextroamphetamine may impair their ability to engage in potentially hazardous activities, such as operating machinery or driving vehicles, particularly if the effects of drug therapy on the individual patient are not yet known.

Ongoing Assessment and Evaluation

Monitor periodic growth and development data for children throughout therapy. Monitor for adverse effects such as anorexia, irritability, depression, headache, GI distress, anxiety, cardiovascular changes, and sleep deprivation. Review the patient's diet periodically and remind the patient to abstain from caffeine-rich products.

It is important to monitor patients for responses to therapy, including improvements in mental and behavioral symptoms in children, decreased baseline rate of motor activity, weight loss, and decreased frequency of narcoleptic attacks.

The patient should show a reduction in symptoms or symptom severity. Patients receiving dextroamphetamines for ADHD should show improved attention span or decreased impulsivity. Patients receiving dextroamphetamines for obesity should show documented weight loss.

MEMORY CHIP

P Dextroamphetamine

- Releases dopamine and norepinephrine in adrenergic nerve terminals and interferes with the reuptake of dopamine; sites of action in the CNS are the cerebral cortex and the reticular activating system
- Most common adverse effects: restlessness, insomnia, dizziness, overstimulation, palpitations, tachycardia, hypertension, dry mouth, unpleasant taste, and diarrhea
- Maximizing therapeutic effects: Take with food in the morning and not less than 6 hours before bedtime.
- Minimizing adverse effects: Obtain a baseline nursing history and physical assessment to compare with treatment outcomes; important assessment items include sleep disturbances, nervousness, complete diet history (including use of caffeine), height, weight, ECG, and drug or alcohol abuse.
- Most important patient education: importance of adhering to dosing instructions, dosage scheduling, possible adverse effects, other drugs to avoid, drug storage, missed doses, abuse potential, and monitoring the effects of therapy
- **Black box warning: High abuse potential. May lead to dependence, non-therapeutic use, or distribution to others.**

Patients receiving dextroamphetamines for narcolepsy should have fewer or less severe episodes. The patient and family should show an increased understanding of how to recognize and manage adverse effects and be able to explain how to store and administer drug therapy safely.

Drugs Closely Related to P Dextroamphetamine

Amphetamine Salts

Amphetamine salts (Adderall, Adderall XR) are a combination of amphetamine salts and dextroamphetamine. Adderall was formerly marketed as Obetrol, a product used primarily for adjunctive short-term treatment of exogenous obesity. The current formula consists of mixed salts of amphetamine aspartate, amphetamine sulfate, dextroamphetamine saccharate, and dextroamphetamine sulfate. It is approved to treat ADHD or narcolepsy.

CRITICAL THINKING SCENARIO

PHARMACOTHERAPY AND ATTENTION DEFICIT HYPERACTIVITY DISORDER

A family friend has a child who has been diagnosed with ADHD. The friend asks you what you think about treating this disorder with drugs. Instead of giving an opinion, construct a patient teaching plan to help this person understand how to maximize the effects of pharmacotherapy. Present three topics for discussion with the family, and explain how you would prioritize these topics.

Like dextroamphetamine, Adderall has a mechanism of action that is unclear. However, its ability to improve symptoms in ADHD is well documented. These include improved attention span, decreased distractibility, increased ability to follow directions or complete tasks, and decreased impulsivity and aggression. The contraindications and the adverse effect profile of Adderall are similar to those for dextroamphetamine; however, Adderall is also associated with increased cardiovascular adverse effects. It is used with caution for patients with medical conditions that may be compromised by hypertension. The benefit of Adderall is its once-daily dosing and its longer duration of action than that of dextroamphetamine. For patients with difficulty swallowing, the Adderall XR capsule may be opened and the beads sprinkled in applesauce.

Dexmethylphenidate

Dexmethylphenidate (Focalin, Focalin XR) is a CNS stimulant that is chemically similar to the amphetamines and is an isomer of methylphenidate. It is used to manage ADHD. Dexmethylphenidate is thought to block the reuptake of norepinephrine and dopamine into the presynaptic neuron and increase the release of these monoamines into the extraneuronal space. This activity results in improved attention spans, decreased distractibility, increased ability to follow directions or complete tasks, and decreased impulsivity and aggression in patients with ADHD. Although dexmethylphenidate does not produce a physical dependence, it may induce tolerance or psychic dependence. The adverse effects of dexmethylphenidate are similar to those of other stimulant drugs. They occur relatively frequently but are usually mild at normally prescribed dosages. They may be more frequent or severe during the initial days of therapy, but most adverse effects disappear within a few weeks of continued use.

Lisdexamfetamine

Lisdexamfetamine (Vyvanse) is a new drug approved for treatment of ADHD in children 6 to 12 years of age. Lisdexamfetamine is a prodrug of dextroamphetamine, which means that lisdexamfetamine is therapeutically inactive until it is converted to dextroamphetamine in the GI tract. Because it must be metabolized in the GI tract and cannot be given by IV or intranasal routes, this drug may have a lower abuse liability. Studies have also indicated that lisdexamfetamine appears less likely to cause euphoria. Efficacy of lisdexamfetamine is comparable to that of Adderall XR.

Methylphenidate

Methylphenidate (Ritalin, Ritalin SR, Ritalin LA, Methylin, Methylin-ER, Metadate-ER, Metadate-CD, Concerta) is an orally administered CNS stimulant that is chemically and pharmacologically similar to the amphetamines. It is clinically used to treat ADHD and narcolepsy. The CNS actions of methylphenidate are milder than those of the amphetamines and have more noticeable effects on mental activities than on motor activities. Methylphenidate shares the abuse

potential of the amphetamines and is a DEA Schedule II controlled substance. Methylphenidate comes in many formulations. Although the active ingredient is the same, these drugs, which are described below, have different pharmacokinetics because of their structure or method of delivery.

Ritalin is the oldest available medication for ADHD and is considered the drug of choice by many prescribers. Its quick onset and short duration make it possible to individualize dosing. Ritalin SR is an extended-release form of methylphenidate with an approximate duration of 8 hours. Ritalin SR tablets must be swallowed whole. Ritalin LA is a long-acting formulation of methylphenidate that provides all-day treatment with one morning dose. This dosing regimen eliminates the social stigma felt by children who have to bring medication to school and decreases the possibility of medication misuse. Advantages include once-daily dosing and the potential for sprinkle administration, if needed.

Methylin is another trade name of methylphenidate. It has three formulations: Methylin and Methylin Chewable tablets, which are comparable to Ritalin; and Methylin-ER, which is comparable to Ritalin SR and Metadate-ER. Methylin Chewable tablets should be taken with 8 ounces of water to minimize the risk of choking.

Metadate-ER is another extended-release form that uses a two-phase process to deliver an initial rapid release of methylphenidate followed by a second, continuous-release phase. Metadate-CD has a controlled delivery system that uses a multiparticulate bead system, with each bead acting as a drug reservoir. The individual beads are coated with different polymers that dissolve and release at different times. Metadate-CD capsules contain immediate-release and extended-release beads in a ratio of 30:70. It has a duration of 12 hours, which is similar to Concerta (see below); however, serum drug levels of Metadate-CD are higher than Concerta for the initial 4 hours of activity. Advantages of Metadate-CD include once-daily dosing, which is especially important for school-aged children, and the ability for sprinkle administration, if necessary. Disadvantages include cost and the fixed ratio of immediate-release to extended-release beads.

Concerta is a once-a-day formulation of methylphenidate that is targeted at patients with moderate ADHD. There is a dose-related size problem with the Concerta capsules. Many patients have difficulty swallowing the larger-dose capsules. The size of the capsule is related to its unique delivery system. The outside of the capsule dissolves and releases the initial methylphenidate within an hour. The inner core has a push layer and a drug layer. Once the capsule is in the GI tract, water enters the osmotic system and dissolves or suspends the drug in the core. The drug is then released by osmotic pressure at a controlled rate through a laser-drilled hole in the membrane. The capsule itself is excreted in the feces. Because of its delivery system, Concerta cannot be crushed, chewed, or opened in any way.

Like Adderall, Concerta is associated with cardiovascular adverse events. Patients with medical conditions that may be compromised by hypertension or tachycardia should not use Concerta. Also, patients with severe ADHD frequently need a larger dose of methylphenidate than can be offered in the Concerta formulation.

In addition to these oral forms of methylphenidate, there is a new delivery system—a transdermal patch (Daytrana). The patch is applied daily but removed after 9 hours to decrease potential adverse effects. If the patient is experiencing severe adverse effects, the patch can be removed early. Warnings and precautions are the same as oral preparations of methylphenidate. Adverse effects are also similar; in addition, the transdermal system may cause skin sensitization. Transdermal patches may fall off with excessive heat or participating in sports activities.

Drugs Significantly Different From P Dextroamphetamine

Atomoxetine

Atomoxetine (Strattera) is a selective norepinephrine reuptake inhibitor initially evaluated for use as an antidepressant. Although it failed to demonstrate efficacy as an antidepressant, further research showed it to be highly effective for ADHD. Atomoxetine is the first ADHD medication that is not a stimulant. Although its true mechanism of action is unknown, it is thought to involve the selective inhibition of the presynaptic norepinephrine transporter. Atomoxetine is metabolized by the cytochrome P-450 2D6 isoenzyme. Concurrent use of drugs that inhibit this pathway, such as SSRIs, increases the serum concentration of atomoxetine and extends its half-life substantially. The only contraindication to the use of atomoxetine is concurrent use of MAOIs. In patients who have been exposed to both drug classes, a 2-week washout period should take place after discontinuing either drug or before starting either drug. Monitor liver enzymes because there is a high incidence of liver damage, elevated liver enzymes, and jaundice requiring discontinuation of the medication for patient recovery. Atomoxetine appears to have a substantial and dose-related effect on growth. Patients may lose weight and gain height while taking atomoxetine. The drug may also increase blood pressure and heart rate and can cause additive cardiovascular effects with albuterol and pressor agents. Atomoxetine should be used cautiously in conditions that predispose patients to hypotension because it has been reported to cause orthostatic hypotension and syncope. The most common adverse effects in adult patients are constipation, dry mouth, nausea, appetite suppression, lethargy, dizziness, insomnia, sexual dysfunction, urinary dysfunction (hesitation or retention), and dysmenorrhea. The most common adverse effects in pediatric patients are lethargy, hypoesthesia, paraesthesia, sensory disturbances, dyspepsia, nausea, vomiting, fatigue, appetite suppression, dizziness, urinary dysfunction (hesitation or retention), and mood swings. The major advantage of atomoxetine is that, because it is not a stimulant, it is not a DEA Schedule II drug—samples can be provided to physicians, prescriptions can be refilled, and the drug does not have be securely stored.

Guanfacine

Guanfacine (Intuniv), a selective alpha-2A adrenergic receptor agonist, is an antihypertensive drugs that has just been approved for the management of ADHD. Because of its selective alpha-2A stimulation, it reduces sympathetic nerve impulses from the vasomotor center to the heart and blood vessels. This results in a decrease in peripheral vascular resistance and a reduction in heart rate, which may also induce its adverse effects. The mechanism by which guanfacine affects ADHD is unclear.

Guanfacine is available as an immediate release or an extended release drug. Only the extended release formulation is approved for ADHD. Common adverse effects associated with its use include syncope, increased weight, depression, and fatigue. Additional adverse effects include hypotension, sedation, headache, and lethargy.

Prior to initiation of therapy, assess heart rate and blood pressure. Continue to monitor during therapy, especially following dose increases. Guanfacine is a pregnancy category B drug.

Modafinil

Modafinil (Provigil) is approved for narcolepsy, obstructive sleep apnea, and shift work sleep disorder. The mechanism of action is unclear. It is theorized that modafinil may alter the balance of gamma-aminobutyric acid and glutamate, resulting in activation of the hypothalamus. Another theory is that is promotes histamine release. Common adverse effects include headache, abdominal pain, anorexia, and insomnia.

Antihypertensive Agents

Antihypertensive agents such as clonidine (Catapres, Kapvay) and guanfacine (Tenex, Intuniv) may be prescribed alone or with a stimulant to manage the symptoms of ADHD, especially in children with tics. These drugs help with impulsivity, sleep problems, frustration tolerance, and activity. They do not have any known effect on inattention. Common adverse effects include drowsiness, dry mouth, and constipation. In-depth information regarding these antihypertensive agents is located in Chapter 28.

Antidepressants

Antidepressants may be used in managing ADHD, especially if comorbid diagnoses are suspected. Tricyclic antidepressants (TCAs), such as desipramine (Norpramin), nortriptyline (Pamelor), and imipramine (Tofranil), improve concentration, mood, and hyperactivity and help regulate emotional ups and downs. It is important to monitor cardiac activity, especially in children, when patients are taking these drugs. SSRIs, such as fluvoxamine (Luvox), paroxetine (Paxil), and fluoxetine (Prozac), are used primarily when mood or anxiety disorders are thought to coexist. SSRIs may increase impulsivity. Venlafaxine (Effexor) is thought to provide the benefits of both TCAs and SSRIs. It is not generally used in children. Common adverse effects with antidepressant drugs include headache, insomnia, weight loss, nervousness, and either constipation or diarrhea. Many of these adverse effects abate after continued use of the drug. For more information regarding antidepressant drugs, see Chapter 16.

C ANORECTIC AGENTS

Obesity is a complex problem that is very difficult to treat. Current views concerning the cause of obesity favor a disturbance in the hypothalamic set-point, which mediates caloric intake and use and energy expenditure. Although drug therapy is helpful, drugs alone cannot manage weight loss. Diet and exercise are equally important. Common agents used as anorectics include phentermine, adrenergic drugs, serotonergic drugs, and orlistat. This section focuses on phentermine (Adipex-P) the prototype anorectic drug. Table 22.4 presents summary of selected anorectic drugs.

Nursing Management of the Patient Receiving P Phentermine

Core Drug Knowledge

Pharmacotherapeutics

Phentermine is a DEA Schedule IV drug classified as an indirect sympathomimetic. It is used as an adjuvant to manage obesity by promoting weight loss. It is indicated for patients with an initial BMI greater than or equal to 30 kg/m^2, or greater than or equal to 27 kg/m^2 with other risk factors such as diabetes mellitus, dyslipidemia, or hypertension. Tolerance to the anorectic effects of phentermine usually develops within a few weeks of starting therapy; therefore, it is indicated for short-term therapy. When tolerance develops to the anorectic effects, it is generally recommended that phentermine be discontinued rather than increased.

Pharmacokinetics

Phentermine is administered orally as either phentermine hydrochloride or phentermine resin complex. Both formulations are metabolized by the liver and excreted, predominately unchanged, by the kidneys. The resin complex formulation has a slower absorption and longer duration of action.

Pharmacodynamics

Phentermine is structurally and chemically related to the amphetamines, therefore, the pharmacologic effects are also similar. Appetite suppression is believed to occur through direct stimulation of the satiety center in the hypothalamic and limbic regions.

Contraindications and Precautions

Phentermine is contraindicated in patients with advanced arteriosclerosis, agitated states, moderate to severe hypertension, glaucoma, or symptomatic cardiovascular disease, including cardiac arrhythmias. Phentermine is not recommended for use in patients with cardiac disease, including valvular heart disease. Phentermine should not be combined with any other drug class used to decrease weight.

Adverse Effects

Adverse effects can affect several body systems. CNS effects include dizziness, dyskinesia, dysphoria, euphoria, headache, insomnia, overstimulation, restlessness, and tremor. Potential ocular effects include blurred vision, mydriasis, and ocular irritation. Cardiovascular effects include hypertension, palpitations, and sinus tachycardia. GI effects include constipation, diarrhea, dysgeusia, nausea and vomiting, and dry mouth. Other adverse reactions include impotence, libido increase, libido decrease, and urticaria.

Drug Interactions

Drug interactions with phentermine may result in "serotonin syndrome," characterized by CNS irritability, motor weakness, shivering, myoclonus, and altered consciousness. This syndrome may occur when phentermine is used in conjunction with selective serotonin reuptake inhibitors and MAOIs. Table 22.5 presents additional drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess for disorders that contraindicate or require precautions with phentermine therapy. Assess also for current or recent use of medications that may interact with phentermine, especially MAOIs and SSRIs. Communicate positive findings to the prescriber before starting phentermine therapy.

Perform a physical examination that includes calculating the BMI. Phentermine is indicated for use only with morbidly obese patients. Obtain baseline blood pressure and heart rate parameters because phentermine may increase both.

Life Span and Gender

Assess female patients for pregnancy or the intention to become pregnant. Phentermine is classified as pregnancy category C drug because adequate, well-controlled studies with phentermine have not been conducted in pregnant women. Women of childbearing potential should use adequate contraception while taking phentermine. Advise patients to notify their physician if they become or intend to become pregnant during phentermine therapy. Additionally, it is unknown whether phentermine is excreted in breast milk; therefore, phentermine is not recommended for breast-feeding mothers. Accordingly, assess female patients for lactation.

Assess for age-related considerations Dosing in older adults should be done cautiously, because of a greater likelihood of decreased hepatic, renal, or cardiac function.

Lifestyle, Diet, and Habits

Assess the patient's diet and make modifications to optimize therapy. Phentermine is most effective when combined with

TABLE 22.5 Agents That Interact with P Phentermine

Interactants	Effect and Significance	Nursing Management
MAOIs	Increased pharmacological effects of phentermine resulting in hypertensive crisis and cerebral hemorrhage.	Avoid combination. Monitor for signs of hypertensive crisis.
SSRIs	Increased sympathomimetic effects and increased risk of serotonin syndrome.	Monitor for increased CNS effects: agitation, anxiety, restlessness.

a low-calorie diet and behavior modification counseling. Assess the use of caffeine and alcohol. Advise the patient to avoid both throughout phentermine therapy.

Environment

Phentermine may be administered in any setting by physicians, nurses, or patients. Assess the patient's environment to ensure safety.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to anorexia
  Desired outcome: *The patient maintains adequate nutrition.*
- Nonadherence to Therapeutic Regimen related to lack of motivation, poor self-image, or negative effects of prescribed drug
  Desired outcome: *The patient adheres to drug regimen.*

Planning and Intervention

Maximizing Therapeutic Effects

Phentermine should be taken once daily. For the long-acting resin complex, advise the patient to take it at least 10 hours before bedtime; for the immediate-release formulation take at least 4-6 hours before bedtime. It is important to remember that phentermine should be used in conjunction with a low-calorie diet and daily exercise routine for maximum results. Some patients benefit from writing a food journal to assess the amount of food intake and the types of foods consumed.

Minimizing Adverse Effects

Adverse effects are minimized by adhering to the contraindications and precautions for this medication. Refraining from using drugs that may induce serotonin syndrome or elevate the blood pressure and heart rate is especially important. At least 2 weeks should elapse between discontinuing MAOI therapy and initiating phentermine therapy. Similarly, at least 2 weeks should elapse after stopping phentermine therapy and starting MAOI therapy. It is also important for female patients to take precautions to avoid pregnancy and to contact their prescriber immediately if pregnancy occurs.

Providing Patient and Family Education

- An important component of health promotion is encouragement and support of the patient's commitment to weight loss. Remind patients that phentermine is only one component in the recipe for weight loss. Behavior modification and exercise are equally important for patients to reach their goals.
- Advise the patient to contact the provider if tolerance begins to develop. Taking a larger dose does not increase its effectiveness and increases the risk for severe adverse effects.
- Reinforce avoidance of caffeine and alcohol.
- Educate patients and families about drugs that may interact with phentermine and encourage patients to contact the prescriber before adding any daily medications, even OTC drugs.
- Instruct patients regarding possible adverse effects of phentermine therapy, especially the potential for hypertension. When possible, teach patients and families how to take blood pressure and pulse.
- When working with women, discuss contraception and the importance of notifying the prescriber if the patient becomes pregnant. Discuss also the need to refrain from phentermine therapy if the patient is breast-feeding.

Ongoing Assessment and Evaluation

Calculate BMI at each follow-up visit in addition to obtaining gross weight measurement. Assessing vital signs is equally important, with a focus on blood pressure and heart rate. When possible, review the patient's food journal and assess the progress of the patient's behavior modification. Reinforce the need for daily exercise to complement phentermine therapy. Finally, arrange for serial laboratory tests, including CBC, liver function, and renal function tests.

Evaluating the patient routinely is important for assessing progress. With phentermine therapy, an adequate diet, and regular exercise, the patient should lose between 8 and 10 pounds per month. The patient should not remain on sibutramine therapy if weight loss does not occur. The time frame depends on the person's specific variables.

Drug Significantly Different From P Phentermine

Adrenergic Drugs

The adrenergic drugs are primarily phenethylamines—drugs similar to amphetamines. These drugs include benzphetamine (Didrex), diethylpropion (Tenuate), and phendimetrazine (Adipost, Bontril). They decrease the appetite by stimulating the CNS. They also have effects similar to those of amphetamines, such as tachycardia, hypertension, nervousness, and anxiety. While they are safer than amphetamines, they still have an abuse potential; thus, they are scheduled drugs. They are not useful for long-term management of obesity because tolerance develops in 6 to 12 weeks.

MEMORY CHIP

P Phentermine

- Used only for patients with a body mass index diagnostic for morbid obesity
- Inhibits dopamine, norepinephrine, and serotonin
- Major contraindications: uncontrolled hypertension
- Most serious adverse effects: "serotonin syndrome" and hypertension
- Most important patient education: Drug must be used in conjunction with a low-calorie diet and exercise plan.

Orlistat

Orlistat (Xenical, Alli) is a GI lipase inhibitor indicated for weight loss and subsequent weight maintenance in morbidly obese patients. As with phentermine, orlistat is used in conjunction with a reduced-calorie diet and physical activity. Orlistat works nonsystemically to block the absorption of dietary fat by approximately 30%. Alli is an over-the-counter formulation of orlistat. A thorough discussion of orlistat appears in Chapter 36.

Off-Label Medications

The antidiabetic drugs pramlintide (Symlin) and exenatide (Byetta) have demonstrated weight loss in diabetic patients. These drugs decrease gastric emptying and increase satiety leading to weight loss. See Chapter 49 for additional information.

Zonisamide (Zonegran) and topiramate (Topamax) are anticonvulsant drugs that are also used off-label for weight loss. Zonisamide acts synergistically by suppressing the NPY/AgRP neuron, which acts in opposition to the POMC (proopiomelanocortin) neuron. The exact mechanism of topiramate is unclear. Several mechanisms have been proposed, including anorexia related to its use, reduction in the activity of salivary enzymes that change taste, reduction in leptin and corticosteroid concentrations, and reduction in serum glucose and insulin concentrations. See Chapter 18 for additional information.

Serotonergic Drugs

Anorectic drugs that affect the serotonergic receptors in the brain include SSRIs, which are generally used as antidepressants. However, they do induce weight loss in the short term. Fluoxetine (Prozac) is the SSRI known best for its ability to induce anorexia. Other serotonergic drugs in this class that cause anorexia are venlafaxine (Effexor) and sertraline (Zoloft). These drugs are discussed in depth in Chapter 16. Bupropion (Wellbutrin), another drug used for depression, is also used for weight control and smoking cessation. Bupropion controls weight by stimulating POMC (proopiomelanocortin) neurons.

RESPIRATORY STIMULANTS

Respiratory stimulants are used to manage postsurgical respiratory depression and apnea in preterm neonates. Caffeine is the prototype respiratory stimulant (Table 22.6). Because of its CNS stimulation, it is also used to maintain alertness and decrease fatigue. Caffeine is also used nontherapeutically in foods such as cocoa and chocolate and in beverages such as coffee, tea, and colas.

Nursing Management of the Patient Receiving P Caffeine

Core Drug Knowledge

Pharmacotherapeutics

Caffeine is used in managing neonatal apnea, asthma, drowsiness, and fatigue. The use of caffeine for apnea of prematurity reduces the rate of bronchopulmonary dysplasia in infants with very low birth weight (Schmidt, 2007).

Caffeine is used in combination with many other drugs such as aspirin, acetaminophen, propoxyphene, and butalbital for treating migraine and other types of headache. Caffeine is also sold without a prescription in products marketed to treat drowsiness or mild water-weight gain.

Caffeine may be administered to patients receiving electroconvulsive therapy (ECT). The desired result from ECT is seizure activity. Seizure augmentation, using proconvulsant agents such as caffeine, is used to overcome resistance to the induction and continuation of seizure activity.

Pharmacokinetics

Caffeine may be administered orally and intravenously. Orally administered caffeine in an adult is well absorbed from the GI tract, reaching peak plasma concentrations within 50 to 75 minutes. In neonates, oral administration results in peak concentrations in 30 to 120 minutes. Formula feedings do not affect the time to maximum concentrations after oral dosing. Caffeine is distributed rapidly to all body tissues and readily crosses the blood–brain and placental barriers. It is distributed into breast milk.

In adults, caffeine is partially metabolized in the liver. Caffeine metabolism in neonates is limited because of their immature hepatic enzyme systems. Unchanged caffeine and its metabolites are excreted in the urine (see Table 22.6).

Pharmacodynamics

Caffeine is a mild, direct stimulant at all levels of the CNS, which also stimulates the cardiovascular system. Caffeine also stimulates the medullary respiratory center and relaxes bronchial smooth muscle. Caffeine stimulates voluntary muscle and gastric acid secretion, increases renal blood flow, and is a mild diuretic. Caffeine is preferred over theophylline in neonates because of the ease of once-daily administration, reliable oral absorption, and a wide therapeutic window. The cellular mechanism of action is unclear.

Contraindications and Precautions

Caffeine should be used cautiously in patients with anxiety disorders, panic disorder, or both because as a CNS stimulant, it can aggravate these conditions. Caffeine is contraindicated for patients suffering from insomnia because insomnia is one of its most frequent adverse effects. In overdoses, caffeine has been associated with seizures; therefore, it should be prescribed cautiously to any patient with a seizure disorder.

Caffeine may stimulate the force of contraction and increase heart rate and blood pressure. It may also increase left ventricular output and stroke volume. Patients who have cardiac disease, angina, hypertension, or a history of cardiac dysrhythmias should be given caffeine cautiously. Patients should not take caffeine within 14 days of a myocardial infarction.

Patients with chronic disorders such as diabetes mellitus, hyperthyroidism, and peptic ulcer disease should not receive or should minimize their intake of caffeine. In patients with diabetes, caffeine can either increase or decrease blood sugar. In neonates, both hypoglycemia and hyperglycemia have been observed with the use of caffeine. In patients with hyperthyroidism, the stimulatory effects of caffeine can be augmented. Because caffeine can stimulate gastric secretions, it may also aggravate stomach ulcerations.

Caffeine should be used cautiously in patients with hepatic disease or hepatic impairment. Caffeine clearance may be delayed, leading to toxicity. Using caffeine cautiously is especially important in neonates because their hepatic metabolism is underdeveloped. Additionally, renal impairment in premature neonates may delay caffeine clearance because caffeine elimination depends more on renal clearance in neonates than in older infants or adults.

Adverse Effects

Many adverse reactions to caffeine are an extension of caffeine's pharmacologic actions. Caffeine can cause tremor, sinus tachycardia, and heightened attentiveness. Other adverse reactions include diarrhea, excitement, irritability, insomnia, headache, muscle twitches, and palpitations. Because caffeine is a mild diuretic, polyuria is a possibility.

Cardiac arrhythmias, seizures, and delirium are possible after deliberate overdoses. In neonates, intolerance or overdose of caffeine may manifest as tachypnea, hyperglycemia, azotemia, fever, or seizures.

High caffeine intake has been reported to inhibit spermatogenesis in male animals. Adverse effects may also occur when a patient abruptly discontinues use of caffeine. Caffeine withdrawal syndrome is characterized by lethargy, anxiety, dizziness, or headache.

Drug Interactions

Caffeine has many potential drug–drug interactions, including with oral contraceptives, psychostimulants, sympathomimetic agents, fluoroquinolone antibiotics, lithium, and MAOIs. Caffeine may also interact with grapefruit juice. Table 22.7 presents these potential drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess for disorders that contraindicate or require precautions with caffeine therapy. Assess for current or recent use of medications that may interact with caffeine, especially MAOIs and sympathomimetic drugs. Assessing for the use of OTC drugs is important because many of them have sympathomimetic ingredients. Communicate positive findings to the prescriber before starting caffeine therapy.

Obtain baseline vital signs. When caffeine is used for respiratory depression or neonatal apnea, appropriate monitoring equipment should be used.

Life Span and Gender

Ask female patients if they are pregnant or would like to become pregnant. Couples who are pursuing pregnancy should probably limit excessive intake of caffeine. Caffeine drug products are generally classified in pregnancy category B; however, injectable forms are classified in pregnancy risk category C because caffeine easily crosses the placenta. It is generally recommended that pregnant women avoid the intake of caffeine-containing beverages (e.g., coffee, teas, and colas) or limit their use to no more than one or two caffeine-containing beverages per day. Likewise, pregnant women should use caffeine-containing medications only when absolutely necessary.

The American Academy of Pediatrics generally considers the casual use of caffeinated beverages to be compatible with lactation. Lactating women should use caffeine-containing drug products cautiously. When breast-fed infants are prescribed caffeine for apnea, their mothers should avoid the use of caffeine.

In neonates, there is a possible association between the use of methylxanthines like caffeine and the development of necrotizing enterocolitis. All preterm neonates treated with caffeine should be monitored for the development of gastric adverse effects such as abdominal distension, vomiting, bloody stools, and lethargy. In addition, monitoring serum caffeine levels is recommended. Neonates should receive caffeine without sodium benzoate.

TABLE 22.7 Agents That Interact with P Caffeine

Interactants	Effect and Significance	Nursing Management
oral contraceptives	Serum concentrations of caffeine may be increased during concurrent administration with oral contraceptives.	Monitor for nausea or tremors. Limit caffeine intake with oral contraceptives.
fluoroquinolone antibiotics • ciprofloxacin • levofloxacin • norfloxacin • enoxacin	Fluoroquinolone antibiotics decrease the clearance of caffeine, resulting in the potential for caffeine toxicity.	Avoid concomitant use of caffeine with fluoroquinolone antibiotics if possible. Monitor for caffeine toxicity.
lithium	Caffeine reduces serum lithium concentration.	Monitor serum lithium levels. Counsel patients taking lithium regarding caffeine intake.
MAOIs	Dangerous cardiac arrhythmias or severe hypertension may occur because of potentiation of sympathomimetic effects.	Do not administer caffeine within 2 wk of MAOI therapy. Counsel patient taking MAOIs of potential adverse effect with caffeine.
phenylpropanolamine	A combination of caffeine and phenylpropanolamine has resulted in cerebrovascular accident.	Do not combine these agents.
psychostimulants • dextroamphetamine • methylphenidate • modafinil • nicotine • pemoline • pseudoephedrine • sympathomimetic agents	When combined with any of these medications, an additive effect may occur, resulting in nervousness, irritability, insomnia, or cardiac arrhythmias.	Avoid these combinations when possible. Monitor blood pressure and heart rate. Monitor for adverse effects.

The benzoate may displace bilirubin and induce kernicterus. In addition, elevated serum concentrations of benzoate have been associated with neurologic disturbances such as hypotension, gasping respiration, and metabolic acidosis.

Lifestyle, Diet, and Habits

Caffeine is found in many foods and beverages. To avoid toxicity, patients should limit their intake of these foods while taking drugs that contain caffeine. To avoid caffeine withdrawal syndrome, patients should decrease their intake of caffeine daily rather than stop caffeine ingestion abruptly. Patients should never take caffeine tablets with grapefruit juice, which increases the effects of caffeine.

Environment

Oral preparations of caffeine may be administered in any setting by physicians, nurses, or patients. When used for respiratory depression or neonatal apnea, injectable caffeine must be administered in a monitored setting with appropriate life-sustaining equipment available.

Nursing Diagnoses and Outcomes

- Disturbed Sleep Pattern related to insomnia
  Desired outcome: *The patient will maintain adequate sleep and rest cycles.*
- Anxiety related to stimulatory effects of caffeine
  Desired outcome: *The patient will remain calm throughout therapy.*
- Deficient Fluid Volume related to diuretic effect of caffeine and potential diarrhea
  Desired outcome: *The patient will remain well hydrated.*

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that the patient takes the caffeine tablets or caplets as directed. It is very important that the patient does not take more than prescribed. If administering an extended-release form of caffeine, advise the patient to swallow the tablet whole, not to crush or chew it. If administering chewable tablets, advise the patient to chew well and then swallow. Consistent intake of caffeine results in tolerance to its effects. Patients obtain maximum therapeutic effects when they use caffeine intermittently.

Minimizing Adverse Effects

Adverse effects are minimized when patients adhere to the contraindications and precautions for caffeine therapy. Patients taking caffeine for its therapeutic effects should limit their ingestion of caffeine from food and beverage sources. The patient should also refrain from taking OTC products that contain caffeine, especially cold and cough medications that also have a sympathomimetic effect.

Providing Patient and Family Education

- The general public typically does not view caffeine as a drug. Convey to the patient that caffeine is a drug and as such may create serious adverse effects. Review the contraindications and precautions of caffeine therapy with patients and families before initiating therapy. Instruct them about potential drug–drug interactions and explain the importance of refraining from using OTC drugs without the prescriber's knowledge.
- Instruct patients regarding the potential adverse effects of caffeine and ways to minimize their potential. Tell patients to contact the prescriber if symptoms such as anxiety or panic reactions, confusion, dizziness, lightheadedness or fainting spells, fast or irregular breathing or heartbeat (palpitations), muscle twitching, nausea and vomiting, seizures, or trembling occur.
- Alert women of childbearing age to the potential difficulty of becoming pregnant when they ingest large amounts (more than 500 mg/day) of caffeine daily. Inform men of the potential for inhibiting spermatogenesis.
- Review dietary sources of caffeine and explain the importance of limiting caffeine from these sources while taking therapeutic caffeine. Discuss the interaction between caffeine and grapefruit juice to avoid caffeine toxicity.

Ongoing Assessment and Evaluation

Caffeine is indicated for short-term or intermittent therapy. When caffeine is used for respiratory depression or neonatal apnea, monitor the patient's vital signs carefully. When administering caffeine for migraine or other types of headaches, monitor for potential adverse effects, especially CNS and cardiovascular stimulation. Conversely, also monitor for signs of caffeine withdrawal.

Drug Closely Related to P Caffeine

Doxapram (Dopram), a parenteral analeptic agent, is used to stimulate postanesthesia respiratory depression or drug-induced CNS depression and to treat chronic pulmonary disease associated with acute hypercapnia. It has an unlabeled use for neonatal apnea. Doxapram works by activating the peripheral carotid chemoreceptors, thereby increasing respiratory rate. It is not usually the drug of choice because of its narrow margin of safety. Adverse effects include hypertension, sinus tachycardia, arrhythmias, skeletal muscle hyperactivity, dyspnea, headache, dizziness, apprehension, disorientation, pupil dilation, convulsions, cough, tachypnea, laryngospasm, bronchospasm, nausea and vomiting, diarrhea, and urinary retention.

MEMORY CHIP

P Caffeine

- Used therapeutically for neonatal apnea, asthma, drowsiness, and fatigue
- Ingested nontherapeutically in cocoa, chocolate, coffee, tea, and cola
- Stimulates medullary respiratory center, CNS, and cardiovascular systems
- Most common adverse effects: usually an extension of its pharmacologic actions; caffeine withdrawal syndrome occurs with abrupt cessation after long-term or high intake of caffeine

CHAPTER SUMMARY

- The CNS acts as a system of control and surveillance for many unconscious and conscious functions. Normal arousal mechanisms are affected through presynaptic release of neurotransmitters, such as norepinephrine, serotonin, and dopamine.
- The CNS stimulants are used therapeutically to treat several pathologic conditions, including narcolepsy, ADHD, obesity, and respiratory depression. CNS stimulants can be divided into three drug classes according to the specific effects they have on the body: central CNS stimulants, anorectic CNS stimulants, and respiratory CNS stimulants.
- The central CNS stimulants stimulate the CNS directly or indirectly, and drugs in this class include those that are used therapeutically and nontherapeutically. Those that are used therapeutically include dextroamphetamine, amphetamine salts, methylphenidate, pemoline, and cocaine. Those used nontherapeutically include amphetamines, cocaine, nicotine, and caffeine.
- The prototype centrally acting CNS stimulant is dextroamphetamine. It is used to treat ADHD and narcolepsy. Nursing management concerns regarding dextroamphetamine relate to preventing abuse, promoting adherence to the therapeutic regimen, and recognizing and managing adverse effects.
- Another stimulant drug used to treat ADHD is methylphenidate, which has many different trade names. Each proprietary drug has a different vehicle for administration, or pharmacokinetics.
- Other classes of drugs used in the management of ADHD include nonstimulants such as atomoxetine, antihypertensive medications, and antidepressant medications.
- The anorectic CNS stimulants may directly stimulate the satiety center in the hypothalamus. These drugs include phentermine, benzphetamine, diethylpropion, mazindol, phendimetrazine, and phenylpropanolamine. Their mechanisms of action relate to adrenergic or serotonergic inhibition of the hypothalamic satiety center.
- Anorectic drug use is controversial and not effective as monotherapy. These drugs should be used as part of an overall strategy to control obesity.
- All anorectic drugs except phenylpropanolamine are available by prescription only. They all exhibit a wide range of adverse effects.
- Nursing management for anorectic drugs should focus on careful pretreatment assessment, adequate therapeutic monitoring, and proper patient and family education.
- The respiratory CNS stimulants directly affect the brain stem and respiratory centers. Respiratory CNS stimulants include caffeine and doxapram.

QUESTIONS FOR STUDY AND REVIEW

1. Many stimulants are used in the management of ADHD. Develop a learning tool to differentiate between short-acting, intermediate- acting, and long-acting stimulants.
2. You are working in an outpatient setting that specializes in the management of ADHD in children. Develop a series of questions that you would ask parents during follow-up visits. Develop a list of observations that you should document after each visit.
3. You have been telephoned by the daughter of your discharged patient, Mrs. Christo. Mrs. Christo was sent home last week with a diagnosis of narcolepsy and was taking dextroamphetamine, 30 mg/day. Her daughter wants to know how effective this drug is. What questions would you ask her to be able to answer her question properly?
4. You are talking with a colleague who tells you, "I must be allergic to my home. Every weekend I have a terrible headache. I feel tired, dizzy, and lethargic. I never feel this way at work. What could be wrong with me?"
5. Your patient has morbid obesity. She is prescribed phentermine. What are the most important teaching points for this patient?
6. How do phentermine and orlistat differ in their mechanisms of action?

Drugs Treating Severe Pain

Learning Objectives

At the completion of this chapter the student will:

1. Define pain.
2. Describe the physiology of the central nervous system (CNS) as it relates to pain.
3. Differentiate the types of pain.
4. Differentiate the various methods used in pain management.
5. Be able to assess pain.
6. Describe the effects of agonist stimulation and antagonist stimulation at the opiate receptors.
7. Identify core drug knowledge about narcotic drugs.
8. Identify core patient variables related to narcotic drugs.
9. Relate the interaction of core drug knowledge to core patient variables for narcotic drugs that relieve pain.
10. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for narcotic drugs used to control pain.
11. Describe nursing interventions that maximize therapeutic effects and minimize adverse effects when narcotics are given for pain management.
12. Describe the key points for patient and family education when narcotics are used in pain management.

Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Pain is a multidimensional, subjective experience encompassing the physiologic, sensory, affective, cognitive, behavioral, and sociocultural dimensions of a patient's life. The International Association for the Study of Pain's definition of pain is the most widely used and emphasizes that pain is multidimensional; it defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association for the Study of Pain). Pain can truly be measured only by subjective data because no objective finding is present in all painful experiences. As early as 1968, the nurse-researcher Margo McCaffery defined pain as "whatever the experiencing person says it is, existing whenever s/he says it does" (McCaffery, 1968). Thus, only the person experiencing pain can accurately state when pain is present and how it is being experienced. Pain may accompany disease or treatment and may change over time. Pain may result from multiple simultaneous causes. If unrelieved, pain can affect the patient's psychological, social, physiologic, and spiritual health and can prevent productive work and enjoyment of personal relationships. Despite the substantial effects that pain has on health status, multiple studies over the years have shown that health care providers undertreat pain, leading patients to suffer needlessly. Approximately one in four Americans age 20 years or older experienced pain lasting a day or longer within the past month (U.S. Department of Health and Human Services, 2006).

Pain may be a major indication for drug therapy, and nurses need knowledge of drug therapy based on core drug knowledge for prescribed drugs. Moreover, pain has an important bearing on multiple core patient variables, which nurses must consider during initial and ongoing assessments and evaluations of drug therapy.

This chapter presents three types of drugs used to treat pain: strong narcotics, mild narcotics, and mixed agonist-antagonists. Morphine is the prototype strong narcotic. Codeine is the prototype mild narcotic. Pentazocine is the prototype mixed agonist-antagonist opioid.

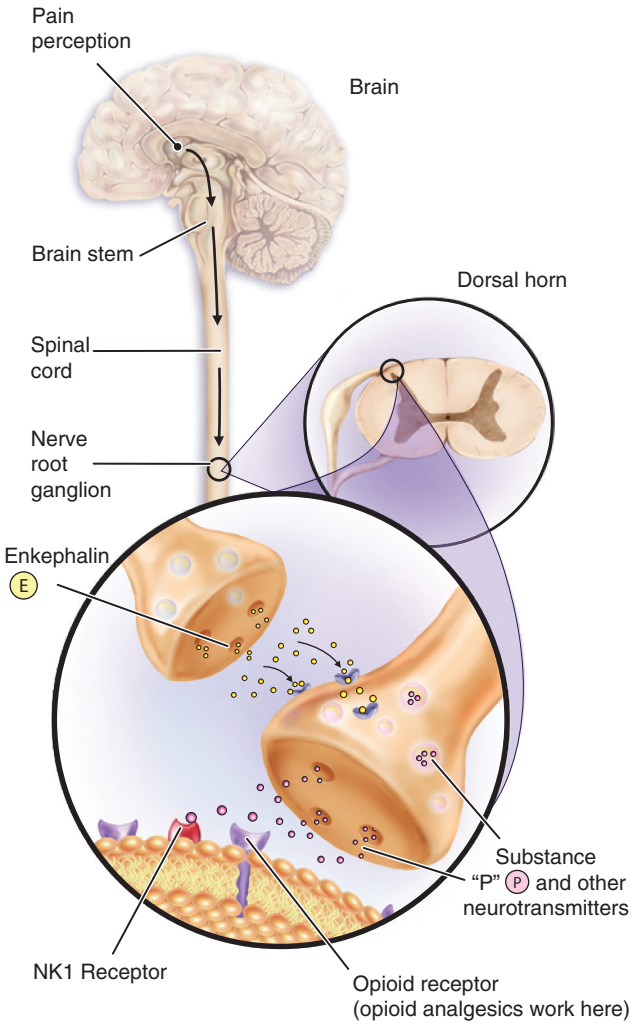
PHYSIOLOGY

The peripheral nervous system and central nervous system (CNS) comprise an integrated system that provides a pathway for pain transmission. The physiologic mechanisms involved in the pain response are complex and are not yet completely understood. Transduction is the term used to describe the phenomena associated with the initiation of a pain signal. Pain receptors are found on the peripheral end plates of afferent neurons. Afferent neurons carry signals into the CNS, whereas efferent neurons carry signals from the CNS to the periphery. The sensation of peripheral pain begins in afferent neurons called nociceptors, which are found in the skin, muscle, connective tissue, circulatory system, and abdominal, pelvic, and thoracic viscera. Nociceptors are preferentially stimulated by a noxious stimulus or to a stimulus that would become noxious if prolonged; these include mechanical, thermal, hormonal (namely prostaglandins), or chemical (namely histamine, bradykinin, and serotonin, which are released during cellular destruction) stimuli. For example, when you stub your toe, pressure in the surrounding tissue causes direct mechanical activation of pain receptors. Potassium, which leaks from the damaged cells into the tissues, then activates the inflammatory response, sending chemical mediators to the site of injury. These mediators are chemically caustic to the nociceptors. Stimulation of the receptors at the end plates then promotes cellular depolarization and generates an action potential.

There are two types of nociceptors: delta fibers and C fibers. Delta fibers are fast traveling, myelinated, and responsive to mechanical stimuli. They sense sharp, stinging, cutting, or pinching pain. C fibers are slow traveling, unmyelinated, and responsive to mechanical, chemical, hormonal, or thermal stimuli. They sense dull, burning, or aching pain. During inflammation, nociceptors become sensitized, discharge spontaneously, and produce ongoing pain. Prolonged firing of the C-fiber nociceptors allows cells to release glutamate, which has a role in the conduction of nerve impulses. Glutamate acts on specialized receptors in the spinal cord, known as *N*-methyl-D-aspartate (NMDA) receptors. Stimulation of the NMDA receptors causes the spinal cord neurons to become more responsive to all incoming stimuli, leading to a central sensitization to pain impulses.

Once the nociceptor depolarizes, transmission of the pain signal has begun. Transmission is the process whereby the pain information is carried from the receptor end plate along the axon of the afferent neuron. Nociceptors enter the spinal cord and terminate in the dorsal horn, where they synapse in distinct regions. Substance P, a peptide in the unmyelinated fibers entering the dorsal horn, is released in response to painful stimuli. Substance P is a neurotransmitter and neuromodulator that activates special receptor sites. It appears to have a role in interpreting pain and regulating self-produced (endogenous) analgesic responses to nociceptor stimulation (Figure 23.1). The release of excitatory amino acids, such as glutamate and aspartate, also has an important role in carrying the painful stimulus to the brain.

From the dorsal horn, impulses are transferred, through the spinothalamic and spinoreticulothalamic tracts, to various higher brain areas for interpretation. Pain is mediated and modulated through forebrain mechanisms, which act at the spinal, brainstem, cerebral, and limbic levels. Stimulation of these various areas produces an affective response to the painful stimuli based on the individual's previous experience with pain as well as on social, environmental, and cultural influences. Thus, the response to any given painful stimulus is different for different people. The forebrain has the greatest control over nociceptor functioning. Indeed, pathology of the forebrain can cause pain, even if the nociceptors have not been activated peripherally. Pain perception involves multiple cerebral structures. During clinical studies of pain, brain imaging with positron emission tomography (PET) has identified some of the principal structures of this central



• FIGURE 23.1 Inhibiting pain perceived over ascending pathways. Once the brain interprets a stimulus as pain, the nervous system responds along descending pathways. From the brain's perception of pain, an impulse is routed through the brainstem and into the spinal cord and travels through the dorsal horn to a dorsal root ganglion. Here, the impulses descending from the raphe nucleus system trigger the release of enkephalin (a peptide or endorphin-like substance). Enkephalin attaches to receptors, causing substance P and other neurotransmitters involved in pain perception to be either released or inhibited from release, depending on the type of receptor to which it attaches. This drawing illustrates that enkephalin is mostly inhibiting the release of substance P and other neurotransmitters. When substance P and other neurotransmitters are released, they attach to neurokinin 1 receptors and the person will sense pain. When substance P and other neurotransmitters are prohibited from release due to extensive enkephalin attachment, the person will not sense pain. The experience of pain can also be diminished by administering opioid analgesics, such as morphine, which attach to the opioid receptors.

network activated by pain. PET imaging has shown synaptically induced increases in regional cerebral blood flow in several regions of the brain when a person is exposed to painful stimuli. The intensity of the blood flow response in the brain correlates parametrically with perceived pain intensity. The areas of the brain involved in interpreting pain include the contralateral insula and anterior cingulate cortex, frontal inferior cortex, posterior cingulate cortex, bilateral thalamus and premotor cortex, and cerebellar vermis. These brain regions are functionally diverse and are involved with sensation, motor control, affect, and attention.

Components That Influence Pain

Pain has sensory-discriminative (physical) components and affective-motivational (emotional) components. The sensory dimension of pain encompasses pain's location, intensity, and quality. The quality of pain is the way it feels to the patient, for example, burning or gnawing. Affective aspects relate to the way that pain influences a patient's well-being, such as whether it is perceived as annoying, tortuous, or killing pain. Stimulation of the limbic system produces this emotional response to the physical stimulus of pain. Phenomena thought to influence the perception of pain are anxiety, fear, apprehension, attention, motivation, and other cognitive processes. For example, anxiety, fear, or apprehension appears to make the patient more sensitive to pain, allowing the patient to experience stimuli as painful when, under other circumstances, they might not be experienced this way. Conversely, the patient who is aware of his or her condition and wants to control pain may deliberately use techniques (e.g., distraction by talking to others) to cope and decrease the pain experienced. Inhibition of pain and the transmission of painful stimuli occur in various regions of the brain. Inhibitory substances such as endogenous opioids, serotonin, norepinephrine, and gamma-aminobutyric acid (GABA) are released into nerve synapses. These substances bind with receptors on primary afferent and dorsal horn neurons to prevent further transmission of painful stimuli. The ability to release these internal pain modulators varies from person to person; this variation partly explains why, when two people have a similar injury, one may feel a great deal of pain, whereas the other does not.

The peripheral and central nervous systems can become overly sensitized to nociceptive input. When the release of inflammatory mediators or the painful stimulus is intense, repeated, or prolonged, the nociceptors in the periphery generate more nerve impulses than usual and release the impulses more frequently. Central spinal neurons can become overexcited by substantial tissue or nerve injury and by recurrent input from the peripheral nervous system. When overexcitation occurs, the pain response may spread to additional areas in the brain. The patient can then experience an increased pain response to the same stimuli, a pain response to stimuli not previously experienced as painful, or pain from an uninjured area (referred pain). The overstimulation of the central spinal neurons may continue to produce a pain response long after the painful stimulus is gone.

Types of Pain

A number of different terms are used to describe and categorize pain. Pain can be categorized based on its presumed underlying pathophysiology as being either nociceptic or neuropathic. **Nociceptic pain** is caused by the activation of the delta and C nociceptors in response to painful stimuli, such as injury, disease, or inflammation. Pain perception and

stimulus intensity are generally closely related to nociceptive pain. Nociceptic pain also indicates real or potential tissue damage. Nociceptic pain is further categorized as either somatic or visceral. Somatic pain results from ongoing activation of peripheral nociceptors found in structural tissues, such as bone, muscle, and soft tissue. It can be further divided as either deep or superficial. It is characterized as well-localized and intermittent, or as constant, aching, gnawing, throbbing, burning, or cramping. The bone and joint pain of arthritis is a common source of somatic pain. Muscle strains after intense physical exertion also result in somatic pain. Both of these are examples of deep somatic pain. Sunburn is an example of superficial somatic pain.

Visceral pain results from stimulation within the deep tissues or organs and surrounding structural tissues. Common visceral pain syndromes include pain associated with cholecystitis, pancreatitis, uterine and ovarian disease, and liver disease. Patients often describe visceral pain as deep, boring, diffuse abdominal pain. Visceral pain is less circumscribed than somatic pain and often has a referred component (e.g., pain from the liver, which can be referred to the right shoulder) or neuropathic processes or causes. Additionally, pain can be described according to its duration (e.g., acute or chronic) or by its underlying pathophysiologic cause (e.g., cancer). Differentiation of pain serves a critical role in diagnostic and therapeutic planning. Adequate pain management is based on accurate pain assessments.

Neuropathic pain is the term used to represent pain in which the underlying pathology is abnormal processing of stimuli in the peripheral or central nervous systems. Thus, neuropathic pain is a result of some injury to the peripheral receptors, afferent fibers, or CNS, or an impairment of the nervous system. Neuropathic pain is unique in character and distribution. It can be described as shooting, burning, or stabbing and generally follows a radicular or radiating pattern. Neuropathic pain is often caused by trauma, inflammation, metabolic disease (e.g., diabetes), infections such as herpes zoster, toxins, and primary neurologic diseases. Several neuropathic pain syndromes may occur in patients with cancer. For example, direct tumor infiltration from adjacent soft tissues or lymph nodes or compression from metastases in the adjacent bony pelvis can damage the lumbosacral plexus. Postmastectomy syndrome is the result of nerve injury, with the development of a traumatic neuroma following surgery. It is characterized by a constricting, burning sensation in the posterior arm, axilla, and anterior chest and is aggravated by movement.

Acute pain, meaning the immediate phase of response to an insult or injury, results from tissue damage. It has cognitive, emotional, and sensory features. Acute pain resolves with the healing of the underlying injury. It is usually nociceptic but can be neuropathic. Acute pain may be related to the treatment of an underlying disease process or to an injury that is expected to resolve. Medical procedures, operations, and trauma are examples of types of treatments resulting in acute pain. Postsurgical pain is the most common treatment-related pain.

Chronic pain is no longer defined purely by how long it is present. In contrast to acute pain, chronic pain may persist well beyond actual tissue injury and healing. The level of identified pathology may be low or insufficient to account for the presence or extent of the pain experienced. Stress and other nonbiologic influences may exacerbate pain intensity, despite a reduction in the physiologic cause of the pain. Chronic pain disrupts sleep and normal living; it does not have an adaptive or useful purpose, as acute pain does. Nearly two thirds of older adults (65 years of age and older) who had pain in the past month stated that their pain has lasted for one year or longer (U.S. Department of Health and Human Services, 2006).

Cancer pain is one type of chronic pain. The pain may be related to the disease itself, or to diagnostic procedures or treatments for the cancer. The pain is usually progressive as the disease advances to end stage and can be severe and debilitating. Additionally, acute episodes may occur, either in response to movement or activity or secondary to therapy or treatment of cancer, such as surgical removal of the tumor or skin irritation from radiation. Cancer pain may also be intermittent. These acute and chronic components make it difficult to classify.

Chronic noncancer pain is another subtype of chronic pain. Chronic noncancer pain usually does not correspond well to identifiable levels of tissue pathology, and it frequently also does not respond well to standard treatments for pain. Chronic noncancer pain may arise from an acute injury that proceeds to chronic pain or from various chronic conditions such as osteoarthritis, migraine headaches, chronic abdominal pain from irritable bowel disease or other conditions, or from neuralgias. Chronic noncancer pain ranges from mild to excruciating.

Whatever the source or classification, pain may delay healing and rehabilitation, prolong other symptoms, and leave the patient immunocompromised. Every effort should be mobilized to manage pain effectively, including stepped pharmacologic intervention (i.e., predetermined, progressive levels of intervention).

DRUG THERAPY TO MANAGE PAIN

When drug therapy is prescribed to treat pain, the pharmacotherapeutics and pharmacokinetics of the drug and relevant core patient variables help govern which drug is selected. Drug therapy may be used to correct the underlying pathophysiologic cause of the pain (e.g., nitroglycerin, a vasodilator, to treat angina pectoris from narrowed coronary vessels), or it may be used to decrease the pain response itself (e.g., morphine to treat postsurgical pain). The degree of pain that the patient is experiencing affects the pharmacodynamics of **analgesics** (drugs used to treat pain). Nowadays, preventing pain is generally accepted to be easier than decreasing pain. It is also easier to treat pain at low levels than at severe levels. Pain that is allowed to escalate requires larger doses of drugs to obtain relief. These interrelationships between pain and core drug variables affect the therapeutic management of pain.

Drug classifications that are normally used for pain management are the **opioid** analgesics and the nonsteroidal anti-inflammatory drugs (NSAIDs). The opioids derive their name from opium because they are natural alkaloids, semisynthetic analogues, or synthetic compounds of opium. Opioids, or **narcotics,** as they are more commonly called, act on the CNS to interfere with the pain experience. Morphine is the standard drug of choice in this category, and all other opioids are compared with it when their efficacy is evaluated. NSAIDs act in the peripheral nervous system, interfering with prostaglandin synthesis and preventing the transmission of pain impulses. Some drugs are combinations of these drug classes, and they act on both the CNS and peripheral nervous system simultaneously. NSAIDs and other nonopiate analgesics, such as acetaminophen (Tylenol), are used to treat mild to moderate pain. Opioids are used in the treatment of moderate to severe pain. For more information on NSAIDs and acetaminophen, see Chapter 24.

The dose and choice of analgesics must be individualized to meet the patient's need for pain relief. However, adverse effects from any given drug may place a ceiling on how large a daily dose can be.

Some other drug classes are used as secondary pain relievers, although their pharmacotherapeutics indicate that their primary uses are for other problems. When drugs are used secondarily for pain relief, they are known as **adjunct analgesics** or co-analgesics. Using multiple types of drugs to treat the exact symptoms of pain experienced is similar to using a combination of drugs (e.g., those that are cell cycle–specific and those that are not cell cycle–specific) to treat cancer. The outcome is more effective than that of any one drug alone. Adjuvant drugs can increase the efficacy of narcotics or provide independent analgesia for specific types of pain. Other CNS depressants that are primarily indicated for other diseases and disorders can be used as adjuncts. Included in this group are drugs that have antiemetic effects (effects against nausea) or mild tranquilizing effects. These CNS depressants are frequently used in acute pain (e.g., postsurgical pain). Classifications of other adjuvant drugs include antidepressants, corticosteroids, and antiepileptics. Antidepressants are the treatment of choice for neuropathic pain described as burning or numbing. In clinical trials, tricyclic antidepressants are the only antidepressant drugs proved effective in managing neuropathic pain. Antipsychotic drugs, especially atypical antipsychotics, have been used as adjuncts to narcotic treatment for pain, although the literature is somewhat mixed about their effectiveness when used in this manner. Additionally, the adverse effects from antipsychotics may make them unsuitable for use in pain control (Seidel et al., 2010).

Steroids are useful for treating short-term, severe, episodic pain, such as that associated with nerve compression. They are also used in managing cancer pain to relieve chronic pressure-related pain states, such as progressive visceral distention, severe lymphedema, increased intracranial pressure, soft-tissue infiltration unrelieved by NSAIDs and opioids, and continuing nerve compression.

Antiepileptics are important adjuncts for neuropathic pain, particularly that described as stabbing or piercing. The antiepileptics are used for conditions such as trigeminal neuralgia, sciatica, migraine headache, and various neuropathic pain states in patients with cancer. These agents directly affect the peripheral nerve conduction of pain impulses, which is completely separate from their central effect. Research now shows that the antiepileptic gabapentin is helpful in decreasing postoperative pain (Box 23.1).

Finally, in addition to pharmacologic interventions to treat pain, nonpharmacologic methods may be used. These methods are not substitutes for analgesics, especially in moderate to severe pain, but they are valuable adjuncts to therapy. The effective use of nonpharmacologic measures may decrease the dose of narcotic that is required, thereby achieving pain control while minimizing adverse effects. Nonpharmacologic techniques include cognitive strategies for relaxation and

Antiepileptics as Adjuncts for Postoperative Pain Control

Ho, K. Y., Gan, T. J., & Habib, A. S. (2006). Gabapentin and postoperative pain: A systematic review of randomized controlled trials. *Pain, 126*(1–3):91–101.

The Study

This literature review evaluated the efficacy and tolerability of perioperative gabapentin, an antiepileptic drug, for the control of acute postoperative pain when used as an adjunct to opioid therapy. Sixteen randomized controlled clinical trials were identified which compared gabapentin to a placebo control in surgical patients. Meta-analysis of the 16 trials showed that gabapentin decreased reported postoperative pain intensity measured 6 and 24 hours after surgery. Gabapentin also decreased the cumulative opioid dose over 24 hours.

Nursing Implications

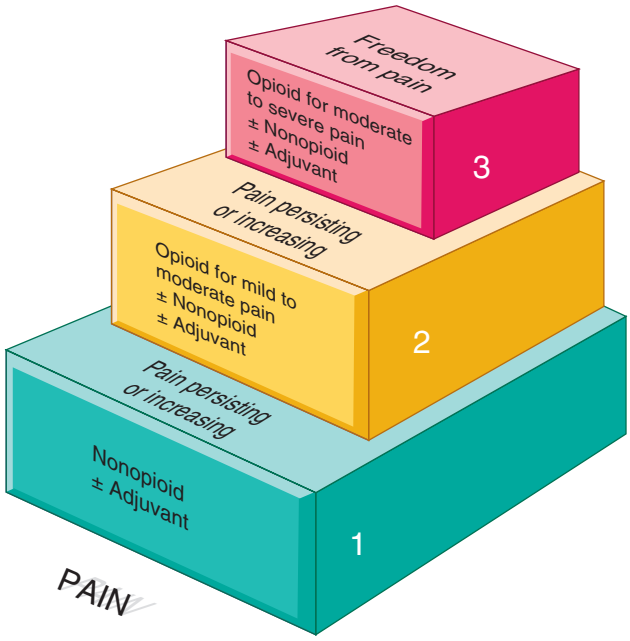
Literature reviews of randomized controlled trials provide an overview of the "state of the science" and help nurses and other health care providers determine if there is any value in a particular intervention. A single research study frequently does not involve enough patients to generalize findings sufficiently, so that they can be applied to all patients in similar circumstances. This review considered the findings from 16 studies together. All these studies were controlled trials with a placebo; this is considered the "gold standard" of a research study, so the findings are most likely to be valid and reliable. Gabapentin has been accepted as an adjunct to chronic pain in the past, but this is new documentation that it may have an important place in the management of acute postoperative pain as well. Nurses might expect to see the use of gabapentin increase in the treatment of postoperative pain. If a particular patient is not a good candidate for receiving opioids (e.g., history of respiratory depression from opioid use, renal or hepatic dysfunction that would impair opioid elimination) or if they have previously had postoperative pain experiences that were difficult to control with an opioid alone, the nurse may consult with the other health care professionals about including gabapentin in the patient's pain management.

TABLE 23.1 Nonpharmacologic Techniques Used in Pain Contro

Technique	Summary Description
Relaxation therapy	Uses progressive muscle relaxation techniques, controlled breathing, and simple hypnosis strategies to help patient achieve physical and emotional relaxation
Guided imagery	Uses visual and auditory imagery selected by the patient and specific to pain-relieving or stress-reducing feelings
Biofeedback	Teaches control of stress through patient's ability to monitor and manipulate some aspects of the autonomic nervous system
Music distraction	Uses music that is selected by the patient for the purpose of distracting the patient from pain and focusing instead on rhythm, tone, harmony, and other aspects of the music
Exercise	Promotes blood flow and tissue oxygenation, prevents muscle atrophy and stiffness, assists in building muscle to stabilize painful joints. An exercise plan defined by a physiatrist is extremely helpful in very debilitated patients. Heat promotes increased blood flow to the affected part, whereas cold reduces swelling associated with the inflammatory response. Take care not to use excessive heat, which can cause burns. Try alternating heat with cold.
Transcutaneous electrical nerve stimulation	Attempts to "confuse" the pain signal by activating other sensory circuits
Massage (various types)	Alleviates muscle stiffness and pain by breaking up fibrous tissue in muscle, increasing circulation, and promoting normal elongation of muscle fibers

physical strategies that interrupt pain transmission. Table 23.1 describes some of the nonpharmacologic techniques used in pain control.

The accepted standard plan for treating pain remains the World Health Organization's model of stepped progression from nonopioid to opioid use, with increasing doses of the opioid until the pain is controlled. Nonopioids, including adjunct medications, may be added to an opioid regimen. Nonpharmacologic methods may also be added. Figure 23.2 illustrates the stepped-progression approach to pain control



• FIGURE 23.2 The World Health Organization's three-step analgesic ladder.

Students need to recognize that the World Health Organization's model is based upon pain starting as mild and then progressing in severity. In an acute care setting, where a patient presents in severe pain for example after surgery) the earliest steps of the model are not employed; instead treatment begins with opioid narcotics. Non-opioids and nonpharmacologic methods can then be added if needed to control pain.

NARCOTIC ANALGESICS

Narcotic analgesics are required for conditions, disorders, or treatments that are accompanied by moderate to severe pain. The narcotic analgesics are the most effective drugs for pain management.

The degree of pain relief that is achieved may be expressed in analgesic equivalents, which is the dose of an analgesic required to produce the same analgesic effect as a 10-mg dose of morphine (the standard measure of pain relief). Some equianalgesic dosages are presented in Table 23.2.

The narcotic analgesics include opiate agonists, mixed agonist-antagonists, and antagonists based on their activity at opioid receptors. Although five types of opiate receptor sites (with the Greek names of mu, kappa, sigma, delta, and epsilon) are known to exist, activity occurs at only three sites (mu, kappa, and delta) with the narcotic analgesics available. From a nursing standpoint, comparing strong with mild to moderate analgesics within the opiate agonist classification may be helpful. This comparison allows examination of two important opiate agonist prototypes: morphine (opiate agonist and strong analgesic) and codeine (opiate agonist and mild to moderate analgesic). Some narcotic analgesics have mixed opioid effects, being agonists at some receptors and antagonists at others. A mixed narcotic agonist-antagonist, pentazocine (Talwin), is also discussed in this chapter.

Narcotics have an important role in pain management and control; however, they are typically underprescribed and underused. Although 26% of American adults reported having pain lasting longer than 24 hours in the past month, only 4.2% of those surveyed reported using a narcotic for pain control (U.S. Department of Health and Human Services, 2006). Research has repeatedly shown that major contributing factors to narcotic underuse are lack of knowledge on the part of health care professionals regarding pain and pain control and misinformation regarding the pharmacokinetics and pharmacodynamics of narcotics. Because patients' pain may be incorrectly assessed and improperly treated, nurses need to be aware of current advances in measuring, classifying, and managing pain.

• C Strong Narcotic Agonists

Strong narcotic agonists include morphine, hydromorphone, levorphanol, oxycodone, oxymorphone, meperidine, fentanyl, alfentanil, sufentanil, methadone, tramadol, and remifentanil. Table 23.3 presents a summary of selected narcotic analgesics and antagonists. The prototype strong narcotic agonist is morphine. The narcotic antagonist naloxone is significantly different from morphine.

Nursing Management of the Patient Receiving P Morphine

Core Drug Knowledge

Pharmacotherapeutics

The most important clinical indication for morphine is moderate to severe acute or chronic pain, including postoperative pain and pain that is nonresponsive to nonnarcotic analgesics. It can be used to treat chronic pain that is either cancer pain or noncancer chronic pain. Morphine is also used in dyspnea associated with acute left ventricular failure and pulmonary edema; it is the only narcotic agonist used to treat the pain of myocardial infarction (MI). Preoperatively, morphine can be used to sedate a patient, relieve anxiety, facilitate induction of anesthesia, or reduce the amount of anesthetic needed.

Morphine can be administered by multiple routes: oral (PO), subcutaneous (SC), intramuscular (IM), intravenous (IV), epidural, rectal, and topical. Oral forms of morphine are preferred in treating cancer pain, unless the patient is unable to take medication by this route. The sustained-release form (MS Contin, Oramorph, or Kadian) is used only for patients who require an opioid analgesic for more than a few days and need around-the-clock pain control. Of the parenteral routes, the SC and IM routes should be limited to occasions when the drug is to be administered only one time. Repeated injections every 3 to 4 hours should be avoided because they cause additional discomfort, and repeated IM injections risk nerve and muscle injury. To provide continuous, 24-hour administration of morphine through a parenteral route, administer the drug by IV infusion regulated by an infusion-control pump.

Pharmacokinetics

Onset of analgesic effect occurs within 15 to 30 minutes and lasts for about 3 to 7 hours. Morphine is metabolized in the liver and gut wall by conjugation to glucuronide, an active metabolite, which is excreted along with unchanged morphine in urine and breast milk. It is also excreted in the feces through biliary and enterohepatic recycling. It has a half-life of 1.5 to 2 hours.

Pharmacodynamics

Morphine is known to be an agonist at the mu, kappa, and possibly delta opiate receptors. Its actions are related to the distribution of opioid receptors; high densities of opioid receptors are found in the brainstem, medial thalamus, hypothalamus, limbic system, and spinal cord. Many other areas with opioid receptors are excitatory nociceptive pathways, which morphine inhibits. Morphine reduces the release of neurotransmitters in the presynaptic space and produces hyperpolarization of postsynaptic dorsal horn neurons; these actions prevent transmission of nociceptor pain. Morphine also decreases the release of substance P, which modulates pain perception. Some specific effects can be attributed to agonist action at specific opioid receptors. Generally, it is thought that mu receptors are responsible for supraspinal analgesia, respiratory and physical depression, euphoria, miosis, and reduced gastrointestinal (GI) motility. Kappa receptors are linked to spinal analgesia, miosis, and sedation. The delta receptors have been linked with dysphoria and psychotomimetic effects (effects, such

as hallucinations, that mimic psychosis). The secondary pharmacologic effects of morphine, like those of other narcotic agonists, are related to various effects of receptor stimulation (Box 23.2).

Contraindications and Precautions

Morphine causes respiratory depression. The main contraindications to the use of morphine are hypersensitivity, preexisting respiratory depression, acute or severe bronchial asthma, and upper airway obstruction. Morphine should also be avoided in premature infants and during labor when delivery of a premature infant is anticipated.

Other contraindications for morphine given by injection or immediate-release oral solutions include heart failure secondary to chronic lung disease, cardiac arrhythmias, increased intracranial or cerebrospinal pressure, head injury, brain tumor, acute alcoholism, or delirium tremens. Because of its stimulating effects on the spinal cord, morphine should not be used during convulsions.

Caution must be used when administering morphine to patients receiving other CNS depressants because chances for respiratory depression increase. Morphine is generally considered contraindicated in cases of head injury and increased intracranial pressure; if it must be used in such cases, it must be given with extreme caution. Morphine, like all narcotics, may obscure clinical findings; the likelihood of respiratory depression and increased intracranial pressure is greater when morphine is given under these conditions. Caution should also be used when morphine is required for older or debilitated patients or those with renal or hepatic impairment. These patients may have altered pharmacokinetic processes and are more likely than other patients to exhibit adverse effects. Dose reduction may be necessary. Caution should also be used if morphine is

Box23.2 SECONDARY PHARMACOLOGIC ACTIONS OF MORPHINE AND OTHER NARCOTICS

Provision of analgesia is the primary action of morphine and other narcotics. In addition, these drugs have a wide variety of other effects on the body.

- **Respiration:** Tidal volume is first increased, then decreased because of reduced sensitivity of the respiratory center to carbon dioxide. Depression is dose related. Deaths from overdose usually result from respiratory arrest.
- **Cough reflex:** Cough reflex is reduced because of direct effects on the cough center in the medulla. This may be useful, or it may promote a buildup of secretions, atelectasis, and airway obstruction.
- **Hypotension and orthostatic hypotension:** These result from peripheral vasodilation, reduced peripheral resistance, and inhibition of baroreceptors. Effect is exaggerated in the presence of hypovolemia.
- **Euphoria, dysphoria, alterations in mood, feelings of relaxation, drowsiness, apathy, mental confusion:** These result from stimulation of opioid receptors.
- **Nausea and vomiting:** These develop from direct stimulation of emetic chemoreceptor trigger zone (CTZ) in the medulla.
- **Itching, flushing, red eyes:** These are produced by release of histamine.
- **Miosis (pinpoint pupils):** This results from stimulation of oculomotor nuclei, which increases parasympathetic stimulation of the eye. No tolerance develops to this effect.
- **Abdominal pain, cramps:** These occur from decreased gastric motility; prolonged gastric emptying time; decreased biliary, pancreatic, and intestinal secretions; and delays in food digestion in small intestine. Resting tone of small intestine increases.
- **Constipation:** This happens because of diminished peristalsis, increased tone of large intestine before spasms occur, and inattention to the normal stimuli for defecation reflex.
- **Biliary colic and epigastric distress:** These are due to the constriction of the sphincter of Oddi.
- **Urinary retention, urinary urgency, and difficulty urinating:** These develop from increased tone of smooth muscles in urinary tract and spasms.

given to patients who are sensitive to CNS effects because of concurrent alterations in their health status (e.g., respiratory compromise from chronic obstructive pulmonary disease).

Adverse Effects

The most hazardous adverse effects of morphine relate to excessive CNS depression; they include respiratory depression, hypoventilation, apnea, respiratory arrest, circulatory depression, cardiac arrest, shock, and coma. The most frequent adverse effects of morphine and other agonist narcotics are respiratory depression, apnea, bradycardia, light-headedness, dizziness, sedation, nausea and vomiting, and sweating.

In addition, patients may experience cardiovascular adverse effects (e.g., hypotension, orthostatic hypotension, flushing, peripheral circulatory collapse); CNS effects (e.g., euphoria, dysphoria, delirium, agitation, anxiety, drowsiness, miosis, blurred vision, increased intracranial pressure); GI effects (e.g., abdominal pain, biliary tract spasm, anorexia, constipation); genitourinary (GU) effects (e.g., urinary retention or hesitancy, dysuria, decreased libido, impotence); and decreased cough reflex. Overdoses of morphine may be life threatening and should be treated with naloxone (Narcan), a narcotic antagonist.

Drug Interactions

Generally, providers can anticipate that concurrent therapy of morphine and any other CNS depressant may produce additive CNS adverse effects and substantial clinical effects. Increased respiratory and CNS depression effects are seen when morphine is given with barbiturate anesthetics, monoamine oxidase inhibitors (MAOIs), amitriptyline, cimetidine, clomipramine, and nortriptyline. Because morphine increases biliary tract pressure, levels of serum amylase or lipase may increase. One study showed that the bioavailability of oral morphine increased significantly following a high-fat meal. Parenteral mixtures of morphine with other drugs are often used when treating patients with a terminal disease who have severe pain. Table 23.4 lists drugs that interact with morphine.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for respiratory depression. Morphine should not be administered to any patient with respiratory depression because it may precipitate respiratory arrest. It should not be given to anyone with a previous hypersensitivity to morphine.

Assess for current alterations in health status that place the patient at risk for increased sensitivity to CNS depressant effects. These include cardiac, renal, hepatic, or pulmonary disease; hypothyroidism; Addison disease; prostatic hypertrophy; or urethral stricture.

Before therapy, perform a physical examination to establish a baseline in order to monitor the drug's effects. Evaluate orientation, affect, respiratory rate, adventitious sounds, and character of bowel sounds. If prolonged use is anticipated or the patient has a history of hepatic dysfunction, ensure that liver function tests are performed, because morphine is metabolized in the liver.

Assess the patient for the presence and severity of pain. Pain is extremely subjective and unique for each person. The current health status can indicate whether pain might be expected. Physiologic changes that may bring on a pain response and indicate the need for drug therapy with morphine include decreased oxygenation of cardiac cells during an MI, inflamed or infected organs, or inappropriate cell growth from tumors pressing on nerves, vessels, or adjacent organs. Some health states are the source of pain for the patient, whereas others bring pain from their diagnosis or treatment. Postoperative pain is an example of pain caused by treatment.

Life Span and Gender

In using morphine or any other narcotic analgesic, assess for characteristics related to age, pregnancy, labor and delivery, and lactation.

For many years, experts believed that pain perception was absent or diminished in the very young and very old, but this belief is not true. Pain is felt by all humans, regardless of age. However, the inability to express that pain is occurring may impair assessment of pain in both very young and very old patients. Adults older than 65 years of

age are less likely to report pain lasting more than one day than are adults aged 20 to 44 years (U.S. Department of Health and Human Services, 2006). The patient's age also influences the treatment of pain. Age-related factors are important when using morphine because it causes respiratory depression and hypotension.

The very young have impaired organ and system functioning because of immaturity. Therefore, doses of pain-relieving drugs need to be adjusted carefully to the child's body size and weight to prevent overdose and adverse effects.

Older adults are more likely to have age-related deterioration of organs, especially the liver and kidneys. Thus, they are more sensitive to adverse effects and can exhibit signs of overdose unless dose adjustments are made. Older adults should receive a reduced initial dose. Assess their response before additional doses are determined.

Nevertheless, children under 18 years of age and older adults may be undertreated for pain. In U.S. emergency department visits related to pain, children are less likely than adults to receive a narcotic for pain, regardless of the reported pain severity. In the same circumstances, older adults with severe pain are less likely to receive a narcotic than younger adults with severe pain (U.S. Department of Health and Human Services, 2006).

Morphine is assigned to pregnancy category C. Like other narcotics, morphine crosses the placenta rapidly. Abuse of narcotics by pregnant women can cause fetal dependency; infant withdrawal occurs after delivery. If narcotics are given during labor, respiratory depression and psychophysiologic effects may appear in the neonate. Resuscitation equipment and the narcotic antidote, naloxone, should be available. The premature infant is at even greater risk for severe respiratory depression from exposure to morphine. For these reasons, morphine should not be given during labor if the delivery of a preterm infant is expected. Morphine has also been shown to increase the length of labor.

Morphine is secreted in breast milk. Although morphine in breast milk does not usually produce serious problems, withdrawal may be precipitated in breast-fed infants if maternal morphine is discontinued rapidly after prolonged exposure. Waiting 4 to 6 hours after dosing with morphine to breast-feed will decrease the amount transferred to the infant.

The sex of the patient may also have an effect on pain and the need for morphine. Women are more likely than men to report pain (U.S. Department of Health and Human Services, 2006).

Lifestyle, Diet, and Habits

Morphine acts by depressing the CNS. Patients who use morphine to control chronic pain, such as that caused by cancer, or who receive morphine for an extended period eventually need higher doses to control their pain as they become tolerant to the drug's therapeutic effects. **Tolerance** means that the body has become accustomed to the effects of a substance and that the patient must use more of it to achieve the desired effect. With morphine, chronic usage may result in a degree of tolerance up to 35-fold. Clearly, as patients develop tolerance to morphine, they require larger doses to achieve adequate pain control. In addition to developing tolerance to therapeutic effects, patients also develop tolerance to adverse effects, including lethal effects, of morphine. Patients in whom drug tolerance develops can thus take dosages that would be potentially lethal in patients who are opioid naive. See Box 23.3 for more information about determining opioid tolerance.

Box23.3 DETERMINING OPIOID TOLERANCE

Certain drugs or drug doses are to be used only if the patient is opioid tolerant. To prevent medication errors and adverse effects to opioid-naive patients, nurses should be able to determine if a patient is opioid tolerant or not. Patients can be considered opioid tolerant if they have been receiving for a week or longer any of the following:

- 60 mg or more daily of morphine
- 30 mg or more daily of oxycodone
- 8 mg or more daily of oral hydromorphone
- Equianalgesic dose of any other opioid

Patients who abuse alcohol, prescription drugs that suppress the CNS (e.g., opioid analgesics or benzodiazepines), or street or illicit drugs have special needs when they have pain. When a patient abuses such substances, he or she may develop a cross-tolerance to morphine's pain-relieving effects. Thus, these patients also require higher than normal doses to achieve the desired therapeutic effects of pain relief.

In morphine use that lasts longer than 3 months, physical **dependence** also occurs. Dependence is characterized by a withdrawal or abstinence syndrome when morphine is discontinued; it represents an exaggerated rebound from its acute effects. Dependence may occur during the treatment of cancer pain, and it is important in the clinical management of such pain to allow for proper agonist coverage during changes in drug dosages, schedules, or type of drug therapy. Otherwise, the patient may experience unnecessary pain and the discomfort of abstinence syndrome. Physical dependence is *not* the same as addiction. Unlike tolerance and dependence, addiction is not an intrinsic, predictable drug effect. **Addiction** involves compulsive use of the drug for a secondary gain, not for pain control. The consensus document of the American Academy of Pain Medicine, American Pain Society, and the American Society of Addiction Medicine (2006) defines addiction as a neurobiologic disease characterized by one or more of these behaviors: impaired control over drug use, compulsive use, continued use despite harm, and craving. Genetic, psychosocial, and environmental factors influence the development of addiction. Patients who receive morphine for pain management, even over a long period, do not normally seek morphine

once the pain stimulus is gone. However, they do need their morphine doses decreased slowly before the drug is discontinued to prevent withdrawal. Thus, they develop dependence but not addiction. It is very rare for patients who are using morphine, or another narcotic, strictly for relief of pain to develop addiction. Patients who currently abuse or have a history of abusing opioids do have a risk of addiction from drug therapy in pain management. This risk is not a reason to withhold morphine or any other opioid if the patient is experiencing pain. Instead, health care providers, in cooperation with the patient, can accomplish careful drug selection and dosage adjustment. If addiction does occur after therapy concludes, it must be addressed separately. Patients should be helped to wean themselves away from drug use before they are discharged from their providers' care.

Environment

Closely monitor patients receiving morphine as part of monitored anesthesia care (MAC) or postoperatively for signs of serious adverse effects, particularly respiratory depression. Health care providers or patients themselves may administer narcotic analgesics, as in patient-controlled analgesia (PCA). Morphine, like all narcotics, is a controlled substance, and by law every dose must be properly accounted for and documented, including partial doses that may be wasted. Although oral doses may be administered in any setting, doses given by IV infusion, injection, and epidural and intrathecal catheters are normally given only in the hospital, where the patient can be closely monitored. The exception is IV infusions, which may be used in the home during hospice care.

Culture and Inherited Traits

The experience of pain is personal and subjective; however, how people respond to painful stimuli reflects what they have learned about pain from their families, society, and cultures of origin. Learned messages about pain are indirect, and people react to them subconsciously. These messages include reasons that people experience pain and what are considered appropriate responses to it. For example, some religions view pain as a punishment from God for sins. Others view pain as a test from God to develop inner strength and faith. Still others may believe that pain is merely an aspect of life like any other. Some stoic cultures believe that people should tolerate pain without verbal complaints. British, German, and Asian groups are thought of as stoic cultures. Other cultural groups are very expressive about pain, see such expressiveness as acceptable, and may encourage it. Spanish, Italian, and Latin groups are thought to be expressive cultures. Recent studies of Americans show that non-Hispanic white adults reported pain more often than adults of other races and ethnicities (U.S. Department of Health and Human Services, 2006). However, not everyone who shares the same cultural background reacts identically to pain. Consider whether a patient may be reflecting stoicism or expressionism in their pain reports. Validate the expressive patient's pain, or encourage stoic patients to take needed pain medication. For both types of patient, offer support as well as pain medication.

CRITICAL THINKING SCENARIO

THINKING CRITICALLY ABOUT DRUG THERAPY IN PAIN MANAGEMENT

Mr. Schneider is 60 years old. He is a second-generation German American. He has worked for 35 years in a local steel mill. He had surgery for a bowel obstruction yesterday. When you assess him, he states he does not have pain, yet he is restless in the bed and moaning. He says he will take something for pain when the pain is very severe. He does not want to get out of bed to ambulate, and he coughs only superficially when asked to demonstrate coughing and deep breathing.

1. Discuss factors that may be contributing to the inconsistencies between the patient's verbal report and nonverbal behavior.
2. Why is appropriate pain management important for this patient?
3. Propose a teaching plan that you think would help this patient with effective pain management.

Nursing Diagnoses and Outcomes

- Ineffective Breathing Pattern, Hypoventilation, related to respiratory depression caused by the drug
  Desired outcome: *The patient maintains effective breathing despite respiratory depression.*
- Ineffective Airway Clearance secondary to cough suppression by the drug
  Desired outcome: *The patient's airway remains patent and clear.*
- Constipation secondary to activity of the drug
  Desired outcome: *The patient remains free of constipation.*
- Urinary Retention related to indirect anticholinergic effects of the drug on the urinary sphincters
  Desired outcome: *The patient maintains normal urinary output.*
- Risk for Injury related to orthostatic hypotension or sedation secondary to drug effects
  Desired outcome: *The patient remains free of injury.*
- Acute Pain related to trauma or disease process and insufficient analgesia
  Desired outcome: *The patient remains free of pain.*
- Deficient Knowledge related to morphine therapy
  Desired outcome: *The patient has adequate knowledge of the drug and its adverse effects and their management.*

Planning and Intervention

The key issue in morphine therapy is adequate control of pain balanced against the considerable adverse effects of respiratory depression and excessive sedation. Goals of treatment include adequate pulmonary ventilation, a

respiratory rate within 12 to 20 breaths per minute, minimal effects of constipation and urinary retention, freedom from injury, and adequate family and patient education for managing drug therapy. It is also important to teach the patient possible adverse effects of morphine and how to manage them. Other goals relate to maintaining safety during potential episodes of orthostatic hypotension.

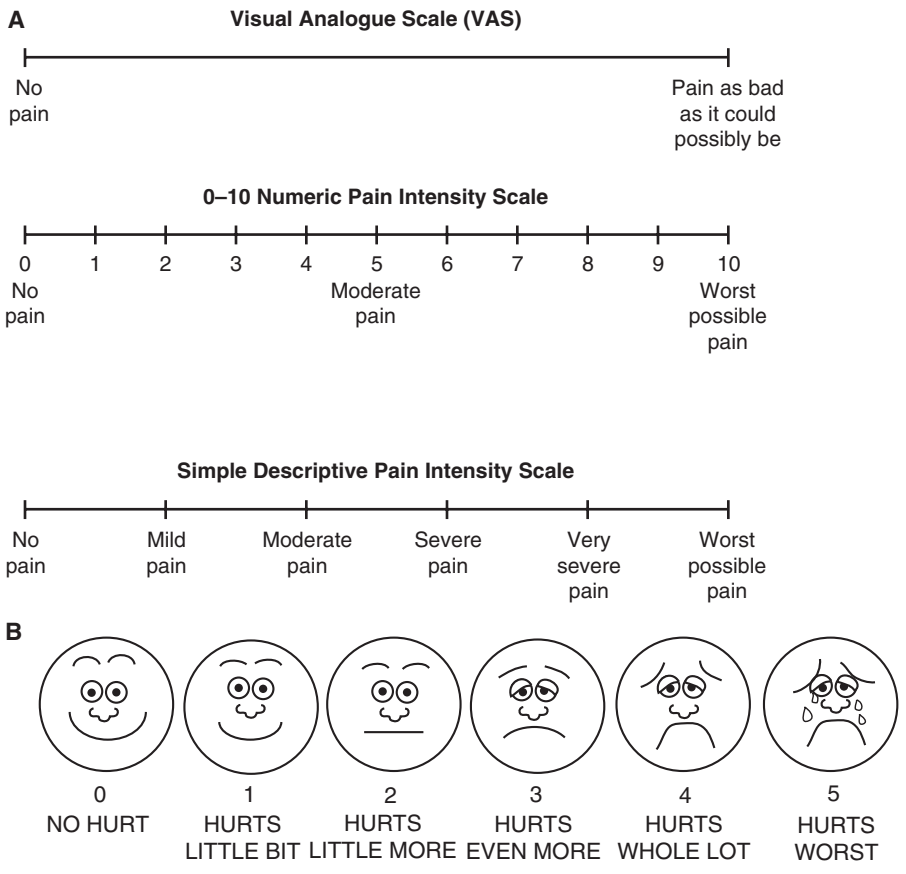
Maximizing Therapeutic Effects

ASSESSING PAIN

The first step in maximizing the therapeutic effects of drug therapy with morphine or any other narcotic is to complete a full pain assessment. Pain has been greatly underassessed and undertreated. Many professional organizations, clinical guidelines, and accreditation bodies now recommend that pain be routinely assessed for all patients; this recommendation has been likened to making pain a fifth vital sign, which requires assessment whenever the other vital signs are assessed during patient care. Remember that pain is a subjective experience. It is whatever the patient says it is, occurring whenever the patient says it does. Objective data, such as elevated blood pressure or pulse rate, moaning, or grimacing, may accompany pain, but the absence of objective data does not indicate that pain does not exist. Many people actually cope with pain by using distraction techniques, such as smiling, talking, quiet rhythmic breathing, or watching television. Patients who experience chronic pain are especially likely to use distraction techniques. Every patient has a different level of tolerance for what he or she feels is an acceptable level of pain. Careful assessment enables you to assist the patient in identifying and achieving this level of control. Pain assessment tools allow the individual's pain to be tracked using the same scale or criteria. Although pain can be assessed by asking questions, this approach is not considered a true tool because a tool must be tangible. Verbal assessment may be necessary in a particular situation, but a true tool that has been shown to be valid and reliable is preferable.

To begin the pain assessment, first determine the location of the pain. Location gives possible clues to the source of the pain and can help identify whether the pain is acute or of a more chronic nature. Many pain assessment tools incorporate a representation of the human body from a frontal and posterior view. The tools ask patients to shade or circle on the diagram to show the location of the pain. Such identification helps the patient define what he or she is experiencing and provides a starting point for further assessment. Each pain location should be recorded in the patient's chart along with its associated intensity and quality.

The next step is to determine the pain intensity. Many assessment tools are available to rate pain intensity (Figure 23.3). Each tool provides a continuum in some



• FIGURE 23.3 Pain assessment tools. Many pain intensity scales are available for ranking the pain of children and adults alike. (**A**) Such scales as the visual analogue, numeric pain intensity, and simple descriptive pain intensity rank pain from no pain to worst pain possible. (**B**) Scales such as the Wong-Baker FACES Pain Rating Scale are ideal for children and others who have difficulty with numeric concepts. To assist children with the FACES scale, the nurse explains that each face represents a person who feels happy because the person has no pain or a person who feels sad because the person has a lot of pain. FACE 0: no hurt; FACE 1: hurts little bit; FACE 2: hurts little more; FACE 3: hurts even more; FACE 4: hurts whole lot; FACE 5: hurts worst. Then, the nurse asks the child to choose the face that best describes his or her own pain and documents the selection. (**Part B:** From Hockenberry, M. J., Wilson D., & Winkelstein, M. L. [2005]. **Wong's essentials of pediatric nursing** (7th ed). St. Louis: Mosby, p. 1259. Used with permission.)

form to represent a range from "no pain" to the "worst pain imaginable." Asking the patient to rate pain using an imaginary scale in his or her head is *not* considered a tool. One of the most widely recognized pain assessment tools for reliability and ease of use is the visual analogue scale, which is numeric. It may be a scale from 0 to 5 or 0 to 10, but both ranges allow patients to rate their pain by assigning a number that demonstrates greater pain as they move up the scale. The visual analogue scale may be printed, with the patient pointing to the appropriate number; or the scale may be on a hand-held device with a sliding pointer; with the patient sliding the pointer to the appropriate number to demonstrate his or her pain.

Because research findings indicate that approximately 7% to 11% of adults cannot conceptualize well enough to use the visual analogue pain scale, other pain assessment tools may be helpful. One alternative is a descriptive pain-intensity tool in which words replace the numbers 0 to 5, again with the two extremes being no pain or the worst imaginable pain. The FACES scale, used frequently with children, cognitively impaired adults, and those who do not speak English, shows a series of facial expressions ranging from very unhappy and crying to very happy and smiling (Hockenberry 2009; Wong & Baker, 1998). The patient is then asked to pick the face that most resembles how he or she feels. In the poker chip tool, four poker chips are placed in front of the patient. Each one is a "piece of hurt," with one piece being "just a little hurt" and four pieces being "the most hurt." Patients are asked to show how many pieces of hurt they have. This tool is also frequently used with children.

Each patient may interpret the extremes of any of the scales differently based on his or her past experiences. However, with consistent use, the pain assessment tool gives the patient and the provider a common ground on which to plan treatment and understand the degree of relief from the treatments provided.

Intensity of pain is only one aspect of pain that should be assessed; pain quality and character (affective descriptions) should also be measured. Not all pain assessment tools currently available assess for all these parameters. Some of the well-tested tools include the Brief Pain Inventory, the McGill Pain Questionnaire, and the Memorial Pain Assessment Card (Melzack, 1975; Daut, Cleeland, & Flanery, 1983; Cleeland & Ryan, 1994; Fishman, Pasternak, Wallenstein, et al., 1987).

Of these, the McGill Pain Questionnaire is the only one that is not a visual tool. Instead, it is a set series of questions to ask the patient, after which you record the patient's answers. This tool has long and short forms; the long form takes 5 to 15 minutes to complete, and the short form can be completed in 2 to 3 minutes, making it preferable in an acute care setting. Assessment of pain intensity and all aspects of pain is an important part of treating pain effectively, especially for patients who are stoic, who use coping mechanisms to deal with pain, or whose pain may be undertreated if you offer drug therapy only to those who state that they are in pain.

PROVIDING ANALGESIA

Morphine, like other drugs that relieve pain, is more effective when it is administered before the level of pain becomes severe. This is another reason why it is important to assess the patient's pain level frequently. When pain exists, analgesic dosages are best administered around the clock rather than as needed. Continual administration promotes a steady blood level of the drug, which prevents drug troughs that allow pain to escalate. In around-the-clock dosing, a baseline amount of the drug is administered over the 24-hour period when acute pain is expected or when severe, chronic pain occurs. Patients should be awakened for the analgesic if receiving it orally; however, they may refuse the drug at any time.

The appropriate dose of morphine must be given to control the patient's pain. No one dose is appropriate for every patient. Titration of dosage is usually required when therapy begins and continues for as long as the patient receives care. To titrate the morphine dose means to increase it incrementally. Aggressiveness of titration depends on pain intensity and response. Remember that patients with a history of substance abuse or drug tolerance need higher dosages of analgesics. Morphine is titrated until the desired therapeutic response, or efficacy, is achieved or until adverse effects occur. Efficacy is usually defined as a pain level below 4 out of 10 or a level determined by both the patient and health care provider. Nonopioids, such as NSAIDs, may be used in conjunction with morphine. Other adjunct drugs may be added to morphine if necessary for pain control.

A review of the literature by Hudcova et al. in 2009 found that patient controlled analgesia (PCA) had better pain control and greater satisfaction than those whose pain was managed with PRN doses of medication administered by the nurse. Those receiving PCA may use more milligrams of opioids than those who are not on PCA, and they may incur more problems with itching. Other adverse effects profiles are similar regardless if the drug is administered via PCA or from the nurse administering the medication on a PRN basis.

Finally, in addition to pharmacologic interventions, nonpharmacologic methods may be used in conjunction with morphine. These methods are not substitutes for morphine, but they are valuable adjuncts to therapy (see Table 23.1).

For patients with chronic pain, the use of a long-acting form of morphine may better manage the patient's pain. Recognizing the need for long-term control and facilitating the conversion from short-acting to long-acting morphine, or other opioid, is important. A thorough assessment is needed to best determine which particular drug and route would best meet the individual patient's needs. Make sure that a fast-acting rescue drug (see Minimizing Adverse Effects) is also prescribed to treat breakthrough pain.

Minimizing Adverse Effects

Minimizing the adverse effects of morphine requires frequent and astute assessment and implementation of basic nursing care (Box 23.4). Dosing the drug carefully to meet the needs posed by core patient variables can minimize adverse effects. In general, dosages need to be lower for children, older adults, and patients with renal or hepatic impairment. Morphine should be administered before pain becomes severe. Because this dosing schedule is more effective, a smaller dose of the drug can be given, which helps prevent or minimize adverse effects.

Breakthrough pain and incidental pain may occur during pain management with drug therapy. Clinicians use the term **breakthrough pain** to describe transitory flare-ups of pain over baseline in a patient receiving opioid therapy. Breakthrough pain is generally graded as moderate to severe in intensity. It may last from a few seconds to a few hours. It may or may not have a precipitating event. Spontaneous, or activity-related, pain is called incidental pain. An incident may be related to a specific movement or to all movements.

Factors to consider when assessing and treating breakthrough and incidental pain are those that relate to cause. When pain does occur, is it related to a specific time during the dosing schedule? If so, a change in the dosing interval or an increase in the drug dose may be beneficial. Does a certain movement cause pain, or is the pain unpredictable? Patients often have incidental or breakthrough pain associated with movement or activity. How long does the pain last? Although morphine has a fairly rapid onset, some severe pain may persist for less time than it takes for the analgesic to take effect.

All patients being treated for pain need access to **rescue doses** for breakthrough pain. The rescue dose should

Box23.4 MINIMIZING ADVERSE EFFECTS OF MORPHINE

For All

- Consult with the physician and pharmacist to individualize dosage and dosing intervals based on the patient's weight, age, pain intensity, diagnosis, concurrent medical status, and use of other CNS depressants.
- Because ambulation may increase occurrence of the frequent adverse effects, have patient lie down after the dose has been taken.
- Because low pain levels may increase occurrence of the frequent adverse effects, consider a nonnarcotic analgesic for patients with mild to moderate pain.

Respiratory Depression

- Assess vital signs, especially respiratory function, on a regular, frequent basis.
- Measure the oxygen concentration of the blood with a pulse oximeter on a regular and as-needed basis.
- Have the patient perform turning, coughing, and deep breathing, and reposition the patient to remove secretions and maintain adequate pulmonary ventilation.
- Place the patient on the side, not flat on the back, to maintain an open airway until condition stabilizes. If the patient must be placed on the back, remove pillow, and tilt the patient's head back slightly to prevent the tongue from occluding the airway. Use an oral airway if necessary.
- Withhold the next dose and notify the physician if the patient is bradypneic.
- Administer oxygen as needed.
- Have emergency respiratory equipment available.
- Keep naloxone, the narcotic antidote, on hand. Administer as needed.

Hypotension

- Monitor blood pressure carefully in postoperative patients, patients who have low circulating blood volume, or patients who are simultaneously receiving a CNS depressant (e.g., phenothiazine) or general anesthetics. These conditions make such patients more prone to hypotension.
- Monitor for orthostatic hypotension, especially during transport, for patients with decreased circulating blood levels or impaired cardiac function and for those receiving sympatholytic (blocking the action of the sympathetic nervous system) drugs.
- Monitor intake and output and replace fluids for patients who are hypovolemic.
- Assess ambulatory patients carefully for orthostatic hypotension.

Constipation

- Encourage dietary fiber when taking morphine orally.
- Encourage oral fluids when tolerated; keep patient well hydrated with IV fluids if NPO.
- Promote ambulation (assisted as necessary) as much as possible.
- Administer stool softeners or laxatives PRN.

Urinary Retention and Decreased Urinary Output

- Monitor intake and output at least every work shift.
- Question to determine whether the patient self-reports difficulty voiding, lack of voiding, frequent voiding of very small amounts, or feelings of bladder fullness or tenderness.
- Palpate the bladder to differentiate urinary retention from oliguria.
- Encourage oral fluids if allowed; provide adequate hydration with IV fluids if NPO.
- Use noninvasive means to promote voiding (ensure female patient sits upright, ensure male patient stands, run water in sink, pour water over perineum, use sitz baths).
- Obtain order and perform urethral catheterization if needed.

Light-headedness, Dizziness, and Sedation

- Assist the patient who is ambulating and getting out of bed.
- Ensure the use of side rails when the patient is in bed.

Nausea and Vomiting

- Keep the patient NPO during acute episodes; maintain the patient on IV fluids for hydration.
- Offer ice chips and clear liquids as symptoms diminish.
- Obtain order and administer antiemetics if indicated.

be equianalgesic to 10% to 30% of the dose the patient receives in 24 hours and is added to the established pain management. Patients who require more than three rescue doses in a day should have their analgesic dosage adjusted either by increasing the baseline dose or maximizing the co-analgesics. A thorough assessment helps the health care provider decide whether the best option is to increase the dosage or to incorporate other therapies. Rescue doses, sometimes referred to as "PRN" or bolus doses, may be administered by a PCA device if the patient is receiving IV or epidural analgesia. Program into the IV pump the dose that has been ordered for the rescue or bolus dose and the frequency that the patient may receive a dose. When patients experience pain, they press a button, similar to a call light, and the pump administers the correct dose if it is time. Some institutions, especially with older adults or others who are at risk for experiencing adverse effects from around-the-clock dosing, may use PCA without a basal rate. In other words, the pump administers medication only when patients request it. When the pump is used in this manner, patients need to request a dose as soon as they begin to experience pain.

Providing Patient and Family Education

- Patients being treated for pain need to know what the treatment plan will be for managing their pain and that they are not expected to suffer. Ensure patients that health care providers will listen to them and act when they report that they have pain.
- Patients need to know that they have an important role to play in managing their pain. Review the following points with them:
  - Know how to use the pain assessment tools.
  - Report honestly how they feel during assessment.
  - Establish (with the health care team) what pain level will trigger automatic re-evaluation of the pain management plan. Ideally, re-evaluation should happen before pain develops or increases (e.g., in the preoperative period or early in the course of a disease).
- Teach patients who are receiving PCA how to appropriately use it. Patients should be instructed to request a dose whenever they have pain; waiting for the pain to become severe before seeking a dose makes it more difficult for the drug to be effective and may require larger doses of the morphine. Emphasize to patients that they cannot overdose themselves because the computer in the pump is programmed to administer only a prescribed dose at a prescribed interval.
- Correct any fears or misconceptions, including the following:
  - Pain is inevitable.
  - Pain must be endured.
  - Patients will "lose control" of themselves if they take drugs for pain.
  - Patients will become addicted.
- Teach patients that drug therapy with morphine over a prolonged period (as in chronic or cancer pain) may produce physical dependence on the drug. Explain that physical dependence is neither the same as addiction nor a reason to withhold pain treatment. If the pain resolves, the patient can be weaned from the drug to prevent withdrawal. Weaning is not appropriate with cancer pain because the pain will not resolve on its own.
- If patients are discharged home on morphine, teach the following:
  - Administration
  - Effects (adverse and otherwise)
  - Avoidance of driving and other hazardous activities during drug therapy
  - Avoidance of alcohol and concurrent CNS depressant therapy, unless a health care provider is managing the concurrent therapy
  - Placement of drug securely away from children and anyone likely to abuse it

Ongoing Assessment and Evaluation

Documentation of pain management with morphine should include the following:

- The pain scale used by the patient
- The rating given by the patient
- The components, sensory and affective, of pain
- The amount of morphine, route, and the time each dose is administered
- The degree of pain relief obtained from morphine therapy
- The effectiveness of adjunct drug therapy and nonpharmacologic interventions used
- Any morphine-induced adverse effects

Increasing pain in a patient previously stabilized on a certain dose of morphine should not be automatically attributed to tolerance without investigating for evidence of disease progression or complications. Cancer pain, for example, changes constantly. It may increase or decrease secondary to anticancer treatment, infectious processes, spreading tumors, or natural degenerative body changes (arthritis). Postoperative pain that morphine does not relieve may indicate postoperative complications, such as compartment syndrome.

The patient should have adequate pain control with minimal adverse effects. Breakthrough pain should be minimal if the pain is adequately controlled. The patient should remain free from injury from orthostatic hypotension or sedation. The patient and family should show an understanding of adverse effects if the patient is discharged on morphine and should be able to describe how to manage those effects should they occur.

MEMORY CHIP

P Morphine

- Narcotic analgesic used in moderate to severe pain
- Standard against which all other narcotic analgesics are measured for effectiveness
- Major contraindications: significant respiratory depression, increased intracranial pressure, and CNS depression
- Most common adverse effects: light-headedness, dizziness, sedation, nausea, and vomiting
- Most serious adverse effect: respiratory depression
- **Life span alert: Avoid use in premature infants or during labor when delivery of premature infant is expected.**
- Maximizing therapeutic effects: Assess pain thoroughly before and during therapy and titrate the dose until the desired pain-relieving effect is achieved.
- Minimizing adverse effects: Individualize dose based on patient-related variables; monitor vital signs, especially respiratory rate, frequently; and have the antidote, naloxone, on hand.
- Most important patient education: For long-term use in cancer pain, physical dependency will develop. This is not the same as addiction and not an appropriate reason to withhold the drug.
- **Patient safety alert: Check dose and patient status carefully; adverse effects and medication errors are common with this drug. Monitor patient closely, because fall risk is increased.**

Drugs Closely Related to P Morphine

Hydromorphone

Hydromorphone (Dilaudid) is a semisynthetic analogue of opium and is used to treat acute and chronic pain (Quigley, 2009). Its effects on the body are almost identical to those of morphine. As an analgesic, hydromorphone is equally effective as morphine, although more potent (Quigley, 2009). Between 1 and 1.5 (1 to 1.50) mg of SC or IM hydromorphone is equal to 10 mg of morphine given through the same routes. Hydromorphone is available in oral, parenteral, and rectal forms. Hydromorphone also has equal antitussive (cough suppression) effects; however, its ability to cause respiratory depression and physical dependency is less than that of morphine. Hydromorphone's ability to cause constipation, sedation, and emesis is unknown; thus, comparisons with morphine cannot be made. Unlike morphine, hydromorphone can cause transient hyperglycemia.

Levorphanol

Levorphanol (Levo-Dromoran), a synthetic compound, can be used to manage pain and as a preoperative agent. It has analgesic, constipating, respiratory-depressive, sedating, and physical dependency qualities similar to those of morphine. It has fewer antitussive and emetic effects. Like hydromorphone, levorphanol is more potent than morphine, with an SC dose of 2 mg equal to 10 mg of morphine.

Oxycodone

Oxycodone is a semisynthetic analogue of opium. Oxycodone is metabolized by the 2D6 isoenzyme. Unlike morphine, it is available only as an oral preparation. It is available in regular-release (Roxicodone), timed-release (OxyContin), and rapid-release formulas (OxyIR). Oxycodone has analgesic, antitussive, constipating, respiratory-depressive, sedating, emetic, and physical dependency effects similar to those of morphine.

The long-acting, timed-release forms are very helpful in managing severe chronic pain, either cancer pain or noncancer chronic pain.

Although oxycodone has been a safe and effective therapy for patients with severe chronic pain, unfortunately, it has also been abused as a street drug. When abused, the drug is crushed before being taken, so that an extremely high dose of the narcotic is available all at once, instead of being released slowly over time. Severe adverse effects are possible when it is used in this manner. Those who abuse it are most probably addicted to the drug.

Oxycodone is often administered as a combination drug with either aspirin (Percodan, Roxiprin) or acetaminophen (Tylox, Percocet, Roxicet). One problem with using combination drugs is that the amount of these other drugs that can be administered daily is limited. When increasing the dosage to provide for adequate pain control, calculate the total daily intake of aspirin or acetaminophen, because overdosage of either of these drugs can cause serious adverse effects (see Chapter 24 for more information).

Oxymorphone

Oxymorphone (Numorphan) is a semisynthetic analogue of opium. It is used in pain control, as a preoperative medication, to support anesthesia, as an obstetric analgesic, and for the relief of anxiety in patients with dyspnea associated with pulmonary edema secondary to acute left ventricular dysfunction. Oxymorphone is available in injection and rectal forms. It has analgesic and constipating effects similar to those of morphine; however, it causes more respiratory depression, emesis, and physical dependence. Oxymorphone has fewer antitussive effects than morphine; its sedating effects are unknown.

Meperidine

Meperidine (Demerol) is a synthetic compound used to treat pain as a preoperative medication, to support anesthesia, and during labor. Meperidine has similar analgesic and respiratory depressive effects and abilities to cause physical dependence as morphine. Meperidine has fewer sedative and constipating effects and substantially fewer antitussive effects than morphine. Meperidine has a longer half-life and is less potent than morphine, requiring 75 mg IM or SC to have an analgesic effect equal to that of 10 mg of morphine. A unique drug interaction occurs between meperidine and the hydantoins (antiepileptics), which decreases the effectiveness of meperidine. This effect may result from an increased hepatic metabolism of meperidine.

The most important difference between morphine and meperidine is related to the pharmacokinetics of meperidine. Meperidine is metabolized to an active metabolite, normeperidine. Normeperidine has a long half-life (15 to 30 hours) and accumulates in the body with chronic dosing. Half-life is further extended in patients with renal impairment, which slows excretion of normeperidine. Normeperidine is a CNS toxin. Accumulated doses in the body can cause tremors, seizures, and changes in level of consciousness. Older adults are especially sensitive to the adverse effects of normeperidine, which may be the result of impaired renal function. For these reasons, meperidine should normally be avoided in pain management when multiple doses will be given. The exception would be if the patient were allergic to morphine; however, the patient must have normal renal function.

Fentanyl

Fentanyl is a synthetic compound. Its major uses are as a preanesthetic, anesthetic, and analgesic. Fentanyl's analgesic properties are equal to those of morphine. It produces fewer respiratory and emetic effects. Its antitussive, constipating, sedating, and physical dependency effects are unknown in comparison with those of morphine. Fentanyl is much more potent than morphine, with 0.1 mg producing equianalgesia to that of 10 mg of morphine.

Fentanyl is available in various forms. Fentanyl as a liquid for injection (Sublimaze) is used as an anesthetic, an analgesic of short duration during anesthesia, and a supplement to general or regional anesthesia. An off-label use is pain control through epidural PCA, usually after surgery.

Fentanyl is also available in a transdermal system (Duragesic). This formulation is used in persistent, moderate to severe chronic pain, usually related to cancer but also in other chronic pain conditions, when continuous opioid analgesia is necessary for pain that cannot be controlled by other methods. When the transdermal system is first used, the full pain-relieving effect is not achieved for approximately 24 hours. Patients should be treated with short-acting opioids during this period. Short-acting opioids are not needed when changing the patch after 72 hours, except for rescue doses for breakthrough pain.

The fentanyl transdermal system contains several Black Box warnings. The drug preparation should be used only in patients who have been taking opioids and have a demonstrated opioid tolerance, never to those who have not been receiving opioids (i.e., those who are opioid naive), because fatal respiratory depression may result. It should never be used in patients who require only short-term opioid treatment (e.g., after a surgical procedure). Another Black Box warning concerns a significant drug interaction. Transdermal fentanyl has a drug interaction with potent cytochrome P-450 3A4 inhibitors (ritonavir, ketoconazole, itraconazole, troleandomycin, clarithromycin, nelfinavir, and nefazodone). Because fentanyl is metabolized by this pathway, inhibition may result in significant increases in plasma concentrations of fentanyl, which could increase or prolong the adverse effects, possibly causing respiratory depression. Patients receiving both fentanyl transdermal and one of the P-450 3A4 inhibitors should be monitored closely for adverse effects; a decreased dose of fentanyl may be warranted. The label for transdermal fentanyl also warns that, due to its potency, transdermal fentanyl may be abused or illegally diverted.

A final Black Box warning is that fentanyl transdermal systems may only be used in children if they are 2 years of age or older and they are opioid tolerant. For information on patient and family education for transdermal fentanyl, see Box 23.5.

Teaching About Transdermal Fentanyl

As more and more patients learn to manage their own health care and drug therapy at home, the nurse assumes an even greater role in teaching patients and their caregivers about safe self-care and drug administration. For a patient who will be discharged while receiving transdermal fentanyl, some important drug administration teaching points for the patient or the caregiver follow:

1. Caregivers who administer or remove a transdermal fentanyl patch should first put on gloves to avoid absorbing any of the drug themselves.
2. Tear open a new patch packet carefully; never cut the patch with scissors. Transdermal systems that have been cut may increase the amount of drug that is absorbed, which increases the risk of developing hypoventilation and respiratory depression.
3. Remove the liner on the sticky side of the patch.
4. Apply the fentanyl patch to nonirritated, smooth, hairless skin (clip hair; avoid shaving to avoid breaking the skin) on the chest, back, flank, or upper arm right after opening the patch package. If necessary, wash the skin with clear water and dry completely before applying the patch. Do not use soaps, creams, alcohol, oils, lotions, or anything else that might irritate the skin or alter its characteristics.
5. Hold the patch in place for 30 seconds to ensure firm adherence.
6. Wear the system continually for 72 hours and then replace with a new patch, placed in a different location.
7. Avoid exposing the transdermal patch site to sources of heat such as heating pads, sun lamps, electric blankets, heated water beds, hot tubs, or saunas. Vasodilation occurs in these situations, which may result in increased absorption of fentanyl, resulting in possible adverse effects or overdose. Contact the prescriber if the patient develops a fever while using the transdermal systems, because this can also increase the absorption rate.
8. If the gel from the drug pad accidentally comes in contact with the skin, clean the area with plain water only. The use of soaps, alcohol, or other chemicals may actually increase the drug absorption through the skin.
9. To discard a used patch, fold it in half with the sticky sides together (to prevent any residual drug from touching the skin) and flush the patch down the toilet, because active drug remains in the patch. (Patches discarded in the trash may be attractive to and accidentally come in contact with children or pets.)
10. Use the short-acting drug prescribed as a rescue dose for any breakthrough pain. Keep a log of how often rescue doses are needed, and bring this information with you to your next appointment. This log provides valuable information about how well the prescribed drug and dose are controlling your pain. Do not adjust the dose of fentanyl except under the direction of the physician.
