The newest form of fentanyl transdermal administration is the fentanyl iontophoretic transdermal system (IONSYS). It is used as a transdermal route of PCA for hospitalized patients. Unlike other transdermal delivery systems of fentanyl, it is used to treat acute postoperative pain in adults. It is not intended for home use, and the system must be removed prior to discharge. Patients must be alert and able to control the device on their own; overdose is possible if someone other than the patient administers a dose. The patient should have received sufficient other opioids to provide comfort prior to starting this system. Each activation of the unit provides 40 mcg of fentanyl over a 10-minute period. To activate the system and release a dose, the patient presses the button on the top of the unit twice firmly within 3 seconds; an audible beep sounds and a red light comes on, indicating that the system is releasing a dose. The red light remains lit during the entire 10-minute dosing period. The system is designed to deliver a maximum of six 40-mcg doses per hour. Each system works for either 24 hours or to deliver 80 doses, whichever comes first. Up to three consecutive systems may be used (one per day). Site-selection criteria for this system are similar to those for transdermal fentanyl patches. A sticker on the back of the system is designed for the nurse to record the date and time the system was applied to the patient; this alerts nurses on subsequent shifts when the system will need to be changed. Pharmacodynamics, adverse effects, and actions for accidental contact and disposal are similar to transdermal fentanyl patches.

Finally, fentanyl is available in a transmucosal and a buccal tablet form—as fentanyl citrate. Both the transmucosal form (Actiq) and the buccal tablet form (Fentora) are used only for the management of breakthrough pain in patients with cancer who are already receiving and are already tolerant of opioid therapy. Only oncologists and pain specialists who are familiar with opioids should prescribe it to treat cancer pain. If it is used in the home, storage of the drug in a safe place is critical, because the dose found in this form may be fatal to children.

Alfentanil

Alfentanil (Alfenta) is used in the operating room as an analgesic during anesthesia, to induce anesthesia when intubation and mechanical ventilation are required, and as the analgesic component of MAC. Its analgesic effects are similar to those of morphine. Its onset of action is immediate.

Sufentanil

Sufentanil (Sufenta) produces a greater analgesic effect than morphine. It is used as an anesthetic and analgesic adjunct to maintain balanced anesthesia when patients are intubated and on a ventilator. It is also used as an epidural analgesic during labor and vaginal delivery (when combined with low-dose bupivacaine).

Methadone

Methadone (Methadose, Dolophine) can be used for pain, to prevent withdrawal symptoms from heroin (detoxification), and as a maintenance treatment for narcotic abuse. Although its ability to produce analgesia and the duration of its analgesic effect (4 to 6 hours, compared with 3 to 7 hours) are similar to those of morphine, its half-life is much longer. The half-life of methadone is 15 to 30 hours, compared with 1.5 to 2 hours for morphine. Adverse effects and signs of overdose may occur when methadone is used as pain management, because of these pharmacokinetic properties. Methadone may be initiated in a hospital setting only for prevention of withdrawal. Only approved treatment programs for narcotic abuse may initiate treatment with methadone for maintenance treatment of addiction. If a patient is already in a maintenance treatment program with methadone and requires hospitalization, the hospital may provide the methadone, after personnel confirm the dose with the treatment center that normally observes the patient.

Remifentanil

Remifentanil (Ultiva), although classified as a narcotic agonist-analgesic, is used as a general anesthetic and as part of MAC. Remifentanil has more analgesic effects than morphine but similar respiratory depressive and emetic effects. Physical dependence and constipation occur less often than with morphine.

Tramadol

Like morphine, tramadol (Ultram) is an opioid analgesic, with many similarities and a few differences. This opioid does not act primarily at the mu receptors; instead, it exerts its effect by inhibiting norepinephrine and serotonin reuptake. It is used in the treatment of cancer pain, moderate to moderately severe chronic pain, and moderate to moderately severe acute pain. Unlike morphine, its safety and efficacy in patients younger than 16 years of age have not been established. The drug should not be used in patients with severe renal or hepatic impairment.

In addition, unlike morphine, tramadol is available only in oral forms (immediate and extended release). It has a much longer half-life than morphine: in its immediate-onset form, the half-life is 6.3 ± 1.4 hours; and in its extended-release form, the half-life is almost 8 hours. Unlike morphine, tramadol does not commonly cause respiratory depression, light-headedness, or urinary retention. It only rarely causes hypotension, and then only orthostatic hypotension. However, unlike morphine, it can cause seizures and hallucinations. If naloxone is given to treat tramadol overdose, it may increase the risk of seizures.

Drug Significantly Different From P Morphine

Naloxone (Narcan) is a narcotic antagonist. It is believed to antagonize the effects of narcotics by competing for opioid receptor sites. It is used to reverse the effects of opiates (e.g., respiratory depression) and to treat opioid overdose. Naloxone is not effective for respiratory depression caused by anything other than narcotic agonist analgesics. Because naloxone competes for opioid receptors it may be combined with preparations of morphine or fentanyl for use in patient

controlled analgesia to minimize adverse effects. Naloxone can be used in adults, children, and neonates.

Although naloxone can be given by the IM, SC, or IV route, the most rapid onset is achieved with IV use, and this route is recommended in emergencies. IV onset is within 2 minutes; duration of action depends on the dose given and the route used, although it is quite short. Careful monitoring of the patient beyond initial response is warranted because the duration of action of the narcotic agonist may be longer than the duration of naloxone. Thus, the patient may relapse into respiratory arrest or depression. Repeated doses may be necessary to maintain reversal of the opiate's effects. Abrupt reversal of narcotic depression may result in the adverse effects of nausea, vomiting, sweating, tachycardia, increased blood pressure, and tremors. Administration of naloxone precipitates withdrawal in people who are physically dependent on narcotics. It also reverses all the analgesic effects in those receiving morphine or other narcotic agonists for pain control if the dose is sufficient.

Naloxone's reversal of respiratory depression from buprenorphine (a mixed agonist and antagonist) may be incomplete, necessitating mechanical assistance for respiration. Naloxone may be combined with sublinguinal preparations of buprenorphine to treat drug addiction. (For further information on buprenorphine, see Drugs Closely Related to Pentazocine, below.)

• C Mild Narcotic Agonists

The mild narcotic agonists include codeine, hydrocodone, and propoxyphene. Codeine is the prototype for the mild narcotic agonists.

Nursing Management of the Patient Receiving P Codeine

Core Drug Knowledge

Pharmacotherapeutics

Codeine is used to control mild to moderate pain in adults and children. For this purpose, it is available in oral tablets and an injectable form for parenteral use. Orally, it may be combined with acetaminophen or with nonsteroidal anti-inflammatory drugs. A review of the literature indicates that a standard dose of 60 mg of codeine, used without other analgesics, provides unsatisfactory post-operative pain control (most trials looked at dental surgery) for most patients. Thus codeine combined with a nonsteroidal anti-inflammatory would be the best option to control post-operative pain, especially after dental surgery (Derry et al., 2010). Codeine is also used for cough suppression. The dose needed to achieve an antitussive effect is less than the dose required for analgesia. Although codeine has fewer antitussive effects than morphine (when comparing similar weights of the drugs), it is more widely used to suppress coughs because it has low adverse effects at the antitussive doses. Codeine may be used alone, in the form of oral tablets, or in combination with other drugs that are expectorants (in a liquid or syrup form) to suppress coughs.

Pharmacokinetics

Codeine is well absorbed from the GI tract. Its peak effect occurs in 1 to 2 hours. (Other pharmacokinetic parameters are identified in Table 23.3.) Codeine is metabolized in the liver by oxidative reactions through the P-450 isoenzyme system. Whether codeine is actually a prodrug, which requires changing by the P-450 system to be active, is the subject of some debate. Codeine is excreted in the urine. It crosses the placenta and is secreted in breast milk.

Pharmacodynamics

Codeine has pharmacologic effects similar to those of morphine, but its actions are milder. Codeine acts at specific opioid receptors in the CNS to produce analgesia, euphoria, and sedation. Codeine also acts directly on the medullary cough center to depress the cough reflex. It has a drying effect on mucous membranes and can increase the viscosity of respiratory tract secretions.

Contraindications and Precautions

Codeine should not be administered to patients receiving other narcotic analgesics for pain relief; such a combination can cause serious respiratory depression and sedation. Codeine should be used with caution in patients who need to cough to maintain the airways (postoperative patients and patients who have undergone major abdominal or thoracic surgery). Careful use is recommended for patients with asthma and emphysema because cough suppression in these patients can lead to accumulation of secretions and a loss of respiratory reserve. Codeine is used with caution in patients with pre-existing cardiac disease because of its potential to induce bradycardia and peripheral vasodilation.

Codeine is assigned to pregnancy category C. Like other opiate narcotics, it crosses the placenta, is secreted in breast milk, and can cause sedation and respiratory depression in the fetus or infant. Therefore, it should be used with caution during pregnancy and lactation. The closer it is given to delivery, the more likely it is for respiratory depression to occur in the newborn. Resuscitation equipment should be on hand if the mother has received codeine or other opiates during labor. Codeine should be avoided if the delivery of a premature infant is expected. Caution should also be used with patients who are hypersensitive to or have a history of addiction to narcotics; codeine is a narcotic and has a potential for addiction. Patients who need to drive or be alert should use codeine with extreme caution because it can cause sedation and drowsiness. Caution is important when codeine is used for patients who have experienced a head injury or undergone a craniotomy. Codeine can increase intracranial pressure, which can be detrimental to these patients.

Adverse Effects

As already stated, codeine has a low incidence of adverse effects when used at the appropriate dosage level as an antitussive. The most frequent adverse effects observed with the use of codeine as a cough suppressant include drowsiness, sedation, dry mouth, nausea and vomiting, and constipation. When dosed as an analgesic, the adverse effects are similar to those of morphine, although they are less severe. Allergic reactions, including rashes and urticaria, have been noted in highly sensitive people. Respiratory depression and cardiovascular effects have occurred with higher doses.

Drug Interactions

An increased likelihood of respiratory depression, hypotension, or profound sedation exists when codeine is given with any other drugs that cause CNS depression, such as antihistamines, phenothiazines, barbiturates, sedative-hypnotics, tricyclic antidepressants, and alcohol. Codeine may also interact with histamine-2 antagonists, such as cimetidine. Table 23.5 lists drugs that interact with codeine.

Assessment of Relevant Core Patient Variables

Health Status

Assess whether the patient needs to cough to maintain a patent airway. Such patients (e.g., postoperative patients) should not receive codeine. In this situation, the cough is a protective mechanism to rid the airways of potentially harmful substances that may lead to pneumonia. The same rationale is used when treating patients with asthma or emphysema. If they do not cough, they have the potential to retain secretions that may exacerbate their disease.

Before therapy, perform a physical examination to establish a baseline to monitor the effects of the drug. Parameters to evaluate include orientation, affect, respiratory rate, adventitious sounds, and character of bowel sounds. If prolonged use is anticipated or the patient has a history of hepatic dysfunction, ensure that liver function tests are performed, because codeine is metabolized in the liver.

Life Span and Gender

Consider the patient's age before administering codeine. Older adult patients are especially sensitive to respiratory depression with the use of narcotics. Therefore, a reduced dosage of codeine is advised. Codeine use is contraindicated in premature infants because of their sensitivity to respiratory depression. In addition, carefully assess whether female patients are pregnant before administering codeine. The drug should not be given to women in labor unless absolutely necessary.

Lifestyle, Diet, and Habits

Codeine has less potential for causing physical dependence than morphine. Withdrawal symptoms from codeine dependency are similar to those seen in withdrawal from morphine, although the symptoms are less severe. Assess patients for a history of drug abuse and administer codeine cautiously in such patients.

Environment

If patients will be taking codeine as an outpatient, assess their need to drive or operate potentially dangerous equipment. Patients must refrain from these activities until the drug's sedative effects are assessed.

Nursing Diagnoses and Outcomes

- Disturbed Sensory Perception related to drowsiness and sedation
  Desired outcome: *The patient will be protected from injury related to sedation and drowsiness.*
- Risk for Ineffective Airway Clearance related to suppression of cough reflex
  Desired outcome: *The patient will maintain baseline respiratory function.*
- Constipation secondary to activity of the drug
  Desired outcome: *The patient remains free of constipation.*

Planning and Intervention

Maximizing Therapeutic Effects

Actions are similar to those for morphine.

TABLE 23.5 Agents That Interact with P Codeine

Interactants	Effect and Significance	Nursing Management
antihistamines	Additive effects when given simultaneously, resulting in CNS depression	Monitor closely for CNS depression. Avoid coadministration if possible.
barbiturates	Additive effects when given simultaneously, resulting in CNS depression	Monitor closely for CNS depression. Avoid coadministration if possible.
histamine-2 receptor antagonists	Actions of narcotic analgesics enhanced, resulting in toxicity and increased risk for respiratory depression	Monitor for respiratory depression. Decrease dosage of narcotic analgesic as needed. Avoid coadministration if possible.
phenothiazines	Additive effects when given simultaneously, resulting in CNS depression	Monitor closely for CNS depression. Avoid coadministration if possible.

Minimizing Adverse Effects

During therapy, ensure the use of safety precautions, such as raising side rails and assisting to walk if the patient is having CNS adverse effects. Monitor movement of air and respiratory status periodically during drug use. The use of codeine should be avoided in patients who need a strong cough reflex. Other actions are similar to those of morphine.

Providing Patient and Family Education

- Remind patients that drowsiness and impaired orientation can occur. Thus, patients should not drive or perform other tasks requiring alertness until the effects of the drug are known.
- Teach patients to avoid combining use of codeine with alcohol or other CNS depressants.
- Instruct patients and their families to report respiratory difficulty at once to you or the prescriber.
- Provide general pain control information, similar to that given for morphine.

Ongoing Assessment and Evaluation

Monitor codeine's effect on motor control and sedation, and the patient's respiratory status. By the end of therapy, the patient should be free from injury related to sedation and have open and functioning airways manifested by breathing without difficulty. Assessment and evaluation of pain control are the same as for morphine.

Drugs Closely Related to P Codeine

A drug similar to codeine is hydrocodone.

Hydrocodone

Hydrocodone, classified as a narcotic agonist, has an action similar to codeine and is administered orally. It is available as combination drug therapy only. When combined with acetaminophen (Lorcet, Lortab, Vicodin, among other trade names), it is used for moderate to severe pain. Hydrocodone can also be combined with ibuprofen (Vicoprofen) as an analgesic that acts via both opioid and NSAID pathways; like codeine, it also has antitussive effects. When hydrocodone is combined with homatropine (Hycodan, Hydromet, Tussigon), it is an antimuscarinic/antitussive. It is available in tablet and syrup forms.

• C Narcotic Agonist-Antagonists

Some narcotic analgesics have mixed opioid effects, being agonists at some receptors and antagonists at others. Pentazocine (Talwin) is an example of a mixed narcotic agonist-antagonist and is also the prototype narcotic agonist-antagonist. Drugs similar to pentazocine include buprenorphine, butorphanol, and nalbuphine.

MEMORY CHIP

P Codeine

- Used to treat mild to moderate pain and as a cough suppressant
- Major contraindications: same as for all narcotics (e.g., respiratory depression, use of other CNS depressants)
- Most common adverse effects: as a cough suppressant—drowsiness, sedation, dry mouth, nausea and vomiting, and constipation (all incidence is low at this dose); as an analgesic— similar to those of morphine, although less severe
- Most serious adverse effect: respiratory depression (in overdoses)
- **Life span alert: same as for morphine**
- Maximizing therapeutic effects: same as for morphine
- Minimizing adverse effects: Avoid use if patient's health status requires a strong cough; other considerations are the same as for morphine.
- Most important patient education: Provide general information on pain management, as for all other narcotics.
- **Patient safety alert: Monitor patient closely, because fall risk is increased.**

Nursing Management of the Patient Receiving P Pentazocine

Core Drug Knowledge

Pharmacotherapeutics

In patients not previously exposed to opioids, pentazocine can be used as an agonist to control pain. In normal doses, pentazocine is effective for moderate to severe pain, such as postoperative pain or pain during labor. It is also used as premedication for anesthesia and as a supplement to surgical anesthetics.

Pharmacokinetics

Pentazocine is well absorbed orally and from SC and IM sites. When given orally, it undergoes a substantial first-pass effect of hepatic metabolism, and bioavailability is less than 20% of the dose given. The peak serum levels from oral doses occur within 1 to 3 hours, with a duration of action of 3 hours (see Table 23.3). Pentazocine's metabolites and the small proportion of drug not metabolized are excreted in urine. Pentazocine crosses the placenta.

Pharmacodynamics

Pentazocine is a mixed agonist-antagonist. It stimulates kappa receptors much as morphine does but also exhibits weak antagonist effects at the mu receptors, the primary morphine receptors. In patients who abuse opioids or are receiving narcotic agonists, such as morphine, for pain control, this drug may precipitate a withdrawal syndrome because of its antagonistic effects. Pentazocine may increase intracranial pressure. When pentazocine is given intravenously, it elevates systemic and pulmonary arterial pressure, systemic vascular resistance, and left ventricular end-diastolic pressure. These effects increase the workload of the heart.

Contraindications and Precautions

Pentazocine is contraindicated for patients with known hypersensitivity to it. Caution and low doses should be used if the drug is administered to patients with respiratory depression, severely limited respiratory reserves, severe bronchial asthma, obstructive respiratory conditions, and cyanosis. Pentazocine may cause allergic reactions in patients sensitive to sulfites. This event is uncommon in the general population but more likely in patients with asthma.

Adverse Effects

The most common adverse effects of pentazocine are nausea, vomiting, dizziness or light-headedness, and euphoria. Pentazocine causes little respiratory depression because of its antagonist action at the mu receptors. Areas that may experience other possible adverse effects include cardiovascular (hypotension, hypertension, tachycardia, circulatory depression, and shock), CNS (sedation, headache, weakness, depression, disturbed dreams, insomnia, syncope, hallucinations, tremor, irritability, excitement, tinnitus, disorientation, and confusion), and dermatologic (soft-tissue induration, nodules, cutaneous depression, ulceration with sloughing, sclerosis of the skin and subcutaneous tissues at site of injection, diaphoresis, stinging during injection, flushed skin, pruritus, and toxic epidermal necrolysis).

Drug Interactions

Pentazocine increases the action of alcohol and subsequently its accompanying CNS-depressant effects. Barbiturate anesthetics increase the effect of respiratory and CNS depression from pentazocine because of additive pharmacologic activity. Table 23.6 lists drugs that interact with pentazocine.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for conditions that are contraindications or precautions to drug therapy as well as for hepatic disease, because decreased metabolism of the drug occurs, which predisposes the patient to greater adverse effects.

Because of the effect of increasing intracranial pressure, pentazocine may compound the clinical course of patients with head injuries. Its use in these patients should be avoided if at all possible; if pentazocine must be used, it should be done very cautiously and the patient carefully monitored. Because of the cardiac effects, IV pentazocine should not be given to patients with an MI. If oral forms are given, they must be administered cautiously, with the patient monitored carefully.

Life Span and Gender

Assess female patients for pregnancy before administration. Pentazocine is a pregnancy category C drug. Infants born to mothers who abuse pentazocine exhibit neonatal withdrawal and have lower birth weights than normal. The safety and efficacy of pentazocine in children younger than 12 years have not been established; therefore, clarify that the pediatric patient is age 12 years or older before administration.

Lifestyle, Diet, and Habits

A common form of pentazocine abuse is called "T's and Blues." The "T's" refers to oral doses of pentazocine (under its trade name Talwin), and the "Blues" refers to tripelennamine (trade name, PBZ), a histamine-1 antihistamine. In this abused form, tablets are dissolved in tap water, filtered, and then injected intravenously as a substitute for heroin. The most frequent and serious complication of this form of addiction is pulmonary disease. Pulmonary disease results from blocking the pulmonary arteries and arterioles with unsterile particles of cellulose and talc from the tablets. Neurologic complications from "T's and Blues" may also occur, including seizures, strokes, and CNS infections. Pentazocine with naloxone (Talwin NX) has been produced in an effort to decrease the prevalence of this abuse. Giving

TABLE 23.6 Agents That Interact with P Pentazocine

Interactants	Effect and Significance	Nursing Management
alcohol	Increased sedation	Avoid concurrent use. Caution against operating hazardous machinery or driving a motor vehicle.
thiopental	Increased CNS depression	Caution patient not to drive until effects subside completely. Avoid concurrent usage.
fluoxetine	Hypertension, diaphoresis, ataxia, flushing, nausea, dizziness, and anxiety	Monitor patient with caution if both drugs are used concurrently.
Methohexital	Increased CNS depression	Consult prescriber about possible dosage adjustment.
zotepine	Increased risk of pentazocine-induced respiratory depression; enhanced sedation	Reduce dosage of pentazocine if necessary. Monitor for respiratory depression.
Tobacco	Metabolism of pentazocine about 40% higher in smokers	Consult prescriber about increasing pentazocine dosage.

pentazocine to patients who are dependent on opiates may induce withdrawal symptoms.

Environment

Pentazocine in parenteral form is administered in a hospital setting; oral forms may be administered in any setting by physicians, nurses, or patients themselves. Discuss any possible risks in the home or living environment with the patient.

Nursing Diagnoses and Outcomes

- Disturbed Sensory Perception related to dizziness and light-headedness
  Desired outcome: *The patient will not be injured from falls while taking pentazocine.*
- Imbalanced Nutrition secondary to nausea and vomiting
  Desired outcome: *The patient's nutrition will not be compromised while he or she is on pentazocine.*
- Ineffective Health Maintenance related to abuse of pentazocine
  Desired outcome: *The patient will use drug therapy appropriately.*
- Deficient Knowledge related to pentazocine therapy
  Desired outcome: *The patient has adequate knowledge of the drug and its adverse effects and their management.*

Planning and Intervention

Maximizing Therapeutic Effects

Be sure to provide environmental controls to reduce sensory stimuli and aid relaxation. For example, dim lights, reduce noise, and adjust room temperature for greatest comfort. General actions for pain control are similar to those described for morphine.

Minimizing Adverse Effects

During therapy, ensure that safety precautions are used, such as raising side rails and assisting with ambulation. In cases of overdosage, naloxone is indicated. General principles for pain control are the same as those followed for morphine.

Providing Patient and Family Education

- Teach patients that pentazocine may cause drowsiness. They must use it with caution while driving or performing tasks that require mental alertness, physical dexterity, or coordination.
- Emphasize that patients must avoid concurrent use of pentazocine with alcohol and other CNS depressants.
- Instruct patients to notify their physician if skin rash, confusion, or disorientation develops.

Ongoing Assessment and Evaluation

Monitor the effect of pentazocine on motor control, sedation, and pain. Adequate pain control should be achieved without adverse effects. Effectiveness of pain control is assessed similarly to that of morphine.

MEMORY CHIP

P Pentazocine

- Used for moderate to severe pain
- Is an agonist at some opioid receptors and a weak antagonist at others
- May precipitate withdrawal in patients physically dependent on narcotics
- Abused on the street (known as "T's and Blues")
- Most common adverse effects: nausea, vomiting, dizziness, light-headedness, and euphoria
- Most serious adverse effects: respiratory depression and circulatory depression
- Maximizing therapeutic effects: same as for all narcotics
- Minimizing adverse effects: same as for all narcotics
- Most important patient education: Avoid alcohol and CNS depressants while taking drug.
- **Patient safety alert: Monitor patient closely, because fall risk is increased.**

Drugs Closely Related to P Pentazocine

Buprenorphine

Buprenorphine (Buprenex), used in the treatment of moderate to severe pain, has a high affinity at the mu receptors and disassociates from these sites slowly. This characteristic may explain its long duration of action (6 hours, versus 3 hours for pentazocine) and its low ability to cause physical dependence. When used as an analgesic, it is administered either by the IV or the IM route. It also possesses very strong antagonist tendencies at opioid receptors, similar to the action of naloxone. Because of this, buprenorphine (either alone [Subutex] or combined with naloxone [Suboxone]) has been approved for use in the initial treatment of drug dependency. Naloxone is added to prevent against IV misuse of buprenorphine. This combination drug is used for maintenance treatment for drug abuse. Initiation of withdrawal symptoms, which could occur if the combination drug were administered parenterally, does not occur if it is used as intended. Buprenorphine and buprenorphine with naloxone are supplied in subinguinal tablets, prescribed only by physicians who have a special United States Drug Enforcement Agency (DEA) registration and have participated in the required education.

How buprenorphine, a narcotic analgesic with strong receptor antagonist action, produces pain relief is not specifically known.

Buprenorphine is metabolized by the hepatic enzyme CYP3A4. Drugs that inhibit this pathway, such as antifungals (e.g., ketoconazole), macrolide antibiotics (e.g., erythromycin), and human immunodeficiency virus (HIV) protease inhibitors (e.g., ritonavir, indinavir, and saquinavir), increase the circulating volume of buprenorphine. Lower doses of Subutex or Suboxone will be required.

Sedation is the most frequently occurring adverse effect of buprenorphine, affecting more than half of the patients. The next most common adverse effects, although their prevalence

is much lower than sedation, are dizziness and vertigo, hypotension, headache, sweating, nausea and vomiting, miosis, and hypoventilation. When given to treat substance abuse, the most common adverse effects from buprenorphine and buprenorphine with naloxone are cold or flu-like symptoms, headaches, sweating, sleeping difficulties, nausea, and mood swings. Adverse effects are most severe in the beginning of treatment and may last several weeks. Strong respiratory depression can occur with buprenorphine, especially if the drug is crushed and given intravenously. Several deaths have occurred with this type of drug abuse; these drugs are especially dangerous if taken concurrently with benzodiazepines, because this combination increases CNS depression. Other CNS depressants, such as other narcotic analgesics, tranquilizers, or alcohol, also potentiate the CNS depression that can occur, possibly with fatal results. Buprenorphine may also produce cytolytic hepatitis and hepatitis with jaundice. The amount of liver damage ranges from a transient asymptomatic elevation in liver enzymes to hepatic failure. It is unclear at this time whether the liver complications are related to the drug or to pre-existing liver problems secondary to IV drug abuse.

Because of these adverse effects, buprenorphine should be used cautiously in patients with compromised respiratory status and those receiving additional drugs that cause respiratory depression. Likewise, it should be used cautiously in those with hepatic disease. Like pentazocine, it is a pregnancy category C drug, and the safety of its use in children under the age of 16 years and during breastfeeding has not been established. Buprenorphine may have some advantages as an analgesic for older adults. This is because the half life of the drug and active metabolites is not lengthened in older adults or in those with renal disease, unlike other opioids. It therefore does not require a reduced dose, or longer interval between doses like other opioids (Pergolizzi et al., 2008). Like pentazocine, if buprenorphine is given to a patient who is opioid dependent, withdrawal occurs. The likelihood of withdrawal is greater with buprenorphine than with pentazocine because buprenorphine has strong antagonist action, whereas pentazocine has only weak antagonist properties. Neonatal withdrawal occurs in those neonates whose mothers received buprenorphine during pregnancy.

When using buprenorphine to treat drug addiction, teach patients to place the tablet under their tongue and allow the tablet to dissolve, which will take 2 to 10 minutes. Tablets should not be swallowed because the medication is not effective this way, and opioid withdrawal may occur. If more than two tablets are prescribed and patients cannot get them all under the tongue at one time, they should place two under the tongue, and as soon as the tablets dissolve, place the additional tablets under the tongue. This medication must be taken regularly to be effective; it cannot be taken on an as-needed basis.

Patient education for those prescribed buprenorphine or buprenorphine with naloxone should include warnings about the serious, and potentially fatal, adverse effects that can occur if the drug is intravenously abused. In addition, if buprenorphine with naloxone is used intravenously in the presence of other narcotics, it induces severe withdrawal symptoms. Buprenorphine, both in Subutex and Suboxone, causes dependency. The drug should not be stopped suddenly because withdrawal occurs.

Assess the patient for concurrent use of benzodiazepines, alcohol, and other CNS depressants that may increase the risk of serious CNS depression from buprenorphine. Patients should be instructed not to take any of these substances while on buprenorphine. Patients should not drive or operate heavy machinery or perform any other dangerous activity until they know whether they experience sedation from the buprenorphine. They should be cautioned about this possibility at the start of therapy and at each dose increase. Assess also for the use of drugs that are inhibitors of the CYP3A4 enzymatic pathway, because these drugs will interact with buprenorphine.

Determine that liver function has been assessed before the beginning of therapy. Additionally, the patient needs to know that re-evaluation of liver function will be important throughout therapy.

Advise patients that they should keep the buprenorphine or buprenorphine with naloxone in a safe place and protect it from theft because it contains a narcotic painkiller, and that selling or giving this medication to another person is against the law. Finally, educate the patient's family that in case of an emergency, such as a drug overdose, emergency department personnel need to be told that the patient is receiving buprenorphine.

Butorphanol

Butorphanol (Stadol) is used as an analgesic, preoperative medication, supplement to balanced anesthesia, and pain reliever during labor. An intranasal form was shown effective in clinical trials in treating the pain of migraine headaches. The analgesic potency of butorphanol, compared by weight, is 20 times that of pentazocine and 3.5 to 7 times that of morphine. Like pentazocine, butorphanol has both narcotic agonist and antagonist effects. Its antagonist activity is approximately 30 times that of pentazocine but only one fortieth that of naloxone. Its mechanism for pain relief is not completely understood. Like pentazocine, it produces the same cardiovascular effects when given intravenously, increases intracranial pressure, is metabolized in the liver (by the 3A4 isoenzyme), is a pregnancy category C drug, and has no known safety data relevant to its use in children. It may induce withdrawal in patients who abuse opiates, although whether it is an antagonist at the mu receptors is not definitely known. Unlike pentazocine, its most common adverse effect is somnolence. Common adverse effects similar to pentazocine include nausea and vomiting and dizziness. Other adverse effects that occur with regularity include confusion, sweating, dry mouth, headache, vasodilation, insomnia, constipation, and an unpleasant taste.

Nalbuphine

Nalbuphine (Nubain) is a potent analgesic with agonist and antagonist effects. Its analgesic potency is essentially the same as that of morphine and about three times greater than that of pentazocine. Its antagonist activity is approximately 10 times that of pentazocine. Nalbuphine is used for moderate to severe pain, as a preoperative analgesic, as a supplement to balanced anesthesia, and as an obstetric analgesic during labor and delivery. Unlike pentazocine, nalbuphine does not increase pulmonary artery pressure, systemic vascular resistance, or cardiac work. Nalbuphine produces respiratory depression similar to morphine. Unlike morphine, the depressive effects seem to have a ceiling effect, with increases beyond 30 mg of nalbuphine producing no further respiratory depression. Like pentazocine, nalbuphine can produce an allergic response in patients with sulfite sensitivity and also trigger withdrawal in patients dependent on narcotics. The most common adverse effect is sedation, which occurs in about one third of the patients who use the drug. Other fairly common adverse effects are sweating, nausea and vomiting, dizziness and vertigo, dry mouth, and headache.

CHAPTER SUMMARY

- Pain is a subjective experience. Objective signs may or may not accompany pain. Lack of objective data does not mean that the pain is not present.
- Pain, a complex physiologic phenomenon, is not clearly or completely understood at this time.
- Pain is mediated through the CNS by nociceptors and perceived by the opiate receptors. When the opiate receptors are stimulated, perception of pain decreases.
- Pain has many types or classifications, which are based on the pathophysiologic origin of the pain (nociceptive versus neuropathic), whether the pain reflects a current injury or period of healing or extends beyond this time (acute versus chronic), or a subgroup of one of these classifications (visceral, somatic, cancer, or noncancer chronic).
- Pain, to be treated appropriately, must be assessed with a pain assessment tool. Simply asking patients to rate their pain on a scale in their head is not the same as using an assessment tool.
- Pain is best controlled when patients take analgesics before pain becomes severe and when doses are administered around the clock.
- Doses of analgesics should be titrated to obtain maximum efficacy with minimal adverse effects.
- Nonanalgesics and nonpharmacologic methods of pain management may be used to supplement drug therapy.
- Patients who have been receiving opioids for an extended period develop tolerance to the pain relief from the analgesics and need increased doses. Patients who abuse substances have cross-tolerance and need higher than expected doses to receive analgesia from drug therapy.
- Morphine is the standard narcotic analgesic. It is an agonist at the opioid receptors. All other narcotics are compared with morphine to measure their efficacy. Morphine is indicated in the treatment of moderate to severe pain.
- In addition to analgesia, morphine, like all narcotics, produces a wide variety of other effects on the body. The most serious of these is respiratory depression, which if severe, can be life threatening.
- The antidote to morphine overdosage and respiratory depression caused by any narcotic is naloxone, a narcotic antagonist.
- Morphine, like all narcotics, is a controlled substance. By law, every dose must be properly accounted for and documented. This rule includes partial doses that may be wasted.
- Relevant core patient variables are important to consider when providing morphine or other narcotics for pain control. The variables may alter the drug chosen, dose, frequency, route, patient's emotional response to pain, or frequency and depth of assessment made while the patient receives morphine or other narcotics.
- Codeine is another narcotic analgesic used for mild to moderate pain. It is also used to suppress coughs. Its effects are similar to those of morphine, but usually milder.
- Pentazocine, a different type of narcotic, is a combination of opioid agonists and opioid antagonists. Because of the antagonist effects at some receptors, it generally causes less respiratory depression than morphine and has less risk for inducing physical dependence. If given to a patient physically dependent on a narcotic, pentazocine may induce withdrawal.
- Patients and their families need education about the importance of pain control and what will be done when they report pain. Moreover, they need to know that they are not expected to suffer. Discuss with them any fears or misconceptions about analgesic use and dispel such mistaken beliefs with facts.
- Reassess patients for pain following changes in drug therapy, after every dose until a set dose controls pain, and periodically during the course of therapy.

QUESTIONS FOR STUDY AND REVIEW

1. Why should morphine not be administered to treat acute pain in an opioid-naive person with respiratory depression?
2. Can morphine be administered to treat chronic pain if the patient's respiratory rate is between 8 and 12 breaths/minute? Why?
3. Your patient has a history of opioid abuse, just came from surgery, and has a chest tube. Explain why this patient might need a larger dose of morphine to control postoperative pain than other patients require.
4. What is a "rescue dose"?

5. Why might more than one dose of naloxone, a narcotic antagonist, be needed when a patient has severe respiratory depression from opiate overdose?
6. Why should codeine not be administered to anyone who needs to be able to cough to clear his or her airway?

Drugs Treating Mild to Moderate Pain, Fever, Inflammation, and Migraine Headache

Learning Objectives

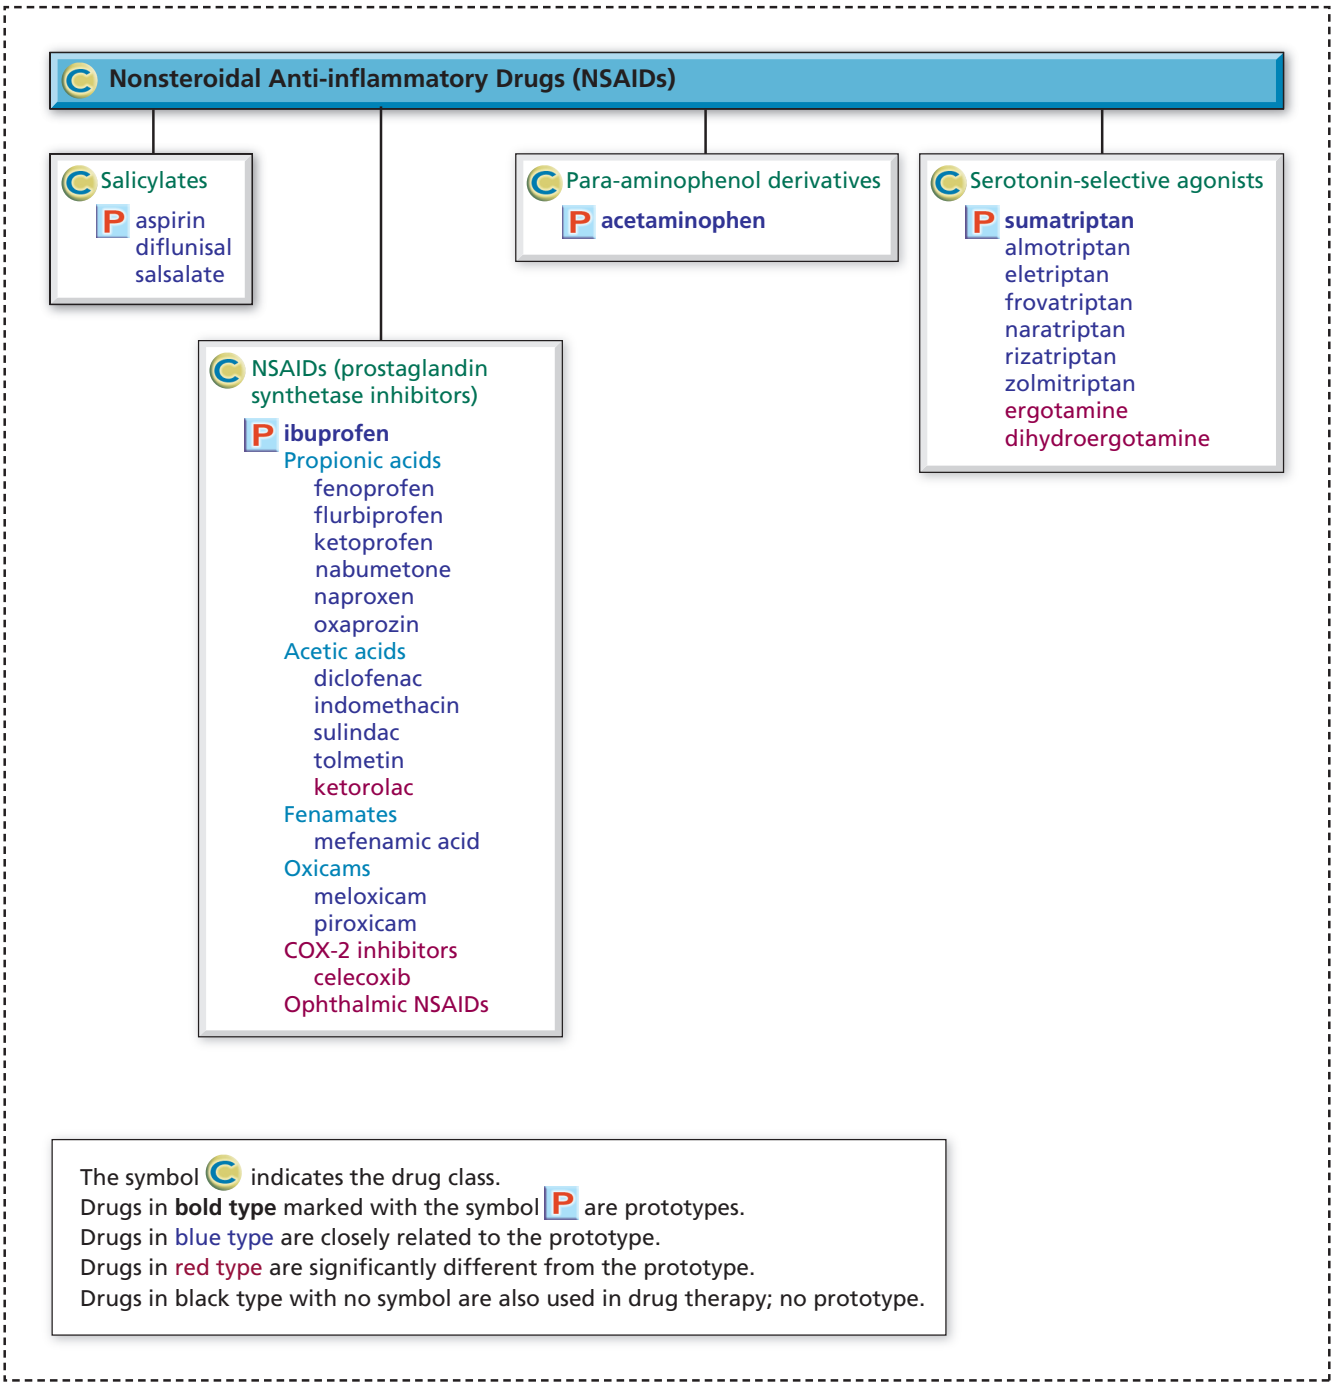
At the completion of this chapter the student will:

1. Correlate the processes of inflammation, fever, and pain with the actions of salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), para-aminophenol derivative drugs, and antimigraine drugs.
2. Identify core drug knowledge pertaining to salicylates, NSAIDs,para-aminophenol derivative drugs, and antimigraine drugs.
3. Identify the core patient variables pertaining to salicylates, NSAIDs, para-aminophenol derivative drugs, and antimigraine drugs.
4. Relate the interaction of core drug knowledge to core patient variables for salicylates, NSAIDs, para-aminophenol derivative drugs, and antimigraine drugs.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for salicylates, NSAIDs, para-aminophenol derivative drugs, and antimigraine drugs.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for salicylates, NSAIDs, para-aminophenol derivative drugs, and antimigraine drugs.
7. Determine key points for patient and family education for salicylates, NSAIDs, para-aminophenol derivative drugs, and antimigraine drugs.

Key Terms

cyclooxygenase
nonsteroidal anti-inflammatory drug (NSAID)
para-aminophenol derivative
prostaglandin synthetase inhibitors
Reye syndrome
salicylate poisoning
salicylates
salicylism
triptans

Drugs Treating Mild to Moderate Pain, Fever, Inflammation, and Migraine Headache



Fever, inflammation, and pain are symptoms of acute illness and frequently coexist. Inflammation and pain also can be symptoms of chronic diseases, such as arthritis and gout. Inflammation may also induce intense pain called migraine headache. Fever, inflammation, and pain commonly are treated with salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs, also known as prostaglandin synthetase inhibitors), or para-aminophenol derivative drugs. Migraine headaches are commonly treated with serotonin-selective drugs called **triptans** or antimigraine agents.

This chapter discusses the therapeutic classes of drugs used for fever, inflammation, pain, and migraine headache. It also addresses the core drug knowledge, core patient variables, nursing management, potential nursing diagnoses, and patient education related to the use of these drugs.

PHYSIOLOGY

Fever

Temperature regulation is a function of the hypothalamus. Normally, a homeostatic balance exists between body heat generated and body heat lost. When heat is excessive, the regulatory mechanism is activated, and the body responds with integumentary vasodilation, leading to perspiration and a net heat loss.

Fever is the result of fever-inducing substances called pyrogens, which activate certain monocytes/macrophages, which in turn secrete cytokines. Cytokines increase the synthesis and secretion of prostaglandin E_2 (PGE_2) in the hypothalamus, and PGE_2 stimulates the hypothalamus to reset the regulating mechanism to tolerate a higher body temperature.

Inflammation

Numerous types of stimuli, such as trauma, surgery, infection, and ischemia, evoke the inflammatory response. The classic signs of local inflammation are swelling (tumor), heat (calor), redness (rubor), pain (dolor), and loss of function (functio laesa). Regardless of the etiology, the sequence of physiologic effects is similar.

Acute inflammation is divided into vascular and cellular responses. The vascular response occurs almost immediately after the injury. Initially, vasoconstriction occurs in the surrounding vessels, quickly followed by vasodilation of both the arterioles and venules in the area. The vasodilation allows increased blood flow to the area, which accounts for the signs of redness and warmth. At the same time, capillary permeability increases, allowing fluid to accumulate in the surrounding tissues, causing swelling. With the swelling of the surrounding tissues and the release of chemical mediators from the injured tissues, pain and impaired function occur.

The cellular response is divided into four phases:

1. Margination of white blood cells (WBCs)—WBCs move to the periphery of the blood vessels to prepare for emigration.
2. Emigration of WBCs—The WBCs pass through the capillary walls and migrate into the tissue spaces.
3. Chemotaxis—Cellular debris or bacteria become more "attractive" to the WBCs.
4. Phagocytosis—Neutrophils and monocytes engulf and degrade the cellular debris.

Rupture of the mast cells, which release biochemical mediators, such as histamine, prostaglandins, and leukotrienes, also contribute to inflammation. Prostaglandins are thought to be pivotal in the inflammatory response by potentiating pain and edema caused by other chemical mediators.

Prostaglandin Synthesis

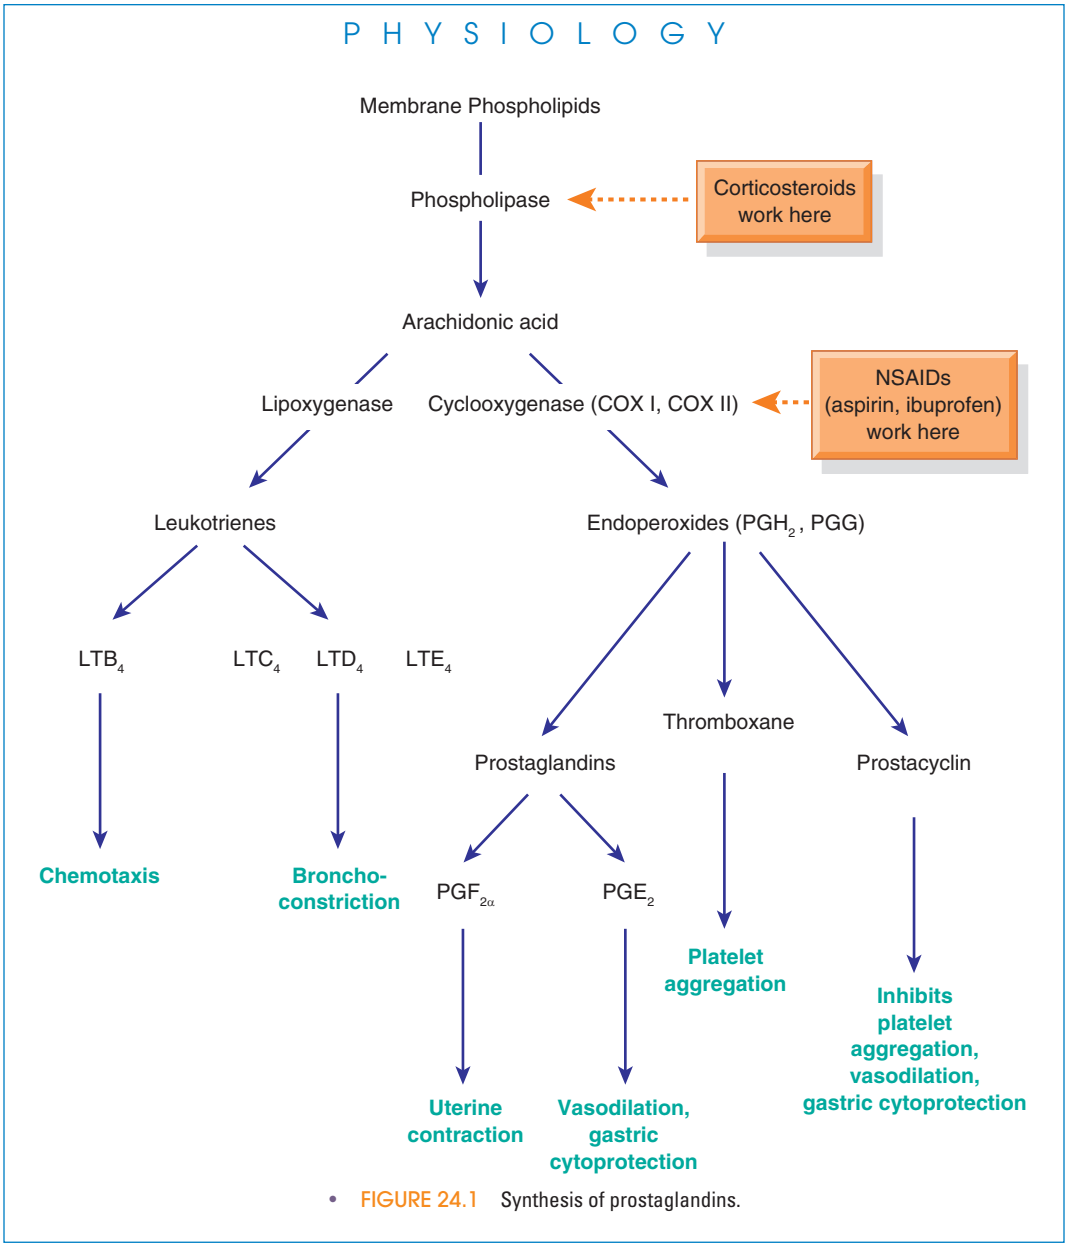
Prostaglandins modulate some components of inflammation, body temperature, pain transmission, platelet aggregation, and many other body actions. They are derived from arachidonic acid, which is liberated from the cell membrane in response to physical, chemical, hormonal, bacterial, or other stimuli (Figure 24.1). They are converted from arachidonic acid to prostaglandins by the enzyme **cyclooxygenase** (COX). There are two forms of the COX enzyme: COX-1 and COX-2. COX-1 synthesizes prostaglandins that are involved in the regulation of normal cell activity, whereas COX-2 appears to produce prostaglandins mainly at sites of inflammation. For instance, in the gastrointestinal (GI) tract, COX-1 is responsible for secretion of cytoprotective mucus and bicarbonate, suppression of the output of gastric acid, and support for submucosal blood flow. In the renal system, COX-1 promotes vasodilation, resulting in increased blood flow to the kidneys. COX-2 is activated by arthritis and other stimuli and produces the prostaglandins that lead to inflammation, swelling, and joint pain. Most NSAIDs indiscriminately target both COX-1 and COX-2, thereby depleting the prostaglandins needed for normal cell function and protection. This lack of discrimination explains the etiology of many of these drugs' adverse effects.

Pain

The physiologic mechanisms involved in the pain response are complex (see Chapter 23). The sensation of peripheral pain begins in afferent neurons called nociceptors, which are found in skin, muscle, connective tissue, the circulatory system, and abdominal, pelvic, and thoracic viscera. Although these receptors may be activated by mechanical, chemical, or thermal stimuli, they also are activated by chemical mediators, such as prostaglandins, histamine, bradykinin, and serotonin, which are released during cellular destruction. It is theorized that the inhibition of prostaglandins may diminish activation of peripheral pain sensors, resulting in decreased pain.

Platelet Aggregation

Simply speaking, platelet aggregation is the clumping together of platelets in the blood. Platelet aggregation can be a beneficial process. In fact, it is one of the body's protective mechanisms. For instance, when bleeding from a wound suddenly occurs, the platelets gather at the wound and attempt to block the blood flow. However, platelet aggregation can also be harmful. It is the first step in a sequence of events that leads to the formation of a thrombus.



• FIGURE 24.1 Synthesis of prostaglandins.

When blood vessels are damaged, fibrils of collagen are exposed. Collagen acts as a potent activator of platelets, changing the platelet from a smooth discoid shape to a spiculated (spiky) form that allows platelets to bind together. The bound platelets release adenosine triphosphate and thromboxane A_2 (TXA_2), which recruit and activate still more platelets circulating in the blood. The risk of platelet aggregation and its associated blood vessel damage is increased in patients who smoke cigarettes and in those who have hypercholesterolemia.

PATHOPHYSIOLOGY

Migraine Headache

Many patients believe that any severe headache is a migraine headache. Actually, migraine headache is much more than just severe pain. In the United States, it affects almost 30 million people, many of whom are undiagnosed. Migraine affects women more frequently than men, possibly because of the interaction between hormones and migraine.

Migraine headache is one of the four types of primary headaches (Box 24.1). The two major subtypes of migraine headache are migraine with aura (previously classic migraine) and migraine without aura (previously common migraine). Migraine headaches are divided into four phases: prodrome, aura, headache, and postheadache. The characteristic symptoms of each phase are listed in Box 24.2. The prodromal phase occurs initially. In the 20% to 60% of patients who experience this phase, symptoms may ease as the headache begins. The aura phase is a group of neurologic symptoms that develop in 15 to 20 minutes and last for up to an hour; 15% to 20% of patients experience this phase. The headache phase develops within 60 minutes after the cessation of the aura and can last from hours to days. The postheadache phase begins after the symptoms of the headache cease.

Box 24.1 INTERNATIONAL CLASSIFICATION OF HEADACHES

The Primary Headaches

1. Migraine
2. Tension-type headache
3. Cluster headache and other trigeminal autonomic cephalalgias
4. Other primary headache

The Secondary Headaches

5. Headache attributed to head and/or neck trauma
6. Headache attributed to cranial or cervical vascular disorder
7. Headache attributed to non-vascular intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disorder of homoeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial or cranial structures
12. Headache attributed to psychiatric disorders

Cranial Neuralgias Central and Primary Facial Pain and Other Headaches

13. Cranial neuralgias and central causes of facial pain
14. Other headache, cranial neuralgia, central or primary facial pain

The understanding of the etiology of migraine headache has been evolving for years. In the past migraine was classified as a vascular event; however, migraine is now classified as a neurovascular disorder. It is postulated that migraine begins when intracranial blood vessels dilate. This dilation stimulates the trigeminovascular system, resulting in abnormally excitable neurons that send pain impulses to the brain's pain receptors. Stimulation of the trigeminovascular system also causes release of brain chemicals called neuropeptides (substance P, calcitonin gene–related peptide [CGRP], neurokinin A, serotonin, and noradrenalin). The release of these chemicals causes inflammation, with resultant increased perception of pain. As the pain increases, activation and sensitization of sensory neurons of the trigeminal nuclei in the caudal brainstem and upper cervical spinal tract occur. This produces a lowered pain threshold, and sensations that are not normally painful (light, touch, noise, movement) are perceived as painful.

DRUGS TO TREAT INFLAMMATION AND FEVER

Salicylates, NSAIDs, and para-aminophenol derivative drugs are used to treat inflammation and fever in a variety of conditions. Salicylates are used in managing conditions ranging from a simple headache to acute myocardial infarction (MI). NSAIDs are used primarily as anti-inflammatory drugs but are also used extensively as analgesics. The newest NSAIDs have been approved for other conditions such as familial adenomatous polyposis (FAP) and are undergoing extensive research into their viability to affect disorders such as Alzheimer and kidney disease.

NONSTEROIDAL ANTI-INFLAMMATORY AGENTS

This class of drugs is conventionally categorized as **salicylates,** nonsteroidal anti-inflammatory drugs (NSAIDs), and para-aminophenol derivatives. The literature sometimes refers to NSAIDs as **prostaglandin synthetase inhibitors.** Both salicylates and NSAIDs work by inhibiting COX and decreasing prostaglandins and thromboxane. A major

Box24.2 PHASES OF MIGRAINE HEADACHE

Prodromal Phase (symptoms vary)

- Depression/moodiness
- Food cravings/thirst
- Difficulty concentrating
- Fatigue
- Shivering
- Stiff neck

Aura Phase

Visual Symptoms:
- Specks
- Flashing
- Shimmering
- Geometric forms
- Telescoping vision

Motor Symptoms:
- Weakness
- Language difficulty

Sensory Symptoms:
- Numbness

Headache Phase

Head Pain:
- Gradual onset
- Unilateral (bilateral in 40%)
- Throbbing, moderate to severe pain
- Aggravated by movement

Associated Symptoms:
- Nausea and vomiting
- Photophobia and phonophobia
- Anorexia
- Blurred vision

Postheadache Phase

- Fatigue
- Irritability
- Impaired concentration
- Scalp tenderness
- Mood changes
- Euphoria or depression

TABLE 24.1 Summary of Selected Salicylates

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Salicylates			
acetylsalicylic acid (aspirin, Bayer Aspirin)	Minor aches, pains, or temperature Anti-inflammatory Acute rheumatic fever Prevention of transient ischemic attacks Prevention of myocardial infarction	*Adult:* PO, dependent on indication, in order of indications listed to the left: 325–1,000 mg q4h; 2.6–5.2 g/d in divided doses; 7.8 g/d in divided doses; 325 mg–1.3 g/d in two to four divided doses; 325 mg/d *Child:* PO, <25 kg; 60–90 mg/kg/d; >25 kg, 2.4–3.6 g/d in divided doses	*Onset:* 15–30 min *Duration:* 3–6 h $t_{1/2}$: 2–3 h
diflunisal (Dolobid)	Arthritis Mild to moderate pain Headache	*Adult:* PO, 250–500 mg bid not to exceed 1.5 g/d *Adult:* PO, 1 g initially followed by 500 mg q12h (under 50 kg or elderly, 500 mg initially followed by 250 mg q12h) *Adult:* PO, 500 mg q12h *Child:* Safe dosage not established	*Onset:* 30–60 min *Duration:* 12 h $t_{1/2}$: 8–12 h
salsalate (Disalcid)	Arthritis Musculoskeletal inflammation	*Adult:* PO, initially 500 mg–1 g bid or tid; maintenance, 2–4 g in divided doses *Child:* Safe dosage not established	*Onset:* 10–30 min *Duration:* 3–6 h $t_{1/2}$: 2–3 h

difference is that the inhibition of COX by salicylates is *irreversible,* whereas the action of the NSAIDs is *reversible*. Salicylates are discussed first, followed by NSAIDs.

• Salicylates

Since salicylates were isolated from the bark of the willow tree in 1829, they have become one of the mainstays of drug therapy in a variety of diseases and disorders. The therapeutic uses of salicylates continue to be researched in all areas of medicine. The prototype salicylate is acetylsalicylic acid, commonly known as aspirin. Table 24.1 presents a summary of selected salicylates.

Nursing Management of the Patient Receiving Aspirin

Core Drug Knowledge

Pharmacotherapeutics

Aspirin has a variety of therapeutic uses. It is indicated for mild to moderate pain, especially pain resulting from inflammation. It is used frequently to relieve headache, neuralgia, myalgia, arthralgia, postpartum pain, dental or oral surgery pain, and dysmenorrhea (painful menstruation). The preferred agent for treating pain and inflammation associated with juvenile arthritis, rheumatoid arthritis, and osteoarthritis, it also is the favored drug in treating fever (in adults), pleurisy, and arthritis. Other inflammatory conditions, such as tendonitis and bursitis, respond well to aspirin. In addition, it is used for treating pericarditis in patients with systemic lupus erythematosus (SLE).

Because of its antiplatelet and anti-inflammatory effects, low-dose aspirin (81 mg daily) is useful in preventing or reducing the risk of transient ischemic attacks (TIAs), MI, and ischemic cerebral vascular accident (stroke or brain attack). It is also indicated for patients with a previous MI, patients with chronic or unstable angina, and those undergoing angioplasty or other revascularization procedures Interestingly, low-dose aspirin therapy affects men and women differently. The maximum recommended daily dose is 4 grams.

Pharmacokinetics

Aspirin absorption usually occurs within 30 minutes, depending on the dosage form, gastric pH, and the presence of food or antacids in the stomach. Although some aspirin is absorbed in the stomach, most is absorbed in the small intestine. Aspirin suppositories are slowly and variably absorbed, resulting in a lower blood concentration than with oral forms. Buffered aspirin does not delay absorption; however, enteric-coated and extended-action preparations do delay absorption.

Aspirin is 99% metabolized into salicylate and other metabolites by the liver. Aspirin and its metabolites are highly bound to plasma albumin and widely distributed throughout the body and body fluids, including breast milk. Additionally, they cross the placental barrier. Peak plasma levels occur within 2 hours. The half-life of aspirin is 15 minutes, whereas the half-life of salicylate is 2 hours. Aspirin and its metabolites are excreted by the kidneys (see Table 24.1).

Pharmacodynamics

Aspirin is used for its antipyretic, anti-inflammatory, analgesic, and antiplatelet effects. The antipyretic effects are a result of inhibited PGE_2 synthesis in the hypothalamus, the body's temperature regulator. Aspirin may enhance peripheral vasodilation and sweating. The anti-inflammatory action is believed to be caused by peripheral inhibition of prostaglandin synthesis, but aspirin also may inhibit the

action and synthesis of other mediators of inflammation. Pain is mediated by prostaglandins in the periphery that sensitize pain receptors. The analgesic effects result from the ability to inhibit COX-2, resulting in decreased production of prostaglandins. The antiplatelet action results from the *irreversible* inhibition of thromboxane A_2, a prostaglandin that induces platelet aggregation.

Contraindications and Precautions

Aspirin is contraindicated in patients with salicylate hypersensitivity. It also is contraindicated in patients with peptic ulcer disease or bleeding disorders. Aspirin should not be given to patients on anticoagulation therapy because of its antiplatelet activity. Additionally, aspirin is contraindicated in patients with gout and for those with renal or liver impairment. Aspirin is contraindicated in children with varicella or flu-like illness because it is associated with the occurrence of **Reye syndrome,** a potentially fatal disease characterized by swelling in the brain, increased intracranial pressure, and seizures.

Aspirin is assigned to pregnancy category D and should be avoided by pregnant women because it can interfere with the prostaglandins that mediate uterine contraction, resulting in delayed or prolonged labor. In addition, aspirin's antiplatelet activity increases the risk of maternal or neonatal hemorrhage. Aspirin also should be avoided by lactating women because it is secreted in breast milk and may exert its antiplatelet action in infants.

Aspirin should be avoided by patients who smoke cigarettes and by patients with a history of alcohol abuse; both agents are known to be ulcerogenic. Aspirin should be given with caution to patients with asthma, nasal polyps, and hyperuricemia. Patients older than 60 years and those taking corticosteroids have a higher risk for aspirin's adverse effects.

Adverse Effects

Two adverse effects specific to aspirin therapy are salicylism and salicylate poisoning. **Salicylism** is mild aspirin toxicity, which may occur with long-term or high-dose aspirin therapy. Typical symptoms include headache, tinnitus, GI distress, paresthesias, and respiratory stimulation (i.e., increased respiratory rate secondary to stimulation in the central nervous system [CNS]). Patients may appear drowsy or confused. The only intervention needed for salicylism is to reduce the dose of aspirin or stop aspirin therapy.

Salicylate poisoning is a life-threatening event. The lethal dose of aspirin is 5 to 8 g for a child and 10 to 30 g for an adult. There is no antidote for salicylate poisoning. Treatment of salicylate poisoning includes gastric lavage; administration of activated charcoal; and life support, if indicated. Consequences of salicylate poisoning include respiratory alterations; fluid, electrolyte, and acid-base imbalances; seizures; high temperature; and shock leading to coma and death. Patients with suspected salicylate poisoning should be taken to an emergency department rather than a clinic or doctor's office for treatment. Children's aspirin has a pleasant flavor and may not be recognized as a drug by children. Therefore, it is important to keep aspirin in a safe place.

Common adverse effects related to aspirin are the result of prostaglandin inhibition. It is important to remember that prostaglandins are found in most body tissues and organs and frequently have opposing effects on the body. Adverse effects occur because of the inhibition of a particular prostaglandin necessary for normal cell function by inhibiting COX-1.

The most common adverse effects of aspirin are related to the GI system. Aspirin may irritate the gastric mucosa, resulting in nausea, vomiting, abdominal pain, ulcerations, perforation, and bleeding. These effects occur because of a direct irritating action to the mucosa of the GI tract and the inhibition of PGE_2, which has a cytoprotective mechanism to the mucosa. Aspirin can be given with antacids to decrease its GI effects; however, antacids also decrease the absorption of aspirin. Severe gastropathies occur most frequently in patients older than 60 years, those with a history of peptic ulcer disease, cigarette smokers, those who concomitantly use alcohol or corticosteroids, and those with dyspepsia during aspirin therapy.

Aspirin may cause hypersensitivity reactions, such as rashes, hives, or bronchoconstriction, and possibly respiratory distress and anaphylaxis. Patients prone to these reactions usually have severe corticosteroid-dependent asthma, nasal polyps, or chronic urticaria. High aspirin levels may induce ototoxicity manifested by tinnitus.

Another potentially serious adverse effect of aspirin is excessive or abnormal bleeding, especially in patients with hemophilia, anemias, or severe liver disease. Aspirin inhibits platelet aggregation by the inhibition of the prostaglandin thromboxane. Aspirin's antithrombotic action lasts for the life of the platelet (8 days). Other hematopoietic problems, such as agranulocytosis and aplastic anemia, have been reported infrequently.

Aspirin has been associated with hepatotoxicity in patients with juvenile arthritis, active SLE, rheumatic fever, or pre-existing hepatic impairment. The hepatotoxicity is thought to be a direct toxicity to the liver and is associated with high-dose therapy.

In the renal system, acute renal failure may occur in susceptible patients. Patients with conditions associated with diminished renal blood flow, such as chronic heart failure (CHF), cirrhosis, renal insufficiency, and advanced age, are at the highest risk. Prostaglandins play a role in opposing potent renal vasoconstrictors. Therefore, when the action of these prostaglandins is inhibited, vasoconstriction occurs, and blood flow is diminished to the renal system, resulting in acute renal failure. Another problem that occurs when renal prostaglandins are inhibited is sodium and water retention. This inhibition is especially problematic for patients with conditions such as hypertension and CHF. Less common renal toxicities include interstitial nephritis and nephrotic syndrome. In addition to increased

blood urea nitrogen (BUN) and creatinine levels, proteinuria occurs. Acute renal failure, water retention, interstitial nephritis, and nephrotic syndrome usually occur early in aspirin therapy and are reversible by stopping aspirin treatment.

Additionally, aspirin decreases uric acid excretion by the kidneys; therefore, aspirin may potentiate gout.

Drug Interactions

Aspirin is a highly protein-bound drug and may interact with other drugs that are also highly protein-bound. Because aspirin displaces the other active drugs into the serum, the pharmacologic effects of the displaced drug are enhanced. Drugs such as anticoagulants, oral hypoglycemics, insulin, methotrexate, and alcohol may be enhanced enough to cause toxicity. Conversely, drugs such as antacids, probenecid, and corticosteroids may decrease the effectiveness of salicylates. Ibuprofen may block aspirin's antiplatelet activity, diminishing its protective effects against cardiovascular and cerebrovascular events.

In addition, aspirin can cause false-negative results on the glucose oxidase test (Tes-Tape) and a false-positive result on the copper reduction test (Clinitest). These false-positive results have become less important since use of home blood glucose monitoring systems has become widespread. A summary of drug–drug interactions for aspirin is provided in Table 24.2.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for potential medical conditions or drugs that contraindicate the use of aspirin or require close patient monitoring. It is important to assess for potential hypersensitivities to salicylates or other NSAIDs and for a history of asthma or nasal polyps because patients with these conditions are prone to bronchospasm. Also, assess gross hearing as a baseline for possible ototoxicity.

For patients on long-term therapy, obtain a history of GI complaints because of the possibility of *Helicobacter pylori* infection. Patients with *H. pylori* have an increased risk of GI complications with aspirin therapy. Assess a baseline complete blood count (CBC), platelet count, and test results for renal and hepatic function. It is important to assess the patient's knowledge concerning the potential adverse effects and drug interactions associated with aspirin and to assess the patient for efficacy of the therapy.

Life Span and Gender

Determine whether female patients are pregnant. Aspirin should not be given to women in the last trimester of pregnancy because of an increased risk of maternal hemorrhage. In addition, taking aspirin during late pregnancy can result in adverse fetal effects, including low birth weight, increased intracranial hemorrhage, stillbirth, and neonatal death. Determine the patient's age before administering aspirin. Aspirin should not be given to children younger than 16 years with flu-like symptoms because of its association with Reye syndrome. Aspirin should be given with caution to patients older than 60 years because of an increased risk of adverse effects, especially gastropathies.

Lifestyle, Diet, and Habits

It is important to inquire about the patient's use of over-the-counter (OTC) drugs because many OTCs contain aspirin as an ingredient. Concomitant use increases the risk of hepatic and renal toxicity. Assess for alcohol or drug abuse because the patient may have undiagnosed pre-existing hepatic dysfunction. Assessing for cigarette smoking also is important because smoking increases gastric acid production. With the loss of the cytoprotective mechanisms in the stomach from aspirin therapy, the risk of GI bleeding is increased.

Environment

Assess the patient's understanding of aspirin therapy. Aspirin is the least expensive and the most common of all household remedies. Because of its OTC availability and low cost, many people do not understand the potentially life-threatening effects it may cause. They do not believe that aspirin is an important therapeutic intervention and are offended by receiving instructions to take it. For these reasons, patient education is vital.

Nursing Diagnoses and Outcomes

- Acute or Chronic Pain related to ineffectiveness of aspirin
  Desired outcome: *The patient will contact the prescriber if pain persists.*
- Risk for Injury: GI Bleeding, Hepatic or Renal Toxicity related to aspirin therapy
  Desired outcome: *The patient will avoid injury by contacting the prescriber if any signs of toxicity occur.*
- Ineffective Protection related to blood dyscrasias or rash

CRITICAL THINKING SCENARIO

ASPIRIN THERAPY FOR ARTHRITIS

Mrs. Tyler, age 55, has been a patient at your clinic for the past 5 years. She has severe persistent asthma and takes oral prednisone as well as beta-adrenergic agonists as needed. She intermittently has an elevated glucose and follows a 2,400-calorie diet. She was diagnosed with degenerative arthritis of her back today. The health care provider advised Mrs. Tyler to take 2 aspirin every 6 hours to relieve her discomfort and to increase the dose to 3 tablets every 6 hours if the pain continues. As Mrs. Tyler leaves, she turns to you and states, "Aspirin—what a joke—I could have gotten that advice from a website on my computer."

1. How would you respond to Mrs. Tyler?
2. What patient education would you do?
3. Does Mrs. Tyler's medical history predispose her to any problems with aspirin?

TABLE 24.2 Agents That Interact with P Aspirin

Interactants	Effect and Significance	Nursing Management
ACE inhibitors	Aspirin decreases the hypotensive and vasodilator effects of ACE inhibitors	Monitor BP and hemodynamic parameters.
antacids	Antacids increase urinary pH, thus reducing renal reabsorption of aspirin and increasing aspirin clearance. As more aspirin is cleared from the body, a potentially subtherapeutic aspirin level may result.	Monitor serum aspirin level when initiating or discontinuing antacid therapy.
Anticoagulants,oral	Aspirins inhibit platelet function, thus prolonging bleeding time. Aspirins displace anticoagulants from protein binding sites, thus increasing their effects. Both actions may result in hemorrhage.	Avoid administering aspirin or other salicylates if possible. Monitor PT, PTT, and INR.
Beta blockers	Salicylates may decrease the antihypertensive effects of beta blockers as well as decrease the beneficial effects on left ventricular ejection fraction (LVEF) in patients with chronic heart failure.	Monitor BP. Monitor for signs of CHF.
Carbonic anhydrase inhibitors (CAIs)	Aspirins displace CAI from protein binding sites and inhibit renal clearance. CAI accumulation and toxicity may result in central nervous system (CNS) depression and metabolic acidosis.	Coadministration should be avoided. When a CAI is required, monitor plasma aspirin level and arterial blood gas (ABG) values. Monitor neurologic status.
clopidogrel	Clopidogrel in combination with salicylates increases the risk of life-threatening bleeding (e.g., intracranial and GI hemorrhage) in patients with transient ischemic attack or ischemic stroke.	Monitor for bruising or bleeding. Monitor neurologic status. Discuss alternative therapy with the health care provider
Corticosteroids	Corticosteroids stimulate metabolism of aspirins and increase renal elimination. Aspirin levels may become subtherapeutic. Discontinuation of corticosteroids may increase aspirin level.	Monitor aspirin concentrations when adding or withdrawing corticosteroids. Monitor for bruising or bleeding. Monitor platelet count.
ethanol (alcohol)	Both aspirin and alcohol damage the gastric mucosal barrier. The production of gastric acid stimulated by alcohol promotes the damage. Aspirin decreases the activity of gastric alcohol dehydrogenase, increasing bioavailability. Alcohol may potentiate aspirin-induced GI blood loss and prolong bleeding time.	Separate aspirin and alcohol intake by 12 h. Use buffered aqueous solutions or enteric-coated or extended-release aspirins.
Heparin	Administration of heparin and aspirin together has an additive effect resulting in an increased risk for adverse effects.	Teach the patient to avoid taking these two drugs together. Monitor for signs of bleeding.
insulin	Basal insulin concentrations are increased, and the acute insulin response to a glucose load is enhanced. This potentiates the serum glucose–lowering action of insulin and results in hypoglycemia.	Monitor blood glucose concentration, and discuss insulin dosage changes with the health care provider.
ketorolac	Aspirin may displace the ability of ketorolac to bind to protein, resulting in an increased ketorolac serum concentration.	Discuss alternate therapy with the health care provider. Teach the patient to avoid this combination.
methotrexate	Aspirins may decrease renal clearance and plasma protein binding of methotrexate, leading to methotrexate toxicity.	Monitor for myelosuppression. Monitor CBC. Monitor methotrexate plasma level.
NSAIDS	NSAIDS decrease the cardioprotective and cerebroprotective effects of low-dose uncoated aspirin. The pharmacologic effect of NSAIDS may be decreased. Both drugs are gastric irritants and may increase the risk for GI distress.	Teach the patient to avoid taking these two drugs together. Monitor for cardiovascular adverse effects. Monitor for efficacy of NSAIDS Monitor for GI distress or bleeding.

(*Continued*)

TABLE 24.2 Agents That Interact with P Aspirin *(continued)*

Interactants	Effect and Significance	Nursing Management
probenecid	Renal filtration of uric acid may be altered, leading to the inhibition of uricosuric action of either drug.	Avoid coadministration.
sulfinpyrazone	Salicylates and sulfinpyrazone impair each other's uricosuric activity.	Teach the patient taking sulfinpyrazone to avoid extended use of aspirin.
Sulfonylureas	Hypoglycemic effect of sulfonylureas may be increased, but the mechanism of this action is not known.	Monitor blood glucose. If hypoglycemia occurs, discuss alternative therapy with the health care provider.
valproic acid	Aspirin displaces valproic acid from protein binding sites. Coadministration may cause valproic acid toxicity.	Monitor serum valproic acid concentrations and liver enzyme levels.

Desired outcome: *The patient will contact the prescriber if any signs of blood dyscrasias or rash occur.*

- Deficient Fluid Volume related to nausea and vomiting
  Desired outcome: *The patient will avoid dehydration by contacting the prescriber if persistent nausea or vomiting occurs.*
- Disturbed Sensory Perception (visual and auditory) related to blurred vision or tinnitus
  Desired outcome: *The patient will contact the prescriber if blurred vision or tinnitus occurs.*
- Risk for Injury related to self-medication
  Desired outcome: *The patient will avoid injury by taking aspirin as prescribed.*

Planning and Intervention

Maximizing Therapeutic Effects

Give aspirin with milk or food to decrease gastric distress, as needed. When giving aspirin for its cardiovascular properties, use uncoated aspirin, because compared with enteric-coated aspirin, its bioavailability and antiplatelet activity are greater.

Minimizing Adverse Effects

Do not administer aspirin to a patient with a medical condition that contraindicates its use. It is important to monitor closely patients with pre-existing medical conditions or those on drug therapy that may interact with aspirin. Anticipate the use of proton pump inhibitors or misoprostol in combination with aspirin to decrease the potential for adverse effects. For patients on long-term aspirin therapy, arrange for periodic laboratory testing, including a CBC, platelet count, and liver and renal function tests.

Providing Patient and Family Education

- Encourage patients to take the drug exactly as prescribed to avoid adverse effects or overdose of aspirin.
- Advise patients to take uncoated aspirin rather than enteric-coated aspirin if they are taking it for its cardiovascular properties.
- Caution patients not to take aspirin if they have problems with their kidney or liver, are asthmatic and have nasal polyps (aspirin can cause an asthma attack), or are in their last trimester of pregnancy (aspirin may cause hemorrhage during delivery and adverse fetal effects).
- Teach patients about potential adverse effects of aspirin and the importance of contacting the prescriber if any occur. Advise the patient to contact the health care provider if any of the following serious adverse effects occur:
- Confusion, dizziness, drowsiness
  - Seizures (convulsions)
  - Difficulty breathing, wheezing
  - Tinnitus (ringing in the ears)
  - Blurred vision
  - Black, tarry stools; unusual bleeding or bruising; red or purple spots on the skin; dark urine; prolonged bleeding from a cut; vomiting blood or what looks like coffee grounds
- Caution patients that if aspirin is taken for a long time or in high doses, it can cause problems with the blood, kidneys, or liver.
- Advise patients to avoid drinking alcohol and smoking when taking aspirin because these activities can increase the risk of gastric irritation and bleeding.
- Explain the importance of taking the drug exactly as prescribed to avoid potential GI distress or bleeding. For example, it is best to adhere to the following directions when taking different types of aspirin:
  - Chewable tablets can be chewed before swallowing, crushed and taken with food, or mixed in a drink.
  - Extended-release tablets should be swallowed whole, never crushed or chewed.
  - Tablets, caplets, or gel-caps should be swallowed with a full glass of water.
  - Suppositories should be removed from the foil, the tip moistened, and then placed in the rectum.
- Caution patients to contact the prescriber in the event of persistent nausea or vomiting to avoid fluid loss.
- Tell patients to take aspirin with food, milk, or antacid to prevent GI upset, and that if they miss a dose, the dose should be taken as soon as possible. If it is time for the next dose, only that dose should be taken; double or extra doses should never be taken.

MEMORY CHIP

P Aspirin

- Used for its analgesic, antipyretic, anti-inflammatory, and antiplatelet effects; irreversibly inhibits cyclooxygenase (COX)
- Major contraindications: peptic ulcer disease, gout, renal or hepatic impairment, bleeding disorders, and patients already on anticoagulation therapy
- Most common adverse effect: GI distress
- Most serious adverse effects: renal impairment, gastric ulceration, and GI bleeding
- **Life span alerts: Aspirin should not be given to children with varicella- or flu-like illness; it should not be given during pregnancy, especially during the third trimester;** monitor patients older than 60 years carefully**. Low-dose aspirin therapy is routinely given to healthy adults older than 40 years age to prevent MI and stroke.**

- Encourage patients to read all OTC drug labels to avoid taking any drugs with aspirin or ibuprofen as an ingredient.
- Encourage patients with diabetes to use blood glucose monitoring rather than urine testing.
- Inform patients never to give aspirin to children younger than 16 years, unless directed to do so by the prescriber, and to keep aspirin out of the reach of children.
- Tell patients to keep aspirin in a cool, dry place to maintain its potency and to discard any aspirin that smells like vinegar.
- Explain to patients that if the fever does not resolve in 3 days or pain does not go away in 10 days, they should see their health care provider.
- Instruct patients on long-term aspirin therapy to see their health care provider every 6 months for blood work to avoid serious adverse effects. Depending on the health care provider, this may not be necessary for the patient taking low-dose therapy.

Ongoing Assessment and Evaluation

Monitor the patient who is taking aspirin for signs and symptoms of GI distress or bleeding, anemia, hepatotoxicity, and renal failure. It is important to discontinue aspirin if the patient develops a rash, unexplained fever, or angioedema. Monitor for tinnitus and contact the prescriber immediately if this symptom occurs. Also, monitor the patient for efficacy of aspirin therapy.

Therapy is considered effective if the patient is free of fever, pain, or inflammation and does not develop serious adverse effects. In addition, the patient realizes and can explain the importance of contacting the health care provider immediately if any adverse reactions occur.

Drugs Closely Related to P Aspirin

Diflunisal

Diflunisal (Dolobid) is similar to aspirin, but it does not metabolize into salicylic acid. It is used for acute or long-term relief of mild to moderate pain, acute and chronic rheumatoid arthritis, and osteoarthritis. It is not recommended for use as an antipyretic. Diflunisal has an onset of 1 hour, and peak action occurs in 2 to 3 hours. The half-life is 8 to 12 hours. Potential adverse effects are the same as for aspirin. The main advantage of diflunisal is its twice-a-day dosing schedule. The main disadvantage of diflunisal is its cost. Its efficacy for children has not been established.

Salsalate

Salsalate (Disalcid) is the ester of salicylic acid. Salsalate is absorbed completely from the GI tract. Absorption occurs in the small intestine because salsalate acid is practically insoluble in acidic gastric fluids. As an anti-inflammatory and analgesic drug, salsalate acid has the same efficacy as aspirin; however, it does not have antiplatelet or antipyretic effects. Salsalate is useful particularly for patients who cannot tolerate aspirin's GI effects or for patients at risk for anticoagulation. Peak action of salsalate occurs in 2 to 4 hours, and therapeutic levels may be maintained for up to 16 hours with twice-a-day dosing. Salsalate is not recommended for children.

• C Nonsteroidal Anti-Inflammatory Drugs

The NSAIDs are grouped by chemical classes—propionic acids, acetic acids, fenamates, oxicams, and COX-2 inhibitors. Despite the chemical differences among NSAIDs, they all inhibit COX and prostaglandin synthesis. Different NSAIDs may inhibit specific isoenzymes of the COX group, which may explain the differences in efficacy and adverse effects among the NSAIDs when used in specific disease states. The therapeutic efficacy of an NSAID in a particular patient is based on clinical response and usually cannot be predicted before its use. As previously mentioned, there are two distinct forms of COX. It is proposed that NSAIDS should be classified as either COX-1 specific, COX nonspecific, COX-2 preferential, or COX-2 specific (Box 24.3). All NSAIDs, regardless of their preference for COX-1 or COX-2, carry a Black Box warning stating that it increases the risk of MI and stroke, and that the risk increases with the duration of therapy.

Ibuprofen has had Food and Drug Administration (FDA) approval since the mid-1970s and currently is available in prescription and nonprescription dosages. Ibuprofen (Motrin, multiple other trade names) is the prototype for NSAIDs. Table 24.3 presents a summary of selected NSAIDs.

Box24.3 SELECTIVITY OF NSAIDS

COX-1 Selective	COX-1 Slightly Selective	COX-2 Selective	COX-2 Slightly Selective
aspirin	**diclofenac**	**celecoxib**	**etodolac**
indomethacin	**ibuprofen**		**meloxicam**
ketoprofen	**naprosyn**		**nabumetone**
piroxicam			
sulindac			

TABLE 24.3 Summary of Selected C Nonsteroidal Anti-Inflammatory Drugs

Drug (Trade) Name	Route and Dosage Range	Pharmacokinetics
C Nonsteroidal Anti-Inflammatory Drugs		
P ibuprofen (Motrin, Advil)	Adult: PO, 200–800 mg tid–qid, not to exceed 3,200 mg/d Child: PO, 20–40 mg/kg/d in three to four divided doses	*Onset: Rapid* *Duration: 24 h* *t1/2: 1.8–2 h*
ibuprofen lysine (NeoProfen)	*Premies <32 wk gestation:* IV, 10 mg/kg IV ×1, then 5 mg/kg IV q24h ×2; wait 24 h between 1st and 2nd dose; may repeat course ×1 if treatment is unsuccessful; all doses based on birthweight	
bromfenac (Xibrom)	*Adult:* Topical, 1 drop 2×/d for 14 d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown
diclofenac sodium (Voltaren, Flector)	*Adult:* PO, 100–200 mg/d in two to four divided doses *Adult:* Transdermal (Flector), 1 patch to the most painful area 2×/d *Child:* Safety and efficacy not established	*Onset:* 1 h *Duration:* 4–6 h $t_{1/2}$: 2 h
fenoprofen (Nalfon)	*Adult:* PO, 300–600 mg tid–qid, not to exceed 3,200 mg/d *Child:* Safety and efficacy not established	*Onset:* 30 min *Duration:* 4–6 h $t_{1/2}$: 3 h
flurbiprofen (Ansaid)	*Adult:* PO, 50–100 mg bid–tid; maximum dose, 300 mg/d *Child:* Safety and efficacy not established	*Onset:* 1 h *Duration:* 4–8 h $t_{1/2}$: 5.7 h
indomethacin (Indocin)	*Adult:* PO, 25 mg bid or tid up to total 150–200 mg/d *Child:* IV, 0.1–0.25 mg/kg/d (patent ductus arteriosus) *Child: PO;* 1–2 mg/kg/d (rheumatoid arthritis)	*Onset:* PO, 30 min; IV, immediate *Duration:* PO, 4–6 h; IV, 15–20 min $t_{1/2}$: 2.6–11 h
ketoprofen (Orudis)	*Adult:* PO, 150–300 mg/d single or divided doses; maximum 300 mg/d *Child:* Safety and efficacy not established	*Onset:* 30 min *Duration:* 4–8 h $t_{1/2}$: 2–4 h
ketorolac (Toradol, Acular)	*Adult:* PO, 10 mg q4–6h for maximum of 5 d; IM/IV, 30–60 mg, followed by 15–30 mg q6h for a maximum of 5 d *Child:* IM/IV, 0.5 mg/kg q6h to a maximum of 72 h	*Onset:* PO, varies; IM/IV, 30 min *Duration:* PO, IM/IV, 6 h $t_{1/2}$: 2.4–8.6 h
mefenamic acid (Ponstel)	*Adult:* PO, initially 500 mg q6h, then decrease to 250 mg q6h; maximum dose, 1,000 mg/d, not to exceed 5–7 d *Child:* Not indicated for age <14 y	*Onset:* 1–2 h *Duration:* 6 h $t_{1/2}$: 2–4 h
meloxicam (Mobic)	*Adult:* 7.5 mg once daily *Child: 2–17 y;* PO, 0.125 mg/kg/d, not to exceed 7.5 mg daily	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 15–20 h
nabumetone (Relafen)	*Adult:* PO, 1,000 mg/d, not to exceed 2,000 mg/d *Child:* Safety and efficacy not established	*Onset:* 1–2 h *Duration:* 24–48 h $t_{1/2}$: 24 h
naproxen (Naprosyn)	*Adult:* PO, 250–750 mg bid, not to exceed 1,500 mg/d; acute gout, 750–825 mg initially, followed by 250–275 mg qid; moderate pain or dysmenorrhea, 500–550 mg, followed by 250–275 mg *Child:* PO, 10 mg/kg in 2 doses	*Onset:* 1–2 h *Duration:* 7–12 h $t_{1/2}$: 12–15 h
nepafenac (Nevanac)	*Adult and Child >10 y:* Topical, 1 drop 3x/d for 15 d; start 1 d post cataract surgery	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown
oxaprozin (Daypro)	*Adult:* PO, 600–1,200 mg once daily *Child 6–16 y:* PO, 10–20 mg/kg daily, not to exceed 1200 mg/d	*Onset:* 1 h *Duration:* 24–48 h $t_{1/2}$: 42–50 h
piroxicam (Feldene)	*Adult:* PO, 10–20 mg/d or in divided dose *Child:* Safety and efficacy not established	*Onset:* 15–30 min *Duration:* 24–48 h $t_{1/2}$: 30–86 h
sulindac (Clinoril)	*Adult:* PO, 150–200 mg bid, not to exceed 400 mg/d *Child:* Safety and efficacy not established	*Onset:* 1 h *Duration:* 7–16 h $t_{1/2}$: 7–8 h

TABLE 24.3 Summary of Selected C Nonsteroidal Anti-Inflammatory Drugs *(continued)*

Drug (Trade) Name	Route and Dosage Range	Pharmacokinetics
tolmetin (Tolectin)	*Adult:* PO, initial 200–400 mg tid–qid; maintenance, 600–1,800 mg in divided doses, not to exceed 1,800 mg *Child:* PO, initial 20 mg/kg/d in three to four divided doses; maintenance, 15–30 mg/kg/d in three to four divided doses	*Onset:* Rapid *Duration:* 6–8 h $t_{1/2}$: 2–7 h
COX-2 Inhibitors		
celecoxib (Celebrex)	*Adult:* PO, 100–200 mg bid	*Onset:* <1 h *Duration:* Unknown $t_{1/2}$: 11 h

Nursing Management of the Patient Receiving P Ibuprofen

Core Drug Knowledge

Pharmacotherapeutics

Labeled uses for ibuprofen include rheumatoid arthritis, juvenile rheumatoid arthritis, osteoarthritis, mild to moderate pain, primary dysmenorrhea, migraine headache, and fever. Ibuprofen lysine (NeoProfen) is an intravenous (IV) formulation used for closure of patent ductus arteriosus in premature infants. Table 24.4 presents labeled and unlabeled indications for selected NSAIDs. The maximum dose is 3.2 g/d.

Pharmacokinetics

Approximately 80% of ibuprofen is absorbed from the GI system after oral administration. Absorption is slower if the drug is taken with food; however, the extent of absorption is not affected. Peak serum concentrations occur in

Health care providers may prescribe any of these drugs for other conditions not represented.

1 to 2 hours. Analgesic and antipyretic effects occur in 2 to 4 hours, whereas a therapeutic inflammatory response takes a few days to 2 weeks. Ibuprofen is highly protein bound and is metabolized in the liver. Plasma half-life is 1.8 to 2 hours, with urinary excretion within 24 hours.

Pharmacodynamics

Ibuprofen's effects are believed to be secondary to inhibited synthesis or release of prostaglandins. Ibuprofen probably has a peripheral rather than a central action as an analgesic. Higher doses are required for an anti-inflammatory effect than for analgesia. Antipyretic activity may be the result of action on the hypothalamus, leading to increased peripheral blood flow, vasodilation, and subsequent heat dissipation.

Contraindications and Precautions

Because chronic use of ibuprofen can result in gastritis, ulceration with or without perforation, or GI bleeding, ibuprofen is contraindicated in patients with a history of or active GI disease, including peptic ulcer disease, ulcerative colitis, or GI bleeding. Other patients at high risk for GI adverse effects are those who routinely consume alcohol or smoke tobacco products because these behaviors are also conducive to ulcer development. Ibuprofen is contraindicated for use before or after a coronary artery bypass graft procedure. It is given with great caution to patients with pre-existing cardiovascular or cerebrovascular disorders because of the associated risk of induction of MI or stroke.

Ibuprofen should be used cautiously in patients with pre-existing hepatic, renal, or hemopoietic dysfunction and in patients older than 60 years. Liver dysfunction can occur during therapy with NSAIDs, resulting in jaundice and fatal hepatitis. Ibuprofen is metabolized in the liver, and accumulation can occur with liver dysfunction, increasing the risk of toxicity. Ibuprofen and its metabolites are excreted renally. Again, accumulation may occur in patients with renal impairment, increasing the risk of toxicity. Additionally, reduced renal blood flow caused by inhibition of prostaglandin synthesis can result in overt renal decompensation. Patients with the highest risk of renal decompensation are those with renal disease, hepatic disease, CHF, diabetes mellitus, SLE, edema, or extracellular volume depletion; those taking diuretics or nephrotoxic drugs; and elderly patients.

Ibuprofen should be used cautiously in patients with pre-existing coagulopathy or hemophilia, because of the effect of the drug on platelet function and vascular response to bleeding. Ibuprofen can prolong bleeding time. Anemia may be exacerbated with the use of ibuprofen.

Conditions associated with fluid retention, such as CHF, can be exacerbated with ibuprofen therapy. Hypertension may be exacerbated by ibuprofen-induced fluid retention.

Ibuprofen is classified as a pregnancy category B drug until the third trimester, when ibuprofen enters pregnancy category D because of the potential for NSAIDs to cause premature closure of the ductus arteriosus in utero. Additionally, persistent pulmonary hypertension arising from ductus arteriosus constriction is a potential complication. NSAIDs also have the potential to prolong pregnancy and inhibit labor if taken during the third trimester.

Adverse Effects

Ibuprofen, like salicylates, inhibits COX-1 and COX-2, resulting in adverse effects. Ibuprofen and all other NSAIDS have a Black Box warning that they may increase the risk of serious and potentially fatal cardiovascular thrombotic events such as MI and stroke. This risk increases with duration of use.

Serious GI events are also listed as a Black Box warning. Nausea, vomiting, diarrhea, constipation, flatulence, and abdominal pain may be representative of minor adverse effects in some patients or serious GI toxicity in others. During long-term administration, the most serious effects are peptic ulcer disease or gastritis that leads to GI bleeding or even perforation. These events can occur at any time, with or without warning. Within the NSAID group, ibuprofen is rated as a low GI risk (Prescriber's Letter, 2010)

Ibuprofen also can induce blurred vision, decreased visual acuity, and corneal deposits. The mechanism for visual disturbances is unclear. Vision generally improves after the drug is discontinued. In addition, like aspirin, ibuprofen may induce tinnitus.

In the renal system, acute renal failure may occur in susceptible patients. Patients with conditions associated with diminished renal blood flow, such as CHF, cirrhosis, renal insufficiency, and advanced age, are at the highest risk. Vasodilatory renal prostaglandins and the potent vasoconstrictor angiotensin II work in concert to maintain renal blood flow. Inhibition of renal prostaglandins diminishes renal blood flow, leading to acute renal failure. Less common renal toxicities include interstitial nephritis and nephrotic syndrome. In addition to increased BUN and creatinine levels, proteinuria occurs. Another problem resulting from the inhibition of the renal prostaglandins is sodium and water retention. This effect is especially problematic for patients with conditions such as hypertension and CHF. Acute renal failure, water retention, interstitial nephritis, and nephrotic syndrome usually occur early in ibuprofen therapy and are reversible by stopping drug therapy.

Ibuprofen may cause excessive or abnormal bleeding, especially in patients with hemophilia, anemias, or severe liver disease. Ibuprofen diminishes platelet aggregation by inhibiting the prostaglandin thromboxane. This effect is transient and reversible. Other blood dyscrasias, such as agranulocytosis and aplastic anemia, have been infrequently reported.

Ibuprofen has been associated with hepatotoxicity, such as hepatitis or jaundice. Hepatotoxicity is uncommon, but patients should be monitored closely if on prolonged therapy.

Some patients taking ibuprofen may experience cross-sensitivity to aspirin or other NSAIDs, including those in a different chemical class. However, cross-sensitivities are not always complete, and patients may be able to take other NSAIDs, even those in the same chemical class.

TABLE 24.5 Agents That Interact with P Ibuprofen

Interactants	Effect and Significance	Nursing Management
aminoglycoside antibiotics	Ibuprofen may cause an accumulation of aminoglycoside antibiotics by reducing the glomerular filtration rate.	Monitor BUN and creatinine. Monitor I and O. Monitor hearing. Monitor neurologic status.
Anticoagulants, oral	Ibuprofen inhibits platelet function and possibly produces gastric erosion. Anticoagulation effect is increased; hemorrhage may develop.	Avoid coadministering salicylates if possible. Monitor PT, PTT, and INR. Monitor for bruising or bleeding.
Aspirin/Salicylates	The pharmacologic effects of NSAIDS may be decreased. The cardioprotective effect of low-dose uncoated aspirin may be reduced. Both drugs are gastric irritants and may increase risk for GI distress.	Teach the patient to avoid taking these two drugs together. Monitor for cardiovascular adverse effects. Monitor for efficacy of NSAIDS Monitor for GI distress or bleeding.
Azole antifungal agents	Azole antifungal agents such as fluconazole and voriconazole inhibit NSAID metabolism. This increases NSAID plasma concentrations which increases the risk for pharmacologic and adverse effects.	Teach the patient to avoid this combination. Monitor for adverse effects and toxicity related to NSAIDS.
beta blockers	Ibuprofen inhibits renal prostaglandin synthesis, allowing unopposed pressor systems to produce hypertension. It also impairs antihypertensive effect of beta blockers.	Avoid coadministering if possible. Monitor blood pressure. Discuss alteration of beta blocker dose with health care provider.
Charcoal, activated	Charcoal inhibits the absorption of NSAIDS which decreases its systemic circulation.	Monitor for efficacy of NSAID therapy.
Heparin	Both heparin and NSAIDS inhibit the clotting cascade and platelet hemostasis. This increases the risk for hemorrhage or other adverse effects.	Monitor for signs of bleeding Monitor aPTT and bleeding time.
lithium	Ibuprofen is suspected to reduce renal elimination of lithium. Interaction may cause lithium toxicity.	Monitor lithium levels every 4–5 d until they stabilize after ibuprofen is added or withdrawn from treatment. Discuss lithium dose adjustment with the health care provider.
loop diuretics	Ibuprofen reduces natriuresis and antihypertensive response, resulting in decreased diuretic effect.	Discuss administration of a salicylate instead of ibuprofen with the health care provider.
methotrexate	Ibuprofen is suspected to reduce renal elimination of methotrexate and may cause methotrexate toxicity. Toxicity is less likely to occur with doses given for rheumatoid arthritis.	Monitor methotrexate levels. Monitor CBC, platelets. Anticipate longer leucovorin rescue therapy in patients receiving ibuprofen if leucovorin is administered at antineoplastic doses.
selective serotonin reuptake inhibitors	Coadministration increases the risk for upper GI bleeding.	Monitor for nausea or vomiting. Monitor for abdominal pain. Monitor for hematemesis or melena.

Drug Interactions

Ibuprofen is highly protein bound and has many interactions similar to those produced by salicylates. Table 24.5 lists drug interactions with ibuprofen. In addition to the drugs listed in the table, ibuprofen should not be given along with salicylates. Giving these drugs together does not increase efficacy but does increase the risk of adverse effects. Ibuprofen should be discontinued 72 hours before adrenal function tests are performed. Ibuprofen also may elevate sodium and chloride levels.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for potential contraindications to ibuprofen therapy. It is important to obtain a drug history to identify potential drug–drug interactions and to assess for

potential hypersensitivities to salicylates or other NSAIDs. Assess for a history of MI or stroke, because patients who take ibuprofen have an increased risk of cardiovascular or cerebrovascular events. Assess for a history of gastric ulcers or GI bleeding. Assess for a history of asthma or nasal polyps, because patients with these conditions are prone to bronchospasm.

In addition, it is important to assess a patient's baseline gross hearing because of the potential for ototoxicity from ibuprofen use. For patients on long-term therapy, obtain a baseline CBC, platelet count, and test results of renal and hepatic function. Assess the patient for efficacy of ibuprofen therapy; severe or visceral pain may not be affected by ibuprofen.

Life Span and Gender

Determine whether female patients are pregnant. Ibuprofen should not be given to women in the last trimester of pregnancy because it may cause premature closure of the ductus arteriosus. Determine the patient's age before administering ibuprofen. Although ibuprofen is considered safe for children, some of the other NSAIDs are contraindicated. Ibuprofen should be given with caution to patients older than 60 years because these patients have an increased risk of adverse effects, especially GI bleeding. Ibuprofen, like aspirin, is thought to be metabolized faster in men, which may result in a shorter duration of action than in women.

Lifestyle, Diet, and Habits

As with aspirin, it is important to inquire about the patient's use of OTC drugs because many OTCs contain ibuprofen or aspirin. Concomitant use of either or both increases the risk of hepatic and renal toxicity.

Assess for alcohol or drug abuse because the patient may have undiagnosed pre-existing hepatic dysfunction. In addition, assess the patient for a history of cigarette smoking because ibuprofen, like aspirin, decreases the cytoprotective mechanisms of the stomach.

Environment

Ascertain the setting in which ibuprofen will be administered. Ibuprofen may be self-administered at home or given in any health care setting. Because this drug first appeared on the market as a prescription drug, the lay public often believes that it is more effective than aspirin or acetaminophen. Because of ibuprofen's reasonable cost and high efficacy, some patients may take the drug at a higher dose than the labeling suggests or for a much longer duration without seeing a medical provider. This practice places patients at a higher risk for adverse effects, or other problems, if the etiology of their symptoms is not addressed.

Nursing Diagnoses and Outcomes

- Acute or Chronic Pain related to ineffectiveness of ibuprofen
  Desired outcome: *The patient will contact the prescriber if pain persists.*
- Increased Risk for Injury related to incorrect self-administration or to drug-induced GI bleeding or hepatic and renal toxicity
  Desired outcome: *The patient will remain free of injury by taking the drug only as directed. In addition, the patient will be able to explain the importance of contacting the health care provider immediately if any adverse effects occur.*
- Increased Risk for Deficient Fluid Volume related to nausea and vomiting
  Desired outcome: *The patient will contact the prescriber immediately if intractable nausea or vomiting occurs.*
- Ineffective Protection related to blood dyscrasias
  Desired outcome: *The patient will contact the prescriber immediately if any signs and symptoms of blood dyscrasias occur.*
- Disturbed Sensory Perception (visual) related to blurred vision
  Desired outcome: *The patient will discontinue ibuprofen immediately and contact the health care provider if vision is affected.*

Planning and Intervention

Maximizing Therapeutic Effects

Give ibuprofen with milk or food to decrease gastric distress, if needed.

Minimizing Adverse Effects

Closely monitor patients with pre-existing medical conditions or drug therapy that may interact with ibuprofen. It is important to administer misoprostol to patients at high risk for developing gastropathies with ibuprofen (Box 24.4). Periodic CBC, platelet count, and liver and renal function tests should be obtained for patients on long-term ibuprofen therapy. Limit 24 hours intake to 3.2 grams.

Providing Patient and Family Education

- Instruct patients to take the drug exactly as directed by the prescriber to avoid adverse effects or overdose with ibuprofen. Daily intake should not exceed 3.2 grams.
- Tell patients not to take ibuprofen if they have problems with their kidneys or liver, to use ibuprofen cautiously

Box 24.4 USING MISOPROSTOL TO REDUCE NSAID ADVERSE EFFECTS

Misoprostol (Cytotec) increases bicarbonate and mucous production in the gastrointestinal tract. It may also inhibit gastric acid secretion. To minimize possible gastropathies in patients on long-term nonsteroidal anti-inflammatory drug (NSAID) therapy, consider prophylactic therapy with misoprostol for patients with any of the following characteristics:

- Age >60 years
- History of peptic ulcer disease
- Cigarette smoker
- Concomitant use of alcohol
- Concomitant use of corticosteroids
- Dyspepsia during salicylate or NSAID use
- Poor surgical risk if ulcer complications occur

during the first two trimesters of pregnancy, and not to take it at all during the third trimester of pregnancy. In addition, patients should not take ibuprofen if they are asthmatic and have nasal polyps, because ibuprofen could cause an asthma attack.
- Advise patients that ibuprofen increases the risk of cardiovascular and cerebrovascular events, especially when taken for a long duration or in patients with a previous history of cardiovascular or cerebrovascular disorders.
- Advise patients to take ibuprofen with food, milk, or possibly an antacid to prevent GI upset.
- Instruct patients that if a dose is missed, it should be taken as soon as possible. If it is almost time for the next dose, only that dose should be taken; double or extra doses should never be taken.
- Caution patients that drinking alcohol and smoking while taking ibuprofen can increase the risk for GI irritation and bleeding.
- Advise patients to contact their health care provider if minor adverse effects such as diarrhea, dizziness, drowsiness, heartburn, nausea, and vomiting do not subside or if they are bothersome.
- Warn patients about serious adverse effects of ibuprofen and to advise them to seek medical attention immediately if they occur. Adverse effects include the following:
  - Black, tarry stools; blood in urine; dark yellow or brown urine
  - Difficulty breathing, wheezing; skin rash, redness, blistering, peeling, or itching; swelling of eyelids, throat, lips, or feet
  - Rapid heartbeat
  - Blurred vision
  - Muscle aches and pains, fever, chills
  - Weight change
  - Unusual bleeding or bruising, unusual tiredness or weakness, prolonged bleeding from a cut, vomiting blood or what looks like coffee grounds
- Instruct patients to change position slowly to avoid dizziness. If dizziness occurs, the patient should refrain from driving a car or operating machinery.
- Tell patients to read the labels of all OTC drugs and to avoid any with aspirin or other NSAIDs as an ingredient.
- Warn patients to seek immediate medical assistance if they accidentally take too many tablets.
- Advise patients with diabetes to monitor their blood glucose levels rather than testing their urine.
- Instruct patients to keep ibuprofen in a cool, dry place to preserve its potency.
- Tell patients to see their health care provider if their fever does not resolve in 3 days or their pain does not go away in 10 days.
- Advise patients on long-term ibuprofen therapy to see their health care provider every 6 months for blood testing to make sure they are not having adverse effects from the drug.

MEMORY CHIP

P Ibuprofen

- Used for its antiinflammatory, analgesic, and antipyretic effects; reversibly inhibits cyclooxygenase (COX)
- Major contraindications: active GI diseases; used with caution in patients with renal or hepatic impairment, hemopoietic dysfunction, pre-existing coagulopathy, cardiac impairment, and age greater than 60 years
- Most common adverse effects: GI related
- Most serious adverse effects: hepatic and renal toxicity
- **Life span alert: Ibuprofen is in pregnancy category D in the third trimester; monitor patients over the age of 60 years carefully**.
- **Black box warning: All NSAIDs, including ibuprofen, have an increased risk of inducing MI or stroke. The risk escalates the longer the duration of therapy.** Monitor patients for signs of MI and stroke**.**

Ongoing Assessment and Evaluation

The patient who is taking ibuprofen requires monitoring for signs and symptoms of cardiovascular or cerebrovascular symptoms, GI distress or bleeding, anemia, tinnitus, hepatotoxicity, and renal failure. Monitor patients older than 60 years closely for these adverse effects. Arrange periodic laboratory tests for patients on long-term therapy or those at high risk for adverse effects. Monitor the patient for relief of pain and inflammation.

Therapy is considered effective if the patient is free of fever, pain, or inflammation and is free from adverse effects.

Drugs Closely Related to P Ibuprofen

Propionic Acids

In addition to ibuprofen, the following drugs are in the propionic class of NSAIDs: fenoprofen (Nalfon), flurbiprofen (Ansaid), ketoprofen (Orudis), naproxen (Naprosyn, Anaprox), and oxaprozin (Daypro). These drugs are similar to ibuprofen in action, indications, nursing management, and patient education. They differ in their onset, peak, and duration of action. Although these drugs are chemically similar, patients may have relief of symptoms from one drug in this group but not another. Naproxen is also available in a combination formulation with lansoprazole (a proton pump inhibitor) by the trade name Prevacid NapraPAC. Naproxen and ketoprofen, like ibuprofen, may be purchased OTC. Adverse effects are most frequently GI in nature, and flurbiprofen causes GI symptoms more frequently than ibuprofen. Naproxen is better tolerated than other NSAIDs and has the lowest cardiovascular risk (Prescriber's Letter, 2010).

Acetic Acids

The acetic acids include diclofenac (Voltaren), etodolac (Lodine), indomethacin (Indocin), ketorolac (Toradol), nabumetone (Relafen) sulindac (Clinoril), and tolmetin (Tolectin). These agents are potent NSAIDs, highly protein bound, and

may displace other protein-bound drugs, which may cause toxicities. They are associated with a high incidence of GI distress and should be given with meals or milk. They also may increase blood pressure or cause sodium and water retention. This group of NSAIDs also has an increased risk for causing liver dysfunction. Patients should have periodic liver function tests evaluated.

Diclofenac is available as a transdermal patch (Flector), an oral solution (Cambia), and a topical formulation (Pennsaid, VoltarenGel). It is approved for acute pain due to migraine headache, strains, sprains, and contusions. The patch or topical formulation should be placed on the most painful area two to four times a day. Diclofenac has the highest cardiovascular risk (Prescriber's Letter, 2010).

Patients taking indomethacin have an increased risk of additional adverse effects. It may aggravate depression, other psychiatric disturbances, epilepsy, and parkinsonism. Indomethacin is also associated with a high incidence of severe frontal headaches. Indomethacin is available in both oral and IV forms, and the other acetic acids are all oral drugs.

Nabumetone (Relafen) is a new type of NSAID indicated for osteoarthritis and rheumatoid arthritis. Despite its high efficacy, it has a relatively low incidence of side effects. It appears to cause less gastric damage than other NSAIDs. It is assumed that its decreased GI effects are related to its partial selectivity to COX-2. Because nabumetone has a long half-life, it can be administered once a day. Again, the disadvantage of this drug is its high cost. Ketorolac (Toradol) is only NSAID that is administered by the intramuscular (IM) or intravenous (IV). It is also available orally. IM, and IV ketorolac is used only for the management of severe pain, most frequently postsurgical pain. The efficacy of its IM and IV administration is similar to that of morphine and opioid analgesics. Despite its parenteral administration, ketorolac may induce the same severe adverse effects, especially GI events, as the other oral NSAIDs and carries the same Black Box warnings. Topical ketorolac (Acular) is an ophthalmic drug used for allergic conjunctivitis and postcataract extraction or laser procedures. Because of its limited systemic absorption, topical ketorolac does not carry the Black Box warnings.

An advantage of acetic acids is their long-half life, with resultant once-daily or twice-daily dosing. A major disadvantage is their high cost.

Fenamates

Mefenamic acid (Ponstel) and meclofenamate (generic) are the only fenamate drugs used in the United States. Both are approved to treat mild to moderate pain and dysmenorrhea. Meclofenamate is also used in the management of osteoarthritis and rheumatoid arthritis. They have no clear advantage over other NSAIDs and have an increased risk of adverse effects, especially diarrhea.

Oxicams

Meloxicam (Mobic) and piroxicam (Feldene) are the only oxicams currently available in the United States. They are equivalent to aspirin, indomethacin, and naproxen in treating osteoarthritis and rheumatoid arthritis. Generally, they are better tolerated because they have some COX-2 selectivity; however, severe adverse effects may still occur. Piroxicam has one of the highest GI risks. The advantage of oxicams is their once-daily dosing. The high cost is a disadvantage.

Ophthalmic NSAIDs

Nepafenac (Nevanac) and bromfenac (Xibrom), which are available only as ophthalmic solutions, are used specifically for pain and inflammation from cataract surgery. Ophthalmic NSAIDs can cause corneal ulceration if administered too long. Ophthalmic NSAIDs may delay healing, so they should not be used concurrently with topical steroids. Bromfenac is contraindicated for patients with sulfite hypersensitivity because the solution contains sodium sulfite. Adverse effects associated with bromfenac include headache, a burning sensation in the eye, conjunctival hyperemia, eye irritation, iritis, and rarely, corneal ulceration. Adverse effects associated with nepafenac include conjunctival edema, dry eyes, a foreign body sensation, light intolerance, reduced visual acuity, and an itching sensation is the eye. A serious, but rare, complication is vitreous detachment.

Emphasize to patients that they should begin therapy 24 hours after surgery and take the drug for only 14 days. Ophthalmic NSAIDs may induce bleeding in the eye tissues; tell patients to contact their health care provider if bleeding occurs. In addition, instruct patients in the correct administration of eye drops, focusing on aseptic technique, and inform them to shake the bottle before use and remove contacts prior to administration.

COX-2 Inhibitors

The discovery of COX-2 has made possible the design of drugs that reduce inflammation without removing the protective prostaglandins in the stomach and kidney made by COX-1. Currently, only the COX-2 inhibitor celecoxib is available in the United States. This drug exhibits anti-inflammatory and analgesic activities by selectively inhibiting COX-2 prostaglandin synthesis but not platelet aggregation. This highly selective drug may be useful not only in conditions such as rheumatic and osteoarthritis but also in colon cancer, Alzheimer disease, and kidney disease.

Rofecoxib (Vioxx) and valdecoxib (Bextra), other COX-2 inhibitors, have been taken off the market in the United States because of an unreasonable risk of cardiovascular and cerebral events. They may be available in other countries and through Internet pharmacies based in those countries.

Celecoxib

Celecoxib (Celebrex), the first COX-2 inhibitor on the market, has pharmacotherapeutics that are similar to those of other NSAIDs. In addition, celecoxib also is approved to reduce the number of adenomatous colorectal polyps in patients with the rare genetic disease called Familial Multiple Polyposis Syndrome. It is given orally.

Celecoxib should not be given to patients who have had salicylate hypersensitivity evidenced by asthma, urticaria, or allergic-type reactions after taking aspirin or other NSAIDs. It is also contraindicated in patients with known sulfonamide

hypersensitivity because it is structurally related to sulfonamides. Precautions are similar to those of ibuprofen, with the exception of hemophilia, because celecoxib does not inhibit platelet aggregation. Celecoxib is not approved for use in adolescents or children.

Potential adverse effects of celecoxib also are similar to ibuprofen. Like other NSAIDs, it carries the same Black Box warning. Theoretically, because of the specificity of celecoxib for the COX-2 pathway, it has the potential to cause less gastropathy and risk for GI bleeding. However, despite its cytoprotective properties, serious GI bleeding or obstruction has been reported.

Celecoxib may interact with multiple drugs. It can decrease the effectiveness of loop or thiazide diuretics and angiotensin-converting enzyme inhibitors. Celecoxib decreases the excretion of methotrexate, vancomycin, and aminoglycosides, resulting in an increased risk of toxicity or adverse effects from these drugs. Celecoxib may increase the serum drug levels of warfarin and lithium, again placing the patient at risk for toxicity or adverse effects. When given with fluconazole, the serum concentration of celecoxib is increased. Celecoxib is in pregnancy category C drug. Like other NSAIDs, it should not be given during the last trimester of pregnancy because it may cause premature closure of the ductus arteriosus.

• C Para-aminophenol Derivatives

Acetaminophen (Tylenol), a widely used analgesic and antipyretic, is the only **para-aminophenol derivative** available in the United States. It was first used in clinical medicine in 1893, but widespread use began after it received FDA approval in 1950. It is available without a prescription as an individual agent and in combination with a variety of other drugs. Table 24.6 presents a summary of acetaminophen's pharmacokinetics.

Nursing Management of the Patient Receiving P Acetaminophen

Core Drug Knowledge

Pharmacotherapeutics

Oral acetaminophen is indicated for treating fever or mild pain. It is used for patients with a hypersensitivity to aspirin or NSAIDs or intolerance to their GI effects and for patients who are receiving anticoagulant therapy. The maximum recommended dose in 24 hours is 4 gram in adults and 200 mg/kg or 10 g/d whichever is less in children. In addition to fever or mild pain in patients who cannot tolerate oral or rectal medications, intravenous acetaminophen (Ofirmev) is indicated for the management of moderate to severe pain with adjunctive opioid analgesics.

Pharmacokinetics

Acetaminophen is administered by oral, rectal, and intravenous routes. When administered enterally, it is absorbed rapidly and completely from the GI tract or rectal mucosa. The drug is predominately metabolized in the liver into nontoxic substances and eliminated by the kidneys. A small amount is metabolized in a different pathway, resulting in a toxic metabolite that is converted by glutathione into a nontoxic form. Acetaminophen crosses the placenta and is secreted in breast milk. Children metabolize less of the drug via the pathway that produces the metabolite than adults. this is why the dose that produces toxicity is higher in children than adults.

Pharmacodynamics

Acetaminophen is primarily centrally acting, has no effects on platelet aggregation, and is a reversible weak inhibitor of COX in the periphery. Its analgesic effect is believed to result from inhibiting prostaglandin synthesis in the CNS and possibly from blocking the generation of pain impulses in the periphery. Its antipyretic activity results from inhibiting prostaglandin synthesis in the CNS. Blocking prostaglandin synthesis in the CNS allows the hypothalamic heat-regulating center to produce peripheral vasodilation, causing increased blood flow through the skin, sweating, and heat loss.

Contraindications and Precautions

Acetaminophen is contraindicated in patients with active hepatic disease, viral hepatitis, chronic malnutrition, severe hypovolemia, or alcoholism. In these diseases, metabolism of the drug may be decreased, resulting in a risk of hepatotoxicity. Because acetaminophen is excreted primarily by the kidneys, serum concentrations may increase in patients with renal impairment, again resulting in an increased risk of toxicity.

TABLE 24.6 Summary of Selected C Para-Aminophenol Derivatives

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Para-Aminophenol Derivatives			
P acetaminophen (Tylenol)	Fever, analgesia	*Adult:* PO, 325–1000 mg q4–6 h, not to exceed 4 g/d IV <50 kg: 15 mg/kg every 6 h IV >50 kg: 1 g every 6 h *Child:* PO, 10 mg/kg q4–6 h IV 2–12 y: 15 mg/kg every 6 h IV >13 y <50 kg: 15 mg/kg every 6 h IV >13 >50 kg: 1 gram every 6 h	*Onset:* 10–30 min orally; 15 min IV *Duration:* 3–5 h $t_{1/2}$: 2–4 h

Acetaminophen is also used with caution in patients with pre-existing anemia because acetaminophen may exacerbate anemias. It is also used carefully in patients who take warfarin. Patients who have phenylketonuria or who must restrict intake of phenylalanine should avoid acetaminophen products containing aspartame (NutraSweet), such as Tempra chewable tablets, Alka-Seltzer Advanced Formula, Children's Anacin-3, Junior Strength Tylenol, Children's Tylenol, and Double-Strength Tempra.

Acetaminophen is assigned to pregnancy category B and therefore should be used cautiously in patients who are pregnant or lactating. However, it is the safest antipyretic or analgesic drug to use, if necessary, during pregnancy or lactation.

Adverse Effects

Acetaminophen is generally well tolerated. Most adverse effects occur when the drug is taken in high doses or for prolonged periods. However, acetaminophen overdose is potentially fatal. As previously mentioned, acetaminophen is partially metabolized into a toxic metabolite that glutathione normally converts to a nontoxic form. In an overdose, glutathione stores are quickly depleted in an attempt to convert the toxic metabolite. Because the glutathione supply is depleted, accumulation of the toxic metabolite occurs, resulting in liver damage.

Symptoms of acute toxicity reflect liver damage and include anorexia, nausea, vomiting, pallor, and abdominal discomfort. During the intermediate stage (days 1 to 3), the patient may complain of right-upper-quadrant pain and experience decreased urine output. The late stage (days 3–5) is characterized by jaundice, elevated aspartate transaminase and alanine transaminase levels, and a dramatic rise in prothrombin time, indicating hepatic necrosis. During this stage, the patient also may experience CNS stimulation followed by CNS depression. Early administration of acetylcysteine, which replaces glutathione reserves, is the antidote for overdose. Acetaminophen overdose is an emergency that must be treated in the hospital as it is the leading cause of acute liver disease in the United States. Liver failure may result.

Acetaminophen may cause adverse effects in the hepatic, renal, hematologic, and GI systems. Hepatotoxicity and hepatic necrosis may occur in patients who are on overdose or high-dose or long-term therapy. Other potential adverse effects in patients with high-dose or long-term therapy are acute renal failure, renal papillary necrosis, or renal tubular necrosis. In the hematologic system, acetaminophen may cause anemia, leukopenia, thrombocytopenia, or pancytopenia. In the GI system, acetaminophen may cause GI bleeding. Bleeding occurs secondarily to low prothrombin levels.

Drug Interactions

Acetaminophen may interact with activated charcoal, antacids, ethanol, hydantoins, warfarin, and sulfinpyrazone. In rats, *S*-adenosyl-L-methionine (SAMe), an herbal product, decreases acetaminophen binding to hepatic microsomal proteins and has been shown to improve survival after acetaminophen overdose. The utility of these findings in preventing acetaminophen hepatotoxicity is uncertain; more studies to evaluate the role of SAMe in human acetaminophen toxicity are necessary. Table 24.7 presents additional information about drug interactions with acetaminophen.

TABLE 24.7 Agents That Interact with P Acetaminophen

Interactants	Effect and Significance	Nursing Management
charcoal, activated	Charcoal reduces gastrointestinal (GI) absorption of ingested drugs and adsorbs enterohepatically circulated drugs. Charcoal may actually remove drugs from the systemic circulation. Depending on the clinical situation, this will reduce the effectiveness or toxicity of a given agent.	Administer activated charcoal as soon as possible in a situation involving toxicity of acetaminophen. Do not administer activated charcoal within 2–3 h of acetaminophen administration if acetaminophen is being used therapeutically.
ethanol (alcohol)	Induction of hepatic microsomal enzymes by chronic ethanol consumption may be associated with acetaminophen-induced hepatotoxicity. Chronic consumption of ethanol may increase the risk of acetaminophen-induced liver damage.	Caution patient who consumes ethanol chronically and in excess about the potential interaction. Advise patients to avoid ethanol ingestion while taking acetaminophen. Monitor suspected ethanol abusers closely for hepatotoxicity.
Hydantoins, sulfinpyrazone	Hydantoins and sulfinpyrazone may induce hepatic microsomal enzymes, which accelerate the metabolism of acetaminophen. An unusually high rate of acetaminophen metabolism could lead to abnormally high levels of hepatotoxic metabolites. The potential hepatotoxicity of acetaminophen may be increased and the therapeutic effects of acetaminophen may be decreased when administered with chronic doses of hydantoins or sulfinpyrazone.	At usual therapeutic doses of acetaminophen and hydantoins or sulfinpyrazone, no special dosage adjustment is required. Risk is greatest when acetaminophen overdose accompanies chronic use of hydantoins or sulfinpyrazone. Monitor for hepatoxicity.
warfarin	Acetaminophen inhibits the metabolism of warfarin, resulting in an elevated serum warfarin concentration, and possibly antagonizes the production of vitamin K.	Monitor PT and INR. Monitor for bruising or bleeding.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient's pain level. Acetaminophen is effective for mild to moderate pain. Assess for pre-existing medical conditions or drug therapy that contraindicates using acetaminophen or necessitates close monitoring of the patient. For patients expected to be on long-term therapy, obtain and document baseline CBC, platelet count, and renal and hepatic function values.

Life Span and Gender

Acetaminophen is an excellent drug for treating children's fever and pain. Unlike aspirin, it is not associated with Reye syndrome. Elderly patients are more likely to develop hepatic and renal toxicity because of age-related decreases in hepatic and renal function. Acetaminophen is the drug of choice for pregnant women because it does not have any antiplatelet activity.

Lifestyle, Diet, and Habits

Inquire about the patient's use of OTC drugs because many of these products contain acetaminophen as an ingredient. Concomitant use increases the risk of hepatotoxicity. Assess for alcohol or drug abuse because the patient may have undiagnosed pre-existing hepatic dysfunction.

Environment

Determine the patient's understanding of acetaminophen therapy. Acetaminophen is self-administered easily at home without medical supervision. Because of its low cost and availability, many people do not understand acetaminophen's potentially life-threatening adverse effects. Patient education is important to avoid unintentional overdose or long-term complications.

Nursing Diagnoses and Outcomes

- Acute or Chronic Pain related to ineffectiveness of acetaminophen
  Desired outcome: *The patient will contact the health care provider if pain persists.*
- Risk for Injury related to drug-induced hepatic and renal toxicity or to improper self-medication
  Desired outcome: *The patient will take drug as directed and contact the health care provider if any signs of toxicity occur.*
- Ineffective Protection related to potential blood dyscrasias
  Desired outcome: *The patient will contact the health care provider if any signs of blood dyscrasias occur.*

Planning and Intervention

Maximizing Therapeutic Effects

Acetaminophen can be administered without regard to meals. Monitor the patient for therapeutic effect of acetaminophen and relief of symptoms.

Minimizing Adverse Effects

Assess patients for medical conditions that contradict the use of acetaminophen. Carefully monitor patients with pre-existing medical conditions or drug therapy that may interact with acetaminophen. Coordinate periodic CBC, platelet count, and liver and renal function tests for patients on long-term therapy. Overdosage is treated with the antidote, acetylcysteine orally or IV. Administer intravenous acetaminophen as a 15 minute infusion.

Providing Patient and Family Education

- Tell patients to take the drug exactly as prescribed by the health care provider to avoid adverse effects or overdose.
- Remind patients that the maximum adult dose is 4 g/d and that exceeding this dose may cause acute liver disease or kidney disease.
- Warn patients not to take this drug if they have kidney or liver dysfunction, or consume more than 3 alcoholic beverages per day.
- Teach patients exact directions for correct administration, because acetaminophen is manufactured in a variety of formulations.
- Teach patients with diabetes to monitor their blood glucose level for signs of hypoglycemia.
- Teach patients who take warfarin to refrain from consistent use of acetaminophen. An occasional dose is acceptable.
- Instruct patients to read all OTC drug labels and to avoid any with acetaminophen as an ingredient.
- Stress the potential for acetaminophen overdose and the importance of seeking medical attention should the patient accidentally take too many tablets.
- Advise patients to keep acetaminophen in a light-resistant container out of the reach of children.
- Encourage patients to contact the health care provider immediately if they have any adverse effects (e.g., signs of blood dyscrasias and signs of hepatic or renal toxicity), if fever does not subside within 3 days, or if pain is not relieved within 10 days.

Ongoing Assessment and Evaluation

Monitor the patient who is taking acetaminophen for sore throat, chills, easy bruising, and unusual bleeding because

MEMORY CHIP

P Acetaminophen

- Used for mild to moderate pain and fever; usually well tolerated; has no anti-inflammatory effect
- Major contraindications: hepatic disease, viral hepatitis, and alcoholism
- Most common adverse effects: rash, urticaria, and nausea
- Most serious adverse effects: Acetaminophen may cause hepatic or renal toxicity in susceptible patients.
- **Life span alert: Acetaminophen is the drug of choice for infants and children with flu or flu-like symptoms; analgesic of choice during pregnancy or lactation.**
- **Patient safety alert: Acetaminophen overdose is potentially fatal. The patient must receive treatment in an acute care facility. Anticipate the use of acetylcysteine as an antidote.**

these signs may indicate blood dyscrasias. It also is important to monitor the patient for any signs and symptoms of hepatotoxicity and renal failure. Do not give acetaminophen if the patient develops a rash, unexplained fever, or angioedema. The patient needs to contact the health care provider immediately if any of these symptoms occur.

Therapy is considered effective if the patient is free of fever and pain. In addition, the patient should remain free of adverse effects and should be able to explain the importance of contacting the health care provider immediately if any adverse effects occur.

• C Serotonin-Selective Drugs

Serotonin-selective drugs are used to relieve pain and inflammation related to migraine headache. These drugs are also known as "triptans" because the generic name of these drugs ends as such. At the moment, triptans are considered first-line drugs for the treatment of acute migraine headache. Sumatriptan (Imitrex), the first 5-$HT_{1B/1D}$ agonist approved for use in the United States, is the prototype for this class of drugs. While sumatriptan and the other triptans are excellent drugs, many patients with migraine cannot take them because of their vasoconstrictive effects that might exacerbate cardio or cerebral pathologies. Another promising class of drugs migraine is the neuropeptide calcitonin gene-related peptide antagonist (Box 24.5). Table 24.8 presents a summary of selected serotonin receptor agonists.

Nursing Management of the Patient Receiving P Sumatriptan

Core Drug Knowledge

Pharmacotherapeutics

Sumatriptan is used to treat acute migraine headache with or without aura and to manage cluster headache. Because of its serotonin agonist properties, it is currently being studied for the treatment of irritable bowel syndrome when constipation is the primary symptom.

Pharmacokinetics

Sumatriptan may be administered orally, intranasally, or subcutaneously. It's newest formulation is a needleless injection (Sumavel DosePro). It is also available as an oral combination with Naprosyn (Treximet). When administered orally, pain relief begins within 1 hour and complete pain relief occurs within 4 hours in 50% to 60% of patients. When administered intranasally, absorption is rapid; the onset of action is 15 minutes. The most effective route of administration is subcutaneous. When administered subcutaneously, onset of pain relief occurs within 10 minutes, and approximately 75% of patients have complete pain relief within 2 hours. The bioavailability of subcutaneous sumatriptan is 97%, that of the oral drug is approximately 15%, and that of the intranasal drug is approximately 17%. Sumatriptan is metabolized in the liver and excreted by the kidneys.

Pharmacodynamics

Sumatriptan is selective for 5-$HT_{1B/1D}$ receptors located on cranial blood vessels and sensory nerves of the trigeminovascular system. Stimulation of these receptors results in vasoconstriction and inhibition of the release of proinflammatory neuropeptides such as CGRP. The end result is a decrease in the vasodilation-caused throbbing sensation in the head and a decrease in vascular inflammation.

Contraindications and Precautions

Sumatriptan is contraindicated in patients with coronary artery disease (CAD), arteriosclerosis, and ischemic cardiac diseases such as uncontrolled hypertension, angina pectoris—especially vasospastic angina—and acute MI or

BOX 24.5 FOCUS ON RESEARCH

TELCAGEPANT FOR THE ACUTE TREATMENT OF MIGRAINE

Connor K.M., Shapiro, R.E., Diener, H.C., Lucas, S., Kos,t J., Fan, X., Fei, K., Assaid, C., Lines, C., Ho, T.W., (2009), Randomized, controlled trial of telcagepant for the acute treatment of migraine, *Neurology,* Sep 22;73(12):970–7.

The Study

Researchers are evaluating other classes of drugs that will be as efficacious as the triptans without causing vasoconstriction. Neuropeptide calcitonin gene-related peptide (CGRP) plays a key role in migraine pathophysiology, thus blocking this action should be helpful in the management of migraine. The study researchers wanted to confirm the efficacy of telcagepant, the first orally bioavailable CGRP receptor antagonist. Adults with moderate or severe migraine with or without aura were treated with oral telcagepant 50 mg (n = 177), 150 mg (n = 381), 300 mg (n = 371), or placebo (n = 365) in a randomized, double-blind trial. The goal endpoints were pain freedom, pain relief, and absence of photophobia, absence of phonophobia, and absence of nausea, all at 2 hours postdose. The key secondary endpoint was 2 to 24 hour sustained pain freedom. Telcagepant 300 mg was more effective than placebo on all primary endpoints and the key secondary endpoint, as was telcagepant 150 mg. Telcagepant 300 mg showed a slight numeric advantage over telcagepant 150 mg on most measures. Telcagepant 50 mg values were numerically intermediate between placebo and telcagepant 150 mg and 300 mg. This study confirmed previous findings that telcagepant 300 mg was effective at relieving pain and other migraine symptoms at 2 hours and providing sustained pain freedom up to 24 hours.

Nursing Implications

Acute migraine headache is a debilitating event. It is estimated that more than 3 million people will experience a migraine headache within their lifetime. While the triptans are the number 1 class of drugs for migraine, many patients cannot take these drugs because of comorbid disorders that would be exacerbated by the vasoconstrictive effects of these drugs. The nurse must keep abreast of new drugs for old disorders. Telcagepant is a promising new drug, although not yet FDA approved in the U.S. It offers hope to many migraineurs.

TABLE 24.8 Summary of C Serotonin Receptor Agonists

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P sumatriptan (Imitrex)	Migraine and cluster headache	*Adult:* PO, 25–100 mg; may repeat once after 2 h *Adult:* nasal spray, 5–20 mg; may repeat once after 2 h *Adult:* SC, 4 or 6 mg; may repeat after 1 h *Adult:* PO (85mg sumatriptan and 500 mg naproxen) 1 tablet; may repeat after 2 h	*Onset:* PO, 30–60 min INH, 15–20 min SC, 10–15 min *Duration:* Short $t_{1/2}$: PO, 2.5 h INH, 2 h SC, 115 min
almotriptan (Axert)	Migraine and cluster headache	*Adult:* PO, 6.25–12.5 mg	*Onset:* 30 min–2 h *Duration:* Short $t_{1/2}$: 3.1 h
eletriptan (Relpax)	Migraine and cluster headache	*Adult:* PO, 20–40 mg	*Onset:* 1 h *Duration:* Long $t_{1/2}$: 4 h
frovatriptan (Frova)	Migraine and cluster headache	*Adult:* PO, 2.5 mg; may repeat in 2 h	*Onset:* 2–3 h *Duration:* Long $t_{1/2}$: 26 h
naratriptan (Amerge)	Migraine and cluster headache	*Adult:* PO, 2.5 mg; may repeat once in >4 h	*Onset:* 1–3 h *Duration:* Long $t_{1/2}$: 6 h
rizatriptan (Maxalt, Maxalt MLT)	Migraine and cluster headache	*Adult:* PO, 5 or 10 mg; may repeat in 2 h	*Onset:* 30 min–2 h *Duration:* Short $t_{1/2}$: 2–3 h
zolmitriptan (Zomig, Zomig ZMT)	Migraine and cluster headache	*Adult:* PO, 2.5 mg; may repeat in >2 h *Adult:* nasal spray, 5 mg; may repeat in 2 h	*Onset:* 15 min *Duration:* Short $t_{1/2}$: 3 h

a history of MI. In addition, it is contraindicated in patients with cerebrovascular diseases, such as stroke, intracranial bleeding, and TIAs, and in peripheral vascular diseases, such as Raynaud disease. It is strongly recommended that sumatriptan not be given to patients with chronic diseases that increase the risk of CAD until those patients have had a cardiac workup. Those diseases include diabetes mellitus, hypertension, hypercholesterolemia, and obesity. Patients with a family history of CAD, those who smoke tobacco, postmenopausal women, and men older than 40 years of age should also have a cardiovascular workup before using sumatriptan.

Because sumatriptan is metabolized by the liver and excreted by the kidneys, it should be used cautiously in patients with hepatic or renal impairment, or in those patients at risk for hepatic or renal dysfunction, such as the elderly. Sumatriptan should also be used with care in patients with a history of seizures because it may induce them.

Studies have shown that sumatriptan is embryolethal in rabbits at dosages that are similar to the maximum recommended dose for humans. No studies indicate that sumatriptan is a human teratogen; however, it should be used during pregnancy only if the benefits outweigh the risk to the fetus.

Adverse Effects

Adverse reactions are less likely to occur when sumatriptan is administered orally or intranasally. The most serious adverse effects of sumatriptan are cardiac events; however, they rarely occur. These events include coronary artery vasospasm, cardiac dysrhythmias such as ventricular tachycardia, or ventricular fibrillation, angina, myocardial ischemia (including MI), and cardiac arrest. These events occur more frequently in patients with risk factors for CAD, especially if they had taken ergotamine within the previous 24 hours.

More frequently, cardiovascular adverse effects include hypotension or hypertension, palpitations, or syncope. Chest pressure syndrome also occurs frequently. This syndrome includes sensations of chest tightness or heaviness, jaw pain or tightness, and regional pain or pressure.

Sumatriptan can also induce cerebrovascular events such as cerebral vasospasm, resulting in intracranial bleeding,

subarachnoid hemorrhage, stroke, or seizures. Again, these events are rare and generally occur in patients with risk factors for, or a history of, cerebral vascular disorders.

More commonly, patients may feel weak, dizzy, or lightheaded. They may also experience myalgias, muscle cramps, and stiffness.

Patients receiving intranasal sumatriptan may experience atypical burning sensations in the ear, nose, throat, nasal cavity, or sinus. They may also experience throat discomfort or dysgeusia (a distortion of the sense of taste). Subcutaneous sumatriptan may induce flushing or a sensation of warmth, burning, or heat.

Drug Interactions

Sumatriptan interacts with drugs that contain ergotamine, other 5-HT_1 agonists, sibutramine, and antidepressants such as selective serotonin reuptake inhibitors and monoamine oxidase inhibitors (MAOIs). Table 24.9 highlights these interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess the characteristics of the headache, including location, quality, intensity, and presence or absence of an aura. Assess also for trigger factors that may have caused or may continue the headache (Box 24.6). Sumatriptan is ineffective for other types of headaches.

Take a careful patient history, focusing on cardiovascular and cerebrovascular disorders or diseases. Question patients with diabetes mellitus, hypertension, hypercholesterolemia, or obesity for signs and symptoms that may suggest CAD. Evaluate available laboratory tests, especially liver and renal function tests, because dysfunction of the liver and kidneys may contribute to accumulation of sumatriptan, resulting in increased risk for adverse effects and toxicity. Communicate any positive findings to the health care provider before administering sumatriptan.

Life Span and Gender

Evaluate female patients for pregnancy, breast-feeding, or menopausal symptoms. As previously stated, there is no evidence that establishes that sumatriptan is a human teratogen. Although sumatriptan is a pregnancy category C drug, it should not be given during pregnancy unless the benefits outweigh the risk to the fetus. It is unclear whether sumatriptan is secreted in breast milk; therefore, it should not be taken by nursing mothers. Postmenopausal women and men older than 40 years should have a cardiovascular workup before receiving sumatriptan, to rule out the potential for CAD.

Lifestyle, Diet, and Habits

Identify trigger factors that may be part of the patient's lifestyle. Evaluate the patient for a history of smoking tobacco because smoking is a risk factor for the development of CAD.

Environment

Sumatriptan is routinely given in the outpatient area.

Nursing Diagnosis and Outcome

- Risk for Tissue Perfusion, Impaired, related to cardiovascular or cerebrovascular events
  Desired Outcome: *The patient will recognize the signs and symptoms of cardiovascular or cerebrovascular events and seek medical assistance immediately.*
- Risk for Injury related to weakness, dizziness or syncope, or light-headedness
  Desired Outcome: *The patient will remain free of injury while taking sumatriptan.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer sumatriptan as soon as the headache begins. Sumatriptan is more efficacious when given before the headache escalates. Decrease the environmental stimuli

TABLE 24.9 Agents That Interact with P Sumatriptan

Interactants	Effect and Significance	Nursing Management
ergotamine-containing drugs ergotamine dihydroergotamine methysergide	Coadministration with ergotamine-containing drugs within 24 h may have additive vasospastic effects.	Do not administer sumatriptan within 24 h of ergotamine-containing drugs.
Monoamine oxidase inhibitors (MAOIs)	MAOIs inhibit the metabolism of oral sumatriptan.	Do not administer sumatriptan within 14 d of MAOI use.
Serotonin receptor agonists	Coadministration with other serotonin receptor agonists increases the risk for vasospastic effects and serotonin syndrome.	Do not administer sumatriptan with other serotonin receptor agonists.
selective serotonin reuptake inhibitors (SSRIs)	Coadministering sumatriptan with SSRIs may cause rapid accumulation of serotonin in the CNS.	Monitor for signs of serotonin syndrome.
sibutramine	Coadministering sumatriptan with sibutramine may have additive effects.	Monitor for signs of serotonin syndrome.

BOX 24.6 COMMUNITY BASED CONCERNS

Migraine Headache Triggers

Migraines sometimes can be prevented, which eliminates the need to treat them. Exactly what triggers a migraine differs from patient to patient, and many patients' migraines can be triggered by multiple factors. You can help patients to track and identify their personal triggers so that they can avoid them and, perhaps, forestall migraine headaches. Common migraine triggers include:

Physiologic Triggers

- Hormonal fluctuations (before or during monthly menstrual period, or during treatment with hormone therapy such as birth control pills or estrogen replacement)
- Sleep deprivation, fatigue, or excessive sleep
- Head trauma

Dietary Triggers

- Alcohol, especially red wine
- Tyramine (aged cheese, marinated foods, fresh-baked yeast products)
- Aspartame (artificial sweetener)
- Monosodium glutamate (MSG)
- Phenylethylamine (present in some OTC drugs and chocolate)
- Nitrates (preservatives used in sausage, bacon, and lunch meats)
- Caffeine (either having more or withdrawal from use)

Psychological Triggers

- Stress, worry, or anxiety (especially after stressful situations; headache occurs over the weekend)
- Depression
- Fear
- Anger

Environmental Triggers

- Light (strong or glaring light, such as flickering lights from TV or computer screen, strobe or laser lights, or reflections)
- Weather changes (high humidity, atmospheric pressure changes, rapid temperature fluctuations, exposure to extreme heat or cold)
- Noises
- Smells, odors (intense, specific food odors, cigarette or other smoke, perfumes, cleaning products)

Pharmacologic Triggers

- Oral contraceptives
- Glyceryl trinitrate
- Theophylline
- Reserpine
- Nifedipine
- Indomethacin
- Cimetidine

during the migraine attack by closing the curtains over the windows and turning the lights off or down. Close the door to the patient's room unless contraindicated.

Minimizing Adverse Effects

Assess the patient for a history of cardiovascular or cerebrovascular disorder that might induce adverse effects during sumatriptan therapy. After administering sumatriptan, monitor for signs and symptoms of vasospasm and allergy.

Administer sumatriptan as ordered—orally, intranasally, or subcutaneously. Use aseptic technique when administering subcutaneously.

Providing Patient and Family Education

- Teach patients to take sumatriptan for migraine or cluster headache only. Emphasize that they should avoid the use of sumatriptan if the headache pain is not the same as their usual pain pattern.
- Explain the importance of avoiding sumatriptan if patients have cardiovascular or cerebrovascular disorders or chronic medical conditions that increase the risk of CAD.
- Teach patients the signs and symptoms of vasospastic events and the importance of seeking medical care immediately if they occur.
- Instruct patients to take the sumatriptan exactly as directed by the health care provider to avoid adverse effects or toxicity. If the pain is not relieved with the first dose of sumatriptan, patients should follow the instructions of the health care provider for subsequent dosing.
- Teach patients that the headache may recur. It is important to take only the prescribed dose and not to exceed 200 mg of sumatriptan in a 24-hour period.
- Teach patients the importance of avoiding smoking cigarettes.
- Teach patients the correct way to take sumatriptan. The oral medication should be taken with a full glass of water and not crushed or chewed. The intranasal inhaler should be used with the head upright. Also, teach patients aseptic technique to administer sumatriptan subcutaneously.
- Teach patients to identify trigger factors that induce migraine. Once they are identified, help the patients develop a plan to avoid or eliminate the trigger factor from their lifestyle.
- Teach patients complementary interventions when taking sumatriptan. They should decrease environmental stimuli, rest in a darkened room, and place an ice bag at the back of the neck.

Ongoing Assessment and Evaluation

Evaluate patients taking sumatriptan for the cessation of headache and for signs and symptoms of vasospastic events. Monitor the patient's blood pressure after administering the drug. Evaluate the frequency of migraine attacks and refer the patient to the health care provider for prophylaxis as needed. The patient should be pain free after sumatriptan is administered. The patient should remain free of symptoms of vasospastic events and serotonin syndrome. Box 24.7 discusses serotonin syndrome.

Drugs Closely Related to P Sumatriptan

The other serotonin receptor agonists, also called triptans, which are used in managing migraine, are all very similar to sumatriptan. They have the same pharmacotherapeutics,

Box24.7 SEROTONIN SYNDROME

Symptoms of serotonin syndrome include:

- excitement
- hypomania
- restlessness
- loss of consciousness
- confusion
- disorientation
- anxiety
- agitation
- motor weakness
- myoclonus
- tremor
- hemiballismus
- hyperreflexia
- ataxia
- dysarthria
- incoordination
- hyperthermia
- shivering
- pupillary dilation
- diaphoresis
- emesis
- tachycardia

pharmacodynamics, and adverse effects. They have very similar contraindications and precautions and drug–drug interactions (see Table 24.9). The major difference among the triptans is the pharmacokinetics. All of the triptans are pregnancy category C drugs and should be used only when the benefits outweigh the risks.

Almotriptan

Almotriptan (Axert) has a rapid onset, short duration, and 70% to 80% bioavailability. It is available as an oral tablet. Almotriptan may be better tolerated than sumatriptan and may have a lower incidence of chest pain, tightness, or pressure. It may be given with MAOIs.

Eletriptan

Eletriptan (Relpax) has a slower onset than almotriptan and a longer duration, with a 50% bioavailability. It, too, is available as an oral tablet. Its bioavailability is increased when taken with a high-fat meal. Like almotriptan, eletriptan may be taken with MAOIs but should be avoided with CYP3A4 inhibitors such as ritonavir, nelfinavir, indinavir, erythromycin, clarithromycin, ketoconazole, and itraconazole.

Frovatriptan

Frovatriptan (Frova) has a very slow onset and a very long duration, and it is only 20% to 30% bioavailable. It is available as an oral tablet. Frovatriptan has the longest half-life of all the triptans; thus, rebound headaches may occur less frequently. Like almotriptan and eletriptan, it may be given with MAOIs.

Naratriptan

Naratriptan (Amerge) has an onset similar to sumatriptan, a longer duration, and 70% bioavailability. It is available as an oral tablet. Naratriptan has less headache recurrence than sumatriptan and may be given with MAOIs.

Rizatriptan

Rizatriptan (Maxalt) has a rapid onset and duration, with a bioavailability of 45%. It is available as an oral tablet or a dissolving tablet. Rizatriptan requires a dosage adjustment if taken with propranolol (Inderal). It may not be used in combination with MAOIs.

Zolmitriptan

Zolmitriptan (Zomig) has the fastest onset of action, a short duration, and a bioavailability of 40%. It is available as an oral tablet, dissolving tablet, or nasal spray. Like rizatriptan, it may not be used with MAOIs.

Drugs Significantly Different From P Sumatriptan

Ergotamine

Ergotamine (Ergomar, Cafergot, Migergot) is another type of drug used to abort an acute migraine or cluster headache. It has a complex mechanism of action that is very different from sumatriptan. Like sumatriptan, ergotamine stimulates 5-$HT_{1B/1D}$ receptors. It also affects serotonergic, dopaminergic, and alpha-adrenergic receptors. In addition, it stimulates uterine contractions and has emetic properties.

MEMORY CHIP

P Sumatriptan

- Used for treatment of acute migraine or cluster headache
- Major contraindications: cardiovascular and cerebrovascular disorders
- Most common adverse effects: flushing, dizziness, weakness, nausea, drowsiness, stiffness, or feelings of tingling, heat, fatigue
- Most serious adverse effects: vasospasm resulting in ischemic events to the cardiovascular and cerebrovascular systems
- Maximizing therapeutic effects: Administer only to patients with documented migraine or cluster headaches.
- Minimizing adverse effects: Avoid administration to patients with cardiovascular or cerebrovascular disorders. Do not administer to patients with atypical headaches.
- Most important patient education: signs and symptoms of ischemic events and importance of seeking medical care should any occur
- **Life span alert: Sumatriptan is embryolethal in rabbits. Do not administer to pregnant women unless the benefit to the fetus outweighs the risk.**

Ergotamine has several routes of administration. It can be given orally, sublingually, rectally, or by inhalation. When given orally or rectally, it is often combined with caffeine, which increases its absorption. Although pain relief occurs within 0.5 to 2 hours of administration, vasoconstriction may persist for up to 48 hours. Ergotamine is metabolized in the liver, and its major metabolites are excreted in bile.

Contraindications for the use of ergotamine include alkaloid hypersensitivity, history of cardiovascular or cerebrovascular disorders, and pre-existing hepatic dysfunction. Ergotamine is a pregnancy category X drug because it stimulates uterine contractions. It is also contraindicated for use when breast-feeding because it may cause ergotism (vomiting, diarrhea, weak pulse, and unstable blood pressure) in nursing infants. Ergotamine is used with caution in patients with chronic diseases that increase the risk of cardiovascular disorders.

The most serious adverse effect of ergotamine is overdose or ergotism. Overdose can cause ischemia to peripheral arteries and arterioles, with resultant hypoxia to the extremities. As hypoxia continues, the extremities become cold, mottled, or numb. Untreated, gangrene may develop, and amputation may be necessary.

More common adverse effects include abdominal pain, nausea or vomiting, myalgias, leg weakness, and numbness or tingling in the extremities. Daily or frequent use of ergotamine may cause physical dependence.

Drug–drug interactions may occur with CYP3A4 inhibitors such as ritonavir, nelfinavir, indinavir, erythromycin, clarithromycin, ketoconazole, and itraconazole. Concurrent use of these drugs may cause vasospasm and cerebral or peripheral ischemia. Concurrent use of beta-blocking agents, hormonal contraceptives, vasoconstrictors, or nicotine increases the risk of peripheral vasoconstriction. The use of ergotamine and triptans should occur at least 24 hours apart.

Dihydroergotamine

Dihydroergotamine is a semisynthetic ergot alkaloid administered parenterally or intranasally to treat migraine. Dihydroergotamine is generally reserved for treating severe migraine because less toxic agents are available for mild to moderate migraine and cluster headache relief. Its pharmacodynamics are similar to those of ergotamine; however, it causes less peripheral vasoconstriction, nausea, and vomiting.

Contraindications and drug–drug interactions are also similar to those of ergotamine. Dihydroergotamine is a pregnancy category X drug because it induces uterine contractions. Although it is not known whether dihydroergotamine is secreted in breast milk, it should not be used by nursing mothers because of its structural similarity to ergotamine.

Analgesics

Several analgesic agents may be used to abort a migraine headache, although the triptans are generally more efficacious. Acetaminophen or acetaminophen combinations (Excedrin, Excedrin Migraine) have been very successful. One small study found them to be as efficacious as triptans.

More powerful analgesics such as codeine combinations (usually combined with acetaminophen) and oxycodone have also been used. Of course, the problem with these drugs is the potential for abuse or tolerance.

Nonsteroidal Anti-inflammatory Drugs

Several NSAIDs have been approved by the FDA for migraine headaches. They include aspirin, indomethacin, naproxen, and ibuprofen. Although not approved by the FDA, fenoprofen, flurbiprofen, ketoprofen, ketorolac, and mefenamic acid are also used to abort migraine headache.

DRUGS USED AS PROPHYLAXIS FOR MIGRAINE HEADACHE

Drugs for migraine prophylaxis may be prescribed for patients with frequent migraine to decrease the frequency and severity of acute migraine. These drugs are not useful in treatment of an acute migraine headache.

Antiepileptics

Antiepileptics are increasingly recommended for migraine prevention. The exact mechanism of action is unclear; however, antiepileptics are thought to prevent migraines by blocking sodium or calcium channels or by enhancing the activity of gamma-aminobutyrate. Divalproex sodium (Depakote) and sodium valproate (Depakene) are the only antiepileptics with FDA approval for migraine prophylaxis. Nausea, vomiting, and GI distress are the most common side effects and are generally self-limiting. Additional adverse effects include weight gain, hair loss, tremor or shakiness, and fetal neural tube defects during pregnancy. Rare but severe adverse effects include fatal pancreatitis and hepatitis.

Several studies have shown the efficacy of gabapentin (Neurontin) as well, although it is not FDA approved for this therapeutic use. The most common adverse events with gabapentin are dizziness or giddiness and drowsiness.

Two other antiepileptics, tiagabine (Gabitril) and topiramate (Topamax), have been efficacious in small studies. However, the sample size in these studies was too small to generalize the conclusions of these studies. For a more thorough discussion of these antiepileptics, see Chapter 21.

Antidepressants

Antidepressants are useful in treating many chronic pain states, including migraine headache. Although the actual mechanism of action is unknown, the pain response occurs sooner than the expected antidepressant effect. Amitriptyline (Elavil) is the most common antidepressant used for migraine prophylaxis. Although other antidepressants have been prescribed, only amitriptyline has been studied in clinical trials.

Common adverse effects to amitriptyline include dry mouth, constipation, blurred vision, urinary retention, weight gain, and orthostatic hypotension. Amitriptyline is discussed in Chapter 19.

Beta-Adrenergic Blocking Agents

Beta blockers are used to prevent migraine headache because of their ability to relax blood vessels. The drug of choice is propranolol (Inderal), although nadolol (Corgard), atenolol (Tenormin), timolol (Blocadren), and metoprolol (Lopressor, Toprol) are also effective. Long-term therapy may induce sleep problems and vivid dreams, memory problems, fatigue, depression, and impotence. Beta blockers require close monitoring in patients with asthma, chronic obstructive pulmonary disease, diabetes, or high cholesterol because they may worsen symptoms of lung disease and asthma, may affect cholesterol levels, and may also affect how the body responds to low blood sugar. Beta-adrenergic blocking agents are discussed in Chapter 13.

Calcium Channel Blockers

Several calcium channel blockers are used as migraine prophylaxis. They include diltiazem (Cardizem), nifedipine (Procardia, Adalat), nimodipine (Nimotop), and verapamil (Calan). Calcium channel blockers are used to prevent migraine headache because of their ability to prevent vasoconstriction.

Constipation is the most frequent adverse effect of calcium channel blockers. Other adverse effects include dizziness, headache, facial flushing, and edema. Additional information regarding calcium channel blockers can be found in Chapter 29.

CHAPTER SUMMARY

- Drugs for fever, inflammation, and pain include salicylates (aspirin), prostaglandin synthetase inhibitors (NSAIDs, e.g., ibuprofen), and para-aminophenol derivatives (acetaminophen). These drugs work by inhibiting the synthesis of prostaglandins.
- Prostaglandins are found in almost all body tissues and affect the body in a multitude of ways. They are subdivided into COX-1 and COX-2 prostaglandins. COX-1 are involved in cell maintenance, whereas COX-2 are generally found at the site of inflammation.
- Salicylates and most NSAIDs block both COX-1 and COX-2. Inhibition of COX-1 is responsible for many of the adverse effects associated with these drugs.
- Aspirin has analgesic, anti-inflammatory, antipyretic, and antiplatelet activity.
- Low-dose aspirin therapy is used in healthy people to decrease the risk of cardiovascular or cerebrovascular events.
- Aspirin is a highly protein-bound drug and may interact with other highly protein-bound drugs.
- Aspirin and acetaminophen overdoses are common. Patients do not realize the potentially serious consequences of ingesting these drugs because they are easily obtained without a prescription.
- The most common adverse effects of aspirin and ibuprofen are GI in nature.
- Serious adverse effects related to aspirin and NSAIDs are renal impairment, gastric ulceration, and GI bleeding.
- The major difference between aspirin and NSAIDs is related to antiplatelet activity. Inhibition of cyclooxygenase by aspirin is *irreversible,* whereas inhibition of cyclooxygenase by NSAIDs is *reversible*.
- Although NSAIDs have antiplatelet activity, they are not used to prevent MI or stroke.
- All NSAIDs, including COX-2 inhibitors, have a Black Box warning regarding the increase in risk of serious and potentially fatal MI and stroke. This risk increases with the duration of use.
- COX-2 inhibitors decrease the potential for GI bleeding, although it may still occur in some patients. These agents do not inhibit platelet aggregation.
- Acetaminophen is an analgesic and antipyretic. It does not have antiplatelet effects.
- The anti-inflammatory effects of acetaminophen occur only in the CNS; therefore, it cannot be used for inflammation in the periphery of the body.
- Because acetaminophen does not affect prostaglandins in the periphery of the body, it does not cause renal impairment or gastric distress.
- The most serious adverse effect of acetaminophen is hepatic dysfunction.
- Migraine headache has a complex etiology. Pain occurs because of both vasodilation and inflammation.
- The drugs used for prophylaxis of migraine headaches include beta-blocking agents, antiepileptics, antidepressants, and calcium channel blocking agents.
- The drugs of choice for managing acute migraine headaches are selective serotonin agonists, also known as "triptans" or antimigraine agents.
- The triptans are generally well tolerated and rarely cause coronary vasospasm.

QUESTIONS FOR STUDY AND REVIEW

1. How do prostaglandins affect the processes of inflammation, pain, and fever?
2. How does prostaglandin inhibition induce adverse effects of salicylates, NSAIDs, and acetaminophen?
3. What are the most potentially serious adverse effects of salicylates, NSAIDs, and acetaminophen, and how might you decrease their occurrence?
4. Describe the major differences between aspirin and NSAIDs.
5. Identify two major differences between nonselective NSAIDs and COX-2 inhibitors.
6. How do the triptans decrease migraine headache pain?
7. What is the key difference between serotonin receptor agonists and ergotamine-containing drugs in the management of migraine headache?

25

Drugs Treating Rheumatoid Arthritis and Gout

Learning Objectives

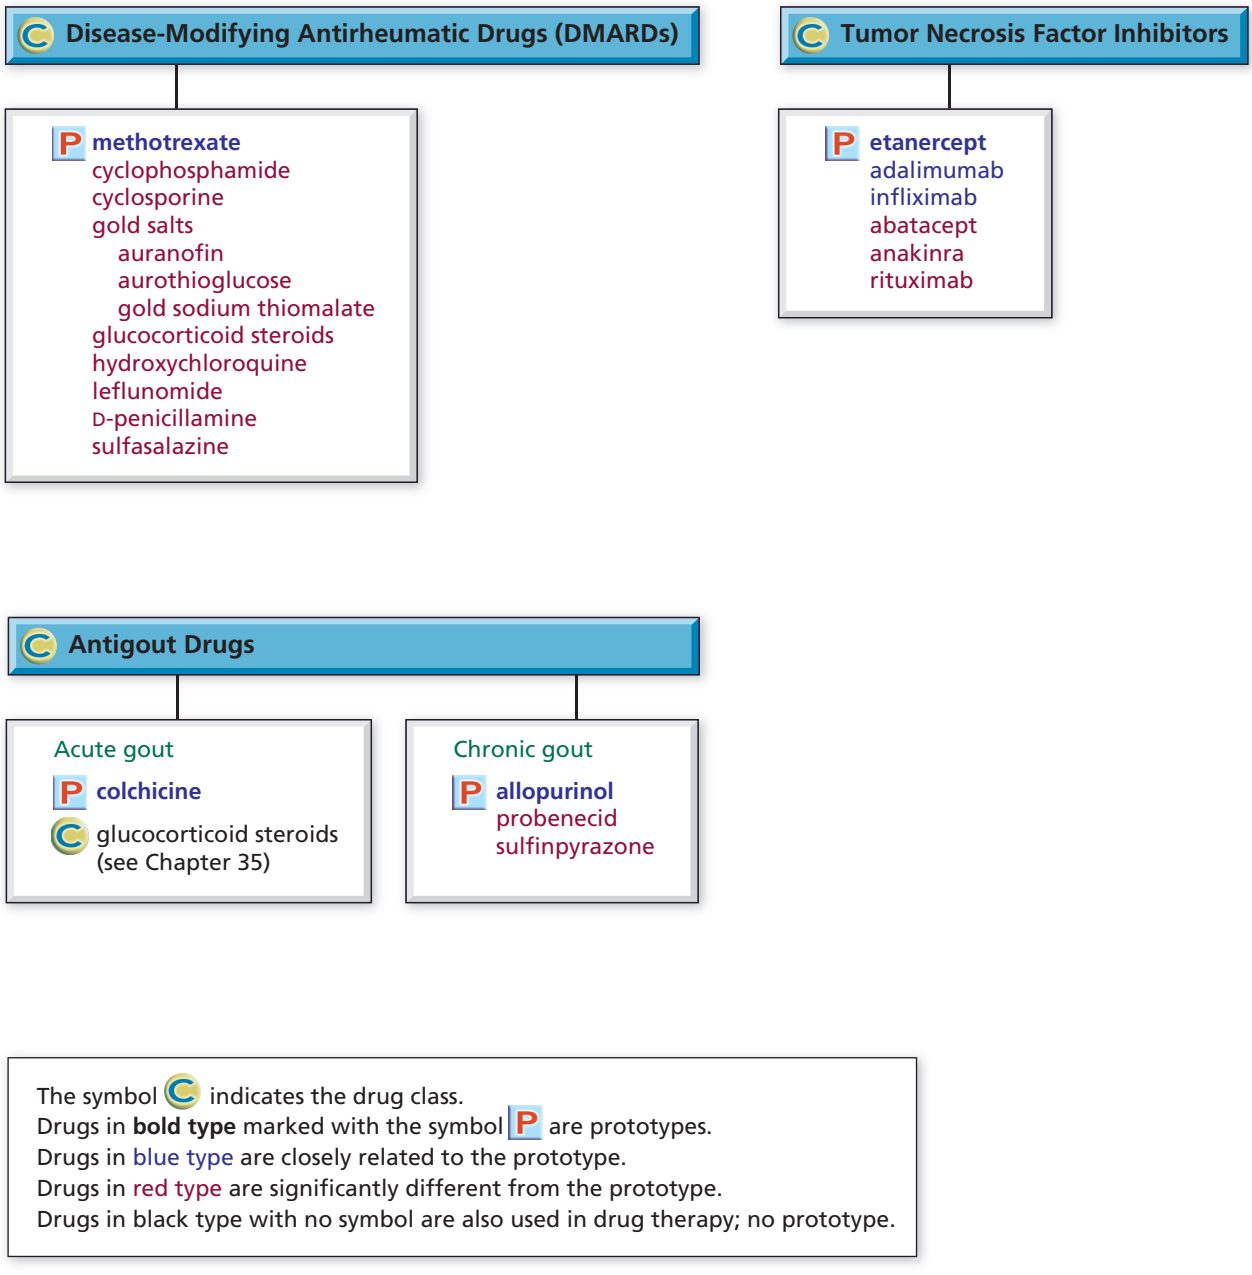
At the completion of this chapter the student will:

1. Correlate the processes of inflammation and pain with antirheumatic drugs, antigout drugs, and uricosuric drugs.
2. Identify core drug knowledge pertaining to antirheumatic drugs, antigout drugs, and uricosuric drugs.
3. Identify core patient variables pertaining to antirheumatic drugs, antigout drugs, and uricosuric drugs.
4. Relate the interaction of core drug knowledge to core patient variables for antirheumatic drugs, antigout drugs, and uricosuric drugs.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for antirheumatic drugs, antigout drugs, and uricosuric drugs.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for antirheumatic drugs, antigout drugs, and uricosuric drugs.
7. Determine key points for patient and family education for antirheumatic drugs, antigout drugs, and uricosuric drugs.

Key Terms

ankylosis
antigout drugs
chrysotherapy
cytokine
disease-modifying antirheumatic drug (DMARD)
monoclonal antibody
nitritoid crisis
pannus
tophi
uricosuric drugs

Drugs Treating Rheumatoid Arthritis and Gout



This chapter focuses on two inflammatory conditions, rheumatoid arthritis (RA) and gout. RA is not a wear-and-tear disease like osteoarthritis; it is an autoimmune disease that eventually causes joint destruction (Figure 25.1) as well as inflammation in many other tissues and organs in the body. There are three classes of drugs used to manage RA: nonsteroidal antiinflammatory drugs (NSAIDS), glucocorticoid steroids, and disease modifying antirheumatic drugs (DMARDS). NSAIDs (Chapter 24) and glucocorticoid steroids (Chapter 48) manage the symptoms associated with RA but do not alter the progression of the disease. Rheumatologists have discovered that joint damage begins very early in RA, even when symptoms are absent or minimal. To decrease the extensive joint damage that occurs with RA, treatment with disease-modifying antirheumatic drugs (DMARDs) or other biologic agents is recommended within 3 months of diagnosis. This chapter discusses the prototype DMARD methotrexate and the prototype biologic agent etanercept.

NSAIDs are the initial drugs of choice for the management of the symptoms of acute gout. When NSAIDs are contraindicated or unable to control the acute episode, colchicine or glucocorticoid steroids may be used (for more information about glucocorticoids, see Chapter 48). The choice between colchicine and steroids is dependent on the preference of the health care provider. In this chapter, colchicine is the prototype for acute gout. Chronic gout, defined as repeated episodes of gout, is treated with uricosuric drugs, which decrease the hyperuricemia associated with gout. The prototype uricosuric drug is allopurinol.

In addition to discussing the therapeutic classes of drugs used to treat RA and gout, this chapter also addresses the core drug knowledge, core patient variables, nursing management, potential nursing diagnoses, and patient education related to the use of DMARDs, antigout drugs, and uricosuric drugs.

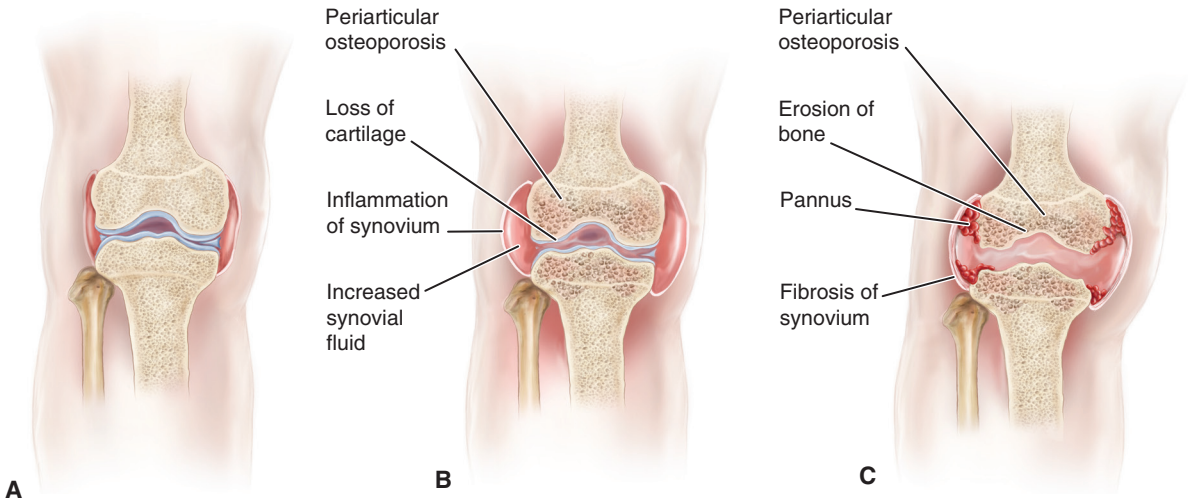
PATHOPHYSIOLOGY

Rheumatoid Arthritis

RA is a systemic inflammatory disease. It is one of the most debilitating forms of arthritis. Not only do the joints ache and throb, they eventually become deformed. The effects are not limited to joint destruction; systemic effects also occur. RA affects all age groups, but it is more prevalent in people in the age group between 20 and 50 years old. Women are three times more likely than men to have the disease.

RA is thought to be an autoimmune disorder because 70% of patients have a substance in their blood, synovial fluid, and synovial tissue called rheumatoid factor (RF), which is an antibody to their own immunoglobulin G (IgG). RA interacts with IgG or other antibodies to form immune complexes. These immune complexes activate the complement system, resulting in an inflammatory response. Leukocytes, monocytes, and lymphocytes are attracted to the area and phagocytize the immune complexes. During that process, lysosomal enzymes are released. These enzymes are capable of destroying joint cartilage, resulting in an inflammatory process that starts the cycle again. As the disease progresses, a destructive granular tissue called **pannus** extends through the synovial space, damaging the articular cartilage. Continued progression destroys the entire joint space, resulting in reduced joint motion and possible **ankylosis** (extreme stiffness or joint fusion).

RA is not an inherited disease; however, certain inherited genes increase the susceptibility to develop RA. In people with these genes, it has been theorized that RA may be triggered by an infection, such as a virus or bacteria. The severity of the disease may also depend on the type of genes inherited. Some experts believe that hormones may be involved in the development of RA, whereas others believe that cigarette smoking is a risk factor.



• FIGURE 25.1 (**A**) Normal joint; (**B**) early rheumatoid arthritis with fluid accumulation and synovial swelling; (**C**) late rheumatoid arthritis with pannus formation, eroded articular cartilage, and joint space narrowing.

The primary characteristic of RA is symmetric polyarticular inflammation, especially in the small joints of the hands and feet. Additional symptoms of RA include:

- Generalized aching or stiffness of the joints and muscles, especially in the morning or after a period of rest
- Loss of motion of the affected joints
- Loss of strength in muscles attached to the affected joints
- Fatigue, especially during an exacerbation
- Low-grade fever
- Malaise

Small lumps, called rheumatoid nodules, may form under the skin at pressure points such as the elbows, hands, feet, and Achilles tendons. In addition to pressure points, rheumatoid nodules may occur anywhere in the body, including the back of the scalp, over the knees, or even in the lungs. Rheumatoid nodules are usually painless and range in size—from as small as a pea to as large as a walnut.

In contrast to osteoarthritis, which affects only the bones and joints, RA can cause inflammation of glands such as tear and salivary glands, the linings of the heart and lungs, the lungs themselves and, in rare cases, the vascular system. Patients with RA have an increased risk of heart attack and stroke (Box 25.1).

The clinical course of RA is highly variable. It tends to vary in severity and may even come and go. Exacerbations of RA (called flare-ups or flares) alternate with periods of relative remission, during which the symptoms of RA fade or disappear.

RA has a substantial effect on quality of life because of the associated pain, fatigue, and depression, and the increased risk of heart disease. Because of these issues, RA can reduce the life span of people who have it.

Gout

Gout is a disease of purine metabolism. It occurs more frequently in men greater than 30 years and women greater than 50 years. The risk of gout increases in women after menopause because uric acid levels rise in women at that time. Hyperuricemia, defined as a uric acid level greater than 6.8 mg/dL, may result from overproduction or underexcretion of uric acid. Gout occurs when the hyperuricemia forms monosodium urate crystals, which precipitate into the synovial fluid and initiate an inflammatory response.

Hyperuricemia is clearly a risk factor for the development of gout, and the risk increases as the urate concentration increases. However, many years of asymptomatic hyperuricemia have usually elapsed before the development of acute gouty arthritis, and in some patients with asymptomatic hyperuricemia, gout never develops. Other risk factors for gout include lifestyle factors such as alcohol consumption (especially beer); obesity; high meat and seafood consumption (especially red organ meat and shellfish) ; medical conditions such as hypertension, hyperlipidemia, chronic renal impairment, cardiovascular disease, insulin resistance, diabetes mellitus, or metabolic syndrome; drugs such as thiazide and loop diuretics, aspirin (low-dose), some antituberculosis drugs, and nicotinic acid or antirejection drugs; and a family history of gout. Transplant patients receiving cyclosporine develop gout because cyclosporine decreases the renal excretion of uric acid.

Gout has four distinct phases: asymptomatic hyperuricemia, acute gouty arthritis (flare), intercritical gout (interval between flares), and chronic advanced gout (uncontrolled hyperuricemia with chronic arthritis tophi). The onset of acute gouty arthritis is rapid. The pain frequently starts during the night and is often described as throbbing, crushing, or excruciating. The affected joints show signs of warmth, redness, and tenderness (Figure 25.2). In more than half of the initial attacks, the onset is in the first metatarsophalangeal joint (MTP), and overall, 90% of patients have the MTP affected at some point. Chronic gout may cause joint deformity and limited motion in affected joints. Uric acid deposits called **tophi** can be found in bursae, synovium, and tendons and along the extensor surface of the forearm. Tophi can also deposit in the kidney, leading to chronic

BOX 25.1 FOCUS ON RESEARCH

Therapeutic Alternative for Chronic Gout

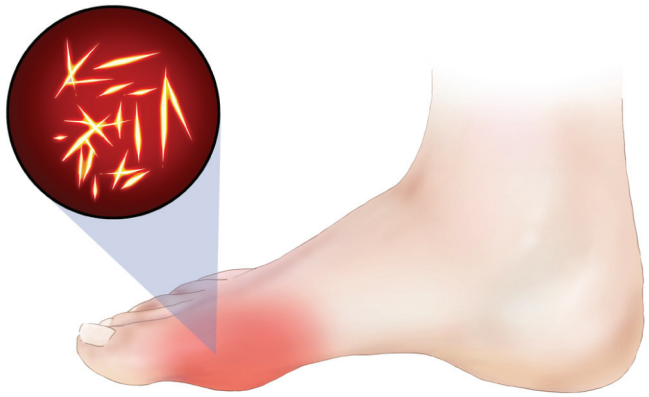
Becker, M. A., Schumacher, H. R., Espinoza, L. R., Wells, A. F., MacDonald, P., Lloyd, E., vLademacher, C. (2010). The urate-lowering efficacy and safety of febuxostat in the treatment of the hyperuricemia of gout: the CONFIRMS trial, *Arthritis Research and Therapy*, 12(2):R63.

The Study

The researchers studied the safety and efficacy of daily febuxostat and allopurinol in subjects with gout and serum urate (sUA) > or = 8.0 mg/dL. The goal was to reach and maintain a sUA < 6 mg/dL. 2,269 patients were randomized to febuxostat 40 mg or 80 mg, or allopurinol 300 mg (200 mg in moderate renal impairment). Safety assessments included blinded adjudication of each cardiovascular (CV) adverse event (AE) and death. In the febuxostat 40 mg group 45% met the end goal; febuxostat 80 mg 67%; and in the allopurinol groups 42%. Achievement of target sUA in subjects with renal impairment was also superior with febuxostat 80 mg (72%) compared with febuxostat 40 mg (50%) or allopurinol (42%). Rates of AEs did not differ across treatment groups. CV event rates were 0.0% for febuxostat 40 mg and 0.4% for both febuxostat 80 mg and allopurinol. One death occurred in each febuxostat group and three in the allopurinol group. Urate-lowering efficacy of febuxostat 80 mg exceeded that of febuxostat 40 mg and allopurinol (300/200 mg), which were comparable. In subjects with mild/moderate renal impairment, both febuxostat doses were more efficacious than allopurinol and equally safe.

Nursing Implications

It is important for nurses to remain knowledgeable regarding treatment options for patients with gout. For approximately 40 years allopurinol was the main therapy in lowering urate production until the FDA approval of febuxostat (Uloric). Become familiar with the action and potential adverse effects of febuxostat. Monitor the patient for diarrhea, headache, and rash. Remember that febuxostat is associated with an increased risk for cardiovascular events and monitor for these potential complications.



• FIGURE 25.2 Gout in the first metatarsal phalangeal joint of the right foot.

kidney failure. Fortunately, chronic advanced gout is a rare occurrence today because of the prevalence of appropriate pharmacotherapy.

The diagnosis of gout is made by identification of uric acid crystals in joints, tissues, or body fluids.

C DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

Disease-modifying antirheumatic drugs (DMARDS) are drugs that are capable of arresting the progression of RA and can induce remission in some patients. They are used in conjunction with salicylates and NSAIDs, or as monotherapy when salicylates and NSAIDs are ineffective or not tolerated. The therapeutic class of DMARDs is subdivided into non-biological DMARDS and biological DEMARDS. These drugs include alkylating agents, antimetabolites, antimalarials, gold salts, sulfonamide antibiotics, TNF inhibitors, monoclonal antibodies, interleukin antagonists, and immune response modifiers. Although the mechanism of action is different for each of these drugs, they are all similar in the fact that they slow the progression of RA.

Non-Biologic Al Demards

Methotrexate (Rheumatrex, Trexall, MTX) is the prototype non-biological-DMARD (Table 25.1). Although there are many treatment options for RA, most rheumatologists concur that methotrexate is the drug of choice, either as monotherapy or in combination with tumor necrosis factor (TNF) drugs or other biologic agents. Anti-TNF monotherapy is similar in efficacy to treatment with methotrexate alone, while the combination of an anti-TNF agent with methotrexate reduces disease activity more and slows radiographic progression to a greater extent than monotherapy with methotrexate or anti-TNF drugs.

Because the onset of action of all DMARDs is slow, salicylates or NSAIDs are given to control the symptoms of RA until the DMARD action begins. Depending on the rheumatologist, when the DMARD begins to work, NSAID therapy may be continued with the DMARD or discontinued.

Nursing Management of the Patient Receiving P Methotrexate

Core Drug Knowledge

Pharmacotherapeutics

MTX is a folate antimetabolite used in treating various malignancies, including osteosarcoma, non-Hodgkin's lymphoma, Hodgkin's disease, cutaneous T-cell lymphoma, head and neck cancer, lung cancer, and breast cancer. Because it also has immunosuppressive effects, it is used to treat adult and juvenile RA and psoriasis.

Pharmacokinetics

MTX is given orally to manage RA. Its absorption may be decreased in the presence of food. A small portion is metabolized in the liver; the drug is excreted in the urine mostly as unchanged drug Relief of symptoms occurs in 3 to 6 weeks.

Pharmacodynamics

MTX exerts immunosuppressive effects by inhibiting the replication and function of T lymphocytes that stimulate the production of cytokines, in particular interleukin-1 (IL-1), IL-6, and IL-8, as well as TNF-alpha. MTX also induces folate depletion, which leads to inhibition of purine synthesis and results in the arrest of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and protein synthesis. Because MTX targets rapidly proliferating cells, such as epithelial cells, it slows progression of psoriasis.

Contraindications and Precautions

MTX is contraindicated in patients with immunosuppression, pre-existing blood dyscrasia, or impaired bone marrow function, and during pregnancy and lactation. It is also contraindicated for patients with psoriasis or RA in patients with alcoholism, alcoholic liver disease, or other chronic liver disease. It is given cautiously to patients with preexisting hepatic or renal dysfunction, malnutrition, or ulcerative colitis. MTX is a pregnancy category X drug because fetal abnormality has been documented. MTX therapy used for cancer has additional precautions, including significant Black Box warnings (Box 25.2).

Adverse Effects

Stomatitis and oral ulcers, mild alopecia and hair thinning, and GI upset may occur and are related to folic acid antagonism. Headache, fatigue, and feeling "wiped out" may occur and is referred to as "methotrexate fog". The most serious adverse effects to methotrexate therapy include hepatic cirrhosis, interstitial pneumonitis, and severe myelosuppression. Because relatively low doses are used to manage RA, the risk of these severe adverse effects is greatly reduced. However, this reduction does not change the need to monitor closely for these potential adverse effects. Lastly, lymphoma has rarely been reported with MTX therapy. It is important to remember that patients with RA have an increased risk of developing lymphoma as a consequence of their autoimmune disease, and may not be related to the MTX therapy.

TABLE 25.1 Summary of Selected Disease-Modifying Antirheumatic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P methotrexate (Rheumatrex, TREXALL, MTX)	RA, psoriasis	*Adult:* PO/IM, 7.5–25 mg/wk in a single dose; administer with folic acid 1 mg daily or leucovorin 5 mg/wk *Child 2–16 y:* PO/IM, 5–15 mg m^2/wk; administer with folic acid 1 mg daily or leucovorin 5 mg/wk	*Onset:* Varies *Duration:* Unknown $t_{1/2}$: 2–4 h
P auranofin (Ridaura)	RA	*Adult:* PO, 5–9 mg/d in 1 or 2 doses *Child:* PO, 0.1 mg/kg/d initially, titrate up to 0.15 mg/kg/d; maximum dose, 0.2 mg/kg/d	*Onset:* Varies *Duration:* 6 mo $t_{1/2}$: 26 d
aurothioglucose (Solganal)	RA	*Adult:* IM, 10 mg initially, then 25 mg for the second and third doses, given at weekly intervals, followed by 50 mg weekly until a total dose of 0.8–1.0 g has been administered Maintenance dosage is 25–50 mg IM given at 3- to 4-wk intervals indefinitely *Child:* IM, 0.25 mg/kg the first week; increase dosage by 0.25 mg/kg weekly up to a maintenance dosage of 0.75–1 mg/kg once per week. Doses are given once per week for a total of 20 doses, then continued every 2–4 wk.	*Onset:* Slow *Duration:* 6 mo $t_{1/2}$: 26 d
azathioprine (Azasan, Imuran)	RA Crohn's disease Ulcerative Colitis	*Adult:* PO 1–2.5 mg/kg/d divided 1-2x/d *Adult:* PO 100–250 mg daily	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 5 h
cyclophosphamide (Cytoxan)	RA	*Adult and child:* PO, 1.5–3 mg/kg/d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 4–6 h
cyclosporine (Neoral, Gengraf)	RA	*Adult:* PO, 2.5–4 mg/kg/d, divided, 2× d *Child:* not approved for this indication	*Onset:* Varies *Duration:* 24–36 h $t_{1/2}$: 17.9 h
hydroxychloroquine (Plaquenil)	RA	*Adult:* PO, 200–600 mg/d in 1 or 2 doses *Child:* not approved	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 3–5 d
gold sodium thiomalate (Myochrysine)	RA	*Adult:* IM, 10 mg in a single injection the first week, 25 mg the following week, then 25–50 mg/wk thereafter	*Onset:* Slow *Duration:* 6 mo $t_{1/2}$: 3–27 d
leflunomide (Arava)	RA	*Adult:* PO, 10–20 mg/d in a single dose	*Onset:* Varies *Duration:* Unknown $t_{1/2}$: 14 d
minocycline	RA	*Adult:* PO 100 mg 2x/d *Child:* not approved for this non-FDA use	*Onset:* rapid *Duration:* unknown $t_{1/2}$: 11-18 h
penicillamine (Cuprimine)	RA	*Adult:* PO, 250–500 mg daily *Child:* PO, 10 mg/kg/d, divided, 1–2× d for 4 mo	*Onset:* Varies *Duration:* Unknown $t_{1/2}$: 1.7–3.2 h
sulfasalazine (Azulfidine EN-tabs)	RA, ulcerative colitis, Crohn's disease	*Adult and elderly:* PO, 2 g/d given in 2–3 divided doses *Child >6 y:* PO, 30–50 mg/kg/d in 2 divided doses	*Onset:* 1 h *Duration:* 6–12 h $t_{1/2}$: 5–10 h

Box25.2 METHOTREXATE BLACK BOX WARNINGS

Methotrexate should be used only by physicians whose knowledge and experience include the use of antimetabolite therapy.

- Because of the possibility of **serious toxic reactions** (possibly fatal):
  1. Methotrexate (MTX) should be used only in life-threatening neoplastic diseases, or in patients with psoriasis or rheumatoid arthritis (RA) with severe, recalcitrant, disabling disease that is not adequately responsive to other forms of therapy.
  2. Deaths have been reported with the use of MTX in the treatment of malignancy, psoriasis, and RA.
  3. Patients should be closely monitored for bone marrow, liver, lung, and kidney toxicities.
  4. Patients should be informed by their physicians of the risks involved and be under a physician's care throughout therapy.
- The use of high-dose MTX regimens recommended for osteosarcoma requires meticulous care. High-dose regimens for other neoplastic diseases are investigational, and a therapeutic advantage has not been established.
- MTX formulations and diluents containing preservatives must not be used for intrathecal or high-dose MTX therapy.
  1. MTX has been reported to cause fetal death or congenital anomalies. Therefore, it is not recommended for women of childbearing potential unless there is clear medical evidence that the benefits can be expected to outweigh the considered risks. Pregnant women with psoriasis or RA should not receive the drug.
  2. MTX elimination is reduced in patients with impaired renal function, ascites, or pleural effusions. Such patients require especially careful monitoring for toxicity and require dose reduction or, in some cases, discontinuation of methotrexate administration.
  3. Unexpectedly severe (sometimes fatal) bone marrow suppression and gastrointestinal toxicity have been reported with concomitant administration of MTX (usually in high dosage) along with some nonsteroidal anti-inflammatory drugs (NSAIDs).
  4. MTX causes hepatotoxicity, fibrosis, and cirrhosis, but generally only after prolonged use. Acutely, liver enzyme elevations are frequently seen. These are usually transient and asymptomatic and also do not appear predictive of subsequent hepatic disease. Liver biopsy after sustained use often shows histologic changes, and fibrosis and cirrhosis have been reported; these latter conditions may not be preceded by symptoms or abnormal liver function tests in the people with psoriasis. For this reason, periodic liver biopsies are usually recommended for patients with psoriasis who are under long-term treatment. Persistent abnormalities in liver function tests may precede appearance of fibrosis or cirrhosis in the RA population.
  5. MTX-induced lung disease is potentially dangerous and may occur acutely at any time during therapy. It has been reported at doses as low as 7.5 mg/wk and is not always completely reversible. Pulmonary symptoms (especially a dry, nonproductive cough) may require interruption of treatment and careful investigation.
  6. Diarrhea and ulcerative stomatitis require interruption of therapy; otherwise, hemorrhagic enteritis and death from intestinal perforation may occur.
  7. Malignant lymphomas, which may regress following withdrawal of MTX, may occur in patients receiving low-dose MTX therapy. They may not require cytotoxic treatment. Discontinue methotrexate first and, if the lymphoma does not regress, institute appropriate treatment.
  8. Like other cytotoxic drugs, MTX may induce "tumor lysis syndrome" in patients with rapidly growing tumors. Appropriate supportive and pharmacologic measures may prevent or alleviate this complication.
  9. Severe, occasionally fatal, skin reactions have been reported following single or multiple doses of MTX. Reactions have occurred within days of drug administration. Recovery has been reported with discontinuation of therapy.
  10. Potentially fatal opportunistic infections, especially *Pneumocystis carinii* pneumonia, may occur with MTX therapy.
  11. MTX given concomitantly with radiotherapy may increase the risk of soft-tissue necrosis and osteonecrosis.

Drug Interactions

MTX may interact with many drugs. In general, MTX should not be given concurrently with other drugs associated with the development of nephrotoxicity, hepatotoxicity, or suppressed bone marrow function. Table 25.2 presents potential drug interactions with MTX.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for comorbid states or drugs that contradict the use of MTX. Complete a thorough physical examination, carefully evaluating for signs of hepatic or renal insufficiency, suppressed bone marrow function, or adventitious lung sounds. Document the severity of joint inflammation and any restriction in range of motion as a baseline for later comparison to assess the efficacy of MTX therapy.

Before beginning therapy, evaluate the results of a complete blood count (CBC); renal and hepatic function tests; hepatitis B and C serologies, and chest x-ray. Coordinate serial laboratory testing. Routine monitoring includes a CBC, liver profile, serum albumin, and serum creatinine every 4 to 8 weeks. Assess the patient's willingness to adhere to this close monitoring. If the patient is female, evaluate for possible pregnancy and help the patient develop a plan for contraception during therapy.

Life Span and Gender

MTX is given cautiously to very young and elderly patients because these patients' livers and kidneys may not be able to adequately clear the drug, and they therefore risk accumulation. Because MTX is a pregnancy category X drug, planning pregnancy is essential: Women should discontinue methotrexate for at least one ovulatory cycle prior to attempting conception, while men should wait 3 months. MTX is secreted in breast milk and may be toxic to the infant.

Lifestyle, Diet, and Habits

Evaluate for the use of alcohol or illicit drugs because these substances may predispose the patient to hepatic dysfunction.

TABLE 25.2 Agents That Interact with P Methotrexate

Interactants	Effect and Significance	Nursing Management
acitretin	Although the mechanism of action is unknown, acitretin increases the risk of hepatotoxicity when administered with MTX.	Monitor liver function tests. Monitor for signs of hepatotoxicity.
aspirin, salicylates	Salicylates decrease the renal clearance of MTX, resulting in an increased risk of MTX toxicity. Less likely to occur with weekly administration of MTX.	See amiodarone.
Charcoal, activated	Charcoal reduces the absorption of MTX.	Monitor for efficacy of MTX therapy.
cyclosporine	Cyclosporine blocks the oxidation of MTX to its relatively inactive metabolite, decreasing its efficacy	Monitor for increased symptoms of RA.
digoxin	MTX may reduce GI absorption of digoxin, resulting in decreased serum digoxin concentration.	Monitor for efficacy of digoxin therapy. Monitor serum digoxin levels frequently.
Hydantoins	MTX may decrease the absorption of Hydantoins resulting in decreased efficacy	Monitor drug levels levels. Monitor for seizure activity. Ensure safety.
NSAIDS	NSAIDS reduce the renal clearance of MTX resulting in toxicity. Less likely to occur with weekly administration of MTX.	Same as amiodarone
penicillins	Penicillins impair the renal excretion of MTX.	Obtain MTX serum concentration if penicillins are initiated. Same as amiodarone.
probenecid	Probenecid impairs the renal excretion of MTX.	Obtain MTX serum concentration if probenecid is initiated. Same as amiodarone
sulfonamides	Sulfonamides displace MTX from protein binding sites and decrease renal clearance of MTX resulting in an increased serum concentration of MTX. MTX may induce folate deficiency, which develops into acute megaloblastic anemia when administered with TMP-SMZ.	Same as amiodarone

Also, evaluate the nutritional status of the patient; malnourished patients are more likely than others to be immunosuppressed or have blood dyscrasias. Evaluate the patient's caffeine intake because caffeine may decrease the effectiveness of MTX. To minimize the potential for MTX photosensitivity, determine how frequently the patient must be in the sun.

Environment

MTX as an oral medication for RA is routinely taken by the patient at home. In some circumstances, MTX may be given by the intramuscular route. In such cases, teach the patient the correct aseptic technique for self-administering an intramuscular injection. If you, the nurse, administer the intramuscular injection, handle MTX according to the facility's protocol, because skin contact with MTX poses a risk for carcinogenicity, mutagenicity, or teratogenicity.

Nursing Diagnoses and Outcomes

- Comfort Impaired: Nausea related to drug therapy
  Desired outcome: The patient will eat small, frequent meals when nauseated to maintain nutritional balance.
- Risk for Infection related to potential depression of bone marrow function and blood dyscrasias
  Desired outcome: The patient will recognize signs of depressed bone marrow function and blood dyscrasias and contact the health care provider immediately for intervention if any appear.
- Imbalanced Nutrition: Less than Body Requirements, related to potential nausea, stomatitis, and gingivitis
  Desired outcome: The patient will maintain nutritional balance throughout therapy.
- Risk for Injury related to drug accumulation caused by hepatic or renal dysfunction
  Desired outcome: The patient will remain injury free throughout therapy.

Planning and Intervention

Maximizing Therapeutic Effects

Administer MTX weekly as ordered. Ensure that the patient drinks enough water to minimize the risk of nephrotoxicity. Encourage the patient to continue pharmacotherapy

with MTX, even if the patient has not yet experienced any beneficial results.

Minimizing Adverse Effects

Vitamin B (folic acid), 1 mg every day, may decrease the potential for adverse effects of MTX. If the patient has mouth ulcers, consult with the prescriber to request an order for allopurinol, 300 mg. Dissolve the allopurinol in 50 mL of water. It is important to instruct the patient to use this solution to rinse the mouth but not to swallow the solution. Remind the patient that MTX can cause photosensitivity. Patients should take care to remain out of the sun, wear protective clothing, and use a lotion with skin protection factor (SPF) 45 if they cannot avoid being in the sun.

Providing Patient and Family Education

- Assist patients in preparing a schedule for MTX because this drug is not taken daily.
- Instruct patients to use puncture-resistant containers to dispose of the needles and syringes.
- Advise patients to contact the health care provider before starting other prescription drugs, or over-the-counter (OTC) medication such as vitamins, minerals, or herbs.
- Instruct patients to contact the prescriber immediately if they experience:
  - Symptoms of infection—fever or chills, cough, sore throat, pain, or difficulty passing urine
  - Symptoms of decreased platelets or bleeding—bruising, pinpoint red spots on the skin, black and tarry stools, blood in the urine
  - Symptoms of anemia—unusual weakness or tiredness, fainting spells, light-headedness
  - Diarrhea
  - Difficulty breathing, a nonproductive cough
  - Mouth or throat ulcers
  - Redness, blistering, peeling or loosened skin, including inside the mouth
  - Skin rash, hives, or itching
  - Changes in vision
  - Vomiting
- Teach patients the importance of adequate nutrition and hydration to minimize the risk of adverse effects.
- Stress the effects of alcohol and drugs in precipitating adverse effects on the liver.
- Encourage patients to limit their intake of caffeine.
- Instruct patients to keep out of the sun or to wear protective clothing outdoors and use a sunscreen. Emphasize that they must not use sun lamps or sun tanning beds or booths.
- Instruct patients on the importance of serial laboratory testing and coordinate dates for testing to occur.
- Explain the importance of self-care in addition to pharmacotherapy:
  - Range-of-motion exercises
  - Weight control
  - Daily exercise, especially walking
  - Healthy diet
  - Heat for aching joints
  - Cold for acute flares
  - Relaxation techniques
- Advise patients that the beneficial effects from MTX take 1 to 2 months and that it is important to continue therapy to allow the benefits to begin.

Ongoing Assessment and Evaluation

Monitor patients for signs of blood dyscrasias, suppressed bone marrow function, pulmonary changes, and hepatic or renal dysfunction at each visit. Assess the degree of joint pain, duration of morning stiffness, limitation of function, and degree of fatigue at each visit. Coordinate serial testing that includes CBC, urinalysis, and liver and renal function tests.

Effective treatment with MTX should decrease (1) subjective symptoms such as perceived pain level and (2) objective symptoms such as decreased joint inflammation and increased range of motion. The patient should be free of adverse effects or be receiving appropriate interventions focused on ameliorating adverse effects.

Drugs Similar to P Methotrexate

Azathioprine

Azathioprine (Azasan, Imuran) is an intravenously infused antimetabolite that splits into a precursor, mercaptopurine. It is a unique antimetabolite agent because it is exclusively an immunosuppressant and not an antineoplastic. Because of its action, it is highly mutagenic and has been associated with the development of secondary malignancies, both

CRITICAL THINKING SCENARIO

DMARD THERAPY

Ms. Ruben, a 50-year-old woman, was diagnosed with rheumatoid arthritis by her primary care physician, who referred her to the rheumatologist at your clinic. She has been taking indomethacin for the past month and has come to the clinic for her first visit. When asked how well the indomethacin is controlling her pain, Ms. Ruben replied, "I barely know it's there." She also denies experiencing any adverse effects. The rheumatologist orders MTX for Ms. Ruben in combination with indomethacin.

1. Why do you think the rheumatologist ordered MTX even though the patient is doing so well on her current medication?
2. What assessments should you document before administering MTX?
3. Consider which laboratory tests you anticipate will be performed before MTX is administered.
4. Prepare patient teaching about MTX for Ms. Ruben.
5. When do you anticipate Ms. Ruben will attain optimal response from MTX therapy?
6. What is the purpose of continuing indomethacin at this time?
7. Ms. Ruben asks, "What if this doesn't work? What then?" How would you respond?

MEMORY CHIP

P Methotrexate

- Disease-modifying antirheumatic drug (DMARD) used as monotherapy or in combination with glucocorticoid steroids, NSAIDs, or other DMARDs to decrease the progression of RA
- Major contraindications: immunosuppression, blood dyscrasias, pregnancy
- Most common adverse effects: nausea, headache, stomatitis, gingivitis, alopecia
- Most serious adverse effect: depressed bone marrow function
- Maximizing therapeutic effects: remain hydrated
- Minimizing adverse effects: Take vitamin B, 5 mg every day.
- Most important patient education: Substantial adverse effects may occur. Be sure to contact the health care provider if they occur.
- **Black box warning: See Box 25.2**

listed as black box warnings. It is indicated as part of a multidrug regimen to prevent rejection in renal transplantation and to treat rheumatoid arthritis not responsive to conventional management. Unlabeled uses include treating Crohn disease and myasthenia gravis and preventing rejection after cardiac transplantation. Notable drug interactions occur with allopurinol, angiotensin-converting enzyme inhibitors, and anticoagulants. The most common and severe adverse event is infection, although GI distress may be great enough to warrant limiting the dose. Azathioprine is given cautiously with other immunosuppressants because of increased risk of infection, and dose reduction is necessary in hepatic dysfunction.

Gold Salts

The administration of gold salts is called **chrysotherapy**. Gold is an antiinflammatory agent that interferes with cells and substances in the immune system. There are two forms of IM gold salts: gold sodium thiomalate (Myochrysine) and aurothioglucose (Solganal). There is also an oral tablet that contains gold, auranofin (Ridaura); however, this preparation is distinct from the injectable forms and much less effective. Gold has been used for RA for over 70 years, but its relatively modest efficacy and high side-effect profile, coupled with the increased use of methotrexate and biologicals, have led to a dramatic decrease in its use.

Hydroxychloroquine

Hydroxychloroquine (Plaquenil) is an antimalarial drug also used in managing RA and discoid lupus erythematosus. In treating malaria, the mechanism of action is the same as for chloroquine. In managing RA and discoid lupus erythematosus, the mechanism of action is unclear. Optimal benefits may take between 2 and 6 months.

Hydroxychloroquine is generally well tolerated. For patients on long-term therapy, those over the age of 60, and patients with significant kidney disease, hydroxychloroquine may cause visual changes or loss of vision.

Drug–drug interactions, adverse effects, nursing management, and patient education are the same as for patients taking chloroquine (see Chapter 47).

Leflunomide

Leflunomide (Arava) is an innovative DMARD that was designed specifically for RA. The pharmacologic activity of leflunomide is accomplished through its active primary metabolite, A77 1725, also known as M1. M1 inhibits dihydro-orotate dehydrogenase, an enzyme involved in the autoimmune process, which inhibits a key step in pyrimidine synthesis. Suppression of pyrimidine synthesis within T and B lymphocytes interferes with RNA and protein synthesis within the cells and prevents further cell-cycle progression. Reduced lymphocyte activity leads to reduced cytokine and antibody-mediated destruction of the synovial joints and decreases the inflammatory process. Symptoms may abate in as little as 4 to 12 weeks. Additionally, because of its unique mechanism of action, leflunomide may be used in conjunction with other drugs such as NSAIDs and other DMARDs.

Leflunomide is contraindicated in patients with severe hepatic insufficiency and in patients with diagnosed hepatitis B or hepatitis C. Leflunomide may increase concentrations of liver enzymes such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT) and has been associated with inducing hepatotoxicity. Leflunomide also is contraindicated for use during pregnancy or breast-feeding. Leflunomide is a category X drug because it has been shown to induce fetal deformity. Women who have received leflunomide and wish to become pregnant must undergo a drug elimination process before conception. Cholestyramine (8 g) is administered three times a day for 11 days. The days do not have to be consecutive, but they must total 11 days. Plasma leflunomide levels are then evaluated twice, at least 14 days apart. The plasma drug level should be less than 0.02 mcg/mL before conception is attempted. Without this procedure, blood levels greater than 0.02 mcg/mL may persist for up to 2 years, depending on individual variations in clearance.

Patients with bone marrow dysplasia, immunodeficiency, or severe uncontrolled infections are poor candidates for leflunomide therapy. Vaccinations with live vaccines are not recommended during therapy.

Common adverse effects include nausea, diarrhea, increased AST and ALT levels, alopecia, rash, headache, and increased risk for immunosuppression and infections.

Potential drug interactions include cholestyramine, charcoal, rifampin, and drugs that induce hepatotoxicity. Women of childbearing age must take a reliable contraceptive agent while taking leflunomide therapy, because it is a pregnancy category X drug. Fortunately, it does not interact with triphasic oral contraceptives.

Minocycline

Minocycline (Minocin, Dynacin) is a tetracycline antibiotic. It is unclear exactly how minocycline exerts an effect on RA. One theory is that RA has a mycoplasma component to it,

thus minocycline affects the mycoplasma. A second theory is that RA may reduce certain proteins that erode cartilage. It is used only for patients with mild RA symptoms. Adverse effects include nausea, dizziness, skin color changes, and rash (especially with sun exposure).

D-Penicillamine

Penicillamine (Cuprimine) is used in treating patients with early, mild, and nonerosive RA. Its antirheumatic action may result from its ability to inhibit the formation of collagen. Penicillamine also appears to depress circulating levels of IgM rheumatoid factor and immune complexes in serum and synovial fluid. It also may decrease cell-mediated immune response by selectively inhibiting T-lymphocyte function. In addition to its use as an antirheumatic drug, penicillamine is used as a chelating agent for removing excess copper from the blood of patients with Wilson disease and in reducing cystine excretion in patients with cystinuria. Optimal benefits may take 3 to 6 months.

Although penicillamine is a by-product of penicillin, it has no antibiotic activity. However, the possibility of cross-sensitization between penicillin and penicillamine exists; therefore, penicillamine should not be given to patients who are allergic to penicillin.

Penicillamine has potentially toxic adverse effects, including cutaneous lesions, blood dyscrasias, and a number of autoimmune disorders. Penicillamine is associated with a high incidence of potentially life-threatening adverse hematologic reactions because it depresses bone marrow function. Patients with a history of hematologic disorders or previous penicillamine-induced dyscrasias could experience these adverse reactions, which include leukopenia, thrombocytopenia, aplastic anemia, pancytopenia, sideroblastic anemia, agranulocytosis, and leukopenia. Penicillamine should be discontinued when the platelet count decreases to less than 100,000/mm^3, the leukocyte count decreases to less than 3,000/mm^3, or neutropenia occurs.

Rare but serious adverse effects are myasthenia gravis (MG) syndrome and obliterative bronchiolitis. Penicillamine should be discontinued at the first sign of ptosis or diplopia (signifying MG syndrome) or exertional dyspnea, cough, or wheezing (signifying obliterative bronchiolitis). These symptoms should be reported immediately.

In the renal system, penicillamine can induce hematuria and proteinuria, which may indicate an impending immune complex membranous glomerulonephritis. This condition can degenerate into nephrotic syndrome. Penicillamine should be discontinued when proteinuria values exceed 1 g per 24 hours.

The most common adverse effects involve the integumentary system. Rash and pruritus occurring in the first few months (early rash) are generally typical of drug hypersensitivity. Early rash usually disappears when the drug is discontinued. Late rash during therapy may be accompanied by intense pruritus, fever, arthralgia, or lymphadenopathy. This rash may take weeks to disappear. Patients may also develop exfoliative dermatitis, increased skin friability, vesicular ecchymoses, and pemphigus.

Penicillamine also can cause GI upset such as nausea, vomiting, anorexia, abdominal pain, and diarrhea. Patients with a history of peptic ulcer, hepatic dysfunction, and pancreatitis may experience reactivation of the disorder.

Because of the potential for adverse effects from penicillamine, patients should be taught carefully about this drug, including the signs and symptoms of potentially serious consequences. Inform female patients that this drug should not be taken if they are pregnant or breast-feeding. It also should not be taken by patients who have severe renal dysfunction or severe anemia; have taken penicillamine before and developed a high fever; or are taking gold salts by mouth or injection. Moreover, patients allergic to penicillin should not take penicillamine.

Explain minor side effects, such as change in taste, diarrhea, loss of appetite, nausea, vomiting, and stomach pain, and advise patients to discuss these effects with the health care team if the effects do not subside or are particularly annoying. Patients should learn to take penicillamine at least 1 hour before or 2 hours after eating food. Patients taking penicillamine for Wilson disease must avoid foods that contain copper, such as chocolate, nuts, liver, and broccoli. In addition, patients should drink plenty of water to prevent kidney stones from forming. Patients should avoid taking antacids and iron preparations because they may prevent the drug from working properly.

A missed dose should be taken as soon as possible, but if it is almost time for the next dose, only that dose should be taken (double or extra doses should never be taken). Instruct patients to continue to take penicillamine even if it appears that it is not working. Penicillamine should be stored away from moisture (particularly away from a bathroom) and out of the reach of children. Urge patients to schedule monthly blood and urine tests to make sure they are not having any adverse reactions to penicillamine.

Sulfasalazine

Sulfasalazine (Azulfidine) is a sulfonamide antibiotic that is considered a first-line treatment for both adult and juvenile RA. Sulfasalazine is a prodrug of sulfapyridine and mesalamine. Mesalamine inhibits cyclooxygenase, resulting in decreased production of arachidonic acid metabolites and reducing inflammation. Benefits occur in 1 to 3 months.

Sulfasalazine is contraindicated in patients with salicylate hypersensitivity, sulfonamide hypersensitivity, furosemide hypersensitivity, thiazide diuretic hypersensitivity, sulfonylurea hypersensitivity, or carbonic anhydrase inhibitor hypersensitivity, because it is broken down to a salicylate component and a sulfonamide component. It is also contraindicated for patients with intestinal or urinary obstruction and porphyria. It is given cautiously to patients with pre-existing megaloblastic anemia or glucose-6-phosphate dehydrogenase (G6PD) insufficiency because, as a sulfonamide, it decreases folate absorption.

The most common adverse reactions associated with Azulfidine EN-tabs are rash, anorexia, headache, nausea,

vomiting, gastric distress, and reversible low sperm count. Serious adverse effects include suppressed bone marrow function and hepatitis. These potentially serious adverse effects require that a baseline CBC, renal function tests, and liver function tests be completed before initiation of therapy and repeated periodically throughout therapy.

Sulfasalazine is a pregnancy category B drug. Although sulfasalazine is not secreted in breast milk, one of its metabolites, sulfapyridine, does enter the milk. Sulfapyridine is generally considered safe except in stressed or ill infants, those with G6PD deficiency, and premature infants.

Drugs Significantly Different From P Methotrexate

Cyclophosphamide

Cyclophosphamide (Cytoxan) is an alkylating agent used primarily for its antitumor activity. Because of the oncogenicity associated with alkylating agents, cyclophosphamide is used primarily in severe, refractory RA and RA vasculitis. Cyclophosphamide is presented as the prototype alkylating agent in Chapter 57.

Cyclosporine

Cyclosporine (Neoral, Sandimmune, Gengraf) is an oral and parenteral immunosuppressive agent used most frequently to prevent organ transplant rejection. It is also approved to treat severe RA in patients unresponsive to conventional therapy, alone or in combination with MTX when the disease has not adequately responded to MTX. It is not generally used as monotherapy in RA because when used alone there is an 80% increase in the likelihood of myocardial infarction and stroke. The immunosuppressive effects of cyclosporine result from inhibiting proliferation of T lymphocytes, production and release of lymphokines, and release of IL-2. Optimal benefits may take 2 to 4 months. As the prototype immune modulator, cyclosporine is presented in depth in Chapter 54.

Glucocorticoid Steroids

Glucocorticoid steroids such as prednisone and prednisolone can be administered as oral or intravenous preparations for systemic effects and as an intra-articular injection for a local effect. They are generally given as "pulse therapy" for an acute exacerbation of RA. This approach allows a "resetting" of the inflammatory thermostat, improves the patient's symptoms, and allows other DMARDs to become active in suppressing joint destruction. Intermittent therapy also decreases the potential for serious adverse effects associated with steroids. Long-term steroid therapy, even at low doses, increases the risk for pneumonia in RA patients. Glucocorticoid steroids are discussed in depth in Chapter 48.

C BIOLOGICAL DMARDS

Etanercept (Enbrel) is the first Tumor Necrosis Factor (TNF) inhibitor developed and the prototype TNF drug. It was produced by recombinant DNA technology. In the past, TNF inhibitors were used in patients who did not respond to MTX. Combination therapy with TNF inhibitors and MTX has exceptional results and is now considered the "gold standard" of RA treatment. Table 23.3 presents a summary of TNF and other biological drugs.

Nursing Management of the Patient Receiving P Etanercept

Core Drug Knowledge

Pharmacotherapeutics

Etanercept is used in managing RA—to reduce signs and symptoms of the disease and to delay structural damage in patients with moderately to severely active RA. The drug is also indicated for reducing signs and symptoms of moderately to severely active polyarticular-course juvenile idiopathic RA (JIA), psoriatic arthritis, ankylosing spondylitis, and moderate to severe active plaque psoriasis..

Pharmacokinetics

Etanercept is a weekly subcutaneous injection. Its onset is slow and duration is uncertain. The pharmacokinetic profile is not affected by age or gender. Benefits from therapy can begin in a few days or may take up to 12 weeks.

Pharmacodynamics

In RA, activated T cells release inflammatory mediators called **cytokines,** including interleukins and tumor necrosis factor. TNF binds to TNF receptors on cellular membranes and triggers a cascade of inflammatory events that results in increased inflammation of the synovial membrane, the release of destructive lysosomal enzymes, and further joint destruction. Etanercept binds specifically to circulating TNF, prevents it from binding to TNF receptors on the cell membranes, and prevents the TNF-mediated cellular response.

Contraindications and Precautions

The only absolute contraindications to etanercept are hypersensitivity and current active infections. However, several cautions must be considered before using this drug. Etanercept has been associated with inducing sepsis and fatal infections in patients with predisposing diseases, such as advanced or poorly controlled diabetes. In addition, etanercept may induce demyelinating disorders such as multiple sclerosis, myelitis, and optic neuritis and should be used cautiously in patients with these disorders.

Because etanercept blocks the biological activity of TNF, it could potentially affect host defenses against infections and malignancy. The safety and efficacy of etanercept in patients with suppressed bone marrow function or other types of immunosuppression are not known. Live vaccines should be avoided during etanercept therapy because definitive clinical data on potential effects are not yet available.

Adverse Effects

Common adverse reactions to etanercept include injection-site reactions, upper respiratory infections, especially sinusitis, headache, nausea, and rhinitis. Less common but very

TABLE 25.3 Summary of Selected Biological Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P etanercept (Enbrel)	RA	*Adult or child >62 kg:* SC, 50 mg/wk or 25 mg 2×/wk, 72–96 h apart *Child 4–17 y:* SC, <31 kg: 0.8 mg/kg weekly 31–62 kg: 0.8 mg/kg weekly given as 0.4 mg/kg ×2 in separate sites on the same day or 72–96 h apart	*Onset:* 2–4 wk *Duration:* Unknown $t_{1/2}$: 115 h
adalimumab (Humira)	RA, psoriasis, ankylosing spondylitis	*Adult:* SC, 40 mg every other week *Child >4y:* SC 20 mg every other week	*Onset:* 1–7 d *Duration:* Unknown $t_{1/2}$: 14 d
abatacept (Orencia)	RA	*Adult and Child >17y:* IV <60 kg: 500 mg initially, repeat dose at 2 and 4 wk then monthly 60–100 kg: 750 mg initially, repeat dose at 2 wk and 4 wk then monthly >100 kg: 1000 mg initially, repeat dose at 2 and 4 wk then monthly	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 13 days
anakinra (Kineret)	RA	*Adult:* SC, 100 mg daily *Child:* not approved	*Onset:* Slow *Duration:* Unknown $t_{1/2}$: 4–6 h
certolizumab pegol (Cimzia)	RA Crohn's Diesease	*Adult:* SC 200 mg wk 2 and 4; maintenance 200 mg every other week *Adult:* SC 400 mg every other week	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 14 d
golimumab (Simponi)	RA Psoriatic arthritis Ankylosing Spondylitis	*Adult:* SC 50 mg monthly *Child:* not approved	
infliximab (Remicade)	RA Psoriasis, Crohn's disease, ankylosing spondylitis	*Adult:* IV, 3 mg/kg every 8 wk *Adult:* IV, 5 mg/kg every 6–8 wk	*Onset:* 3–7 d *Duration:* 6–12 wk $t_{1/2}$: 9.5 d
Rituximab (Rituxan)	RA	*Adult IV:* 1000 mg, repeat in 2 wk	*Onset:* unknown *Duration:* 3–6 mo $t_{1/2}$: 59.8 h
tocilizumab (Actemra)	RA	*Adult:* IV 4 mg/kg over 1 h every 4-wk; increase to 8 mg/kg based on clinical response *Child:* not approved	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 11–13 d

serious adverse effects include severe infections; induction of multiple sclerosis; seizure activity; optic neuritis; blood dyscrasias; new or recurrent heart failure; psoriasis; lupus-like syndrome; and hepatitis..

There are three important black box warnings for all TNF inhibitors, including etanercept. The first is a reminder to weigh the treatment benefits and risk in patients with chronic or recurrent infections; pulmonary and extrapulmonary TB, invasive fungal infections (i.e., histoplasmosis, coccidiomycosis, and blastomycosis), and other opportunistic infections. The second is an increased risk for lymphoma and other malignancies, especially in children and adolescents. In addition, all TNF inhibitors, including etanercept, may induce hepatosplenic T-cell lymphoma (HSTCL), a rare type of cancer. HSTCL has occurred most frequently in teenagers or young adults, who also have either Crohn disease or ulcerative colitis and concurrently receiving azathioprine or 6-mercaptopurine.

Drug Interactions

Etanercept interacts with many of the other drugs used to treat RA and psoriasis, especially other biologic DMARDS. Coadministration with other TNF inhibitors does not increase the effectiveness of treatment but substantially increases the risk for severe infections. Table 25.4 presents potential drug interactions with etanercept.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for comorbid states or drugs that contradict the use of etanercept or require close monitoring.

TABLE 25.4 Agents That Interact with P Etanercept

Interactants	Effect and Significance	Nursing Management
abatacept	Coadministration increases the risk for serious infections.	Monitor CBC. Monitor for signs of myelosuppression. Assess lung sounds daily. Use aseptic technique consistently. Caution patient to refrain from contact with people who are ill.
anakinra	Coadministration increases the risk of serious infections and neutropenia.	Same as abatacept
cyclophosphamide	Coadministration increases the risk of noncutaneous solid malignancy.	Monitor CBC. Monitor ESR.
imatinib	Coadministration increases the risk of myelosuppression.	Same as abatacept
natalizumab	Coadministration increases the risk of serious infections, including PML.	Monitor for clumsiness, progressive weakness, visual or speech changes, and personality changes.
TNF Inhibitors	Coadministration increases the risk of serious infections.	Same as abatacept
sulfasalazine	Coadministration may decrease neutrophil count.	Same as abatacept
Live-vaccines	Coadministration decreases immunologic response and increases risk of disseminated infections.	Do not administer

Assess for rubber or latex allergy because the needle covers of the syringe contain dry natural rubber. Assess for a history of recurrent infections, pulmonary or extrapulmonary TB, invasive fungal infections or malignancies. Convey any positive response to the healthcare provider immediately.

Complete a thorough physical examination, carefully evaluating for signs of infection, suppressed bone marrow function, and adventitious lung sounds. Complete a baseline neurologic examination. Document the severity of joint inflammation and any restriction in range of motion as a baseline for later comparison to assess the efficacy of etanercept therapy.

Before beginning therapy, document the results of a TB skin test (PPD), complete blood count (CBC), urinalysis, tests for C-reactive protein level and ESR, hepatitis screen, and chest x-ray. Coordinate serial laboratory testing. Assess the patient's willingness to adhere to close monitoring.

Lifespan and Gender

Etanercept is a pregnancy category B drug. Whether it is excreted into breast milk or has potential risks to the infant is unknown. Etanercept is not approved for use in children under the age of 4 years. Assess the immunization status of children; vaccinations should be avoided during therapy.

Lifestyle, Diet, and Habits

As with MTX, evaluate the nutritional status of the patient; malnourished patients are more likely than others to be immunosuppressed or have blood dyscrasias.

Environment

Etanercept is generally administered in the home environment. Assess if the patient lives with or has close contact with anyone with active tuberculosis.

Nursing Diagnoses and Outcomes

- Risk for Infection related to potential depression of bone marrow function and blood dyscrasias
  Desired outcome: The patient will recognize signs of depressed bone marrow function and blood dyscrasias and contact the health care provider immediately for intervention if any appear.
- Comfort Impaired: Nausea related to drug therapy
  Desired outcome: The patient will eat small, frequent meals when nauseated to maintain nutritional balance.

Planning and Intervention

Maximizing Therapeutic Effects

Administer etanercept weekly as prescribed. Rotate the injection site between the middle of the thigh, on the abdomen except around the navel, and the back outer area of the upper arm. Do not inject within one inch of the previous injection. Avoid areas that are tender, red, or hard. Keep the medication refrigerated.

Minimizing Adverse Effects

Use aseptic technique when administering etanercept. Do not administer if the drug solution is discolored, cloudy, or contains particles. Avoid placing hospitalized patients taking etanercept in the same room with other patients who

have colds, the flu, or other contagious illnesses. Do not administer live-virus vaccines.

Providing Patient and Family Education

- Advise the patient to read the accompanying Medication Guide with each administration of etanercept.
- Teach the patient to report symptoms of possible adverse effects to the healthcare provider:
  - CNS symptoms: numbness or tingling to extremities, vision changes, weakness in arms or legs dizziness
  - Infection: fever, sweat, or chills; muscle aches; red, warm or painful skin or abscess formation; diarrhea; dysuria, fatigue
  - Blood dyscrasias: fever, bruising, bleeding easily, or looking pale.
  - Heart failure: shortness of breath, swelling in lower legs and feet
  - Psoriasis: red scaly patches or hard raised bumps
  - Lupus-like syndrome: rash to face and arms that intensifies in sunlight
  - Hepatitis B infection: fatigue, jaundice, anorexia, vomiting, right upper quadrant pain, muscle aches, dark urine, clay-colored feces, fever or chills.
  - TB: anorexia, weight loss, night sweats, cough, fatigue, chest pain, shortness of breath
- Teach aseptic technique to patients for the subcutaneous injection. Instruct the patient how to use SureClick auto injector if ordered.
- For patients using the multi-dose vial, teach patients to roll the vial, rather than shake it, when administering the drug.
- Instruct patients to use puncture-resistant containers to dispose of needles and syringes.
- Assist the patient to prepare a chart of injection sites to ensure regular rotation of sites.
- Explain the potential for an injection site reaction such as redness, rash, swelling, itching, or bruising. Assure patients that these reactions usually disappear within 3 to 5 days. If they do not, patients should contact their health care provider.
- Teach patients the importance of contacting their health care provider before taking any other prescription medication, or OTC medicines, including vitamins, minerals, and herbal products.
- Stress the importance of avoiding others with coughs, colds, or flu.
- Urge patients to refrain from receiving live-vaccinations while taking etanercept.
- Explain the importance of follow-up with the health care provider to evaluate the efficacy of therapy and monitor for adverse effects.

Ongoing Assessment and Evaluation

Assess patients taking etanercept for improved range of motion, decreased early morning stiffness, and painful or swollen joints. Assess patients each visit for potential adverse effects to etanercept, especially for signs infection, TB or malignancies. Coordinate laboratory testing for CBC, C-reactive protein levels, and ESR. Review aseptic technique at each visit. Evaluate the efficacy of etanercept therapy; successful etanercept therapy is demonstrated by decreased RA symptoms and an absence of adverse effects.

Drugs Closely Related to P Etanercept

Adalimumab

Adalimumab (Humira) is a TNF inhibitor approved for the management of RA, idiopathic juvenile arthritis, psoriatic arthritis, plaque psoriasis, ankylosing spondylitis, and Crohn's disease. Adalimumab differs from etanercept because it is a **monoclonal antibody** (a cell that is produced with the ability to recognize and bind to a specific antigen) that specifically inhibits the activity of TNF-alpha. It may be given as monotherapy or in combination with other DMARDS. Adalimumab is administered biweekly. Assessment (including baseline labs), contraindications and precautions, adverse effects and patient teaching are the same as etanercept and it carries the same Black Box warnings. The most common adverse effects associated with adalimumab are injection site reactions, upper respiratory infections such as sinusitis, headaches, rash, and nausea. Risk for hepatosplenic T-cell lymphoma. It is available in a prefilled syringe or pen. Advise the patient to return the syringe to the pharmacy if the solution is cloudy or contains large particles. Advise the patient not to use adalimumab if the syringe or pen was frozen or left in direct sunlight. Adalimumab is a pregnancy category B.

Certolizumab Pegol

Certolizumab pegol (Cimzia) is another TNF inhibitor that is a monoclonal antibody. It approved for the management of RA and Crohn's disease. Certolizumab is the only PEGlyated

MEMORY CHIP

P Etanercept

- Disease-modifying antirheumatic drug (DMARD) used in combination with methotrexate to decrease the progression of RA
- Major contraindications: immunosuppression, blood dyscrasias, infections
- Most common adverse effects: nausea, headache, upper respiratory infections, injection site reactions
- Most serious adverse effects: severe infections, blood dyscrasias
- Maximizing therapeutic effects: rotate site of injection
- Minimizing adverse effects: Use aseptic technique for injections.
- Most important patient education: high risk for severe infection. Be sure to contact the health care provider if they occur.
- **Black box warning: Risk/benefit ratio due to serious infections and malignancies. Increased risk for lymphoma with children and adolescents**

TNF inhibitor currently on the market. PEGylation provides a protective barrier around part of the medication that allows it to remain in the body longer. After initial administration of certolizumab, it is repeated at weeks 2 and 4. Maintenance is then monthly thereafter. Like adalimumab, assessment, contraindications and precautions, adverse effects and patient teaching are the same as etanercept and it carries the same Black Box warnings. The most common adverse effects with certolizumab are upper respiratory infections such as flu or colds, urinary tract infections, and rash. It is available in a prefilled syringe that should be kept refrigerated. Advise the patient to return the syringe to the pharmacy if the solution is cloudy or contains visible particles. Teach the patient to allow certolizumab to reach room temperature before self-administration. Advise the patient not to use certolizumab if the syringe was frozen or left in direct sunlight. Certolizumab is a pregnancy category B.

Golimumab

Golimumab (Simponi) is the newest monoclonal antibody TNF inhibitor on the market. It is approved for the treatment of RA (in combination with MTX), active psoriatic arthritis, and active ankylosing spondylitis. Golimumab is administered monthly. Like other TNF inhibitors, assessment, contraindications and precautions, adverse effects and patient teaching are the same as etanercept and it carries the same Black Box warnings. The most common adverse effects associated with golimumab are upper respiratory infections, colds/flu, sinusitis, rhinitis, bronchitis, hypertension, injection site reactions, abnormal liver function tests, nausea, and paresthesias. Golimumab is available in a prefilled syringe or SmartJect autoinjector. Teach the patient to remove the prefilled syringe or SmartJect autoinjector from the refrigerator 30 minutes before administration. Advise the patient that it is normal to see tiny particles in the solution but not to use if the solution is cloudy or contains large particles. Golimumab is a pregnancy category B

Infliximab

Infliximab (Remicade) is another monoclonal antibody TNF inhibitor approved for the management of moderate to severe active RA, ankylosing spondylitis, psoriatic arthritis, plaque psoriasis, and Crohn's disease or ulcerative colitis, in patients unresponsive to other therapy. In patients with RA, it is given concurrently with MTX. Infliximab is administered intravenously at weeks 0, 2, and 6, then every 6 to 8 weeks as maintenance. Like other TNF inhibitors, assessment, contraindications and precautions, adverse effects and patient teaching are the same as etanercept and it carries the same Black Box warnings. The most common adverse effects associated with infliximab are respiratory infections such as sinus infections and sore throat, headache, rash, cough, and abdominal pain. Children with Crohn's disease on infliximab therapy frequently experienced anemia, neutropenia, leukopenia, viral and bacterial infections, flushing, bone fractures, and melena.

Infuse infliximab over at least 2 hours. Infliximab is a pregnancy category B.

Drugs Significantly Different From P Etanercept

Abatacept

Abatacept (Orencia) is a T cell costimulation blocking agent. It is given by intravenous infusion over 30 minutes; this is repeated 2 and 4 weeks after the first infusion and every 4 weeks thereafter. It was developed specifically to manage moderate to severe RA as monotherapy or in combination with other DMARDs, although it should not be given with TNF inhibitors or anakinra. Fully activated T-lymphocytes are implicated in the pathogenesis of RA and are found in the synovium of patients with RA. Abatacept binds to specific receptors on the antigen-presenting cell and prevents optimal T-cell activation.

Contraindications and precautions of abatacept are similar to those of etanercept, with the addition of cautious administration to elderly patients because, due to their age, they have a higher risk of infection and malignancy. Infusion-related adverse effects include hypotension, hypertension, dyspnea, nausea, flushing, urticaria, cough, hypersensitivity, pruritus, rash, and wheezing. Like other biologicals, abatacept may cause serious infections and malignancy.

Abatacept is a pregnancy category C drug and not recommended for use in women who are breast-feeding. It is not approved for use in children.

Anakinra

Anakinra (Kineret), a recombinant form of the human interleukin-1 receptor antagonist (IL-1Ra), is produced by recombinant DNA technology. It is approved for use in patients with moderate to severe active RA who have unsuccessfully tried therapy with one or more DMARDs. It is administered as a subcutaneous injection. Therapeutic response occurs in 1 to 3 weeks.

Anakinra acts similarly to the native IL-1Ra. IL-1 and TNF are the primary proinflammatory cytokines associated with RA. IL-1 plays a dominant role in cartilage damage and bone resorption in rheumatoid arthritis, whereas TNF-alpha is more responsible for inflammation. By antagonizing IL-1, stimulation of osteoclasts is decreased, resulting in decreased bone resorption and joint destruction.

Anakinra is contraindicated in patients with hypersensitivity to Escherichia coli protein. It is also contraindicated in immunocompromised patients because it further decreases the immune response. The drug is administered as a subcutaneous injection, and the needle cover of the syringe contains latex, which may cause reactions in patients (and health care workers) with latex hypersensitivity. Anakinra should not be given to patients with an active infection, because the risk of infection is increased during therapy. It should be given cautiously to patients with pre-existing renal dysfunction because it is renally excreted. Live-virus vaccines should not be administered during anakinra therapy because of the drug's effects on the immune response.

Common adverse effects include headache, sinusitis, abdominal pain, diarrhea, upper respiratory infection, and injection site reactions. More serious adverse effects include neutropenia and severe infections.

Anakinra is a pregnancy category B drug. It is unclear whether it is secreted in breast milk. Safety and efficacy have not been established for children.

Rituximab

Rituximab (Rituxan) is a monoclonal antibody B cell depleting agent. The depletion of B cells has been shown to be effective in reducing signs and symptoms of RA and in slowing radiographic progression. It is approved for use in patients with RA who have not responded to TNF inhibitors and those with non-Hodgkin's lymphoma. Effects from rituximab are not seen for up to 3 months after an infusion, however, may last between 6 months and 2 years following a single infusion course. It is used off-label for chronic lymphoid leukemia, thrombocytopenic purpura, and Waldenström's macroglobulinemia (a type of cancer of the blood).

Rituximab has many severe adverse effects. It has Black Box warnings regarding fatal infusion reactions, tumor lysis syndrome, and severe mucocutaneous reactions, as well as progressive multifocal leukoencephalopathy, a viral infection of the brain caused by reactivated JC virus, which is present in about 80% of adults. Rituximab is a prototype monoclonal antibody presented in Chapter 55.

Tocilizumab

Tocilizumab (Actemra) is a monoclonal antibody interleukin-6 receptor antagonist specifically developed for the treatment of RA. IL-6 has been identified as having a fundamental role in the inflammation process in RA. Tocilizumab is used for the management of adult patients with moderate to severe RA who are unable to take or have had an inadequate response to MTX or other DMARDS. Studies of tocilizumab have been promising. The AMBITION trial demonstrated that monotherapy with tocilizumab is more efficacious than monotherapy with MTX (Jones, 2010). In addition the OPTION study concluded that combination therapy with tocilizumab and MTX is more effective than MTX monotherapy in inhibiting the progression of structural joint damage in rheumatoid arthritis (Garnero, Thompson, Woodworth, et al., 2010). The RADIATE trial concluded that tocilizumab, in combination with MTX, was able to achieve and maintain improvement in RA symptoms in patients with an inadequate response to TNF-inhibitors (Emery, Keystone, Tony, 2008). Because tocilizumab is a monoclonal antibody, assessment, contraindications and precautions, adverse effects and patient teaching are the same as etanercept and it carries the same Black Box warnings. The most common adverse effects to tocilizumab include upper respiratory tract infection, nasopharyngitis, headache, increased AST/ALT, and hypertension. Tocilizumab is given intravenously every 4 weeks. It is a pregnancy category C.

ANTIGOUT DRUGS

Antigout drugs are used to treat an acute attack of gout, prevent or decrease the frequency of flares, and prevent complications associated with the development of tophi. As previously explained, gout is associated with hyperuricemia, although it may occur in patients with normal uric acid levels. Hyperuricemia occurs either because of increased uric acid production or by accumulation of uric acid because of decreased renal excretion. Antigout drug therapy focuses on either decreasing the inflammatory response caused by hyperuricemia or on reducing hyperuricemia itself.

• Drugs for Treating Acute Gout

As previously mentioned, the first-line drugs for acute gouty arthritis are NSAIDs. The most common NSAIDused is indomethacin, however, ibuprofen, naproxen, piroxicam, sulindac, and ketoprofen are also effective. NSAIDS are continued for at least 24 hours after the resolution of the acute attack and then taped over 2 to 3 days. For patients who are unable to take NSAIDs or those who respond inadequately, second-line drugs are colchicine and glucocorticosteroids. Colchicine (Colcrys) is the prototype for the management of acute gout (Table 25.5)

Nursing Management of the Patient Receiving P Colchicine

Core Drug Knowledge

Pharmacotherapeutics

The most common use of colchicine is for treating acute gouty arthritis and as presurgical prophylaxis to prevent gout. A short course of colchicine may be given when uricosuric drug therapy is initiated to prevent a flare-up of gout symptoms. It is occasionally effective for other types of arthritis. Non–FDA-approved uses of colchicine include

TABLE 25.5 Summary of Selected Antigout Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
colchicine (Colcrys)	Acute gouty arthritis	*Adult PO:* 1.2 mg initially, then 0.6 1 h later max: 1.8 mg per attack	*Onset:* PO, 0.5–2 h *Duration:* PO, unknown; $t_{1/2}$: PO, 20 min
	Gout prophylaxis	*Adult:* PO, 0.6 2x/d *Child:* Safety and efficacy not established	

treatment of amyloidosis, Behçet syndrome, biliary cirrhosis, hepatic cirrhosis, Mediterranean fever, and scleroderma, as well as prophylaxis for recurrent pericarditis.

Pharmacokinetics

Colchicine can be given either orally or intravenously. However, parenteral use is avoided because of potential toxicity. Colchicine should never be injected subcutaneously or intramuscularly because such injections cause severe local irritation. Oral colchicine is rapidly absorbed, metabolized in the liver, and excreted primarily in the feces, with 10% to 20% eliminated unchanged in the urine. Patients with hepatic disease may have increased renal elimination. Enterohepatic recirculation occurs to a large extent and can lead to adverse GI effects with larger dosages. Colchicine distributes to the kidney, liver, spleen, and intestinal tissues and concentrates primarily in the leukocytes. It can be found in leukocytes for 10 days after administration.

Pharmacodynamics

Colchicine possesses anti-inflammatory properties. Although it is highly effective in treating acute gouty arthritis, it is not an effective analgesic for other types of pain, nor does it affect uric acid clearance. Colchicine inhibits the activity of leukocytes by decreasing their migration into the affected area, resulting in an interruption of the cyclic inflammatory response. Another action of colchicine is to prevent the release of an inflammatory glycoprotein from phagocytes, although it does not inhibit phagocytosis of uric acid crystals. Additional pharmacologic actions of colchicine include lowering body temperature, suppressing the respiratory center, and vasomotor stimulation, leading to hypertension. These actions can be extremely serious in cases of overdose.

Contraindications and Precautions

Colchicine is contraindicated in patients with severe cardiac disease, hepatic disease, and renal disease because these patients are at risk for developing cumulative toxicity. Other patients at risk for cumulative toxicity are elderly or debilitated patients. These patients should be monitored closely.

Patients with renal impairment or elevated plasma levels of colchicine because of renal disease can develop a myoneuropathy characterized by proximal weakness and elevated serum creatine kinase levels. This reaction usually occurs in patients who have been taking colchicine for several years; however, it is prudent to monitor all patients with renal insufficiency for this reaction.

Colchicine is eliminated primarily through the biliary pathway. Patients with hepatic disease should be monitored closely during treatment with colchicine. Additionally, patients at risk for hepatic disease, such as those with alcoholism, should be monitored closely.

Colchicine should be used cautiously in patients with pre-existing GI disease or depressed bone marrow function. These patients are at a higher risk for adverse effects of colchicine.

Patients with myelosuppression are at risk for infections or bleeding. Dental work should be performed before initiating colchicine therapy or deferred until blood counts return to normal.

Oral colchicine is classified as a pregnancy category C drug, and parenteral colchicine is in pregnancy category D.

Adverse Effects

The most common adverse effects of colchicine affect the GI tract. Up to 80% of patients taking colchicine may experience nausea, vomiting, diarrhea, abdominal pain, and paralytic ileus. These reactions can indicate toxicity, and the drug should be discontinued until the symptoms resolve.

Long-term therapy with colchicine may depress bone marrow function, inducing aplastic anemia, pancytopenia, thrombocytopenia, leukopenia, or agranulocytosis. Patients receiving parenteral colchicine experience depressed bone marrow function more frequently than do patients receiving the drug orally. Signs and symptoms of serious adverse reactions that must be reported to the prescriber include fever, chills, or sore throat; wheezing or difficulty breathing; muscle weakness; numbness or tingling in hands and feet; skin rash, itching; stomach pain; swelling of face or mouth; unusual bleeding, bruising, and pinpoint red spots on skin; and unusual tiredness or weakness.

Other adverse effects include renal, integumentary, hematologic, and endocrinologic effects. In the renal system, potential adverse effects are bladder spasms, nephrotoxicity, proteinuria, hematuria, anuria, and acute renal failure. Integumentary effects include angioedema, urticaria, injection-site reaction, skin necrosis, tissue necrosis, and median nerve neuritis. Effects on the endocrine system can include hypothyroidism.

Acute colchicine poisoning is a rare adverse effect. Symptoms include gastroenteritis, hypotension, lactic acidosis, and prerenal azotemia.

Drug Interactions

Colchicine can enhance the effects of radiation therapy or drugs that depress bone marrow function. Colchicine also may interact with cyanocobalamin (vitamin B_{12}), cyclosporine, erythromycin, and NSAIDs. Colchicine use may interfere with certain test results, yielding a false-positive finding when assessing for hemoglobin in urine. Table 25.6 presents potential drug interactions with colchicine.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for potential medical conditions or drugs that contradict the use of colchicine or require close patient monitoring. Assess the joints for edema, erythema, or increased warmth. In addition, assess for signs of hypothyroidism. Obtain a baseline CBC, platelet count, and tests for renal and hepatic function.

Life Span and Gender

Determine whether a female patient is pregnant or breastfeeding. Because oral colchicine is classified as a pregnancy

TABLE 25.6 Agents That Interact with P Colchicine

Interactants	Effect and Significance	Nursing Management
agents that cause bone marrow suppression	Drugs possessing hematoxic properties similar to those of gold salts may potentiate the action of both agents, resulting in bone marrow suppression.	Avoid coadministration if possible. Monitor complete blood count (CBC) and platelet count frequently. Monitor patient for sore throat, chills, easy bruising, or bleeding tendencies.
cyclosporine	Cyclosporine may cause hyperuricemia. Concomitant use of cyclosporine and colchicine may also increase cyclosporine concentrations, resulting in a high risk of nephrotoxicity.	Avoid coadministration, if possible. Monitor blood urea nitrogen, creatinine, and cyclosporine levels. Monitor intake and output.
macrolide antibiotics	The addition of macrolide antibiotics to colchicine therapy may lead to colchicine toxicity.	Monitor for fever, gastrointestinal (GI) symptoms, myalgia, and leukopenia.
ethanol (alcohol)	Ethanol ingestion increases the risk of adverse GI effects and can increase serum urate concentration, thus decreasing the antigout effects of colchicine.	Avoid alcohol ingestion during therapy. Monitor for effectiveness of colchicine.
nonsteroidal anti-inflammatory drugs (NSAIDs)	Concomitant use of NSAIDs and colchicine increases the likelihood of developing adverse GI effects, especially ulceration or hemorrhage.	Avoid coadministration. Monitor for adverse GI effects. Monitor for easy bruising or bleeding.

category C drug, it should be avoided by pregnant or breast-feeding women. Parenteral colchicine, in pregnancy category D, should never be administered to pregnant or breast-feeding women.

Lifestyle, Diet, and Habits

Evaluate the patient's diet. High consumption of red meat products and seafood confers a high risk of hyperuricemia and resultant gout. Dairy products, vegetables, nuts, legumes, fruits (with minimal sugar), and whole grains may help prevent gout by reducing insulin resistance. (Choi, 2010). Also, evaluate the patient's intake of alcohol and beer. Alcohol can cause both overproduction and underexcretion of uric acid. Beer contains a high content of the purine guanosine, which increases the uric acid level. Assess the patient's fluid intake, because dehydration can trigger acute gout attacks. It is important to ensure that the patient consumes adequate amounts of fluids. Plasma uric acid levels rise during starvation. Therefore, ensure that the patient eats at regular intervals throughout the day.

Environment

Be aware that colchicine is self-administered most frequently by patients in the home environment. Patients are advised to take the drug three to four times a day unless nausea, vomiting, or diarrhea occurs, or the maximum dose for one day is reached. In special circumstances, colchicine can be given intravenously in an acute care setting. However, this is rarely done because of colchicine's narrow therapeutic margin and because the drug has been associated with induction of aplastic anemia, which can result in death.

Nursing Diagnoses and Outcomes

- Acute Pain related to drug-induced abdominal cramps or paralytic ileus
  Desired outcome: The patient will contact the prescriber if abdominal pain occurs.
- Risk for Injury related to drug-induced renal toxicity or possible extravasation of IV colchicine
  Desired outcome: The patient administering colchicine at home will contact the prescriber if urinary changes occur. The hospitalized patient will remain free of extravasation of IV colchicine.
- Risk for Deficient Fluid Volume related to drug-induced nausea, vomiting, and diarrhea
  Desired outcome: The patient will contact the prescriber if GI symptoms occur.
- Ineffective Protection related to possible blood dyscrasias
  Desired outcome: The patient will contact the prescriber if sore throat, easy bruising, or lethargy occurs.

Planning and Intervention

Maximizing Therapeutic Effects

In an acute care setting, administer colchicine with a full glass of water at evenly spaced intervals throughout the day. Patients who self-administer the drug should follow the regimen prescribed by the health care provider. Generally, patients who have less than one attack per year take low-dose colchicine 3 or 4 days a week. For patients with more frequent attacks, colchicine is taken daily. Adherence to diet and alcohol restrictions decreases hyperuricemia, thus allowing colchicine to achieve its maximum effect.

Minimizing Adverse Effects

Closely monitor patients with pre-existing medical conditions or those on drug therapy that may interact with colchicine. For an acute attack, the patient needs to take colchicine at the first sign of an acute gout attack.

It is important to question the female patient about the possibility of pregnancy before administering intravenous colchicine. Administer intravenous colchicine cautiously and monitor frequently for signs of extravasation.

Providing Patient and Family Education

- Advise patients not to take colchicine if they have severe cardiac disease, hepatic disease, or renal disease.
- Make sure that pregnant or breast-feeding patients are not given intravenous colchicine.
- Advise patients to take colchicine at the first sign of a gout attack and to follow the directions on the drug container.
- Tell patients that if they miss a dose, they should take it as soon as they can. If it is almost time for the next dose, only that dose should be taken; patients should not take double or extra doses.
- Emphasize that colchicine can cause minor side effects, such as loss of appetite and hair loss, and that patients should tell their health care teams if the adverse effects do not go away or if they are particularly annoying.
- Caution patients to report GI adverse effects (e.g., nausea, vomiting, diarrhea, and abdominal pain) because these symptoms could indicate drug toxicity or lead to fluid loss over time.
- Stress to patients that colchicine can cause serious adverse effects and that they should call their prescribers immediately if any signs and symptoms occur, including sore throat, easy bruising, lethargy, or signs of renal toxicity.
- Advise patients to avoid alcohol because it can cause stomach problems and increase uric acid concentrations in the blood, making a gouty attack more likely. Review foods that are high in purines to decrease dietary intake of uric acid.
- Inform patients that colchicine may produce severe adverse effects when coadministered with many prescription and OTC drugs and advise them never to take any other drugs without consulting their prescribers.
- Tell patients to keep colchicine away from light and out of the reach of children.
- Stress that patients must see their health care teams every month for blood and urine tests to make sure that they are not experiencing adverse effects from colchicine.

Ongoing Assessment and Evaluation

Monitor for hematopoietic and renal toxicity, joint involvement, deformity, and range of motion. The patient needs to be monitored for efficacy of colchicine therapy.

Therapy is considered effective if the patient reports decreased frequency of acute gout attacks and remains free of adverse effects. The patient should understand and be able to explain the importance of contacting the health care team immediately if any adverse effects occur, of scheduling periodic hematologic and renal testing, and of contacting the prescriber before taking any other prescription or OTC drugs.

MEMORY CHIP

P Colchicine

- Decreases the inflammatory reaction of **acute** gout
- Major contraindications: severe cardiac, hepatic, or renal diseases
- Most common adverse effects: related to gastrointestinal system
- Most serious adverse effects: blood dyscrasias, including bone marrow suppression
- Maximizing therapeutic effects: adherence to diet and alcohol restrictions to reduce hyperuricemia
- Minimizing adverse effects: Take colchicine at the first sign of an attack, then only until the symptoms start to resolve.
- Most important patient education: related to diet and alcohol restrictions

Drugs Significantly Different From P Colchicine

Glucocorticoid steroids are also prescribed for acute gout. They may be given orally or as an intra-articular injection. Teach patients taking oral steroids to follow the health care provider's instructions carefully and never abruptly stop the medication. Explain the process of tapering the drug to avoid complications. For patients receiving an intra-articular injection, teach them to avoid overuse of the joint until the acute attack is resolved. For in-depth coverage of glucocorticoid steroids, see Chapter 48.

• Drugs for Gout Prophylaxis

Uricosuric drugs balance urate concentration. Because they have no anti-inflammatory or analgesic activity, they are not useful in treating acute gout attacks. In fact, when first initiated, they can exacerbate an acute attack of gout. Uricosuric drugs include allopurinol, probenecid, and sulfinpyrazone. Allopurinol (Zyloprim, Lopurin) is the prototype uricosuric drug. Table 25.7 presents a summary of uricosuric drugs.

Nursing Management of the Patient Receiving P Allopurinol

Core Drug Knowledge

Pharmacotherapeutics

Allopurinol is indicated for the management of chronic gout, recurrent calcium renal stones, and hyperuricemia related to cancer or tumor lysis syndrome. Off-label uses include prevention of ischemic reperfusion tissue damage and arrhythmias in patients who have undergone

TABLE 25.7 Summary of Selected Uricosuric Drugs

P allopurinol (Zyloprim)	Gout Prophylaxis	Adult: PO, 200–600 mg/d divided 2–4× d Child: Not approved	Onset: 30 min–1 h Duration: 18–30 h $t_{1/2}$: 1–2 h; metabolite, 18–30 h
febuxostat	Gout Prophylaxis	Adult: PO 40–80 mg daily Child: Not approved	Onset: rapid Duration: unknown T1/2: 5–8 h
probenecid (Benemid;	Gout Prophylaxis	Adult: PO, 500 mg 2× d Child: Not approved	Onset: 30 min Duration: 3–8 h $t_{1/2}$: 4–7 h
sulfinpyrazone (Anturane)	Chronic gout, inhibition of platelet aggregation	Adult: PO 100–400 mg 2× d Child: Safety and efficacy not established	Onset: 30 min Duration: 4–6 h $t_{1/2}$: 3 h
Combination Drugs			
probenecid and colchicine (ColBenemid, Col-Probenecid, Proben-C)	Chronic gout	Adult: PO, 1 tablet 2×/d (500 mg probenecid and 0.5 mg colchicine)	See individual drugs

coronary artery bypass surgery; decrease in Helicobacter pylori–induced duodenal ulcer recurrence rates; treatment of hematemesis from NSAID-induced erosive gastritis; decrease in pain in patients with acute pancreatitis; and reduction of renal transplant rejection in patients receiving triple immunosuppressive therapy.

Pharmacokinetics

Allopurinol may be administered orally or intravenously. When given orally, approximately 90% is absorbed. It is widely distributed except to the central nervous system. It undergoes hepatic metabolism and is rapidly oxidized to oxypurinol. Both the parent drug and oxypurinol have renal elimination.

Pharmacodynamics

Allopurinol decreases the production of uric acid by inhibiting the action of xanthine oxidase, an enzyme that converts hypoxanthine to xanthine and xanthine to uric acid. Because of the decrease in uric acid concentration, there are fewer urate deposits, a circumstance which prevents or decreases tophi formation, chronic joint changes, and the formation of uric acid or calcium oxalate calculi.

Contraindications and Precautions

The only contraindication to allopurinol is hypersensitivity. The drug should be given cautiously to patients who cannot sustain a fluid intake of 2 L/d (e.g., those with CHF), because increased fluid intake is required to avoid complications such as formation of xanthine calculi or renal precipitation of urates. Other precautions include decreased renal or liver function. Care should be used in patients taking thiazide diuretics or drugs that may induce myelosuppression such as azathioprine.

Adverse Effects

Therapeutic dosages of allopurinol are generally well tolerated, with few adverse effects. The most common adverse effects include pruritus, maculopapular rash, nausea and vomiting, elevated liver function tests, and acute gout symptoms. Serious adverse effects include blood dyscrasias, myelosuppression, hepatic or renal toxicity, exfoliative dermatitis, and Stevens-Johnson syndrome.

Drug Interactions

Allopurinol interacts with many drugs that increase the potential for a hypersensitivity reaction to allopurinol. Allopurinol interacts with many immunosuppressive and cytotoxic drugs, resulting in an increased risk of myelosuppression. Table 25.8 presents potential drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for potential medical conditions or drug therapies that contraindicate the use of allopurinol or require close patient monitoring. Obtain baseline CBC, uric acid level, liver function tests, and metabolic profile. Document baseline joint stiffness and range of motion and patient's pain level.

Life Span and Gender

Determine whether a female patient is pregnant or breastfeeding. Allopurinol is a pregnancy category C drug. There are no human clinical trials to ensure its safety during pregnancy. Fortunately, gout is very rare in women during their reproductive years. The potential effect to an infant who receives breast milk is unknown.

Dosage adjustment is necessary for elderly patients with impaired renal function.

Lifestyle, Diet, and Habits

Administer allopurinol after a meal to decrease the potential for nausea or vomiting. Encourage the patient to follow the same diet plan for patients taking colchicine to avoid

TABLE 25.8 Agents That Interact with P Allopurinol

Interactants	Effect and Significance	Nursing Management
ampicillin/amoxicillin	Although the mechanism of action is not understood, allopurinol may increase the frequency of ampicillin-induced rash.	Monitor for rash; contact the health care provider should rash appear. Do not assume ampicillin-induced rash; hypersensitivity to allopurinol must be considered.
antacids, aluminum salts	Antacids and aluminum salts decrease the absorption of allopurinol, decreasing its efficacy	Monitor for signs of acute gouty arthritis.
azathioprine/mercaptopurine	Azathioprine converts to mercaptopurine. Allopurinol inhibits the first-pass metabolism of mercaptopurine, resulting in an increased risk of toxicity.	Discuss the need for dosage adjustment of azathioprine with the health care provider (dosage should be decreased 25%–33%). Monitor for immunosuppression.
captopril	Captopril is associated with an increased risk of hypersensitivity to allopurinol.	Monitor for rash. Monitor CBC. Monitor renal/hepatic status.
cyclophosphamide	Allopurinol may increase the myelosuppressive effects of cyclophosphamide.	Monitor CBC. Monitor for bruising and bleeding. Monitor for signs of infection.
hydantoins	Allopurinol inhibits the metabolism of hydantoins, resulting in an increased risk of adverse effects and toxicity.	Monitor hydantoin levels. Monitor CBC, liver function tests. Monitor for changes in speech, thought process, and gait.
theophylline/aminophylline	Allopurinol decreases the renal clearance of theophylline, resulting in an increased risk of adverse effects and toxicity.	Monitor for signs of toxicity, such as nausea, tachycardia, and nervousness.
warfarin	Allopurinol may inhibit the hepatic metabolism of warfarin. This interaction is unpredictable.	Monitor PT/INR Monitor for signs of bleeding.

decreasing the efficacy of drug therapy. Teach the patient to ingest 2.5 to 3 L of fluid daily to avoid renal calculi.

Nursing Diagnoses and Outcomes

- Increased Risk for Injury related to allopurinol-induced renal toxicity
  Desired outcome: The patient will contact the prescriber if any urinary changes occur.
- Deficient Fluid Volume related to nausea and vomiting
  Desired outcome: The patient will contact the prescriber if nausea and vomiting persist.
- Ineffective Protection related to drug-induced blood dyscrasias
  Desired outcome: The patient will contact the prescriber if sore throat, easy bruising, or lethargy occurs.

Planning and Intervention

Maximizing Therapeutic Effects

Administer allopurinol in conjunction with colchicine to decrease the potential for a gout flare-up in the initial stages of therapy. Assist the patient to develop meal plans that limit uric acid production.

Minimizing Adverse Effects

Administer after meals to decrease nausea or vomiting. Fluid intake should range between 2.5 and 3 L/d (unless contraindicated) to minimize potential for renal stone formation. Review the allopurinol order. Allopurinol therapy is generally started at 100 mg daily, then increases 100 mg at weekly intervals until the uric acid level is less than 6 mg/dL or the maximum dose is reached. Teach the patient the importance of following this schedule to avoid an acute gout flare.

Providing Patient and Family Education

- Emphasize the need to follow the health care provider's dosage instructions. Advise patients not to hasten the schedule or double the dose, even if a dose is missed.
- Advise patients that allopurinol can cause minor adverse effects, such as nausea, vomiting, and pruritus. Teach patients to contact the health care provider if they do not go away or if they are particularly annoying.
- Advise patients that any rash needs to be evaluated by the health care provider.
- Be sure patients understand that allopurinol can cause serious adverse effects and that they should call their health care teams immediately if they observe signs of

renal toxicity (urinary changes) or signs of blood abnormalities (e.g., sore throat, easy bruising, or lethargy).
- Advise patients that optimal benefits from allopurinol therapy may take 2 to 6 weeks.
- Stress to patients that they should avoid alcohol because it can cause stomach problems and increase uric acid levels in the blood, which makes a gouty attack more likely.
- Inform patients of foods that decrease uric acid production.
- Tell patients to drink at least 2.5 to 3 L of water a day to prevent renal stones.
- Explain the importance of routine follow-up to assess efficacy of drug therapy and to monitor for potential adverse effects.
- Advise patients to never start or stop allopurinol therapy during an acute flare.

Ongoing Assessment and Evaluation

Coordinate serial laboratory tests, including uric acid level, CBC, and liver and renal function tests. The goal of therapy is to lower the uric acid level to less than 6 mg/dL. Consistently monitor for rash at each visit. Ask the patient to describe joint stiffness or pain and any limitation of movement.

Therapy is considered effective when the patient reports reduced pain and inflammation and remains free of adverse effects. In addition, the patient should express an understanding of the need to contact the health care provider immediately if a rash occurs, and of the advantages of increasing fluid intake, refraining from alcohol, and making appropriate diet choices.

Drugs Similar to P Allopurinol

Febuxostat

Febuxostat (Uloric) is a xanthine oxidase inhibitor approved for the management of hyperuricemia in patients with gout. It differs from allopurinol because it is not a purine base analogue. In a recent study febuxostat outperformed allopurinol in its ability to achieve and maintain a uric acid level less than 6 mg/dL (Becker, Schumacher, MacDonald, 2009).

Febuxostat should not be used in patient taking theophylline, azathioprine, or mercaptopurine. It raises the serum levels of these drugs and increases the risk for toxicity of these drugs.

A gout flare may occur with the initiation of febuxostat. Encourage patients to continue the drug despite the flare. NSAIDS or colchicine may be given to control the flare. Common adverse effects include nausea, arthralgias, rash and liver function abnormalities. Febuxostat is also associated with an increased risk for thromboembolic events such as heart or brain attacks (MI and CVA, respectively). Monitor carefully for these potential adverse effects. Febuxostat is a pregnancy category C.

Drugs Significantly Different From P Allopurinol

Probenecid (Benemid, Probalan) and sulfinpyrazone (Anturane) are also uricosuric drugs, which differ from allopurinol by their mechanism of action. Allopurinol works by inhibiting uric acid formation, whereas probenecid and sulfinpyrazone work by increasing uric acid excretion.

Probenecid

Probenecid is an oral drug that interferes with tubular handling of organic acids within the nephron. It inhibits the active resorption of uric acid at the proximal convoluted tubules, resulting in increased excretion of uric acid. It also reduces the renal tubular secretion of some antibiotics. Because the antibiotics are not excreted, serum concentrations are elevated, and their activity is prolonged.

Probenecid is contraindicated in patients with blood dyscrasias or uric acid kidney stones because the drug can exacerbate these conditions. It should not be administered to patients with severe renal impairment (glomerular filtration rate less than 50 mL/min) or to patients with medical conditions in which uric acid production can increase acutely, such as those undergoing cancer chemotherapy or radiation therapy.

Therapeutic dosages of probenecid are generally well tolerated, with few adverse effects. The most common adverse effects are similar to those of allopurinol. Some patients with gout can experience an increased incidence of uric acid stones or of acute gouty attacks during the first 6 to 12 months of therapy. These increases occur because of increased renal clearance of uric acid. Probenecid interferes with the copper sulfate urine glucose tests that may be used by patients with diabetes. Advise patients with diabetes who are taking the drug to use capillary blood glucose monitoring.

In addition to the dietary considerations for allopurinol, teach patients to avoid cranberry juice and vitamin C. These substances tend to acidify the urine, which decreases probenecid excretion; thus, there is an increased risk of adverse effects and toxicity. Nursing management and ongoing assessment are similar to those with allopurinol.

MEMORY CHIP

P Allopurinol

- Used for the management of **chronic** gout
- Major contraindications: coadministration with drugs that induce myelosuppression.
- Most common adverse effects: pruritus, maculopapular rash, nausea and vomiting, elevated liver function test values, and acute gout symptoms
- Most serious adverse effects: blood dyscrasias, severe dermatologic disorders
- Maximizing therapeutic effects: adhere to diet that limits uric acid production
- Minimizing adverse effects: Ingest 2.5 to 3 L of fluid daily.
- Most important patient education: Any rash must be evaluated by the health care provider.
- Nursing alert: Many drugs increase the incidence of hypersensitivity that is potentially fatal.

Sulfinpyrazone

Sulfinpyrazone is an active metabolite of the NSAID phenylbutazone, so it has some anti-inflammatory effects. Its action is the same as that of probenecid; however, it is longer acting and more potent. In addition to increasing uric acid excretion, sulfinpyrazone inhibits platelet aggregation and thus can be used in the prophylaxis of myocardial infarction. Because of its antiplatelet action, monitor the patient for signs of bleeding and do not administer sulfinpyrazone with other drugs, such as salicylates or anticoagulants (warfarin), which affect platelet aggregation. Sulfinpyrazone may induce GI distress; thus, administering the drug with meals or milk may be helpful.

CHAPTER SUMMARY

- Arthritic inflammatory diseases are initially treated with salicylates and NSAIDs.
- Disease-modifying antirheumatic drugs (DMARDs) delay joint destruction and should be initiated within 3 months of diagnosis of rheumatoid arthritis.
- DMARDs have a common goal of reducing the progression of rheumatoid arthritis but have different mechanisms of action to achieve that goal.
- There are two types of DMARDS: non-biological and biological. Pharmacologic classes of DMARDs include alkylating agents, antimetabolites, antimalarials, gold salts, sulfonamide antibiotics, tumor necrosis factor (TNF) inhibitors, monoclonal antibodies, interleukin antagonists, and immune response modifiers.
- Methotrexate is the DMARD of choice for most rheumatologists. Its efficacy is enhanced when given in combination with TNF inhibitors or other biological DMARDS.
- TNF inhibitors and other biologic DMARDs may induce serious infections or malignancies.
- Patients receiving biological DEMARDS must be evaluated for systemic infections including bacteria, virus, fungi, or TB prior to initiation of therapy and throughout therapy.
- Gout is a disease of altered purine metabolism resulting in hyperuricemia. However, hyperuricemia alone does not always result in gout.
- Antigout drugs resolve symptoms in two different ways: colchicine opposes leukocyte phagocytosis, which inhibits further urate deposits, whereas uricosuric agents reduce hyperuricemia.

QUESTIONS FOR STUDY AND REVIEW

1. What advantage do DMARDs have over salicylates, NSAIDs, and acetaminophen?
2. What is the major disadvantage of using DMARDs?
3. What is the advantage of using DMARDs within 3 months of diagnosis of RA?
4. Why are so many different classes of medications under the umbrella term DMARD?
5. What is TNF?
6. What contraindication and potential adverse effect is common to all TNF inhibitors? Why?
7. Why are biologic drugs such as etanercept, abatacept, and anakinra not given as combination therapy with each other?
8. Compare colchicine and allopurinol.

UNIT 7

Hematopoietic, Cardiovascular, and Renal System Drugs

26

Drugs Affecting Blood Pressure

Learning Objectives

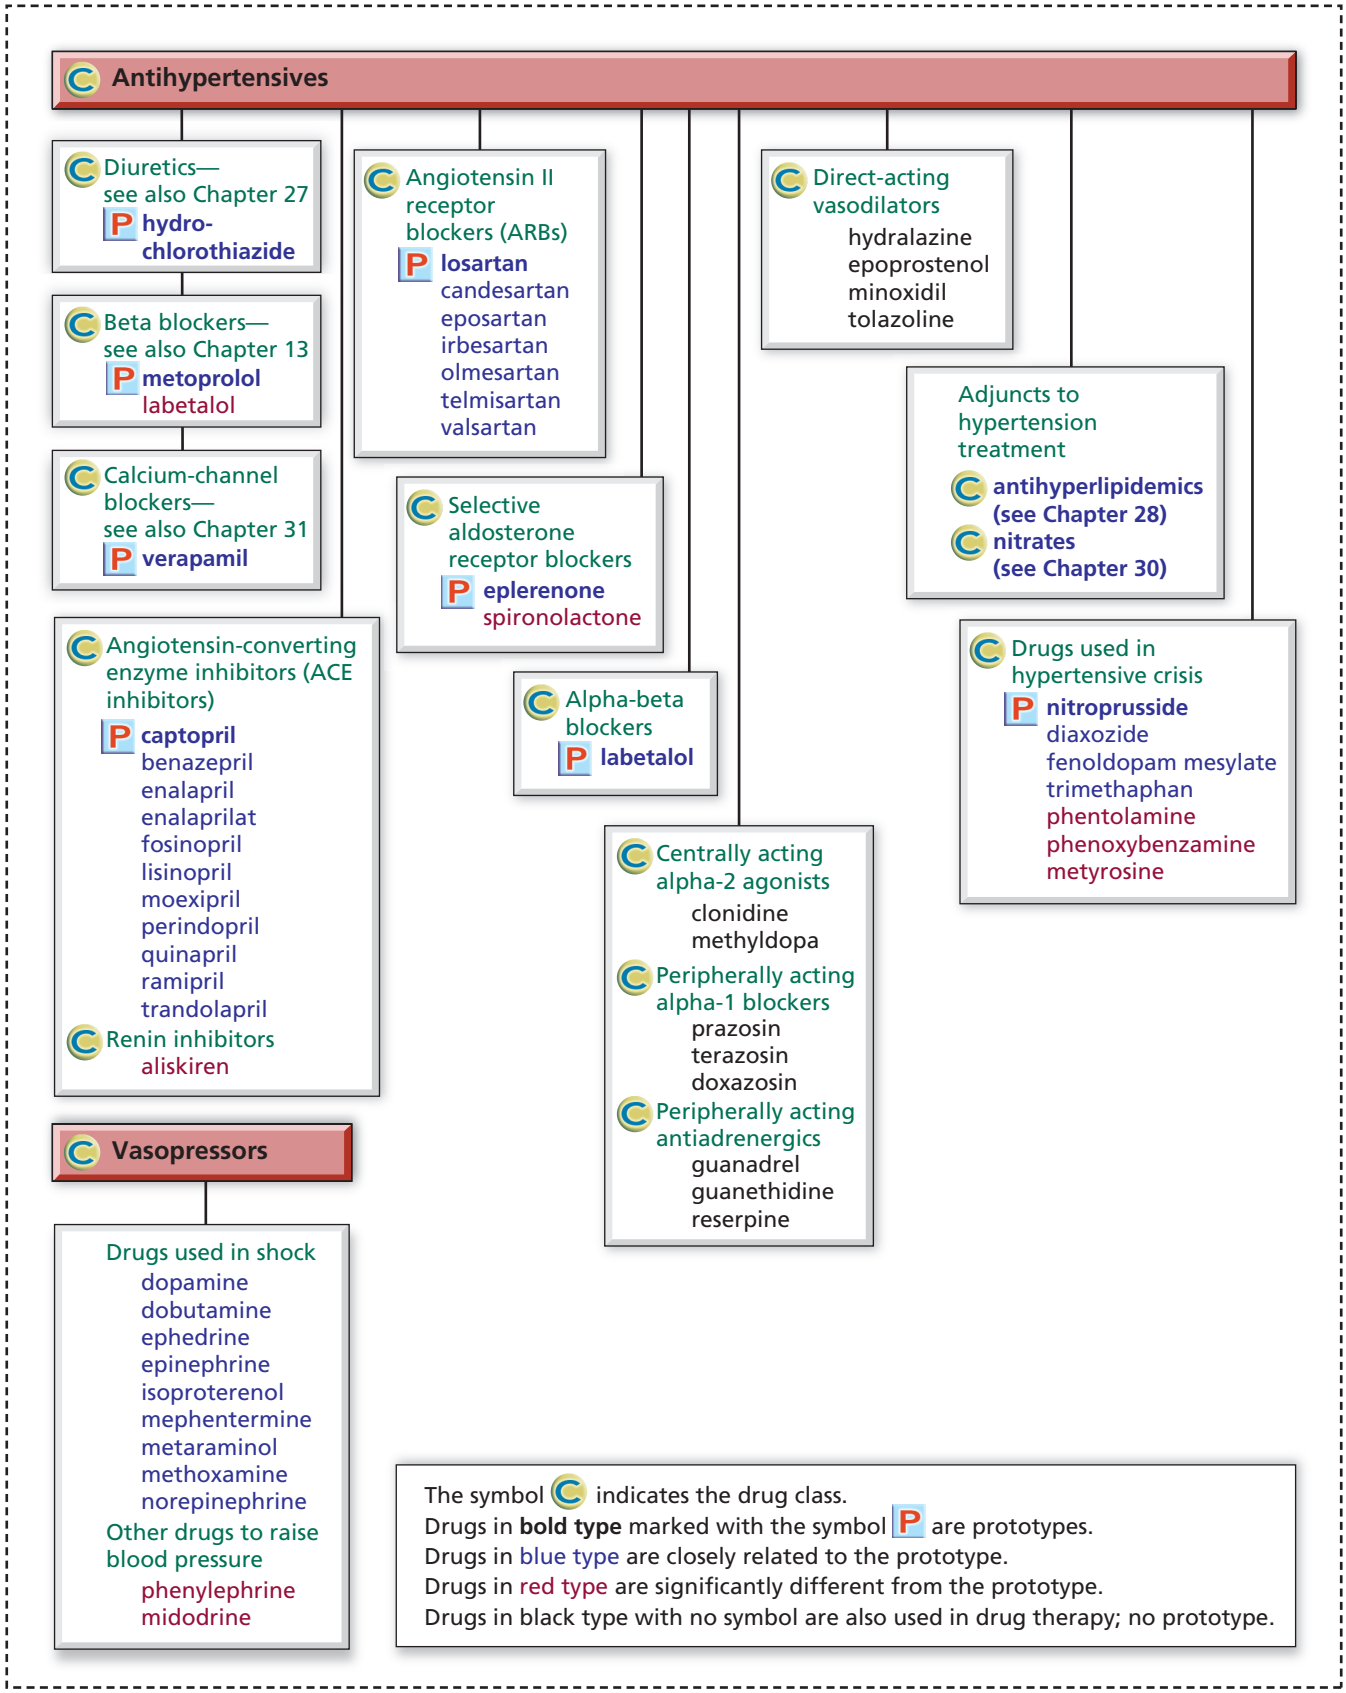
At the completion of this chapter the student will:

1. Describe therapy appropriate for prehypertension, stage 1 hypertension, and stage 2 hypertension.
2. Identify the core drug knowledge for drugs that affect blood pressure.
3. Differentiate the antihypertensive drug classes.
4. Identify core patient variables relevant to drugs that affect blood pressure.
5. Relate the interaction of core drug knowledge to core patient variables for drugs that affect blood pressure.
6. Generate a nursing plan of care from the interaction between core drug knowledge and core patient variables for drugs that affect blood pressure.
7. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect blood pressure.
8. Determine key points for patient and family education for drugs that affect blood pressure.

Key Terms

cardiac cycle
diastole
diastolic blood pressure
essential hypertension
hypertension
hypertensive crisis
primary hypertension
renin-angiotensin-aldosterone system
secondary hypertension
shock
sympatholytic
sympathomimetic
systole
systolic blood pressure

Drugs Affecting Blood Pressure



Hypertension occurs when systolic or diastolic blood pressure is elevated beyond normal ranges over time. Lifestyle changes and antihypertensive drugs may be used to restore blood pressure to normal levels and to prevent the adverse effects of hypertension. The main drug classes used as first-line treatment for hypertension are diuretics, beta blockers, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and selective aldosterone blockers. The drug classes used as second-line treatment for hypertension are direct vasodilators, alpha-2 stimulators, alpha-1 blockers, and antiadrenergics. These drugs are discussed briefly in this chapter.

Although many of these drug classes have multiple therapeutic indications, this chapter focuses on their capacity as antihypertensives. Diuretics, beta blockers, and calcium channel blockers and their prototypes are discussed in greater depth elsewhere in the text. The prototype ACE inhibitor is captopril (Capoten). A drug significantly different is the novel renin inhibitor, aliskiren (Tekturna). The prototype ARB is losartan (Cozaar). The prototype selective aldosterone receptor blocker is eplerenone (Inspra). The prototype beta blocker is metoprolol (Lopressor), and a drug significantly different from metoprolol is labetalol an alpha-beta blocker. Another alpha-beta blocker, carvedilol (Coreg), is also used in the treatment of chronic heart failure (HF); this is discussed further in Chapter 29.

This chapter also examines drugs used to treat hypertensive crises and drugs used to increase blood pressure. The prototype drug used to treat hypertensive crises is nitroprusside. The prototype vasopressor is dopamine. The use of dopamine in shock is discussed in this chapter, and the full discussion of dopamine as a prototype is in Chapter 13. Treatment of hypotension from other conditions is also presented briefly.

PHYSIOLOGY

The heart is composed of four chambers: the left atrium, the right atrium, the left ventricle, and the right ventricle. Blood is returned from the body to the right atrium and then progresses to the right ventricle and on to the lungs, where it is reoxygenated and carbon dioxide is removed. The reoxygenated blood returns to the left atrium and then to the left ventricle. The contraction of the left ventricle pushes the blood into the aorta; thus, it returns to systemic circulation.

Blood is circulated throughout the body by a coordinated sequence of chamber contractions and valve openings and closings known as the **cardiac cycle.** The two phases of the cardiac cycle are systole and diastole. Together they describe the timeframe from the beginning of one heartbeat to the beginning of another. During **systole,** the ventricles contract, and the aortic and pulmonic valves open, allowing blood to be ejected into the aorta and pulmonary artery. During **diastole,** the ventricles relax, and the mitral and tricuspid valves open; at the same time, blood flows into the atria. This blood is propelled into the ventricles by atrial contraction, which occurs at the end of diastole. As systole begins again, the increased pressure from ventricular contraction causes the mitral and tricuspid valves to shut.

Contractions of the heart propel blood through the vascular system. Each contraction increases outflow from the heart and pushes along the volume of blood already in the systemic circulation. As the blood moves through the circulatory system, the tightness or constriction (tension) of the vessels provides resistance. Arterial pressure, which results from these forces, is measured as blood pressure. The highest pressure is achieved during systole (when the heart contracts and ejects blood into the circulation) and is known as **systolic blood pressure.** The lowest pressure that can be measured is achieved during diastole (when the heart relaxes and fills with blood and the vessels propel the blood already in circulation) and is known as **diastolic blood pressure.**

Blood pressure is measured in millimeters of mercury (mm Hg) and is calculated by measuring the amount of blood leaving the heart multiplied by the amount of resistance in the peripheral vessels. The formula for measuring blood pressure is blood pressure = cardiac output × peripheral resistance, or BP = CO × PR. Figure 26.1 depicts the mechanisms involved in regulating blood pressure.

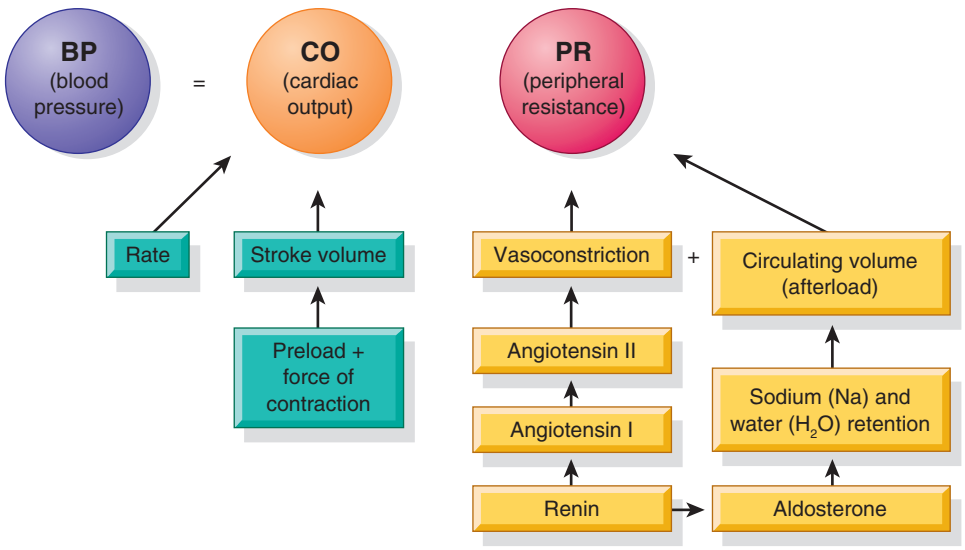
When cardiac output or peripheral resistance increases, blood pressure increases. When cardiac output or peripheral resistance decreases, blood pressure decreases. When cardiac output and peripheral resistance move in opposite directions, the effect on blood pressure is related to the net difference between the two (example: if cardiac output decreases more than peripheral resistance increases, then the net effect will be to decrease the blood pressure). Several innate mechanisms regulate blood pressure by affecting either cardiac output or peripheral resistance. If you think of blood pressure as a math equation, then it makes sense that drug therapy to change blood pressure (the product) must either effect cardiac output or peripheral resistance (the two factors) in some way.

Role of Adrenergic Receptors

Adrenergic receptors in the nervous system have a role in blood pressure management. Adrenergic receptors are grouped into receptor sites—alpha-1, alpha-2, beta-1, and beta-2. When alpha-1 receptors are stimulated, they cause peripheral constriction, and blood pressure increases as a result. This effect, which is similar to stimulation of the sympathetic nerves, is called a **sympathomimetic** effect (one that mimics the effect of the sympathetic system). Conversely, blockage of these receptor sites dilates resistance vessels (arterioles) and capacitance vessels (veins), thereby decreasing pressure.

Alpha-2 receptor sites are located on the presynaptic side of the neural synapse within the brain. Stimulation of these receptors inhibits the sympathetic system, causing a **sympatholytic** effect (one that stops the effect of the sympathetic system). The resulting reduction in sympathetic outflow from the central nervous system (CNS) has two effects. It decreases the heart rate and, therefore, cardiac output. It also decreases vasoconstriction, which reduces peripheral resistance. The effect from both of these actions is a decrease in blood pressure.

Beta-1 receptor sites are located primarily in the heart. Stimulation of beta-1 receptor sites increases the heart rate, the speed



• FIGURE 26.1 Mechanisms involved in regulating blood pressure. To alter blood pressure, either cardiac output or peripheral vascular resistance must change. The ideal is a balance between them. Some antihypertensive drugs alter cardiac output and some change vascular resistance.

of cardiac conduction, and the force of cardiac contraction. Cardiac output is increased, thereby increasing blood pressure.

Beta-2 receptor sites are located primarily in the bronchial and vascular musculature. Stimulation of these sites induces bronchial and peripheral dilation. The peripheral dilation contributes to decreased blood pressure by decreasing peripheral resistance. If beta-1 and beta-2 receptors are stimulated at different rates, the one with the greatest stimulation will show its effect on blood pressure. If both beta-1 and beta-2 receptor sites are stimulated equally and simultaneously, the effect on blood pressure is negligible. (See Chapter 13 for more information about adrenergic receptors.)

Role of Renin-Angiotensin-Aldosterone System

Another mechanism involved in blood pressure regulation is the **renin-angiotensin-aldosterone system.** Renin, which is synthesized by the kidneys, produces angiotensin I. Angiotensin I is a basically inactive substance until it is converted to the active angiotensin II by a special enzyme, angiotensin-converting enzyme (ACE). Angiotensin II is formed from various alternative pathways and is also formed at the cellular level. Angiotensin II is a potent vasoconstrictor. It also stimulates secretion of aldosterone from the adrenal medulla. Aldosterone increases retention of sodium and water in the body, which, in turn, increases circulating volume. The resulting vasoconstriction and increased circulating volume raise blood pressure by increasing peripheral resistance and cardiac output. The effects on vasoconstriction and circulating volume have traditionally been viewed as the total effects of aldosterone and angiotensin II on hypertension. Additional effects from angiotensin II and aldosterone are now recognized that contribute to the pathologies seen with hypertension. These hormones also promote the growth of certain cells and stimulate increased mass in both the arterial wall and the left ventricle. Angiotensin II and aldosterone make the following more likely to occur: inflammation of the vessels, thrombosis, oxidative stress, chronic heart failure (CHF), cardiac arrhythmias, reduced fibrinolysis, and sudden cardiac death. Aldosterone is also believed to play a role in structural renal injury, proteinuria, collagen synthesis, and myocardial fibrosis. When released by the adrenals into the circulation, aldosterone appears to be taken up by cardiac tissue, resulting in cardiac damage (Fiebeler, Nussberger, Shagdarsuren, et al., 2005). Although the interruption of the renin-angiotensin-aldosterone system is target-organ protective, complete blockade is difficult to achieve because the body has some escape mechanisms; aldosterone levels remain elevated even though angiotensin II production is inhibited or its action is blocked. These escape mechanisms are not completely understood, but aldosterone has been identified as an important escape mediator (Fiebeler, Nussberger, Shagdarsuren, et al., 2005).

PATHOPHYSIOLOGY

Hypertension is a chronic disorder. Why is hypertension a problem? The answer to this is clear from these statistics about adults with hypertension from the American Heart Association (statistics are from the most current year available as of 2009).

> "In the United States, hypertension affects an estimated 73.6 million people aged 20 years and older, or approximately 1 in 3 adult Americans Twenty-one percent of these people do not realize that they have high blood pressure. High blood pressure was listed on death certificates as the primary cause of death of 57,356 Americans in 2005. High blood pressure was listed as a primary or contributing cause of death in about 319,000 of the more than 2.4 million U.S. deaths in 2005. The 2005 overall death rate from HBP (per 100,000 people) was 18.4. From 1995 to 2005 the death rate from HBP

increased 25.2 percent, and the actual number of deaths rose 56.4 percent." (American Heart Association, 2009a).

Hypertension is common in all racial groups, although some groups are more prone to hypertension than others. In the United States, Native Americans have about the same, or a somewhat higher, incidence of hypertension than the general population. Hispanics have generally the same, or a lower, rate than non-Hispanic whites, but African Americans have the highest rate. About 40% of African Americans have hypertension (American Heart Association, 2009b). Compared with white Americans, African Americans have an earlier onset, higher prevalence, and greater rate of stage 2 hypertension. This explains why African Americans also have a greater rate of nonfatal stroke, fatal stroke, death from heart disease, and end-stage kidney disease. Rates of hypertension do vary within the African American population. Those African Americans with the highest rates are more likely to be middle aged or older, less educated, overweight or obese, physically inactive, and diabetic. Death rates from hypertension are higher for African Americans than for whites and are higher for black males than black females (American Heart Association, 2009a).

Part of the explanation for the variation in hypertension among races may be the variation of obesity, a known risk factor for hypertension. Obesity and being overweight are defined by an elevated body mass index (determined by dividing the weight in kilograms by the height in meters squared), an indicator of how much body fat is present. For adults, a BMI score of 30 or greater indicates obesity (Box 26.1). According to the Centers for Disease Control, adult "blacks had 51% higher prevalence of obesity, and Hispanics had 21% higher obesity prevalence compared with whites. Greater prevalences of obesity for blacks and whites were found in the South and Midwest than in the West and Northeast. Hispanics in the Northeast had lower obesity prevalence than Hispanics in the Midwest, South or West" (CDC, 2009b).

Minority (Mexican American, African American, Native American) children are also more likely to be overweight or obese compared to nonminority (Caucasian American) children and thus are more likely to have hypertension (Flynn, 2009; Eichner, Moore, Perveen, et al., 2008; Moore, Stephens, Wilson, et al., 2006; Urrutia-Rojas, Egbuchunam, Bae, et al., 2006; Ogden, Carroll, Curtin, et al., 2006).

Women who take oral contraceptives have a small increase in both systolic and diastolic pressures, although the blood pressure usually continues to remain within the normal range. However, women who take oral contraceptives, smoke, are overweight, and are older than 35 years do experience hypertension. It is three times more common in this group than in women without these risk factors. High blood pressure is extremely common in older adults. Depending on their race, between almost two thirds and nearly three fourths of older adult Americans have hypertension. Older adults often are responsive to lifestyle changes, which should be included as part of their treatment along with drug therapy.

Hypertension is also now a problem in children and adolescents because of high rates of childhood obesity, with accompanying lack of exercise and the increasing prevalence of type I diabetes. The incidence of hypertension has been steadily increasing since 1988 (Flynn, 2009; Din-Dzietham, Liu, Bielo, et al., 2007). Research has indicated that between approximately 5% and 20% of American school-age children and adolescents have hypertension; and the prevalence of obesity among children aged 6 to 11 more than doubled in the past 20 years, going from 6.5% in 1980 to 17.0% in 2006. The rate among adolescents aged 12 to 19 more than tripled, increasing from 5% to 17.6% (Centers for Disease Control, 2009a). Overweight and obesity as determined by high BMI has been consistently shown to be an important risk factor for hypertension in school-aged children and adolescents (Eichner, Moore, Perveen, et al., 2008; Urrutia-Rojas, Egbuchunam, Bae, et al., 2006; Moore, Stephens, Wilson, et al., 2006; Ogden, Carroll, Curtin, et al., 2006; Sorof, Lai, Turner, et al., 2004). The likelihood of hypertension is more than three times higher in overweight children (Urrutia-Rojas, Egbuchunam, Bae, et al., 2006; Box 26.2). The long-term consequences of hypertension in children and adolescents cannot be predicted at this time, as there is no research yet on this topic (Flynn, 2008).

The American Heart Association defines adult hypertension as persistent elevation of systolic pressure equal to or greater than 140 mm Hg or diastolic pressure equal to or greater than 90 mm Hg. The diastolic pressure for all age groups is based on the fifth Korotkov sound, which is the disappearance of sound. Many factors, ranging from exercise to stress to a variation in normal sodium intake, may increase blood pressure temporarily. Therefore, a definitive diagnosis of hypertension is not made until the average of two or more readings, each recorded at two or more visits, reveals persistent elevations (Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure— 7th report, 2003). Diagnosis of hypertension in children requires more than knowledge of the systolic and diastolic pressure because children vary widely in their body size based on age, height, and gender. The blood pressure reading is compared to standardized charts to determine if the child has normal blood pressure, pre-hypertension, or hypertension.

There are two main categories of hypertension: primary hypertension and secondary hypertension. **Primary hypertension,** also known as **essential hypertension,** is responsible for 90% to 95% of all hypertension; secondary hypertension accounts for the remaining percentage. Primary hypertension has no identified cause. However, it can be managed successfully with lifestyle changes and drug therapy to prevent the adverse effects of hypertension. Risk factors associated

Box 26.1 UNDERSTANDING BMI

When the BMI is …..	It is considered this…
Below 18.5	Underweight
18.5–24.9	Normal
25.0–29.9	Overweight
30.0 and Above	Obese

The Basal Metabolic Index (BMI) is considered an obesity index. It is the relationship of weight to height.

BOX 26.2 FOCUS ON RESEARCH

Obesity, High Blood Pressure, and School-Aged Children

Urrutia-Rojas, X., Egbuchunam, C. U., Bae, S., et al. (2006). High blood pressure in school children: Prevalence and risk factors. Retrieved from *http://www.biomedcentral. com/1471-2431/6/32.*

The Study

Children from 17 elementary schools in Fort Worth, Texas, chosen to represent the ethnic and geographical profile of the school district's student population, were studied to determine the prevalence of hypertension and its risk factors in children. The 1,066 children were fifth-graders and ranged in age from 8 to 13 years, with the overwhelming majority being between 10 and 12 years. By race, there were 58.7% Hispanic, 24.6% African American, and 16.7% Caucasian children. (Although there was a very small percentage of Asian students and other races, the numbers were too small to include.) Approximately one third of the children were overweight (defined as a body mass index of greater than or equal to the 85th percentile). About one third (32.8%) of the African American children were overweight, nearly one third (31.9%) of the Hispanic children were overweight, and less than one fourth (23.5%) of the Caucasian children were overweight. Overall, about one in five children had hypertension (20.6%) (defined as a blood pressure greater than or equal to the 95th percentile; either systolic alone was elevated or both systolic and diastolic were elevated). Overweight children were at least three times more likely to have hypertension. The Hispanic children were much more likely to have hypertension in comparison to African American and Caucasian children, and the African American children were more likely than Caucasian children to have hypertension. These findings conflict somewhat with previous studies, where it was found that African American children had the highest risk of hypertension.

Nursing Implications

This study highlights some important public health concerns. Overweight and obese children are more common now than 30 or 40 years ago. In this study, being overweight was the most significant risk factor for childhood hypertension. Without correction of this significant risk factor, children will develop long-term complications related to hypertension, such as MI, stroke, heart failure, and renal disease, which have been historically associated with adults, at an earlier and earlier age. Minority children are more at risk of obesity and hypertension. The finding that Hispanic children had the highest risk for hypertension appears to contradict the conclusion drawn from previous studies that African American children were at most risk. A likely explanation is that unlike other studies that compared only two races, this study compared all three races together; thus, it is the first study to identify risk for hypertension by race truly. Nurses have an important role in teaching children and their parents about the risk of obesity and hypertension to help prevent long-term morbidity and mortality.

with the development of primary hypertension include elevated blood lipid levels, obesity, smoking, diabetes, age older than 60 years, gender (male and postmenopausal women), and family history of cardiovascular (CV) disease (women younger than 65 years or men younger than 55 years).

Secondary hypertension occurs secondary to another condition, such as renal stenosis or renal tumor. Therapy aims to correct or remove the underlying cause. If this therapy is successful, the secondary hypertension will be eliminated. However, when the cause cannot be treated successfully, antihypertensive agents are used to control the blood pressure.

Hypertension, if untreated, can lead to stroke, myocardial infarction (MI), kidney disease, CHF, and even death. These diseases and disorders result from several physiologic changes. Persistently elevated pressure constricts the arterioles, which increases peripheral vascular resistance. The increased peripheral vascular resistance in turn increases the workload of the left ventricle, which results in ventricular hypertrophy. The myocardium must work ever harder to overcome the increased resistance to outflow. Hence, the demand for oxygen increases. Eventually, the heart can compensate no longer, and CHF results. Hypertension is the most common risk factor for CHF. At least 90% of the time, hypertension precedes CHF. A recent study of Native Americans aged 14 to 39 found that ventricular hypertrophy begins at an early age if the patient has hypertension or prehypertension; compared to individuals without hypertension, left ventricular hypertrophy was three times higher among those with hypertension and two times higher in those with prehypertension (Drukteinis, Roman, Fabsitz, et al., 2007). Yet, as previously stated, many people do not realize that they have high blood pressure and therefore do not seek medical attention; thus, their hypertension remains uncontrolled, increasing the risk of heart failure and other complications.

Another change resulting from persistent hypertension is a sclerosing (thickening and hardening) of the blood vessel wall, which narrows the blood vessel's lumen. The narrowed lumen inhibits blood flow, leading to decreased organ perfusion and, possibly, arterial thrombosis and tissue ischemia. Tissues at the greatest risk for damage include the brain, heart, eyes, and kidneys. As mentioned earlier, angiotensin II and aldosterone are now believed to be associated with inflammation of the arteries and cell growth in the arteries and heart; these effects may contribute to narrowed arteries, increased ventricular size, and stiffening of the ventricle. Aldosterone's proposed effects on the kidney (structural renal injury, proteinuria) may account for the renal damage seen with hypertension.

Chronic hypertension produces changes that may result in a stroke. However, hypertension can also develop after a stroke in patients who previously had normal blood pressure. Sudden and severe blood pressure increases after a stroke may indicate or cause intracerebral hemorrhage. This situation often warrants therapy to decrease blood pressure. To complicate matters somewhat, some degree of hypertension is physiologically necessary after a stroke to help maintain perfusion to the brain. Additionally, after a stroke, elevations in blood pressure may be related to other factors such as emotional stress, bladder distention, pain, or hypoxia.

Memory changes may be an outcome from narrowing of vessels that supply the brain. Research has shown that hypertension, likely due to related vessel wall changes in the brain, chronic brain hypoperfusion, or cerebrovascular disease, increases the risk for some aspects of Alzheimer disease (Cechetto, Hachinski, and Whitehead, 2008; Goldstein, Ashley, Endewshaw, et al., 2008; Skoog & Gustafson, 2006). Whether the treatment of hypertension will decrease the severity of Alzheimer disease is debatable, as there are conflicting

findings in the literature (Poon, 2008; Johnson, Margolis, Espeland, et al., 2008; Peters, Beckett, Forette, et al., 2008; Launer, Ross, Petrovistch, et al., 2000). It has been postulated that the positive effects found in some of the major studies may be related to the types of antihypertensive drugs used in each study, with the use of angiotensin converting enzyme inhibitors, angiotensin receptor blockers, diuretics, and calcium channel blockers may be more effective in reducing dementia risk than other antihypertensives (Poon, 2008).

People with primary hypertension are relatively symptom free for a long time. Hypertension often is detected initially at an incidental blood pressure screening or during a routine physical examination. Because it is painless and symptom free, primary hypertension often remains undiagnosed until the symptoms of end-organ damage surface.

Hypertension is classified according to the degree of elevation. The risk of coronary vascular disease doubles with each increment of 20/10 mm Hg above 115/75 mm Hg. The treatment guidelines for hypertension from the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (JNC 7), released in 2003, created a new category of hypertension, prehypertension. Individuals with a systolic reading of 120 to 139 mm Hg or a diastolic blood pressure of 80 to 89 mm Hg are considered to have prehypertension, which means that they are at increased risk for hypertension later in life and should take steps to modify their lifestyles to minimize the risk of developing coronary vascular disease. Stage 1 hypertension occurs when the systolic pressure is 140 to 159 mm Hg or the diastolic pressure is 90 to 99 mm Hg. Stage 2 hypertension occurs when the systolic pressure is equal to or greater than 160 mm Hg or the diastolic pressure is equal to or greater than 100 mm Hg. *The eighth report of the Joint National Committee is due to be available after the text is published. Please refer to the revised report for any updates.*

Table 26.1 shows the classifications of blood pressure for individuals 18 years and older. If the systolic and diastolic blood pressure readings are in different categories, then the classification is based on the higher values.

Hypertension in children is defined as an average systolic or a diastolic blood pressure greater than or equal to the 95th percentile when the child is compared to others of the same sex, age, and height. Prehypertension in children is defined as an average systolic or diastolic blood pressure level greater than or equal to the 90th percentile; average readings less than the 90th percentile are considered normal. Adolescents should be considered to have prehypertension if their blood pressure readings are equal to or greater than 120/80 mm Hg. Children older than 3 years of age should have their blood pressure checked when they are in a medical setting, preferably by the auscultation method with a cuff of the appropriate size. Elevated readings should be confirmed on repeated visits before the diagnosis of hypertension is made (National High Blood Pressure Education Program Working Group on Adolescents and Children, 2004). For information on home blood pressure assessment, see Box 26.3.

TABLE 26.1 Blood Pressure and Hypertension Categories*

Category	Systolic	Diastolic
Normal	<120 mm Hg	<80 mm Hg
Prehypertension	120–139 mm Hg	80–89 mm Hg
Stage 1 hypertension	140–159 mm Hg	90–99 mm Hg
Stage 2 hypertension	≥160 mm Hg	≥100 mm Hg
Hypertensive crisis	>210 mm Hg	>120 mm Hg

*In the categories of prehypertension, stage 1 hypertension, and stage 2 hypertension, diagnosis is made based on either the systolic or the diastolic reading being at the specified level.

Hypertensive Crisis

When the patient's blood pressure is elevated acutely, the condition is termed a **hypertensive crisis.** This situation is defined as systolic blood pressure exceeding 210 mm Hg and diastolic blood pressure exceeding 120 mm Hg. When hypertensive crisis occurs, the patient is in danger of rapidly developing damage to one of the vital organs, such as the brain, heart, or kidneys, and it is considered an emergency. The situation requires immediate assessment and intervention. The priority is to reduce the blood pressure as quickly as can be managed safely to prevent injury. However, blood pressure does not need to be reduced to a normal level immediately. Although it must be reduced, it must stay high enough to maintain perfusion of vital organs. The initial goal of treatment in hypertensive emergencies is to reduce the blood pressure by no more than 25% within minutes and up to 2 hours. It should then be reduced toward 160/100 mm Hg within 2 to 6 hours. The purpose of the gradual reduction is to avoid excessive falls in pressure that could induce renal, cerebral, or coronary ischemia. The exact level of pressure reduction depends on patient-related variables.

Hypertensive crisis may be caused by an ongoing condition, such as hypertensive encephalopathy, cerebral hemorrhage, eclampsia, pheochromocytoma (a tumor of the adrenal medulla), dissecting aortic aneurysm, unstable angina pectoris, acute MI, or acute left ventricular failure with pulmonary edema. It also could be induced from a drug–food interaction, for example, when monoamine oxidase inhibitors (MAOIs) are prescribed as drug therapy and tyramine-rich food is eaten. The symptoms manifested are acute and include decreased level of consciousness, neurologic deficits, decreased renal output, vomiting, and severe headache (cephalalgia). Emergencies initially are treated with intravenous (IV) administration of an appropriate agent for rapid onset.

A hypertensive crisis that is less serious occurs when it is desirable to reduce the blood pressure within a few hours, but risk of target organ damage is not imminent. This situation is called hypertensive urgency. Examples of hypertensive urgency are upper levels of stage 2 hypertension, hypertension with optic disc edema, and severe perioperative hypertension. Urgent situations may be treated with oral doses of drugs with relatively fast onset of action, including loop diuretics, beta blockers, ACE inhibitors, alpha-2 agonists, or calcium channel blockers.

BOX 26.3 COMMUNITY BASED CONCERNS

How do we determine if the antihypertensive drug therapy is effective? The answer is by monitoring the blood pressure to confirm that the reading is moving toward, or has achieved, the targeted blood pressure goal. More frequent monitoring provides better data as it is not a single snapshot of the blood pressure at a particular time, but a pattern of readings that can show the average reading over 1 day or several days. The most common method for checking a patient's blood pressure is to have them return to the health care provider's office or clinic periodically. However, it is not reasonable to expect that patients will return daily or even weekly to have their blood pressure assessed. And it is well known that the blood pressure can be be elevated during office visits due to "white coat effect" (temporary elevation of blood pressure due to stress of having a health care provider take your blood pressure). If the patient measured their blood pressure at home, these problems could be resolved. However, it can be difficult for many patients to learn how to measure their blood pressure with a cuff and stethoscope. A joint scientific statement of the American Heart Association, the American Society of Hypertension, and the Preventive Cardiovascular Nurses Association has called for widespread use of home blood pressure monitoring with oscillometric equipment. In oscillometric blood pressure monitoring, an electronic pressure sensor detects changes in the blood flow instead of using a stethescope and one's ears to hear the Korotkoff sounds. The cuff, which fits around the patient's upper arm or sometimes the wrist, is automatically inflated and deflated; thus it is extremely easy to use. While these monitors are not quite as accurate as ambulatory home monitoring (where the patient wears sensors for 24 to 78 hours at home to obtain blood pressure readings throughout the day), they are easier to use and still accurate and reliable. Home readings have been found to be more reproducible than those taken periodically in the provider's office and appear to better predict risk for cardiovascular complications. Additionally, readings from home blood pressure monitoring with oscillometric equpiment are closer to the average readings from the ambulatory home monitor (which is the blood pressure that best predicts cardiovascular risk), and home readings show better correlation with the measures of target organ damage. Home blood pressure readings eliminate the risk of falsely elevated readings from white coat effect. Another advantage is that with home blood pressure monitoring, the patient can take multiple readings easily, the larger data base helps to identify the true blood pressure throughout the patient's day. Oscillometric equipment is not excessively expensive (about $100), however, some patients cannot afford them. The position of these three organizations was that this cost should be reimbursed to patients or covered by insurance policies as it is an evidenced-based practice of effective monitoring. Although hypothesized, it is not yet known whether frequent home monitoring will improve adherence with therapy or decrease the long-term cost of drug therapy by controlling blood pressure sooner. Additional research is still needed in this area. In the meantime, nurses should teach patients to monitor their blood pressure and encourage them to monitor it at home frequently via the oscillometric method. As patients take a more active role in their own health, hopefully they will have more therapeutic and less adverse effects from their blood pressure medication.

LIFESTYLE MODIFICATION AND HYPERTENSION

In prehypertension, therapy usually consists of lifestyle changes, which include reducing weight and adopting a healthy diet and life style. Dietary and life style changes should be continued if the patient becomes hypertensive and is treated with drug therapy. The American Heart Association suggests the following:

- Lose weight or maintain a healthy body weight.
- Exercise.
- Eat a diet rich in vegetables and fruits.
- Eat whole-grain, high-fiber foods.
- Eat fish, especially oily fish, at least twice a week.
- Limit your intake of saturated fat to 7% of energy, *trans* fat to 1% of energy, and cholesterol to 300 mg/d by
  - choosing lean meats and vegetable alternatives;
  - selecting fat-free (skim), 1%-fat, and low-fat dairy products; and
  - minimizing intake of partially hydrogenated fats.
- Increase intake of potassium.
- Decrease salt intake.
- Minimize your intake of beverages and foods with added sugars.
- Consume alcohol in moderation.
- Don't smoke.

(Lichtenstein, Appel, and Brands, et al., 2006; Appel, Brands, and Daniels, et al., 2006).

Two examples of diets that meet these recommendations are the DASH diet (Dietary Approaches to Stop Hypertension) and the TLC diet (Therapeutic Lifestyle Changes). See Table 26.2 for examples of these diets.

Research indicates that following a diet such as the DASH diet promotes salt excretion and increases urine production, similar to the effects seen with diuretic drugs. These effects appear to be most prominent in those whose blood pressure is sensitive to the effects of sodium (e.g., African Americans or older adults). About half of the population with hypertension is salt sensitive. It is not known whether these effects are from specific foods in the diet or the combination of foods. African Americans who adhere to a low-sodium diet in addition to the DASH diet achieve a greater lowering of blood pressure than with the DASH diet alone; this effect is more pronounced in African American than other races (Douglas, Bakris, Epstein, et al., 2003). Potassium and calcium cause natural sodium loss and are found in high levels in this diet, but the effects on salt excretion seem greater than accounted for by either of these dietary sources of electrolytes, suggesting that a combination of factors is likely to be involved (American Heart Association, 2007).

Lifestyle modification remains an important aspect of therapy for patients in stage 1 or stage 2 hypertension. Lifestyle modifications may decrease the required drug therapy dosage.

OVERVIEW OF DRUG THERAPY AND HYPERTENSION

Drug therapy is now recommended to be started with every patient who has been diagnosed as having hypertension, whether it is stage 1 or stage 2. Drug therapy is also

TABLE 26.2 Two Examples of Daily Dietary Patterns That Are Consistent With AHA-Recommended Dietary Goals at 2000 Calories

Eating Pattern	DASH (Dietary Approaches to Stop Hypertension)	TLC (Therapeutic Lifestyle Changes)	Serving Sizes
Grains	6 to 8 servings per day	7 servings per day	1 slice bread; 1 oz dry cereal; 1/2 cup cooked rice, pasta, or cereal
Vegetables	4 to 5 servings per day	5 servings per day	1 cup raw leafy vegetable, 1/2 cup cut-up raw or cooked vegetable, 1/2 cup vegetable juice
Fruits	4 to 5 servings per day	4 servings per day	1 medium fruit; 1/4 cup dried fruit; 1/2 cup fresh, frozen, or canned fruit; 1/2 cup fruit juice
Fat-free or low-fat milk and milk products	2 to 3 servings per day	2 to 3 servings per day	1 cup milk, 1 cup yogurt, 1 1/2 oz cheese
Lean meats, poultry, and fish	6 oz per day	5 oz per day	Lean cuts include sirloin tip, round steak, and rump roast; extra lean hamburger; and cold cuts made with lean meat or soy protein. Lean cuts of pork are center-cut ham, loin chops, and pork tenderloin
Nuts, seeds, and legumes	4 to 5 servings per week	Counted in vegetable servings.	1/3 cup (11/2 oz), 2 Tbsp peanut butter, 2 Tbsp or 1/2 oz seeds, 1/2 cup dry beans or peas
Fats and oils	2 to 3 servings per day	Amount depends on daily calorie level	1 tsp soft margarine, 1 Tbsp mayonnaise, 2 Tbsp salad dressing, 1 tsp vegetable oil
Sweets and added sugars	5 or fewer servings per week	No recommendation	1 Tbsp sugar, 1 Tbsp jelly or jam, 1/2 cup sorbet and ices, 1 cup lemonade

A Scientific Statement From the American Heart Association Nutrition Committee. *Circulation : Journal of the American Heart Association.* Retrieved from http://circ.ahajournals.org/cgi/reprint/CIRCULATIONAHA.106.176158v2

recommended in prehypertension if the patient has compelling indications, such as type 1 diabetes with proteinuria, heart failure, isolated systolic hypertension (older adults), or MI. Drug therapy for treating hypertension has proven efficacy in decreasing CV morbidity and mortality. Additionally, the use of drug therapy has been found to be protective against stroke, coronary events, heart failure, progression of renal disease, progression to more severe hypertension, and deaths from all causes.

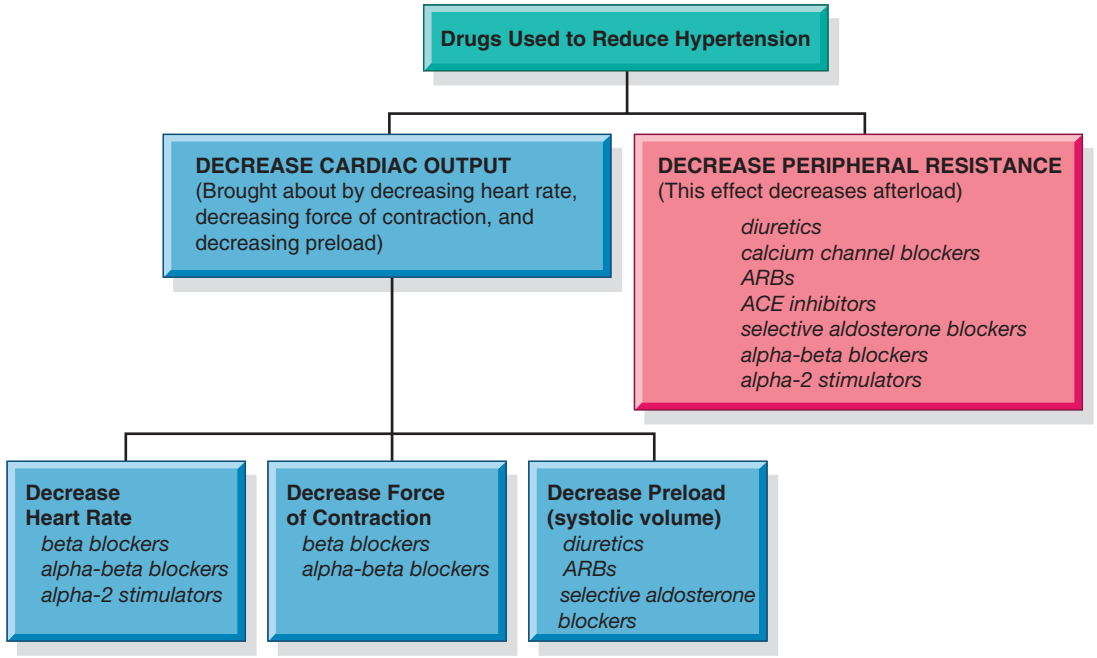
Drugs used to manage blood pressure primarily include those classified as diuretics, beta blockers, calcium channel blockers, ACE inhibitors, and angiotensin II receptor blockers. Combination therapy, where more than one drug is prescribed, is common. Figure 26.2 provides an overview of how the various drug classes work to decrease blood pressure.

Additional therapy, which may be added when hypertension cannot be adequately controlled with combinations of first-line therapy, includes the selective aldosterone blockers, renin inhibitors, alpha-2 stimulators, alpha-beta blockers, and direct vasodilators. The renin inhibitor aliskiren is discussed in the section on Drugs Significantly Different from Captopril. The other second line drugs are discussed later in the chapter.

Adjunctive treatment includes the lipid-lowering agents to help, decrease the narrowing of the blood vessels from fat deposits and nitrates for vasodilation.

A thiazide diuretic should be used in drug treatment for most patients with uncomplicated hypertension, either alone or with drugs from other classes. Thiazide diuretics have been shown to be as effective as, but less expensive than, other drug classes (ALLHAT Officers and Coordinators, 2002). First-line treatment with dose doses of a thiazide have been found to reduce morbidiy and mortality from hypertension (Wright & Musini, 2009). Sometimes, hypertension occurs in conditions in which another complicating physiologic condition is present. These other conditions may respond best to other agents and are considered compelling reasons for starting single-agent drug therapy with a drug class other than a thiazide. Single-agent therapy is usually tried in stage 1 hypertension, although combination therapy (two or more drugs) may be used. Monotherapy may be effective when the blood pressure is not significantly elevated over the target blood pressure.

Combination therapy is indicated for stage 2 hypertension. Most patients with hypertension require two or more antihypertensive drugs to achieve a target blood pressure of less than 140/90 mm Hg or a target of less than 130/80 mm Hg if they have diabetes or chronic kidney disease. Two drugs as initial therapy should be considered in patients with blood pressures that are more than 20/10 mm Hg above their goal blood pressure (JNC 7, 2003).



• FIGURE 26.2 Focus of drug therapy in reducing hypertension.

The exact combinations of drugs used to treat hypertension will vary, based on whether the hypertensive patient has comorbidities. As new information is acquired regarding pharmacodynamic effects of antihypertensives, the clinical guidelines concerning drug therapy choices are likely to change. These recommendations are from the JNC 7, which were current at time of publication. The reader should check for updates to these recommendations when the JNC 8 is released.

The drug dosage should be started low and titrated up to what is considered an adequate dose for efficacy. Ideally, the drug should have a therapeutic effect for 24 hours, requiring a dose to be taken only once daily. If some therapeutic response occurs from one drug given at a moderate dose, but the target blood pressure has not been achieved, then a second may be added. Adding a drug at this point, rather than after raising the first drug to an ultimate maximum, has two advantages. First, therapeutic response is frequently achieved with a relatively low dose; adding a second drug also at a low dose may increase efficacy not seen by merely maximizing the dose of the first drug. Second, using lower doses of a drug or drugs usually decreases the risk of adverse effects, so the therapy is better tolerated and adherence is improved. Many antihypertensives are now available from drug manufacturers as a combination of more than one drug in the same tablet. Combination antihypertensives provide the patient with the benefits of both types of therapy and the added advantage of needing to take only one pill, thereby improving adherence. Table 26.3 lists health status considerations for selecting drugs as first-line therapy for hypertension. Table 26.4 provides a summary of selected antihypertensives.

FIRST-LINE DRUGS TO TREAT HYPERTENSION

• Diuretics

Diuretics exert their effect in different areas of the renal tubules to promote excretion of sodium and water from the body. Because water is not reabsorbed to as great an extent as usual from the kidneys, the volume of circulating fluid decreases. Although the exact mechanism of how diuretics reduce blood pressure is not known, it is generally accepted that the resulting decrease in peripheral resistance, from decreased circulating volume, is what lowers blood pressure. Findings from the landmark Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), a study of more than 33,000 North American hypertensive patients with at least one other coronary heart disease (CHD) risk factor, showed that thiazide-type diuretics are superior to ACE inhibitors or calcium channel blockers in preventing one or more major forms of CV disease (ALLHAT Officers and Coordinators, 2002). Meta-analysis of 57 clinical trials (58,040 patients in all) also showed that low-dose diuretics were effective in reducing the incidence of CHD, CV disease events, stroke, and mortality, however high-dose thiazide treatment does not decrease CHD. (Wright & Musini, 2009). This confirms findings from a previous meta-analysis of 42 clinical trials (192,478 patients in all) from 2003 (Psaty, Lumley, Furberg, et al., 2003). First-line ACE inhibitors and calcium channel blockers may be similarly effective as low-dose thiazides, but the evidence is not as strong (Wright & Musini, 2009). Low-dose thiazides have been found to be effective, so if a patient is not achieving the desired therapeutic response from

TABLE 26.3 Health Status Considerations for Selecting Drugs as First-Line Therapy for Hypertension

Health Status	Drug Class
Compelling Indications (Unless Contraindicated by Comorbidity)	
Diabetes mellitus (type 1)	ACE inhibitors, beta blockers, calcium channel blockers
Heart failure (asymptomatic)	ACE inhibitors, diuretics, beta blockers
Isolated systolic hypertension (older adults)	Diuretics (preferred), calcium channel blockers (long-acting dihydropyridine)
Myocardial infarction	Beta blockers (nonintrinsic sympathomimetic activity), ACE inhibitors (with systolic dysfunction)
Possible Indications	
Angina	Beta blockers, calcium channel blockers
Atrial tachycardia and fibrillation	Beta blockers, calcium channel blockers (nondihydropyridine)
Cyclosporine-induced hypertension (caution with the dose of cyclosporine)	Calcium channel blockers
Diabetes mellitus (types 1 and 2) with proteinuria	ACE inhibitors (preferred), angiotensin II receptor blockers
Diabetes mellitus (type 2)	Low-dose diuretics
Dyslipidemia	Alpha blockers
Essential tremor	Beta blockers (noncardioselective)
Heart failure (symptomatic)	Angiotensin II receptor blockers, aldosterone receptor blockers
Hyperthyroidism	Beta blockers
Migraine	Beta blockers (noncardioselective), calcium channel blockers (nondihydropyridine)
Myocardial infarction	Diltiazem, verapamil
Osteoporosis	Thiazides
Preoperative hypertension	Beta blockers
Benign prostatic hypertrophy (BPH)	Alpha blockers
Chronic kidney disease	ACE inhibitors, angiotensin II receptor blockers, loop diuretics
Possible Precautions (Needs Special Monitoring) and Contraindications	
Bronchospastic disease	Beta blockers (contraindicated)
Depression	Beta blockers, central alpha stimulants, reserpine (contraindicated)
Diabetes mellitus (types 1 and 2)	Beta blockers, high-dose diuretics (precaution)
Dyslipidemia	Beta blockers (nonintrinsic sympathomimetic activity), diuretics (high dose) (precaution)
Gout	Diuretics (precaution)
Second- or third-degree heart block	Beta blockers (contraindicated), calcium channel blockers (nondihydropyridine) (contraindicated)
Heart failure	Beta blockers (except carvedilol), calcium channel blockers (except amlodipine, felodipine) (precaution)
Liver disease	Metoprolol, methyldopa (contraindicated)
Peripheral vascular disease	Beta blockers (precaution)
Pregnancy	ACE inhibitors (contraindicated), angiotensin II receptor blockers (contraindicated)
Renal insufficiency	Potassium-sparing diuretics (precaution)
Renovascular disease	ACE inhibitors, angiotensin II receptor blockers (precaution)

From the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure. (2003). Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Journal of the American Medical Association,* 289 (19), 2560–2571.

thiazide therapy, increasing the dose generally does not bring additional efficacy. In this situation, a second drug should be added.

When polypharmacy is indicated to achieve blood pressure control, thiazide diuretics can be combined with beta blockers, ACE inhibitors, ARBs, or calcium channel blockers. Because of their ability to minimize the circulating volume, diuretics increase the efficacy of all other antihypertensives. The combination of a thiazide with an ACE inhibitor or an ARB also helps minimize hypokalemia, hyperuricemia, and hyperlipidemia that can be adverse effects when thiazides are used in monotherapy.

Although thiazide diuretics are recommended as the first drug therapy for most hypertensive patients, loop diuretics might be used if the patient had pre-exisiting renal disease as thiazides decrease the glomerular filtration rate.

TABLE 26.4 Summary of Selected C Antihypertensives

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Angiotensin-Converting Enzyme (ACE) Inhibitors			
P captopril (Capoten)	Hypertension	*Adult:* PO, 25–150 mg bid or tid *Child (off-label):* 0.05–0.5 mg/kg PO q 12 h	*Onset:* 15 min *Duration:* Dose related $t_{1/2}$: <2 h
	Heart failure LVD after MI Diabetic neuropathy	*Adult:* PO, 25–100 mg tid *Adult:* PO, 50 mg tid *Adult:* PO, 25 mg tid	
benazepril (Lotensin)	Hypertension	*Adult*: PO, 20–40 mg/d	*Onset*: 1 h *Duration*: 24 h $t_{1/2}$: 10–11 h
enalapril (Vasotec)	Hypertension	*Adult*: PO, 10–40 mg/d *Adult*: IV, 1.25 mg over 5 min every 6 h	*Onset*: 1 h *Duration*: 24 h $t_{1/2}$: 1.3 h *Onset*: 15 min *Duration*: 6 h $t_{1/2}$: 1.3 h
fosinopril (Monopril)	Hypertension CHF	*Adult*: PO, maintenance: 20–40 mg/d *Adult*: PO, 20–40 mg/d	*Onset*: 1 h *Duration*: 24 h $t_{1/2}$: 12 h
lisinopril (Prinivil, Zestril)	Hypertension CHF Acute MI	*Adult*: PO, maintenance: 20–40 mg/d *Adult*: PO, 5 mg/d with diuretics and digitalis *Adult*: PO, maintenance: 10 mg/d	*Onset*: 1 h *Duration*: 24 h $t_{1/2}$: 12 h
moexipril (Univasc)	Hypertension	*Adult*: PO, maintenance: 7.5–30 mg/d	*Onset*: 1 h *Duration*: 24 h $t_{1/2}$: 2–9 h
ramipril (Altace)	Hypertension	*Adult*: PO, 2.5–20 mg/d	*Onset*: 1–2 h *Duration*: 24 h $t_{1/2}$: 13–17 h
quinapril (Accupril)	Hypertension CHF	Adult: PO, 20–40 mg/d Adult: PO, 20–80 mg/d with diuretics and digitalis	Onset: 1 h Duration: 24 h t1/2: 2 h
C Angiotensin II Receptor Antagonists			
P losartan (Cozaar)	Hypertension	*Adult:* PO, 25–100 mg/d	*Onset:* 1 wk (therapeutic effect) *Duration:* Unknown $t_{1/2}$: 2 h
C Selective Aldosterone Receptor Blockers			
P eplerenone (Inspra)	Hypertension	*Adult:* PO, 50–100 mg/d	*Onset:* 4 wk (full therapeutic) *Duration:* Unknown $t_{1/2}$: 4–6 h
C Centrally Acting Alpha-2 Stimulators and Others			
clonidine (Catapres)	Hypertension	*Adult:* PO, 0.2–0.6 mg/d in divided doses not to exceed 2.4 mg/d; transdermal, one 0.1-mg to two 0.3-mg patches q7d *Child:* PO, 0.05–0.4 mg bid	*Onset:* 30–60 min *Duration:* 12–24 h $t_{1/2}$: 12–16 h *Onset (transdermal):* Slow *Duration:* 7 d $t_{1/2}$: Unknown
prazosin (Minipress)	Hypertension	*Adult:* PO, maintenance, 6–15 mg/d in divided doses *Child:* PO, 0.5–7 mg tid	*Onset:* 2 h *Duration:* 6–12 h $t_{1/2}$: 2–3 h

TABLE 26.4 Summary of Selected C Antihypertensives *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
terazosin (Hytrin)	Hypertension	*Adult:* PO, maintenance, 1–5 mg/d up to 20 mg/d	*Onset:* Up to 15 min
	Benign prostatic hypertrophy	*Adult:* PO, 10 mg/d	*Duration:* 12–24 h
			$t_{1/2}$: 9–12 h
doxazosin (Cardura)	Hypertension	*Adult:* PO, initially 1 mg/d, increasing to maximum of 16 mg/d, if needed	*Onset:* Unknown
			Duration: Unknown
	Benign prostatic hypertrophy	*Adult:* PO, 1–8 mg/d	$t_{1/2}$: 22 h
C Direct-Acting Vasodilators			
hydralazine	Hypertension	*Adult:* PO, 50 mg qid	*Onset:* Unknown
		Child: PO, 7.5 mg/kg/d or 200 mg/d	*Duration:* 6–8 h
		Adult: IV or IM, 20–40 mg, repeat as needed	$t_{1/2}$: 3–7 h
		Child: IV or IM, 0.1–0.2 mg/kg/dose every 4 to 6 h as needed	
	Hypertension in eclampsia	*Adult:* IV, 5–10 mg bolus every 20 min; after 20 mg, try another drug	*Onset:* 10–20 min
			Duration: 2–4 h

Hydrochlorothiazide is the prototype thiazide diuretic. A brief description of its use in hypertension is presented here.

Nursing Management of the Patient Receiving P Hydrochlorothiazide

Hydrochlorothiazde is normally administered orally once or twice a day in low doses. Twelve and a half milligrams provides the full antihypertensive effect, althouqh increased urine production can be achieved with larger doses. The full reduction in blood pressure can be measured after 4 weeks on drug therapy. Hydrochlorothiazide, like other thiazide diuretics, is equally effective as monotherapy in African Americas as European Americans. Monotherapy with hydrochlorothiazie is more effective in African American than monotherapy with beta blockers, ACE inhibitors, and ARBs. Adding a thiazide diuretic to those drug classes improves their ability to lower blood pressure in African Americans (Ferdinand & Armani, 2007; Douglas, Bakris, Epstein, et al., 2003). For a listing of some practice tips for assisting the African American with hypertension (see Box 26.4).

The common adverse effects from hydrochlorothiazide are related to fluid and electrolyte imbalances (i.e., hypovolemia, low potassium, magnesium, and sodium levels, and elevated uric acid and elevated blood glucose levels). Patients receiving too great a dose for their needs may demonstrate hypotension. The nurse should monitor the patient's intake and output, weight changes, and electrolyte levels while they receive hydrochlorothiazide. Because patients with hypertension will normally require more than one drug to control their hypertension, hydrochlorothiazide is also found in many combination antihypertensive drugs. Diuretics are discussed in detail in Chapter 27.

Box 26.4 TIPS FOR HELPING AFRICAN- AMERICANS WITH HYPERTENSION

- Across the lifespan and in all primary care settings, African Americans need to have their blood pressure checked regularly
- Across the lifespan and in all primary care settings, African Americans need assessment for risks for cardiovascular disease.
  i. Assess for inactivity and obesity. Provide patient education and encouragement on diet and exercise to maintain a normal weight.
  ii. Assess for high salt intake. Provide patient education about the Dietary Approaches to Stop Hypertension (DASH diet) to help mange their hypertension and assist the patient to make dietary changes.
  iii. Monitor lipid levels. African Americans should receive anti-lipid therapy to achieve or maintain a low-density lipoprotein cholesterol goal of less than 100 mg/dL to help decrease their risk for CHD.
- Patient education for African Americans should emphasis the link between hypertension, lifestyle choices, and cardiovascular and renal outcomes.
- African Americans may use all types of antihypertensive drug therapies. Monotherapy is most effective with low dose thiazide diuretics and calcium channel blockers. Combination therapy is frequently warranted to treat hypertension, however.
- If clinical guidelines indicate that there are compelling reasons to start hypertensive therapy with a specific class of antihypertensive other than a thiazide, these guidelines should also be applied to African American patients.
- If African Americans are prescribed an ACE inhibitor, monitor them closely for the adverse effects of angiodema and/or cough, as they are more at risk for these adverse effects.

Based on Table 11 Treatment Pearls: management of High Blood pressure in African Americans from: Douglas, J. G., Bakris, G. L., Epstein, M., et al. (2003). Management of high blood pressure in African Americans: Consensus statement of the Hypertension in African Americans Working Group of the International Society on Hypertension in Blacks. *Archives of Internal Medicine, 163*(5), 525–541. Retreived from: http://ishib.org/supportfiles/Mgt_of_Hypertension_in_African_Americans.pdf

• C Beta Blockers

How beta blockers work is arguable, and several mechanisms of action have been proposed to explain how they reduce hypertension. Clinically, they have been proven to slow heart rate, decrease cardiac output, and lower blood pressure. Although beta blockers (at beta-2 receptor sites) increase peripheral resistance through vasoconstriction, this effect is outweighed by the substantial decrease in cardiac output, thereby lowering blood pressure. The peripheral vasoconstriction appears to be temporary, with resistance returning to baseline or lower levels with prolonged therapy. It is also believed that beta blockers have a central effect, which may decrease sympathetic outflow to the peripheral nervous system. Additionally, beta-adrenergic receptors are responsible for the release of renin from the kidneys. This release is prevented by using beta blockers.

Beta blockers may be selected as primary therapy for patients with hypertension and the following comorbidities: MI, stable heart failure, asymptomatic left ventricular dysfunction, atrial fibrillation, and angina. If these comorbidities are not present, the use of beta blockers as primary therapy for hypertension should be avoided, because, while they reduce stroke and cardiovascular events, they do not decrease CHD or mortality. First-line use of beta blockers appears to be inferior to low-dose thiazides (Wright & Musini, 2009). Beta blockers only weakly reduce the risk of stroke and may not have any effect on coronary heart disease; additionally, beta blockers seem to create worse outcomes in comparison to calcium channel blockers, renin-angiotensin system inhibitors, and thiazides (Wiysonge, Bradley, Mayosi, et al., 2007).

Metoprolol is the prototype beta blocker. A full discussion of metoprolol is in Chapter 13. Here are a few key points related to its use in treating hypertension.

Nursing Management of the Patient Receiving P Metoprolol

Metoprolol is used to treat hypertension, as well as the cardiac problems angina and congestive heart failure. It is usually administered as a sustained-release oral tablet for blood pressure control, although a rapid release formula is also available. A full week of therapy should be used to determine the effectiveness of a particular dose before increasing the daily dose. Metoprolol may be used in monotherapy or in combination with other antihypertensives. Use of a beta blocker as monotherapy to treat hypertension in African Americans will produce less therapeutic effect than when used to treat European Americans with hypertension (Ferdinand & Armani, 2007; Douglas, Bakris, Epstein, et al., 2003).

Because of its effects on blocking beta-1 receptors, metoprolol slows heart rate, the speed of conduction, and decreases the force of contraction, thus cardiac output is decreased, decreasing blood pressure. Metoprolol is a relatively selective beta-1 blocker, meaning that there is little stimulation of beta-2, alpha-1, or alpha-2 receptors. This helps to minimize adverse effects to drug therapy. As the dose increases, however, metoprolol becomes less selective for beta-2 receptors, and so the patient may begin to experience adverse effects from having the other adrenergic recetors blocked (such as bronchospasm, wheezing, or dyspnea). One adverse effect common to metoproplol and all beta blocker is depression (nurses sometimes use the expression “beta blocker blues” to remember this adverse effect). Assess patients carefully for a history of depression, suicidal ideation, or attempted suicide as metoprolol, like all beta blockers need to be used very cautiously in these patients; depending on the patient history, this class of drugs may not be suitable. Sudden discontinuation of the drug may create rebound hypertension. If the patient also has angina it can also create rebound angina, possibly precipitating an MI. It is important to consult with the surgeon and anesthetist before major surgery because metropolol may or may not be discontinued. The physician may wish for the patient to receive the drug for blood pressure control on the morning of surgery. Withdrawal of beta-blocking drug therapy before major surgery is controversial because hypersensitivity to catecholamines has been noted in patients after withdrawal. Because reflex hypertension or angina can occur with sudden stoppage of a beta blocker, the dose of metoprolol is recommended to be slowly tapered downwards over 2 weeks if the drug is to be discontinued. Teach your patients not to stop taking their medication on their own and to be certain not to allow their prescriptions to run out. As metoprolol decreases both pulse rate and blood pressure, be sure to assess both of these before administering the drug. Do not administer the dose if the patient is bradycardic or hypotensive. Let the physician know of these findings. Teach your patients or their families how to check their pulse and blood pressure at home, and what to do if there is a problem.

Drugs significantly different from metoprolol

Labetalol

Labetalol is an adrenergic blocking agent that has a nonspecific beta-blocking action at both the beta-1 and beta-2 receptor sites, and a selective alpha-1-blocking action, unlike metoprolol, which blocks beta 2 receptors selectively. The ratio of alpha-beta-blocking action is 1:3 with oral use and 1:7 with IV use. The alpha-blocking actions cause peripheral vasodilation. Because the alpha-blocking action decreases standing blood pressure more than it decreases supine blood pressure, orthostatic hypotension may occur (in about 2% of patients), although it is transient. The beta-1 and -2 blocking action prevents reflex tachycardia. It also prevents exercise-induced tachycardia and elevations in blood pressure; however, it has no effect on respiratory rate. The beta-blocking effect also results in a decrease in the plasma renin level.

Labetalol is used for treating hypertension, usually with other agents, especially thiazide and loop diuretics, although it may be used alone. Labetalol reduces blood pressure while maintaining glomerular filtration rate and renal blood flow. The parenteral form is used for managing severe hypertension and is given only in the hospital. Labetalol is often used to manage acute, severe hypertension that occurs after an acute ischemic stroke. Unlabeled uses include lowering hypertension associated with encephalopathy. Labetalol also has been used in clonidine-withdrawal hypertension. Labetalol has similar contraindications and precautions, and adverse effects as the prototype, metoprolol.

When labetalol is administered orally, it is completely absorbed and the peak action occurs in 2 to 4 hours. Maximum steady-state blood pressure response occurs within 24 to 72 hours. Labetalol has an extensive first-pass effect and is metabolized rapidly by the liver. It is excreted in the stool and urine. Labetalol penetrates the CNS, crosses the placenta, and appears in breast milk in minimal amounts. Verify that orthostatic blood pressure remains stable after an initial oral dose or after a dosage increase.

The drug also can be administered parenterally, with the onset occurring rapidly and peaking in 5 minutes. Although labetalol can be parenterally administered as either repeated IV boluses or a continuous IV infusion, IV infusion has certain benefits, including greater control of antihypertensive action and a decrease in the severity and rate of adverse effects. IV labetalol is administered only in the hospital. Prepare IV infusions of labetalol carefully. Multiple concentrations may be ordered, and the required diluent varies depending on the desired concentration. Different manufacturers make different concentrations of labetalol, which also influences how much drug volume needs to be added to the diluent. Carefully read the labels and follow the manufacturer's instructions when preparing IV infusions of labetalol.

Monitor closely the blood pressure of patients receiving IV infusions of labetalol. The blood pressure should be assessed every 5 to 10 minutes during the infusion. In addition, assess orthostatic blood pressures. Keep patients who receive IV labetalol flat during infusion to prevent orthostatic hypotension, and assess patients' tolerance to an upright position before allowing them to ambulate. When labetalol infusion is used to treat hypertension after acute ischemic stroke, it is imperative to reduce blood pressure gradually to reduce the risk of intracerebral hemorrhage while maintaining sufficient cerebral perfusion. After IV infusions of labetalol have been stopped, assess blood pressure (including orthostatics) carefully and frequently to confirm that the blood pressure remains stable. After IV therapy is discontinued, blood pressure returns gradually to near-baseline levels in 16 to 18 hours. For information on managing complications of labetalol see Box 26.3. More information about beta blockers is found in Chapter 13.

CRITICAL THINKING SCENARIO

MANAGING COMPLICATIONS OF LABETALOL THERAPY

Your patient, Mr. Parker, is receiving labetalol IV for hypertension. Today, for the first time, he has rales (crackles) in the mid and lower lobes of both lungs. He has gained 3 lb since he was last weighed 2 days ago. On checking, you note that his urinary output has decreased in the last 2 days also.

1. What do you conclude from these findings? And what is the rationale for your conclusions?
2. Based on your assessment, which type of orders might you seek from the physician or nurse practitioner?
3. Which nursing actions would you propose implementing independently?

• C Calcium Channel Blockers

Calcium channel blockers inhibit the movement of calcium ions across cell membranes, which decreases the mechanical contraction of the heart, reduces impulse formation (automaticity), and lessens conduction velocity. Calcium channel blockers also dilate coronary vessels and peripheral arteries, thereby decreasing peripheral resistance and blood pressure. Although decreased contractions of the heart usually result in decreased cardiac output, cardiac output is not decreased by calcium channel blocker therapy, most likely because of the reflex tachycardia that occurs secondary to vasodilation.

Use of calcium channel blockers as primary therapy in hypertension appear to be effective (Law, Morris, & Wald, 2009), although the literature that supports this is not considered robust (Wright & Musini, 2009). Calcium channel blockers provide some additional protection from stroke than other classes of hypertensives (Law, Morris, & Wald, 2009). Patients with comorbid atrial fibrillation or angina are prescribed a calcium channel blocker as the initial antihypertensive agent. African Americans respond equally as white Americans to monotherapy with calcium channel blockers (Douglas, Bakris, Epstein, et al., 2003). The prototype calcium channel blocker is verapamil. A full discussion of verapamil is in Chapter 31. Here are a few key points related to its use in treating hypertension.

Nursing Management of the Patient Receiving P Verapamil

Verapamil is used to treat hypertension as well as angina and cardiac arrhythmias. When used as an antihypertensive, it is administered orally. Calcium channel blockers, like verapamil, are effective as monotherapy or combination therapy when used in African Americans (Ferdinand & Armani, 2007; Douglas, Bakris, Epstein, et al., 2003).

Verapamil selectively blocks the movement of calcium ions into arterial smooth muscles of all tissue, including conductile and contractile myocardial cells, without affecting the concentration of serum calcium. Its hypertensive effect is attributed to the reduction of systemic vascular

resistance and selective vasodilation of peripheral arteries, thus it decreases afterload. One of the main adverse effects is hypotension. Because it can alter the rhythm of the heart and decrease the rate and force of contraction, verapamil may cause cardiac adverse effects such as new or worsening arrhythmias, bradycardia, angina, and worsening of congestive heart failure. A unique adverse effect of verapamil is that it can cause significant constipation; this adverse effect is less with other calcium channel blockers.

Assess the patient's blood pressure and pulse before administering a calcium channel blocker such as verapamil. Withhold the dose of the drug if the patient is hypotensive or bradycardic and notify the physician. Teach your patient and their family how to assess the pulse and blood pressure and when they should notify the physician. Encourage fluid intake of at least 2000 cc/d and a diet rich in fruits and vegetables to help prevent constipation.

C ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

In the renin-angiotensin-aldosterone sequence, a special enzyme is needed to convert the inactive angiotensin I to the active angiotensin II. Angiotensin II is a potent vasoconstrictor. Its presence increases secretion of aldosterone. When aldosterone levels rise, sodium and water are retained, and other effects are exerted on the heart, vessels, and kidneys. The ACE inhibitors prevent the conversion of angiotensin I to angiotensin II, which in turn decreases peripheral arterial resistance and sodium and water retention. ACE inhibitors are also likely to decrease the other negative effects from angiotensin and aldosterone.

ACE inhibitors are used as first-line antihypertensives if the patient has any of the following comorbidities: heart failure, asymptomatic left ventricular dysfunction, history of ST-elevation MI, history of non-ST elevation MI with an anterior infarct, diabetes, systolic dysfunction, or proteinuric chronic renal failure. Combination therapy with an ARB may be especially beneficial in patients with heart failure or proteinuric chronic renal failure. Combination therapy with an ARB may provide more antihypertensive effect and help to prevent end-organ damage more than use of either of these classes alone (Weir, 2007). Reviews of the literature indicate that there are no clinically significant differences in the blood pressure lowering abilities of different ACE inhibitors, they all create a modest effect (Heran, Wong, Heran, & Wright, 2008a). African Americans do not have as great a response as white Americans to monotherapy with ACE inhibitors; adding a thiazide diuretic or a calcium channel blocker to an ACE inhibitor greatly improves its effectiveness (Ferdinande & Armani, 2007; Douglas, Bakris, Epstein, et al., 2003).

Captopril (Capoten) is the prototype angiotensin-converting enzyme (ACE) inhibitor.

Nursing Management of the Patient Receiving P Captopril

Core Drug Knowledge

Pharmacotherapeutics

Captopril, like other ACE inhibitors, is administered orally to lower blood pressure in hypertensive patients. Captopril is also used in treating CHF (usually in combination with diuretics, beta blockers, and digitalis, although digitalis is not required for captopril to be effective). In addition, captopril is useful in treating diabetic nephropathy and left ventricular dysfunction after MI. Unlabeled uses include treating hypertensive crisis, neonatal and childhood hypertension, non-diabetic kidney disease, kidney imaging in renovascular hypertension; as an adjunct in treating acute pulmonary edema; renovascular hypertension hypertension related to scleroderma, renal crisis; captopril is also used to diagnose anatomic renal artery stenosis (captopril test) and primary aldosteronism.

Pharmacokinetics

Captopril is absorbed rapidly after oral ingestion. Food decreases absorption. Captopril has a rapid onset of action. The drug is metabolized (50%) by the liver. It crosses the placenta and also appears in breast milk. It is in pregnancy category C in the first trimester and category D in the second and third trimesters. Captopril does not cross the blood–brain barrier. It is eliminated unchanged (50%) by the kidneys. Its half-life is less than 2 hours in normal renal function and 3.5 to 32 hours in renal impairment (Table 26.4).

Pharmacodynamics

Captopril inhibits the ACE needed to change the inactive angiotensin I to the active form angiotensin II. This reduction of angiotensin II decreases the secretion of aldosterone, thus preventing sodium and water retention. Captopril therefore decreases peripheral vascular resistance and lowers blood pressure. Cardiac output increases, but the heart rate does not. However, peripheral vascular resistance is lowered more than cardiac output is increased, resulting in a substantial decrease in blood pressure. Captopril also increases renal blood flow but has no effect on the glomerular filtration rate. The serum potassium level may increase slightly as a result of decreased aldosterone levels.

ACE is similar to bradykinase (kinase II). Therefore, ACE inhibitors increase the levels of bradykinin, and bradykinin stimulates the synthesis of prostaglandins. It has been hypothesized that the prostaglandins contribute to the antihypertensive effect of the ACE inhibitors.

Contraindications and Precautions

Captopril (and all other ACE inhibitors) can cause injury and death to a developing fetus during the second and third trimesters and carry a Black Box warning for this effect. It is contraindicated in patients with a history of angioedema and in patients with a hypersensitivity to the drug, and there may be a cross-sensitivity to other ACE inhibitors. Captopril should be administered cautiously to patients

with hypovolemia (from aggressive diuretic use or dialysis), aortic stenosis (theoretically, patients treated with vasodilators are at risk for decreased coronary perfusion because they do not develop the afterload reduction as other patients do), hepatic dysfunction, hyperkalemia greater than 5.5 mEq mL, neutropenia, proteinuria, and renal insufficiency. Care should also be used with children (safety and efficacy are not established), pregnant women (pregnancy category C for first trimester, D for second and third trimesters) and breast-feeding women (concentrations of captopril in breast milk equal about 1% of maternal concentrations, although are usually compatible with breast-feeding). In addition, caution is also necessary if the patient is undergoing surgery or anesthesia, because this may increase the risk of hypotension.

Adverse Effects

Chronic cough can occur with captopril and all ACE inhibitors, presumably because the drug inhibits the degradation of endogenous bradykinin. The cough is nonproductive and persistent. It resolves within 1 to 4 days after therapy stops but is a major reason for nonadherence to therapy. The next most common adverse effect is rash. Other adverse effects that may occur are first-dose hypotension (especially in severely salt- or volume-depleted patients, i.e., those treated aggressively with diuretics), and hypotension, although this effect usually is limited to patients with CHF and is transient. Although the risk is uncommon, captopril, like other ACE inhibitors, carries the risk for two serious life-threatening effects—angioedema and neutropenia. Angioedema can occur after the first dose of captopril, or at any other time during therapy. Angioedema confined to the face and lips may resolve untreated. Angioedema associated with laryngoedema can be fatal and needs immediate emergency care. The risk for neutropenia depends on the patient's clinical status. Most at risk are patients with collagen vascular diseases, such as systemic lupus erythematosus (SLE), and impaired renal function. Also at risk are patients with heart failure. Neutropenia generally resolves quickly after captopril is discontinued. Fatalities have occurred, mostly in patients ill with the above-mentioned diseases.

Allergic reactions and anaphylaxis also are possible with captopril. Other adverse effects, which are not common, include:

- Proteinuria
- CV: chest pain, angina, MI, palpitations, orthostatic hypotension, tachycardia, and rhythm disturbances
- CNS: insomnia, paresthesia, dizziness, headache, fatigue, drowsiness, ataxia, confusion, depression, malaise, and nervousness
- Gastrointestinal (GI) and genitourinary (GU): abdominal pain, nausea and vomiting, diarrhea, constipation, anorexia, oliguria, dry mouth, dyspepsia, pancreatitis, and hepatitis
- Respiratory: asthma, bronchospasm, and dyspnea
- Dermatologic: alopecia, pruritus, flushing, photosensitivity, erythema multiforme, and exfoliative dermatitis
- Miscellaneous: impotence, syncope, asthenia, anemia, blurred vision, fever, myalgia, arthralgia, eosinophilia, and vasculitis

Overdosage of captopril most frequently results in hypotension. Vascular re-expansion with IV normal saline solution is the treatment of choice.

Drug Interactions

Captopril interacts with several other drugs, as presented in Table 26.5. Captopril may cause a false-positive test result with urine acetone. Food greatly decreases the bioavailability of captopril (by 30% to 40%), but it remains unknown whether the therapeutic effects of captopril are affected to a similar degree.

Assessment of Relevant Core Patient Variables

Health Status

Blood pressure should be determined before captopril therapy begins. Patients receiving captopril to treat CHF are likely to be receiving concurrent diuretics. If the drug history reveals that the patient has received diuretics, especially high doses of diuretics, assess for signs of hypovolemia, which places the patient at increased risk for hypotension. Other factors that may cause hypovolemia include excessive perspiration, vomiting, and diarrhea. Watch for signs of dehydration and determine whether the patient has renal impairment, because some patients have developed increases in blood urea nitrogen (BUN) and serum creatinine levels after blood pressure is reduced.

Patients with CHD may develop stable elevations of the BUN and serum creatinine with long-term captopril use, although discontinuation of treatment is not usually required. Electrolytes, especially potassium and sodium, should be in normal ranges to start therapy because hyperkalemia and hyponatremia may result from therapy.

Life Span and Gender

Determine whether the patient is pregnant. Patients who are pregnant should not receive captopril or other ACE inhibitors. If the patient becomes pregnant while taking captopril, therapy should be discontinued as soon as possible. Also, determine whether the patient is breast-feeding because captopril crosses into breast milk; the American Academy of Pediatrics has reported that captopril and breast-feeding are compatible.

Note that the adverse effect of cough appears to affect women more than men.

Lifestyle, Diet, and Habits

Assess the patient's normal dietary habits before administering captopril. Poor oral intake and decreased sodium intake may predispose the patient to adverse effects of captopril. If the patient normally uses a salt substitute containing potassium or potassium supplements, these substances may need to be discontinued to avoid possible hyperkalemia. Also, explore with the patient lifestyle changes intended to decrease blood pressure, such as weight loss, smoking cessation, increased exercise, and limited salt intake.

TABLE 26.5 Agents That Interact with P Captopril

Interactants	Effect and Significance	Nursing Management
antacids	Decreases bioavailability of captopril	Stagger drug administration by at least 2-h intervals.
azathioprine	Myelosuppression (anemia or leukopenia) can be induced by this combination, although the exact mechanism is unknown.	Avoid this combination. If coadministration cannot be avoided, monitor carefully for myelosuppression.
bupivacaine	Suppression of the renin-angiotensin system may increase the risk of bradycardia and hypotension from spinal anesthesia.	Monitor patients closely during surgery, and treat any hemodynamic instability appropriately.
loop diuretics and other diuretics	First-dose postural hypotension can be severe when ACE inhibitors are added to loop diuretics if patient is sodium depleted or hypovolemic. Effect is transient. Other types of diuretics increase this risk also.	Titrate dose of ACE inhibitors to minimize first-dose hypotension. Monitor blood pressure closely for 4 h after first dose. If possible, administer at bedtime.
capsaicin	Increases effect of captopril and may exacerbate coughing	Inform patient that coughing may attend coadministration, and suggest cough-control measures. Assess for adherence to therapy.
cyclosporine	Potential to induce acute renal dysfunction	Monitor patients for renal dysfunction.
interferon alfa-2a	Possible increased risk of hematologic abnormalities (granulocytopenia, thrombocytopenia)	Monitor CBCs closely during combined therapy.
phenothiazine antipsychotics	Increases pharmacologic effects of captopril via synergistic action	Monitor blood pressure for hypotension.
probenecid	Increases effect of captopril, possibly raising serum levels and decreasing total clearance	Monitor blood pressure for hypotension.
allopurinol	Possibility for cross-sensitivity	Avoid concurrent administration. Monitor for signs of allergic reaction.
digoxin	Increases plasma digoxin levels	Monitor for possible bradycardia and other adverse effects.
epoetin alfa	Patients receiving hemodialysis may need higher doses of epoetin alfa to achieve therapeutic effect if receiving an ACE inhibitor.	Monitor red blood cell count. Seek orders to adjust dose if needed.
lithium	Increases serum lithium levels	Monitor laboratory data for evidence of lithium level elevation and patient for symptoms of lithium toxicity.
potassium preparations or potassium-sparing diuretics, aldosterone blockers	Increases serum potassium levels	Monitor electrolyte values. Observe patient for signs of hyperkalemia.
NSAIDs	May decrease the antihypertensive effect and loss of sodium in the urine	Caution is advised if an NSAID is coadministered with an ACE inhibitor, especially in patients predisposed to or with preexisting nephropathy. Monitor blood pressure and cardiovascular function for a reduction in the efficacy of the ACE inhibitor. Also monitor patient for hyperkalemia or acute renal failure.
aspirin	Aspirin when used in anti-inflammatory doses can decrease the antihypertensive effect of captopril, especially in low-renin hypertensives, possibly related to an inhibition of prostaglandin synthesis. However, aspirin did not alter captopril's positive effects post-MI.	Although studies have suggested an interaction between ACE inhibitors and aspirin, the clinician should weigh the benefits against the risks of combining these two agents. A dose adjustment may be necessary if the antihypertensive effect is not achieved.

TABLE 26.5 **Agents That Interact with P Captopril** *(continued)*

Interactants	Effect and Significance	Nursing Management
ma huang (Ephedra)	May decrease the antihypertensive effectiveness through antagonist effects	Avoid this combination.
vasodilators	Additive hypotensive response	Monitor blood pressure carefully during combined therapy.
yohimbine	Increased norepinephrine release by yohimbine may counteract the hypotensive effect of ACE inhibitors.	Avoid concomitant use.

Environment

Although captopril may be given in any environment, it is important to assess the safety of the patient's environment before taking the first dose because of the possibility of first-dose hypotension.

Culture and Inherited Traits

Note the patient's ethnic and cultural background before administering captopril. When captopril is used as monotherapy in African Americans who are "low-renin hypertensive," a smaller antihypertensive response occurs than that seen in the general population, although the drug is still effective. Adding a thiazide diuretic will increase its effectiveness.

Nursing Diagnoses and Outcomes

- Risk for Injury from first-dose hypotension related to effect of drug therapy and from drug-induced neutropenia
  Desired outcome: *The patient will not sustain injury from a hypotensive event or neutropenia.*
- Ineffective Therapeutic Regimen Management, Nonadherence, related to persistent dry cough secondary to drug therapy
  Desired outcome: *Adherence to drug therapy will be unaffected by chronic cough.*
- Disturbed Sensory Perception related to possible electrolyte imbalance, hyperkalemia, and hyponatremia, related to effects of captopril
  Desired outcome: *The patient's electrolyte levels will remain within normal ranges.*
- Risk for Impaired Skin Integrity related to drug-induced rash and pruritus
  Desired outcome: *Skin integrity will not be impaired.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer captopril 1 hour before meals because food decreases absorption.

Minimizing Adverse Effects

FIRST-DOSE HYPOTENSION

Monitor the patient for at least 2 hours after the initial dose and until blood pressure stabilizes. Transient hypotension does not indicate that captopril should be discontinued; the dose can be restarted after blood pressure stabilizes. It is important to assist the patient to a supine position and give normal saline solution IV if severe hypotension occurs. Assess patients receiving diuretic therapy, especially when the diuretic dose increases, because salt deficiency or volume depletion increases risk.

HYPOTENSION

Assess patients with CHF very carefully. It is important to start therapy with low doses, to decrease the diuretic before starting captopril therapy, or to increase salt intake about 1 week before starting captopril therapy.

Altered Laboratory Results

Assess blood reports for hyperkalemia, hyponatremia, and neutropenia, and assess urine for proteinuria.

Allergic Reactions

If a polyacrylonitrile dialyzer is used, extreme care is needed during dialysis of a patient on captopril. Allergic reactions may occur suddenly, with severe or fatal effects. Make sure that dialysis stops at the first sign of nausea, abdominal cramping, burning, angioedema, or shortness of breath leading to severe hypotension. Be prepared to intervene if the patient experiences anaphylactic reactions.

Providing Patient and Family Education

- Explain the purpose of the drug therapy and its possible adverse effects. If patients are to start on captopril at home, advise them to take the first dose at bedtime to minimize the possibilities of injury from first-dose hypotension.
- Tell patients to arise slowly from a lying or seated position in case of orthostatic hypotension and dizziness.
- Explain that the drug may produce a persistent dry cough, but that it is not serious. It is a good idea to encourage patients to continue therapy and to provide ideas for minimizing the cough. However, tell patients to consult the prescriber if the cough becomes intolerable.
- Advise patients to notify the prescriber promptly about the following adverse effects: sore throat; fever; swollen hands or feet; irregular heartbeat; chest pain; swollen face, eyes, lips, and tongue; difficulty breathing; or hoarseness. A rash may also appear and should be reported, although this finding is not as urgent as the others.
- Tell patients not to use potassium supplements or salt substitutes containing potassium, because of the risk of hyperkalemia.

- Explain the importance of adhering to schedules for follow-up blood tests.
- Counsel patients to make lifestyle changes (e.g., diet, weight loss, and exercise) to reduce blood pressure. Offer positive reinforcement for changes made, and encourage patients to sustain these changes.
- Teach patients how to self-monitor blood pressure to assess drug effectiveness.

Ongoing Assessment and Evaluation

Monitor blood pressure throughout captopril therapy. Blood pressure that decreases to a normal range is indicative of successful drug therapy. Monitor white blood cell counts, potassium and sodium levels, and urine protein values throughout therapy as well. Levels that remain in the normal range demonstrate that adverse effects have not occurred. In patients with CHF, cardiac output increases because of decreased peripheral resistance, and the patient's exercise tolerance time increases. These findings also indicate effective drug therapy. The decreased peripheral resistance (afterload) improves ejection fraction in patients who have left ventricular dysfunction resulting from MI, reducing the incidence of overt heart failure that requires hospitalization.

Monitor for evidence of renal insufficiency in patients receiving captopril for diabetic nephropathy. Progressing renal insufficiency and serious clinical outcomes (need for dialysis, need for kidney transplantation, and death) should be slowed. Also, monitor these patients for proteinuria, even though captopril should decrease proteinuria.

MEMORY CHIP

P Captopril

- Inhibits the angiotensin-converting enzyme (ACE) needed to change angiotensin I (inactive) to angiotensin II (active). Angiotensin II is a potent vasoconstrictor, so that less angiotensin II means less vasoconstriction.
- Decreased angiotensin II also decreases secretion of aldosterone, which thus prevents retention of sodium and water
- Lowers blood pressure by decreasing peripheral vascular resistance; smaller antihypertensive response (monotherapy) in African Americans than whites
- Most common adverse effect: chronic cough
- Most serious adverse effects: angioedema and neutropenia
- **Life span alert: avoid use during second and third trimesters of pregnancy.**
- Minimizing adverse effects: Monitor blood pressure for 2 hours after initial dose until stabilized, and monitor patient's blood pressure throughout therapy.
- Most important patient education: Urge continuation of lifestyle changes while on drug therapy, and teach the signs and symptoms of hypotension.
- **Black box warning: Captopril can cause injury and death to a developing fetus during the second and third trimesters**.

Drugs Closely Related to P Captopril

The other ACE inhibitors that are closely related to captopril are benazepril (Lotensin), enalaprilat (Vasotec IV; IV form of enalapril), enalapril (Vasotec), fosinopril (Monopril), lisinopril (Prinivil, Zestril), moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), and trandolapril (Mavik). The differences between these drugs and captopril relate to labeled indication, being a prodrug for the active ACE inhibition, half-life, or the route of administration. The following drugs have different labeled indications from captopril: benazepril (labeled for hypertension only, but used off-label for CHF); enalaprilat (labeled for hypertension only); enalapril (labeled for hypertension, heart failure, and renal disease for patients without diabetes); fosinopril (labeled for CHF and hypertension only); lisinopril (labeled for hypertension, CHF, and acute MI); moexipril (labeled for hypertension only); perindopril (labeled for hypertension and as prophylaxis in patients with risk of CV events or stable coronary artery disease); quinapril (labeled for use in CHF or hypertension only); and ramipril (labeled for use in CHF, hypertension, and reduction of CV events). The following drugs, unlike captopril, are actually prodrugs that are converted into the active form: benazepril; perindopril; quinapril; ramipril; and trandolapril. All of the other ACE inhibitors, except enalapril, have longer half-lives (some of them extremely longer) than captopril. Enalaprilat is the intravenous form of enalapril.

Drugs Significantly Different From P Captopril

Aliskiren (Tekturna) is the first drug in a new class of antihypertensives, the renin inhibitors. Unlike captopril, which prevents the conversion of angiotensin I to angiotensin II, aliskiren directly inhibits renin, thus decreasing plasma renin activity and preventing the formation of angiotensin I. Even though the negative feedback loop in the renin-angiotensin-aldosterone loop is altered, additional renin is not released due to the action of aliskiren. This makes aliskiren also different from the actions of ARBs and selective aldosterone inhibitors (further discussed in later sections), where the circulating plasma levels of renin increase because there is not a high enough level of angiotensin II and aldosterone to shut off the renin production. The long-term effect (positive or negative) of reducing renin levels is not yet known. For this reason, aliskiren is not currently used as initial therapy in treating hypertension, however with additional research it may become a first-line drug.

Aliskiren was tested and found effective in treating mild to moderate hypertension, either alone or in combination therapy with other antihypertensives. Its therapeutic effectiveness was evident after 2 weeks of therapy. Clinical trials showed aliskiren to be at least as effective as an ARB or an ACE inhibitor, such as captopril (Musini, Fortin, Bassett, Wright, 2009; Andersen, Weinberger, Egan, et al, 2008; Strasser, Puig, Farsang, et al., 2007). Although aliskiren lowers blood pressure, no long-term studies have yet demonstrated that morbidity or mortality from hypertension is decreased. Similar to other drugs that alter

the renin-angiotensin-aldosterone system, monotherapy with aliskiren produced fewer antihypertensive effects in African Americans than in Caucasians or Asians, probably because most African Americans are "low-renin hypertensives."

Aliskiren may be helpful in treating diabetic nephropathy from hypertension based on the findings of the Aliskiren in the Evaluation of Proteinuria in Diabetes (AVOID) trial. This clinical trial found that treatment with aliskiren led to a greater reduction in albuminuria at 6 months compared to placebo in patients with hypertension, type 2 diabetes and nephropathy receiving losartan and additional optimal antihypertensive therapy concomitantly (Parving, Persson, Lewis, et al., 2008). Use of aliskiren for diabetic nephropathy is an off-label use.

Like ACE inhibitors, such as captopril, and ARBs, aliskiren carries a Black Box warning that it should not be used in the second or third trimester of pregnancy because it can cause fetal injury and death. It is a pregnancy category D drug (second and third trimesters).

Aliskiren is metabolized by the P-450 isoenzyme system, specifically 3A4. It does not induce or inhibit any part of the P-450 system. Some drugs can alter the levels of aliskiren when used in combination. Irbesartan, one of the ARBs, decreases the availability of aliskiren. Atorvastatin, an antilipid statin drug, and ketoconazole, an antifungal agent, significantly increase the availability of aliskiren. When given with furosemide, the loop diuretic, aliskiren significantly reduces the available amount of furosemide. Changes in the dosage may be indicated if the patient is receiving any of the drugs that interact with aliskiren.

Aliskiren is usually well tolerated. Patients tolerate aliskiren similarly to how they tolerate ACE inhibitors (Strasser, Puig, Farsang, et al., 2007). Hypotension is unlikely, although it may occur if patients are already salt and volume depleted from aggressive diuretic therapy. These conditions should be corrected before starting treatment with aliskiren. If hypotension does occur, treatment with IV infusions of a normal saline solution is necessary. Hyperkalemia can occur when aliskiren is administered to patients with diabetes who are also receiving an ACE inhibitor, such as captopril, but this condition is rare otherwise. Serum levels in these patients should be monitored closely. GI adverse effects, such as diarrhea, may occur, although these adverse effects are usually mild; they occur more frequently when larger doses of aliskiren are administered. Cough can occur in patients taking aliskiren, similar to captopril and other ACE inhibitors; however, the incidence of cough from aliskiren is much less. At this time, it is not known whether a patient who has been taken off captopril or any other ACE inhibitor because of cough would be more likely to develop a cough from aliskiren.

C ANGIOTENSIN II RECEPTOR BLOCKERS

Angiotensin II receptor blockers, or ARBs (sometimes referred to as angiotensin II receptor antagonists, or AIIRAs), block the action of angiotensin II from all the different pathways where it is formed, not just the single substrate altered by ACE inhibitors. These drugs are effective in lowering blood pressure modestly and are similar in effectiveness to ACE inhibitors as a class (Heran, Wong, Heran, and Wright, 2008b). In addition, they seem to block deleterious effects from angiotensin II at the end-organ stage, which is where serious complications of sustained hypertension occur (Weir, 2007). This effect seems to be independent of the antihypertensive effect produced by the drugs. Combining an ACE inhibitor and an ARB such as losartan may provide greater antihypertensive effect and end-organ protection than use of either drug class alone (Weir, 2007). For patients with diabetic renal disease, ARBs have been shown to reduce the rate of end-stage renal disease (Igarashi, Hirata, Kadomoto, et al., 2006; Osawa, Nakamura, Shirato, et al., 2006; Prisant, 2003). Combination of an ACE inhibitor with an ARB has been found to help remodel the left ventricle to improve its function again after hypertension has caused deleterious effects; it is more effective than the combination of an ACE inhibitor with a calcium channel blocker (Grandi, Solbiati, Laurita, et al., 2008).

The indications for ARBs and their efficacy are similar to those of ACE inhibitors. An ARB is used if a patient cannot tolerate the adverse effects from an ACE inhibitor. Patients can be safely switched from an ACE inhibitor to an ARB with similar effects on blood pressure control occurring from either drug (Spinar, Vitovec, Soucek, et al., 2009). A unique comorbidity in which an ARB appears to be preferred as first-line therapy is severe hypertension with electrocardiographic (ECG) evidence of left ventricular hypertrophy. Like ACE inhibitors, ARBs do not create the same efficacy in African American as in white Americans if they are used as monotherapy (Douglas, Bakris, Epstein, et al., 2003). Losartan (Cozaar) is the prototype angiotensin II receptor blocker (ARB).

Nursing Management of the Patient Receiving P Losartan

Core Drug Knowledge

Pharmacotherapeutics

Losartan, a monopotassium salt, is used to treat hypertension. Clinical trials have shown that if a patient was receiving an ACE inhibitor for hypertension, he or she could be safely switched to the ARB losartan while maintaining effective blood pressure control (Spinar, Vitovec, Soucek, et al., 2009). Losartan is also used to treat diabetic nephropathy. For these patients, losartan reduces the rate of progression of nephropathy, determined by the doubling of serum creatinine or end-stage renal disease requiring dialysis or renal transplantation. Losartan has been found to decrease the risk of fatal and nonfatal stroke in patients with hypertension and left ventricular hypertrophy, but there is evidence that this benefit does not apply to African American patients. Losartan can be used in treating heart failure, but this use is currently unlabeled. (See Chapter 29 for more about the use of ARBs in heart failure.) Another off-label use is the treatment of erythrocytosis.

Pharmacokinetics

Losartan undergoes a substantial first-pass metabolism and is converted to an active metabolite, which performs most of the antagonism at the angiotensin II receptors. Cytochrome P-450 2C9 and 3A4 isoenzymes are involved in the metabolism of losartan. Both the drug and the active metabolite (which produces the therapeutic effect) are highly protein bound. The peak concentration occurs in 1 hour for losartan and in 3 to 4 hours for its metabolite. The half-life is about 2 hours for the drug and 6 to 9 hours for the metabolite. Excretion occurs in the urine and stool.

Pharmacodynamics

Angiotensin II receptor blockers do not inhibit ACE. Instead, they block the vasoconstricting and aldosterone-secreting effects of angiotensin II by selectively blocking the binding of angiotensin II to the angiotensin I receptors in many tissues, especially in the vascular smooth muscle and adrenal gland tissues. Although an angiotensin II receptor exists, it does not seem to have an effect on the CV system. ARBs have a much greater affinity for angiotensin I than angiotensin II receptors. Losartan has about a 1,000-fold increase in affinity for angiotensin I. Losartan is a reversible, competitive inhibitor of the angiotensin I receptor. The active metabolite appears 10 to 40 times more potent by weight than losartan. It appears to be a reversible but not competitive inhibitor of the angiotensin I receptor.

Losartan, like other ARBs, inhibits the pressor effect of angiotensin II, removing the negative feedback that occurs normally. This effect causes a twofold to threefold increase in plasma renin activity and a rise in angiotensin II plasma levels. These increases are not enough to offset the positive effects that ARBs have on hypertension. Although aldosterone secretion decreases, potassium levels do not seem to be affected by losartan. There is a minimal decrease in serum uric acid when oral losartan is administered long-term.

Research indicates that losartan contributes to the regression of left ventricular hypertrophy that is associated with chronic hypertension. Additionally, losartan appears to increase exercise capacity in patients with either asymptomatic or symptomatic heart failure.

Contraindications and Precautions

Like ACE inhibitors and renin inhibitors, ARBs such as losartan carry a black box warning that it may cause fetal injury or death if used in the second or third trimesters. Losartan is a pregnancy category C for the first trimester and category D for the second and third trimesters. The only other contraindication to losartan is hypersensitivity to any component of the drug.

Adverse Effects

A major advantage of losartan and other ARBs is that it does not cause the dry cough that occurs so frequently with ACE inhibitors. Overall, ARBs are well tolerated, with only about 2% of patients receiving losartan experiencing adverse effects bothersome enough to warrant discontinuing the drug. Of the adverse effects that do occur, the most frequent are hypotension, diarrhea, asthenia, dizziness, and fatigue. The most serious adverse effects are all rare: thrombocytopenia, rhabdomyolysis, and angioedema. Other effects that may occur, but are not common, include anxiety and nervousness; musculoskeletal pain, cramps, and myalgia; nasal congestion, sinus disorder, and sinusitis; rash; tachycardia; and urinary tract infection.

Overdosage of losartan may produce hypotension, dizziness, and tachycardia. Bradycardia may be produced from parasympathetic (vagal) stimulation. Hypotension should be treated with supportive therapy. Valsartan cannot be removed by dialysis.

Drug Interactions

Losartan is known to interact with lithium, increasing the resorption of lithium and the risk of lithium toxicity. Fluconazole, indomethacin, and rifampin can also interact with losartan. Food slows the absorption of losartan but has minimal effects on the activity of the drug. Losartan, when taken with either potassium supplements or drugs that spare potassium loss (e.g., triamterene), may lead to elevated serum potassium levels. Grapefruit juice will slow the metabolism of losartan to its active form and thus may decrease the effectiveness of losartan. Table 26.6 presents a summary of agents that interact with losartan.

Assessment of Relevant Core Patient Variables

Health Status

Patients who have pathologies that are dependent on the renin-angiotensin-aldosterone system (e.g., patients with severe CHF) should not use ARBs because oliguria, progressive azotemia, or (rarely) acute renal failure or death may result. Patients receiving ACE inhibitors who have renal artery stenosis have shown elevated serum creatinine or BUN, and it is hypothesized that ARBs would have the same effect. Assess patients for these conditions and monitor them for possible effects. Elevations in serum creatinine or BUN also may occur in other patients taking losartan. Of all patients who use losartan for hypertension, minor elevations in BUN and creatinine occur in fewer than 1%. Although elevated serum levels of losartan have been found in patients with decreased creatinine clearance, the active metabolite is not affected. Therefore, no dose adjustment is required for these patients.

Determine whether the patient is taking a prescribed potassium supplement or a potassium-sparing diuretic, either of which can produce hyperkalemia when taken with losartan, because of the potassium in its chemical formulations.

Patients who have impaired hepatic impairment do have increased bioavailability of losartan because metabolism is impaired. They should be given a lower starting dose of the drug and be monitored for therapeutic and adverse effects. Small decreases in hemoglobin and hematocrit occur in patients taking losartan. Although the effect is normally not clinically important, monitor these patients.

TABLE 26.6 Agents That Interact with P Losartan

Interactants	Effect and Significance	Nursing Management
lithium	Increased renal resorption of lithium may produce lithium toxicity.	Monitor lithium levels.
fluconazole	Metabolism of losartan via CYP2C9 may be inhibited; possibility of hypotension or adverse effects	Monitor blood pressure and assess for adverse effects if coadministered.
indomethacin	May decrease the effectiveness of losartan; blood pressure may not be as well controlled	Monitor blood pressure closely if coadministered; contact prescriber if loss of blood pressure control.
rifampin	Increases the metabolism of losartan; blood pressure may not be as well controlled	Monitor blood pressure closely if coadministered; contact prescriber if loss of blood pressure control.
potassium-sparing diuretics; other potassium-sparing drugs; potassium supplements; salt substitutes containing potassium	Additive effects to increase potassium levels; serious elevations of serum potassium may occur	Avoid coadministration with losartan.
grapefruit juice	Decreases the metabolism of losartan, which decreases the conversion to its active form. Decreased active drug can decrease the antihypertensive effect achieved.	Monitor for therapeutic effect.
ma huang (Ephedra)	May decrease the antihypertensive effectiveness through antagonist effects.	Avoid this combination
yohimbine	Increased norepinephrine release by yohimbine may counteract the hypotensive effect of ACE inhibitors.	Avoid concomitant use

Hypovolemia and salt depletion (usually from diuretic therapy) pose the same risk for hypotension to patients receiving losartan as to patients receiving captopril. It is important to correct these conditions before giving losartan.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding before administering losartan. Because of adverse effects on the fetus and neonate, losartan should not be used during pregnancy. Animal studies indicate that losartan passes into breast milk; it is not known whether losartan also passes into human milk. However, because of the serious effects that may occur, patients should not breast-feed while taking losartan. Additional concerns for women taking losartan come from other animal studies showing that female rats receiving the drug have a slightly higher rate of pancreatic cancer and impaired fertility. Again, the effects in humans are not known. The safety and efficacy of losartan and other ARBs in children younger than 18 years is not known. No dosage adjustments seem to be necessary for older adults, because losartan is equally safe and effective in this group compared with younger adults. Older adults generally tolerate ARB therapy better than therapy with other antihypertensive drug classes. Because losartan has essentially no contraindications, older adults with hypertension and other comorbidities can still take losartan at standard doses.

Lifestyle, Diet, and Habits

Assess the patient's usual lifestyle. Lifestyle modifications that are general for all patients requiring hypertensive therapy should be followed for patients taking losartan. Assess whether the patient is taking an over-the-counter (OTC) potassium supplement or uses a salt substitute containing potassium, because either one in combination with losartan may produce hyperkalemia. Assess for use of grapefruit juice because it may decrease the effectiveness of the drug.

Environment

Losartan may be administered in any setting.

Culture and Inherited Traits

It is a good idea to note the patient's racial background before administering losartan. Like captopril, losartan is less effective when used as monotherapy in hypertensive African Americans than in other racial groups. This effect may be because this racial group usually carries a low renin level. Again, adding a thiazide diuretic to the therapy will increase its effectiveness (Ferdinand & Armani, 2007; International Society of Hypertension in Blacks Guidelines, 2003).

Nursing Diagnoses and Outcomes

- Risk for Injury related to adverse effects on fetus and neonate.
  Desired outcome: *The patient receiving losartan will report pregnancy to prescriber as soon as possible.*

- Risk for Injury related to fall secondary to adverse effect of dizziness.
  Desired outcome: *The patient will not fall.*
- Risk for Infection (upper respiratory) related to adverse effects of drug therapy.
  Desired outcome: *The patient will not develop an upper respiratory infection, or if one develops, it will be managed appropriately to minimize complications.*

Planning and Intervention

Maximizing Therapeutic Effects

Like all drug therapy for hypertension, the use of losartan should be accompanied by the recommended lifestyle changes. Determine whether the patient has made these changes and provide encouragement to continue with them throughout drug therapy.

If losartan is ineffective alone, add a diuretic. Hydrochlorothiazide has been found to have an additive effect. A combination of losartan and hydrochlorothiazide is available. Consult with the physician or nurse practitioner for additional drug orders if indicated. Avoid giving losartan with grapefruit juice.

Minimizing Adverse Effects

Help the patient out of bed when he or she is first started on losartan therapy, in case dizziness occurs. It is important to treat the patient symptomatically for upper respiratory tract infections and diarrhea, if they are present. Monitor creatinine, BUN, hemoglobin, and hematocrit levels to verify that changes are not clinically meaningful. If the patient is currently prescribed a potassium supplement or a drug that increases potassium levels indirectly, consult with the prescriber about changing this therapy before starting losartan.

Providing Patient and Family Education

- If female patients are of childbearing age, caution them about the adverse effects that losartan can have on the fetus and neonate. Teach women to notify their prescriber immediately if they become pregnant.
- Explain the importance of arising slowly until the effects of the drug are known or if dizziness is present.
- Teach patients to avoid hazardous activities until effects of the drug are known.
- Teach patients not to take OTC potassium supplements or use a salt substitute that contains potassium.
- Tell patients to notify the prescriber if upper respiratory infection occurs.
- Provide general teaching about hypertension, lifestyle changes, and losartan core drug knowledge.

Ongoing Assessment and Evaluation

Monitor blood pressure throughout losartan therapy and determine whether the desired blood pressure goal has been achieved. Consider adding a diuretic if losartan is not effective in monotherapy. Verify that the patient continues with lifestyle changes. Treatment is effective if the desired reduction in blood pressure occurs in either monotherapy or multidrug therapy without the patient having serious adverse effects.

MEMORY CHIP

P Losartan

- Used to treat hypertension and kidney damage in people with type 2 diabetes
- Blocks vasoconstricting and aldosterone-secreting effects of angiotensin II by preventing angiotensin II from binding to receptor sites
- Does not produce ACE cough
- Most frequent adverse effects: upper respiratory infections, dizziness, and diarrhea
- No serious adverse effects in normal dosing
- **Life span alert: Do not give to women who are pregnant or breast-feeding.**
- Maximizing therapeutic effect: Continue with lifestyle changes.
- Minimizing adverse effects: Assist patient out of bed and with ambulation.
- Most important patient education: Use caution until it is known whether drug will cause dizziness; avoid OTC potassium supplements and salt substitutes containing potassium.
- **Black box warning: Can cause injury and death to a developing fetus during the second and third trimesters.**

Drugs Closely Related to P Losartan

ARBs that are closely related to losartan are candesartan (Atacand), eprosartan (Teveten), irbesartan (Avapro), olmesartan (Benicar), telmisartan (Micardis), and valsartan (Diovan). Major differences from losartan relate to labeled indication, half-life, and means of metabolism. The following drugs have differences in labeled indications: candesartan (heart failure and hypertension only); eprosartan (hypertension only); irbesartan (diabetic nephropathy and hypertension only); olmesartan (hypertension only); telmisartan (hypertension only); and valsartan (hypertension; additionally labeled for use in MI but not for diabetic nephropathy). The following drugs have a longer half-life than losartan: candesartan, eprosartan, irbesartan, olmesartan, and valsartan. Unlike losartan, olmesartan, telmisartan, and valsartan do not rely on the P-450 system for metabolism.

DRUGS USED AS SECOND-LINE ANTIHYPERTENSIVES

Second-line antihypertensives are added, usually as fourth or fifth drugs in a patient's drug therapy, when it is difficult to control the blood pressure with combinations of the first-line antihypertensives.

• C Selective Aldosterone Blockers

Selective aldosterone blockers are approved for use in treating hypertension. These drugs block the mineralocorticoid receptors while having little interaction with androgen and progesterone receptors (thus the term *selective aldosterone blocker*). Blockade of these selective aldosterone receptors lowers blood

pressure and reduces the end-organ damage that occurs with hypertension. The use of ACE inhibitors and ARBs alone does not protect organs from damage completely because the body uses renin-angiotensin-aldosterone system escape mechanisms. Aldosterone blockers, when added to either ACE inhibitor therapy or ARB therapy, provide added benefit, which may be attributable to preventing the deleterious effects from renin-angiotensin-aldosterone system escape mechanisms. One study showed that the addition of the aldosterone blocker spironolactone to therapy with an ARB helped reduce the left ventricular mass index and had beneficial effects on CV remodeling (Taniguchi, Kawai, Date, et al., 2006). Aldosterone blockers, like spironolactone, when added to other antihypertensive therapy, may help decrease albuminuria in patients with diabetic nephropathy (Schjoedt, Rossing, Juhl, et al., 2005).

Although JNC 7 guidelines do not list aldosterone blockers as part of primary therapy for hypertension, eplerenone is labeled for use as monotherapy or combination therapy and spironolactone is labeled for combination therapy in primary hypertension. As more research is completed with these drugs, it is likely that they may become part of primary therapy. These drugs are also indicated in the treatment of CHF (see Chapter 29). Eplerenone (Inspra) is the prototype selective aldosterone blocker.

Nursing Management of the Patient Receiving P Eplerenone

Core Drug Knowledge

Pharmacotherapeutics

Eplerenone is used to treat hypertension, either alone or with other antihypertensives. Eplerenone has been shown to lower blood pressure and reduce end-organ damage that can occur in hypertension. The full therapeutic effect of eplerenone takes 4 weeks to be evident. When given after MI to patients with evidence of systolic left ventricular dysfunction and symptoms of heart failure, eplerenone reduced hospitalizations for CV problems and deaths from CV disease (Stier, 2003). Eplerenone has been approved for treatment of heart failure after an MI.

Pharmacokinetics

Eplerenone is well absorbed from the GI system and reaches mean peak plasma concentrations within 1.5 hours after administration. Absorption is not affected by food. Eplerenone is about 50% protein bound and is bound primarily to alpha-1 acid glycoproteins. Metabolism of eplerenone is through the liver and CYP3A4 is the primary isoenzyme involved in its metabolism. Metabolism produces inactive metabolites. Elimination half-life is about 4 to 6 hours. Steady state is achieved within 2 days. Less than 5% of eplerenone is excreted unchanged. About two thirds of the drug is excreted by the kidneys through the urine, and about one third is excreted through the GI tract through stool.

Pharmacodynamics

Eplerenone binds selectively to the mineralocorticoid receptors, thereby blocking aldosterone from binding to these receptors. Eplerenone does not bind significantly to the glucocorticoid receptors, or to the progesterone or androgen receptors, which are also stimulated by aldosterone. By preventing aldosterone from binding to its receptor sites in the kidney, heart, blood vessels, and brain, eplerenone inhibits sodium and water retention as well as the other effects of aldosterone, which cause hypertension. For this reason, eplerenone can also be considered a potassium-sparing diuretic. By inhibiting aldosterone from attaching to its receptors, eplerenone also impairs the negative regulatory feedback mechanism of the renin-angiotensin-aldosterone system. Because the body does not receive the feedback message that aldosterone levels are sufficiently high, the body produces extra renin and aldosterone. However, increasing renin activity and elevated plasma levels of aldosterone do not offset the beneficial effects on blood pressure exerted by eplerenone.

Contraindications and Precautions

Eplerenone is contraindicated if patients have a serum potassium level greater than 5.5 mEq/L; type 2 diabetes with microalbuminuria; serum creatinine greater than 2 mg/dL in men or greater than 1.8 mg/dL in women; or a creatinine clearance less than 50 mL/min. Eplerenone is also contraindicated if patients are currently taking any of the following medications: potassium supplements; potassium-sparing diuretics (amiloride, spironolactone, triamterene); or a strong inhibitor of CYP3A4 (e.g., ketoconazole or itraconazole). All of these conditions increase the risk of developing hyperkalemia. Weak inhibitors of CYP3A4 (e.g., erythromycin, saquinavir, verapamil, fluconazole) may potentially also cause this, so precaution must be used. No adequate and well-controlled studies have been conducted for eplerenone in pregnant women, although animal studies have not shown potential complications; it is considered a pregnancy category B drug.

Adverse Effects

Generally, eplerenone is well tolerated, and adverse effects are mild. Hyperkalemia is the primary adverse effect. This is a potentially serious adverse effect, because the potassium levels may be high enough to cause serious or fatal arrhythmias. Another electrolyte imbalance that can occur, although not as frequently as hyperkalemia, is hyponatremia. Elevated triglyceride levels are also possible. Dizziness is another fairly common adverse effect, although its incidence is less than half that of hyperkalemia. Other possible serious adverse effects include angina and MI.

Other adverse effects that can occur, but are rare or infrequent, include:

- GI: diarrhea, abdominal pain
- GU: albuminuria, painful breasts and gynecomastia (in men), abnormal vaginal bleeding
- Metabolic: hypercholesterolemia, increased BUN, increased uric acid, increased serum creatinine, and increased ALT
- Miscellaneous: coughing, fatigue, flu-like symptoms

Drug Interactions

Eplerenone interacts with a few other drugs, mostly those that are ACE inhibitors, ARBs, or CYP3A4 potent inhibitors. Drugs that increase potassium levels, either directly or indirectly, can also have an additive effect with eplerenone. Administration with St. John's wort decreases the availability of eplerenone by about 30%. Grapefruit juice increases the availability of eplerenone by about 25%. Both of these changes are related to interactions involving the P-450 system. Table 26.7 presents a summary of drugs that interact with eplerenone.

Assessment of Relevant Core Patient Variables

Health Status

Before administering eplerenone, verify that the patient has hypertension. Assess serum potassium, serum creatinine, and creatinine clearance for alterations that indicate a contraindication to the drug. Also, assess whether the patient is receiving any concurrent drug therapy that is considered a contraindication to eplerenone therapy. The safety and efficacy of eplerenone in severe liver disease have not been established.

Life Span and Gender

Assess the life span status of the patient. Because the exact effect of eplerenone on pregnancy is not known, assess whether the patient is pregnant. The drug should be used only if potential benefits outweigh potential risks. Eplerenone passes into breast milk, but the exact concentration of the drug is unknown. The effects on the breast-fed infant are unknown at this time. Nursing mothers should most likely either discontinue the drug or discontinue nursing. The efficacy and safety of eplerenone are not known for children. Older adults may safely take eplerenone unless they have severe renal impairment.

Lifestyle, Diet, and Habits

Assess whether the patient uses an OTC potassium supplement or a salt substitute containing potassium; both are contraindications to drug therapy with eplerenone. Determine whether the patient uses St. John's wort or drinks grapefruit juice, both of which change the amount of drug available.

Environment

Eplerenone can be administered in any environmental setting and does not require special assessment of the environment.

TABLE 26.7 Agents That Interact with P Eplerenone

Interactants	Effect and Significance	Nursing Management
ACE inhibitors, ARBs	Increased risk of hyperkalemia; may cause arrhythmias	Avoid coadministration if possible; monitor serum potassium levels closely if coadministered.
potent CYP3A4 inhibitors (e.g., ketoconazole, itraconazole); weak CYP3A4 inhibitors (e.g., erythromycin, saquinavir, verapamil, fluconazole)	Potent inhibitors increase circulating levels of eplerenone fivefold; weak inhibitors increase them twofold. This increases risk of adverse effects, especially hyperkalemia.	Avoid coadministration of potent CYP3A4 inhibitors. Give lower initial dose of eplerenone if weak inhibitors are coadministered; titrate slowly while monitoring serum potassium levels.
ma huang (Ephedra)	May decrease the antihypertensive effectiveness through antagonist effects	Avoid this combination.
NSAIDs	Theoretical interaction; NSAIDs given with other potassium-sparing antihypertensives decrease antihypertensive effect and produce severe hyperkalemia in patients with impaired renal function. This interaction may possibly also occur with eplerenone.	Monitor blood pressure and potassium levels closely if these drugs are coadministered.
St. John's wort	Decreases available eplerenone by 30%	Avoid starting St. John's wort after dosage has been titrated to achieve therapeutic effect from eplerenone; alternately, monitor for therapeutic effect if herb is to be started. Increase dose of eplerenone if needed.
lithium	Theoretical interaction; coadministration of lithium and diuretics or ACE inhibitors has led to lithium toxicity	Monitor lithium levels if coadministered with eplerenone.
yohimbine	Increased norepinephrine release by yohimbine may counteract the hypotensive effect of ACE inhibitors.	Avoid concomitant use.

Nursing Diagnoses and Outcomes

- Risk for Injury related to the adverse effect of dizziness
  Desired outcome: *The patient will not become injured from a fall caused by dizziness while on eplerenone therapy.*
- Potential Complication: Hyperkalemia related to eplerenone therapy
  Desired outcome: *The patient will maintain normal potassium levels while taking eplerenone therapy.*
- Deficient Knowledge related to avoiding potassium supplements and potassium-based salt substitutes
  Desired outcome: *Patient will have adequate knowledge to make informed decisions when choosing OTC supplements and salt substitutes while taking eplerenone.*

Planning and Intervention

Maximizing Therapeutic Effects

The nursing actions to maximize the therapeutic effects of eplerenone therapy are discussed under Patient and Family Education.

Minimizing Adverse Effects

Monitor the patient's serum potassium level periodically during eplerenone therapy. Monthly assessments throughout therapy are indicated for those at risk for hyperkalemia (including those on ACE inhibitors and ARBs); however, more frequent assessment (every other week) is warranted initially until the effects of the drug on the patient are known. Hyperkalemia occurs more frequently as renal function decreases, so that patients with deteriorating renal function need to be assessed carefully. If the patient is receiving drugs that are weak CYP3A4 inhibitors (e.g., erythromycin, saquinavir, verapamil, fluconazole), the initial dose should be half of what is normally given until the effect on the potassium level is known. Patients who are experiencing dizziness while on eplerenone therapy should be assisted in ambulation and protected from falls.

Providing Patient and Family Education

- Teach patients to take eplerenone daily, as it is most effective if taken as directed.
- Encourage patients to make lifestyle changes that are known to decrease hypertension, including following a DASH diet (with the exception of adding potassium-rich food).
- Teach patients and their families to avoid foods very high in potassium, such as bananas.
- Teach patients to avoid salt substitutes that contain potassium. This advisory is especially important because many patients use a salt substitute when they are limiting sodium intake as part of implementing the lifestyle changes recommended for hypertension.
- Teach patients to avoid potassium supplements and the contraindicated drugs while taking eplerenone.
- Teach patients and families the rationale for and importance of periodic blood tests to check potassium levels.
- Teach patients that eplerenone may be taken either with or without food.
- Teach patients and families to avoid using St. John's wort or drinking grapefruit juice without first contacting the patient's physician or nurse practitioner because these substances change the amount of eplerenone available in the bloodstream. For patients who use these substances, the dosage of eplerenone may need to be adjusted downward with grapefruit juice consumption and upward with the start of St. John's wort.
- Teach patients who experience dizziness to use handrails when going up and down stairs, to stand slowly from a sitting or a lying position, and to obtain assistance when walking to prevent falls.

Ongoing Assessment and Evaluation

Potassium levels and renal function should be assessed throughout therapy. Drug therapy with eplerenone is successful if the patient has a decrease in blood pressure and does not experience substantial adverse effects.

Drug Significantly Different From P Eplerenone

Spironolactone

Spironolactone (Aldactone) is a nonspecific aldosterone blocker and a potassium-sparing diuretic. Like eplerenone, it can block the mineralocorticoid receptors for aldosterone, preventing sodium and fluid retention that contributes to hypertension. Hyperkalemia is possible with both spironolactone and eplerenone. However, unlike eplerenone, spironolactone also equally stimulates androgen and progesterone receptors, which is likely the cause of the frequent endocrine adverse effects, such as inability to achieve an erection, gynecomastia (in men), irregular bleeding or postmenopausal bleeding (in women), hirsutism, and deepening of the voice.

MEMORY CHIP

P Eplerenone

- Used in treating hypertension
- Works by selectively blocking aldosterone receptors
- Major contraindications: elevated potassium levels, severe renal failure, type 2 diabetes with microalbuminuria, concurrent administration of drugs that increase potassium levels either directly or indirectly
- Most common adverse effects: hyperkalemia, dizziness, hyponatremia
- Most serious adverse effect: hyperkalemia
- Maximizing therapeutic effect: Take regularly, implement or continue lifestyle changes along with drug therapy.
- Minimizing adverse effects: Monitor potassium levels and renal function.
- Most important patient education: Avoid potassium-based salt substitutes; avoid potassium supplements.

The frequency of these adverse effects (compared with their rarity with eplerenone) makes spironolactone less desirable as an antihypertensive agent.

Like eplerenone, spironolactone is labeled for used in hypertension and CHF. Unlike eplerenone, spironolactone is also labeled for use in ascites, nephritic syndrome, edema, hypokalemia, and primary aldosteronism. More information about spironolactone is provided in Chapter 27.

Direct-Acting Vasodilators

Hydralazine, minoxidil, epoprostenol, and tolazoline are all direct-acting vasodilators. Hydralazine and minoxidil are second-line drugs for hypertension; epoprostenol and tolazoline are used solely for treating pulmonary hypertension.

Hydralazine (Apresoline), a direct-acting vasodilator, is normally used as an adjunct to other antihypertensives, perhaps as the third or fourth drug in a therapeutic regimen. Parenteral hydralazine is used for severe hypertension when the need to reduce the blood pressure is urgent or the patient cannot take oral drugs. It may also be given alone. In unlabeled use, hydralazine is used following valve replacement, for treating severe aortic insufficiency, and for reducing afterload to manage CHF.

Hydralazine produces direct smooth muscle relaxation of the arterioles. Hydralazine alters cellular calcium metabolism, thereby interfering with calcium movement within the vascular smooth muscles responsible for venous contraction and dilation. Peripheral vasodilation results, promoting a decrease in arterial blood pressure and decreased peripheral resistance. As a reflexive action to the peripheral vasodilation, the body increases heart rate, stroke volume, and cardiac output. The reflex mechanism is caused by an increase in sympathetic stimulation. Because hydralazine preferentially dilates arterioles rather than veins, orthostatic hypotension does not occur as frequently as with other antihypertensives. However, this effect promotes an increase in cardiac output. Hydralazine also increases plasma renin activity, leading to production of angiotensin II. Angiotensin II increases aldosterone production, which increases sodium and water retention. Because of the reflexive increases in cardiac function, hydralazine is commonly given with drugs that decrease sympathetic activity, such as beta blockers or the alpha-2 stimulant clonidine. Because of the increases in sodium and water retention, hydralazine is coadministered frequently with a diuretic. Consult with the physician or nurse practitioner if these drugs are not currently ordered.

Hydralazine is a pregnancy category C drug. It crosses the placenta and may enter breast milk. It is compatible with breast-feeding, according to the American Academy of Pediatrics.

The drug is contraindicated with coronary artery disease, and mitral valvular rheumatic disease. It should be administered cautiously to patients with advanced renal damage, cerebral vascular accidents, suspected coronary artery disease, pulmonary hypertension, and sensitivity to tartrazine (FDC yellow dye #5) because some of the products contain this substance. The adverse effects of hydralazine usually resolve when the dose is reduced. Occasionally, the drug needs to be discontinued because of adverse effects. Many of the adverse effects are related to increased cardiac output. The most common adverse effects include palpitations, tachycardia, angina, anorexia, nausea, and vomiting.

A serious adverse effect that may occur while taking hydralazine is the development of symptoms of systemic lupus erythematosus (SLE), an autoimmune disease, such as arthralgia, dermatoses, fever, splenomegaly, and glomerular nephritis. The syndrome usually occurs after 6 months of drug therapy or more, and the likelihood of occurrence increases with larger doses and longer duration of therapy. Complete blood counts (CBCs) and antinuclear antibody titer are affected. Monitor these lab result s to assess for adverse effects from the drug.

Assess for signs of peripheral neuritis (numbness, tingling in hands and feet). If these signs are present, seek an order to administer pyridoxine (a B vitamin) because the neuritis may be caused by the antipyridoxine effect of drug therapy. If hydralazine is given parenterally, administer it as soon as possible after drawing it into a syringe to promote stability of the drug. (Note: hydralazine changes color after contact with a metal filter.)

Minoxidil (Loniten), like hydralazine, is a direct-acting vasodilator. It also does not create orthostatic hypotension because it does not affect vasomotor reflexes. It appears to block calcium uptake through the cell membrane. Like hydralazine, it is used with beta blockers to control reflex tachycardia and with a diuretic—preferably one acting in the ascending loop of Henle—to prevent substantial fluid accumulation.

Minoxidil differs in its serious adverse effects. It can cause pericardial effusion, occasionally progressing to cardiac tamponade, and it can worsen angina pectoris. Fluid retention and several hundred milliequivalents of salt accumulation can occur in a few days of use if the drug is not prescribed with a loop diuretic.

Hypertrichosis (excess hair growth) occurs in 3 to 6 weeks after starting therapy in 80% of patients receiving minoxidil. Elongation, thickening, and enhanced pigmentation of fine body hair develops. It is usually noticed first on the temples, between eyebrows, at the hairline, and in the eyebrows or sideburn area of the upper lateral cheek. It will progress down the back, arms, legs, and scalp. New hair growth stops when minoxidil use is discontinued, although it will take 1 to 6 months for appearance to return to normal. This adverse effect of hypertrichosis spawned a new therapeutic use for minoxidil—treating male pattern baldness and female hair loss or thinning of hair in the frontoparietal area. For growing hair, topical minoxidil (Rogaine) is the drug of choice. (See Chapter 51 for more information.)

Epoprostenol (Flolan), like hydralazine, also directly dilates peripheral vessels. Unlike hydralazine, epoprostenol

also directly dilates pulmonary vascular beds and inhibits platelet aggravation. For these reasons, the sole clinical indication for epoprostenol is to treat primary pulmonary hypertension. It is administered via IV infusions through a central venous catheter with the rate regulated by an infusion pump.The correct dose is determined by increasing the amount infused until the desired effect on the pulmonary arteries is achieved. This dose is then continued as the maintainence dose. Abrupt withdrawal, including interruptions in the drug delivery (e.g., temporarily running out of drug), or sudden large dose reductions, may result in rebound pulmonary hypertension. Treatment of primary pulmonary hypertension is chronic. Patients are discharged with the drug and the infusion pump. Treatment may last up to several years. Patients should be aware of this fact before instituting therapy. Patients who will receive epoprostenol at home (and their families) need teaching regarding drug reconstitution, administration, and central catheter care in addition to information about the drug. A firm commitment to this treatment on the part of patient and families is required for the drug therapy to be effective.

Epoprostenol is contraindicated in patients who have CHF with severe left ventricular systolic dysfunction. The drug is in pregnancy category B; whether it is excreted in breast milk is unknown.

Adverse effects of epoprostenol are mostly cardiovascular and include: chest pain, hypotension, bradycardia or tachycardia, arrythmias, palpitations, MI, right-sided heart failure, edema, and shock. Other adverse effects include facial flushing, sweating, and muscular aches and pains.

Tolazoline (Priscoline) is a peripheral vasodilator and an alpha blocker. Administered via the IV route, it is used to treat pulmonary hypertension. CV adverse effects such as palpitations, hypertension, hypotension, and tachyarrhythmias are common; headache and vertigo also occur frequently. Serious adverse effects such as leukopenia, thrombocytopenia, hepatitis, or renal failure are rare. Tolazoline is a pregnancy category C drug.

Centrally Acting Alpha-2 Agonists

Clonidine (Catapres) and metheldopa are the two centrally acting alpha-2 agonists used to lower blood pressure. Clonidine's alpha-2 stimulation results in decreased heart rate, decreased blood pressure, decreased vasoconstriction, and decreased renal vascular resistance. However, renal blood flow and glomerular filtration rate remain unchanged essentially. Clonidine is considered a secondary or supplemental antihypertensive. It is used in step 2 antihypertensive therapy. Clonidine may be administered orally, parenterally, or, most frequently, transdermally. When administered transdermally, the drug is released at a constant rate for 7 days.

Some adverse effects of clonidine, such as dry mouth, drowsiness, dizziness, sedation, and constipation, are fairly common. Dry mouth and drowsiness also occur frequently when clonidine is administered transdermally. Rebound hypertension may occur if the drug is discontinued abruptly. Erythema is a common adverse effect.

Before the initiation of therapy, the nurse should confirm that the patient does not have severe coronary insufficiency, recent MI, or cerebrovascular disease, which may be affected adversely by decreased sympathetic outflow from the CNS. Assess for chronic renal failure because this condition increases the drug half-life, and a decreased dose may be needed.

In the hospital before surgery, drug administration with clonidine may continue for up to 4 hours before the procedure and be resumed as soon as possible thereafter to prevent hypertensive rebound from withdrawal. When clonidine is self-administered in the home setting with a transdermal patch, teach patients to discard used patches with care so that children cannot find the patch, play with it, or suck on it and sustain severe hypotension. Because clonidine can be used to prevent the symptoms of narcotic withdrawal, a black market exists for clonidine in some communities, and the patient may be tempted to sell the prescription. Nurses and other health care providers should be alert to patients returning for a duplicate prescription of clonidine, claiming to have lost the original shortly after it was prescribed. This may indicate the patient has sold or stored the prescription. In such cases, the prescriber may be notified and consulted about a change in the prescription, particularly if it appears that the patient is not taking the clonidine. Because of these concerns and the risk for adverse effects clonidine's use as an antihypertensive is currently limited. A discussion of clonidine's off-label uses is presented in Chapter 13.

Methyldopa (Aldomet) is similar to clonidine except that it stimulates both alpha-1 and alpha-2 receptors to lower blood pressure. This drug also works centrally to achieve its effects. It is contraindicated if the patient is currently receiving any monoamine oxidase inhibitor (MAOI). Adverse effects are fairly common and affect the following systems: CV (angina, bradycardia, hypotension); GI; neurologic (asthenia, dizziness, headache, sedation); and psychiatric (anxiety, depression, dream anxiety disorder). Because of its many adverse effects, methyldopa is not widely used at this time.

Peripherally Acting Alpha-1 Blockers

The alpha-1 blockers are also secondary hypertensive drugs; they are composed of prazosin (Minipress), terazosin (Hytrin), and doxazosin (Cardura). These drugs block postsynaptic alpha-1 adrenergic receptors, producing vasodilation of resistance vessels (arterioles) and capacitance vessels (veins) and thereby decreasing blood pressure. Both standing and lying blood pressures are reduced, particularly the diastolic blood pressure. A substantial first-dose effect of hypotension, especially orthostatic hypotension, can occur with

these drugs. Prazosin has the unique disadvantage of causing sodium and water retention and increasing plasma volume. For these reasons these drugs are used infrequently in treating hypertension.

These drugs differ from metoprolol in that they have unique therapeutic actions. Terazosin and doxazosin also are used in treating benign prostatic hypertrophy. The reduction of symptoms and increase in urine flow rate are attributed to relaxation of smooth muscle from the alpha-1 blockade in the bladder neck and prostate gland. Bladder contractility is not affected because there are few alpha receptors in the bladder body.

Unlabeled uses of these drugs include treating refractory CHF, managing Raynaud vasospasm, treating benign prostatic hyperplasia (prazosin and terazosin), and treating CHF with concurrent digoxin and diuretics (doxazosin). Frequent adverse effects of these drugs are dizziness, hypotension, somnolence, asthenia, headache, palpitations, and nausea. These drugs are in pregnancy category C.

Peripherally Acting Antiadrenergics

Reserpine, guanethidine, and guanadrel are peripherally acting antiadrenergics and are secondary antihypertensives.

Unlike metoprolol, reserpine (Resa, Serpalan) is also used to relieve symptoms in agitated psychotic states, such as schizophrenia, primarily if the patient cannot tolerate phenothiazides. Reserpine as a peripherally acting antiadrenergics has a different mechanism of action than metoprolol. Reserpine depletes the stores of norepinephrine. Therefore, less norepinephrine is available for release into the synaptic cleft, which causes depression of sympathetic nerve function and also decreases heart rate and blood pressure. Reserpine also has sedative and tranquilizing effects believed to result from depletion of catecholamine and 5-hydroxytryptamine.

Adverse effects associated with reserpine are serious. This drug can cause severe depression— severe enough to result in suicide—and therefore is contraindicated if the patient's emotional health record shows a history of depression. The drug should be discontinued at the first sign of depression. This drug is used only if other drug therapies have been unsuccessful in controlling hypertension.

Both guanethidine (Ismelin) and guanadrel (Hylorel) are used to treat hypertension as adjuncts to other therapy. Guanethidine can also be used in treating renal hypertension. Guanethidine and guanadrel inhibit or interfere with the release and distribution of norepinephrine at the sympathetic neuroeffector junction, which leads to decreased sympathetic function and results in decreased heart rate and blood pressure.

Contraindications for both drugs are pheochromocytoma (rare adrenal tumor), uncontrolled CHF, and use of MAOIs. A major adverse effect is orthostatic hypotension, which can occur frequently with these drugs because they decrease the reflexive vasoconstriction that occurs when arising from a lying position.

ADJUNCT THERAPY IN HYPERTENSION

C Antihyperlipidemic Drugs

Antihyperlipidemic drugs reduce blood lipid levels. They are used as adjuncts to hypertensive drug therapy. Because hypertension can be caused or aggravated by the narrowed arterial passages when fat is deposited on the wall of the vessel, decreasing fat levels circulating in the blood is advantageous. Dietary modifications are a common first step for both hypertension and elevated cholesterol levels. Therefore, patient education should stress dietary modifications heavily for patients who are hypertensive and have elevated serum lipid levels. Antihyperlipidemic drugs are discussed in more detail in Chapter 28.

C Nitrates

Nitroglycerin is a nitrate that is sometimes used as an adjunct therapy in treating hypertension. Nitroglycerin is a vasodilator and has most of its effect on the venous side, causing venous dilation, peripheral pooling of blood, and decreased return to the heart. These factors decrease peripheral resistance and cardiac output, thus lowering blood pressure. IV nitroglycerin is used to treat severe hypertension. Nitroglycerin is discussed fully in Chapter 30.

C DRUGS USED IN HYPERTENSIVE CRISIS

As described earlier in the chapter, a hypertensive crisis is an acute event and is defined as systolic blood pressure exceeding 210 mm Hg and diastolic blood pressure exceeding 120 mm Hg. When hypertensive crisis occurs, the patient is in danger of rapidly developing damage to one of the vital organs. The goal is to reduce the blood pressure by no more than 25% in the initial period of drug therapy (within minutes of starting therapy and up to 2 hours after the start of the infusion). Further blood pressure reductions toward 160/100 mm Hg should then be the goal within 2 to 6 hours after starting drug infusion. A recent meta-analysis found that there is insufficient evidence from randomized controlled clinical trials to determine which drug or drug class is the most effective in reducing mortality and morbitiy form hypertensive crisis (Perez & Musini, 2008). The prototype drug chosen for use in hypertensive crisis is nitroprusside (Nitropress; Table 26.8).

Nursing Management of the Patient Receiving P Nitroprusside

Core Drug Knowledge

Pharmacotherapeutics

Nitroprusside is the drug of choice when an immediate reduction of blood pressure is indicated in hypertensive crisis. It should be administered concurrently with longer-acting antihypertensives to minimize the duration of treatment. Other uses include reducing bleeding during surgery

TABLE 26.8 Summary of Selected Drugs for Hypertensive Crisis

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P nitroprusside (Nitropress)	Hypertensive crisis	*Adult:* IV, 0.3 mcg/kg/min with gradual upward titration until desired effect or maximum rate of 10 mcg/kg/ min occurs	*Onset:* 1–2 min *Duration:* 3–5 min $t_{1/2}$: 2 min
diazoxide (Hyperstat IV)	Hypertensive crisis	*Adult:* direct IV, 1–3 mg/kg to a maximum of 150 mg in a single injection; repeat every 5–15 min until blood pressure drops, then repeat at 4- to 24-h intervals to maintain blood pressure until oral drug can begin	*Onset:* 1–2 min *Duration:* <12 h $t_{1/2}$: 28 ± 8.3 h
phentolamine (Regitine)	Preoperatively to prevent or control hypertension with pheochromocytoma Prevent or treat dermal necrosis and sloughing resulting from administration or extravasation of IV norepinephrine Diagnosis of pheochromocytoma	*Adult:* IV/IM, 5 mg 1 or 2 h before surgery, repeated if needed; 5 mg as needed during surgery *Child:* IV/IM, 1 mg *Adult:* IV (prophylactic), 10 mg/L of norepinephrine solution; SC (treatment), 5–10 mg in 10 mL of saline solution into area of extravasation within 12 h *Child:* 0.1–0.2 mg/kg to maximum 10 mg *Adult:* IV, 2.5 mg dissolved in 1 mL sterile water, injected directly by syringe into vein *Child:* 1 mg as above	*Onset:* Immediate *Duration:* 3–10 min $t_{1/2}$: Unknown

through the production of a controlled hypotensive state. It is also used for treating acute HF.

Pharmacokinetics

Nitroprusside is administered intravenously for immediate onset. Maximum effects are observed in 1 to 2 minutes. Resting circulating half-life is about 2 minutes. When the drug is discontinued, the blood pressure may return to its previous level within minutes. The metabolism of nitroprusside is important to understand because it has bearing on dosing and adverse effects. Nitroprusside is metabolized rapidly to cyanide through a reaction with hemoglobin. Cyanide is poisonous. Thiosulfate, an endogenous sulfate derivative created through normal physiologic mechanisms, reacts with the cyanide to produce another element, thiocyanate. The thiocyanate is processed by the liver and then excreted in the urine. Cyanide that becomes thiocyanate and is excreted is prevented from producing poisonous effects in the patient. Cyanide that does not become thiocyanate will bind with cytochromes. This binding prevents the cytochromes from participating in oxidative metabolism. Without oxidative metabolism, the cells cannot provide for their energy needs. Lactic acid is created, and eventually the cells die from hypoxia. Conversion of cyanide to thiocyanate occurs at a rate of 1 mcg/kg per minute. This rate of cyanide clearance corresponds to steady-state processing when nitroprusside is infused at slightly more than 2 mcg/kg per minute. If this rate is exceeded, cyanide builds up and poisons the patient. The half-life of thiocyanate increases from about 3 days to double or triple this time in patients with renal failure.

Pharmacodynamics

Nitroprusside directly relaxes vascular smooth muscle, allowing dilation of peripheral arteries and veins. It is more active on veins than on arteries, thereby promoting peripheral pooling of blood. This effect decreases venous return to the heart, reducing left ventricular end-diastolic pressure and pulmonary capillary wedge pressure (preload). The arteriolar dilation that occurs reduces systemic resistance and decreases mean arterial pressure (afterload). Dilation of coronary vessels also occurs. These processes produce a marked reduction in blood pressure, a slight increase in pulse rate, a slight decrease in cardiac output, and an increased production of renin. The ability to decrease the blood pressure is seemingly unlimited.

Contraindications and Precautions

Nitroprusside is contraindicated for compensatory hypertension in which the primary hemodynamic lesion is aortic coarctation or arteriovenous shunting. Nitroprusside also is contraindicated for providing surgical hypotension in patients with known inadequate cerebral circulation or in moribund patients undergoing emergency surgery. Another contraindication is acute HF associated with reduced peripheral vascular resistance, such as high-output heart failure, which may be seen in endotoxic sepsis. Additionally, the drug is contraindicated in patients with the rare condition of congenital optic atrophy or tobacco amblyopia; these patients have unusually high cyanide-to-thiocyanate ratios.

Nitroprusside is used cautiously in older adults and in patients with renal and hepatic impairment, hypovolemia, and anemia. Nitroprusside given for its hypotensive effect during surgery may decrease the patient's ability to compensate for hypovolemia and anemia. Nitroprusside is a pregnancy category C drug.

Nitroprusside carries the following Black Box warnings: (1) after reconstitution it must be further diluted;

(2) severe drop in blood pressure is possible which can lead to irreversible ischemic injuries or deaths; monitor blood pressure continuously; and (3) cyanide poisoning is possible with high doses.

Adverse Effects

Small, transient excesses in the rate of nitroprusside infusion can result in excessive hypotension, sometimes compromising perfusion of vital organs. This hypotension is self-limiting after discontinuation of the drug. A too-rapid reduction of blood pressure can result in abdominal pain, apprehension, diaphoresis, dizziness, headache, muscle twitching, nausea, palpitations, restlessness, retching, and retrosternal discomfort. Symptoms quickly subside when the nitroprusside infusion slows or stops; they do not return when the infusion resumes at a slower rate.

A life-threatening and unique adverse effect from nitroprusside is cyanide toxicity. Cyanide toxicity can occur when the nitroprusside infusion rate exceeds the rate of cyanide excretion. Cyanide toxicity may manifest as venous hyperoxemia (in which venous blood appears bright-red, similar to arterial blood, as the cells become unable to extract the oxygen delivered to them), metabolic (lactic) acidosis, air hunger, confusion, and death.

Elimination of cyanide increases with the administration of thiosulfate. Coadministration with thiosulfate prevents most cases of nitroprusside induced cyanoide poisoning except when the dose is extremely large. However, this action also has risks. Thiosulfate increases the production of thiocyanate. Thiocyanate is mildly neurotoxic; neurotoxicity is signaled by tinnitus, miosis, and hyperreflexia at serum levels of 1 mmol/L (60 mg/L). Thiocyanate toxicity is life threatening when levels are three or four times higher (200 mg/L). Thiocyanate also interferes with iodine uptake by the thyroid.

Methemoglobin, derived from hemoglobin, can hide cyanide. After nitroprusside is administered, hemoglobin can convert to methemoglobin, leading to methemoglobinemia. This adverse effect is rare, occurring when a patient receives the maximum rate of nitroprusside infusion for a prolonged period (greater than 16 hours). Methemoglobinemia is characterized by blood that appears chocolate brown and that does not change color after exposure to air.

Like other vasodilators, nitroprusside may increase intracranial pressure and cause adverse CV effects, such as bradycardia or tachycardia, and ECG changes. Platelet aggregation may be decreased, and flushing, venous streaking, irritation at the infusion site, rash, hypothyroidism, and ileus may be detected.

Drug Interactions

Additional vasodilation will occur if co-administered with PDE5 inhibitors used to treat erectile dysfunction (Table 26.9).

Assessment of Relevant Core Patient Variables

Health Status

Initially, assess the patient's blood pressure and check for physical states that are contraindications for nitroprusside use, such as compensatory hypertension, acute HF associated with reduced peripheral vascular resistance, inadequate cerebral circulation before anesthesia, moribundity before emergency surgery, congenital optic atrophy, or tobacco amblyopia. Also, determine whether intracranial pressure is elevated. Determine if the patient is at risk of having deficient entrinsic stores of thiosulfate. Patients with relative deficiencies of thiosulfate can include those who are malnourished, have had recent surgery, or are taking diuretics; these patients would be more at risk of cyanonide poisoning from nitroprusside, as they would not clear the cyanonide at the normal rate.

Life Span and Gender

Determine the patient's age before administering nitroprusside. Nitroprusside is given with caution to children and the elderly, who may be more sensitive to the hypotensive effects of the drug. Determine whether the patient is pregnant before administering nitroprusside. In patients who are pregnant, nitroprusside is given only if clearly indicated because it is a pregnancy category C drug.

Environment

Be aware of the setting in which nitroprusside may be administered. Nitroprusside is administered in a hospital setting, where blood pressure can be monitored continuously by a continually reinflated sphygmomanometer (automatic blood pressure cuff) or preferably by an intra-arterial pressure sensor. Once diluted, nitroprusside is sensitive to light and will lose some of its efficacy.

Culture and Inherited Traits

Nitroprusside has a prompt hypotensive effect on all populations.

TABLE 26.9 Agents That Interact with P Nitroprusside

Interactants	Effect and Significance	Nursing Management
PDE5 inhibitors: sildenafil, vardenafil, tadalafil	Additional vasodilation effects and hypotensive effects. Whether a nitrate can be administered after sildenafil treatment is unknown.	These drugs are contraindicated to be given together. However, if the patient develops a sudden pathology where nitroprusside is warranted, the blood pressure should be monitored carefully and the nitroprusside dose should be slowly increased.

Nursing Diagnoses and Outcomes

- Decreased Cardiac Output related to venous dilation, diminished preload, and severe hypotension secondary to therapeutic and adverse effects of drug therapy
  Desired outcome: *Hypotension will not occur to an extent that cardiac output cannot meet the perfusion needs of the vital organs.*
- Acute Pain related to decreased comfort from rapid blood pressure reduction secondary to too-rapid drug infusion
  Desired outcome: *The patient's blood pressure will not drop so quickly that adverse effects result.*
- Risk for Injury related to increased intracranial pressure, cyanide poisoning, or thiocyanate toxicity secondary to adverse effects of drug therapy.
  Desired outcome: *The patient will not suffer injury while on drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

The infusion rate for nitroprusside must be titrated to reduce blood pressure without compromising organ perfusion. When it is given for CHF, titrate the nitroprusside infusion so that measured cardiac output does not increase and systemic blood pressure remains as low as possible without compromising organ perfusion or the maximum infusion rate has been reached—whichever comes first.

Nitroprusside can be inactivated by reactions with trace contaminants. If these reactions have occurred, the nitroprusside will appear blue, green, or red; it will be much brighter than its normal faint brownish color. If the solution appears discolored or if particulate appears, the solution should not be used.

After reconstituting nitroprusside in 2 to 3 mL of dextrose in water or sterile water, dilute it in 250 to 1,000 mL of 5% dextrose in water (D_5W). Reconstituted nitroprusside should not be injected directly. Protect the container of diluted solution from light by placing it in an opaque sleeve or wrapping it in aluminum foil for stability of the solution. It is not necessary to cover the drip chamber or the IV tubing.

Minimizing Adverse Effects

To avoid extreme hypotensive effect, start nitroprusside at a low infusion rate (0.3 mcg/kg/min) and increase it gradually until the desired effect has been achieved or the maximum infusion rate (10 mcg/kg/min) is attained. Each 100 mg of sodium nitroprusside should be mixed with 1 g of sodium thiosulfate to maintain an adequate level of thiosulfate to promote cyanide elimination and prevent nitroprusside-induced cyanide poisoning in the majority of patients.

Do not adjust the infusion rate by gravity because slight variations in infusion rate can lead to substantial variations in blood pressure. Always use an infusion pump, preferably a volumetric infusion pump. It is important to monitor the patient's blood pressure constantly during the infusion, either with a continually inflating sphygmomanometer or (preferably) with an intra-arterial pressure sensor. Excessive or too-rapid reduction in arterial blood pressure may produce nausea, diaphoresis, anxiety, restlessness, and muscle twitching. If these occur, then the infusion rate should be slowed. The purpose of the gradual reductionin blood pressure is to avoid excessive falls in pressure that could induce renal, cerebral, or coronary ischemia.

The usual dosage rate is 0.3 to 10 mcg/kg/min. However, cyanide clearance occurs when the dosage rate is less than 2 mcg/kg/min. To prevent dangerous, possibly lethal, buildup of cyanide, the maximum infusion should never exceed 10 minutes.

If the blood pressure remains uncontrolled after 10 minutes at the maximum infusion rate, stop the infusion immediately. Cyanide level assay is technically difficult to perform, and cyanide levels in body fluids other than packed red blood cells are difficult to interpret. Therefore, it is difficult to determine cyanide toxicity directly from laboratory findings.

Monitoring the acid-base balance and venous oxygen concentrations may help indicate cyanide toxicity. However, these tests do not always accurately reflect cyanide levels. Clinical studies show that metabolic acidosis, although normally occurring with elevated cyanide levels, may lag behind peak cyanide levels by an hour or more. Therefore, monitor also for other signs of cyanide toxicity, such as red venous blood, dyspnea, or confusion. It is also important to monitor for signs of thiocyanate toxicity (tinnitus, miosis, hyperreflexia) and methemoglobinemia (chocolate-brown blood).

Toxicity to nitroprusside can occur even if the dose is well within recommended limits. Toxicity may be evident by excessive hypotension, cyanide toxicity, or thiocyanate toxicity. Closely monitoring the patient throughout therapy is the key to safety. The development of nausea, vomiting, or altered mental function should be considered signs of potential cyanide toxicity unless proven otherwise. Symptoms of thiocyanate toxicity include fatigue, tinnitus, mental confusion, skin rash, psychosis, and anorexia.

Administer other longer-acting antihypertensives as needed during nitroprusside therapy to limit the dosage of nitroprusside as necessary. It is important to monitor for signs that blood pressure has been reduced too rapidly (e.g., abdominal pain, apprehension, diaphoresis, dizziness, headache, muscle twitching, nausea, palpitations, restlessness, retching, or retrosternal discomfort). Slow or discontinue the infusion until symptoms diminish. The infusion may then resume at a slower rate.

Also, assess for signs of increased intracranial pressure and other adverse effects; correct pre-existing anemia and hypovolemia before administration with anesthesia, if appropriate. Administer to a pregnant patient only if clearly indicated.

Providing Patient and Family Education

- Explain to patient and families that the drug is being given to lower blood pressure quickly and that blood pressure will be monitored constantly to prevent it from dropping too low.
- Urge patients to report adverse effects (such as abdominal pain, apprehension, diaphoresis, dizziness, headache, muscle twitching, nausea, palpitations, restlessness, retching, or retrosternal discomfort) immediately to the nurse.

Ongoing Assessment and Evaluation

Monitor blood pressure throughout nitroprusside therapy so that it is reduced without sacrifice to vital organs. Signs of increasing intracranial pressure and other adverse effects should be assessed as well. Drug therapy is effective when blood pressure falls to a safe level, organ damage is averted, and severe hypotension, cyanide toxicity, or thiocyanate toxicity does not develop.

Drugs Closely Related to P Nitroprusside

Fenoldopam

Fenoldopam (Corlopam) is a newer drug for treating hypertensive emergencies. A rapid vasodilator, fenoldopam works differently than nitroprusside; it stimulates dopamine receptors and moderately binds to alpha-2 receptors. Because of its dopaminergic effects, it increases renal blood flow. Fenoldopam is administered only as a continuous IV infusion, never as a bolus dose. The dose should be titrated up or down every 15 minutes until the desired blood pressure has been achieved.

MEMORY CHIP

P Nitroprusside

- Drug of choice for hypertensive crisis when blood pressure must be reduced immediately
- Major contraindications: compensatory hypertension resulting from aortic coarctation or arteriovenous shunting, and surgical procedures on patients with inadequate cerebral circulation
- Most common adverse effect: hypotension from too-rapid infusion
- Most serious adverse effects: severe hypotension and cyanide poisoning
- Maximizing therapeutic effects: Wrap diluted bag of drug in an opaque sleeve or aluminum foil to protect from light.
- Minimizing adverse effects: Always use an IV pump to regulate infusion; start the infusion at a low dose and slowly increase; once the maximum infusion rate has been achieved, do not continue for more than 10 minutes; and monitor blood pressure throughout therapy.
- **Black box warning: Nitroprusside is not suitable for direct injection after initial reconstitution but must be further diluted. Nitroprusside can cause sudden substantial decreases in blood pressure. Nitroprusside can cause cyanide toxicity, which can be lethal.**

Unlike nitroprusside, fenoldopam does not carry Black Box warnings. It is a pregnancy category B drug. The most common adverse effects are flushing, GI disturbances; dizziness, headache, and dose-related tachycardia. Hypotension may also occur.

Trimethaphan

Trimethaphan (Arfonad) differs slightly from nitroprusside in its therapeutic action. It is used to treat hypertensive crisis when there is aortic dissection when nitroprusside is ineffective or cannot be used. It is labeled for use in treating intraoperative hypertension and malignant hypertension. Like nitroprusside, it is a direct vasodilator, but only when given in high doses. Unlike nitroprusside, trimethaphan is also a short-acting ganglionic blocker. It blocks the transmission in autonomic ganglia (both symspathetic and parasympathetic) without producing a change in the membrane potential. It does not modify impulse conduction in the preganglionic or postganglionic neurons, or prevent acetylcholine release by preganglionic impulses. It occupies ganglionic receptors and stabilizes postsynaptic membranes from the action of acetylcholine, which is released by the presynaptic nerve endings.

Trimethaphan shows a fall in cardiac output, whereas nitroprusside exhibits no change or a slight increase. Nitroprusside increases heart rate and decreases central venous pressure. Early tachyphylaxis seen with trimethaphan is not seen with nitroprusside. Recovery of arterial blood pressure after nitroprusside is rapid (2 to 6 minutes) compared with trimethaphan (10 to 15 minutes). Trimethaphan, unlike nitroprusside, does not carry Black Box warnings.

Only physicians properly trained to use and monitor this drug therapy should attempt surgical hypotension with trimethaphan. The nurse assists in monitoring the patient closely during surgery for signs of complications; severe hypotension, with its ramifications, may occur.

Drugs Significantly Different From P Nitroprusside

Phentolamine (generic only), phenoxybenzamine (Dibenzyline), and metyrosine (Demser) are used only to treat the marked elevations in blood pressure associated with pheochromocytoma, a catecholamine-secreting tumor of the adrenal medulla. Phentolamine is also used in preventing and treating dermal necrosis and sloughing after IV extravasation of norepinephrine.

Phentolamine and phenoxybenzamine are both alpha-adrenergic blockers. They lower peripheral vascular resistance and therefore decrease blood pressure. Metyrosine inhibits tyrosine hydroxylase, which is the catalyst for the first transformation in catecholamine biosynthesis. Because of this blockade, endogenous levels of catecholamine decrease. Most patients receiving this drug experience decreased frequency and severity of hypertensive attacks. Patients who respond to therapy normally experience a decrease in blood pressure within the first 2 days of therapy. Metyrosine is administered orally as chronic therapy, unlike nitroprusside.

Cardiac stimulation occurs with phentolamine. The concomitant use of a beta blocker may be needed to control tachycardia. Tachycardia may occur with phenoxybenzamine but to a lesser extent. Cardiac responses do not occur with metyrosine. Orthostatic hypotension may occur with both phentolamine and phenoxybenzamine. Sedation, galactorrhea, sexual dysfunction, nasal sinus congestion, and diarrhea are adverse effects unique to metyrosine. Extrapyramidal effects and hallucinations are possible serious adverse effects from metyrosine.

PATHOPHYSIOLOGY OF SHOCK

Shock is the result of inadequate tissue perfusion, leaving the cells without the necessary oxygen and nutrients they need to have normal function and survive. When cell dysfunction is widespread, the result can be death for the patient. Shock has multiple causes. Hypovolemic shock results from a decrease in circulating blood volume from bleeding or hemorrhage. It occurs when intravascular volume decreases more than 15% to 25%. Cardiogenic shock is caused by the heart's inability to pump enough blood to adequately perfuse the vital organs, which may itself be caused by MI, ventricular arrhythmias, severe cardiomyopathy, or CHF. Septic shock occurs when a severe infection brings about circulatory insufficiency. Obstructive shock is caused by a massive blockage in blood flow and results in inadequate tissue perfusion. This event could be caused by a large pulmonary embolus, cardiac tamponade, restrictive pericarditis, or severe cardiac valve dysfunction. Neurogenic shock is uncommon. It occurs as a result of blockade of neurohormonal outflow. This event may be induced by drugs (e.g., spinal anesthesia) or trauma to the spinal cord.

Shock has two phases—early (or compensated) and late (or noncompensated). In early shock, the body tries to compensate for the decreased perfusion. The heart and respiratory rates increase, and blood pressure is generally maintained, or it may be low to normal. The body begins to shunt some blood flow away from the skin, although the skin is still perfused. Urine output decreases slightly as renal blood flow is reduced. Emotionally, the patient may be anxious or confused. When the body is no longer able to make up for changes brought on by shock, the patient develops late, or uncompensated, shock. Tachycardia persists, but the blood pressure falls dramatically, and respiration rates decrease. Venous constriction occurs; with the circulation shut off, the skin becomes cold and clammy. Urine output declines dramatically and may cease as the kidneys are no longer perfused. The patient becomes nonresponsive and unconscious.

DRUGS TO TREAT HYPOTENSION RESULTING FROM SHOCK

Vasopressors

Drug therapy in shock is directed toward increasing blood pressure to help support tissue perfusion. Drugs are given in addition to fluid volume. Vasopressors, drugs to increase the blood pressure, are sympathomimetic. They increase cardiac contractility and heart rate, constrict veins (vasoconstriction), and dilate arteries. See Table 26.10 for a summary of selected vasopressors.

Dopamine

Dopamine (Intropin) is used to correct the hemodynamic imbalances present in shock caused by MI, trauma, endotoxic septicemia, open heart surgery, renal failure, and chronic cardiac decompensation (CHF). For the treatment to be most effective, the patient should not be experiencing severe disruptions in urine production, myocardial function, and blood pressure. In other words, the earlier the signs of shock are recognized and treatment is started with fluids and dopamine, the more successful the therapy. The onset of action of IV dopamine is less than 5 minutes, and duration of action is less than 10 minutes. The drug is distributed widely in the body but does not cross the blood–brain barrier.

Dopamine is a naturally occurring catecholamine and a precursor to norepinephrine. It stimulates alpha-1 and beta-1 receptors through direct and indirect (by releasing the stored epinephrine) methods. It also has dopaminergic effects. Beta-1 stimulation produces increased cardiac output by increasing the force of contraction and heart rate. Although there is an increase in the oxygen needs of the myocardium from dopamine, this effect is less pronounced than when isoproterenol is administered. Tachyarrhythmias usually do not occur. Systolic blood pressure increases, whereas diastolic pressure usually does not. Minimal increases in the diastolic pressure may occur. Total peripheral resistance (from alpha effects) is not changed substantially if dopamine is given at low or intermediate levels of dosing. Although blood flow to the peripheral beds may decrease, blood flow to the mesenteric beds increases. Dopamine dilates renal and mesenteric vasculature as well as cerebral and cardiac beds; this effect is believed to be caused by stimulation of dopaminergic receptors. An increase in renal blood flow, glomerular filtration rate, and urinary output is then seen. The dopaminergic effect of no change in the peripheral resistance is lost as the dose becomes high, with the alpha stimulation taking precedence. The alpha stimulation brings about increased peripheral resistance, raising blood pressure at higher doses of dopamine. The drug's dosage should be titrated upward until adequate perfusion of vital organs is achieved.

Dopamine is discussed fully as a prototype drug in Chapter 13.

Dobutamine

Dobutamine is another vasopressive drug that is chemically similar to dopamine. Like dopamine, its primary influence is on beta-1 receptors, with similar effects on the force of contraction. Dobutamine is somewhat less effective than dopamine at increasing the rate at the sinoatrial (SA) node. Also like dopamine, dobutamine's beta-2 effects on vasodilation are minimal. Unlike dopamine, dobutamine has almost no effect on alpha receptors to cause vasoconstriction. Although cardiac output and blood pressure are similarly increased with both drugs,

TABLE 22.10 Summary of Selected Vasopressors

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
dopamine (Intropin)	Hemodynamic imbalances	*Adult:* IV, 2–5 mcg/kg/min *Seriously ill adult:* IV, 5 mcg/kg/min; increase in increments of 5–10 mcg/kg/min up to a rate of 20–50 mcg/kg/min *Child:* Safety and efficacy not established	*Onset:* IV, 1–2 min *Duration:* IV, length of infusion $t_{1/2}$: 2 min
dobutamine (Dobutrex)	Cardiac decompensation due to decreased contractility	*Adult:* IV infusion, 2.5–10 mcg/kg/min	*Onset:* 1–2 min Duration: Unknown $t_{1/2}$: 2 min
epinephrine (Adrenaline)	Cardiac arrest Respiratory distress	*Adult:* IV, 0.5–1.0 mg *Child:* Injection, 1:1,000 solution, 0.01 mg/kg or 0.3 mg/m^2 SC q4 h *Adult:* SC, 0.3–0.5 mg of 1:1,000 solution; inhalation, individualize dosage; wait 1–5 min between doses. *Child:* SC, 0.01 mg/kg; topical nasal solution, same as adult	*Onset:* SC, IM, 5–10 min; IV, instant; inhalation, 3–5 min *Duration:* SC, IM, IV, short-acting inhalation, 1–3 h
isoproterenol (Isuprel)	Bronchospasm (during anesthesia) Shock or cardiac standstill and arrhythmias	*Adult:* IV, 0.01–0.02 mg of diluted solution *Adult:* IV infusion, 5 mcg/min of diluted solution; IV push, 0.02–0.10 mg of diluted solution; IM/SC, 0.2 mg of undiluted 1:5,000 solution	*Onset:* IV, immediate *Duration:* IV, 1–2 min $t_{1/2}$: Unknown
mephentermine (Wyamine)	Hypotension attendant to spinal anesthesia Hypotension following spinal anesthesia Shock following hemorrhage	*Adult:* IM, 30–45 mg 10–20 min prior to procedure *Adult:* IV, 30–45 mg as a single injection *Adult:* IV, 0.1% solution in 5% dextrose in water just until blood replacement achieved	*Onset:* IM, 10–15 min; IV, immediate *Duration:* IM, 1–2 h $t_{1/2}$: 15–20 min
norepinephrine (levarterenol, Levophed)	Acute hypotension, shock Cardiac arrest	*Adult:* IV, 8–12 mcg/min; maintenance rate, 2–4 mcg/min *Adult:* IV, administer during cardiac resuscitation to restore and maintain blood pressure after effective heartbeat and ventilation established	*Onset:* IV, rapid *Duration:* 1–2 min after discontinuation of infusion $t_{1/2}$: Unknown
phenylephrine (Neo-Synephrine)	Mild/moderate hypotension Severe hypotension/shock Pediatric hypotension	*Adult:* SC or IM, 2–5 mg; IV, 0.2 mg, do not repeat injections more often than every 10–15 min *Adult:* IV, add 10 mg to 250 or 500 mL of dextrose injection; start at 100–180 mcg/min; maintenance, 40–60 mcg/min *Child:* SC or IM, 0.5–1 mg/11.3 kg	*Onset:* IV, immediate; IM/SC, 10–15 min *Duration:* IV, 15–20 min; SC/IM, 1–2 h $t_{1/2}$: Unknown

dobutamine does not produce the increased renal output that dopamine does. Furthermore, its effect on peripheral resistance is always to decrease it, whereas dopamine may increase or decrease peripheral resistance. Dobutamine does not cause the release of endogenous norepinephrine that dopamine causes.

The pharmacotherapeutic uses of dobutamine differ from those of dopamine. Dobutamine is indicated in the short-term treatment and support of patients experiencing cardiac decompression caused by depressed contractility. The decreased contractility may be secondary to either organic heart disease or cardiac surgery. Patients with atrial fibrillation and a rapid ventricular rate should be treated first with digoxin, before dobutamine treatment, to protect the ventricles. Onset of action is 1 to 2 minutes, but it may take as long as 10 minutes to reach peak effect.

A contraindication unique to dobutamine is the presence of idiopathic hypertrophic subaortic stenosis. Although elevated pulse usually does not occur when using dobutamine, tachycardia can occur, with increases of 30 bpm or more. Accompanying the tachycardia is a rapid and substantial increase in blood pressure, with the systolic pressure rising 50% or greater. These adverse effects are usually dose related, and reducing the dose promptly corrects the problem. Interestingly, dobutamine also can cause substantial hypotension if given in excessive amounts; again, decreasing the dose usually corrects the problem. Dobutamine may cause or exacerbate ventricular ectopic beats, although ventricular tachycardia is rare. Other rare adverse effects include nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath. Phlebitis and local inflammation

at the IV site may occur; a large vein should be chosen to administer the drug to minimize this possibility.

Patients receiving dobutamine, like dopamine, need to be monitored continuously on a cardiac monitor while receiving the drug. Blood pressures should be checked frequently. Pulmonary wedge pressure and cardiac output should be checked whenever possible.

Isoproterenol

Like dopamine, isoproterenol (Isuprel) has a strong effect on beta-1 receptors, producing similar increases in contractility. However, isoproterenol's effect on the heart rate and vasodilation is much greater than dopamine's. Isoproterenol does not stimulate the alpha receptors for vasoconstriction. Isoproterenol increases cardiac output like dopamine. Renal perfusion is also affected, although unlike dopamine, it can increase or decrease it. Peripheral resistance is always decreased, but blood pressure may be increased or decreased by isoproterenol. Although isoproterenol may be used to treat shock, this practice is not common because it can cause tachycardia. The other uses of isoproterenol and more complete information about it are found in Chapter 13.

Epinephrine

Epinephrine is also a vasopressor, as is dopamine. Epinephrine stimulates both alpha and beta receptors. Its effect on the contractility of the heart (beta-1) is similar to dopamine's effect, whereas its effects on SA node rate (beta-1), vasodilation (beta-2), and vasoconstriction (alpha-1) are stronger than dopamine's effects. Although epinephrine increases the cardiac output, its other pharmacodynamic effects differ from those of dopamine. It decreases renal perfusion, decreases total peripheral resistance, and elevates systolic blood pressure, while lowering diastolic blood pressure. Epinephrine is indicated in the treatment and prophylaxis of cardiac arrest and attacks of transitory atrioventricular heart block with syncopal seizures (Stokes-Adams syndrome). Epinephrine is discussed completely in Chapter 13.

Norepinephrine

Norepinephrine (Levophed) is another vasopressor that stimulates the adrenergic system. Its beta-1 effects on contractility are less than the effects of dopamine, whereas its effect on the SA node rate is similar. Similar to dopamine, norepinephrine has strong alpha-receptor stimulation, producing vasoconstriction, but no effect on vasodilation from beta-2 receptors. Although peripheral resistance and blood pressure are raised, norepinephrine decreases renal perfusion and either has no effect on, or decreases, cardiac output. Norepinephrine is used to restore blood pressure when hypotension is caused by one of the following conditions: pheochromocytomectomy, sympathectomy, poliomyelitis, spinal anesthesia, MI, blood transfusion, and drug reactions. It also is used as an adjunct in treating cardiac arrest and severe hypotension. More information about norepinephrine is also found in Chapter 13.

Ephedrine

Ephedrine has less effect on contractility (beta-1 receptors) and less effect on vasoconstriction (alpha-1) than dopamine. Its effect on heart rate (beta-1) and vasodilation (beta-2) is similar to the effect of dopamine. Ephedrine's pharmacodynamic effects of increasing blood pressure, increasing cardiac output, and increasing or decreasing peripheral resistance are similar to those of dopamine. Unlike dopamine, ephedrine decreases renal perfusion. Ephedrine, administered parenterally (most commonly via the IV route), is used clinically in acute hypotension, especially that caused by spinal anesthesia, Stokes-Adams syndrome with complete heart block, use of a CNS stimulant in narcolepsy and depressive states, and acute bronchospasm (occasionally). It is also used as a vasopressor following sympathectomy or drug overdosage (from ganglionic blocking drugs, antiadrenergic drugs, *Veratrum* alkaloids, or other drugs used to lower blood pressure during treatment of hypertension). Ephedrine is also used in enuresis and myasthenia gravis. Oral ephedrine is included in some nasal decongestants.

Metaraminol

Metaraminol is used to prevent and treat acute hypotensive states that occur with spinal anesthesia. It is an adjunct treatment for hypotension caused by hypovolemia, reactions to drug therapy, surgical complications, and shock associated with brain damage caused by trauma or tumor.Metaraminol has only minor effects on beta-1 receptors, creating mild increases in contractility and heart rate. It has more effect on vasoconstriction from alpha-1 stimulation than mephentermine, but less than dopamine. It has no effect on vasodilation from beta-2 stimulation. It primarily increases blood pressure by increasing peripheral resistance. Unlike dopamine, it lowers cardiac output and renal perfusion. Although the SA node is stimulated somewhat (which theoretically should increase the heart rate), the net effect on the heart is bradycardia, resulting from a strong reflexive response to the substantial vasoconstriction this drug achieves. Unlike dopamine, it can be given intramuscularly or subcutaneously as well as by IV infusion.

DRUGS TO TREAT HYPOTENSION RESULTING FROM VARIOUS MECHANISMS

Vasopressors also treat hypotension resulting from mechanisms other than shock.

Phenylephrine

Unlike dopamine, the effects of phenylephrine are solely on alpha-1 receptors, producing strong vasoconstriction effects. Renal perfusion and cardiac output are decreased. Blood pressure is increased by the increase in peripheral resistance.

Phenylephrine is used to treat vascular failure in shock-like states, drug-induced hypotension, or hypersensitivity. It is

also used to overcome paroxysmal supraventricular tachycardia, to prolong spinal anesthesia, as a vasoconstrictor in regional analgesia, and to maintain an adequate blood pressure during spinal and inhalation anesthesia. Phenylephrine is discussed completely in Chapter 13.

Midodrine

Midodrine (ProAmatine) raises blood pressure, but it is not used as a vasopressor in shock. Instead, it is used for symptomatic treatment of orthostatic hypotension in patients whose lives are impaired substantially by this condition, despite standard clinical treatment. It carries a Black Box warning that its use should be so limited. Midodrine is administered orally. It is a prodrug that becomes active when it changes into the metabolite desglymidodrine. The metabolite is an alpha-1 agonist that increases the tone of the arteriolar and venous vasculature, increasing peripheral resistance. It results in increased standing, sitting, and lying blood pressures. Because supine systolic blood pressure can rise to 200 mm Hg or greater, midodrine should not be given less than 4 hours before bedtime. Suggested dosing times are shortly before or just after arising in the morning, midday, and late afternoon. This dosing schedule should assist the patient to maintain his or her normal daytime activities and prevent supine hypertension during the night. If supine hypertension does occur, it may be controlled by preventing the patient from lying completely flat (e.g., lying with the head of the bed elevated). Midodrine is a pregnancy category C drug.

CHAPTER SUMMARY

- Blood pressure is derived from the amount of blood leaving the heart times the resistance in the peripheries (blood pressure = cardiac output × peripheral resistance). When either cardiac output or peripheral resistance increases, the blood pressure rises. Drug therapy to reduce hypertension is designed to decrease either cardiac output or peripheral resistance or both. Drug therapy to increase blood pressure increases cardiac output, peripheral resistance, or both.
- Hypertension is classified in 3 stages (from prehypertension to stage 2), according to the degree of blood pressure elevation.
- In prehypertension, blood pressure is usually managed by lifestyle changes alone. These changes include weight reduction, dietary restriction of saturated fat, moderation of alcohol intake, regular physical activity, reduction of sodium intake, increased intake of potassium- and calcium-rich foods, and smoking cessation. Lifestyle modifications continue even if the patient advances to stage 1 or 2 hypertension.
- Drug therapy may be initiated in prehypertension if the patient has certain other comorbidities. Drug therapy is always initiated in stage 1 or 2 hypertension. Most patients require the use of at least two types of antihypertensives to achieve full therapeutic effect. Patients whose blood pressure is difficult to control may be on three or more first-line drugs as well as some second-line drugs.
- Drug classes used as first-line therapy include: thiazide diuretics, beta blockers, ACE inhibitors, ARBs, calcium channel blockers (for some patients), and occasionally aldosterone blockers.
- Drug classes used as second-line therapy include: vasodilators, alpha-2 stimulants, alpha-1 blockers, peripheral antiadrenergics.
- Thiazide diuretics (such as hydrochlorothiazide) are effective and less expensive than other antihypertensives. A thiazide diuretic is usually used as the drug of first choice in monotherapy. Other classes of first-line drugs may be added if necessary. Thiazides are effective in monotherapy in African Americans unlike most of the first-line drugs. The most common adverse effects are related to electrolyte changes and fluid volume loss (i.e., hypovolemia, low potassium, magnesium, and sodium levels, and elevated uric acid and blood glucose levels).
- Beta blockers (such as metoprolol) slow heart rate, speed conduction, and decrease force of contraction and thus decrease cardiac output. This decreases the blood pressure. Although beta blockers (at beta-2 receptor sites) increase peripheral resistance through vasoconstriction, this effect is outweighed by the substantial decrease in cardiac output, thereby lowering blood pressure. Beta blockers also decrease the release of renin from the kidneys so the renin-angiotensin-aldosterone system is not activated, so vasoconstriction does not occur. Beta blockers are used as the initial therapy for patients with certain comorbidities; they are not as effective as monotherapy in African Americans.
- Captopril, an ACE inhibitor, inhibits the angiotensin-converting enzyme needed to change the inactive angiotensin I to the active form angiotensin II, thereby preventing sodium and water retention, decreasing peripheral vascular resistance, and lowering blood pressure. A major adverse effect is a chronic cough, which may be so severe that the patient cannot tolerate or continue drug therapy. First-dose hypotension may occur. As monotherapy it does not achieve the same therapeutic effects in African Americans as in other races.
- Aliskaren is a renin inhibitor. Similar to other drugs that alter the renin-angiotensin-aldosterone system, monotherapy with aliskaren produced fewer antihypertensive effects in African Americans, probably because most African Americans are “low-renin hypertensives.”
- Losartan is an ARB; it does not inhibit ACE. Instead, it blocks the vasoconstricting and aldosterone-secreting effects of angiotensin II by selectively blocking the binding of angiotensin II to the angiotensin receptors in many tissues, especially in the vascular smooth muscle and adrenal gland tissues.

- Eplerenone is a selective aldosterone receptor blocker. It interferes with the renin-angiotensin-aldosterone system. By blocking the mineralocorticoid aldosterone receptors, it prevents sodium and fluid reabsorption that leads to hypertension.
- Nitroprusside, an agent used in hypertensive crisis, directly relaxes vascular smooth muscle. It is more active on veins than arteries, thereby promoting peripheral pooling of blood. This effect decreases venous return to the heart, reducing left ventricular end-diastolic pressure and pulmonary capillary wedge pressure (preload). The resultant arteriolar dilation reduces systemic resistance and decreases mean arterial pressure (afterload). The result is markedly reduced blood pressure. The ability to decrease the blood pressure is seemingly unlimited. Nitroprusside is rapidly metabolized to cyanide through a reaction with hemoglobin. Cyanide poisoning may occur during its use. If blood pressure remains uncontrolled after 10 minutes at the maximum infusion rate, stop the infusion immediately. The nitroprusside infusion should be controlled by an administration pump, and the blood pressure must be monitored constantly.
- Dopamine, a vasopressor, is used to correct the hemodynamic imbalances present in shock. Dopamine is a naturally occurring catecholamine and a precursor to norepinephrine. It stimulates alpha-1 and beta-1 receptors through direct and indirect (releasing the stored epinephrine) methods. It has either no or only a minimal effect on beta-2 receptors. It also has dopaminergic effects. The effects from dopamine are increased renal perfusion, increased cardiac output, increased or decreased peripheral resistance (depending on the dose), and increases in blood pressure. Dopamine is administered by IV continuous infusion. The patient must be monitored closely and continuously while on dopamine infusion.

QUESTIONS FOR STUDY AND REVIEW

1. What lifestyle changes constitute Step 1 in antihypertensive therapy?
2. Why are thiazide diuretics now the agents of first choice for most patients with hypertension?
3. How do ACE inhibitors such as captopril lower the blood pressure?
4. Describe how an ARB works differently than an ACE inhibitor. What are the advantages of ARB therapy over ACE inhibitor therapy?
5. What is the black box warning that is carried by ACE inhibitors, ARBs, and renin inhibitors?
6. Which electrolyte imbalance is most likely to occur when the selective aldosterone receptor blocker eplerenone is administered?
7. Describe nursing actions that promote safety for the patient receiving nitroprusside.
8. Why is dopamine dosage determined by urinary output and CV response?

Drugs Affecting Urinary Output

Learning Objectives

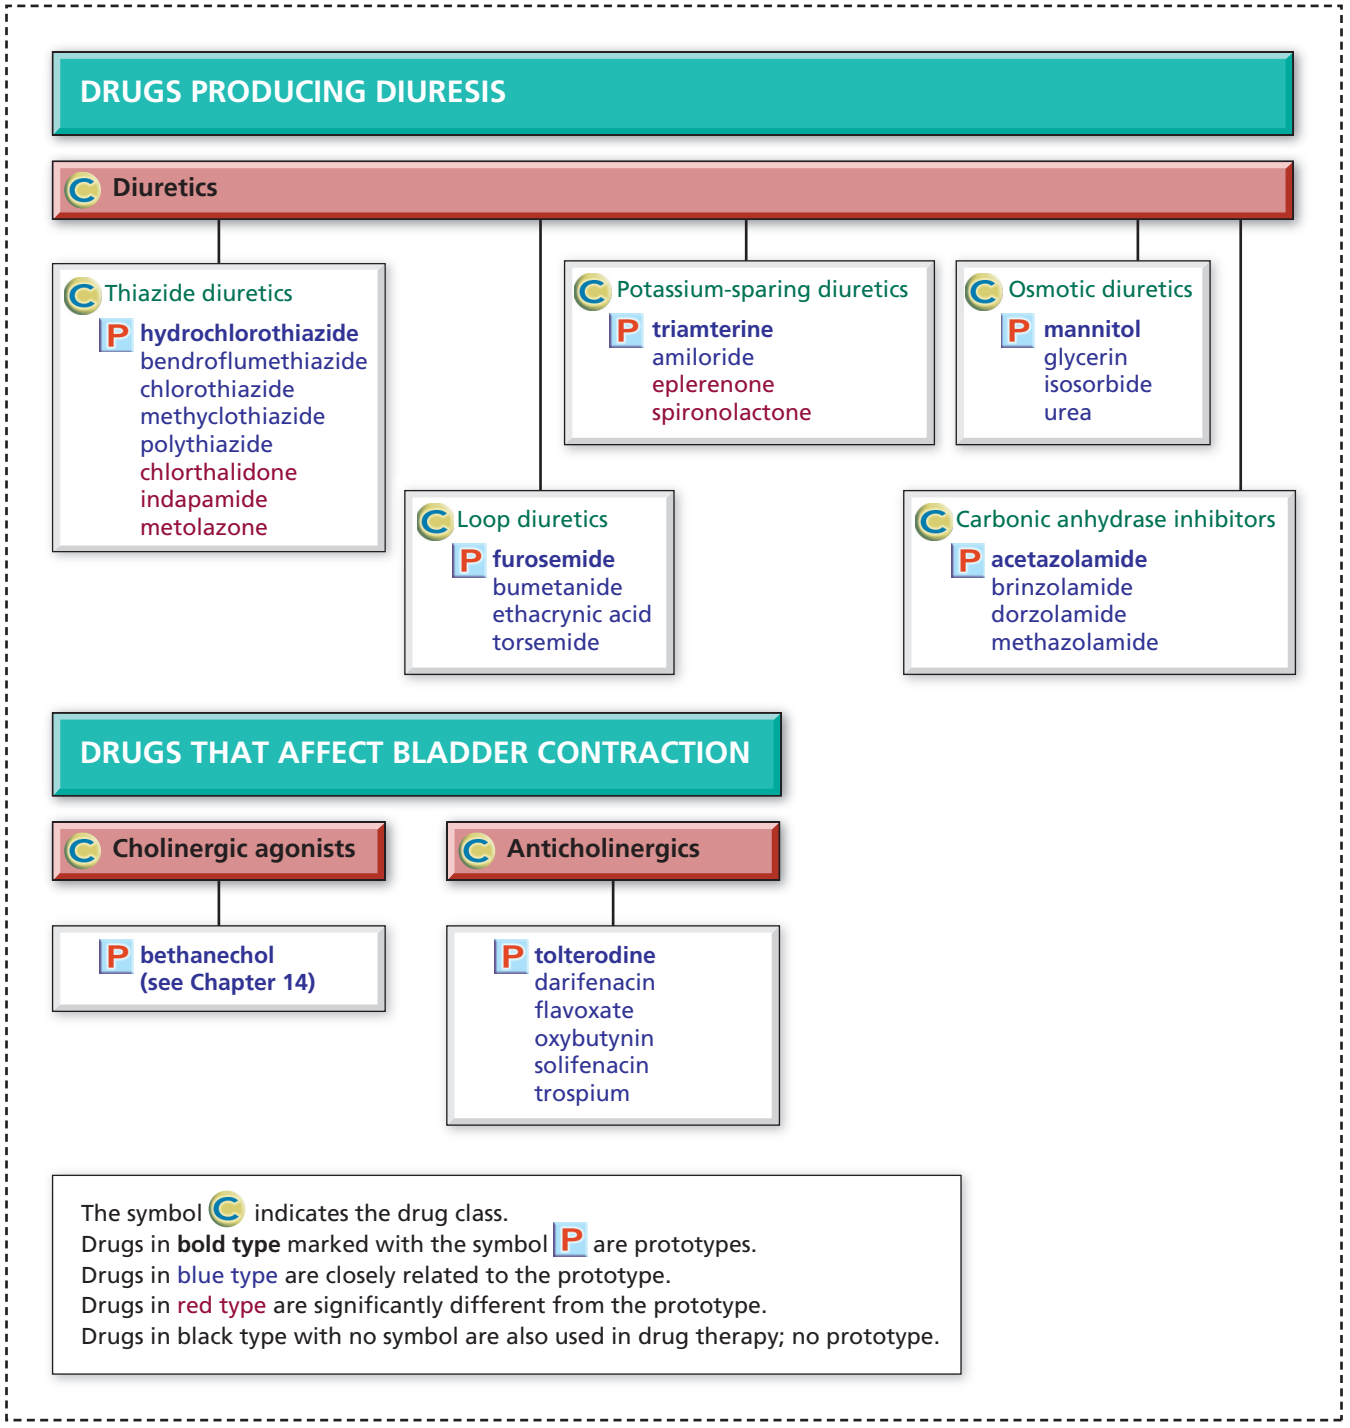
At the completion of this chapter the student will:

1. Describe normal kidney function and explain how diuretics work in the kidney.
2. Identify core drug knowledge about drugs that affect diuresis.
3. Identify core patient variables related to drugs that affect diuresis.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that affect diuresis.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect diuresis.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect diuresis.
7. Determine key points for patient and family education for drugs that affect diuresis.

Key Terms

diuresis
diuretic
edema
glomerular filtration
hyperkalemia
hypertension
hypervolemia
hypokalemia
osmolality
renal tubular reabsorption
renal tubular secretion

Drugs Affecting Urinary Output



Diuresis is the process of ridding the body of fluids by increasing production of urine and excretion of water and electrolytes, such as sodium, by the kidneys. Diuresis occurs naturally if fluid intake has exceeded the body's normal requirements. This self-regulating or homeostatic mechanism keeps the body's fluid volume in balance.

A **diuretic** is a substance that causes diuresis. Drugs that are diuretics are used to decrease fluid volume in pathologic conditions in which the body cannot regulate fluid volume effectively. Diuretics decrease renal reabsorption of sodium and promote its excretion in water. The greater the sodium excretion, the greater the water excretion will be. During this process, reabsorption of other electrolytes (e.g., potassium) may also decrease, thereby promoting their excretion as well.

The various types of diuretics work differently in the body. Which diuretic is prescribed for a patient depends on the patient's underlying pathologies and the desired therapeutic effects. This chapter discusses five classes of diuretics: thiazide, loop, potassium-sparing, osmotic, and carbonic anhydrase inhibitors. The thiazide, loop, and potassium-sparing classes all are used to decrease circulating volume and complications related to excess volume. Thiazide diuretics work in the distal tubule of the kidney, whereas loop diuretics work in the loop of Henle. Potassium-sparing diuretics are used commonly in combination with other diuretics, and they work in the distal tubule. Prototype drugs for thiazide, loop, and potassium-sparing classes are hydrochlorothiazide, furosemide, and triamterene, respectively.

The osmotic diuretics, for which mannitol is the prototype, are used to decrease intraocular and intracranial pressure and to treat or prevent acute renal failure (ARF). The osmotic diuretics are filtered by the kidneys but poorly reabsorbed in the tubule. Acetazolamide, which is the prototype for the carbonic anhydrase inhibitors, induces diuresis by decreasing hydrogen ion secretion by the tubules and increasing excretion of sodium and water. Although the diuretic effect is limited, aqueous humor formation is reduced, thereby making these drugs useful for reducing intraocular pressure in glaucoma.

Urinary output can also be modified by drugs that bind to cholinergic receptors in the bladder. Cholinergic stimulation of these receptors stimulates bladder contraction. Bethanechol, a cholinergic drug used for this therapeutic effect, is discussed in Chapter 14. Drugs that have an anticholinergic effect on these receptors decrease bladder contraction and are used to treat overactive bladder. The prototype for this class, tolterodine, is discussed in this chapter.

PHYSIOLOGY

The renal system is a complex mechanism that has several important functions in maintaining health. It is the body's filtering and purifying center, ridding the body of impurities and waste by producing urine and excreting water, electrolytes, and other substances. Other functions of the renal system include regulating the body's acid-base balance, maintaining blood pressure, influencing circulating fluid volume, assisting in the production of red blood cells, and contributing to calcium metabolism (Figure 27.1).

The renal system consists of the kidneys, ureters, and bladder. The kidneys are a pair of intricate, bean-shaped organs located behind the upper abdomen outside the peritoneal cavity. They are active in filtering, reabsorbing, and excreting fluid, electrolytes, and waste products. The ureters are tubes that transport waste products and excess fluid from the kidneys to the bladder, a balloon-like receptacle, for later excretion.

Urine formation, which occurs as a result of kidney function, involves three complex processes: glomerular filtration, renal tubular reabsorption, and renal tubular secretion. These mechanisms, which are discussed individually below, work together in a part of the kidney called the nephron, which processes blood plasma into urine.

The nephron has many parts, including the glomerulus, Bowman capsule, and various tubules and membranes. In the nephron, water and solutes move from the blood plasma across a glomerular capsular membrane into an area known as a Bowman capsule. This movement across the capsular membrane is called **glomerular filtration.**

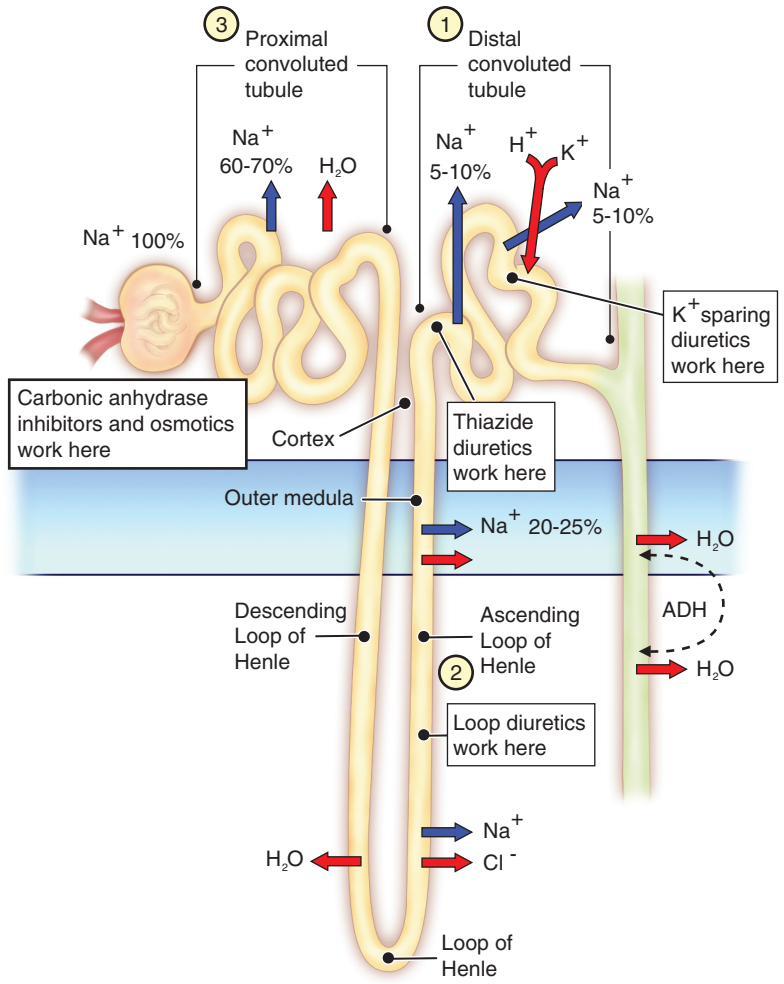
As the blood flows through the kidney capillaries, pressure in the capillaries causes fluid to filter into the Bowman capsule. The glomerular capsular membrane (the basement membrane), which lies between the glomerulus and the Bowman capsule, allows fluid and electrolytes but not blood cells and plasma proteins to pass into the Bowman capsule. The average glomerular filtration rate is 125 mL/min (or about 180 L of plasma in 24 hours). More than 99% of the plasma filtered is reabsorbed in the tubules.

Usually, the kidneys produce less than 2 L of urine daily. However, changes in colloid osmotic pressure or capsular hydrostatic pressure can alter glomerular filtration. For example, a decrease in colloid osmotic pressure may increase filtration. Conversely, an increase in capsular hydrostatic pressure, which occurs in obstructive disease, may decrease filtration.

The conversion of the filtrate into urine occurs in the renal tubule by processes known as renal tubular reabsorption and renal tubular secretion. In **renal tubular reabsorption,** molecules move from the renal tubule across a semipermeable membrane into the peritubular blood (the blood surrounding the renal tubule). In **renal tubular secretion,** molecules move from the blood surrounding the renal tubule into the tubule. In both reabsorption and secretion, diffusion and active transport are key mechanisms.

The strength, or concentration, of the urine produced is known as **osmolality,** which is the density of active particles in solution or the osmotic concentration, determined by the ionic concentration of dissolved substances per unit of solution. Urine osmolality depends on the volume and composition of extracellular fluids. It also depends on a countercurrent mechanism in the renal medulla (a part of the kidney), which controls the flow of water and solute so that water is kept out of the area around the tubule and so that sodium and urea are retained. An important contributor to this process

PHYSIOLOGY



• FIGURE 27.1 Diuretics work in the nephron. The main organ of the renal system is the kidney, which houses a tangled mass of nearly 1 million nephrons. The nephron is the structure known for its role in urine production. Different diuretic drugs work in different parts of the nephron: thiazide, thiazide-like, and potassium-sparing diuretics work in the distal convoluted tubule (**1**), loop diuretics in the ascending loop of Henle (**2**), and carbonic anhydrase inhibitors and osmotic diuretics in the proximal convoluted tubule (**3**). Fluid and electrolyte alterations depend on where the specific diuretic works in the kidney.

is antidiuretic hormone (ADH), which is released when the osmolality of the extracellular fluid increases.

To enable water to move out of the tubule and into the surrounding capillaries, ADH increases the permeability of the collecting tubule to water; from the capillaries, it returns to the vascular system for circulation. As a result of increased water reabsorption, urine osmolality (concentration) increases. Without ADH, the renal tubules are impermeable to water, water is not reabsorbed, and dilute urine is produced.

The kidneys play a major role in regulating acid-base balance and maintaining a normal blood pH (7.35–7.45) by excreting hydrogen ions or reabsorbing bicarbonate. The kidneys regulate hydrogen ion secretion so that bicarbonate levels remain within normal limits. Most of the hydrogen ions excreted in the urine are secreted into the tubular fluid. Tubular fluid pH is acidic, and the kidney depends on buffers in the urine to combine with the hydrogen ion for excretion. The three buffers are bicarbonate (HCO_3), phosphate (HPO_4), and ammonia (NH_3).

The first step in bicarbonate reabsorption is the movement of carbon dioxide (CO_2) into a tubular cell, where the CO_2 combines with water to form a hydrogen ion and a bicarbonate ion. The hydrogen ion is then secreted into the tubular fluid, and a sodium ion is reabsorbed. The sodium ion and bicarbonate ion pass into the extracellular fluid. The free hydrogen ion then combines with a filtered bicarbonate ion to form carbon dioxide and water. The water is eliminated in the urine, and the CO_2 diffuses into the tubular cell to combine with water, thereby forming a hydrogen ion and a bicarbonate ion to begin the process again.

Additional hydrogen ions are excreted in the urine in combination with a phosphate or ammonium buffer. The phosphate ion is filtered into the tubular fluid, where it combines with a free hydrogen ion and is excreted. Ammonia is synthesized in the tubular cells and diffuses into the tubular fluid, where it combines with a hydrogen ion to form an ammonium ion (NH_4), which is excreted.

Normally, the number of hydrogen ions secreted by the tubules is about equal to the number of bicarbonate ions

filtered in the glomerulus. However, in metabolic acidosis, the number of hydrogen ions secreted exceeds bicarbonate filtration, and the urine becomes acidic. In metabolic alkalosis, bicarbonate filtration exceeds hydrogen ion secretion, and the urine becomes alkaline.

The kidneys also play a role in the reabsorption and secretion of electrolytes. Vast quantities of sodium and chloride are filtered through the glomerulus. Most of the filtered sodium and chloride (60% to 65%) is reabsorbed in the proximal tubule, and about 20% is reabsorbed in the loop of Henle. Smaller amounts are reabsorbed in the distal tubule and the collecting tubule. Sodium reabsorption occurs primarily through active transport. Filtered potassium is then mostly reabsorbed, much of this occurring in the loop of Henle. Coupled with the sodium transport, potassium moves by active transport into the proximal tubule from cells. (Remember, potassium moves opposite to sodium.) This transport moves some potassium into the urine in the distal and collecting tubule. Again, most of it is reabsorbed, but some of it is excreted in the urine.

Additional work of the kidneys includes endocrine functions, whereby chemicals are produced to exert action elsewhere in the body. In this regard, the kidneys help maintain and regulate blood pressure and vascular resistance, red blood cell production, and calcium metabolism.

Blood pressure is also affected by the kidneys' role in the renin-angiotensin-aldosterone mechanism. Renin, an enzyme, is synthesized and stored in the kidney and released in response to decreased blood flow or a change in the composition of fluid in the distal tubule. The release of renin plays a role in converting angiotensin I, a substance in the blood, into the powerful vasoconstrictor angiotensin II. The vasoconstriction increases peripheral resistance, resulting in an increase in blood pressure. Angiotensin II also stimulates the adrenal cortex to secrete the hormone aldosterone. Aldosterone has an effect in the distal tubule and the collecting tubule, where it promotes sodium and water reabsorption as well as potassium loss. Only about 3% of the original filtered sodium remains in the distal and collecting tubule; the body varies its reabsorption based on signals it receives related to fluid status. Higher amounts of aldosterone cause the body to reabsorb more sodium and water. This in turn increases blood pressure.

The kidney produces erythropoietin, which stimulates the bone marrow to produce and release red blood cells, particularly in response to hypoxia (oxygen deprivation). The kidneys play a vital role in the chemical transformation of compounds that are precursors to the active form of vitamin D, which is needed to absorb calcium from the gastrointestinal (GI) tract. Vitamin D also helps to regulate calcium deposition in the bones.

Stimulation of the adrenergic and cholinergic receptors in the genitourinary (GU) tract has a role in urinary production and bladder emptying.

- Alpha-1 receptor stimulation causes the muscles of the bladder neck to contract, preventing bladder emptying; blockade of these receptors has the opposite effect.
- Beta-1 stimulation causes the release of renin, setting off the renin-angiotensin-aldosterone system, which ultimately has an effect on the reabsorption of sodium and water.
- Adrenergic dopamine-1 receptor stimulation in the proximal tubule maintains or increases the glomerular filtration rate (GFR), whereas in the distal tubules this stimulation increases sodium loss in the urine (natriuresis) and diuresis. A consequence of this is an increase in aldosterone production.
- Adrenergic dopamine-2 receptor stimulation has the opposite effect: decreased renal blood flow, decreased GFR, decreased sodium and water loss, and thus less aldosterone production.
- Cholinergic receptor stimulation in the bladder results in contraction of the detrusor muscle, producing micturition; blockade of these receptors has the opposite effect.

PATHOPHYSIOLOGY

When the body cannot maintain a balance of body fluid levels, fluid overload or volume depletion occurs. **Hypervolemia** (an abnormal increase in circulating blood volume) may result from excessive sodium and water retention. Shifting of fluid into the interstitial spaces (**edema**) may occur with fluid volume excess. Peripheral edema increases the cardiac workload and decreases tissue perfusion. Moreover, other organ systems may be affected adversely by the congestion associated with edema. When systemic edema is severe, the congestion backs up into the lungs, affecting breathing and gas exchange.

Diuretic drugs are used in treating pathologic conditions in which fluid overload and, frequently, edema have occurred. These conditions include chronic heart failure (CHF), pulmonary edema, hypertension, cirrhosis, nephrotic syndrome, and kidney failure. Additionally, diuretics are used for treating adverse effects from long-term steroid or antiepileptic drug therapy and symptoms of fluid overload such as increased intracranial and intraocular pressure and premenstrual syndrome.

Ineffective pumping of the heart can result in CHF because the heart does not empty well, and cardiac output is diminished. Increased demands placed on the heart by other systemic problems can also cause the heart to fail. When the heart chambers do not empty well with each contraction, blood backs up into the body, and congestion occurs in the body tissues. Edema in CHF usually results from increased sodium and water retention and venous congestion, which increases capillary pressure in the peripheral and pulmonary circulation. As a result of the ineffective pumping ability of the heart, the kidneys receive a diminished blood supply. Impaired glomerular filtration and reduced blood flow to the renal tubules then occur. The kidney interprets these occurrences as signs of hypovolemia (insufficient circulating fluid or volume depletion) and activates mechanisms to retain sodium and water and increase circulating volume. Thus, volume is increased in an already congested system, and CHF actually worsens.

Drug therapy for CHF is now focused on improving survival. Drugs proven to reduce morbidity and mortality in CHF are angiotensin-converting enzyme (ACE) inhibitors, diuretics, and beta blockers. Diuretics have been found in small clinical studies to reduce the risk of death and worsening of heart failure. Compared to other drug classes used in treating CHF, diuretics appear to improve exercise capacity (Faris, Flather, Purcell, et al., 2006). In large clinical trials and meta-analysis of trials, thiazides have been found to be superior to other drug therapies used in treating hypertension to prevent heart failure (Wright, J.T. Jr, Probstfield, J.L., Cushman, W.C., et al., 2009).

For a complete discussion of CHF and its treatment, see Chapter 29.

The increased urinary output resulting from diuretic therapy is useful in CHF because it reduces edema and circulating volume and prevents further fluid retention by the kidneys. These actions have a net effect of decreasing preload (volume returned to the heart) and afterload (resistance exerted by the vessels to blood pumped by the heart) and easing the heart's workload. Pulmonary edema, characterized by fluid-filled lungs, is a life-threatening condition. It commonly results from CHF, but it also can result from infections, exposure to toxic gases, and reactions to drugs. However, the pulmonary edema associated with CHF occurs because pulmonary capillary pressure is greater than capillary osmotic pressure (because of increased left ventricular end-diastolic pressure). In addition, the capillary permeability of the pulmonary capillary membrane increases, thereby allowing fluid to leak into the lungs' interstitial spaces and the alveoli. This leakage impairs gas exchange, which stiffens the lungs and impairs expansion. Diuretics return fluid to the vascular space and increase fluid excretion, which eases breathing. Loop diuretics are now most commonly used in treatment of CHF.

Nephrotic syndrome is a kidney disorder characterized by generalized edema. This condition alters glomerular permeability to protein, allowing massive proteinuria, because plasma proteins are lost by way of the kidney. This loss causes hypoalbuminemia (a lower-than-normal blood level of the protein albumin). Low albumin levels decrease colloid osmotic pressure, which allows fluid to move out of the vascular system, resulting in edema and decreased circulating volume. The kidneys attempt to compensate for the decreased blood volume by retaining sodium and water, which contributes to additional edema. Diuretics promote excretion of sodium and water, and therefore decrease the circulating blood volume.

A potentially reversible condition, acute renal failure results from acutely reduced kidney function. Chronic kidney disease (CKD), an irreversible and progressive reduction of kidney function, is caused by various conditions, although hypertension and diabetes mellitus are responsible for two-thirds of the incidence (other conditions that may lead to CKD include: systemic lupus erythematosus (SLE); glomerulonephritis; inherited diseases, such as polycystic kidney disease; recurrent urinary tract infections; obstruction; and congenital malformation). Chronic kidney disease leads to renal failure. Chronic kidney disease is defined as structural or functional kidney abnormalities (most commonly persistent albuminuria or microalbuminuria) that last for at least 3 months, with or without a decreased GFR or a decreased GFR with or without evidence of kidney damage. Twenty-six million American adults have chronic kidney disease (National Kidney Foundation, 2009). Chronic kidney disease is classified into five stages (Levy, Coresh, Balk, et al., 2003) (Box 27.1). As renal failure becomes more severe, the following may be observed: hypervolemia, hyperkalemia, metabolic acidosis, hypertension, anemia, and bone disease. With end-stage renal failure, uremia is present; signs and symptoms include anorexia, nausea, vomiting, pericarditis, peripheral neuropathy, and central nervous system abnormalities ranging from loss of concentration or lethargy to seizure to coma and death.

In pathologic conditions in which sodium and water reabsorption cause hypervolemia, diuretics are used to promote sodium loss. Sodium loss from a diuretic is related to the dose of the diuretic. Natriuresis is not seen until a threshold rate of drug excretion is attained. A patient who does not respond to a particular dose of a diuretic may not be reaching this threshold. Thus, the single dose should be increased, rather than two equal doses administered twice as often. In end-stage renal failure (where anuria is present), diuretics are generally of little value, and increasing the dose does not increase the therapeutic response.

In kidney failure, loss of the ability to produce erythropoietin contributes to anemia. Exogenous erythropoietin can be given as a replacement when this occurs. Chapter 33 discusses erythropoietin.

Hypertension (blood pressure that is chronically elevated above normal), one of the most common cardiovascular disorders in the United States, is closely associated with kidney function. Renin is released by the kidneys. The outflow of renin activates several mechanisms that lead to activation of angiotensin II, a potent vasoconstrictor. Angiotensin II stimulates secretion of aldosterone, which promotes sodium retention. Sodium retention promotes water retention. The resulting increased vascular resistance and the increased fluid volume elevate blood pressure.

Although hypervolemia is not necessarily present in the hypertensive patient, the action of diuretics effectively

Box 27.1 STAGES OF CHRONIC KIDNEY DISEASE

STAGE 1	Normal GFR (>90 mL/min per 1.73 m^2) and persistent albuminuria
STAGE 2	GFR between 60 and 89 mL/min per 1.73 m^2 and persistent albuminuria
STAGE 3	GFR between 30 and 59 mL/min per 1.73 m^2
STAGE 4	GFR between 15 and 29 mL/min per 1.73 m^2
STAGE 5	GFR of less than 15 mL/min per 1.73 m^2 (end-stage renal disease)

lowers the blood pressure. Blood pressure (BP) is cardiac output (CO) multiplied by peripheral resistance (PR): BP = CO × PR. By reducing circulating volume, diuretics decrease cardiac output and reduce blood pressure. In reducing circulating volume, fluid is pulled back into the vascular space, reducing edema and the symptoms associated with it. Peripheral vascular resistance is thus decreased, further promoting reduction in blood pressure and decreasing the workload on the heart. Diuretics have been found to be at least as effective as other antihypertensives, and findings from the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) indicate that they, and specifically the thiazides, should be used as first-line therapy in hypertension. In fact, findings from ALLHAT, in a study of more than 33,000 North American hypertensive patients with at least one other CHF risk factor, showed that thiazide-type diuretics are as good if not superior to ACE inhibitors or calcium channel blockers in preventing one or more major forms of cardiovascular disease (CVD) (ALLHAT Officers and Coordinators, 2002). Evidence from subsequent analyses of ALLHAT and other clinical outcome trials have confirmed that no other drug therapy for hypertension is superior to thiazide-type diuretics as initial therapy for reduction of cardiovascular or renal risk from hypertension (Wright, J.T. Jr., Probstfield, J.L., Cushman, W.C., et al., 2009).

Diuretics may be used alone or with antihypertensive drugs to lower blood pressure. The kind of diuretic drug prescribed depends on the patient's condition and the severity of the hypertension. For more information on hypertension and its treatment, refer to Chapter 26.

A completely different problem with urinary output arises from alterations in the stimulation of adrenergic or cholinergic receptors in the bladder. When there is excessive cholinergic stimulation, an overactive bladder can result. An overactive bladder is a condition that results from sudden, involuntary contraction of the muscle in the wall of the urinary bladder. Overactive bladder causes an immediate need to urinate (urinary urgency). This condition is also referred to as urge incontinence and is a form of urinary incontinence (unintentional loss of urine).

THIAZIDE DIURETICS

The thiazides comprise the largest group of diuretics. They are related structurally to the antibacterial sulfonamides. Thiazide diuretics include hydrochlorothiazide, chlorothiazide, bendroflumethiazide, hydroflumethiazide, polythiazide, and methyclothiazide. A few thiazides differ slightly in chemical structure. These drugs are called thiazide-related diuretics and include indapamide, chlorthalidone, and metolazone. They exhibit the same diuretic mechanism of action, efficacy, and adverse reactions as the thiazides. The prototype thiazide diuretic is hydrochlorothiazide (HydroDIURIL). Table 27.1 presents a summary of selected diuretic drugs.

Nursing Management of the Patient Receiving P Hydrochlorothiazide

Core Drug Knowledge

Pharmacotherapeutics

Hydrochlorothiazide is used widely in managing hypertension, either alone or with other drugs. Several days are required to see the antihypertensive effects, and full therapeutic effects may not occur for 2 to 4 weeks. Hydrochlorothiazide or other thiazide diuretics have long been recommended by clinical guidelines to be the first drug prescribed to treat hypertension. Only about one-third of practitioners actually prescribe a thiazide diuretic as first-line treatment for hypertension, however (Bonds, D.E., Hogan, P.E., Bertoni, A.G., 2009). Sometimes hydrochlorothiazide is also used in treating edema resulting from CHF, hepatic cirrhosis, and long-term steroid or estrogen therapy. Paradoxically, hydrochlorothiazide is used in diabetes insipidus as an antidiuretic, possibly because it enhances the action of ADH as a consequence of sodium depletion. Hydrochlorothiazide is only administered orally.

Hydrochlorothiazide appears to prevent recurrence of calcium kidney stones in individuals who have unexplainable elevations of calcium in the urine and have experienced kidney stones (Escribano J., Balaguer A., Pagone F., et al., 2009; Arrabal-Martin, Fernandez-Rodriguez, Arrabal-Polo, et al., 2006; Fernandez-Rodriguez, Arrabal-Martin, Garcia-Ruiz, et al., 2006). Thiazides appear to produce this effect this by promoting reabsorption of calcium.

Pharmacokinetics

Administered orally, hydrochlorothiazide is absorbed rapidly from the GI tract, and more than 50% of the circulating drug is bound to plasma proteins. Action begins within a few hours. The drug crosses the placental barrier and is secreted in breast milk. Hydrochlorothiazide is metabolized by the liver and excreted in the urine.

Pharmacodynamics

Hydrochlorothiazide acts in the distal tubule and possibly in the diluting segment of the ascending loop of Henle. It increases excretion of sodium and chloride in the distal convoluted tubule by slightly inhibiting the ion pumps that work in sodium and chloride reabsorption. This action also inhibits water reabsorption. Because most of the sodium is reabsorbed before the distal tubule, hydrochlorothiazide has a weak diuretic effect. It also increases the excretion of potassium, bicarbonate, and magnesium and decreases the urinary excretion of calcium. The effects on electrolytes occur early in therapy. With long-term treatment at the same dose (and assuming that sodium intake remains constant), the kidney undergoes some compensatory changes to maintain homeostasis.

The initial volume depletion from the thiazide leads to increases in a variety of sodium-retaining factors, such as angiotensin II and aldosterone. These sodium-retaining forces eventually equal the sodium-losing activity of the

TABLE 27.1 Summary of Selected Diuretic Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Thiazide Diuretics			
P hydrochlorothiazide (Esidrix, HydroDIURIL, Oretic)	Hypertension	*Adult:* PO, 12.5–50 mg/d; increase to 25–100 mg/d as a single or two divided doses *Child:* PO, 1–2 mg/kg/d in single or two divided doses; infants <6 mo may require 3 mg/kg/d in two doses	*Onset:* 2 h *Duration:* 6–12 h $t_{1/2}$: 5.6–14.8 h
	Edema	*Adult:* PO, 25–200 mg/d initially, then 25–100 mg/d *Child:* PO, 1–2 mg/kg/d in two doses; infants <6 mo may require 3 mg/kg/d in two doses	
C Loop Diuretics			
P furosemide (Lasix;)	Edema	*Adult:* PO, 20–80 mg/d in a single dose, may repeat 6 to 8 h later; titrate up to 600 mg/d in severe edema *Adult:* IM, IV, 20–40 mg, may repeat 2 h later	*Onset:* PO, within 1 h; IV, within 5 min *Duration:* PO, 6–8 h; IV, 2 h $t_{1/2}$: 2 h
	Hypertension	*Adult:* PO, 40 mg bid *Child:* PO, 2 mg/kg; may increase by 1–2 mg/kg, not to exceed 6 mg/kg	
	CHF, CRF Pulmonary edema	*Adult:* PO, IV, 2–2.5 g/d *Adult:* IV, 40 mg over 1–2 min; may increase to 80 mg *Child:* IV, 1 mg/kg; may increase by 1 mg/kg but not more than 6 mg/kg	
C Potassium-Sparing Diuretics			
P triamterene (Dyrenium)	Hypertension	*Adult:* PO, 100 mg bid when used alone; decrease starting dose when given with other diuretics; decrease dose of each, adjust to need; not to exceed 300 mg/d	*Onset:* PO, 2–4 h *Duration:* 12–16 h $t_{1/2}$: 3 h
amiloride (Midamor)	Hypertension	*Adult:* PO, add 5 mg/d to usual antihypertensive or other diuretic therapy; increase up to 10 mg/d	*Onset:* 2 h *Duration:* 24 h $t_{1/2}$: 6–9 h
spironolactone (Aldactone;	Hyperaldosteronism Edema	*Adult:* PO, 100–400 mg/d *Adult:* PO, 100 mg/d (range: 25–200 mg/d) *Child:* PO, 3.3 mg/kg/d in single or divided doses	*Onset:* 24–48 h *Duration:* 48–72 h $t_{1/2}$: 20 h
	Hypertension	*Adult:* PO, 50–100 mg/d, single or divided doses *Child:* PO, 1–2 mg/kg bid	
	Diuretic-induced hypokalemia	*Adult:* PO, 25–100 mg/d	
C Osmotic Diuretics			
P mannitol (Osmitrol)	Acute renal failure	*Adult:* IV, 50–100 g of 5%–25% solution (preventive) or 50–100 g of 15%–25% solution (treatment)	*Onset:* 0.5–1 h *Duration:* 6–8 h $t_{1/2}$: 15–100 min
	Intracranial pressure Intraocular pressure	*Adult:* IV, 1.5–2 g/kg as 15%–25% solution infused over 30–60 min *Adult:* IV, 1.5–2 g/kg as 15%–20% solution infused over 30 min	
	Diuresis in intoxications	*Adult:* IV, up to 200 g	
	Urologic irrigation	*Adult:* Bladder catheter, 2.5% solution; add two 50-mL vials (25% mannitol) to 900-mL sterile water	
C Carbonic Anhydrase Inhibitors			
P acetazolamide (Diamox)	Chronic open-angle glaucoma	*Adult:* PO, 250 mg–1 g daily in divided doses	*Onset:* PO, 1–1.5 h; IV, 2 min *Duration:* PO, 8–12 h; IV, 4–5 h $t_{1/2}$: Unknown
	Secondary glaucoma/ preoperative acute congestive closed-angle glaucoma	*Adult:* PO, IV, 250 mg q4h or 250 mg bid, or 500 mg followed by 125 or 250 mg q4h *Child:* IM, IV, 5–10 mg/kg/dose q6h; PO, 10–15 mg/kg/d in divided doses	
	CHF	*Adult:* PO, 250–375 mg (5 mg/kg)/d	
	Drug-induced edema	*Adult:* PO, 250–375 mg daily; give every other day, or 2 d on then 1 d off *Child:* PO, IV 5 mg/kg/dose	
	Epilepsy	*Adult and child:* PO, IV, 8–30 mg/kg/d in divided doses	
	Mountain sickness	*Adult:* PO, 500–1,000 mg/d in divided doses; may use sustained-release preparation	
C Anticholinergic Agents			
P tolterodine (Detrol)	Overactive bladder	*Adult:* IR, 2 mg 2×/d ER, 4 mg 2×/d	*Onset:* 1 wk *Duration:* Unknown $t_{1/2}$: 1.9–3.7 h (parent compound)

diuretic; the net effect is a new steady state in which the extracellular fluid volume is reduced by the amount of sodium lost from initial therapy. Structural adaptations in the distal and collecting tubules are also likely to increase the compensatory sodium retention. Blood pressure is then maintained at the new, lower level in response to the diuretic. The same process occurs when hydrochlorothiazide or other diuretics are given to treat edema, such as from heart failure. The compensatory mechanisms are not activated until the fluid volume has been returned to a normal level. To state that there is a new steady state of sodium balance does not mean that no effect is achieved from hydrochlorothiazide or other diuretics. Sodium is lost while the diuretic is acting, but sodium loss will be very low for the remainder of the day due to increased activity of the sodium-retaining forces.

Water-soluble vitamins also are lost with the increased urine elimination from hydrochlorothiazide, as well as other diuretics. Hydrochlorothiazide decreases GFR and increases blood urea nitrogen (BUN).

Long-term thiazide use appears to increase bone density and decrease the risk of fracture, but these effects are modest, and thiazide treatment is not recommended routinely for its effects on bone density. However, if patients with osteoporosis also have hypertension or nephrolithiasis, then they would receive some additional benefit from using the thiazide to treat their condition.

Contraindications and Precautions

Important contraindications to hydrochlorothiazide therapy include severe renal impairment or anuria (urine output greater than 250 mL daily), hepatic coma, and hypersensitivity to the drug or to sulfonamide antibiotics, which are similar chemically to hydrochlorothiazide and therefore increase the risk for cross-sensitivity. Thiazides should be used with caution in patients with renal disease, lupus erythematosus, liver disease, fluid and electrolyte imbalances, diabetes, gout, elevated cholesterol levels, elevated triglycerides, bronchial asthma, advanced arteriosclerosis, and heart disease. Hydrochlorothiazide is a pregnancy category B drug.

Adverse Effects

Adverse effects are due mostly to the effects of fluid loss or imbalance or from the effects of electrolyte imbalances, which may include hypokalemia, hyponatremia, hypochloremia, and hypercalcemia. Variation in electrolyte levels, which is largest within the first 2 weeks of therapy, is most problematic with larger doses of hydrochlorothiazide; small doses that are now frequently used in treating hypertension (e.g., 12.5 mg) have only a small risk of causing electrolyte imbalance. Thus, fear of electrolyte imbalance should not be a reason to avoid using thiazide diuretics to treat hypertension (Jiang JY, Wong MC, Ali MK, et al., 2009).The most common adverse effects occur in various systems, as follows: cardiovascular (hypotension), central nervous system (CNS; dizziness, light-headedness, and vertigo), GI (anorexia, nausea, and vomiting), and GU (polyuria and nocturia).

Other adverse effects related to fluid and electrolyte imbalances include CNS effects, such as paresthesia (numbness and tingling), headache, and drowsiness. Cardiovascular effects include orthostatic hypotension, volume depletion, cardiac arrhythmias, and chest pain. GI disturbances include diarrhea, constipation, jaundice, and pancreatitis. Dermatologic effects include poor skin turgor and dry mucous membranes. Finally, the musculoskeletal system may be prone to weakness and muscle cramps or spasms resulting from potassium loss, and possibly gout resulting from increased uric acid levels.

Drug Interactions

Hydrochlorothiazide and other thiazide diuretics interact with many drugs and drug classes. Table 27.2 provides the complete list of agents that interact with hydrochlorothiazide. The one drug that should not be used with hydrochlorothiazide is dofetilide, because severe cardiac effects, including lethal arrhythmias, are possible. High-sodium food decreases the effectiveness of hydrochlorothiazide. With large doses of hydrochlorothiazide, the measurement of acetaminophen levels in the blood may be altered.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient is allergic to sulfa or to other thiazides, because these allergies are contraindications for use. Renal status must be assessed because severe renal impairment is a contraindication for hydrochlorothiazide use. Patients who have pre-existing renal disease, a creatinine clearance rate of 40 to 50 mL/min, a GFR of 25 mL/min, or a history of nonresponsiveness to thiazides most likely should be treated with loop diuretics instead of hydrochlorothiazide. If used, hydrochlorothiazide therapy in these patients must be monitored carefully.

Assess hepatic status because hepatic coma is a contraindication, and hepatic disease warrants cautious use. Other problems include a history of systemic lupus erythematosus, diabetes, gout, bronchial asthma, arteriosclerosis, heart disease, or elevated triglyceride or cholesterol levels. In patients with diabetes, blood glucose levels must be assessed; in patients with gout, uric acid levels must be assessed; and in patients with kidney disease or kidney failure, creatinine levels must be assessed, because hydrochlorothiazide elevates blood glucose, lipid, and uric acid levels. The elevation of blood glucose from thiazides also can create new onset of diabetes, however research does not show that it increases the incidence of cardiovascular disease as endogenous diabetes does (Wright, J.T. Jr, Probstfield, J.L, Cushman, W.C., et al., 2009).

Before therapy begins, it is important to assess fluid and electrolyte status because hydrochlorothiazide causes fluid

TABLE 27.2 Agents That Interact with P Hydrochlorothiazide

Interactants	Effect and Significance	Nursing Management
ACE inhibitors	Increased risk of first-dose orthostatic hypotension when the ACE I is started	Start with low doses of ACE inhibitors and then titrate upwards. Monitor blood pressure carefully for 4 h after first dose.
allopurinol	May increase the incidence of hypersensitivity reactions to allopurinol	Monitor for allergic effects.
anesthetics	More anesthetic effect	Dosage may need to be decreased. Monitor/correct fluid imbalance prior to surgery if possible.
anticoagulants	Decreased anticoagulant effect	Monitor prothrombin time, partial thromboplastin time; dose may need adjustment.
antidiabetic agents	Increased blood glucose	Dose may need adjusting.
antigout agents	Decreased effect with thiazides; increased uric acid levels	Monitor uric acid levels; dose may need to be adjusted.
antineoplastics	Enhanced myelosuppression may result in granulocytopenia.	Monitor white blood cell count.
calcium salts	Hypercalcemia because thiazides promote calcium retention	Monitor calcium levels.
carbamazepine	Hyponatremia from additive effects	Monitor calcium levels during therapy.
corticosteroids	Additive potassium loss may result in hypokalemia.	Monitor potassium level during therapy.
diazoxide	Hyperglycemia possible	Monitor blood glucose level.
digitalis glycosides	Hypokalemia from thiazides, which may induce digitalis toxicity	Monitor potassium level. Monitor for digitalis toxicity. Provide potassium in diet or supplements.
dofetilide	Increased plasma concentration of dofetilide, leading to increased risk of cardiotoxicity	Coadministration of these drugs is contraindicated. After stopping dofetilide, a washout period of at least 2 d should be allowed before starting hydrochlorothiazide.
droperidol	Possible additive cardiac effects related to potassium loss may increase risk of cardiotoxicity.	Administer droperidol with extreme caution if coadministration required.
ginkgo	May possibly increase blood pressure	Assess for use of this herb. Monitor carefully if coadministered; ginkgo may need to be stopped.
levomethadyl	Additive hypokalemia or hypomagnesemia effects may increase risk of QT prolongation.	Coadminister with extreme caution.
licorice	Pseudoaldosteronism from licorice can increase the risk of hypokalemia or reduce the effectiveness of hydrochlorothiazide.	Avoid coadministration.
lithium	Sodium possibly lost instead of lithium ions, inducing lithium toxicity	Monitor blood lithium levels.
loop diuretics	Profound diuresis and serious electrolyte imbalance	Monitor electrolyte levels.
ma huang	Oppositional effects many reduce the hypotensive effect from hydrochlorothiazide.	Avoid coadministration.
mermantine	Altered plasma levels of either drug may result	Monitor for effectiveness of each drug if coadministration is required.

TABLE 27.2 Agents That Interact with P Hydrochlorothiazide *(continued)*

Interactants	Effect and Significance	Nursing Management
methyldopa	Rare occurrences of hemolytic anemia with concurrent use	Monitor complete blood chemistry.
nondepolarizing muscle relaxants	Possible prolonged neuromuscular blocking effects and respiratory depression	Assess respiratory status.
porfimer	Additive photosensitizing effects may lead to excessive tissue damage.	Advise patients to avoid exposure of skin and eyes to direct sunlight or bright indoor light if taking both drugs; sunscreens do not protect against the photosensitivity reactions.
propranolol	Hyperglycemia and hypertriglyceridemia may result, as propranolol may potentiate these effects.	Avoid coadministration in patients with diabetes or hyperglycemia. Monitor glucose and lipid levels if coadministration required.
vitamin D	Biologic actions of vitamin D enhanced; hypercalcemia may have role	Monitor calcium levels.
amphotericin B, corticosteroids	Electrolyte depletion intensified	Monitor electrolyte levels, particularly potassium.
anticholinergics	Increased absorption of thiazides	Monitor blood pressure, electrolyte levels.
bile acid sequestrants (cholestyramine, colestipol)	Bind thiazides, reduce absorption	Give thiazides at least 2 h before resin.
methenamines	Possible decreased effect of thiazides due to alkalinization of urine	Monitor blood pressure, electrolyte levels; may need to adjust dosage.
nonsteroidal anti-inflammatory drugs	Reduced diuretic, natriuretic, and antihypertensive effects	Observe for therapeutic effect.
sotalol	Additive potassium and magnesium loss increases the risk of cardiotoxicity.	Correct potassium and magnesium imbalance prior to starting sotalol therapy. Monitor for complications.
topiramate	Increased levels of topiramate	Assess for adverse effects of topiramate; adjust dose if necessary.
yohimbine	Increased blood pressure; yohimbine increases norepinephrine release; reduced effectiveness of hydrochlorothiazide	Avoid use of yohimbine.

and electrolyte losses. If the patient has fluid and electrolyte deficiencies before therapy, additional losses increase the risk of serious adverse effects. If the patient receives large doses of hydrochlorothiazide, it is more likely that he or she will experience hyponatremia or **hypokalemia** (low levels of potassium in the blood). However, electrolyte imbalances are rarely significant when low-dose therapy is used. Additional baseline measurements should include blood pressure and other vital signs; body weight; edema in the ankles, sacrum, and abdomen; and urinary elimination patterns and output volume. Because many drugs interact with hydrochlorothiazide, assess the patient's drug history, particularly the current drug regimen. Drug therapy that also causes electrolyte loss or that may be affected adversely by the electrolyte loss induced from hydrochlorothiazide therapy should be most closely assessed. For example, hydrochlorothiazide causes hypokalemia. Hypokalemia increases the effect of the drug digoxin. Therefore, patients receiving digoxin for CHF have an increased risk for digoxin toxicity if they become hypokalemic during hydrochlorothiazide therapy.

Life Span and Gender

It is important to determine whether the patient is pregnant or breast-feeding. Although hydrochlorothiazide is a pregnancy category B drug, it can be present in breast milk, and the drug must be used with caution by pregnant or breast-feeding women.

Determine the patient's age before administering hydrochlorothiazide therapy. Hyponatremia is more likely to occur in older adults (> 65 years), especially women (Clayton, Rodgers, Blakey, et al., 2006). Larger doses of thiazide diuretics greatly increase the risk of hyponatremia in older adults.

Such individuals also tend to have more risk factors (e.g., decreased dietary potassium intake, diminished renal reserve, concurrent disease, and concomitant therapy with drugs such as glucocorticoids) for hypokalemia. As previously stated, electrolyte imbalances are most likely to occur within the first 2 weeks of therapy. Sodium deficiency may develop at a later time, but only if there was a physiological change (e.g., heart failure) or an increase in the dose of hydrochlorothiazide. Later development of hypokalemia can occur if the diuretic dose is increased, extrarenal potassium losses increase, or dietary potassium intake is reduced. One small study found that older adults also appear to be at increased risk for vitamin B_1 deficiency while taking hydrochlorothiazide or other diuretics. This deficiency is caused by vitamin loss with increased urination. In addition, the diets of older adults receiving hydrochlorothiazide may contain less thiamine than recommended (McCabe-Sellers, Sharkey, & Browne, 2005).

Lifestyle, Diet, and Habits

Assess the patient's dietary sodium intake, because a high sodium intake can prevent a net fluid loss from the hydrochlorothiazide. Assess the patient's normal fluid intake and dietary sources of electrolytes, particularly potassium, to evaluate whether the patient's nutritional intake can compensate adequately for electrolytes lost during drug therapy.

Environment

Assess whether the patient can get easily to a toilet, especially at the beginning of therapy, when urine output increases. The patient's home must be set up for safety because falls may occur as a result of adverse effects of therapy. Hydrochlorothiazide can be self-administered at home or administered in acute care, long-term care, or subacute care settings.

Culture and Inherited Traits

Note the patient's ethnic background. In African Americans, hydrochlorothiazide therapy is somewhat more effective than in patients who are of European descent. It is believed that hypertensive African Americans have features that are consistent with a theory of corrected volume status where the sodium and potassium pump is inhibited. Because hydrochlorothiazide stimulates excretion of sodium and potassium, it exerts an additional effect in hypertensive African Americans.

Nursing Diagnoses and Outcomes

- Risk for Deficient Fluid Volume related to action and adverse effects of hydrochlorothiazide
  Desired outcome: *The patient will not experience fluid imbalance while on hydrochlorothiazide therapy.*
- Risk for Injury, Falls, related to adverse effects of hydrochlorothiazide
  Desired outcome: *The patient will not suffer injury from falls while taking hydrochlorothiazide.*
- Risk for Injury, Drug Interactions, related to multiple drug therapies
  Desired outcome: *The patient will not have adverse effects from drug interactions while taking hydrochlorothiazide.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer hydrochlorothiazide in the morning so that the maximum diuretic effect does not disturb sleep (assuming the patient is awake days and sleeps nights). It is important to provide ready access to a bathroom (or bedside urinal, bedpan, or commode) to ensure comfort during peak drug action.

Monitor fluid intake, urine output, and body weight for changes. It is important to encourage the patient to avoid foods high in sodium content and not to increase sodium intake after hydrochlorothiazide dosage has been regulated, because that increase could counteract the effect of drug therapy. Encourage continued efforts at lifestyle changes that lower blood pressure (when used to treat hypertension). Work with the patient to identify and correct lifestyle factors that can affect adherence, as described in Box 27.2.

BOX 27.2 COMMUNITY BASED CONCERNS

Factors That Can Decrease Adherence to Diuretic Therapy

Older adults are often prescribed diuretic therapy as part of their drug regimen to treat hypertension or chronic heart failure. Sometimes, therapeutic or adverse effects from the drug therapy cause older adults to choose not to take their prescribed diuretic regularly. Here are some common reasons patients give for not wanting to take a diuretic, and some suggestions for how you can help the patient minimize these problems.

- *I have to get up and go to the bathroom several times during the night.* Encourage the patient to take the drug early in the morning. If he is to take it twice a day, have him take the second dose before 6 PM. If timing the dose this way still does not minimize the problem, consult with the prescriber to see if the dose can be given as one daily dose instead of two daily doses.
- *I can't get to the bathroom quick enough, and I wet myself.* The problem may not be the diuretic itself, but impaired mobility or fine motor skills required to unzip pants or manipulate clothing. If the patient has difficulty moving quickly, suggest that he empty his bladder routinely throughout the day so that he doesn't ever get an extremely full bladder, which may contribute to feelings of urgency. A bedside commode might be helpful if the patient is having trouble getting to the bathroom in the middle of the night. Clothing modifications, such as Velcro closures, might make manipulating clothing easier. A consultation with an occupational therapist may be helpful.
- *I can't go anywhere, because if I can't find a bathroom right away, I might have an accident.* Time the dosing of the diuretic so that it will have had a chance to reach full effect before the patient wants to go out. For example, if the patient wishes to go out at 10 AM, he might want to vary the time he takes his medication, taking it earlier in the morning that day. If he takes the drug at 6 AM and the drug's peak effect occurs in 2 hours, then by 10 AM, the effect on urinary output would be less. Explore the patient's feelings regarding the use of absorbent pads or briefs. Some patients find these provide a feeling of security, knowing that they cannot accidentally wet their clothing, and others find the use of these items humiliating and refuse to wear them.

Minimizing Adverse Effects

Correct any electrolyte imbalance prior to starting hydrochlorothiazide therapy. Monitor serum electrolyte levels for hypokalemia, hyponatremia, hypomagnesemia, and hypercalcemia after the first 2 weeks of therapy. Decreasing the dose of the hydrochlorothiazide usually corrects any electrolyte loss. Potassium supplements are given if serum potassium levels fall below 3.0 mEq/L or if levels are less than 3.5 mEq/L in patients who are receiving digitalis, have ischemic heart disease, or have ectopic rhythms. Monitor for hyperglycemia, hyperuricemia, serum triglyceride, cholesterol, and creatinine levels throughout therapy. Also, closely monitor older adults for hyponatremia. In addition, assess older adults for signs of water-soluble vitamin deficiencies; a multivitamin may be indicated, especially if patients do not eat a nutrient-rich diet.

It is important to assess the complete blood count (CBC) to detect blood abnormalities, and to inspect the skin for rashes or hives to detect sensitivity responses. Observe patients for related signs and symptoms of fluid and electrolyte abnormalities. It also is important to weigh patients regularly to determine extraordinary fluid loss (reflected in weight loss) and complications (reflected in weight gain). They may be weighed daily during the initial period of therapy and then weekly or biweekly once therapy is stabilized. A weight gain exceeding 3 lb in 1 day—a sign of fluid retention and complications—should be reported to the prescriber.

Caution patients to avoid rapid position changes that may intensify orthostatic hypotension and precipitate falls. As needed, elderly or debilitated patients should be assisted with walking to the bathroom to prevent injury. Hydrochlorothiazide can be administered with meals or milk to prevent or minimize GI upset. It is important to assess for signs of drug interactions if patients are currently receiving other drug therapies known to interact with hydrochlorothiazide.

Providing Patient and Family Education

- Explain the importance of follow-up blood work to monitor electrolyte levels.
- Urge patients to report signs and symptoms of hypokalemia (irregular pulse rate, muscle weakness or cramps, constipation, or abdominal pain).
- Tell patients to take their pulse and compare the rate with former or normal rates. (You may need to teach them how to take a pulse.)
- Encourage patients to consume potassium-rich foods, such as bananas, apricots, and orange juice, and other electrolyte-rich beverages and food to counter electrolyte losses, especially potassium.
- Teach older adults and their family members to report signs and symptoms of hyponatremia (weakness, nerve disorders, loss of weight, "salt hunger," cramps, problems with digestion).
- Teach patients to avoid injury from falls by rising slowly and balancing carefully to counter orthostatic hypotension.
- Instruct patients to take hydrochlorothiazide with food if they have problems with GI discomfort.
- Explain the importance of wearing sunglasses, sunscreen, wide-brimmed hats, and cover-up clothing to avoid a possible photosensitivity reaction.
- Store hydrochlorothiazide safely to prevent accidental poisoning of children, forgetful adults, or others.

Ongoing Assessment and Evaluation

Evaluate the effects of therapy and the degree to which expected outcomes have been achieved. Most patients receiving hydrochlorothiazide can expect to have a reduction in fluid retention, edema, and blood pressure. To that end, edema and blood pressure may be compared with baseline values. Fluid balance may be evaluated by weighing the patient at the same time of day on the same scale, ideally with the patient wearing the same weight of clothing. Laboratory tests may be reviewed regularly to detect electrolyte imbalances and blood abnormalities.

Patients who appear resistant to therapy should have a 24-hour urine specimen collected to assess sodium excretion. Because daily sodium excretion is approximately equal to intake, high levels of sodium in a 24-hour urine specimen indicate that the patient has not been adherent with dietary sodium restrictions. A value greater than 100 mEq/d in a patient whose daily weight is stable indicates that there has been an adequate diuretic response but the dietary intake of sodium is too great to see the whole therapeutic response. Random single voided specimens are often misleading about the patient's total sodium intake, depending on when the specimen is obtained in relation to when the drug was administered.

Drugs Closely Related to P Hydrochlorothiazide

Bendroflumethiazide (Naturetin), chlorothiazide (Diuril), methyclothiazide (Enduron), and polythiazide (Renese) are all thiazide diuretics. They are all extremely similar to hydrochlorothiazide, with a few minor differences. Bendroflumethiazide is not approved for use in children; it is a pregnancy category C drug. Chlorothiazide can be given either orally or intravenously to adults, it has a much shorter half-life than hydrochlorothiazide, and it is a pregnancy category C drug. Methyclothiazide is not approved for use in children. Polythiazide is not labeled for use in children and has an unknown pregnancy category: Infant risk from breast milk cannot be ruled out.

Drugs Significantly Different From P Hydrochlorothiazide

The thiazide-related drugs chlorthalidone (Hygroton), indapamide (Lozol), and metolazone (Zaroxolyn) have a slightly different chemical structure than hydrochlorothiazide and other thiazides. Other differences are related to labeled indications and pharmacokinetics. Chlorthalidone is not

MEMORY CHIP

P Hydrochlorothiazide

- Widely used alone or with other agents to reduce blood pressure; also used to treat edema from CHF, from hepatic or renal disease, or secondary to drug use
- Works in the distal tubule to promote excretion of sodium, chloride, potassium, and water
- Major contraindication: severe renal disease
- Most common adverse effects: from fluid and electrolyte loss (dizziness, light-headedness, vertigo, nausea, and vomiting)
- Most serious adverse effects: aplastic anemia and thrombocytopenia (although not normally life-threatening)
- Minimizing adverse effects: Monitor blood pressure, weight, intake and output, and serum electrolyte levels during therapy with this drug.
- Most important patient education: Explain the importance of periodic blood work to monitor electrolytes.

approved for use in children and has a much longer half-life. Indapamide is specifically used for edema in CHF as opposed to other causes of edema, is not approved for use in children, and is extensively metabolized in the liver. Dosage adjustments are required in liver disease. Metolazone is not approved for use in children.

C LOOP DIURETICS

The loop diuretics work in the loop of Henle to inhibit reabsorption of sodium and chloride. They exert a powerful effect on fluid and electrolyte balance. Loop diuretics are sometimes referred to as high-ceiling diuretics because the maximum diuretic effect that can be achieved is higher than with other diuretics. Loop diuretics include furosemide, bumetanide, ethacrynic acid, and torsemide. The prototype drug in this class is furosemide (Lasix).

Nursing Management of the Patient Receiving P Furosemide

Core Drug Knowledge

Pharmacotherapeutics

Furosemide is a potent diuretic that is effective in reducing peripheral edema from CHF and hepatic and renal diseases, including nephrotic disease. It is highly effective in treating pulmonary edema. It also is effective in treating hypertension and is the first choice over thiazides in patients with pre-existing renal disease because, unlike thiazides, it does not decrease GFR. Furosemide can be given either orally or intravenously.

Pharmacokinetics

After oral administration, furosemide is absorbed rapidly and well from the GI tract. However, after intravenous (IV) administration, furosemide acts even more rapidly—within 10 minutes. Duration of action is 2 hours. The drug is about 95% bound to plasma proteins. Furosemide is metabolized in the liver and excreted by the kidneys. It crosses the placenta and may be excreted in breast milk (Table 27.3).

Pharmacodynamics

Furosemide inhibits the reabsorption of sodium, chloride, and water in the ascending loop of Henle. It also has some effect in the proximal and distal tubules. As a result, excretion of sodium, chloride, potassium, and water increases. Excretion of filtered sodium is between 20% and 25%. Excretion of magnesium and calcium occurs as well. The negative calcium balance created by furosemide and other loop diuretics may increase the risk of hip fracture. As with thiazide diuretics, most of the electrolyte loss occurs in the first 2 weeks of therapy, as long as the dose remains constant. Electrolytes, especially sodium and potassium, will level off with continued therapy as compensatory mechanisms for sodium retention occur, creating a new steady state for sodium. For a complete discussion of this process, see the Pharmacodynamics section for hydrochlorothiazide.

Furosemide can increase blood glucose, low-density lipoprotein, total cholesterol, and triglyceride levels. In addition, it decreases excretion of uric acid, which may raise uric acid levels.

Contraindications and Precautions

Furosemide should not be used in anuria or if hypersensitivity to the compounds or allergy to sulfa drugs exists. Cautious use must be exercised in patients with poor renal function and lupus erythematosus. Furosemide is a pregnancy category C drug.

Adverse Effects

Most of furosemide's adverse effects relate to fluid or electrolyte imbalance. Electrolyte imbalances, which are most likely to occur within the first 2 weeks of therapy, include hyponatremia, hypokalemia, hypochloridemia, and hypocalcemia. Loss of hydrogen ions can also lead to metabolic alkalosis. A marked diuretic effect (from large doses) decreases the volume returning to the heart and can lead to a decrease in cardiac output of as much as 20%. Hypotension, especially orthostatic hypotension, dizziness, and vertigo, may result.

Excessive diuresis from furosemide can result in dehydration, reduction in blood volume with circulatory collapse, and the possibility of vascular thrombosis and embolism, particularly in the elderly. Warning signs of dehydration and significant electrolyte imbalance are dry mouth, thirst, anorexia, weakness, lethargy, drowsiness, restlessness, muscle pains or cramps, muscle fatigue, tetany (rarely), hypotension, oliguria, tachycardia, arrhythmia, and GI disturbances (e.g., nausea/vomiting). BUN levels and serum creatinine levels may rise after aggressive diuresis from furosemide due to poor renal perfusion if cardiac output falls significantly. Patients with hepatic cirrhosis and ascites must be monitored carefully because rapid electrolyte shifts

TABLE 27.3 Agents That Interact with P Furosemide

Interactants	Effect and Significance	Nursing Management
ACE inhibitors	First-dose postural hypotension when ACE inhibitor is added to diuretic therapy	Start therapy first with ACE inhibitors if possible; otherwise, start with small doses of ACE inhibitors and titrate upwards. Monitor blood pressure closely for first 4 h after dose of ACE inhibitors.
aminoglycosides	Increased ototoxicity; possible hearing loss	Avoid coadministration if at all possible. Monitor BUN and creatinine; adverse effects will increase if drugs are not excreted well. Assess for hearing problems; stop drug therapy at first indication of ototoxicity if coadministered.
anticoagulants	Enhanced anticoagulant action possible	Monitor PT, PTT.
beta blockers (propranolol)	Increased plasma levels of propranolol	Monitor therapeutic effect and adverse effects of propranolol.
corticosteroids	Increased potassium loss; hypokalemia	Monitor potassium levels.
chloral hydrate	Rare transient diaphoresis, hot flashes, hypertension, tachycardia, weakness, and nausea	Consider drug interaction if these effects occur.
Class III antiarrhythmics	Hypokalemia from furosemide increases the risk of serious, potentially life-threatening cardiotoxicity.	Use extreme caution if coadministered. Monitor serum potassium levels and maintain in normal range.
digitalis glycosides	Furosemide-induced hypokalemia, increasing digitalis toxicity	Monitor serum potassium level. Supply potassium in diet or as supplement. Monitor for signs of digitalis toxicity.
droperidol	Additive cardiac effects increasing risk of cardiotoxicity	Coadminister with extreme caution.
germanium, ginseng	May increase blood pressure and decrease effectiveness of diuretics	Avoid coadministration.
hydralazine	Increased plasma clearance of furosemide, creating an enhanced diuretic response	Monitor for diuretic response; dose adjustments may be needed.
licorice	Increased risk of hypokalemia and/or reduced diuretic effect	Avoid coadministration.
lithium	Possible increased plasma lithium levels and toxicity	Monitor lithium levels.
ma huang, yohimbine	Increase in blood pressure and reduced hypotensive effect of furosemide	Avoid coadministration.
nondepolarizing muscle relaxants	Antagonized or potentiated action of muscle relaxants, perhaps depending on furosemide dose	Monitor for therapeutic effect.
sulfonylureas	Loss of sulfonylureas' effect, resulting in hyperglycemia	Sulfonylureas dosage may need adjustment.
theophylline	Theophylline effect enhanced or inhibited	Monitor for therapeutic effect of theophylline.
charcoal	Decreased absorption of furosemide	Monitor for therapeutic effect. May be antidote in case of furosemide overdose.
cisplatin	Additive ototoxicity	Avoid coadministration if at all possible. Monitor BUN and creatinine; adverse effects will increase if drugs are not excreted well. Assess for hearing problems; stop furosemide therapy at first indication of ototoxicity if coadministered.

(*Continued*)

TABLE 27.3 Agents That Interact with P Furosemide *(continued)*

Interactants	Effect and Significance	Nursing Management
clofibrate	Exaggerated diuretic response	Monitor intake and output, blood pressure, edema, and fluid and electrolyte levels.
phenytoin and other hydantoins	Decreased diuretic response	Monitor for therapeutic response.
NSAIDs	Decreased diuretic response	Monitor for therapeutic response.
probenecid	Decreased diuretic response	Monitor for therapeutic response.
salicylates	Diuretic response impaired in patients with cirrhosis and ascites	Monitor for therapeutic response.
thiazides	Profound diuresis and serious electrolyte levels	Monitor blood pressure, edema, and fluid and electrolyte levels.

resulting from furosemide therapy may induce hepatic encephalopathy and coma. Because hyperuricemia is also possible from furosemide therapy, patients with a history of gout may find its use problematic.

A common and serious adverse effect is ototoxicity. Ototoxicity can occur with rapid IV therapy, especially in patients with poor renal function, and in those patients receiving high doses of oral of IV furosemide. Signs of ototoxicity include tinnitus, vertigo, a feeling of fullness in the ear, and medium- and high-frequency hearing loss. Although usually transient (lasting 1 to 24 hours), ototoxicity may result in permanent damage, including deafness. Ototoxicity is believed to be due to furosemide's inhibition of the Na-K-Cl active cotransport system. An isoform of this transporter is present in the inner ear, and it appears that when the transport system is inhibited in the kidney, it is also inhibited in the inner ear, causing deafness, imbalance, or structural damage to the inner ear.

Another major problem from furosemide is related to hypersensitivity and allergic responses. Hypersensitivity reactions include rash or acute interstitial nephritis (rare); these reactions are similar to those produced by other sulfonamide drugs. Allergic responses from those with a known sulfonamide antibiotic allergy include asthma, eczema, urticaria, dermatitis, Stevens-Johnson syndrome, and anaphylaxis.

Other adverse effects occur in various systems, as follows: CNS (paresthesias, xanthopsia, blurred vision, and fever); cardiovascular (chronic aortitis), GI (constipation, diarrhea, cramping, pancreatitis, jaundice, ischemic hepatitis); hematologic (leukopenia, anemia, thrombocytopenia, and agranulocytosis); GU (urinary bladder spasm); dermatologic (photosensitivity); and metabolic (increases in blood glucose and alterations in glucose tolerance tests; increases in low-density lipoprotein, total cholesterol, and triglycerides; and minor decreases in high-density lipoprotein).

Patients with SLE may have exacerbations of the illness when receiving furosemide.

Drug Interactions

Furosemide and aminoglycoside antibiotics should not be coadministered because they both can cause ototoxicity. The hypokalemia that may result from furosemide increases the risk of digoxin toxicity without increasing digoxin levels. Furosemide interacts with many other drugs. Bioavailability and degree of diuresis are reduced when furosemide is administered with food. Table 27.3 lists agents that interact with furosemide.

Assessment of Relevant Core Patient Variables

Health Status

Initially, assess for allergies to furosemide or other contraindications. A baseline assessment is then performed. This assessment is much like the one for a patient receiving hydrochlorothiazide. Begin by taking blood pressure and vital signs and reviewing relevant blood test results and electrolyte levels. Patients who receive digoxin or have a history of arrhythmias or other cardiac abnormalities may be especially prone to complications from the hypokalemia that can result from furosemide. Potassium levels should generally be greater than 4.0 mEq/L prior to starting furosemide. To assess fluid status and obtain baseline data for therapy, weigh the patient. Apparent edema is inspected and palpated. It is important to auscultate breath sounds, particularly in patients with CHF or pulmonary edema. Assess skin turgor and mucous membranes and measure fluid intake and urinary output.

During assessment, keep the proposed route of administration in mind because IV furosemide may have a substantially more potent effect than oral furosemide on blood pressure and vital signs (cardiac arrest has been reported). As with hydrochlorothiazide, also assess for gout, diabetes, and high serum cholesterol and triglyceride levels.

Life Span and Gender

Determine whether the female patient is pregnant. Furosemide, a pregnancy category C drug, should be used

during pregnancy only if necessary and then with great caution. It also is important to determine the patient's age before administering furosemide. Furosemide may increase the risk for developing patent ductus arteriosus when given during the first few weeks of life to premature infants with respiratory distress syndrome. Development of renal calcifications (kidney stones) also has been reported when furosemide is used in severely premature infants. Premature infants have a greater risk of ototoxicity. Furosemide can be used safely in children, but doses should not exceed 6 mg/kg of body weight.

If severe diuresis occurs from use of the drug, acute hypotensive episodes may occur, especially in elderly people. Elderly patients are at increased risk for rapid changes in fluid volume, which can lead to circulatory collapse. Moreover, elderly adults also are less tolerant of the rapid changes in blood pressure that may occur with furosemide therapy. In older adults, the rapid loss of plasma volume and the resulting hemoconcentration are likely to cause thromboembolic episodes, such as cerebral vascular thromboses and pulmonary embolism.

In postmenopausal women, who are already at risk of osteoporosis and hip fracture, the additional calcium loss from furosemide and other loop diuretics can increase the risk of hip fracture.

Lifestyle, Diet, and Habits

Assess the patient's dietary sodium intake, because a high sodium intake can prevent a net fluid loss from the diuretic

Exactly how much sodium should be consumed daily in relationship to how much furosemide is still under debate for patients who have heart failure. One recent research study of patients with class 2 to 4 chronic, compensated heart failure found that a normal sodium intake with fluid restrictions of 1,000 cc/d and oral furosemide in high doses (250 mg twice a day) significantly reduced the need for readmission compared to lower sodium levels and conventional (for heart failure) doses of furosemide (Paterna, Parrinello, Cannizzaro et al., 2009). However, when the patient has acute decompensated heart failure, higher doses of furosemide IV seem to be deleterious (see Maximizing Therapeutic Effects below, and the Focus on Research Box 27.3.). Furosemide may promote severe electrolyte imbalances, especially in patients who have high dosages and who are on sodium-restricted diets. Therefore, normal fluid intake and dietary preferences should be determined and evaluated for the adequacy of electrolyte content, especially potassium.

Environment

Assess whether the patient can get to a toilet easily when needed, especially at the beginning of therapy, when urine output increases. The patient's home should be assessed for risk factors that may contribute to injuries (falls) resulting from adverse effects of drug therapy. Oral furosemide can be self-administered at home or administered by others in acute care, long-term care, or subacute care environments. Parenteral dosing is generally restricted to an acute care environment.

BOX 27.3 FOCUS ON RESEARCH

What Is the Proper Dose of Furosemide for Treating Acute Decompensated Heart Failure?

Peacock, W. F., Costanzo, M. R., De Marco,T., et al., for the ADHERE Scientific Advisory Committee and Investigators. Impact of Intravenous Loop Diuretics on Outcomes of Patients Hospitalized with Acute Decompensated Heart Failure: Insights from the ADHERE Registry. *Cardiology*, 113:12–19.

The Study

The ADHERE registry (**A**cute **D**ecompensated **He**art Failure National **Re**gistry) is the largest database on acute heart failure in the world with over 100,000 patients enrolled in the United States.

Findings of the retrospective analysis of hospitalized patients with acute decompensated heart failure suggest that treatment with high doses of fuosemide (160 mg/d or greater IV) is associated with poorer renal function, the need for more hospital resources, and increased mortality, compared to patients with acute heart failure who received lower IV doses of furosemide (less than 160 mg/d IV). Other observational data from the ADHERE registry shows that renal dysfunction is associated with poorer outcomes for patients with acute decompensated heart failure.

As heart failure progresses, resistance develops to furosemide; most commonly in practice this is addressed by administering larger doses or more frequent doses of furosemide to bring about the same diuretic effect. This review questions that practice and indicates that for this may worsen the condition of patients already seriously ill.

Nursing Implications

There are some problems with this study, as the authors point out that limit the interpretation of the data. Because the data from the ADHERE registry analysis was retroactive and observational, none of the findings can be considered to demonstrate a direct cause and effect. One can only draw the conclusion of an apparent association between factors in this type of study. And because medical chart reviews are dependent on what is written into the record, and medical records are not always completely accurate or complete, data could have been lost or misinterpreted. The study also could not differentiate between giving the furosemide via IV bolus or continuous infusion.

Despite these limitations, this study gives the nurse some important information to consider. The evidence seems to show that the current practice of continually increasing the dose of furosemide to treat worsening acute decompensated heart failure may not be the best practice to improve patient outcomes. While urine output may increase, this does not appear to be clinically important in improving renal function, and renal function is the more important issue for decreased mortality. Nurses should be aware that as research continues on furosemide use in acute decompensated heart failure, the standards of care may evolve from where they are today. It is important that more research be done to determine the best dose of furosemide in treatment for both acute and chronic heart failure and that nurses stay abreast of the research findings.

Nursing Diagnoses and Outcomes

- Risk for Deficient Fluid Volume related to action and adverse effects of furosemide
  Desired outcome: *The patient will not experience fluid and electrolyte imbalance while taking furosemide.*
- Risk for Injury, Falls, related to adverse effects of furosemide
  Desired outcome: *The patient will not suffer injury while taking furosemide.*
- Risk for Injury, Drug Interactions, related to multiple drug therapies
  Desired outcome: *The patient will not have adverse effects from drug interactions while taking furosemide.*

Planning and Intervention

Maximizing Therapeutic Effects

If therapy begins in the hospital, the patient receives small doses that may increase gradually and incrementally. If the response to a daily dose is not adequate in relieving edema, then the daily dose should be increased, rather than a second equal dose being administered later in the day. In patients with severe CHF, a continuous infusion is more effective than an equal dose given as an IV bolus in decreasing edema. However, the best IV dose of furosemide given for acute decompensated heart failure is not completely known. A recent review of American patients enrolled in the Acute Decompensated Heart Failure National Registry (ADHERE), the largest database on acute heart failure in the world with over 100,000 patients enrolled, examined 62,866 patients receiving less than 160 mg IV of furosemide and 19,674 patients greater than or equal to 160 mg IV of furosemide. The patients receiving the lower doses had a lower risk for in-hospital mortality, ICU stay, prolonged hospitalization, or adverse renal effect (Peacock, Costanzo, De Marco, et al., 2009). Other interventions are the same as for hydrochlorothiazide.

Minimizing Adverse Effects

When giving furosemide, follow the same procedures used for minimizing adverse effects of hydrochlorothiazide therapy. Hypokalemia is a greater risk from furosemide than from hydrochlorothiazide; closely monitor potassium levels during the first 2 weeks of chronic therapy and whenever an increase in the daily dosage occurs. The drug administration route must be considered carefully because furosemide may be given intravenously or orally.

Several interventions help minimize the risk of ototoxicity. Administer 20 to 40 mg of IV-push furosemide slowly over at least 1 to 2 minutes. Dilute high-dose infusions of furosemide into normal saline, Ringer's lactate, or D_5W and then administer no faster than 4 mg/minute. Slow, continuous infusions as opposed to bolus doses are believed to prevent high peaks in blood levels, which are associated with ototoxicity. However, the data are still somewhat inconclusive (Salvador, Rey, Ramos, et al., 2005). Although there is no set serum level for therapeutic efficacy, it may be necessary to obtain serum levels of furosemide to identify patients at high risk for ototoxicity; blood levels greater than 50 mcg/mL are associated with hearing problems. Consider a divided daily dose, which decreases the peak level of the drug and may help prevent hearing problems. Finally, avoid giving aminoglycoside antibiotics with furosemide, because the additive adverse effects on hearing greatly increase the risk of hearing damage. If increasing azotemia, oliguria, or BUN or creatinine levels occur in patients with renal impairment, discontinue furosemide therapy.

It is a good idea to give oral furosemide with food or milk to minimize possible GI upset. Report the adverse effects of rapid onset or worsening of edema and deterioration in breath sounds to the prescriber. These signs indicate that dosage may need to be adjusted or that a complication is developing.

Providing Patient and Family Education

The patient's and family's educational needs are similar to the needs of patients taking hydrochlorothiazide.

Ongoing Assessment and Evaluation

To judge an identified therapeutic outcome of furosemide, such as a reduction in edema and blood pressure, ongoing assessments of the following parameters are obtained: CBC, serum electrolyte and uric acid levels, and other test values are compared with baseline values to measure progress or complications. For example, in a patient with diabetes mellitus, it is important to monitor regularly serum glucose levels because furosemide therapy may alter the amount of insulin or oral antidiabetic needed. Patients who appear to be resistant to therapy should have a 24-hour urine specimen collected to assess sodium excretion. A value greater than 100 mEq/d in a patient whose daily weight is stable indicates that there has been an adequate diuretic response but the dietary intake of sodium is too great to see the whole therapeutic response.

Drugs Closely Related to P Furosemide

There are three other loop diuretics: bumetanide (Bumex), ethacrynic acid (Edecrin), and torsemide (Demadex). They resemble furosemide in action and adverse effects with the following exceptions. Bumetanide is more potent than furosemide and carries a Black Box warning that it can cause profound diuresis, water loss, and electrolyte loss if given in too large a dose. Unlike furosemide, bumetanide is used to treat only edema, not hypertension; bumetanide is not approved for use in children. Ethacrynic acid differs from furosemide in several ways. It is not a sulfonamide and is used primarily in people who are allergic to other sulfa-based drugs. It is given only to treat edema. A pregnancy category B drug, it is not approved for use in children. Torsemide is metabolized by the P-450 system to active and inactive metabolites.

MEMORY CHIP

P Furosemide

- A potent diuretic used to treat edema from CHF, pulmonary edema, and in hepatic and renal disease; may be used as an antihypertensive
- First-choice diuretic for treating hypertension with preexisting renal disease
- Works in the loop of Henle to promote excretion of large amounts of sodium, chloride, potassium, and water
- Most important contraindication: anuria in CRF
- Most common adverse effects: related to fluid and electrolyte loss, especially potassium loss
- Most serious adverse effects: significant hypokalemia, permanent deafness, and activation or exacerbation of SLE
- **Life span alert: Older adults are more sensitive to effects of rapid fluid loss.**
- Minimizing adverse effects: Administer IV push slowly, and monitor blood pressure, edema, breath sounds, weight, intake and output, and serum electrolyte levels while therapy continues.

C POTASSIUM-SPARING DIURETICS

The potassium-sparing diuretics promote sodium and water excretion in the distal tubule. At the same time, potassium is not excreted; rather, it is reabsorbed. This group of drugs produces weak diuresis and antihypertensive effects when used alone. However, the drugs are used more frequently in combination with loop and thiazide diuretics to minimize potassium loss because they work synergistically with other diuretics. Patients taking potassium-sparing diuretics are at risk for developing hyperkalemia. Potassium-sparing diuretics include triamterene, amiloride, eplerenone, and spironolactone (Table 27.1). Eplerenone and spironolactone work differently compared with the other two drugs and block aldosterone receptors. They are used in treating CHF and hypertension and are fully discussed in Chapter 26. The prototype of the potassium-sparing diuretics is triamterene (Dyrenium).

Nursing Management of the Patient Receiving P Triamterene

Core Drug Knowledge

Pharmacotherapeutics

Like furosemide, triamterene is used as an adjunct to manage edema and hypertension. The edema may be associated with CHF, cirrhosis, nephrotic syndrome, steroid use, or secondary hypoaldosteronism. It typically is used with other diuretics because it allows potassium to be reabsorbed and sodium to be excreted. Triamterene is given orally.

Pharmacokinetics

Triamterene is absorbed incompletely after oral administration. The drug is metabolized in the liver and excreted by the kidneys. Triamterene crosses the placenta and is excreted in small amounts in breast milk.

Pharmacodynamics

Triamterene achieves its diuretic effect by inhibiting transport of sodium in the distal tubules independent of aldosterone. This mechanism causes increased loss of sodium, chloride, water, bicarbonate, and calcium. However, the drug causes only 1% to 2% of filtered sodium to be excreted; thus, it has a small diuretic effect. The drug promotes retention of potassium and magnesium. Triamterene does not inhibit uric acid excretion and thereby elevates serum uric acid levels, as do the loop diuretics.

Contraindications and Precautions

Contraindications to triamterene include known hypersensitivity, use of other potassium-sparing diuretics, pre-existing **hyperkalemia** (serum potassium level >5.5 mEq/L), anuria, severe or progressive renal disease (except nephrosis), severe liver disease, and hepatic coma.

Precautions to its use include electrolyte imbalance, history of renal stone formation (it has been found in some renal calculi), diabetes (it can raise blood glucose), and when folic acid stores have been depleted (it is a weak folic acid antagonist). It is in pregnancy category C, and safety and efficacy have not been established in children.

Triamterene carries a Black Box warning that it can raise serum potassium levels to greater than or equal to 5.5 mEq/L. Hyperkalemia is more likely to occur in patients with renal impairment and diabetes (even without evidence of renal impairment) and in the elderly or severely ill.

Adverse Effects

Serious adverse effects include hyperkalemia (potentially fatal), electrolyte imbalance, and signs of fluid and electrolyte loss (weakness, nausea, anorexia, vomiting, and dry mouth). Triamterene is potentially nephrotoxic, possibly leading to crystalluria and cast formation (in up to 50% of the patients treated) and (very rarely) to triamterene stones or ARF.

Other adverse effects occur in various systems, as follows: GI (diarrhea, jaundice, and liver enzyme abnormalities); renal (azotemia, elevated BUN and creatinine levels); hematologic (thrombocytopenia and megaloblastic anemia); CNS (fatigue, dizziness, and headache); and miscellaneous (anaphylaxis, photosensitivity, and rash).

Drug Interactions

Triamterene increases the effect of amantadine and potassium preparations. ACE inhibitors, cimetidine, and indomethacin all increase the effect of triamterene. Triamterene interferes with the fluorescent measurement of serum quinidine levels. Table 27.4 lists agents that interact with triamterene.

Assessment of Relevant Core Patient Variables

Health Status

Assessment activities include determining whether the patient has any known hypersensitivity to triamterene and carefully examining electrolyte values, especially potassium

TABLE 27.4 Agents That Interact with P Triamterene

Interactants	Effect and Significance	Nursing Management
amantadine	Increased amantadine plasma levels and decreased urinary excretion; more risk for adverse effects	Monitor for adverse effects.
potassium preparations and drugs that increase potassium levels	Severe hyperkalemia; possible cardiac arrhythmias or cardiac arrest	Avoid concurrent use.
ACE inhibitors	Elevated serum potassium from ACE inhibitors; hyperkalemia	Monitor serum potassium level.
cimetidine	Increased bioavailability and decreased renal clearance of triamterene	Monitor for increased therapeutic effect.
indomethacin	Rapid progress into acute renal failure with concurrent use	Use together only if truly necessary.

levels. As for other diuretic drugs, additional assessments include measuring blood pressure, edema, weight, and urine output; examining serum glucose and creatinine levels; and identifying pre-existing conditions, such as diabetes mellitus, that may affect triamterene therapy. Assess for drug therapy that also increases potassium levels, because this increases the risk of hyperkalemia.

Life Span and Gender

Triamterene must be used cautiously in pregnancy; it is in risk category C. Triamterene crosses into breast milk, and because safety has not been established in children, the drug should not be used in breast-feeding women.

Glomerular filtration decreases with age; consequently, elderly patients do not excrete as much potassium as younger adults. Therefore, triamterene should be given cautiously to older adults because of the increased risk for hyperkalemia.

Lifestyle, Diet, and Habits

Determine whether the patient normally eats a diet high in potassium, takes a potassium supplement, or uses a potassium chloride salt substitute.

Environment

Assess whether the patient can get to a toilet easily when needed, especially at the beginning of therapy, when urine output increases. The patient's home should be assessed for risk factors that may contribute to injuries (falls) resulting from adverse effects of drug therapy. Triamterene can be self-administered at home or administered by others in acute care, long-term care, or subacute care environments.

Nursing Diagnoses and Outcomes

- Risk for Deficient Fluid Volume related to action and adverse effects of triamterene
  Desired outcome: *The patient will not experience fluid and electrolyte imbalance while taking triamterene.*
- Risk for Injury related to adverse effects of triamterene, including risk for hyperkalemia
  Desired outcome: *The patient will not suffer injury, and potassium levels will remain within normal limits while patient is on triamterene therapy.*
- Risk for Injury, Drug Interactions, related to multiple drug therapies
  Desired outcome: *The patient will not have adverse effects from drug interactions while taking triamterene.*

Planning and Intervention

Maximizing Therapeutic Effects

As with other diuretics, triamterene should be administered in the morning so that increased diuretic effect occurs during waking hours.

Minimizing Adverse Effects

Monitor blood potassium levels and assess for signs of hyperkalemia (nausea, diarrhea, muscle weakness or cramping, oliguria, weak pulse, and cardiac arrhythmias). The greatest risk of electrolyte imbalance with triamterene, as with all diuretics, occurs within the first 2 weeks of therapy. It is important to limit the patient's intake of potassium-rich foods and avoid potassium supplements. Monitor for signs of fluid and electrolyte imbalance. Give oral triamterene with food or milk to prevent GI upset. It is a good idea to have the patient get out of bed slowly; assist with ambulation to prevent falls from dizziness.

Providing Patient and Family Education

The main distinction between triamterene and other diuretics is the hyperkalemia that may develop with drug use. Because triamterene is usually added to therapy with other types of diuretics, patients may become accustomed to being at risk for hypokalemia. The patient needs to learn to cope with the different risks associated with triamterene. Other patient and family education points are similar to those points provided for the other diuretics.

- Teach patients to avoid potassium-rich foods, supplements, and potassium chloride salt substitutes.
- Teach patients the signs and symptoms of hyperkalemia.

CRITICAL THINKING SCENARIO

ADDING TRIAMTERENE TO HYPERTENSION THERAPY

Mr. Nixon is a 53-year-old white man being treated for hypertension with hydrochlorothiazide. After 2 weeks of therapy, his potassium level is 2.9 (N=3.5-5). He is started on 20 mEq of potassium as a daily supplement. His potassium levels continue to be low (3.1). Mr. Nixon's prescriber writes an order to add triamterene to his drug regimen.

1. Identify the major electrolyte imbalance that Mr. Nixon may now experience.
2. Suggest actions that you can take to prevent this electrolyte imbalance.

Ongoing Assessment and Evaluation

Monitor the patient's potassium and other electrolyte levels, blood pressure, edema, weight, and urine output. Drug therapy with triamterene is effective when blood pressure is reduced to therapeutic levels or edema is reduced without the patient developing hyperkalemia.

Drug Closely Related to P Triamterene

Amiloride (Midamor), which has the same mechanism of action, efficacy, and adverse reactions as triamterene, has two unique uses. It is approved for use specifically in CHF. In addition, in patients taking lithium, amiloride can reduce lithium-induced polyuria without increasing lithium levels; this is an off-label use of amiloride. Compared with triamterene, amiloride is different in the following ways: it is generally better tolerated, it is not metabolized similarly, it does not cause crystalluria or cast formation, it is a pregnancy category B drug, and it is not approved for use in children.

MEMORY CHIP

P Triamterene

- Potassium-sparing diuretic used to manage edema and hypertension
- Major contraindication: the patient is already receiving a potassium-sparing diuretic
- Most common adverse effects: nausea, vomiting, anorexia, dry mouth, and headache
- Most serious adverse effect: hyperkalemia (electrolyte imbalance)
- **Life span alert: Older adults are especially at risk for hyperkalemia.**
- **Patient safety alert: Life-threatening hyperkalemia may result when combined with potassium supplements or drugs that increase potassium levels indirectly.**
- Most important patient education: Tell the patient to avoid eating potassium-rich food, taking potassium supplements, or using a salt substitute containing potassium chloride.

Drugs Significantly Different From P Triamterene

Spironolactone

Like triamterene, spironolactone (Aldactone) works in the distal tubule to increase sodium and water loss and to retain potassium. Unlike triamterene, spironolactone is an aldosterone antagonist. It blocks all aldosterone receptors: mineralocorticoid, glucocorticoid, progesterone, and androgen receptors. This accounts for its positive effects as well as its adverse effects. It interferes with testosterone synthesis, which leads to altered estrogenic and androgenic activity. Like other potassium-sparing diuretics, spironolactone can be used as an adjunct therapy to treat hypertension and edema associated with CHF, nephrosis, and cirrhosis. Its benefits in CHF are believed to extend beyond merely decreasing edema. It has been found to have marked and sustained antiproteinuric effect when combined with an ACE inhibitor and an angiotensin-receptor blocker in patients with type 2 diabetic nephropathy (Box 27.3). In addition, it is used in preventing or treating hypokalemia in high-risk patients, particularly those patients also taking digitoxin for cardiac disease or those patients with cardiac arrhythmias. Because of its antialdosterone effects, a major use is in diagnosing and treating primary hyperaldosteronism. Unlabeled uses of spironolactone include treatment of hirsutism, familial male precocious puberty, symptoms of premenstrual syndrome, and acne vulgaris (short-term use).

The effect of spironolactone is delayed. Onset of action may not occur for 24 to 48 hours. This delayed onset occurs because the drug blocks the effect of aldosterone, which then blocks the synthesis of the proteins required for sodium and potassium transport. The existing proteins continue to do their job, and diuretic effect does not occur until the existing proteins are inactive. Spironolactone carries a Black Box warning that it has been found to be tumorigenic in chronic toxicity studies in rats. Unnecessary use should be avoided.

Nursing management unique to spironolactone therapy involves helping the patient understand and cope with such adverse effects as impotence, menstrual irregularities, and gynecomastia. Additionally, it is important to teach the patient about the drug interaction between spironolactone and salicylates, such as aspirin, which decreases the diuretic effect of therapy.

Eplerenone

Eplerenone (Inspra) also is an aldosterone blocker and potassium-sparing diuretic. Unlike spironolactone, it is specific for the mineralocorticoid aldosterone receptors. It is used in CHF and hypertension and discussed as the prototype in Chapter 26.

C OSMOTIC DIURETICS

Osmotic diuretics are filterable freely in the glomerulus and not reabsorbed by the tubules. They increase osmotic pressure and pull fluid into the vascular space. Because they are not reabsorbed by the tubules, they prevent water reabsorption as

well. They also prevent reabsorption of sodium and chloride. Osmotic diuretics include mannitol glycerin, isosorbide, and urea (Table 27.1). The prototype osmotic diuretic is mannitol (Osmitrol).

Nursing Management of the Patient Receiving P Mannitol

Core Drug Knowledge

Pharmacotherapeutics

Mannitol is not used to treat hypertension or peripheral edema. Instead, it is used more in acute situations. Major uses include preventing and treating ARF, reducing intracranial pressure in cerebral edema, reducing intraocular pressure when other drugs have not worked, and promoting excretion of toxic substances in urine. In addition, mannitol is used diagnostically to measure GFR and postoperatively as an irrigant after transurethral procedures. It is sometimes used as an adjunct to promote renal excretion of drugs that are at toxic levels.

Pharmacokinetics

Mannitol, a sugar, usually is administered as an IV solution because it does not diffuse across the GI epithelium and is not distributed like other sugars. It can be administered as a urinary irrigant but only in transurethral prostatic resections or other transurethral surgical procedures. It is metabolized poorly, and most of it is excreted in the urine. When used as an irrigant, mannitol has a rapid onset and a short duration of action. Mannitol crosses the placenta and may enter breast milk.

Pharmacodynamics

As a systemic agent, mannitol elevates blood plasma osmolarity that draws fluid from tissues, including the brain, cerebrospinal fluid, and the eye into the vascular space. As a result, cerebral edema, elevated intracranial pressure, cerebrospinal fluid volume, and intraocular pressure may be reduced. As a diuretic, mannitol increases the concentration of molecules in the glomerular filtrate because it is not reabsorbed in the renal tubule. This increased osmolality causes the osmotic pressure to rise, and the increased pressure inhibits water reabsorption, which leads to an increased and faster flow of water in the tubules and therefore water loss. Mannitol also decreases reabsorption of sodium and chloride.

Contraindications and Precautions

Mannitol is contraindicated in severe renal disease, severe pulmonary congestion or frank pulmonary edema, active intracranial bleeding (except during craniotomy), severe dehydration, progressive renal damage or dysfunction after mannitol therapy, and progressive heart failure or pulmonary congestion after mannitol therapy.

Mannitol must be used very cautiously in CHF, renal disease, electrolyte imbalance, pseudoagglutination, and hemoconcentration. Mannitol is a pregnancy category C drug. Safety and efficacy for children 12 years and younger have not been established.

Adverse Effects

Several adverse effects result from mannitol use. They are related mostly to the fluid changes induced by its use. Problems with volume overload or volume depletion are both possible. When very high doses of mannitol are given or if the kidney is not able to excrete the mannitol, fluid volume expansion occurs. Sodium levels are diluted by the excessive fluid volume, so hyponatremia is possible. The most serious adverse effect is acute CHF or pulmonary edema in susceptible patients, resulting from the sudden expansion of the extracellular fluid.

Fluid and electrolyte alterations may occur suddenly with the rapid expansion of extracellular fluid. Therefore, monitor for possible water intoxication and advise the patient to report chest pain or shortness of breath. These symptoms may occur when fluid or electrolyte losses induce hypotension or tachycardia.

Volume depletion, resulting mostly from free water loss, can result in hypernatremia when significant diuresis occurs from mannitol. The patient may show signs of dehydration. The most common indications of this are CNS related (dizziness) and GI related (nausea, anorexia, dry mouth, and thirst). Overdosage from larger than recommended doses may result in increased loss of electrolytes, particularly sodium, chloride, and potassium. Electrolyte depletions may be severe enough to cause hypotension and cardiac irregularities.

Drug Interactions

Mannitol does not interact with any foods, interfere with any laboratory test results, or create any major drug–drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Initially determine any contraindications to mannitol therapy, including anuria resulting from severe renal disease, pulmonary congestion, impaired cardiac function or CHF, active intracranial bleeding, or severe dehydration. These conditions contraindicate therapy because they may worsen with mannitol, which increases extracellular fluid volume. If urine output does not range between 30 and 50 mL/h after two test doses of mannitol, the drug should not be used.

Assess blood pressure, pulse rate and character, respiratory rate and character, and breath sounds. Other general assessments include checking skin color and edema, hydration status, level of consciousness, reflexes, and muscle strength before and during the mannitol infusion to detect adverse effects.

Life Span and Gender

Assess the patient for pregnancy and breast-feeding. Pregnant patients should only receive mannitol, which is a pregnancy category C drug, if therapy is clearly warranted and the benefits outweigh potential fetal harm. Explain

to breast-feeding patients that mannitol may or may not be secreted in breast milk. It also is important to note the patient's age before administering mannitol. Mannitol's effect on children younger than 12 years remains unknown. Elderly patients are at increased risk for developing dizziness, disorientation, and confusion caused by rapid fluid loss when receiving mannitol.

Environment

Note that mannitol is administered only in an acute-care setting.

Nursing Diagnosis and Outcome

- Risk for Deficient Fluid Volume or excessive fluid volume related to the action of mannitol
  Desired outcome: *The patient's fluid and electrolyte levels will remain within normal limits after the therapeutic effect has been achieved.*

Planning and Intervention

Maximizing Therapeutic Effects

Concentrations of mannitol that exceed 15% have a tendency to crystallize. This crystallizing is a characteristic of the drug because it is a sugar; it is not a sign that the drug is old and should be discarded. Therefore, the drug vial should be warmed to no more than body temperature before administration to eliminate crystals. An in-line filter should be used for the infusion.

Minimizing Adverse Effects

Monitor the patient's hourly urine output. Accuracy is essential; therefore, an indwelling catheter normally is required. It is important to adjust the drug infusion rate to maintain the patient's urine output between 30 and 50 mL/h.

Adequacy of renal function is determined in patients with renal impairment by administering one or two test doses of 0.2 g/kg over 3 to 5 minutes before beginning an infusion. If urine output is less than 30 mL/h after the test doses, mannitol is usually withheld.

Monitor blood pressure, pulse rate, electrocardiographic tracings, intake-to-output ratios, renal function test results, and serum electrolyte levels to monitor for rapid fluid and electrolyte alterations. It is important to assess for water intoxication as evidenced by nausea, chest pain, and shortness of breath. Breath sounds and respiratory rate and character should be assessed regularly to detect complications, such as pulmonary congestion.

Provide mouth care and ice chips for dry mouth or thirst. It also is important to assess for hives, itching, or pain at the IV site, and to provide comfort and corrective measures as needed. It is a good idea to assist patients in rising slowly from bed and provide assistance when they walk if they must get out of bed. Treatment of overdosage includes discontinuing infusion therapy at once and institution of measures to normalize electrolyte levels. Hemodialysis may be needed to eliminate mannitol and reduce serum osmolarity.

Providing Patient and Family Education

- Explain the purpose of mannitol therapy.
- Urge patients to report any difficulty breathing, chest pain, or peripheral swelling (edema).
- Tell patients that blurred vision or a runny nose (if these findings occur) should subside when therapy is discontinued.

Ongoing Assessment and Evaluation

Monitoring is ongoing throughout therapy with mannitol and includes measuring urine output and checking for signs of fluid or electrolyte imbalance. Therapy is effective when urine output increases and intracranial or intraocular pressure is decreased without complications to the patient.

Drugs Closely Related to P Mannitol

Glycerin (Glycerol)

Glycerin is an osmotic agent given orally to reduce intraocular pressure before ophthalmic surgery and during acute glaucoma attacks. It is metabolized and eliminated by the kidneys. Peak reduction of intraocular pressure occurs 1 hour after administration. Duration of action is about 5 hours. Contraindications are similar to those for mannitol and include well-established anuria, severe dehydration, frank or impending acute pulmonary edema, severe cardiac decompensation, and hypersensitivity to any ingredient. Caution should be used if the patient has acute urinary retention, hypervolemia, chronic heart disease, diabetes, or cardiac, renal, or hepatic disease. It can cause adverse reactions similar to those reactions caused by mannitol (e.g., nausea, vomiting, headache, confusion, and disorientation). Serious complications of severe dehydration, cardiac arrhythmias,

MEMORY CHIP

P Mannitol

- Treats acute renal failure, increased intracranial pressure, and increased intraocular pressure
- A sugar that draws water into the vascular space through osmosis. Freely filtered but not reabsorbed; thereby causes diuresis
- Major contraindications: anuria due to severe renal disease, pulmonary edema, and intracranial bleeding
- Most common adverse effects: dizziness and GI problems
- Most serious adverse effects: worsening of CHF; serious imbalances of fluid and electrolytes; and obscure or worsened hypovolemia
- Maximizing therapeutic effects: Warm the drug vial in water before using if crystals are seen, and administer no warmer than body temperature, using an in-line filter.
- Minimizing adverse effects: Give a test dose for patients with marked oliguria or inadequate renal function. If urine output does not increase after two test doses, discontinue use.

and hyperosmolar nonketotic coma are possible and may be fatal. Glycerin is a pregnancy category C drug.

A suppository form (glycerin suppositories, Fleet Babylax, Sani-Sipp) also is available and is used as a hyperosmolar laxative for temporary relief of constipation.

Isosorbide

Isosorbide (Ismotic) also is used to provide short-term reduction of intraocular pressure before and after intraocular surgery and to interrupt acute attacks of glaucoma. Isosorbide causes less risk for nausea and vomiting, and it should be used in place of other osmotics when these adverse effects are undesirable for the patient. Isosorbide has a much longer half-life than mannitol. Like glycerin, it is given only orally. It is a good idea to pour the drug over cracked iced and have the patient sip the drug to improve its taste and acceptance. Contraindications and adverse effects are similar to those of mannitol. Isosorbide is a pregnancy category B drug.

Urea

Urea (Ureaphil), like mannitol, is administered by IV infusion and is used to decrease intracranial pressure (in the control of cerebral edema) and intraocular pressure. An unlabeled use has been to induce abortion. Contraindications are severely impaired renal function, active intracranial bleeding, marked dehydration, and frank liver failure. Urea is a pregnancy category C drug.

No serious adverse effects occur if urea is infused slowly, if renal function is adequate, and if intracranial bleeding is not present. Adverse effects that occur are similar to those effects seen with mannitol and include headache, nausea, vomiting, syncope, and disorientation.

Urea should be mixed with 5% or 10% dextrose solution to prevent the hemolysis produced by pure solutions of urea. Infusions should be slow, because rapid infusion may be associated with hemolysis and a direct effect on the cerebral vasomotor centers, causing increased capillary bleeding. It is important to avoid using veins in lower extremities of older adults because phlebitis and thrombosis of superficial and deep veins may occur. Monitor the infusion site carefully because extravasation may cause mild irritation to tissue necrosis.

CARBONIC ANHYDRASE INHIBITORS

Carbonic anhydrase is an enzyme that plays a role in renal excretion of acid urine and reabsorption of sodium and potassium in the proximal tubule. However, an agent that inhibits carbonic anhydrase promotes the excretion of sodium, potassium, bicarbonate, and water, resulting in an alkaline diuresis. However, carbonic anhydrase inhibitors are not used in the treatment of CHF, hypertension, or CKD. Inhibition of carbonic anhydrase decreases aqueous humor formation and consequently decreases intraocular pressure; this is the primary use of these drugs. Carbonic anhydrase inhibitors include acetazolamide, methazolamide, brinzolamide, and dichlorphenamide (Table 27.1). The prototype carbonic anhydrase inhibitor is acetazolamide (Diamox Sequels).

Nursing Management of the Patient Receiving P Acetazolamide

Core Drug Knowledge

Pharmacotherapeutics

Acetazolamide is used to treat chronic open-angle glaucoma. It also can be used in acute closed-angle glaucoma when delay of surgery is desired to reduce intraocular pressure; as an adjunct in treating edema resulting from CHF or use of drugs; as an adjunct in treating epilepsy; and in preventing and treating acute mountain sickness. It can be administered orally or intravenously.

Pharmacokinetics

Acetazolamide is well absorbed from the GI tract and excreted unchanged by the kidneys.

Pharmacodynamics

Acetazolamide is a nonbacteriostatic sulfonamide that blocks the action of carbonic anhydrase, which is needed for active transport of ions across the proximal tubule. Inhibition of carbonic anhydrase results in decreased hydrogen ion secretion by the tubules and increased sodium, potassium, bicarbonate, and water excretion. Increased excretion of these electrolytes reduces the pH of body fluids. Another effect of carbonic anhydrase inhibition is decreased formation of aqueous humor, which thereby lowers intraocular pressure. It also delays abnormal, paroxysmal excessive discharge from CNS neurons.

Contraindications and Precautions

Contraindications to acetazolamide therapy are hypersensitivity, depressed sodium or potassium serum levels, marked kidney and liver disease or dysfunction, suprarenal gland failure, hyperchloremic acidosis, adrenocortical insufficiency, severe pulmonary obstruction, cirrhosis, and long-term use in chronic noncongestive closed-angle glaucoma.

Acetazolamide should be administered cautiously to patients with adrenocortical insufficiency because patients with this disorder are susceptible to electrolyte imbalances. Acetazolamide is a pregnancy category C drug. It is secreted in breast milk, although dosage received by the infant is minute. However, safety and efficacy in children have not been established.

Adverse Effects

Sulfonamide-type adverse reactions may occur because of cross-sensitivity. Adverse effects are varied. The most common are GI related and include anorexia, nausea, vomiting, and constipation. Symptoms of overdose include drowsiness, anorexia, nausea, vomiting, dizziness, paresthesia, ataxia, tremor, and tinnitus. The electrolyte disturbance most likely to occur from overdosage is hyperchloremic acidosis. Treatment involves inducing vomiting or performing gastric lavage. Hyperchloremic acidosis may respond to bicarbonate administration. Potassium supplements may be required.

Drug Interactions

Acetazolamide interacts with a few other drugs. Because acetazolamide promotes excretion of bicarbonate ions, the patient's urine will become alkaline, which may cause some laboratory test results to be false positive for urinary protein. Table 27.5 lists agents that interact with acetazolamide.

Assessment of Relevant Core Patient Variables

Health Status

Assessment should focus on whether the patient is allergic to acetazolamide or to the chemically similar sulfonamide antibiotics and thiazide diuretics. Investigate any history of chronic closed-angle glaucoma, renal or hepatic disease, respiratory acidosis, and chronic obstructive pulmonary disease.

Review blood tests for electrolyte and fluid disturbances, because the drug should be used cautiously in patients with fluid and electrolyte imbalances, especially hyponatremia, hypokalemia, and hyperchloremic acidosis; hepatic disease; adrenocortical insufficiency; respiratory acidosis; or chronic obstructive pulmonary disease.

Life Span and Gender

Determine the patient's breast-feeding status and age before administering acetazolamide. Safety has not been established for breast-feeding women because safety and efficacy have not been established in children. Elderly patients do not tolerate excessive diuresis and may experience hypotension and orthostatic changes. In these patients, dosage may need to be reduced.

Environment

Note the setting in which acetazolamide may be administered. Acetazolamide may be administered in any environmental setting. However, IV administration is performed only in the hospital.

Nursing Diagnoses and Outcomes

- Risk for Deficient Fluid Volume related to therapeutic action of acetazolamide
  Desired outcome: *The patient will have desired fluid volume changes without experiencing complications from these changes.*
- Risk for Injury related to adverse effects of acetazolamide (blood dyscrasias, metabolic acidosis, paresthesia)
  Desired outcome: *The patient will not suffer injury while taking acetazolamide.*

Planning and Intervention

Maximizing Therapeutic Effects

Use acetazolamide with miotics or mydriatics for complementary effect when treating open-angle glaucoma. The best diuretic effects in CHF and drug-induced edema occur when the drug is given every other day or daily for 2 days, with the third day off. Palatability may be enhanced with honey or other sweet syrup for crushed oral tablets.

Minimizing Adverse Effects

It is important to allow the kidneys to recover and prevent overdosage when acetazolamide is used as a diuretic to reduce edema. If reduction in edema ceases after first dose, do not increase the dose; instead, a day of medication should be skipped. Overdosage can be treated by gastric lavage or by inducing vomiting.

Monitor CBC and platelet counts during therapy; bone marrow suppression is rare but may occur. It also is important to monitor serum potassium levels (especially if severe cirrhosis is present or there is concurrent use of steroids or adrenocorticotropic hormones).

Administer orally or by IV injection; intramuscular administration is painful. Do not add to syrups containing glycerin or alcohol if the drug must be crushed.

Providing Patient and Family Education

- Explain the importance of returning for follow-up blood work to check CBC and electrolyte levels.
- Urge patients to notify the prescriber if sore throat, easy bruising, petechiae, and mucosal ulcerations develop (signs of blood abnormalities).

TABLE 27.5 Agents That Interact with P Acetazolamide

Interactants	Effect and Significance	Nursing Management
cyclosporine	Increased trough levels of cyclosporine; possible nephrotoxicity and neurotoxicity	Monitor for signs of nephrotoxicity and neurotoxicity.
primidone	Decreased concentrations of primidone in blood and urine	Monitor for therapeutic effect.
salicylates	Accumulation and toxicity of acetazolamide, including CNS depression and metabolic acidosis; CAI-induced acidosis may allow increased CNS penetration by salicylates	Monitor for therapeutic effects.
diflunisal	Significant decrease in intraocular pressure; increased adverse effects possible	Monitor for therapeutic response. Monitor for adverse effects.

MEMORY CHIP

P Acetazolamide

- Used primarily in treating chronic, open-angle glaucoma because it prevents formation of aqueous humor and decreases intraocular pressure
- Inhibits hydrogen ion secretion in renal tubule, and therefore increases loss of sodium, potassium, bicarbonate, and water
- Major contraindications: severe renal or hepatic disease
- Most common adverse effects: related to gastrointestinal system
- Most serious (although rare) adverse effect: bone marrow suppression
- **Life span alert: Older adults may have hypotension and orthostatic changes; dosage may need to be reduced.**
- Maximizing therapeutic effects (of CHF diuresis): Give every other day or every 2 days, with the next day off.
- Minimizing adverse effects: Allow kidney to recover, and prevent overdosage when used to reduce edema.
- Most important patient education: Explain the importance of follow-up blood work.

- Tell patients to notify the prescriber if nausea, fatigue, abdominal pain, tinnitus, hyperpnea, and numbness in extremities occur (signs of metabolic acidosis).
- Encourage patients to take acetazolamide with food if GI upset occurs.
- Caution patients to avoid prolonged sunlight exposure.
- Tell patients to use caution when performing activities requiring alertness until effects of the drug are known.

Ongoing Assessment and Evaluation

Throughout acetazolamide therapy, the patient should be alert for unusual vision problems and should maintain the follow-up schedule previously established. Drug therapy and nursing care are considered successful if ocular pressure remains controlled and the patient's fluid and electrolyte values stay within normal ranges.

Drugs Closely Related to P Acetazolamide

The other carbonic anhydrase inhibitors are methazolamide (Neptazane), brinzolamide (Azopt), and dorzolamide (Trusopt Ocumeter). Like acetazolamide, methazolamide is used in the treatment of glaucoma but not as often as the prototype, as it has lesser efficacy. It is sometimes used off-label in the prophylactic treatment of acute mountain sickness. It is administered orally to adults. Brinzolamide and dorzolamide differ from the prototype in that they are ophthalmic drops.

C ANTICHOLINERGIC AGENTS

Anticholinergic drugs affect bladder contraction because receptors for these agents are found in the bladder. When the receptors are blocked, bladder contraction cannot occur, and urinary output decreases. Anticholinergics are used to treat overactive bladder. The prototype is tolterodine (Detrol). Drugs closely related to tolterodine are oxybutynin, darifenacin, solifenacin, trospium, and flavoxate (Table 27.1).

Nursing Management of the Patient Receiving P Tolterodine

Core Drug Knowledge

Pharmacotherapeutics

Tolterodine is used in treating overactive bladder, to help manage the symptoms of urinary frequency, urgency, and urge incontinence. It is administered orally twice a day and is available in regular and extended-release forms.

Pharmacokinetics

Oral absorption of tolterodine is rapid, although the absolute bioavailability can vary a great deal. Maximum steady-state serum levels usually occur within 1 to 2 hours. Tolterodine is a highly protein-bound drug, although its active metabolite is not. Extensive, although variable, first-pass metabolism occurs after an oral dose. Several metabolites are formed, including an active one. This metabolite is formed from oxidation through the P-450 2D6 isoenzyme. Most hepatic metabolism is through P-450 3A4. Excretion of drug and metabolites is in the urine, primarily, and in the stool.

Pharmacodynamics

Tolterodine is a competitive anti-cholinergic. Although cholinergic (specifically the muscarinic) receptors exist in both the bladder and the salivary glands, tolterodine has relative selective preference for the cholinergic receptors in the bladder. Blockade of these cholinergic receptors decreases the ability of the bladder to contract. Tolterodine and its active metabolite do not have affinity for other neurotransmitter receptors or other potential cellular targets, such as the special channels for calcium ions. Tolterodine produces a pronounced effect on the bladder function. It can cause an increase in residual urine and a decrease in detrusor pressure.

Contraindications and Precautions

Tolterodine is contraindicated if the patient has urinary retention, gastric retention, uncontrolled narrow-angle glaucoma, or hypersensitivity to the drug. Patients with renal or hepatic impairment should receive doses that are half of what is normally prescribed. Use cautiously if the patient has bladder outflow obstruction or GI obstructive disorders (e.g., pyloric stenosis), as urinary retention or gastric retention may occur. Tolterodine is a pregnancy category class C drug.

Adverse Effects

The most frequent adverse effect of tolterodine is dry mouth, which is related to the anticholinergic effects from the drug. Headache is another fairly common adverse effect. Other adverse effects that are related to the antimuscarinic (anticholinergic) effects of the drug are constipation, abnormal vision (accommodation abnormalities), urinary retention, and xerophthalmia (conjunctival dryness).

TABLE 27.6 Agents That Interact with P Tolterodine

Interactants	Effect and Significance	Nursing Management
Cytochrome 3A4 inhibitors (erythromycin, clarithromycin, ketoconazole, itraconazole, miconazole)	Inhibition of this metabolic pathway may make hepatic function suboptimal and place the patient at increased risk for adverse effects.	Dosage should be limited to 1 mg/d (half usually prescribed).

Drug Interactions

A few drug interactions are known to occur with tolterodine; most are not clinically important. Fluoxetine, a potent inhibitor of P-450 2D6, interacts with tolterodine and increases unbound tolterodine drug concentrations, but no dosage changes are needed. Drugs that inhibit P-450 3A4 (e.g., macrolide antibiotics such as erythromycin and clarithromycin, and antifungal agents such as ketoconazole, itraconazole, and miconazole) increase levels of tolterodine and require smaller doses. Food increases the bioavailability of tolterodine, although not the levels of active metabolite. Dosage changes are not needed. Interactions that require nursing management are listed in Table 27.6.

Assessment of Relevant Core Patient Variables

Health Status

Assess for urinary retention, bladder outlet obstruction, gastric retention, GI obstructive disorders, renal impairment, hepatic impairment, and uncontrolled narrow-angle glaucoma, which are contraindications or precautions to using the drug.

Life Span and Gender

The safety and efficacy of tolterodine have not been established in children. The drug is in pregnancy category C, meaning that animal studies produced teratogenic effects. If the woman is pregnant or might become pregnant, the drug should be used only if the benefit to the mother is believed to outweigh the potential risk to the infant. It is not known whether tolterodine is excreted in human breast milk; hence, breast-feeding should be avoided.

Although older adults have higher serum levels of tolterodine, adjustments are not needed. However, older adults may have decreased renal function or hepatic impairment and should be checked for these problems. Men and women can achieve equal therapeutic effects from drug therapy.

For men, a combination treatment of tolterodine with tamsulosin (an alpha-1 receptor blocker used in benign prostatic hypertrophy) has been found to provide more benefit than either drug alone in decreasing urinary frequency and incontinence in men with overactive bladder and other lower urinary tract symptoms (Kaplan, Roehrborn, Chancellor, et al., 2008).

Environment

Tolterodine is usually administered in the home environment.

Nursing Diagnosis and Outcomes

- Altered Urinary Elimination related to overactive bladder
  Desired outcome: *Urinary elimination will be normal with tolterodine drug therapy.*
- Risk for Urinary Retention related to adverse effects of tolterodine
  Desired outcome: *Urinary retention will not occur while taking tolterodine.*

Planning and Intervention

Maximizing Therapeutic Effect

Administer the drug on a regular prescribed basis.

Minimizing Adverse Effects

If the patient has renal or hepatic dysfunction, or is receiving drugs that are P-450 3A4 inhibitors, administer a dose of tolterodine that is no more than half of what is commonly administered daily.

Providing Patient and Family Education

- Teach patients and family to be alert for problems with urinary retention, GI retention, or visual changes such as blurred vision, and to report these adverse effects to the prescriber.
- Suggest that patients keep a diary that records the episodes of incontinence and frequency of urination, which may be helpful in determining whether drug therapy is effective.
- Tell patients for whom dry mouth is a problem to suck on hard candies or ice chips to relieve the dryness.

Ongoing Assessment and Evaluation

Treatment with tolterodine is effective if urinary incontinence and frequency are decreased and the patient does not develop serious adverse effects.

MEMORY CHIP

P Tolterodine

- Blocks cholinergic muscarinic receptors in the bladder, decreasing bladder function
- Used to treat overactive bladder, controlling symptoms of urinary frequency, urgency, or urge incontinence
- Major contraindications: urinary retention, gastric retention, and uncontrolled narrow-angle glaucoma
- Most common adverse effects: dry mouth and headache
- Minimizing adverse effects: Decrease the dose if patient has renal or liver disease.
- Most important patient education: Urinary retention, GI retention, or visual changes such as blurred vision may occur and need to be reported.

Drugs Closely Related to Tolterodine

Drugs closely related to tolterodine are oxybutynin (Oxytrol), darifenacin (Enablex), solifenacin (Vesicare), trospium (Sanctura), and flavoxate (Urispas). These drugs have similar actions and indications to tolterodine. Oxybutynin is a transdermal system instead of an oral drug like tolterodine and is a pregnancy category B drug. Darifenacin, solifenacin, and trospium have longer half-lives than tolterodine, so they can be given once daily. Unlike the prototype tolterodine, flavoxate is not used for overactive bladder but is prescribed for symptomatic relief of cystitis, urethritis, prostatitis, urethritis, or urethrocystitis/urethrotrigonitis.

CHAPTER SUMMARY

- Diuretics are used widely to treat conditions in which increased extracellular fluid and edema are problems. Examples include hypertension, CHF, cirrhosis, renal disorders, intracranial pressure, and intraocular pressure.
- Diuretics work along the renal tubule and inhibit sodium and water reabsorption to increase water loss. The degree of diuretic effect depends on the section of the tubule in which the drug works.
- Diuretic drugs affect the excretion and reabsorption of other electrolytes, especially potassium, leading to one of the major adverse effects of diuretic therapy, an electrolyte imbalance.
- Thiazide and loop diuretics are the two classes of diuretics most frequently used.
- To prevent hypokalemia, patients taking non–potassium-sparing diuretics may need to increase their dietary intake of potassium or take supplements. Conversely, patients taking potassium-sparing diuretics are at risk for hyperkalemia and need to avoid excess potassium intake.
- Osmotic diuretics work by increasing the osmotic pressure within the vascular space. They are used primarily in ARF, in increased intracranial pressure, in increased intraocular pressure, and to promote excretion in the urine of toxic substances.
- Carbonic anhydrase inhibitors work by a different mechanism to cause a mild diuresis. They are used in treating open-angle glaucoma.
- Tolterodine is an antimuscarinic used to treat overactive bladder disease. Tolterodine selectively blocks muscarinic receptors in the bladder to produce its effects.

QUESTIONS FOR STUDY AND REVIEW

1. Identify the physical assessments for health status that should be completed before a patient starts thiazide therapy for hypertension.
2. Identify at least three conditions treated by diuretic therapy.
3. Discuss at least three fluid and electrolyte problems likely to occur in patients receiving thiazide or loop diuretics.
4. Why is a patient more likely to develop hypokalemia when on loop diuretics than on thiazide diuretics?
5. How are osmotic diuretics different from thiazide or loop diuretics?
6. What is the primary therapeutic use of carbonic anhydrase inhibitors?
7. What is the effect on the bladder from excessive blockade of muscarinic receptors?

Drugs Affecting Lipid Levels

Learning Objectives

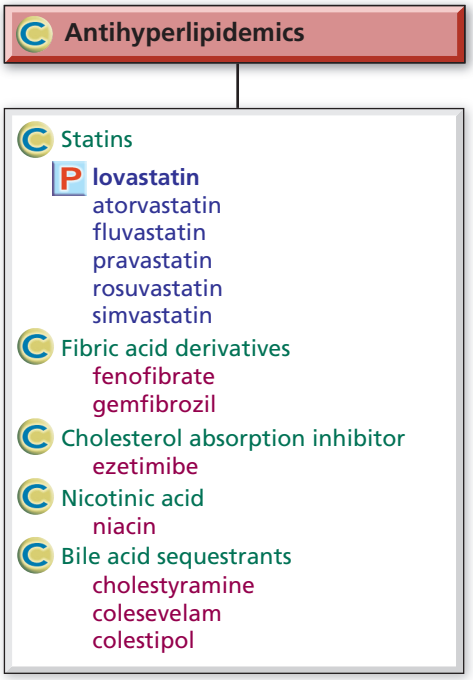
At the completion of this chapter the student will:

1. Identify the core drug knowledge for drugs that affect lipid levels.
2. Differentiate the drug classes that affect lipid levels.
3. Identify core patient variables relevant to drugs that affect lipid levels.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that affect lipid levels.
5. Generate a nursing plan of care from the interaction between core drug knowledge and core patient variables for drugs that affect lipid levels.
6. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect lipid levels.
7. Determine key points for patient and family education for drugs that affect lipid levels.

Key Terms

arteriosclerosis
atherosclerosis
hyperlipidemia
lipids

Drugs Affecting Lipid Levels



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Lipids are fats or fat-like substances that are composed largely of carbon and hydrogen. They are generally insoluble in water. Involved mainly with long-term energy storage, they also function as structural components (as in the case of phospholipids, which are the major building blocks in cell membranes) and as "messengers" (hormones) that play roles in communications within and between cells. However, when serum lipid levels are too high, harmful effects on the body can result. High serum lipid levels are associated with hypertension, coronary artery disease, coronary heart disease, and other cardiovascular disorders. To decrease the risk of morbidity and mortality from lipid-induced pathologies, drug therapy to lower lipid levels is prescribed. This chapter discusses drugs used to lower serum lipid levels. The prototype drug is lovastatin (Mevacor).

PHYSIOLOGY

Serum **lipids** are fats found in the bloodstream. These lipids include cholesterol, cholesterol esters (compounds), phospholipids, and triglycerides. They are transported in the blood as part of large molecules called lipoproteins. The five major families of blood (plasma) lipoproteins are:

Chylomicrons
Very-low-density lipoproteins (VLDLs)
Intermediate-density lipoproteins (IDLs)
Low-density lipoproteins (LDLs)
High-density lipoproteins (HDLs)

Cholesterol is a soft, waxy substance found among the lipids in the bloodstream and in all of the body's cells. The body, mostly in the liver, produces essentially all of the cholesterol needed for normal functioning—about 1,000 mg a day. Cholesterol plays a role in forming cell membranes, some hormones, and other needed tissues. LDL is the major cholesterol carrier in the blood; about two thirds to three quarters of blood cholesterol is carried by LDL. LDL has a structure that can vary, based on its size and density. LDL includes VLDL and IDL. (IDL is considered an abnormal lipoprotein.) Lipoprotein a (Lp[a]) is a type of LDL and is considered a genetic variation. About one third to one fourth of blood cholesterol is carried by HDL. Chylomicrons are the largest and least dense of the lipoproteins. Triglycerides are transported primarily by the chylomicrons and VLDL, a subgroup of LDL.

PATHOPHYSIOLOGY

Hyperlipidemia is an elevation of blood lipid levels. Hyperlipidemia is considered a risk factor for the following disorders: **atherosclerosis** (also called **arteriosclerosis**), a narrowing of the arterial interior caused by buildup of hard, thick deposits, and a hardening and loss of elasticity of the arterial wall; coronary artery disease (CAD); and production of thromboses. How can cholesterol be both beneficial and potentially harmful? The receptors for LDL on the cell surface normally bind LDL circulating through the bloodstream, allowing the LDL and its cholesterol to enter cells and create its beneficial effects. When the amount of cholesterol within cells builds up, the number of these receptors on cell surfaces is reduced, preventing all of the lipids from entering the cells, thus allowing blood levels of LDL to increase. This can lead to more cholesterol being available for deposit in artery walls and the harmful effects.

Patients with narrowed arteries from atherosclerotic cardiovascular disease are more likely to have hypertension because the blood must be pushed harder to get through the narrowed lumen. The narrowness of the vessels increases peripheral resistance. Myocardial infarction (MI) and stroke are likely sequelae from hypertension and atherosclerosis, which contribute to morbidity and mortality. (See Chapter 26 for a complete discussion of hypertension and its treatments.)

Blood work to evaluate lipid levels should include a total cholesterol level, an LDL level, and an HDL level. Sometimes, the ratio of HDL to LDL is also given (Box 28.1). Non-HDL cholesterol, the difference between the total cholesterol and HDL cholesterol, is often measured and reported. It has been suggested that non-HDL cholesterol is a better tool for determining the patient's risk of cardiovascular problems than simply LDL cholesterol.

A high level of LDL cholesterol (more than 130 mg/dL) reflects an increased risk of heart disease, which is why LDL cholesterol is often called "bad" cholesterol. Lower levels of LDL cholesterol reflect a lower risk of heart disease. A high level of Lp(a) is an important risk factor for developing atherosclerosis prematurely. The way an increased Lp(a) level contributes to disease is not understood. The lesions in artery walls contain substances that may interact with Lp(a), leading to the buildup of lipids in atherosclerotic plaques.

Box28.1 INTERPRETING BLOOD LIPID LEVELS

Total Cholesterol

- Less than 200 mg/dL: desirable blood cholesterol level
- 200 to 239 mg/dL: borderline-high blood cholesterol level
- 240 mg/dL and over: high blood cholesterol level

High-Density Lipoprotein (HDL) Cholesterol

- 40 to 59 mg/dL: desired HDL level
- Less than 35 mg/dL: low HDL level

Low-Density Lipoprotein (LDL) Cholesterol

- Less than 100 mg/dL: optimum desired LDL level
- Less than 70 mg/dL: reasonable goal if patient already has coronary or other atherosclerotic vascular disease
- More than 130 mg/dL: elevated LDL level

Non-HDL Concentration (recommended as second target of therapy if triglycerides greater than or equal to 200 mg/dL)

- Less than 130 mg/dL: desired goal

Medical experts think HDL tends to carry cholesterol away from the arteries and back to the liver, where it is passed from the body. Some experts believe HDL removes excess cholesterol from atherosclerotic plaques and thus slows their growth. HDL cholesterol is known as "good" cholesterol because a high level of HDL seems to protect against heart attack. The opposite is also true: a low HDL level (less than 35 mg/dL) indicates a greater risk of heart disease.

In most patients with cardiovascular disease, the underlying disorder is atherosclerosis, for which LDL is known to be a major risk factor. Elevated lipid levels are also a risk factor for CAD included in a group of atherosclerotic risk factors, known collectively as metabolic syndrome. The other risk factors include insulin resistance, obesity, and hypertension. Approximately 34% of American adults have metabolic syndrome. As age increases, it is more likely that the person will have metabolic syndrome, as men and women ages 40 to 59 years of age are about three times as likely as those 20 to 39 years of age to have metabolic syndrome, while men 60 years of age and over are more than four times as likely and women 60 years of age and over are more than six times as likely as the youngest age group to have metabolic syndrome. (Ervine, National Health statistics Reports, 2009). It is more difficult to describe the state of the problem in children and adolescents. At this time, there are limited studies examining how these risk factors (elevated lipid levels, insulin resistance, obesity, and hypertension) in children may relate to adult cardiovascular disease. A further complications is the fact that "there is still no universally accepted definition of metabolic syndrome in children and adolescents, the criteria used in pediatric studies have been variably adapted from adult standards with the use of gender- and age-dependent normal values" (AHA scientific statement, 2009). Despite the lack of a research-based definition, there is agreement that known adult cardiovascular-metabolic risk factors should be assessed in youth, and that early detection and preventive measures for these risk factors in children and adolescents is important. The current state of the science encourages assessing children and adolescents for these risk factors for metabolic syndrome: obesity, inflammation, insulin resistance, dyslipidemia, and hypertension, as long term in adulthood these increase morbidity. The best recommendation at the present time for the treatment of children with these cardiovascular-metabolic risk factors is to reduce obesity, encourage an increase in physical activity, and to treat the various components of the metabolic syndrome (e.g., hypertension or hyperlipidemia; AHA scientific statement, 2009).

Data from epidemiologic studies and from clinical trials have shown that lowering cholesterol levels is associated with a lower overall risk for morbidity and mortality because of coronary heart disease. Additionally, aggressive reduction of cholesterol can yield more clinical benefits than can be achieved with less aggressive therapy even after acute coronary syndrome (Murphy, Cannon, Wiviott, et al., 2007; Wiviott, de Lemos, Cannon, et al., 2006; Grundy, Cleeman, Bairey Merz, et al., 2004). Left ventricular mass is also a powerful predictor for future cardiovascular events; hyperlipidemia is associated with higher left ventricular mass. The healthy endothelium usually provides an anticoagulant, vasodilatory, and anti-inflammatory array of functions, which are basic to vascular homeostasis. Dysfunction of the endothelium is a common pathologic feature evident in all phases of atherosclerosis. Hypercholesterolemia (elevated LDL levels) provokes many aspects of endothelial dysfunction, both before and during the thickening of the walls of the larger arteries in atherosclerosis.

Guidelines from the Third Report of the National Cholesterol Education Program (NCEP), Adult Treatment Panel (ATP III) (Grundy et al., 2004) (NOTE TO EDITOR: the fourth report is due out summer 2010) recommend that total cholesterol levels be less than 200 mg/dL; LDL cholesterol levels optimally should be less than 100 mg/dL, and HDL levels should be between 40 and 59 mg/dL. The recommended LDL levels have been shifted downward considerably from previous recommendations, as studies continue to show that lower LDL levels decrease risk of coronary heart disease (CHD). Many Americans have cholesterol levels that greatly exceed these recommendations. About 17% of adult Americans aged 20 years and older have high total cholesterol (240 mg/dL or above). The average blood cholesterol level in adult Americans is about 203 mg/dL (CDC website). Put another way, over 106 million American adults (age 20 and older) have total blood cholesterol values of 200 mg/dL and higher, and about 37 million American adults have levels of 240 or higher. Elevations of LDL cholesterol (130mg/dL or higher), the "bad" cholesterol, occurs in about 30% to 40% of the populations, with variations by sex and race. The highest occurrence is in Mexican-American men (39%) and the lowest is in black women (29.8%; American Heart Association cholesterol statistics, 2008). Unfortunately, several studies and literature analyses have shown that practitioners undertreat elevated cholesterol levels, either by not prescribing drug therapy or by not prescribing a dose high enough to aggressively and effectively bring the total cholesterol and LDL levels down to recommended levels. In these studies, only 6% to 38% of patients had their lipid levels lowered to the level recommended in current clinical guidelines (Smith, Allen, Blair, et al., 2006).

Triglyceride levels have also been shown to be an independent risk factor for CHD. It has been hypothesized that triglyceride-rich lipoproteins move into macrophages in the bloodstream and then interact with small, dense LDL and HDL particles to form arterial thromboses. However, so far, clinical studies have not been able to demonstrate that lowering triglycerides alone will decrease the rate of MIs. The effect of lowering triglyceride levels may therefore be linked to lowering cholesterol, or to some other, unknown, process.

Patients who have combined hyperlipidemia (elevation of more than one lipid) exhibit a set lipid profile; it is hypothesized that such patients have an atherogenic lipoprotein phenotype. This phenotype is associated with elevated triglyceride levels, low levels of HDL, and a preponderance of small, dense, atherogenic LDL particles. These patients

are at an increased risk of CHD, regardless of their total LDL. Research suggests that when plasma triglycerides exceed a critical level, approximately 133 mg/dL, the formation of small, dense LDL from larger, less dense LDL particles is more likely to occur. Lipid-lowering drugs that are also capable of lowering triglyceride levels below this critical level thus cause a shift to a less dense, and therefore less atherogenic, LDL profile.

Patients with diabetes are considered to be at high risk from elevated lipid levels because a link has been established between elevated cholesterol levels and diabetic nephropathy. High serum cholesterol levels seem to have the same effect on glomerular mesangial cells as on the endothelial cells in the vasculature. Thus, an atherosclerotic-like process appears to occur in the cells of the kidneys because the mesangial cells possess binding sites for LDL and oxidized LDL. Cholesterol lowering has been shown to have a beneficial effect on renal function in patients with diabetes.

Lifestyle and Reduction of Low-Density Lipoprotein Levels

The NCEP ATP III recommends a multipronged approach in reducing LDL levels. They title this approach *therapeutic lifestyle changes*. These lifestyle changes include reduced intake of saturated fats, trans fats, and cholesterol; minimum intake of fatty acids; weight reduction; increased physical activity; increased intake of soluble fiber; and possibly increased intake of plant stanols and sterols (Table 28.1). Drug therapy is added if lipid levels are substantially elevated, if the patient has major risk factors for CHD even if lipid levels are not elevated (Box 28.2), or if the patient has been diagnosed with CHD. Please consult online for updates, to be published as NCEP ATP IV.

TABLE 28.1 Daily Recommendations in Therapeutic Lifestyle Changes Die

Food Element	Recommended Daily Intake
Saturated fat	Less than 7% of total calories
Trans fatty acids	No percentage established; should be kept low
Polyunsaturated fat	Up to 10% of total calories
Monounsaturated fat	Up to 20% of total calories
Cholesterol	Less than 200 mg
Carbohydrate (predominantly complex sources including whole grains, fruit, and vegetables)	50%–60% of total calories
Fiber	20–39 g
Protein	Approximately 15% of total calories
Total calories	Balance intake with expenditure to maintain desirable body weight and prevent weight gain

From: Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). (2004). Executive Summary [O nline]. Available: *http://www.nhlbi.nih.gov/ guidelines/cholesterol/atp3xsum.pdf.*

Box 28.2 CORONARY HEART DISEASE (CHD) EQUIVALENTS AND MAJOR RISK FACTORS FOR CHD

CHD equivalents are those risk factors that place the patient at similar risk for CHD events as a history of actual CHD.

- Diabetes mellitus
- Symptoms of carotid artery disease
- Peripheral arterial disease
- Abdominal aortic aneurysm
- Multiple risk factors (listed below)

Major CHD risk factors increase the risk of CHD. When two or more of them are present in a patient without CHD or CHD equivalent, they should be treated as if they have diagnosed CHD.

- Cigarette smoking
- Hypertension (blood pressure greater than 140/90 mm Hg or use of antihypertensive medication)
- Low HDL cholesterol (<40 mg/dL)
- Family history of premature CHD
- Age (men = 45 years, women = 55 years)

Although other risk factors for CHD have been suggested, there is no evidence from controlled trials that targeting these risk factors will improve patient outcomes. Thus, their presence does not influence current guidelines for cholesterol lowering. These other possible risk factors include obesity; physical inactivity; impaired fasting glucose; markers for inflammation, homocysteine, and abnormalities of thrombosis; and endothelial dysfunction.

ANTIHYPERLIPIDEMICS

Lowering serum lipid levels decreases the risk of atherosclerosis, hypertension, and CHD. Lowering cholesterol levels can stop or reverse atherosclerosis in all vascular beds. Each 10% reduction in cholesterol levels is associated with a reduction of approximately 20% to 30% in the incidence of CHD. Because most cholesterol is carried by the LDL and VLDL, it is important to target these lipoproteins, especially in drug therapy. The antihyperlipidemics are composed of the statins (also referred to as 3-hydroxy-3-methyl-glutaryl coenzyme A [HMG-CoA] reductase inhibitors), the fibric acid derivatives, cholesterol absorption inhibitors, nicotinic acid, the bile acid sequestrants, and dextrothyroxine sodium. Although these types of antihyperlipidemics work in slightly different ways, they all decrease cholesterol levels; most decrease triglyceride levels, most decrease LDL and VLDL levels, and most also increase HDL levels.

Statins

Statins lower blood cholesterol levels and thus decrease the uptake of modified lipoproteins by vascular cells. Statin therapy can lower LDL cholesterol by approximately 20% to 55% when given at the maximum recommended dose. Statins

also raise HDL levels between 5% and 15% and lower triglycerides between 7% and 30%. (ATP III, 2004). In addition, evidence exists that statins work in other ways besides lowering cholesterol levels to decrease the occurrence of cardiovascular events. The drugs appear to have a positive effect on the vascular endothelium, by restoring it or improving its function. Statins seem to exert this effect by increasing the bioavailability of nitric oxide, which promotes vasodilation, promoting re-endothelialization, reducing oxidative stress (antioxidant effect), and inhibiting the inflammatory response (levels of C-reactive protein, an inflammatory marker, fall with statin therapy). Statins are also known to stabilize plaque in blood vessels (ruptured plaque is a central component of acute coronary syndrome) and to decrease thrombogenicity of blood (i.e., the likelihood that blood clots).

Statins are the only class of antilipid drugs identified in clinical trials to decrease overall mortality in both primary (before the patient has clinical evidence of CAD) and secondary (established CAD) prevention. Statins have also been found to decrease the risk of stroke in both primary and secondary prevention studies. Long-term statin use has been found to decrease mortality by 24% to 42% in patients with CAD. They provide additional effectiveness when used jointly with other therapies for heart disease, such as angiotensin converting enzyme inhibitors (ACE inhibitors), angiotensin receptor blockers (ARBs), and beta blockers. Unfortunately, many patients are not prescribed statins as often as recommended. (See Focus on Research Box 28.3: Statins Are Underprescribed.) The Heart Protection Study showed statin therapy to be effective in preventing CAD in patients at high risk (those with cerebrovascular disease, peripheral arterial disease, or diabetes), even if their blood lipid levels were not elevated when therapy began. In fact, this study suggests that the target level of less than 100 mg/dL, recommended by the Third Report of the NCEP Expert Panel, should be even lower (i.e., below 70 mg/dL), and that continued benefit may be derived from decreasing lipids to such levels. Those with acute coronary syndrome or at very high risk for CHD events may benefit the most from intensive lipid-lowering therapy. Two large-scale clinical trials, the Aggrastat to Zocor (A to Z) trial and the Pravastatin or Atorvastatin Evaluation and Infection Therapy-Thrombolysis in Myocardial Infarction 22 (PROVE-IT-TIMI 22) trials, found that continued intensive therapy with statins to lower lipids significantly decreased mortality in patients after an MI (Murphy, Cannon, Wiviott, et al., 2007; Wiviott, de Lemos, Cannon, et al., 2006). Older adults, as well as middle-aged adults, benefit from aggressive statin use in hypercholesterolemia. Thus, aggressive use of statin therapy has been found to be effective in primary and secondary prevention of a variety of cardiac complications.

Not all researchers agree, however, with the conclusion that an LDL level below 70 mg/dL is likely to bring additional cardiovascular benefits (Hayward, Hofer, & Vijan, 2006). Patients may need large doses of a statin to decrease their LDL to this level. However, high doses of statins carry an increased risk of adverse effects. Therefore, a more moderate dosing approach is suggested by some experts as prudent for patients who do not have very high cardiovascular risks; the dose should be the lowest possible that can achieve an LDL below 100 mg/dL . Whether the absolute value of the LDL or the percentage that the LDL has been decreased is the best indication of potential benefit from statin therapy is still the subject of debate.

Because of the anti-inflammatory effects of statins, further research indicates that statins can decrease morbidity and mortality associated with peripheral arterial disease (Hankey, Norman, & Eikelboom, 2006). They may play a role in the treatment of rheumatoid arthritis, multiple sclerosis, other neuroinflammatory disorders, and chronic renal disease (Weber and Zamvil, 2009; Shaw, Fildes, Yonan, et al., 2009; Steffens & Mach, 2006). More research is needed on the potential future uses of statins.

Although all the statins are considered to act similarly, some pharmacologic differences exist among them. The most notable difference is metabolism by the P-450 3A4 isoenzyme. All of the statins, with the exception of pravastatin and fluvastatin, are primarily metabolized by this pathway. Coadministration of drugs that inhibit this pathway will therefore decrease the metabolism of these statins and increase their circulating blood levels. This increase may contribute to adverse effects, especially myalgia (muscle aches or weakness without creatine kinase [CK] elevations), myositis (muscle symptoms with elevated CK levels), and rhabdomyolysis (a potentially lethal event with muscle symptoms with high CK levels and creatinine elevations). Individual, innate differences in the amount of P-450 3A4 isoenzyme available are also a factor in the metabolism of these statins. These differences can account for why some patients can tolerate a particular dose of a statin, or tolerate a statin in combination with an inhibitor of P-450 3A4 without complications, whereas others cannot. There is no way to predict inherited variability to increases in drug concentration from drug–drug interactions. Thus, patients need to be assessed for individual response to therapy. Certain fibric acid derivatives (also called fibrates), another drug class used to alter lipid levels, which may be combined with statins, have been found to have their own independent adverse effect of myopathy. When combined with some statins, but again not with pravastatin, elevations of statin levels may occur in some individuals, increasing the risk of myopathies.

Because so much research has shown the superior effectiveness of the statins, they are the most used antihyperlipidemic agents. When a patient follows a low-fat diet, the benefits of statin therapy are greater than those achieved by drug therapy alone. Unfortunately, multiple research studies show that statins continue to be underutilized (Smith, Allen, Blair, et al., 2006), and patients are not being treated to achieve the levels recommended in clinical guidelines (see Box 28.3).

Lovastatin (Mevacor) is the prototype statin discussed in this chapter. The other classes of antihyperlipidemic drugs will be discussed as drugs significantly different from lovastatin. Table 28.2 displays a summary of selected antihyperlipidemics.

BOX 28.3 FOCUS ON RESEARCH

Statins Are Underprescribed

Lee, H. Y., Cooke, C. E., Robertson, T. A. (2008). Use of secondary prevention drug therapy in patients with acute coronary syndrome after hospital discharge. *Journal of managed care pharmacy,* 14(3):271–280.
Kristianson, K., Fyhrquist, F., Devereux, R. B., et al. (2003). An analysis of cholesterol control and statin use in the Losartan Intervention for Endpoint Reduction in Hypertension Study. *Clinical Therapeutics,* 25(4):1186–1199.

The Study

With the onset of a acute coronary syndrome (ACS, which includes unstable angina, non-Q-wave myocardial infarction, and Q-wave-myocardial infarction), clinical guidelines call for the use of an angiotensin converting enzyme (ACE) inhibitor (or an angiotensin receptor blocker, ARB), a beta blocker, and a statin as combination therapy to decrease the risk of complications and death from the acute coronary syndrome. Research was conducted over a 1-year period on patients from a Mid-Atlantic managed care insurance group with a prescription benefit; the selected patients had been hospitalized with a diagnosis of ACS. The purpose of the study was to determine whether patients were receiving the evidence-based drug therapy for their ACS.

Of the 1,135 members with ACS, less than one-third (only 29.9%) of them filled at least one prescription for all three drugs while a little more than half filled at least 1 prescription for 1 or more of the three drugs in the 3-month period after their hospitalization for ACS. Patients who were between the ages of 45 to 64 years were the most likely to receive statins, compared to other age groups ($p < 0.05$). Women were less likely than men to receive statins ($p = 0.004$) and all 3 drug classes ($p = 0.012$). The severity of their illness played a significant role in whether they received the evidence-based drug therapy, as patients with intermediate coronary syndrome were significantly less likely than those with acute MI to receive any of the recommended drugs ($p < 0.001$). Patients who received the recommended drug therapy before hospitalization for ACS were more likely to receive these drugs again after hospitalization, compared to those who did not receive these drugs pre-hospitalization.

What is especially distressing about this study is that the findings are nearly identical to the findings on statin use in a previous, large, multicenter research study, the Losartan Intervention for Endpoint Reduction in Hypertension Study, published in 2003, that was conducted with 9,193 patients aged 55 to 80 years with hypertension and left ventricular hypertrophy. The use of statin therapy was left to the discretion of the cardiologist who was the investigator at each trial center location. After the primary study on losartan use was completed, a secondary study examined the baseline and the end-of-study mean total cholesterol and high-density lipoprotein cholesterol levels and the use of statins.. At the end of the study, only approximately 22% of the patients had been started on statin therapy, and almost 60% of these patients still had cholesterol levels above guideline recommendations. Of those not receiving statins by the end of the study, nearly 79% had cholesterol levels in excess of those recommended. In this large study, statins were not optimally administered, and cholesterol levels were poorly controlled.

Nursing Implications

Elevated cholesterol levels have been known for some time to be a risk factor for cardiovascular events in patients. It has also been known for some time that lipid levels are undertreated, even with effective drug therapy available. Although in the 5 years between the reporting of these 2 studies there was a slight increase in the prescribed use of statins, statins are still under-prescribed despite clinical guidelines that show they are evidence-based care for patients with ACS. Although it is possible that patients were not filling the prescriptions given to them by their health care provider, the results of these studies lead additional credence to the belief that even cardiologists, who work with patients known to have high cholesterol and high-risk factors for cardiovascular events, tend to undertreat patients. Clearly more aggressive therapy is warranted to help reduce morbidity and mortality from elevated lipid levels. Additionally, this newer research confirms that there is some prescribing bias for statin use, where women and older adults are less likely to receive statin therapy even when it would be clinically useful. Exactly why this occurs is not known.

So why are the clinical guidelines regarding statin use not being followed, and what can nurses do to help patients with elevated cholesterol levels? First, nurses need to be knowledgeable about current guidelines for lipid management. Nurse practitioners should aggressively treat lipid levels in their patients with elevated lipid profiles by prescribing statin therapy and making sure that the prescribed drug and dose effectively lower lipid levels. Nurses who do not prescribe drug therapy should monitor patients' lipid levels carefully and consult with either the physician or nurse practitioner when the levels are above guideline recommendations and indicate that drug therapy is warranted. Nurses should pay special attention to female patients and older adult patients, as these patients appear less likely to receive evidence-based drug therapy with statins than other groups of patients. Nurses in a hospital setting may also participate in hospital-wide, multidisciplinary committees or quality-improvement projects that are charged with setting drug protocols and standards to ensure that the institution is following the current clinical guidelines. To help minimize the risk that prescriptions are being written but not filled by patients, nurses in all practice settings need to be active in patient education to help patients and their families understand the importance of reducing blood cholesterol and lipid levels and the role that drug therapy can play in achieving this goal. Additionally, nurses should include diet modification information and stress the importance of exercise in their patient teaching about reducing blood lipid levels.

Nursing Management of the Patient Receiving P Lovastatin

Core Drug Knowledge

Pharmacotherapeutics

Lovastatin is used in the treatment of primary hypercholesterolemia and combined hyperlipidemia (also referred to as mixed dyslipidemia). It is also used in the secondary prevention of coronary events (e.g., MI, stroke) from thrombus formation.

Off-label uses of lovastatin include the treatment of diabetic dyslipidemia, nephrotic hyperlipidemia, neck artery disease, familial dysbetalipoproteinemia (alterations of the beta or LDL lipoproteins in the blood), and familial combined hyperlipidemia.

Lovastatin is available in both rapid-release and extended-release forms. Unlike the other statins, it is now available as both a trade name and a generic drug.

TABLE 28.2 Summary of Selected C Antihyperlipidemics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Statins			
P lovastatin (Mevacor	Reduce serum cholesterol levels	*Adult:* PO, 20–80 mg/d in single or divided dose	*Onset:* 1–2 wk *Duration:* Length of therapy $t_{1/2}$: 3–4 h
simvastatin (Zocor)	Reduce serum cholesterol and triglyceride levels	*Adult:* PO, 5–40 mg/d as single dose in the evening	*Onset:* 1–2 wk *Duration:* Length of therapy $t_{1/2}$: 3 h
pravastatin (Pravachol)	Reduce serum cholesterol and triglyceride levels	*Adult:* PO, 10–40 mg/d at bedtime	*Onset:* 1–2 wk *Duration:* Length of therapy $t_{1/2}$: 1.8 h
fluvastatin (Lescol)	Reduce serum cholesterol and triglyceride levels	*Adult:* PO, 20–80 mg/d single dose in the evening	*Onset:* 1–2 wk *Duration:* Length of therapy $t_{1/2}$: 1.2 h
Other Antihyperlipidemics			
cholestyramine (Questran)	Lower serum cholesterol levels	*Adult:* PO, powder, 4 g, one to two times daily, mixed in 60–180 mL of water or noncarbonated drink	*Onset:* Unabsorbed *Duration:* 1 mo after therapy concludes $t_{1/2}$: Unknown
colestipol (Colestid)	Lower serum cholesterol levels	*Adult:* PO, granules, 5–30 g/d mixed in about 90 mL of liquid; tablets, 2–16 g/d; may be divided	*Onset:* Unabsorbed *Duration:* Same as above $t_{1/2}$: Unknown
clofibrate (Atromid-S)	Reduce serum cholesterol and triglyceride levels	*Adult:* PO, 2 g/d in divided doses	*Onset:* Unknown *Duration:* Length of therapy $t_{1/2}$: 15 h (up to 110 h in renal impaired)
nicotinic acid (niacin, vitamin B_3)	Reduce serum cholesterol and triglyceride levels	*Adult:* PO, 1–2 g tid with meals; maximum 8 g/d; dietary supplement, 100–500 mg/d	*Onset:* Up to several days *Duration:* Length of therapy $t_{1/2}$: Unknown
gemfibrozil (Lopid)	Reduce serum cholesterol and triglyceride levels	*Adult:* PO, 1,200 mg/d in two divided doses, 30 min before meals	*Onset:* Unknown *Duration:* Length of therapy $t_{1/2}$: 1.5 h (plasma)

Pharmacokinetics

Although about 35% of the drug is absorbed, lovastatin has a high first-pass effect because metabolism by the isoenzyme CYP3A4 (an important subset of the CYP-450 family) allows less than 5% of the oral dose to reach the general circulation. An active metabolite, lovastatin acid, is formed from metabolism. The drug is highly protein bound (more than 95%). It is excreted primarily through the gastrointestinal (GI) tract in the feces, but about 10% is eliminated in the urine. Severe renal disease increases plasma concentration of lovastatin. Immediate-release forms are best absorbed after a meal. In contrast, extended-release forms have their absorption impaired by food.

Pharmacodynamics

Lovastatin, as well as the other statins, competitively inhibits its HMG-CoA reductase, which is the enzyme that catalyzes the early rate-limiting step in cholesterol biosynthesis. The effect is to increase HDL and to decrease LDL, total cholesterol, VLDL, and plasma triglycerides. The mechanism that lowers LDL may involve both reduction of VLDL concentrations and increased catabolism of LDL. In clinical trials, lovastatin reduced total cholesterol between 16% and 29%, decreased LDL levels between 21% and 40%, decreased triglyceride levels between 6% and 30%, and increased levels of HDL between 2% and 9.5%.

This drug, as well as the others in the class, is highly effective in reducing total cholesterol and the LDL level in heterozygous familial and nonfamilial forms of hypercholesterolemia. The lipid lowering that occurs with the statins, such as lovastatin, is known to reduce the progression of atherosclerosis, reduce blood thrombogenicity, prevent MI and stroke, and prolong survival in patients with atherosclerosis.

Contraindications and Precautions

Contraindications include active liver disease, unexplained persistently elevated results of liver function

tests, pregnancy (lovastatin is pregnancy category X), and breast-feeding. Heavy alcohol use increases the risk of liver dysfunction. Precaution should be used if lovastatin is coadministered with drugs that inhibit the CYP3A4 hepatic pathway (such as erythromycin or protease inhibitors), with large intake (more than 1 quart daily) of grapefruit juice, or with drugs that also can produce myopathy, such as fibric acid derivatives. Older adults, especially if they have other complicated co-morbidities, are more at risk of myopathy or rhabdomyolosis and thus should be monitored closely if they receive lovastatin. High-dose therapy of lovastatin is also associated with more risk for myopathy and rhabdomyolysis (see discussion below under Adverse Effects).

Precaution should be used if the patient has preexisiting amyotrophic lateral sclerosis (ALS), as the rate of functional decline that occurs with ALS may accelerate if given statins. Caution is needed if the patient has a history of renal insufficiency, as there can be an increased risk of rhabdomyolysis, especially in larger doses. Patients who must stop taking lovastatin due to needing surgery or hospitalization for a major medical condition may be at increased risk of developing rhabdomyolysis and should be monitored closely. Finally, patients who have homozygous familial hypercholesterolemia are at risk for reduced efficacy of lovastatin and an increased risk of elevated liver enzymes.

Adverse Effects

Adverse effects of lovastatin are usually mild and transient; the drug is generally well tolerated. A fairly common complaint with all statins, including lovastatin, is nonspecific muscle aches or joint aches, weakness, and/or cramps (myalgias), which are not associated with any signs of muscle damage. Usually this adverse effect is tolerable, but occasionally it is bothersome enough that the drug needs to be discontinued.

One adverse effect with potentially serious consequences is muscle damage, the exact cause of which is not known. The most serious skeletal muscle effect that may result from lovastatin is rhabdomyolysis, although it is very rare (occurring in 0.1% of patients on statins as monotherapy). Rhabdomyolysis is an acute, sometimes fatal disease, in which direct injury to the plasma membrane of the skeletal muscle occurs (manifested by increased levels of CK, also known as creatine phosphokinase [CPK]). The damage to the muscle causes leakage of the skeletal muscle components (myoglobin) into the blood or the urine. Brown urine usually occurs. Rhabdomyolysis can lead to acute renal failure and death. Diagnosis of rhabdomyolysis is made when the CK (1) is greater than 10,000 U/L regardless of whether there is any change in renal function or (2) is greater than 10 times the upper normal limit with worsening renal function and/or a medical requirement for intravenous hydration therapy. The risk of renal failure from rhabdomyolysis is increased if the patient is also taking drugs that share the same common metabolic path, such as cyclosporine or nicotinic acid.

Less serious muscle damage can also occur from statin therapy, and this is called myopathy. Myopathy should be considered in any patient who receives lovastatin and who shows diffuse myalgia, muscle tenderness or weakness, *and* has CK levels 10 times above the upper limit of normal. According to some sources, CK laboratory tests greater than 10 times the upper limit of normal should be repeated to confirm them prior to making a final diagnosis. The rate of serious myopathy appears to be equivalent among all the statins. Elevations of CK are believed to be dose dependent. If the myopathy is intolerable, then statin therapy should be discontinued. Stopping the drug should eliminate the symptoms (McKenney, Davidson, Jacobson, et al., 2006).

Transient, mildly elevated CK levels are common, especially in the first 3 months of therapy. These levels do not indicate a serious problem and should not be confused with myopathy or rhabdomyolysis. Drug therapy does not need to be stopped or modified so long as the patient is asymptomatic.

Lovastatin is likely to produce an elevation in the hepatic enzymes (measured by the laboratory tests alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) to more than three times the upper limit of normal. This may occur fairly frequently and is usually dose related. The exact cause is not known. The increased levels of ALT and AST are usually transient, resolving spontaneously even if the specific statin and its dose are unchanged. Because of this, some sources believe that laboratory studies must indicate high enzyme levels on two consecutive occasions prior to making changes in the drug therapy. About 2% of patients taking lovastatin have marked persistent elevations of liver enzymes. There is still debate whether these greatly elevated liver enzymes can cause serious liver dysfunction or failure. Although some sources show that the rate of reported liver failure is the same whether or not a statin is used, the Food and Drug Administration (FDA) label on lovastatin and other statins states that liver failure is a rare adverse effect of the drug (McKenney, Davidson, Jacobson, et al., 2006).

Adverse effects that can occur but are not considered serious include effects in the central nervous system, such as headache, dizziness, and insomnia. GI complaints include nausea and vomiting, diarrhea, abdominal pain and cramps, constipation, flatulence, heartburn, dyspepsia, and altered taste. Other adverse effects are chest pain, rash, blurred vision, and alopecia. Statins such as lovastatin have not been found to cause renal failure (Kasiske, Wanner, & O'Neill, 2006; McKenney, Davidson, Jacobson, et al., 2006). Rarely, if ever, do the drugs cause peripheral neuropathy (Law & Rudnicka, 2006; McKenney, Davidson, Jacobson, et al., 2006).

Drug Interactions

Because lovastatin is metabolized through the hepatic enzyme CYP3A4, all inhibitors of this pathway have

the potential to interact with the drug, decreasing its metabolism and elevating, sometimes dramatically, its level in the blood. Examples of CYP3A4 inhibitors are itraconazole (an antifungal), erythromycin (an antimicrobial), protease inhibitors (anti-HIV drugs) and grapefruit juice, which has been shown to substantially increase the serum levels of lovastatin and lovastatin acid (the active metabolite). Drugs that compete with lovastatin for metabolism by CYP3A4 also have the potential to interact with lovastatin. Rhabdomyolysis has been reported in heart transplant recipients who were treated with both lovastatin and cyclosporine (an antirejection drug used in the process of organ transplantation that is also metabolized by CYP3A4). Table 28.3 lists drugs that interact with lovastatin.

Food appears to increase drug absorption and elevate blood levels of lovastatin.

Laboratory tests that are altered by lovastatin use include increased serum transaminases AST, ALT, CPK, alkaline phosphatase, bilirubin, and γ-glutamyl transpeptidase, as well as thyroid function test abnormalities.

CRITICAL THINKING SCENARIO

MANAGING ADVERSE EFFECTS OF LOVASTATIN THERAPY

Janice Klinefelter, age 64 years, has been taking the lipid-lowering statin drug lovastatin for 9 months. She has tolerated the drug therapy well and up to this point has had no major adverse effects. Her cholesterol and LDL levels are close to reaching the desired goal. During an office follow-up visit, she complains that she must be getting old because she feels stiff and her leg muscles are cramping and painful, problems she has never complained of before. Her blood work, drawn the day before the office visit, shows that her liver function enzyme levels (AST and ALT) are mildly elevated, and her creatine kinase levels are four times upper normal levels. At baseline, both blood tests were within the normal range. She denies having started any new medication.

1. What questions would you ask Ms. Klinefelter as part of your assessment?
2. What course of action would you choose now?
3. What teaching would you provide to Ms. Klinefelter?

TABLE 28.3 Agents That Interact with P Lovastatin

Interactants	Effect and Significance	Nursing Management
azole antifungals itraconazole ketoconazole	Increases lovastatin levels about 20-fold. May increase risk of adverse effects, including myopathy.	Consult with provider regarding temporarily stopping or reducing the dose of lovastatin while on the antifungal.
bile acid sequestrants	Decreases the bioavailability and effect of lovastatin and other statins.	Give the bile acid sequestrant 4 h after lovastatin.
cyclosporine	Increases circulating levels of lovastatin and increases risk of severe myopathy or rhabdomyolysis.	Consult with provider about stopping lovastatin or decreasing the dose. Monitor closely for adverse effects.
erythromycin	Increases circulating levels of lovastatin and increases risk of severe myopathy or rhabdomyolysis.	Consult with provider about stopping lovastatin or decreasing the dose. Monitor closely for adverse effects.
gemfibrozil	Increases circulating levels of lovastatin; severe myopathy or rhabdomyolysis reported.	Avoid this combination if at all possible.
isradipine	May increase clearance of lovastatin and its metabolites by increasing hepatic blood flow. This decreases the effect of lovastatin.	Increased dose for lovastatin may be needed; consult with provider if patient is not achieving desired cholesterol goals.
nicotinic acid	Increases circulating levels of lovastatin and increases risk of severe myopathy or rhabdomyolysis.	Consult with provider about stopping lovastatin or decreasing the dose. Monitor closely for adverse effects.
digoxin	Elevates digoxin levels slightly.	Monitor digoxin levels. Assess for signs of digoxin toxicity.
Warfarin	Increases prothrombin time. Bleeding has occurred in some patients receiving both drugs.	Monitor for bleeding. Consult with provider regarding adjusting dose of warfarin downward as needed to keep prothrombin time in therapeutic range.
grapefruit juice	Decreases metabolism of lovastatin via CYP3A4, so circulating levels of lovastatin will increase, placing the patient at increased risk of adverse effects.	Monitor for adverse effects. Assess labs for elevated liver enzymes and CPK levels.

Assessment of Relevant Core Patient Variables

Health Status

Before lovastatin therapy begins, the patient's serum cholesterol and lipid levels should be determined and a health history of diseases that contribute to increased blood cholesterol and LDL levels taken. These conditions include hypothyroidism, poorly controlled diabetes mellitus, nephrotic syndrome, dysproteinemia, obstructive liver disease, and alcoholism. These conditions should be investigated and treated before starting lovastatin. Assess for active liver disease because it is a contraindication for taking lovastatin. Also, determine liver function through liver enzyme measurements for baseline knowledge. Lovastatin, as well as other statins, should not be given if the patient has active liver disease or unexplained persistently elevated liver function test results (e.g., liver enzymes greater than three times the upper normal limit) because additional elevation of liver enzyme levels occurs during therapy with lovastatin and all statins. A baseline CK level should be drawn; many patients routinely have asymptomatic CK elevations, and knowing of such elevations at baseline assists in clinical decision making later in therapy.

Be aware that patients who have undergone organ transplantation and who require lifelong multidrug therapy are at increased risk for experiencing drug–drug interactions when also receiving lovastatin. Patients with chronic disease states such as diabetes and hypothyroidism are also at risk.

Determine whether the patient is receiving other drugs that are metabolized by (i.e., are substrates of) CYP3A4 or that inhibit metabolism by CYP3A4, because there may be potential drug interactions when starting lovastatin.

Assess the patient's body frame because a small body frame and frailty pose an increased risk for drug-related myopathy.

Assess for the presence of amyotrophic lateral sclerosis (ALS, also referred to as Lou Gehrig disease), as research has shown that these patients have a 63% increase in the rate of functional decline from their ALS when they take a statin drug.

Life Span and Gender

Determine whether the patient is pregnant or considering becoming pregnant because lovastatin is a pregnancy category X drug. Animal studies have shown skeletal malformations, but no such data exist for humans. However, fetal harm is likely because of the decrease in cholesterol synthesis and possibly other products in the cholesterol biosynthesis pathway. Lovastatin is excreted in breast milk; thus, breast-feeding should be avoided while taking this drug.

Older adults, because they are likely to have more drugs prescribed to them than younger people, are more at risk for drug interactions when receiving lovastatin. Adults older than 80 years, especially women, seem most at risk for statin-associated myopathy. However, information gleaned from clinical trials indicates that older adults benefit from lipid-lowering therapy as much as younger adults; therefore, treatment with lipid-lowering drugs is worthwhile in older adults and is recommended.

Safety and efficacy in patients younger than 18 years have not been determined. Treatment in this age group is not recommended at this time.

Lifestyle, Diet, and Habits

Before starting drug therapy, patients should be treated with nonpharmacologic methods of controlling cholesterol and lipids, including dieting to reduce cholesterol levels and LDL levels, exercising, and normalizing weight if needed. Diet therapy usually continues for 12 weeks before drug therapy starts and should be continued even after drug therapy is started.

Determine whether the patient has alcoholism, which may be a secondary cause of hyperlipidemia. High alcohol use also increases the risk of liver dysfunction. Determine whether the patient regularly drinks grapefruit juice and how much is usually consumed, because grapefruit juice is a major inhibitor of the CYP3A4 isoenzyme necessary for lovastatin metabolism. Patients should not consume more than a quart per day of grapefruit juice, as this amount is likely to produce alterations in metabolism of lovastatin and increase the risk for adverse effects.

Environment

Lovastatin may be started in any environment. Because therapy extends over a prolonged period, the drug is usually taken by the patient at home or in a long-term care facility.

Culture and Inherited Traits

Explore whether the patient observes cultural or religious dietary practices that promote high intake of fats and cholesterol.

Nursing Diagnoses and Outcomes

- Risk for Injury related to elevated blood lipid levels
  Desired outcome: *The patient's blood lipid levels will be controlled without the patient's sustaining an injury.*
- Risk for Injury to skeletal muscles related to adverse effects of drug therapy
  Desired outcome: *The patient will not incur serious skeletal muscle injury while on drug therapy.*
- Risk for Injury to liver function related to adverse effects of drug therapy
  Desired outcome: *The patient will not incur serious liver injury while on drug therapy.*
- Risk for Altered Nutrition: Less than Body Requirements, related to adverse effects of drug therapy
  Desired outcome: *The patient will not have GI adverse effects serious enough to alter meeting the body's nutritional needs.*

Planning and Intervention

Maximizing Therapeutic Effects

Lovastatin is most effective when administered in the evening, possibly because evening is also when most cholesterol synthesis occurs. Immediate-release lovastatin should be administered after the evening meal; extended-release lovastatin is administered at bedtime without food to be most effective. The patient should be advised to continue a cholesterol-reducing diet.

Minimizing Adverse Effects

Liver function test (AST and ALT) results should be monitored before starting therapy. The FDA label for lovastatin supports monitoring these enzymes at 12 weeks after starting therapy or after each dose adjustment, and then yearly or as indicated, but some experts do not believe this is necessary. Fractionated bilirubin may be monitored instead, because this is more likely to indicate significant liver injury (McKenney, Davidson, Jacobson, et al., 2006). Consult with the prescriber about reducing the dose or stopping the drug if the increased liver enzyme levels (more than three times the upper limits of normal) persist and other potential causes of this elevation have been ruled out.

Evaluate the patient carefully for muscle soreness, tenderness, or pain and CK levels before starting therapy. Reassess for muscle symptoms after 6 to 12 weeks of therapy and at each follow-up visit. CK levels may be monitored more frequently and on a regular basis depending on the patient's risk factors for myopathy and physician preference.

Rule out common causes of muscle aches, such as exercise or strenuous work, if the patient is experiencing muscle symptoms. Encourage the patient to avoid strenuous physical activity. Obtain a CK measurement when the patient has unexplained muscle symptoms and compare to baseline levels. If the CK levels are moderately elevated (3 to 10 times the upper limit of normal), continue with drug therapy but follow the patient's symptoms and CK levels weekly until either symptoms disappear or the CK levels return to within normal range. If CK levels reach above 10 times the upper limit of normal and the patient has symptoms, therapy should be stopped. This should eliminate the symptoms. Once the patient is asymptomatic, the same or different statin can be started at the same or a lower dose to test if the symptoms are reproduced. Recurrence of symptoms with multiple statins requires that a different type of antilipid drug be used than a statin (McKenney, Davidson, Jacobson, et al., 2006).

Monitor the older adult who receives polypharmacy carefully for drug interactions with lovastatin. Also, carefully monitor adults older than 80 years, especially women, who have small body frames and are frail, because they are more at risk for myopathies.

Providing Patient and Family Education

Stress the importance of following a low-cholesterol and low-saturated-fat diet while on drug therapy (Box 28.4).

Instruct patients to report any unexplained muscle pain, tenderness, or weakness at once.

Because of the risks of fetal harm, advise female patients to avoid taking lovastatin if they become pregnant.

In some patients taking lovastatin, photosensitivity may occur. Urge all patients to avoid prolonged exposure to sunlight and other ultraviolet light until their response to therapy is known.

Ongoing Assessment and Evaluation

The patient should have liver function tests and CK measurement performed periodically throughout drug therapy with lovastatin. Monitor the results of these tests for elevations. Assess the patient for muscle pain throughout therapy. Blood work that monitors the complete lipid profile should be obtained periodically throughout therapy. Therapy is considered effective when the total cholesterol level is below 200 mg/dL, LDL is lower than 100 mg/dL, and HDL is above 40 mg/dL and the patient has not incurred any serious adverse effects.

BOX 28.4 COMMUNITY BASED CONCERNS

Diet Teaching to Lower Cholesterol Levels

An important role of the nurse is to provide health education. Because heart disease is a leading cause of death in the United States, teaching the benefits of a low- cholesterol diet is an important nursing action—not just for patients with elevated cholesterol levels and their families, but also for the population at large.

Encourage a diet that is low in saturated fats, which would include the following foods:

- Fruits and vegetables
- Whole grains, such as cereal, rice, and pasta
- Lean red meats and poultry (no skin)
- Low-fat or skim milk dairy products
- Lean fish and shellfish
- Beans and peas

Unsaturated oils such as olive oil, corn oil, and safflower oil

Encourage a diet that limits foods that are high in saturated fat and cholesterol. This means avoiding or limiting the following foods:

- High-fat dairy products, such as whole milk, cream, ice cream, butter, and cheese
- Egg yolks
- Saturated oils such as coconut oil, palm oil, and palm kernel oil
- Solid fats such as shortening, soft margarine, and lard
- Organ meats such as liver, sweetbreads, kidneys, and brain
- High-fat processed meats such as hot dogs, sausage, bologna, and salami
- Fatty red meats that have not been trimmed
- Duck and goose meat
- Fried foods

Emphasize that patients should avoid not only highly saturated fats, but also foods that are made with them.

MEMORY CHIP

P Lovastatin

- Used to treat hyperlipidemia. It lowers LDL, triglycerides, and total cholesterol, and raises HDL.
- Major contraindications: active liver disease, unexplained persistently elevated liver function test results, and pregnancy
- Most common adverse effect: elevated liver enzyme levels
- Most serious adverse effects: rhabdomyolysis and myopathy
- **Life span alert: pregnancy category X; avoid lovastatin if the patient is breast-feeding. Older adults are more likely to have drug interactions.**
- Minimizing adverse effects: Monitor liver enzyme levels for at least first year of therapy.
- Most important patient education: Teach patients to continue on a low-fat diet and to report any unexplained muscle pain, tenderness, or weakness at once.

Drugs Closely Related to P Lovastatin

Atorvastatin (Lipitor), fluvastatin (Lescol), pravastatin (Pravachol), rosuvastatin (Crestor), and simvastatin (Zocor), and the newest statin, pitavastatin (Livalo), all work similarly to lower LDL cholesterol and have similar adverse effects. Pravastatin differs from the prototype lovastatin because it is not metabolized via the P-450 system and thus does not produce the drug interactions of lovastatin. Fluvastatin is primarily metabolized via a different isoenzyme pathway, 2D6, so is not as likely to have the same drug interactions. Unlike lovastatin, rosuvastatin does not raise digoxin levels but leads to other similar drug interactions. Asian subjects (including Filipino, Chinese, Japanese, Korean, Vietnamese or Asian-Indian origin) appear to be more sensitive to rosuvastatin; a twofold increase in drug levels can occur, so these patients should be started on the lowest dose possible. Pitavastatin is very similar to lovastatin, except that it is much more potent, requiring a daily dose of 1 to 4 mg as opposed to 10 to 80 mg daily for lovastatin. Pitavastatin carries additional warnings that if the patient has a moderate decrease in renal function, the dose should be decreased, and for severe renal impairment, pitavastatin is not recommended. A higher percentage of pitavastatin is renally eliminated than in lovastatin. See Table 28.4 for a comparison of statins.

Drugs Significantly Different From P Lovastatin

Fibric Acid Derivatives

Like lovastatin and the other statins, the fibric acid derivatives (also known as fibrates) fenofibrate (TriCor, Lipofen, and others) and gemfibrozil (Gemcor, Lopid), work to lower triglyceride levels and increase HDL cholesterol. These drugs can reduce triglyceride levels between 35% and 53%. However, unlike lovastatin and other statins, their effect on LDL cholesterol may be either to lower it between 6% and 20% or raise it slightly. These fibric acid derivatives are available as oral tablets or capsules.

Although in certain patients these drugs may be used alone, most frequently they are used in combination with statins. Some patients, such as those with diabetes or metabolic syndrome, need to lower triglycerides and increase HDL, and a combination of a fibric acid derivative and a statin may be the drug therapy of choice. The combined use of a fibrate and a moderate-dose statin carries a somewhat increased risk of myopathy, but the incidence is low, especially if used in populations without multisystem diseases or currently taking multiple medications. Gemfibrozil may substantially increase the circulating blood levels of some statins, such as lovastatin. Fenofibrate has not been linked as strongly, but the potential exists for a drug interaction with lovastatin or other statins. The fibric acid derivatives have similar common adverse effects: rash; gastrointestinal problems such as diarrhea, flatulence, and nausea and vomiting; and myalgia. These agents are pregnancy category C drugs. Safety and efficacy for children have not been established.

Fenofibrate

Fenofibrate (TriCor) reduces total cholesterol, LDL cholesterol, total triglycerides, and triglyceride-rich lipoprotein (VLDL) in treated patients while it increases HDL. (However, treatment of some patients with hyperlipoproteinemia may result in an increase in LDL cholesterol). Exactly how fenofibrate works has not been clearly established. The metabolite of fenofibrate, fenofibric acid, lowers plasma triglycerides apparently by inhibiting the synthesis of triglycerides, which reduces the amount of VLDL released into the circulation. It also stimulates the catabolism of triglyceride-rich VLDL. Fenofibrate reduces the serum uric acid levels in patients with

TABLE 28.4 Comparison of Statins

Property	Lovastatin	Atorvastatin	Fluvastatin	Pravastatin	Rosuvastatin	Simvastatin
LDL reduction	29%–48%	38%–54%	17%–33%	19%–40%	52%–63%	28%–?
Protein binding	>95%	80%–90%	>99%	43%–55%	88%	95%
P-450 metabolism	3A4	3A4	2C9	None	Limited 2C9	3A4
Approximate monthly wholesale cost (U.S. dollars) based on usual dose	$90 (generic forms $30)	$96	$49	$122	$100	$122

normal and elevated uric acid levels by increasing the urinary excretion of uric acid.

Fenofibrate is well absorbed from the GI tract; food increases absorption. Peak levels occur within 6 to 8 hours. Fenofibrate is highly protein bound (99%). It is rapidly hydrolyzed by esterases to the active metabolite, fenofibric acid, which is primarily conjugated with glucuronic acid and then excreted in the urine. Fenofibrate has a half-life of 20 hours. It is excreted, in the form of its metabolites, in the urine.

Fenofibrate is contraindicated in hepatic or severe renal dysfunction (including primary biliary cirrhosis and patients with unexplained persistent liver function abnormality), preexisting gallbladder disease, and hypersensitivity. Serious adverse effects of fenofibrate are rare and include pancreatitis, hepatotoxicity, and rhabdomyolysis.

Gemfibrozil

Gemfibrozil (Gemcor, Lopid) reduces plasma triglyceride (VLDL) concentrations and increases HDL concentrations. Its effect on LDL is varied; in some patients it may slightly reduce LDL cholesterol concentrations, in others it significantly increases them, and in still others it may have no significant effect. Exactly how gemfibrozil works is not known, but it may inhibit peripheral lipolysis and decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. In addition, the drug may reduce the incorporation of long-chain fatty acids into new triglycerides. It may also increase the turnover and removal of cholesterol from the liver and increase excretion of cholesterol in the feces.

Gemfibrozil is well absorbed from the GI tract. Peak levels occur 1 to 2 hours after administration of the dose. Gemfibrozil is primarily oxidized to hydroxymethyl and a carboxyl metabolite. Excretion is mostly renal.

Contraindications include hepatic or severe renal dysfunction, including primary biliary cirrhosis, preexisting gallbladder disease, or hypersensitivity.

Serious adverse effects of gemfibrozil include abnormal liver function tests and rhabdomyolysis. The drug causes a moderate hyperglycemic effect; special monitoring is necessary for patients with diabetes.

Cholesterol Absorption Inhibitor: Ezetimibe

Ezetimibe (Zetia) is an antilipid drug that is used to treat hypercholesterolemia. Its pediatric use is restricted to children older than 10 years of age with familial homozygous hypercholesterolemia. It is given orally once daily either as monotherapy or in combination therapy with a statin. Ezetimibe is available as a single-entity drug or as a combination drug with simvastatin (the combination has a trade name of Vytorin). Ezetimibe has a unique way of working compared with other antilipid drugs. The mechanism of action of ezetimibe is complementary to that of the statins, explaining why patients may receive both. It localizes and appears to act at the brush border of the small intestine, where it inhibits the absorption of cholesterol, leading to a decrease in the delivery of intestinal cholesterol to the liver. This causes a reduction of hepatic cholesterol stores and an increase in the clearance of cholesterol from the blood. Ezetimibe decreases LDL about 17% but has no effect on HDL or triglycerides.

Food does not affect its bioavailability. Much of the drug is excreted in the feces unchanged, and the rest of it is metabolized in the liver.

Ezetimibe is contraindicated in active liver disease or if the patient has persistently elevated liver enzymes (when coadministered with a statin). It should be administered with caution to children under 10 years old because it is not labeled for this use. Other precautions are moderate to severe hepatic insufficiency as well as pregnancy and lactation (when coadministered with a statin).

Ezetimibe has some adverse effects; the most common are abdominal pain, diarrhea, arthralgia, back pain, myalgia, headache, and sinusitis. The potential serious adverse effects are all uncommon. They include hepatitis, increased liver function tests, hypersensitivity responses (anaphylaxis and angioedema), myopathy (very rare), and rhabdomyolysis (very rare).

Ezetimibe is a pregnancy category C drug, and the risk to the infant during breast-feeding cannot be ruled out.

Nicotinic Acid

Nicotinic acid (niacin or vitamin B_3) is used to treat hyperlipidemia. Like lovastatin, nicotinic acid reduces levels of triglycerides and LDL cholesterol levels and raises levels of HDL cholesterol. Triglycerides and VLDL levels are reduced by 25% to 30% in 1 to 4 days. LDL level reductions may be seen in 5 to 7 days, with the maximal effect seen in 3 to 5 weeks. The effect on LDL is dose dependent and ranges from 10% to 25%. The decrease would be greater if the patient is also receiving bile acid sequestrants (40% to 60% decrease). HDLs are increased between 15% and 35%. Although the exact mode of action is unknown, nicotinic acid is known to inhibit lipolysis in adipose tissue, to decrease esterification of triglyceride in the liver, and to increase lipoprotein lipase activity.

Nicotinic acid is rapidly absorbed from the intestine, with peak effects achieved 45 minutes after administration. It is excreted, mostly unchanged, in the urine. Contraindications to its use include hepatic dysfunction, active peptic ulcer, severe hypotension, and hemorrhaging.

The newer sustained-release forms of nicotinic acid have fewer adverse effects, making them more tolerable for patients and, therefore, excellent choices to elevate HDL levels. To achieve the lipid-lowering effects of nicotinic acid, doses that are larger than those used to treat niacin deficiency (pellagra) are needed. These larger doses produce peripheral vasodilation, mostly in the cutaneous vessels of the face, neck, and chest. Vasodilation results in flushing of the skin, which is usually transient. Vasodilation and increased blood flow from niacin administration are attributable to histamine release. Other common adverse effects, which include GI irritation, nausea, and vomiting, make niacin intolerable for many patients. Myalgias are possible when nicotinic acid is

combined with statins, although they are uncommon. The most serious possible adverse effect is hepatotoxicity, but this is rare. An increase in uric acid levels can also occur.

Bile Acid Sequestrants

The bile acid sequestrants cholestyramine (LoCholest, Questran, Prevalite) and colestipol (Colestid) are used to reduce elevated serum cholesterol levels in patients with primary hypercholesterolemia who have not responded to other drug therapy A third, new bile acid sequestrant is colesevelam (WelChol). Cholestyramine and colestipol are also used to relieve pruritus associated with partial biliary obstruction.

Bile acid sequestrants are not absorbed orally but work in the GI tract. The reduction in LDLs is apparent in 4 to 7 days and ranges between 15% and 30%. A decline in serum cholesterol levels is usually apparent after 1 month of treatment. Once drug therapy is discontinued, cholesterol levels return to baseline within 1 month. These drugs do not increase HDL or change triglyceride levels (although an initial and transient elevation in triglycerides may occur).

A major difference between the bile acid sequestrants and lovastatin is how they achieve a decrease in the cholesterol levels. Unlike lovastatin, which works by decreasing the synthesis of cholesterol, the bile acid sequestrants promote the oxidation of cholesterol to bile acids. Cholesterol is the major, and perhaps the only, precursor to bile acids. Bile acids are secreted from the gallbladder and liver into the intestine during digestion. In the intestine, bile acids emulsify the fat and lipid particles from food, promoting absorption. Much of the bile acid that is secreted is reabsorbed and returned to the liver by hepatic circulation.

The bile acid sequestrants bind with the bile acids in the intestine to make them nonresorbable. The bile acids are then eliminated in the stool. The decrease in available bile acid causes the body to increase the oxidation of cholesterol to bile acids, which in turn decreases the LDL and serum cholesterol levels. Although hepatic synthesis of cholesterol rises, serum cholesterol levels fall because of an increased clearance of cholesterol-rich lipoproteins from the plasma. Because of their mechanism of action the bile acid sequestrants are all administered before a meal.

Patients with partial biliary obstruction have an increased bile acid concentration. Cholestyramine and colestipol, by decreasing circulating bile acid, reduce bile acid deposits in the skin tissues, with a resultant decrease in pruritus. Colesevelam is not noted to have this effect.

Cholestyramine and colestipol are extremely similar. Because of their adverse effects and frequent drug interactions, these agents are not frequently prescribed. The most common adverse effect is constipation, which can be severe and may lead to fecal impaction. Less frequently experienced adverse effects include abdominal pain, distention, and cramping; GI bleeding; belching; bloating; flatulence; nausea and vomiting; diarrhea and loose stools; indigestion and heartburn; anorexia; and steatorrhea. Chronic use of cholestyramine can result in prolonged bleeding resulting from vitamin K deficiency. Headache can also occur with both cholestyramine and colestipol. In addition, dizziness, anxiety, vertigo, drowsiness, and fatigue have been noted with colestipol.

Absorption of fat-soluble vitamins such as A, D, E, and K may be impaired because cholestyramine interferes with the normal fat absorption and digestion. Because cholestyramine is a chloride anion exchange resin, prolonged use may cause hyperchloremic acidosis.

Cholestyramine and colestipol interact with many different drugs and may impair the absorption of those drugs. Consult a drug guide to determine whether a drug interaction is likely before giving these bile acid sequestrants with any other drug.

Before starting therapy with cholestyramine or colestipol, determine whether both the patient's serum cholesterol and triglyceride levels are elevated. If so, elevated triglyceride levels should be treated first with other drug therapy because triglycerides may rise initially from the treatment with cholestyramine.

Consideration should be given to the patient's life span before treatment with either of the bile acid sequestrants. Cholestyramine is a pregnancy category C drug, whereas colestipol is a pregnancy category B drug. Younger and smaller patients are more at risk for developing hyperchloremic acidosis. In adults older than 60 years, constipation is more likely to develop with ongoing cholestyramine therapy. Cholestyramine and colestipol come in a powdered form, which needs to be diluted with fluid. These preparations are considered unpalatable by some patients, and therefore, adherence with therapy may be limited. Both drugs also come in tablet form.

Colesevelam differs from cholestyramine and colestipol in some ways. Colesevelam is contraindicated in bowel obstruction. It is a pregnancy category B drug. Unlike the other bile acid sequestrants, it does not seem to reduce the absorption of fat-soluble vitamins, although a class effect is possible, so caution should be used if the patient has deficiency of one of these vitamins or is at risk of developing one of these deficiencies. It also does not seem to have the drug interactions that the other drugs in the class have. The GI adverse effects are much less frequent from colesevelam, so the drug is better tolerated than either cholestyramine or colestipol.

CHAPTER SUMMARY

- Hyperlipidemia is a known risk factor for atherosclerosis and the problems and complications associated with atherosclerosis. The blood lipids include the total cholesterol, HDL cholesterol, LDL cholesterol, VLDL cholesterol, and triglycerides.
- Use of statins decreases primary and secondary risks for cardiac disease and stroke. In addition to lowering lipid levels, statins appear to have protective and healing effects on the endothelium. Cardiovascular disease risk is decreased with statin use even if the LDL baseline is not considered elevated when therapy is started.

- Many patients being treated for elevated cholesterol levels do not achieve the recommended treatment goals of total cholesterol under 200 mg/dL, LDL under 100 mg/dL, and HDL above 40 mg/dL.
- Lovastatin, the prototype statin, lowers LDL, VLDL, triglyceride levels, and total cholesterol levels, and raises HDL levels. It has been shown to decrease mortality from cardiovascular complications associated with elevated cholesterol levels and LDL levels.
- Lovastatin is metabolized through the hepatic enzyme CYP3A4. All other drugs or agents that are inhibitors of this pathway may have a drug interaction with lovastatin, decreasing lovastatin metabolism and sometimes dramatically raising blood levels of lovastatin.
- All lipid-lowering drugs can elevate liver enzyme levels. This elevation is not normally serious, although the patient's liver enzyme levels should be monitored closely for up to the first year of therapy. Liver enzyme levels usually return to normal spontaneously while drug therapy continues; if this does not occur, then enzyme levels return to normal with either a dose reduction or discontinuation of the drug.
- Lipid-lowering drugs can produce myalgias and potentially serious myopathies. These occur most frequently with high doses of statins, or the combination of another antilipid with a statin. Some patients may be genetically predisposed to these adverse effects due to inherited differences in P-450 isoenzymes, because the statins are metabolized via these pathways.
- Dietary modifications to limit fat and cholesterol intake should be implemented before starting any drug to lower lipid levels. These modifications need to be continued once drug therapy has begun.
- The fibric acid derivatives gemfibrozil and fenofibrate lower triglyceride levels and increase HDL cholesterol. Their effect on LDL cholesterol can be either to lower it slightly or to increase it slightly. They are usually coprescribed with a statin. Gemfibrozil reduces hepatic triglyceride production. The mechanisms of fenofibrate are not clear.
- A cholesterol absorption inhibitor is ezetimibe, which decreases the absorption of cholesterol in the small intestine to lower serum LDL levels. It is also available in combination with the statin simvastatin.
- Nicotinic acid (niacin or vitamin B_3) reduces triglycerides, reduces LDL cholesterol, and increases HDL. Although the exact mode of action is unknown, nicotinic acid is known to inhibit lipolysis in adipose tissue, decrease esterification of triglyceride in the liver, and increase lipoprotein lipase activity.
- The bile acid sequestrants cholestyramine, colestipol, and colesevelam decrease LDL. They work differently than other lipid-lowering drugs by binding with the bile acids in the intestine so that the bile acids are nonresorbable and are eliminated in the stool. The decrease in available bile acid causes the body to convert cholesterol to bile acids.

QUESTIONS FOR STUDY AND REVIEW

1. Which of the forms of cholesterol is believed to provide some protective mechanism for the body and is termed "good" cholesterol?
2. How do elevated cholesterol levels contribute to hypertension?
3. Why is it important to determine whether other drugs received by a patient taking lovastatin are metabolized by CYP3A4 or are inhibitors of CYP3A4?
4. Why is it important to monitor liver enzymes while a patient is receiving lovastatin or other lipid-lowering drugs?
5. Why do CK levels greater than 10 times the upper limit of normal require that lovastatin therapy be discontinued?

Drugs Treating Heart Failure

Learning Objectives

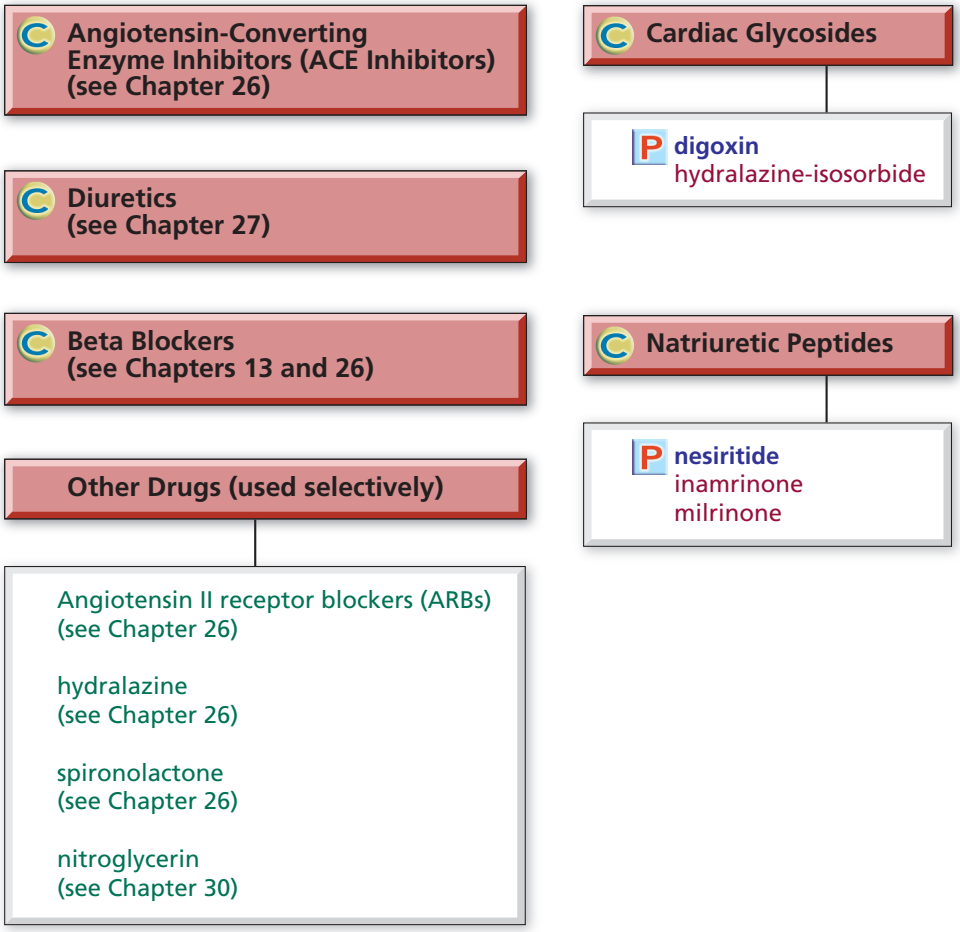
At the completion of this chapter the student will:

1. Understand the rationale for polypharmacy in treating heart failure.
2. Identify core drug knowledge about drugs used to treat heart failure.
3. Identify core patient variables relevant to drugs used to treat heart failure.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that are used to treat heart failure.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that are used to treat heart failure.
6. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs used to treat heart failure.
7. Determine key points for patient and family education for drugs used to treat heart failure.

Key Terms

afterload
cardiac output
cardiomyopathy
chronotropic
contractility
digitalization
dromotropic
ejection fraction
inotropic
peripheral resistance
preload
stroke volume

Drugs Treating Heart Failure



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

The heart is the muscle responsible for pumping blood through the circulatory system. When disease processes interfere with the ability of the heart to pump blood effectively, the organs and tissues are affected and damage may occur. Heart failure (HF), historically referred to as congestive heart failure (CHF), is one such disease process. In HF, the heart does not pump effectively to meet the needs of the body.

The drug classes primarily used to treat chronic HF are angiotensin-converting enzyme (ACE) inhibitors, loop diuretics, and beta blockers. Additional drugs that have a selected place in therapy are the angiotensin II receptor blockers (ARBs), cardiac glycosides, aldosterone antagonists, and a combination of the vasodilator–antianginal drugs (hydralazine–isosorbide). The natriuretic peptides are a drug class used to treat decompensated acute HF. Except for the cardiac glycosides and the natriuretic peptides, which are discussed thoroughly in this chapter, these drug classes are described fully in other chapters. The prototype cardiac glycoside is digoxin (Lanoxin). The prototype natriuretic peptide is nesiritide (Natrecor).

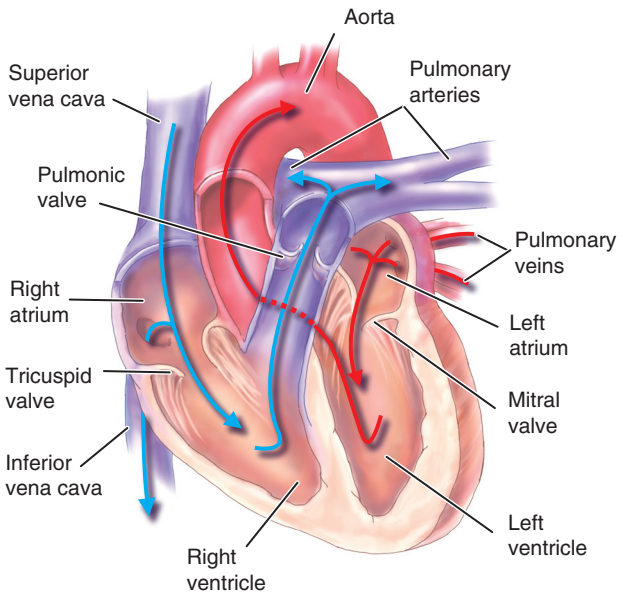
PHYSIOLOGY

As stated in Chapter 26, the heart is composed of four chambers—the left atrium, the right atrium, the left ventricle, and the right ventricle. Blood is returned to the right atrium from the body. It progresses from the right atrium, moving to the right ventricle, and then to the lungs, where it is reoxygenated and has carbon dioxide removed. The reoxygenated blood returns to the left atrium and then to the left ventricle. The contraction of the left ventricle moves the blood back into systemic circulation, as is seen in Figure 29.1.

The volume of blood that leaves the left ventricle in 1 minute is the **cardiac output.** Cardiac output consists of two elements, stroke volume and heart rate, and is the product of these two elements (cardiac output = stroke volume × heart rate). **Stroke volume** is the amount of blood that leaves the left ventricle with each contraction. Stroke volume is normally about 75 mL. Heart rate is how fast the heart is beating, or the number of contractions per minute. The normal adult range is 70 to 80 bpm. Cardiac output is affected by factors that alter either stroke volume or heart rate.

Stroke volume is dependent on three factors: preload, contractility, and afterload. **Preload** is the passive stretching force exerted on the ventricular muscle created by the amount of blood that has filled the heart by the end of diastole. Preload is affected by the amount of blood that has returned to the heart (venous return), the ability of the atria to contract forcefully enough to move blood into the ventricles, and how much blood was left in the ventricle during the last contraction. **Contractility** is the force of the squeezing that the ventricle is able to achieve to eject the blood into the systemic circulation. **Afterload** is the amount of pressure the ventricular muscles must overcome

PHYSIOLOGY



• FIGURE 29.1. Cardiac circulation. The unoxygenated blood is returned through the superior and inferior vena cava to the right atrium, where it is removed to the right ventricle. Blood leaves the ventricle through the pulmonary artery to be reoxygenated in the lungs. The oxygenated blood returns to the left atrium via the pulmonary veins and then into the left ventricle. Blood is ejected from the ventricle to the body through the aorta.

to eject the blood into the systemic circulation. Contractility also is affected by the concentration of catecholamines in the heart muscle; that is, the more catecholamines, the greater the contractility. Afterload is controlled by the diameter of the vessel and the pressure within the vessel, which is known as **peripheral resistance** (PR = pressure × diameter of vessel).

Contractions of the heart are dependent on the unique electrical conduction system of the cardiac muscle. The physiology of the conduction system of the heart is described within the physiology section of Chapter 31, Drugs Affecting Cardiac Rhythm.

PATHOPHYSIOLOGY

Heart failure, a major pathologic problem in the United States, is associated with high morbidity and high mortality. Approximately 5 million people in the United States have HF; 550,000 people are diagnosed with the condition annually. More than three and a half million adults are hospitalized yearly in the United States with a primary or secondary diagnosis of HF. Heart failure is primarily a disease of older adults; about 80% of those admitted to the hospital with HF are older than 65 years of age. Total direct and indirect costs of HF are approximately $28 billion; the cost of drug therapy alone is almost $3 billion (American College of Cardiology/

American Heart Association [ACC/AHA] guidelines, 2009). Despite how common HF is, few Americans actually understand HF. A Harris Interactive Survey in December 2007 was commissioned by the American Association of Heart Failure Nurses, Preventive Cardiovascular Nurses Association, and the Society of Chest Pain Centers to determine what adults know about HF. Of the 4912 U.S. adults who were surveyed, only 47% were able to correctly define HF; only 4% were able to identify correctly all of the common symptoms of HF, nearly one third thought HF was the same as a heart attack, and nearly three fourths of them believed chest pain was a symptom of HF; and almost one third did not know that HF can be treated with drug therapy (Trupp & Wingate, 2008).

Pathologic processes that may cause HF occur either in the heart itself, such as an aortic stenosis, valvular heart disease, or myocardial deficiency after an infarction, or systemically, such as from systemic hypertension, coronary artery disease, or renal failure. The primary causes are coronary artery disease and hypertension. The symptoms of heart failure for most patients are related to decreased left ventricular function.

Left ventricular dysfunction begins with some injury to or stress on the heart and then is generally a progressive process. Cardiac output decreases when the left ventricle is unable to eject its normal volume of blood during systole; the **ejection fraction** (the amount leaving the ventricle with contraction compared with the total amount in the ventricle before contraction) is therefore decreased. For a while, the body attempts to compensate for the decreased cardiac output. The heart muscle enlarges (**cardiomyopathy**) to provide more contractile force to try to improve cardiac output. However, the heart eventually becomes less and less effective in contracting. As output becomes greatly diminished, the kidneys retain sodium and water to increase circulating volume. Unfortunately, this mechanism places more of a burden on the already overworked heart, increasing preload and afterload. The ventricles then eject less and less. As blood accumulates in the ventricles, the pressure in the vessels coming to the heart increases. Buildup of blood in the left ventricle causes pulmonary congestion or left-sided HF. The cardinal symptoms of heart failure are dyspnea (including rales, rhonchi, and shortness of breath) and fatigue (which may limit exercise tolerance), as well as fluid retention. Buildup of fluid in the right ventricle causes systemic congestion or right-sided heart failure. Symptoms include peripheral edema, positive jugular vein distention, and a third heart sound (S_3).

In HF, left-sided failure occurs first, then right-sided failure. This effect is sometimes called backward failure. In most patients, the compensatory hypertrophy of the heart muscle eventually leads to some degree of "stiffness," or loss of elasticity of the ventricle. This "stiffness" alters ventricular diastolic function and does not allow the ventricle to fill completely, further decreasing cardiac output. Although most patients develop systolic dysfunction first and then diastolic dysfunction, some patients do initially develop diastolic dysfunction. Diastolic dysfunction may also be caused by systemic hypertension and coronary artery disease. Additional causes of diastolic dysfunction are fibrosis from aging, infiltrative diseases (such as myocarditis), and constrictive pericarditis. Cardiac output is decreased with diastolic dysfunction, although the ejection fraction may be normal. The compensatory mechanisms of the body are identical in response to the diminished cardiac output. Initially with this type of failure, the body does not have a fluid overload; hence, the symptoms of fluid overload (e.g., S_3, jugular venous distention, and peripheral edema) are not present. For this reason, the term "heart failure" is now considered a more accurate description of the entire disease process than "congestive heart failure" (abbreviated CHF), although some practitioners still use the term "congestive heart failure" and the abbreviation CHF this way. Because of the chronicity of the disease, some authors and practitioners continue to refer to the pathology as the well-known abbreviation CHF but consider that the meaning of the "C" has changed and now represents "chronic" rather than "congestive." All of these terms—heart failure, congestive heart failure, and chronic heart failure—may be used in practice and should be considered synonyms. CHF (chronic heart failure) and HF are used interchangeably in this text.

Natriuretic peptides are endogenous cardiac hormones. Brain natriuretic peptide, working with atrial natriuretic peptide, regulates cardiovascular homeostasis and fluid volume. It is secreted primarily by the ventricular tissue in response to changes in wall tension. This hormone promotes natriuresis (sodium loss in the urine), diuresis, vasodilation, and smooth-muscle relaxation. It also inhibits the renin-aldosterone axis. The concentration of endogenous brain natriuretic peptides is elevated in CHF, acute myocardial infarction (MI), acute coronary syndrome, aortic stenosis, hypertension, end-stage renal failure, and cirrhosis with ascites. The presence of elevated natriuretic peptides may help to confirm the diagnosis of heart failure, although as these hormones may be elevated in some other situations (such as pulmonary embolism, chronic obstructive pulmonary disease, or in women over 60 years old who do not have heart failure); elevations of these natriuretic peptides without other symptoms or diagnostic findings should not be considered conclusive for the diagnosis of heart failure (ACC/AHA 2009; Anderson, 2008).

Because patients with CHF vary in the severity of their symptoms with progression of the pathologies, a classification system is used to group patients. Therapies are usually prescribed based on the classification. The most common classification historically used is the New York Heart Association (NYHA) groupings. Patients are placed into one of four classes depending on their functional abilities. More recently, the revised 2009 clinical guidelines from the American College of Cardiology and the American Heart Association have created four stages of heart failure with stages A and B representing patients at risk of developing HF. Patients with coronary artery disease, diabetes, and hypertension who are asymptomatic and who do not have left ventricular hypertrophy or dysfunction are in Stage A, while those who are asymptomatic but have left ventricular hypertrophy or dysfunction are grouped in Stage B. These new Stages of Heart Failure are not meant to replace the NYHA groupings,

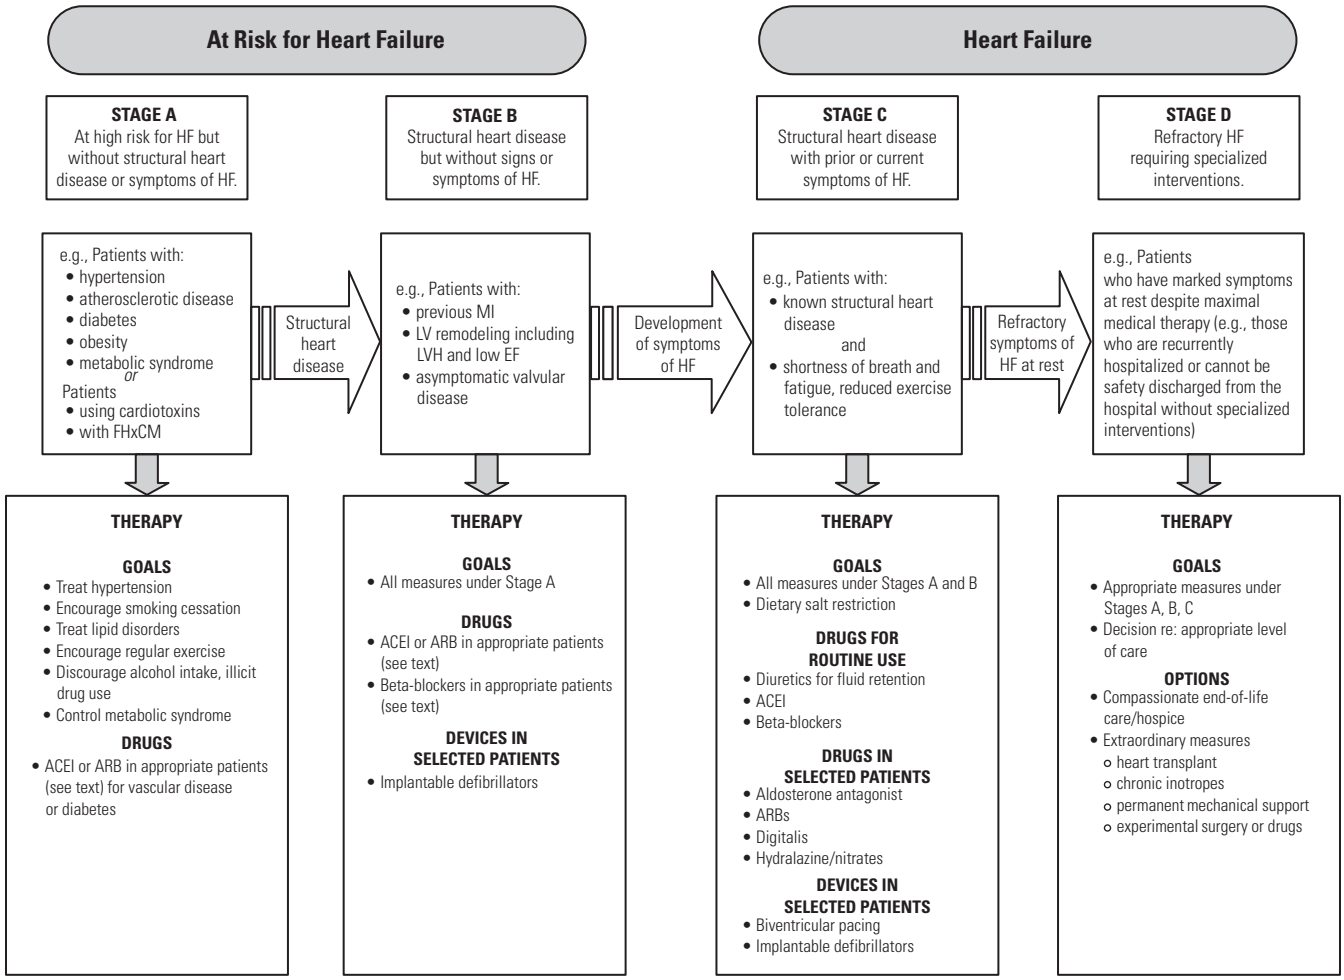
Box 29.1 NEW YORK HEART ASSOCIATION CLASSIFICATION FOR CHRONIC HEART FAILURE

- Class I: Patients are asymptomatic; patients have no limitation of their activities, and they do not have symptoms from ordinary activities.
- Class II: Patients are short of breath or fatigued with moderate activity such as climbing two flights of stairs; they are comfortable at rest or with mild exertion and have slight limitation of activity.
- Class III: Patients are short of breath or fatigued with very mild exertion activity, such as climbing one-half flight of stairs; are comfortable only with rest; and have marked limitation of their activity.
- Class IV: Patients are exhausted, short of breath, or fatigued at rest; any activity brings on discomfort and symptoms; they have severe limitations on their activity and are confined to bed or chair.

but to supplement them. The goal of the new stages is to help highlight for clinicians that there is a need for therapy before the patient develops complications of the left ventricle. Box 29.1 summarizes the NYHA classifications for CHF. Display 29.1 shows the ACC/AHA new classifications for HF and appropriate interventions.

DRUGS TO TREAT CHRONIC HEART FAILURE

When the heart cannot achieve the normal cardiac output for various reasons, a backlog of blood, or congestion, occurs, and heart failure develops. Several drug classes are used to treat CHF, and polypharmacy is considered the standard and most effective treatment. The *ACC/AHA 2009 Guideline Update for the Diagnosis and Management of Chronic Heart Failure in the Adult* suggest that drug therapy begin in the pre-HF stages of A and B. Initially, in stage A the underlying risk factor should be addressed with the goal to correct or minimize the risk (e.g., return the blood pressure readings to a normal level with drugs to treat the hypertension, control elevated glucose levels in those with diabetes, etc.). Additionally, other drug therapy may be started based on patient risk factors; these drugs include angiotensin converting enzyme inhibitors (ACE Is), angiotensin II receptor blockers (ARBs), and (occasionally) beta blockers. Drug therapy for Stage B is similar,with the emphasis that a beta blocker should be started on everyone who has had an MI. By Stage C when the patient now is diagnosed with heart failure, the guidelines state that the following therapies are



• Display 29-1. Stages in the evolution of HF and recommended therapy by stage. FHx CM, family history of cardiomyopathy; IV, intravenous; LV, left ventricular; and MI, myocardial infarction.

appropriate for all patients with CHF (in the absence of contraindications): ACE inhibitors (or an ARB can be used if the patient cannot tolerate an ACE inhibitor), loop diuretics (with dietary salt restriction), and beta blockers. These drugs are to be considered the standard basis of care for CHF. Research suggests that the clinical benefits of ACE inhibitors and beta blockers are related to modifying the changes that occur in the left ventricle with CHF. ACE inhibitors seem to prevent progression of left ventricular dilation, and beta blockers such as carvedilol may reverse hypertrophy and improve systolic function.

Additionally, the following agents should be given to selected patients (in the absence of contraindications): aldosterone antagonists, ARBs, and a combination vasodilator–antianginal (hydralazine–isosorbide) for black patients. Cardiac glycosides (digoxin) may also be added to therapy as they have been found useful in the symptom management of CHF. Although digoxin, the prototype, does not decrease mortality, it has been shown to decrease the need for hospitalization.

Early diagnosis and treatment can improve quality of life expectancy for people who have heart failure (CDC, 2010). Drug therapy has been effective in increasing survival of individuals with CHF. Although the effective use of drug therapy with ACE inhibitors, diuretics, and beta blockers has been proved to decrease mortality from CHF, and clinical guidelines support their use, implementation of these therapies is still less than 100% in practice. Although drug therapy may be modified in the future, polypharmacy is, and will remain, the standard treatment of choice for CHF. Nurses have an important role in helping CHF patients receive drug therapy recommended by clinical practice guidelines.

In addition to drug therapy, two medical devices are recommended in selected patients with HF: an implantable cardioverter-defibrillator and cardiac resynchronization therapy with biventricular pacing. Because patients frequently meet the criteria for both of these devices, a combination device is often used.

CRITICAL THINKING SCENARIO

MULTIPLE DRUG THERAPY FOR CHRONIC HEART FAILURE

Ms. Mahoney, a 65-year-old woman who lives alone in a two-story home, comes to the emergency department complaining of difficulty breathing. She reports increased shortness of breath, especially when climbing the stairs and walking; weakness; and ankle swelling. A diagnosis of chronic heart failure is made. She is hospitalized and stabilized. Her discharge medications include the ACE inhibitor lisinopril, the loop diuretic furosemide, the beta blocker carvedilol, digoxin, and an oral potassium supplement.

1. What is the desired therapeutic effect of this combination drug therapy?
2. Why should hypokalemia be prevented in Ms. Mahoney?
3. What blood work needs to be carefully monitored in Ms. Mahoney?

Angiotensin-Converting Enzyme Inhibitors

As circulating volume to the kidneys decreases in CHF, the renin-angiotensin-aldosterone system is activated as the body attempts to "correct" for the low levels of circulating volume. Renin stimulates the production of angiotensin I, which is converted by a special enzyme, angiotensin-converting enzyme, into an extremely potent vasoconstrictor, angiotensin II. In turn, angiotensin II stimulates the production of aldosterone, which causes sodium and fluid retention, thereby increasing circulating blood volume. As a result, the already overworked heart must work harder. Vasoconstriction is designed to direct the diminished blood volume to vital organs. It also increases peripheral resistance, which decreases cardiac output and further increases the workload on the failing heart. ACE inhibitors stop the conversion of angiotensin to the active vasoconstrictor form, thereby preventing the deleterious effects from the renin-angiotensin-aldosterone system. These drugs are part of standard therapy for HF because they reduce mortality for all affected individuals regardless of whether their HF is symptomatic or whether it develops after an MI. Although it is known that hypertension is a risk factor for developing HF and its sequelae, the risk reduction achieved in HF from drug therapy with inhibitors of the renin-angiotensin-aldosterone system appears to be greater than one would expect solely from lowering the blood pressure. Drugs that inhibit the renin-angiotensin-aldosterone system also seem to reduce the risk of renal impairment (Berra & Miller, 2009). These agents also significantly decrease the risk of MI and further hospitalization (decrease morbidity).

Clinical trials have demonstrated overall general efficacy of ACE inhibitors, and examination of findings related to various demographic subgroups also demonstrate effectiveness. ACE inhibitors have been shown to provide benefits for older adults similar to those for younger adults. A meta-analysis of several studies examining the effect of ACE inhibitors on CHF (Agency for Healthcare Research and Quality, 2003) found that the drugs are effective in reducing mortality whether or not the patients have diabetes. The sex of the patient does not seem to greatly change effectiveness of ACE inhibitors, although women who have symptomatic CHF may experience somewhat less benefit than men. However, women who are asymptomatic do not appear to achieve a mortality benefit from ACE inhibitors. Whether race influences the effectiveness of ACE inhibitors is debatable. It appears that black patients may demonstrate less of a therapeutic response to ACE inhibitors than whites. However, none of the literature suggests that any harm can occur to black patients if they receive ACE inhibitor therapy, so current guidelines state that all patients should receive an ACE inhibitor as part of their therapy.

Certain ACE inhibitors have been approved for use in CHF: captopril (Capoten), fosinopril (Monopril), lisinopril (Prinivil), enalapril (Vasotec), and quinapril (Accupril). ACE inhibitors used off-label to treat CHF include benazepril (Lotensin) and perindopril (Aceon). Clinical trials, on which drug efficacy and guidelines are based, have titrated ACE inhibitor doses to a higher level than those frequently pre-

scribed in practice. If the patient tolerates these higher doses, they should be used to maximize effectiveness of ACE inhibitor therapy. In addition, there also appears to be a cost benefit.

Adverse effects related to ACE inhibitors include cough (which often is severe enough that patients cannot tolerate using the drug), hypotension, worsening renal function, potassium retention, and angioedema. ACE inhibitors carry a Black Box warning that they should not be used in pregnant women.

More information about ACE inhibitors is found in Chapter 26.

Loop Diuretics

Loop diuretics are used to decrease fluid volume and edema present in CHF. Because loop diuretics increase the loss of sodium significantly and to a much greater extent than thiazide diuretics, loop diuretics are generally considered the diuretic of choice for treating HF. Other advantages of a loop diuretic over a thiazide include the enhancement of free water clearance and that the drugs do not lose effectiveness with kidney disease unless the kidney function is severely impaired. However, thiazide diuretics may be used in patients who also have hypertension and have limited fluid retention from HF. If the patient is admitted to the hospital, they should receive intravenous loop diuretics, regardless of their home therapy (ACC/AHA, 2009).

In general, diuretics act in the nephrons of the kidney to increase urinary output and electrolyte loss. This action decreases circulating volume and peripheral resistance, reducing the workload on the failing heart. Removal of fluid from the vascular space allows mobilization of edema from the interstitial spaces. With less volume in the vascular space, less blood is returned to the heart (decreased preload) and cardiac output is decreased. The drop in cardiac output is not usually clinically important unless the patient has been too aggressively treated with loop diuretics and overdiuresed. Cardiac output that is significant decreases tissue perfusion. To determine if this has occurred, assess the blood urea nitrogen (BUN) levels; a stable BUN implies adequate perfusion to the kidneys and other organs. If the patient remains edematous and the BUN is stable, it is safe to continue with diuretic therapy.

Appropriate diuretic therapy leads to the resolution of pulmonary and peripheral edema. The efficacy of the diuretic can be enhanced by concurrent therapy with an ACE inhibitor, which lowers the concentrations of both angiotensin II and aldosterone. In combination with loop diuretics, aldosterone antagonists also modestly enhance the diuresis and minimize the potassium loss; the combination has been found to improve survival. With loop diuretics, the maximum diuretic effect and loss of potassium occur within the first few days of daily therapy. After 2 weeks of continued use, the diuretic does not cause further fluid loss, but it does maintain the fluid loss that has been attained. Additional diuretic effect is seen only if the dose is increased or a second diuretic drug is added to the therapy.

The potential adverse effects of diuretics include loss of electrolytes, especially potassium and magnesium, which can predispose a patient to serious cardiac arrhythmias, particularly if the patient is also taking digoxin. Other adverse effects include hypotension and azotemia (increased urea in the blood).

Diuretics should be prescribed for all patients with fluid retention HF. They are used to treat fluid overload, and then as maintenance drugs to prevent reoccurrences of fluid imbalance. The dose of the diuretic should be large enough to correct the fluid volume excess, but not large as to cause significant adverse effects such as severe hypotension or significant electrolyte imbalances. As heart failure progresses, it is common that the patient will need a large dose of the diuretic to achieve the same therapeutic response.

Diuretics are discussed fully in Chapter 27.

Beta Blockers

Beta blockers have been shown to be highly effective in the treatment of all grades of HF that are attributable to left ventricular systolic dysfunction. Beta blockers, like ACE inhibitors, have been found to decrease mortality from CHF as well as decrease morbidity and enhance the patient's overall well-being. Although beta blockers can decrease contractility of the heart, thereby decreasing cardiac output (which is detrimental initially in CHF), they also block the effect of the sympathetic nervous system and cause vasodilation and decreased peripheral vascular resistance (which is helpful to patients with CHF). Clinical studies demonstrate that beta blockers actually reverse the remodeling process by reducing left ventricular volumes and improving systolic function (ACC/AHA, 2009). These changes can produce long-term clinical benefits to patients with CHF, even if coronary artery disease is the cause of heart failure. Beta blockers are known to suppress renin release in patients taking ACE inhibitors.

Because beta blockers improve survival and slow disease progression, treatment with a beta blocker should be started as soon as left ventricular dysfunction is diagnosed. Three beta blockers have been shown to be effective in reducing the risk of death in patients with CHF: bisoprolol (Zebeta) and sustained-release metoprolol (Lopressor), both of which selectively block beta-1 receptors, and carvedilol (Coreg), which blocks alpha-1, beta-1, and beta-2 receptors. Carvedilol, the first beta blocker approved for treating mild-to-moderate CHF, was the first new drug approved for treating CHF in many years.

Research on beta blocker effectiveness is limited to these three drugs, and use of other beta blockers is not currently recommended. Meta-analysis of many research studies (Agency for Healthcare Research and Quality, 2003) shows that beta blockers reduce mortality for men and women with symptomatic heart failure as well as for patients with and without diabetes. Black and white patients have the same risk reduction whether they receive bisoprolol, metoprolol, or carvedilol.

Beta blocker therapy is initiated once the HF is controlled, not during acute episodes of CHF. The patient should not have fluid overload from HF or hypovolemia from aggressive diuretic therapy; the patient should not be currently in the intensive care of a hospital for treatment of the HF. Beta blockers are recommended to be started, along with an ACE inhibitor, in patients who are asymptomatic (NYHA class I). In general, it is recommended that individuals start taking the ACE inhibitor prior to starting therapy with a beta blocker. Patients who are symptomatic (NYHA classes II–IV) should have normal fluid volume, or only minimal evidence of fluid retention, when they begin beta blocker treatment. Pretreatment with diuretics is important for these patients to prevent an acute exacerbation of CHF caused by the slowing of the heart rate and decrease in contractile force that occurs with beta blockers. Diuretic therapy should continue once other therapy has begun. The patient should be started on a small dose and monitored carefully for signs of hypotension and worsening CHF. Dosage is increased gradually over several weeks until the therapeutic dosage range is reached. Full therapeutic effects may not occur for 1 to 3 months, although some immediate response can be seen with carvedilol. Treatment is most effective if begun in the early stages of the disease. Patients who have been on long-term therapy with a beta blocker and develop an exacerbation of HF do not need to have the beta blocker therapy stopped immediately. This may in fact be detrimental to them, as it may increase the risk of further decompensation. Initially, the dose of the diuretic should be increased to offset fluid overload. If the worsening of their clinical status is accompanied by hypoperfusion of the organs, or requires intravenous drugs to increase the force of contraction, beta blocker therapy should either be decreased or halted temporarily. Once stabilized, the beta blocker should be reintroduced (ACC/AHA, 2009).

Potential adverse effects of beta blockers include fluid retention, worsening of heart failure, fatigue, bradycardia and heart block, and hypotension. With each new dose, the patient should be observed for dizziness or lightheadedness for 1 hour. Patients who have had initial difficulties with a beta blocker often have success when the drug is tried again. Although beta blocker use may worsen reactive airway disease, such as asthma, beta blockers may be considered for patients with HF who have reactive airway disease or asymptomatic bradycardia; however, they must be initiated very cautiously, because beta blockers may not be appropriate for patients with persistent symptoms of either condition.

For more information on beta blockers, see Chapters 13 and 31.

Angiotensin II Receptor Blockers

Like ACE inhibitors, angiotensin II receptor blockers (typically referred to as ARBs) work on the renin-angiotensin-aldosterone system. How ARBs achieve their effects is different from ACE inhibitors. Whereas ACE inhibitors block the formation of angiotensin II, ARBs block the binding of angiotensin II to its primary receptor. ARBs do not affect kinin metabolism; because the disturbance of kinin metabolism is what produces the adverse effect of cough in ACE inhibitors, this adverse effect does not occur with ARBs. Like ACE inhibitors, ARBs reduce sympathetic activation that occurs in HF and appear to prevent hypertrophy of the left ventricle after an MI. ARBs decrease the level of proinflammatory cytokines that are present in HF; it is not certain whether ACE inhibitors do this.

Current ACC/AHA guidelines recommend that ARBs be used in patients with current or prior symptoms of HF and reduced left ventricular ejection fraction who are ACE inhibitor intolerant. The three ARBs used in the treatment of CHF are valsartan (Diovan), losartan (Cozaar), and candesartan (Atacand). Clinical trials have shown that ARBs reduce mortality when given to patients who are not able to tolerate ACE inhibitors. Although the efficacy is less well established, it appears that when ARBs are coadministered with an ACE inhibitor, no changes in the mortality rate occur but the morbidity rate and need for hospitalization decrease significantly. Current recommendations therefore state that the combination of an ARB and an ACE inhibitor is reasonable, especially in patients who remain symptomatic on conventional drug therapy (ACE inhibitor, beta blocker, loop diuretic). In some patients, ARBs may be used as first-line therapy in place of an ACE inhibitor.

For more information on ARBs, see Chapter 26.

Aldosterone Antagonists

Aldosterone antagonists also work on the renin-angiotensin-aldosterone system. Aldosterone levels are elevated with HF. The heart has many mineralocorticoid receptors that are stimulated by aldosterone, so increased levels produce additional cardiac effects. Long-term elevation of aldosterone and stimulation of these cardiac mineralocorticoid receptors are believed to be responsible for some of the end-organ damage that can occur from HF. Aldosterone antagonists, when added to a standard regimen of HF drug therapy, improve survival in patients with moderately severe to severe symptoms of HF and reduced left ventricular ejection fraction. These drugs, spironolactone (Aldactone) and eplerenone (Inspra), are also potassium-sparing diuretics, so their use increases serum potassium levels. For this reason, they cannot be used if the patient has diminished renal function (because this causes potassium levels to increase).

Hyperkalemia is a potential serious adverse effect of aldosterone antagonists, and patients receiving these drugs need to be monitored carefully. Eplerenone differs from spironolactone in that it selectively blocks the mineralocorticoid receptors, whereas spironolactone blocks mineralocorticoid, glucocorticoid, androgen, and progesterone receptors. Endocrine adverse effects from eplerenone are thus much less common, but the drug cost is more expensive, leading to more frequent use of spironolactone.

For more information on aldosterone blockers, see Chapter 26.

Cardiac Glycosides

The cardiac glycosides also are known as digitalis preparations or digitalis glycosides. Currently, the only cardiac glycoside available in the United States is digoxin. Digoxin is used to maintain clinical stability and improve symptoms, quality of life, and exercise tolerance in patients with all phases of CHF; it does not decrease mortality from CHF. Current AHA/ACC guidelines recommend that digoxin can be added to reduce hospitalizations for HF or for rate control if patients also have atrial fibrillation. Digoxin is not used as the primary treatment for stabilizing patients with acute episodes of noncompensated heart failure; rather, it should be added after other drug therapy has stabilized the patient, as long as the patient is in normal sinus rhythm.

Digoxin increases the force of cardiac contraction, increasing cardiac output, which in turn increases perfusion to the kidneys. Higher renal perfusion increases the production of urine. Thus, the drug reduces preload and afterload. Although this effect historically has been considered the main pharmacodynamic action of digoxin, there is evidence that its primary benefit actually occurs through neurohormonal modulation. Digoxin has been shown to enhance vagal tone, slowing ventricular rate and reducing sympathetic tone when abnormally high (as in CHF). It also slows heart rate.

Combination Vasodilator–Antianginal Drugs

The combination vasodilator and antianginal drug hydralazine–isosorbide (BiDil) is recommended as an add-on therapy for black patients with a reduced left ventricular ejection fraction and persistent symptoms of CHF despite therapy with an ACE inhibitor and a beta blocker. Hydralazine–isosorbide is discussed in more depth in Drugs Significantly Different From Digoxin.

Drugs Under Investigation for Use in CHF

Natriuretic peptides such as nesiritide have been approved for use in the management of acute HF as in this setting it does improve symptoms. However, whether nesiritide will decrease mortality or morbidity is not known yet. Additionally, there are clinical trials underway that are trying to determine if nesiritide can be used as an adjunct therapy for intermittent intravenous administration in an outpatient setting for those with CHF. It is still unknown whether nesiritide will be useful when given to this patient population.

Vasopressin receptor antagonists are another new drug class that is under investigation for use in CHF. Early findings indicate that they reduce body weight and edema and normalize serum sodium in the presence of hyponatremia. However, the ramifications of these findings are not known at this time. One of these drugs is tolvaptan (Samsca), a vasopression two (V_2) receptor antagonist approved in 2009 to treat hyponatremia that occurs with clinically significant hypervolemia (such as in heart failure). It is not established though if the drug provides symptomatic benefits to HF patients (FDA, 2009). More research is needed to know if drugs in this class may provide benefit in treating CHF.

Drugs to Be Avoided in Heart Failure

For most patients, there are three classes of drugs that can exacerbate the symptoms of HF and thus should be avoided. These agents are: antiarrhythmics, calcium channel blockers, and nonsteroidal anti-inflammatory drugs. The antiarrhythmics depress cardiac function and can induce other cardiac arrhythmias. The only two that have not been found to decrease survival for HF patients are amiodarone and dofetilide. Calcium channel blockers worsen HF and are associated with increasing the risk of cardiovascular events. The vasoselective ones are the exception to this finding. Nonsteroidal anti-inflamatory drugs produce peripheral vasoconstriction, increase sodium retention, and increase the risk for adverse effects from diuretics and ACE inhibitors.

C CARDIAC GLYCOSIDES

The prototype cardiac glycoside drug is digoxin (Lanoxin).

Nursing Management of the Patient Receiving P Digoxin

Core Drug Knowledge

Pharmacotherapeutics

Digoxin is used in treating symptomatic CHF. It is added to the standard therapy of ACE inhibitor, beta blocker, and loop diuretic. Digoxin is also used in treating chronic atrial fibrillation to maintain a satisfactory resting ventricular rate. Table 29.1 provides a summary of selected drugs used to treat heart failure. (A complete discussion of drugs used to treat arrhythmias can be found in Chapter 31.)

The therapeutic range for digoxin is generally considered to be 0.5 to 2 ng/mL. A lower range of 0.5 to 0.8 ng/mL has been suggested to minimize adverse effects without sacrificing efficacy. Digoxin has been shown to improve symptoms, increase the quality of life, and increase the exercise tolerance of patients with CHF. These benefits occur regardless of the underlying heart rhythm (normal sinus or atrial fibrillation), the etiology of the heart failure, or other drugs used in therapy (e.g., ACE inhibitors, beta blockers). Digoxin does not decrease mortality from HF.

Pharmacokinetics

Absorption of digoxin varies with the type of preparation. Tablet absorption is about 60% to 80%; elixirs, 70% to 85%; and solution-filled capsules, 90% to 100%. Taking digoxin with food slows down absorption, but total absorption usually is unchanged. The exception is when digoxin is taken with a meal that is very high in bran fiber, which may reduce absorption. Digoxin also may be administered intravenously. Digoxin is distributed widely in the tissues. High concentrations are found in the myocardium, skeletal muscle, liver, brain, and kidneys. Digoxin crosses the blood–brain barrier and the

TABLE 29.1 Summary of Selected Drugs Used to Treat Heart Failure

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P digoxin (Lanoxin)	Chronic h eart failure (CHF), atrial fibrillation, atrial flutter	*Adult:* PO, loading dose, 0.75–1.25 mg in divided doses; maintenance of 0.125–0.25 mg/d; IV, loading, 0.4–1.0 mg in divided doses; maintenance, 0.063–0.25 mg *Child:* Dosage individualized	*Onset:* PO, 30–120 min; IV, 5–30 min *Duration:* PO, 6–8 d; IV, 4–5 d $t_{1/2}$: 30–40 h
hydralazine–isosorbide (BiDil)	CHF adjunct therapy for black patients	*Adult:* PO, one tablet (hydralazine, 37.5 mg/isosorbide, 20 mg) tid	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: Hydralazine, 4 h; isosorbide (parent compound), 2 h; metabolites, 2–5 h
P nesiritide (Natrecor)	HF, acutely decompensated	*Adult:* IV bolus, 2 mcg/kg, followed by IV infusion of 0.01 mcg/kg/min; may increase by 0.005 mcg/kg/min no more frequently than every 3 h, up to a maximum dose of 0.03 mcg/kg/min	*Onset:* hemodynamic improvement after bolus, 15 min; hemodynamic improvement after start infusion, 15–30 min; diuresis, natriuresis, 30–60 min after start infusion; plasma aldosterone reduction, 15–60 min after start infusion; dyspnea improvement, 3 h after start infusion (pharmacodynamic effects greater than pharmacokinetic half-life would indicate) *Duration:* about 3 h $t_{1/2}$: 18 min

placenta. Serum drug levels are not affected significantly by changes in fat tissue weight; thus, dosing is best calculated on lean (ideal) body weight rather than actual weight if the patient is obese. Metabolism takes place in the liver. However, much of the drug, 50% to 75%, is excreted unchanged by the kidneys. Digoxin is not removed by dialysis. Because of digoxin's long half-life, several days are required for a steady state to be achieved and for optimal clinical effects to be seen.

To speed the onset of therapeutic effects, a dose higher than normal, a loading dose, may be given to raise the blood level quickly to the desired range. This practice is known as **digitalization.** The total dose needed for digitalization is divided into several doses, with roughly half the loading dose given as the first dose. The remainder is divided and given at 6-hour to 8-hour intervals for oral (PO) dosage and 4-hour to 8-hour intervals for parenteral dosage. The dose is lower if the loading dose is given intravenously instead of orally. To avoid cumulative and toxic effects, dosage adjustments must be made when there is renal failure or suspected age-related deterioration of renal function.

Pharmacodynamics

The effect of digoxin on the heart is dose related. It exerts an indirect effect on the heart from stimulation of the autonomic nervous system and a direct action on both the cardiac muscle and the specialized electrical conduction system of the heart. The indirect effect of digoxin is to create a vagomimetic effect, one that mimics the action of stimulating the vagus nerve. The increase in the vagal tone is now believed to be the central effect of digoxin, which is primarily responsible for the therapeutic effects of the drug. Stimulating the vagus nerve depresses the sinoatrial (SA) node and prolongs conduction to the atrioventricular (AV) node. This decrease in conduction is known as a negative **dromotropic** effect. Because of the prolonged conduction time, heart rate slows. This effect is termed a negative **chronotropic** effect. Cardiac output is increased as a result of these factors. The improved cardiac output results in an increase in renal perfusion, causing mild diuresis. Digoxin also inhibits sympathetic tone, especially when it is abnormally high, as it is in CHF. Inhibiting sympathetic tone decreases sympathetic stimulation of the heart rate and thereby slows the heart rate. This effect on sympathetic tone is partly from vagotonic action and is partly a direct effect.

The direct effect of digoxin is to strengthen the contractile force of the heart, which is called a positive **inotropic** effect. This effect is believed to be caused by digoxin increasing the movement of calcium ions across the myocardial cell membrane during depolarization discharge. Because calcium is needed for contraction, a stronger contraction can occur with more calcium. The way digoxin increases calcium in the cell is by directly blocking a special enzyme, Na^+-K^+-ATPase, on cell membranes. Because of the blockade, Na^+ concentration increases in the cell. The increased Na^+ concentration causes increases in intracellular Ca^{2+} levels because of the Na^+-Ca^{2+} exchanger. Digoxin competes with potassium to attach to Na^+-K^+-ATPase. When digoxin is attached, potassium cannot be attached at the same site. Digoxin also directly increases the refractory period at the AV node. During this time, the heart muscles cannot be stimulated into contracting again. Digoxin also is known to increase total peripheral resistance.

Contraindications and Precautions

Digoxin is contraindicated in heart block, ventricular fibrillation, certain cases of ventricular tachycardia, some cases

of sick sinus syndrome, beriberi-related heart disease, hypersensitivity to digoxin, and allergies (although allergies are rare), and in the presence of digitalis toxicity. Caution must be used when administering digoxin over the long term to patients with CHF who are difficult to regulate or who have a greater than normal risk for developing toxicity (e.g., those with unstable renal function or a tendency toward hypokalemia). For these patients, the physician may consider a cautious withdrawal of digoxin. Monitor these patients very carefully for signs of returning or recurrent heart failure.

Also use caution when giving digoxin to patients with severe carditis, acute MI, severe pulmonary disease, and severe heart failure because these patients may be more sensitive to digoxin-induced arrhythmias. Patients with renal insufficiency are more likely to have adverse effects and develop digoxin toxicity. Use caution in patients who have thyroid disorders because plasma levels of digoxin are inversely proportional to thyroid status. In untreated hypothyroidism, digoxin requirements are reduced; in thyrotoxic patients, larger doses of digoxin may be necessary. Patient response to digoxin is unchanged in compensated thyroid disease. The electrolyte imbalances of hypokalemia, hypomagnesemia, and hypercalcemia potentiate the effect of digoxin, and the patient may develop signs of toxicity even with normal drug serum levels. Remember that digoxin competes with potassium for Na^+-K^+-ATPase receptor sites on cell membranes. Therefore, low potassium levels allow digoxin to occupy more receptors, increasing the risk for adverse effects. Hypocalcemia may nullify the effects of digoxin because digoxin creates its effect by increasing intracellular calcium to increase contraction. Serum calcium levels will need to be rectified to achieve therapeutic effects of digoxin.

Digoxin is a pregnancy category C drug, and its safety for use in breast-feeding women has not been established. Children may receive digoxin; however, premature and immature infants are very sensitive to its effects. Dosage must be titrated carefully in children, and they should be monitored closely for signs of toxicity.

Adverse Effects

Adverse effects are dose related and are signs of digoxin toxicity. Adverse effects occur in 5% to 20% of patients receiving digoxin, with between 1% and 4% experiencing serious reactions. The most common adverse effects are cardiac toxicity, followed by gastrointestinal (GI) disturbances and central nervous system (CNS) toxicity. The cardiac toxicities include bradycardia, AV block, complete heart block, ventricular tachycardia, premature ventricular contractions, ventricular fibrillation, paroxysmal and nonparoxysmal nodal rhythms, AV dissociation, accelerated junctional nodal rhythm, paroxysmal atrial tachycardia, and atrial fibrillation. Almost any type of arrhythmia can be stimulated by digoxin toxicity. It may seem paradoxical that digoxin slows the rate of the ventricles but can allow ventricular arrhythmias to occur. When digoxin slows down the normal pacemaker of the heart, ectopic pacemakers in the ventricle can take over, producing serious arrhythmias.

GI effects are anorexia, nausea, vomiting, diarrhea, and abdominal pain. CNS effects are headache, weakness, apathy, drowsiness, visual disturbances (e.g., blurred, yellow vision; halo effect in vision), confusion, restlessness, disorientation, seizures, electroencephalogram abnormalities, delirium, hallucinations, neuralgia, and psychosis.

When toxicity is suspected, an electrocardiogram (ECG) may help identify whether digoxin toxicity has occurred. Digoxin causes a normal slowing of heart rate, a narrower QRS complex, and a depressed T wave. However, toxicity results in a prolonged P-R interval and a shortened Q-T interval. In the event of toxicity, the drug must be discontinued until all signs of toxicity are gone. Occasionally, if severe arrhythmias have occurred, additional treatment may be necessary. Potassium chloride may be given to help correct the arrhythmia, especially if hypokalemia is present. It may be given orally or intravenously if the need is urgent. Women appear to achieve higher serum levels on the same dose compared with men, which may increase their risk for developing toxicity. Digoxin toxicity is usually associated with serum levels greater than 2 ng/mL; however, it can occur with lower serum levels if hypokalemia, hypomagnesemia, or hypothyroidism is also present. Evidence exists that higher doses of daily digoxin (>0.25 mg/d) or trough (the low point) serum levels greater than 1 ng/mL increase the risk of digoxin toxicity, including death. Digibind (digoxin immune Fab) is used as the antidote to digoxin toxicity.

Drug Interactions

Digoxin interacts with many drugs. The interactions usually relate to decreased or increased serum levels of digoxin or increased incidence of adverse effects, as can be seen in Table 29.2.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient has ventricular fibrillation, ventricular tachycardia, heart block, sick sinus syndrome, beriberi-associated heart disease, or hypersensitivity to digoxin, because these conditions are contraindications to its use. Obtain a baseline ECG for comparison in case digoxin toxicity is later suspected. Also, determine whether the patient is taking a drug that promotes the loss of potassium, such as a thiazide or loop diuretic, because hypokalemia increases the net effect of digoxin, placing the patient at increased risk for digoxin toxicity. Examine laboratory findings for indications of hypokalemia, hypomagnesemia, or hypercalcemia, all of which predispose to digoxin toxicity. Determine thyroid function, which can alter the dosage requirement of digoxin. In addition, determine whether the patient has renal impairment, because poor renal excretion may allow digoxin levels to build up to toxic levels.

TABLE 29.2 Agents That Interact with P Digoxin

Interactants	Effect and Significance	Nursing Management
amiodarone, anticholinergics, atorvastatin, beta blockers, benzodiazepines, calcium channel blockers, cimetidine, clarithromycin, cyclosporine, demeclocycline, diclofenac, diphenoxylate, dirithromycin, doxycycline, erythromycin, esomeprazole, etodolac, felodipine, flecainide, fluoxetine, frangula (buckthorn bark or berry), gatifloxacin, hydroxychloroquine, indomethacin, indecainide, itraconazole, lansoprazole, lenalidomide, lornoxicam, minocycline, neomycin, omeprazole, propafenone, propantheline, quinidine, quinine, quinupristin/dalfopristin, rifapentine, ritonavir, roxithromycin, simvastatin, telithromycin, tetracyclines, quercetin	Increased serum digoxin levels resulting from various mechanisms, such as altered GI flora, increased absorption, decreased clearance; may increase patient's risk for excessive levels and effects of digoxin	Monitor patient and blood tests for signs of digitalis toxicity.
activated charcoal, aminosalicylic acid, antacids, acarbose carbimazole, cholestyramine, colestipol, cyclophosphamide, kaolin/pectin, metoclopramide, penicillamine, rifampin, sucralfate, sulfasalazine, St. John's wort, vincristine	Decreased serum digitalis level, by various mechanisms, leads to decreased effectiveness.	Monitor patient to assess effects of drug therapy. Effect of digoxin may be reduced. Teach patient to take acarbose and digoxin daily at the same time interval to avoid fluctuations in digoxin levels after effective dose of digoxin is determined.
aloe, amphotericin B, thiazide and loop diuretics, cascara sagrada, ethacrynic acid, licorice, senna	Decreased potassium levels, which increase the risk for digoxin toxicity	
arbutamine	Altered heart rate from digoxin can lead to unreliable arbutamine test results.	
calcium IV	Additive or synergistic cardiac toxicity, resulting in arrhythmia and cardiovascular collapse	Avoid giving calcium IV if possible while patient is on digoxin. If calcium is needed in a digitalized patient, it should be infused over several hours or given orally.
canrenoate	Canrenoate displaces digoxin from the receptor sites, where digoxin exerts its therapeutic effect (Na-K-ATPase); enhances the cardiac contractility in digitalized patients	Monitor cardiac function closely in patients receiving both drugs.
carob seed powder	Increases digoxin concentrations by unknown mechanism, increasing risk of digoxin toxicity.	Teach patients to avoid use of carob seed flour.
chan su (an aphrodisiac), lily of the valley, oleander, pheasant's eye, sea cucumber	Additive digoxin effect increases risk of toxicity.	Teach to avoid concurrent use.
conivaptan	Decreased digoxin clearance by 30%, via unknown mechanism	Monitor digoxin concentrations when conivaptan is added to, changed during, or discontinued from concomitant treatment with digoxin. Also, monitor patients for signs and symptoms of digoxin toxicity. Adjust digoxin dose accordingly.
disopyramide	Altered pharmacologic effect of digoxin	Monitor for therapeutic effect of digoxin.
gossypol	Reduction of calcium release from the sarcoplasmic reticulum may decrease the effectiveness of digoxin or increase risk of digoxin toxicity	Teach patients to avoid coadministration.
khella	May antagonize the effects of digoxin, decreasing effectiveness	Teach patients to avoid coadministration.
kyushin (toad venom toxin)	Additive digoxin effects, increasing risk of toxicity	Teach patients to avoid coadministration.

TABLE 29.2 Agents That Interact with P Digoxin *(continued)*

Interactants	Effect and Significance	Nursing Management
nondepolarizing muscle relaxants and succinylcholine	Increased potential for toxic levels of either digoxin or interactant	Monitor patient and laboratory test values for signs of toxicities.
metformin	Reduced metformin clearance leading to increased metformin levels, possible hypoglycemia	Monitor serum levels if both are administered, and be alert for altered glucose levels.
mibefradil, nefazodone, rabeprazole, ranolazine, sitagliptin, telmisartan, trazodone, trimethoprim, valspodar	Significant increases in digoxin serum concentrations, by unknown mechanism, increase risk of digoxin toxicity.	Monitor serum digoxin levels and assess for signs of digoxin toxicity. An initial digoxin dose reduction of 50% is recommended when treatment with valspodar is started.
spironolactone	Increased or decreased serum digoxin level	Monitor patient, electrolyte levels, and laboratory values to detect signs of toxicities and decreasing therapeutic drug effects.
sympathomimetics	Enhanced pacemaker activity, leading to increased risk for cardiac arrhythmias	Monitor pulse for arrhythmias, and evaluate ECG as indicated.
tramadol	Increased risk of digoxin toxicity, by unknown mechanism	Monitor serum digoxin levels.
antithyroid hormones	Increased serum levels of digoxin when patient first becomes euthyroid	Monitor digoxin levels when drug is first introduced.

Patients with renal impairment may require a lower dose of digoxin. Assess the patient's weight before beginning digoxin therapy, because along with renal function, weight is considered in determining dosage. Serum concentrations are not affected by large changes in fat tissue weight; therefore, to prevent potential overdose, calculate and use the obese patient's ideal body weight, instead of true weight, to determine proper dosage. Assess the patient for depression, as multiple studies have indicated that symptoms of depression in patients with HF is reported in 14% to 60% of the adults with HF (Delville & McDougall, 2008; see also the Focus on Research Box 29.2).

Life Span and Gender

Determine whether the patient is pregnant. Digoxin is administered with caution during pregnancy because 50% to 83% of the maternal serum concentration of digoxin affects the fetus. Also, determine whether the patient is breast-feeding because safety in infants has not been established. Carefully monitor women receiving digoxin because they may be at increased risk for toxicity.

Accidental poisoning of children in the home is common with digoxin. In these cases, digoxin usually had been prescribed for a parent or grandparent, not for a child.

Elderly patients must be given digoxin carefully because they tend to have low body mass and decreased renal functioning, making them more prone to adverse effects of the drug. A lower maintenance dosage (0.125 to 0.25 mg/d) should be used. Noncardiac signs of digoxin toxicity may be difficult to identify in older adults because the signs are often vague. Also, the older adult may be confused because of adverse effects from other drug therapies or the confusion may be mistakenly believed to be caused by changes from aging. Additionally, some of the signs, such as nausea and weakness, can also occur with uncontrolled CHF.

Lifestyle, Diet, and Habits

Determine the patient's normal dietary intake of potassium, calcium, and magnesium because intake may have a bearing on the serum levels of these electrolytes. Low serum levels of potassium or magnesium increase the risk of toxicity, whereas low calcium decreases the effectiveness of digoxin.

Alternative medicines are a consideration with digoxin use. St. John's wort, an herbal preparation, should not be started after digoxin therapy is begun because it has been known to reduce the serum level of digoxin by about 25% and to decrease therapeutic activity. Patients already using St. John's wort who stop using it after digoxin therapy has been regulated are at risk for having adverse effects from the higher serum levels of digoxin.. Other complementary medicines can trigger digoxin toxicity. These substances include strophanthus and oleander, which contain cardiac glycosides. Senna and cascara may increase potassium loss, leading to digoxin toxicity (see Table 29.2).

Environment

Be aware of the environment in which digoxin will be administered. Digitalization of a patient most often occurs in the hospital where the patient can be monitored closely for adverse effects. In addition, intravenous (IV) doses of

BOX 29.2 FOCUS ON RESEARCH

Which patients are more likely to be involved in managing their Chronic Heart Failure?
Schnell-Hoehn, K., Naimark, B. J., Tate, R. B. (2009). Determinants of Self-care Behaviors in Community-Dwelling Patients with Heart Failure. *The Journal of Cardiovascular Nursing,* 24(1):40–47.

The Study

A convenience sample of 65 patients, 50 men and 15 women, ages 21 to 88 with HF were studied to determine what factors influenced their likelihood of engaging in the self-care strategies needed to manage their heart failure. Study participants were administered the Self-care of Heart Failure Index (SCHFI)-research version 3-22-01. This tool has 22 items with three subscales: self-care maintenance, self-confidence, and self-care management. The self-care maintenance subscale measures a person's ability to adopt seven therapeutic self-care behaviors: (1) weighing oneself daily; (2) keeping daily dietary salt intake less than 2 to 3 g; (3) exercising at least 3 times weekly; (4) taking medications as prescribed; (5) keeping within 10% of ideal weight; (6) seeking physician guidance; and (7) obtaining annual immunizations. The self-confidence subscale assesses the participant's belief of how effective they can be at performing self-care to manage their HF. The self-care management subscale measures the person's ability to recognize HF symptoms in themselves and implement self-therapy. Each subscale is scored out of 100, where a higher score indicates better self-care ability in that area. Patients were also assessed for the presence of anxiety or depressions with the General Well-being schedule designed for community-dwelling individuals; this 18-item scale measures 6 areas of mental well-being: anxiety, depresson, self-control, positive well-being, vitality, and general health. Participants were also assessed for the number and type of comorbdities they possessed.

The findings showed that the most common self-care behavior self reported by the participants was taking medications as ordered. The behaveiors of seeking advice from health care providers and following a low-sodium diet were the next most frequently reported self- care items. Participating in regular exercise was the least self reported self-care activity; almost half of the participants reported difficulty meeting the recommendations for exercise. Neither age, marital status, sex, educational level, or socioeconomic status of the participant correlated to their self-care practices. Participants with five or more co-morbidities were less likely to participate in self-care activities. High levels of anxiety and stress were also found to decrease the amount of self-care that participants reported, compared to those with more positive feelings. Those participants who reported higher levels of self confidence in managing their HF were more likely to engage in self-care activities, and those with more confidence in recognizing symptoms of HF in themselves were significantly less likely to be admitted to the hospital. Thus, the authors concluded that "those with confidence in their abilities to manage self-care will likely achieve better symptom management."

Nursing Implications

Understanding that patients with HF are more likely to effectively self manage their disease if they feel confident in their knowledge of HF and can recognize symptoms of exacerbation is important for nurses working with this population. Nurses can focus their patient education to help provide this foundation. Additionally, nurses need to evaluate the effectiveness of their teaching to confirm that patients feel confident in their abilities before discharge. As patients with multiple co-morbidities are less likely to engage in self-care activities, nurses need to recognize these patients as being at high risk of recurrent hospitalization and disease progression from HF. Again, these patients need additional help in understanding what can be a complex pharmaceutical and medical management of their HF and co-morbidities so that they can develop feelings of confidence in their abilities for self-care. Finally, as patients with high anxiety and depression are less likely to engage in needed self-care activities to manage their HF, nurses should assess for these problems and, if identified, consult with the physicians for additional help for those patients.

digoxin are administered in the hospital. Once the patient is stabilized and on a PO maintenance dose, administration of digoxin may be performed in any setting, including self-administration at home.

Nursing Diagnoses and Outcomes

Decreased Cardiac Output related to altered cardiac function
Desired outcome: *The patient's CHF will be well controlled.*
Risk for Injury related to drowsiness, confusion, disorientation, seizures, delirium, hallucinations, and psychosis secondary to adverse effects of drug therapy
Desired outcome: *The patient will not sustain an injury related to adverse drug events while on drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

To achieve rapid onset of therapeutic effects, the patient is digitalized with an IV or PO loading dose. Roughly half the loading dose is given in the first increment, and the remainder is given in divided doses at appropriate intervals. Assess for therapeutic and adverse effects before each dose.

Minimizing Adverse Effects

Digoxin has a narrow therapeutic index, which means that there is not much difference between the dosage needed to produce therapeutic effects and the dosage that produces toxic effects. It is important to monitor the serum levels of digoxin to help prevent serious drug toxicity. The safe therapeutic serum level is 0.5 to 2.0 ng/mL (some sources now state that the upper limit is 0.8 ng/mL). Unfortunately, some patients exhibit signs of digoxin toxicity even when their serum levels are within a "normal" range. Therefore, it is important to monitor for signs of digoxin toxicity. Box 29.3 provides guidelines for minimizing adverse effects of digoxin toxicity.

Providing Patient and Family Education

Explain the reason for taking digoxin and the adverse effects of the drug.
Teach patients how to check their own radial or carotid pulse. Instruct them to take the pulse for a full minute before taking digoxin. If the pulse is below 60 bpm (or another parameter set by the prescriber for the patient), patients should not take the drug without consulting with the prescriber.

Box 29.3 MINIMIZING ADVERSE EFFECTS FROM DIGOXIN TOXICITY

Monitor serum digoxin levels

- Measure levels at least 8 hours following the last oral dose and preferably 24 hours after the last dose if the patient is receiving maintenance therapy. Following this procedure will prevent reading falsely elevated digoxin blood levels.
- Monitor most closely when digoxin is first started, when the dose is changed, or when the patient has signs of toxicity.
- Periodic monitoring is needed when digoxin is used in long-term maintenance. The frequency of monitoring is based on patient response to drug therapy.

Assess for bradycardia

- Take the patient's apical pulse for 1 full minute to determine heart rate accurately before administering each dose of digoxin. If the pulse is below 60 beats/min, do not administer the dose without approval from the health care provider.

Correct electrolyte imbalances

- Monitor for low levels of potassium and magnesium and high levels of calcium, because these altered levels place the patient at risk of developing digoxin toxicity.
- If potassium and magnesium levels are low, seek an order for replacement of the electrolytes.
- Electrolytes should not be administered rapidly. Calcium and potassium, especially, may bring on serious arrhythmias when administered by IV.
- Encourage the patient to follow a diet of potassium-rich foods while taking digoxin to prevent hypokalemia and digoxin toxicity. However, potassium intake should just be normal if the patient is on a potassium-sparing diuretic, ACE inhibitor, or potassium chloride supplement.

Assess for other symptoms of digoxin toxicity

- Monitor for anorexia, nausea, vomiting, diarrhea, headache, blurred vision, confusion, and drowsiness.
- Anorexia, nausea, vomiting, and diarrhea may also be evident when CHF is uncontrolled. This makes the assessment for digoxin toxicity more difficult.

Treatment of digoxin-induced arrhythmias

- Oral or slow IV potassium often is used as a treatment. IV doses are for more urgent problems.
  - Divided oral doses for adults should total 3 to 6 g (40 to 80 mEq), as long as normal renal function exists.
  - When given to adults by IV, 40 to 80 mEq is diluted in 5% dextrose and water (D_5W) to a concentration not greater than 40 mEq/100 mL. The drug should be administered at a rate not exceeding 20 mEq/h and more slowly if the patient reports pain at the catheter insertion site.
  - For children, oral doses totaling 1 to 1.5 mEq/kg or about 0.5 mEq/kg/h IV are given, with careful ECG monitoring.
  - The ECG should be monitored for potassium toxicity (peaking of T waves). If the arrhythmia is corrected, the infusion should be stopped.
  - Potassium should not be used when renal failure exists or when complete heart block is secondary to digoxin toxicity and not related to tachycardia.
- Phenytoin, an antiepileptic, may be used to treat atrial and ventricular arrhythmias.
  - Give 50 to 100 mg of phenytoin every 5 minutes. Total dose should not exceed 600 mg.
  - Phenytoin is used when potassium is *not* effective.
- Lidocaine, an antiarrhythmic, is used to treat ventricular arrhythmias.
  - Give IV for a dose of 1 mg/kg over 5 minutes, then 15 to 50 mcg/kg/min to maintain rhythm.
  - Lidocaine is used when potassium is not effective.
- Atropine, an anticholinergic, may be used symptomatically to treat severe sinus bradycardia or slow ventricular rate due to secondary AV block.
  - Give 0.01 mg/kg IV.
- Cholestyramine, colestipol (both are antilipids), or activated charcoal may be used to bind with digoxin in the intestine and prevent enterohepatic recirculation.

Use of the digoxin antidote

- The drug digoxin immune Fab (Digibind) is considered the antidote to digoxin. This drug, used to treat potentially life-threatening toxicity, is given at approximately the same dosage as the digoxin in the patient's body. It combines with digoxin to make it unable to bind at its receptor site, therefore inactivating it.
- Improvement generally begins within 30 minutes of IV administration.
- Give digoxin immune Fab over 15 to 30 minutes through a 0.22-mm filter, although it may be given as a bolus when cardiac arrest is imminent. This may be given to children or adults.
- Serum digoxin levels will remain high after administration of digoxin immune Fab. Therefore, serum digoxin levels should not be used as a guideline for the antidote's effectiveness. Instead, the nurse should evaluate the patient's response to determine the antidote's effectiveness.

Miscellaneous

- Avoid administration of IM digoxin because it causes site pain.

Caution patients not to discontinue digoxin without approval from the prescriber.

Tell patients to avoid over-the-counter antacids and cough, cold, allergy, and diet drugs, except on the advice of the prescriber, because these drugs frequently contain antihistamines that may interact with digoxin.

Explain the importance of notifying the prescriber if any of the following occur while taking digoxin: loss of appetite, nausea, vomiting, diarrhea, stomach pain, unusual tiredness or weakness, drowsiness, headache, blurred or yellow vision, skin rash or hives, or mental depression.

It is important to instruct patients to return for requested laboratory work to check the serum digoxin level and electrolyte levels.

Caution patients to keep digoxin out of the reach of children (Box 29.4).

BOX 29.4 COMMUNITY BASED CONCERNS

Prevention of Digoxin Poisoning

Digoxin can cause fatal effects if taken accidentally by children. Adults prescribed digoxin should be aware of these risks and take the following precautions in their homes:

- Store digoxin out of the reach of children.
- Have a child-safety cap placed on the medication container.
- Do not leave loose pills out where children can see them.
- Do not tell children that digoxin is "candy."

Ongoing Assessment and Evaluation

Monitor the patient's pulse rate throughout therapy. Assess serum digoxin levels after the drug is first started and has reached a steady state, at each dosage change, and whenever signs of digoxin toxicity are present. Renal function is monitored periodically throughout therapy by measuring BUN, creatinine, and electrolyte levels (potassium, calcium, and magnesium). Again, blood work needs to be monitored when digoxin is first started; recurrent blood work will be done based on the individual's response to therapy.

Symptoms of CHF should improve, and the patient should have increased urinary output, less edema, less shortness of breath, and fewer rales. When digoxin is given for atrial fibrillation, the arrhythmia should be corrected. Assess for development of arrhythmias. Development of arrhythmias may be a sign of digoxin toxicity. When the patient's CHF or arrhythmia is controlled without injury to the patient from adverse effects or toxicity, the drug therapy is considered effective.

Drugs Significantly Different From P Digoxin

Vasodilator–Antianginal Combinations

Like digoxin, the new drug combination hydralazine–isosorbide (BiDil) has been found to prolong time to hospitalization for heart failure and to improve functional status. Unlike digoxin, it has also been found to improve survival. Vasodilators are occasionally used as adjuncts to CHF therapy. Hydralazine, a peripheral vasodilator and antihypertensive, relaxes arteries only. Nitrates provide coronary dilation that would be helpful to the patient with CHF; however, tolerance develops to nitrates when they are used continually. Isosorbide, an antianginal drug that dilates veins and arteries, apparently by releasing nitric oxide at the blood vessel wall, is a nitrate like nitroglycerine. Hydralazine–isosorbide provides the benefit of both of these therapies while avoiding the tolerance that can occur when isosorbide is used alone. How the two drugs work together is not known. Hydralazine–isosorbide is used as an adjunct to CHF drug therapy in black patients.

MEMORY CHIP

P Digoxin

- Used in treating CHF and atrial fibrillation
- Direct effect is to strengthen force of cardiac contraction (positive inotropic effect).
- Indirect effect is to depress the SA node and slow conduction to the AV node (negative dromotropic effect), thus slowing heart rate (negative chronotropic effect).
- Can cause the same arrhythmias it is used to treat
- Antidote for digoxin overdose is digoxin immune Fab.
- Major contraindications: heart block, ventricular fibrillation, certain cases of ventricular tachycardia, some cases of sick sinus syndrome, and digitalis toxicity
- Most common adverse effects: cardiac toxicity; hypokalemia, hypomagnesemia, and hypercalcemia increase the risk of toxicity
- Most serious adverse effect: ventricular fibrillation
- **Life span alert: Older adults tend to have increased risk for adverse effects due to decreased renal function. Children are often poisoned accidentally by digoxin.**
- Maximizing therapeutic effects: Achieve rapid onset of therapeutic effects with a loading dose ("digitalization").
- Minimizing adverse effects: Monitor serum digoxin levels, assess for bradycardia (take apical pulse for 1 minute before giving drug), monitor and correct electrolyte imbalances, and assess for noncardiac signs of digoxin toxicity.
- Most important patient education: Teach how to take pulse and to avoid taking the dose if pulse is below 60; keep digoxin out of the reach of children.

What truly sets hydralazine–isosorbide apart is that it is the first drug specifically labeled to be used to treat patients of a particular race. Initial clinical trials examining the effects of hydralazine–isosorbide in a general population (mixed races) with CHF found the drug noneffective, but retrospective analysis indicated that there was a positive benefit in the subgroup of patients who were black, indicating an apparent inherited response due to race to this combination therapy. An additional study of 1,050 self-identified black patients with stable symptomatic heart failure (more than 95% of them were NYHA class III) found a significant benefit from adding hydralazine–isosorbide to their standardized therapy. Those treated with hydralazine–isosorbide showed a 43% decrease in mortality and a 39% decrease in risk of first hospitalization for CHF. Blood pressure measurement also averaged 3/3 mm Hg lower than for patients who did not receive hydralazine–isosorbide in the study. Because most people with CHF have hypertension, this is an additional, although modest, benefit.

Major adverse effects from hydralazine–isosorbide are related to its arterial and venous dilatory effects. Patients are at increased risk of hypotension, especially if they are currently taking hypertensive drugs. Those who receive any potent parenteral antihypertensive require several hours of

close monitoring, because significant hypotension may occur. A common adverse effect is headache, especially when starting to take the drug; this is usually transient and resolves with continued dosing. Light-headedness with standing is also possible, especially after standing from a seated or lying position. Patients should be taught to arise slowly to help prevent this. Patients should also remain well hydrated to help prevent hypotension and light-headedness. Patients should be cautioned about conditions that decrease fluid volume levels, such as vomiting, diarrhea, or excessive perspiration, and encourage them to drink extra fluids during these periods. Men should not take erectile dysfunction drugs that are phosphodiesterase-5 inhibitors, such as sildenafil, vardenafil, or tadalafil, because these drugs also produce vasodilation. Concurrent use of any of these agents in combination with hydralazine–isosorbide could produce an extreme drop in blood pressure significant enough to induce fainting, chest pain, or an MI. Because of a drug interaction, concurrent use of hydralazine–isosorbide with any monoamine-oxidase inhibitor may produce hypotension and should also be avoided.

Information related to each component of hydralazine–isosorbide is also relevant to use of this combination product. For more information on hydralazine, see Chapter 28. For more information on isosorbide, see Chapter 30.

NATRIURETIC PEPTIDES

The natriuretic peptide is a new class of drugs used to treat CHF. Nesiritide (Natrecor), which is the only drug in the class, is the prototype.

Nursing Management of the Patient Receiving Nesiritide

Core Drug Knowledge

Pharmacotherapeutics

Nesiritide is labeled for use in adults with acute, decompensated HF (congestive variety). It is used when some resistance to diuretics has occurred. Nesiritide has not been found to increase urinary output or sodium loss when used alone (Sica, Oren, Gottwald, et al., 2010). It is not used in chronic HF, although this use is being studied. Potential off-label uses include, cor pulmonale, hypertension, and diagnosis of MI, although there is inconclusive evidence that nesiritide is effective as treatment for any of these conditions (Table 29.1).

Pharmacokinetics

Onset of action of nesiritide is fairly rapid. Hemodynamic improvement is seen within 15 to 30 minutes, and peak hemodynamic improvement is within 1 hour of IV infusion. An IV bolus is generally used initially. The other effects of nesiritide take slightly longer to be evident: plasma aldosterone reduction takes 15 to 60 minutes, whereas diuresis and natriureses take 30 to 60 minutes after starting an infusion. The decrease in dyspnea is evident in 3 hours. Nesiritide is eliminated in the kidney, where it binds to special cell surface–clearing receptors and is then internalized into the cell and broken down. Two other processes are involved in the elimination of nesiritide, although they play less of a role than the cell surface–clearing receptors. The first is that a special enzyme, called an endopeptidase, found within the blood vessels breaks apart the peptide (a process called proteolytic cleavage). The second is renal filtration.

Pharmacodynamics

Nesiritide stimulates natriuretic peptide A/B receptors, promoting smooth-muscle cell relaxation and dilation of veins and arteries. This results in reduced pulmonary capillary wedge pressure, decreased vascular resistance, and decreased dyspnea and fatigue in patients with acute decompensated congestive heart failure. A recent review of the literature shows conflicting date as to whether nesiritide improves quality of life (Dontas, Xanthos, Dontas, et al., 2009).

Contraindications and Precautions

Nesiritide should not be used as the primary therapy to treat cardiogenic shock. It is contraindicated if there is hypersensitivity to nesiritide or if the systolic blood pressure is less than 90 mm Hg. Caution should also be used if any of these cardiovascular conditions are present: atrial arrhythmias, ventricular arrhythmias, or conduction defects; constrictive pericarditis; hypotension; pericardial tamponade; restrictive or obstructive cardiomyopathy; significant valvular stenosis; or suspected low cardiac filling pressures. Nesiritide should be used with caution in hepatic or renal insufficiency. Nesiritide is a pregnancy category C drug.

Adverse Effects

The most common adverse effect of nesiritide is hypotension, which occurs in 11% to 35% of patients. The effect on blood pressure is dose related. Hypotension may be significant enough that therapy needs to be discontinued. Less common adverse effects include headache and nausea. Other adverse effects include injection site reactions, rash, sweating, itching, leg cramps, anemia, confusion, light-headedness, dimmed vision, increased creatinine levels, cough, apnea, and hemoptysis.

The most serious adverse effects are all cardiac. They are ventricular tachycardia, atrial fibrillation, atrial-ventricular node conduction abnormalities, bradycardia, and angina. These cardiac abnormalities occur in about 1% of the patients. Some research indicates that an increased risk of mortality from renal impairment may accompany nesiritide use, and that it should be used after other therapies have failed (Sackner-Bernstein, Kowalski, Fox, et al., 2005). Yet other research finds that most clinical trials have not found nesiritide to decrease renal function or increase mortality

TABLE 29.3 Agents That Interact with P Nesiritide

Interactants	Effect and Significance	Nursing Management
ACE inhibitors	Increase in symptomatic hypotension due to an additive hypotensive response	Monitor blood pressure.
arsenic trioxide	Likely to induce hypokalemia or hypomagnesemia, increasing the risk of QT prolongation	Administer with extreme caution if they must be coadministered. Monitor ECG closely for QR changes; monitor serum potassium and magnesium levels.
heparin and heparin-coated central line catheters	Binds with heparin, decreasing amount of nesiritide delivered	Administer through a non–heparin-coated catheter. Administer heparin infusions via unique IV catheter if coadministration needed.
insulin, ethacrynate sodium, bumetanide, enalaprilat, hydralazine, furosemide, sodium metabisulfite (a preservative)	Physically or chemically incompatible if coadministered through same IV catheter	Administer these drugs through a separate IV catheter from that for nesiritide.

(Dontas, Xanthos, Dontas, et al., 2009). More research is needed to understand the adverse effects from nesiritide in relation to this drug's place in therapy.

Drug Interactions

Nesiritide is known to interact with some drugs (Table 29.3).

Assessment of Relevant Core Patient Variables

Health Status

Determine that patients are experiencing decompensated HF prior to starting nesiritide therapy. Assess their clinical symptoms of HF (e.g., shortness of breath). In addition, determine the patients' baseline hemodynamic measurements (e.g., pulmonary capillary wedge pressure, pulmonary arterial pressure, cardiac output), their baseline blood pressure and heart rate, and their baseline plasma brain natriuretic peptide concentrations and plasma aldosterone levels. Determine whether patients may have cirrhosis with ascites, because they may experience a significant blunting of hemodynamic/natriuretic response from nesiritide, possibly requiring a larger dose.

Life Span and Gender

Nesiritide is approved for use in adults. Determine the patient's age. In one open-label, retrospective study, nesiritide was well-tolerated in children with HF who were already receiving inotropic and diuretic therapy; it was associated with improved natriuresis and diuresis (Mahle, Cuadrado, Kirshbom, et al., 2005). Assess whether the patient could be pregnant or breast-feeding, as there is little clinical experience for using the drug under these conditions. It is not known whether nesiritide is excreted into breast milk, but risk to the infant cannot be ruled out.

Environment

Significant ECG or rhythm changes can occur from nesiritide therapy. Therefore, administer the drug only where patients can receive continuous cardiac monitoring, such as in an intensive care or cardiac care unit.

Nursing Diagnosis and Outcome

Decreased Cardiac Output related to altered stroke volume
Desired outcome: Drug *therapy with nesiritide will increase cardiac output*.

Maximizing Therapeutic Effects

Nesiritide must be reconstituted and then further diluted for infusion. Reconstitute one vial by adding 5 mL of diluent, which has been removed from a 250-mL plastic IV bag containing either 5% dextrose injection, 0.9% sodium chloride injection, 5% dextrose and 0.45% sodium chloride injection, or 5% dextrose and 0.2% sodium chloride. Do NOT shake the vial. Rock the vial gently so that all surfaces, including the stopper, are in contact with the diluent. When diluted, the solution should appear clear and essentially colorless. Add the entire contents of the reconstituted vial back to the 250-mL plastic IV bag, and invert the bag several times to ensure complete mixing. The resulting solution has a nesiritide concentration of approximately 6 mcg/mL.

Use the reconstituted nesiritide solution within 24 hours. The initial IV bolus must be drawn from the prepared infusion bag and administered over approximately 60 seconds through an IV port. Use an IV infusion pump to administer the infusion. Calculate the correct rate of infusion based on the patient's weight in kilograms and follow the guidelines for infusion that come with the medication.

Minimizing Adverse Effects

Monitor the patient's cardiac response to nesiritide therapy by keeping the patient on a continuous cardiac monitor during therapy. Assess for changes in QT intervals or for serious rhythm changes. Asses for renal changes. Stop the therapy if serious changes occur and notify the physician. Monitor the patient's blood pressure and pulse; if hypotension or bradycardia develops, slow the infusion rate or stop the infusion altogether. Nesiritide has a longer half-life than other drugs used to treat decompensated HF; thus, it is important not to increase the rate of infusion more frequently than every 3 hours, as needed (unlike

other drugs, for which frequent titrations are common). Do not exceed the recommended dose, because this is likely to cause serious adverse effects.

Providing Patient and Family Education

Teach patients and families the purpose of nesiritide therapy and the rationale for frequent hemodynamic measurements and vital sign assessment.

Instruct patients to notify a nurse if the IV insertion site becomes sore or itches.

Ongoing Assessment and Evaluation

Monitor plasma brain natriuretic peptide concentrations and plasma aldosterone levels, both of which should decrease in response to the drug. Assess for improvement of clinical symptoms such as decreased shortness of breath and fatigue. In addition, monitor for signs of improvement in CHF by assessing hemodynamic measures (pulmonary artery wedge pressure, pulmonary arterial pressure, cardiac output). Monitor blood pressure and pulse throughout therapy. Nesiritide therapy is considered effective if the symptoms of CHF are controlled and the patient does not experience significant adverse effects.

Drugs Significantly Different From P Nesiritide

Inamrinone

Inamrinone (Inocor) was previously known as amrinone. The name was officially changed in the United States by the *U.S. Pharmacopeia* (USP) and the United States Adopted Names Council in July 2000 because of several drug errors that occurred when the drug was confused with a similar sounding drug, amiodarone, which is an antiarrhythmic. This name change has not yet been adopted internationally. The International Nonproprietary Name (INN) is still amrinone. If this drug is purchased from a source outside of the United States, the label lists the ingredient as amrinone, not inamrinone. United States health care workers need to be very careful if faced with this situation to prevent making a drug error.

Like nesiritide, inamrinone is used in treating CHF. However, it is used only for short-term management of those patients who have not responded positively to treatment with digoxin, diuretics, and vasodilators. Unlike nesiritide, inamrinone is *not* a natriuretic peptide. Inamrinone has a positive inotropic effect like that of digoxin but a vasodilatory effect similar to that of nesiritide. However, inamrinone has a different structure and mode of action from nesiritide. Its mechanism of action is believed to be related to its ability to inhibit phosphodiesterase, which inactivates cyclic adenosine monophosphate (cyclic AMP) and alters calcium, resulting in the contraction of myocardial muscle cells. Afterload and preload are reduced by the direct relaxant effect of inamrinone on the vascular smooth muscle, creating vasodilation. These effects produce a prompt increase in cardiac output from the failing heart.

Like nesiritide, inamrinone is administered by IV infusion. The peak of action occurs within 10 minutes; duration of action varies with the size of the dose. Duration of action is about 2 hours when larger doses are given. The main route of elimination is in urine.

Some of the adverse effects of inamrinone are similar to those seen with nesiritide. Although hypotension and nausea can occur, they are not seen as frequently. Unlike nesiritide, inamrinone can also cause abdominal pain, diarrhea, loss of appetite, vomiting, and elevation of body temperature. Serious cardiac arrhythmias are possible and more likely than with nesiritide. In addition, inamrinone may cause two serious adverse effects—thrombocytopenia and hepatotoxicity. Thrombocytopenia occurs in about 2.5% of patients receiving the drug, although it is more common in patients receiving prolonged therapy. Hepatotoxicity is rare. Thrombocytopenia and hepatotoxicity may be fatal, which is why the drug is not considered first-line therapy and is limited to short-term use.

Milrinone

Milrinone (Primacor) is also used to treat CHF. It is indicated for short-term IV use in patients already receiving digoxin and diuretics. Unlike nesiritide, it is not a natriuretic peptide. Although it is not a cardiac glycoside it increases the force of contraction similarly to digoxin. Like nesiritide, milrinone is a vasodilator, although it works in the same way as inamrinone; it inhibits phosphodiesterase, which inactivates cyclic AMP and alters calcium, resulting in the contraction

MEMORY CHIP

P Nesiritide

- Used in the treatment of adults with acute, decompensated HF (congestive type)
- Administered by IV bolus and infusion
- Stimulates natriuretic peptide A/B receptors, promoting smooth-muscle cell relaxation and dilation of veins and arteries, resulting in reduced pulmonary capillary wedge pressure, decreased vascular resistance, and decreased dyspnea and fatigue
- Major contraindication: Avoid use as the primary therapy for cardiogenic shock.
- Most common adverse effect: hypotension
- Most serious adverse effects: cardiac arrhythmias (ventricular tachycardia, atrial fibrillation, AV node conduction abnormalities, bradycardia) and angina
- Maximizing therapeutic effect: Reconstitute via label instructions; use an infusion pump to administer.
- Minimizing adverse effects: Administer only if the patient can receive continuous cardiac monitoring (e.g., in ICU, CCU); monitor for ECG changes; monitor pulse and BP closely and slow or stop drug if bradycardia or hypotension occurs; avoid increasing infusion rate more frequently than every 3 hours.
- Most important patient education: Notify nurse if IV site becomes sore or itches.

of myocardial muscle cells. Milrinone also has vasodilating effects. In addition to improving cardiac contractility, milrinone improves left ventricular diastolic relaxation. Milrinone produces a prompt increase in cardiac output and decreases pulmonary capillary wedge pressure and vascular resistance similar to nesiritide.

Like nesiritide, milrinone can have the adverse effect of hypotension or headache, although not as frequently. Serious ventricular arrhythmias are possible; this is the most common adverse effect of milrinone, occurring in about 12% of patients (much more often than with nesiritide). Milrinone can also cause thrombocytopenia, but much less frequently than inamrinone, and rarely hepatotoxicity. These serious and potentially fatal adverse effects limit the usefulness of milrinone in CHF therapy.

CHAPTER SUMMARY

- Heart failure (HF) occurs when the heart is unable to effectively contract and pump out the volume of blood in the left ventricle. The defining symptoms of heart failure are dyspnea (including rales, rhonchi, and shortness of breath), fatigue (which may limit exercise tolerance), as well as fluid retention.
- Chronic heart failure (CHF) is treated with combinations of drug therapy. Primary drug therapy includes the use of an ACE inhibitor, a beta blocker, and a diuretic. An ARB may be used if the patient cannot tolerate therapy with and ACE inhibitor. Digoxin may also be added.
- The combination of an ACE inhibitor and a diuretic has been shown to decrease mortality from CHF. The addition of a beta blocker also has been shown to decrease mortality. Digoxin does not decrease mortality from CHF, but it decreases symptoms and improves exercise tolerance, thereby improving the quality of life.
- Digoxin strengthens the force of contraction of the heart (positive inotropic effect), prolongs conduction to the AV node (negative dromotropic effect), and slows the heart rate (negative chronotropic effect).
- Adverse effects of digoxin are dose-related and are signs of digoxin toxicity. The most common adverse effects are cardiac toxicity, GI disturbances, and CNS toxicity.
- A low potassium level, low magnesium level, or high calcium level potentiates the effect of digoxin, and digoxin toxicity may occur. This effect can occur even if the serum level of digoxin is in "normal" range.
- Bradycardia is a clinical sign of excessive digoxin. Always check an apical pulse for 1 full minute to detect for bradycardia before administering digoxin. Notify the physician and do not give the drug if the pulse is less than 60 bpm, unless approved by the physician.
- Digoxin can be used to treat an arrhythmia, but it also may cause an arrhythmia.
- Nesiritide stimulates natriuretic peptide A/B receptors, promoting smooth-muscle cell relaxation, and dilation of veins and arteries. This results in reduced pulmonary capillary wedge pressure, decreased vascular resistance, and decreased dyspnea and fatigue in patients with acute decompensated congestive heart failure when given intravenously. It is not used in CHF.

QUESTIONS FOR STUDY AND REVIEW

1. What are digoxin's primary effects on the heart?
2. Which classes of drugs used in treating HF decrease mortality? Which class decreases only morbidity (severity of symptoms and risk for hospitalization)?
3. What effect may occur if digoxin is given to someone with decreased renal function? What actions could be taken to minimize this effect?
4. How do beta blockers such as carvedilol or metoprolol assist patients with CHF?

Drugs Treating Angina

Learning Objectives

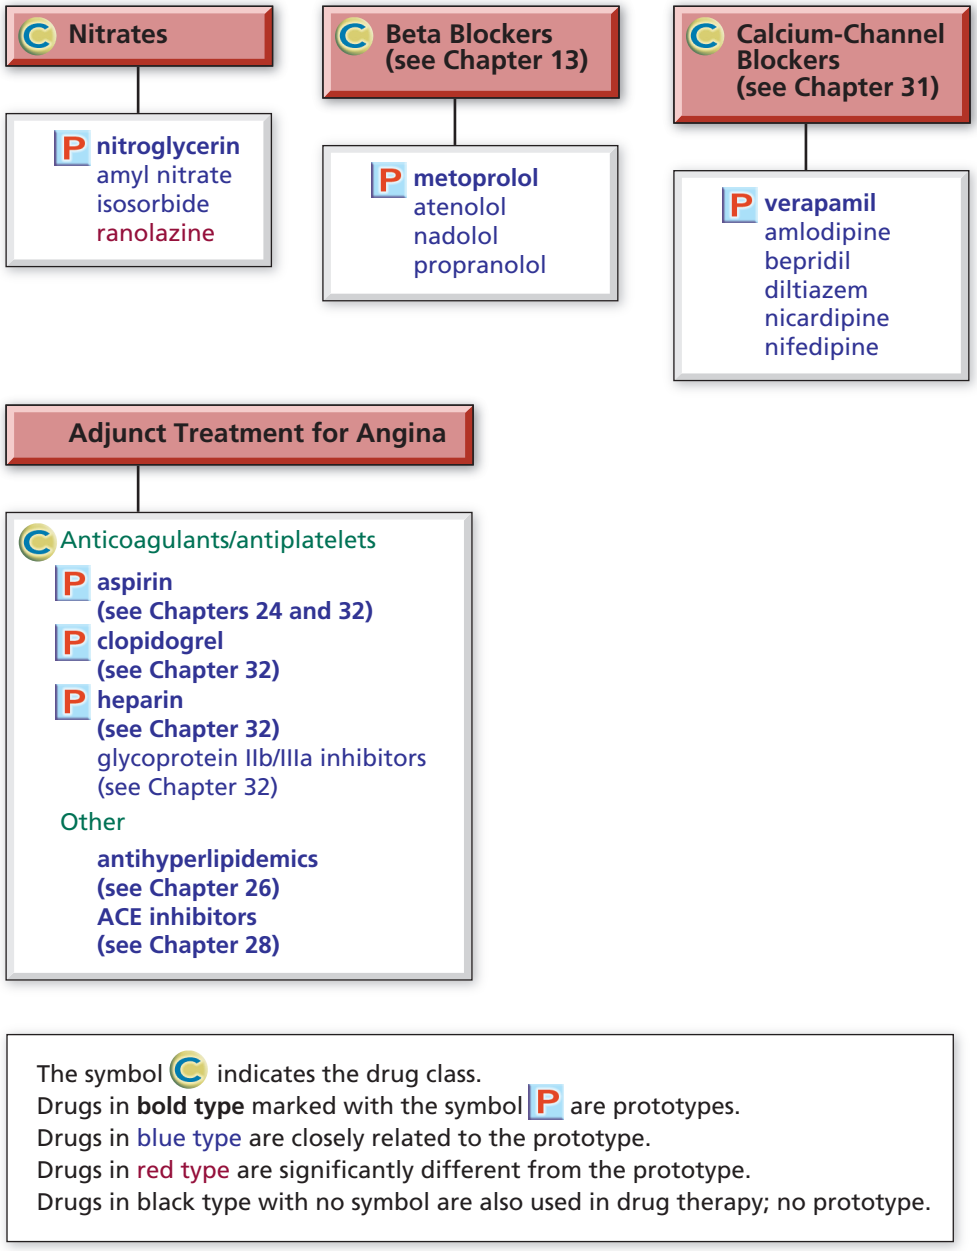
At the completion of this chapter the student will:

1. Differentiate drug therapy for chronic stable angina from unstable angina.
2. Identify core drug knowledge about drugs used to treat angina.
3. Identify core patient variables relevant to drugs used to treat angina.
4. Relate the interaction of core drug knowledge to core patient variables for drugs used to treat angina.
5. Generate a nursing plan of care based on interactions between core drug knowledge and core patient variables for drugs used to treat angina.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs used to treat angina.
7. Determine key points for patient and family education for drugs used to treat angina.

Key Terms

acute coronary syndrome
angina
microvascular angina
myocardial infarction
Prinzmetal angina
stable angina
unstable angina
variant angina

Drugs Treating Angina



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Angina is pain in the chest that occurs because the heart muscle is not receiving enough oxygen. Drug therapy to treat angina allows more oxygen to be delivered to the heart or decreases the oxygen needs of the heart, or both, which stops the pain. This chapter discusses the three main drug therapies used in angina—beta blockers, calcium channel blockers, and nitrates. Because the prototypes for beta blockers and calcium channel blockers are presented in Chapters 13 and 26, respectively, only the nitrates are presented in this chapter. The prototype nitrate is nitroglycerin.

PHYSIOLOGY

The heart is a muscle in the chest that pumps oxygenated blood to the organs, muscles, tissues, and cells of the body. The heart itself requires oxygen delivered to its cells. The coronary arteries deliver oxygenated blood to the heart. Oxygen requirements of the heart increase as the heart pumps faster and works harder. Oxygen demands of the heart also increase if the heart has to overcome a greater peripheral resistance in the vessels to eject blood from the left ventricle.

PATHOPHYSIOLOGY

When the oxygen requirements of the heart are greater than the supply of oxygen it is getting, the heart muscle becomes ischemic. The oxygen imbalance may be from a reduced coronary blood flow or from a need for increased oxygen. Ischemia of the heart muscle will produce symptoms of chest pain in the patient. Chest pain that results from ischemia is termed **angina.** Angina is usually intermittent and substernal, although the pain may radiate elsewhere, often to the left arm or left shoulder. The pain is usually described as pressure on the chest. Additionally, the following symptoms may be present: nausea, sweating, weakness, loss of appetite, shortness of breath or difficulty breathing, upper back pain, and pain that feels knife-like. The four major risk factors associated with coronary heart disease and angina are cigarette smoking, diabetes, elevated blood lipid levels, and hypertension. Angina and/or myocardial infarction as considered coronary heart disease

It is estimated that:

- 9,800,000 people in the United States currently have angina
- 500,000 new cases of stable angina occur each year.
- The age-adjusted prevalence of angina in women age 20 and older was 4.1% for non-Hispanic white women, 6.7% for non-Hispanic black women and 4.5% for Mexican-American women. Rates for men in these three groups were 4.1%, 4.4%, and 3.5%, respectively

(American Heart Association webpage)

The incidence of angina pectoris in those ages 45 to 74 is highest in black women. However, when only considering those over age 65, then men are more likely to have angina than women, and white men are more likely than black men (National Institute of Heart, Lung and Blood, 2006).

There are four types of angina:

- Stable angina
- Unstable angina
- Prinzmetal or variant angina
- Microvascular angina

In **stable angina,** oxygen need exceeds the ability of the body to supply oxygen. This disparity may be caused by a narrowing of the coronary arteries from atherosclerosis (deposits of fat in the vessel) or from an activity that increases the oxygen needs of the heart temporarily. Stable angina occurs during exercise, stress, or periods of increased physical exertion and is normally reversed with rest. No permanent damage to the heart usually occurs after an episode of stable angina. An episode of stable angina does not indicate that the patient is about to have a **myocardial infarction** (MI), a complete blockage of one of the vessels supplying blood and nutrients to the muscle of the heart. An episode of stable angina does not place the person at a greater risk for having an MI later.

Unstable angina is caused by severely decreased coronary blood flow. Pain in unstable angina occurs when the patient is resting; it can even occur during sleep and awaken the patient. Unstable angina may develop suddenly on exertion, which may be the first time the patient has had anginal pain. It also can occur in patients who have previously had stable angina. For these patients, unstable angina is a marked increase in the frequency or the severity of their pain. In some patients, unstable angina may present not with chest pain, but with atypical findings of shortness of breath, nausea, profuse sweating, fainting, and pain in the arms, upper middle abdomen, shoulder, or neck. Individuals more likely to have atypical unstable angina are older adults, women, those who have diabetes, and/or have prior heart failure (ACC/AHA 2007; Canto, Shlipak, Rogers, et al., 2000). Patients who do not have chest pain delay longer in seeking care and when they do they are less likely to be accurately diagnosed than patients who present with chest pain. Other presentations of unstable angina include non–Q-wave MI, or post-MI onset of angina (more than 24 hours after the MI).

Unstable angina results most frequently from plaque rupture in the vessel, followed by a local thrombus formation. Plaque rupture is caused by a complex sequence of events, including local inflammatory activity. *Because of this etiology, unstable angina is considered a critical phase of coronary heart disease and places the patient at high risk for having an MI.* For this reason anticoagulants, antiplatelets, and antilipids are used in treatment. The term **acute coronary syndrome (ACS)** is used to define a grouping of symptoms that are produced by acute myocardial ischemia; it represents a continuum of cardiovascular disease and vessel occlusion. ACS encompasses unstable angina, non-ST-segment elevation MI (NSTEMI), and ST-segment elevation MI (STEMI).

Special cardiac biomarkers, not normally found in the blood, have been found in patients with unstable angina and ACS. These regulatory contractile proteins are called cardiac troponin T and cardiac troponin In (jointly referred to as the "cardiac tropronins." As they are not normally found in the blood, their presence has been shown to be a sensitive and specific marker for ischemic myocardial cell damage. In addition, troponin T is a marker of thrombosis. Troponins T and I, which can be measured by a special blood test, appear to be better indicators of damage and early risk from unstable angina than the traditionally used creatine kinase myocardial band (isoenzyme M). Both fatal and nonfatal MIs were more frequent in patients with unstable angina who had elevations of one or both of these markers. There appears to be a direct relationship between the degree of troponin elevation and mortality even after revascularization procedures have occurred (ACC/AHA 2007; James, Lindbäck, Tilly, et al., 2006; Ohman, Armstrong, Christenson, et al., 1996; Antman, Tanasijevic, Thompson, et al., 1996).

The guidelines for American College of Cardiology/American Heart Association [ACC/AHA], 2007b) state that testing for biomarkers of cardiac injury should be performed in all patients who present with chest discomfort that is consistent with ACS; cardiac troponins T and I are the preferred markers. Cardiac tropronins wll begin to rise as early as 2 to 4 hours after the onset of symptoms. In some patients, the troponin level may not be elevated at the time they come to the emergency department but will rise within 12 hours of admission. Patients who are more likely to have a late rise in troponin levels are those who have ST-segment deviation; present to the emergency department less than 8 hours after the onset of symptoms; have had no prior percutaneous coronary intervention; have not used beta blockers; have unheralded angina; or have a history of previous MI (Januzzi, Newby, Murphy, et al., 2006).

Other cardiac markers of value are the natriuretic peptides, which are neurohormones produced mostly in the ventricular myocardium. Both B-type natriuretic peptide, as well as its less predominant relative N-terminal (NG) pro-B-type natriuretic peptide, have vasoactive properties and are markers of hemodynamic stress. They have been studied in relation to chronic heart failure (CHF) and ACS. Elevations of these peptides are associated with adverse outcomes, especially high mortality, in patients admitted with ACS (ACC/AHA 2007; James, Lindbäck, Tilly, et al., 2006). Measurement of B-type natriuretic peptide should be included in the assessment of risk factors for complications in ACS (James, Lindbäck, Tilly, et al., 2006; See & de Lemos, 2006; Wiviott, de Lemos, & Morrow, 2004). Heart failure can develop after ACS, and elevated B-type natriuretic peptide indicates an increased risk of developing heart failure after ACS (Scirica, Morrow, Cannon, et al., PROVE IT-TIMI 22 Investigators, 2006).

Another cardiac marker, C-reactive protein (a systemic sign of inflammation, associated with atherosclerosis), has been found to be important in unstable angina. Inflammation and atherosclerosis have both been associated with increased mortality and recurrent cardiac problems in patients with ACS. The higher the C-reactive protein level on admission to a hospital, the greater the likelihood of a cardiovascular event long-term (Tanaka, Tsurumi, & Kasanuki, 2006; Cannon & Turpie, 2003; Rosenson & Koenig, 2003; Lenderink, Boersma, Heeschen, et al., CAPTURE Investigators, 2003).

An additional risk factor for patients hospitalized for ACS is moderate to severe anemia. Patients with ACS who are discharged with moderate to severe anemia (i.e., a hematocrit of 33% or lower) have a 2.5 times greater risk of dying within 2 years after discharge than those with mild to no anemia (Vaglio, Safley, Rahman, et al., 2005).

Prinzmetal angina, also called **variant angina,** is caused by sudden coronary artery spasms that induce ischemia in the heart muscle. These spasms, if lengthy, can lead to sudden death. However, this type of angina is rare. Prinzmetal angina may be precipitated by emotional stress, medications, street drugs (e.g., cocaine), or exposure to cold temperatures.

Microvascular angina is a newly discovered form of angina. Patients with this type of angina experience chest pain but have no apparent coronary blockages. The pain results from impaired function of the tiny blood vessels that perfuse the heart, arms, and legs. Microvascular angina can be treated with some of the same drugs used to treat stable angina.

DRUGS TO TREAT ANGINA

Three main drug groups are used to treat angina—beta blockers, calcium channel blockers, and nitrates. Table 30.1 presents a summary of selected antianginal drugs. Some other drugs may be used as adjunct drug therapies.

Beta Blockers

Beta blockers prevent the beta-adrenergic receptors from being stimulated. These drugs have multiple effects on the heart and cardiovascular system, including slowing the heart rate, depressing atrioventricular (AV) conduction, decreasing cardiac output, and reducing systolic and diastolic blood pressure at rest and during exercise. These effects decrease the oxygen demands of the heart and thereby decrease angina. Beta blockers used commonly for treating angina are propranolol, atenolol, metoprolol, and nadolol. Other beta blockers that may be used in treating angina are bisoprolol (Zebeta), carteolol (Cartrol), and esmolol (Brevibloc), although this is an off-label use of these drugs. The beta blockers are discussed fully in Chapter 13.

Calcium Channel Blockers

Calcium is needed in the automatic and conducting cells of the heart to help create an action potential. In the cells of the heart that contract, calcium links excitation with contraction and controls energy storage and use. Calcium travels to these cells through special channels. Calcium channel blockers inhibit calcium from moving across cell membranes.

TABLE 30.1 Summary of Selected C Antianginal Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Nitrates			
P nitroglycerin (Nitrostat, Nitro-Bid IV, Nitrol, Nitro-Dur, Nitrolingual)	Acute angina Prophylaxis Hypertension	*Adult:* SL, 1 tablet under tongue, every 5 min; total of 3 tablets *Adult:* Topical (transdermal paste or patch), apply 12 inches q8 h; increase by 12 inches to achieve desired results; translingual spray, 0.4 mg/ metered dose into oral mucosa, not to exceed 3 doses/15 min *Adult:* IV, 5 mg/min by infusion pump; increase by 5-mg increments every 3–5 min as needed *Child:* Safety and efficacy not established	*Onset:* IV, 1–2 min; sublingual, 1–3 min; TL spray, 2 min; topical and transdermal, 30–60 min *Duration:* IV, 3–5 min; SL, 30–60 min; topical/ transdermal, up to 24 h $t_{1/2}$: IV, 1–4 min
isosorbide dinitrate (Isordil)	Treatment and prevention of angina pectoris	*Adult:* SL, 2.5–5 mg; PO, 5–40 mg tablets or capsules *Child:* Safety and efficacy not established	*Onset:* PO, 20–40 min; SL, 2–5 min *Duration:* PO, 4–6 h; SL, 1–2 h $t_{1/2}$: Unknown
C Beta Blocker			
atenolol (Tenormin)	Hypertension Angina pectoris Acute myocardial infarction	*Adult:* PO, 50 mg/d; after 1–2 wk, dose may be increased to 100 mg *Child:* Dose has not been established *Adult:* PO, 50 mg daily; if optimal response not achieved in 1 wk, increase to 100 mg/d, up to 200 mg/d *Adult:* IV, 5 mg over 5 min; follow with 5 mg, 10 min later; switch to 50 mg PO 10 min after last IV dose; follow with 50 mg PO 12 h later; administer 100 mg PO daily or 50 mg PO bid for 6–9 d *Child:* Safety and efficacy not established	*Onset:* PO, varies, IV, immediate *Duration:* PO and IV, 24 h $t_{1/2}$: 6–9 h
C Calcium Channel Blocker			
nifedipine (Adalat, Procardia; *Canadian:* Apo-Nifed)	Angina pectoris, stable angina, hypertension	*Adult:* PO, 10 mg tid, titrate over 7–14 d; SR: PO, 30–60 mg daily, titrate over 7–14 d *Child:* Safety and efficacy not established	*Onset:* PO and SR, 20 min *Duration:* 8–24 h $t_{1/2}$: 2–5 h
C Other Antianginal			
ranolazine (Ranexa)	Chronic angina unresponsive to other treatment; used in combination with nitrates, beta blockers, or amlodipine	*Adult:* PO, 500 mg bid, may increase up to 1000 mg bid only	*Onset:* 2.5 h *Duration:* Unknown $t_{1/2}$: 8.9 h

The effects of this inhibition on the cardiovascular system are decreased contraction, depression of impulse formation (automaticity), and slowing of conduction velocity. These have the effect of decreasing the oxygen needs of the heart. Calcium channel blockers also cause arteriolar dilation, decreasing afterload. Calcium channel blockers are used in chronic stable angina when the patient cannot tolerate beta blockers, or if the symptoms are not adequately controlled while on this therapy (ACC/AHA, 2007b). The calcium channel blockers used for chronic stable angina are verapamil (Calan), amlodipine (Norvasc), bepridil (Vascor), diltiazem (Cardizem), nicardipine (Cardene), and nifedipine (Procardia). The calcium channel blocker used in unstable angina is verapamil. Amlodipine, nifedipine, verapamil, and diltiazem are used in treating Prinzmetal angina. The calcium channel blockers are discussed more fully in Chapter 31.

Nitrates

Nitrates dilate vascular smooth muscle and both venous and arterial vessels (although more relaxation occurs on the venous side). Venous dilation decreases the returning flow of blood to the heart (preload). Arterial dilation reduces systemic vascular resistance and arterial pressure (afterload). These

effects decrease the workload on the heart and its oxygen needs. Nitrates also improve the circulation to the heart itself by redistributing blood flow to the collateral vessels.

Adjunct Drug Therapies

Some other drugs are used as adjuncts to the main drug therapies for treating angina. These drug therapies are not designed to decrease oxygen demands on the heart. Rather, they are used to slow down the progression of coronary artery disease, prevent complications that may arise with angina, or minimize symptoms.

As mentioned earlier, thrombus formation is an important concern with unstable angina and some of these therapies specifically target this problem. Aspirin is one drug that is used in chronic stable angina and unstable angina. Per the 2007 Chronic Angina focused update of the ACC/AHA clinical guidelines, a patient with chronic angina should receive 75 to 162 mg of aspirin per day indefinitely, unless it is contraindicated. A patient with acute coronary syndrome should chew an aspirin tablet (325 mg) immediately. This anti-inflammatory agent has anticoagulant properties and antiplatelet properties, which are helpful in preventing thrombus formation and a potentially resulting MI. Aspirin's use as an antiplatelet agent is further discussed in Chapter 32, and aspirin is described as a prototype drug for mild to moderate pain in Chapter 24.

Clopidogrel, an antiplatelet drug, can be used in place of or in addition to aspirin in some patients with chronic or unstable angina. Other major uses of clopidogrel are when a patient has a cardiovascular event from a clot or is at risk for such an event; this use of clopidogrel is discussed in Chapter 32.

Another class of drugs is the glycoprotein IIb/IIIa receptor antagonists; these are monoclonal antibodies and a new class of platelet inhibitors that are more potent than aspirin. Glycoprotein IIb/IIIa receptor antagonists target the final common pathway of platelet aggregation. The glycoprotein IIb/IIIa complex is a membrane receptor for platelet aggregation. It binds platelets to fibrinogen and allows for the creation of interplatelet bridges. This receptor is the common end point of all platelet activities (Gabriel & Oliveira, 2006). Blocking this receptor therefore prevents platelet aggregation. Glycoprotein IIb/IIIa receptor antagonists include abciximab, tirofiban, and eptifibatide. Use of glycoprotein IIb/IIIa inhibitors is associated with lower rates of death, MI, and rehospitalization for acute coronary syndrome (Sabatine, Morrow, Guigliano, et al., 2004). Both clopidogrel and glycoprotein IIb/IIIa receptor antagonists are discussed in Chapter 32. One of these drugs should be added to aspirin and heparin therapies if the patient with unstable angina is to have percutaneous coronary intervention and cardiac catheterization (ACC/AHA, 2007a).

Heparin, an anticoagulant given by the intravenous (IV) or subcutaneous (SC) route, is used in conjuncture with antiplatelets (aspirin, clopidogrel, or both) in unstable angina to prevent thrombus formation. The use of low-molecular-weight heparin instead of unfractionated heparin is fairly common because it provides a more stable pharmacodynamic response and is easier to use. Low-molecular-weight heparin has been shown to be as effective as traditional, unfractionated heparin and appears to be most beneficial to patients who are at the highest risk for complications from unstable angina. Heparin is discussed in Chapter 32. Bivalirudin (Angiomax), an anticoagulant, is used in patients with unstable angina who are undergoing percutaneous transluminal coronary angioplasty. This specific and reversible direct thrombin inhibitor is also discussed in Chapter 32. Warfarin, an oral anticoagulant, may be added to aspirin and/or clopidogrel therapy for chronic angina if needed, however, it increases the risk of bleeding and requires close monitoring of the patient and their clotting times (ACC/AHA, 2007b).

Lipid-lowering agents called statins are used in conjuncture with drugs to treat both chronic and unstable angina to slow the progression of coronary heart disease if the low density lipid-type cholesterol (LDL-C) levels are 100 mg/dL or greater (ACC/AHA, 2007b). Decreasing circulating fats in the blood decreases the rate at which fatty deposits are deposited on the walls of the vessels. These fatty deposits narrow the vessel and block the blood flow, causing angina. Such blockages are especially problematic in the coronary arteries. Intensive statin therapy has been shown to decrease the risk of hospitalization for heart failure after ACS by 27% (Scirica, Morrow, Cannon, et al., PROVE IT-TIMI 22 Investigators, 2006). Lipid-lowering agents are discussed in Chapter 26.

An ACE inhibitor is used in patients with chronic angina if they also have: left ventricular ejection fraction of 40% or less, diabetes, hypertension, or chronic kidney disease unless contraindicated (ACC/AHA, 2007b). ACE inhibitors are discussed in detail in Chapter 26.

Angiotensin receptor blockers (ARBs) are recommended for patients with chronic angina who also have: indications for an ACE inhibitor but are intolerant of them, hypertension, heart failure, or have had an MI with left ventricular ejection fraction of 40% or less. ARBs may also be considered to be used in combination with ACE inhibitors in chronic angina (ACC/AHA, 2007b). ARBs are discussed in detail in Chapter 26.

Aldosterone blockers are also recommended for use in patients with chronic angina who are post MI without significant renal dysfunction or hyperkalemia and already are receiving therapeutic doses of an ACE inhibitor and/or a beta blocker, have left ventricular ejection fraction of 40% or less, have diabetes, or have heart failure (ACC/AHA, 2007b).

The most current clinical guidelines for chronic angina also recommend that these patients receive an annual flu vaccine (ACC/AHA, 2007b).

If the pain of unstable acute angina is not controlled by nitrates or anti-ischemic therapy, morphine, a narcotic, may be used. Morphine is discussed in Chapter 23.

NITRATES

Nitrates include nitroglycerin (Nitrostat), which is the prototype; isosorbide; and amyl nitrate (see Table 30.1).

Nursing Management of the Patient Receiving P Nitroglycerin

Core Drug Knowledge

Pharmacotherapeutics

Therapeutic uses of nitroglycerin vary by the route of administration. Given sublingually or by transmucosal or translingual spray or aerosol, nitroglycerin is used to treat acute angina. It also is used through topical, transdermal, translingual spray or aerosol, and oral sustained-release methods to prevent chronic recurrent angina. When given intravenously, nitroglycerin is used to treat to treat angina unresponsive to sublingual nitrates or beta blockers, to treat CHF associated with acute MI; to treat hypertension secondary to surgical procedures; and to create controlled hypotension during anesthesia. An unlabeled use for intravenous nitroglycerin includes reducing cardiac workload in patients with acute MI and CHF; although this is an unlabeled use, it is widely accepted in clinical practice.

Pharmacokinetics

Nitroglycerin is absorbed rapidly sublingually; it also is absorbed through the skin. Metabolism occurs in the liver, and the drug has an extensive first-pass effect when given orally. It is excreted in the urine. Absorption of sublingual products depends on salivary secretion; dry mouth decreases absorption. The drug is absorbed directly into the vascular system through this route; it is not swallowed and absorbed through the gastrointestinal (GI) tract. Thus, it bypasses the first-pass effect. Absorption of transdermal products is through the skin and into the vascular system. Ointments and transdermal systems provide a gradual release of drug into the circulatory system. The drug reaches its target organs before it is inactivated by the liver. Transdermal absorption will be increased with physical exercise, with elevated external temperatures (e.g., saunas), and if the drug is applied to broken skin.

Pharmacodynamics

Nitroglycerin relaxes vascular smooth muscle and dilates both arterial and venous vessels. Dilation of veins is more predominant than dilation of arteries, resulting in peripheral pooling of blood and decreased preload. Blood pressure will decrease as a result of venous dilation. Reflex tachycardia may follow the drop in blood pressure. Arteriolar dilation reduces systemic vascular resistance and arterial pressure, thus reducing afterload. Myocardial oxygen consumption is decreased. Nitroglycerin redistributes blood flow in the heart, improving circulation to ischemic areas.

Tolerance to the vascular and antianginal effects may develop. Tolerance is minimized by starting with as small a dose as possible and removing the nitroglycerin (paste or transdermal patches) from the patient for 10 to 12 hours a day. The sublingual and translingual spray forms of the drug are the least likely to produce tolerance. The transmucosal form also appears to produce minimal tolerance.

Contraindications and Precautions

Nitroglycerin is contraindicated with the use of phosphodiesterase inhibitors (drugs to treat erectile dysfunction) such as sildenafil or vardenafil because of a significant increase in the hypotensive effect. Nitroglycerin is contraindicated in hypersensitivity or idiosyncratic reactions to nitrates or to adhesives (transdermal patches only), severe anemia, orthostatic hypotension, when there is or is a risk for increased intracranial pressure, as it will further increase the pressure (such as in head trauma or cerebral hemorrhage; sublingual route), pericardial tamponade (intravenous route), constrictive pericarditis (intravenous route), restrictive cardiomyopathy (intravenous); and symptomatic hypotension.

Caution must be used when using nitroglycerin in patients with: hypotension secondary to volume depletion that is uncorrected, as increases in intraocular pressure can occur; hypertrophic cardiomyopathy; cerebral hemorrhage or head trauma; gastric hypermotility (sustained-release dosage form); hyperthyroidism; concurrent use of alcohol, CNS depressants, antihypertensives, or other drugs which cause hypotension (additive hypotension); or patients undergoing MRI procedures (transdermal patches), as the metal contained in patches can overheat. Caution also is advised when administering IV nitroglycerin to patients with hepatic disease and severe renal disease. Nitroglycerin is in pregnancy category C, and it is not known whether nitrates are excreted in breast milk; therefore, cautious use is advised.

Adverse Effects

The most common adverse effect of nitroglycerin is headache, which may be persistent and severe. Cardiovascular effects may include hypotension, postural hypotension, tachycardia, palpitations, and syncope. Other effects on the central nervous system (CNS) include dizziness, vertigo, anxiety, and weakness. These adverse effects are related to the vasodilation and cardiovascular effects that occur with nitroglycerin use. Dermatitis can occur from topical application. Local burning under the tongue can occur with sublingual administration. Alcohol intoxication can develop in patients receiving high doses of IV nitroglycerin because many of the IV products contain alcohol as a diluent.

Overdosage results in hypotension, tachycardia, flushing, perspiring skin turning cold and cyanotic, headache, vertigo, palpitations, visual disturbances, diaphoresis, dizziness, syncope, nausea, vomiting, and anorexia. Other signs and symptoms of overdose include initial hyperpnea, dyspnea and slow breathing, heart block, and increased intracranial pressure exhibited by cerebral symptoms of confusion, moderate fever, and paralysis. These signs and symptoms are related to excessive cardiovascular action.

Drug Interactions

A few drugs interact with nitroglycerin (Table 30.2), most notably the phosphodiesterase inhibitors such as sildenafil, which is noted above as a contraindication for nitroglycerin

TABLE 30.2 Agents That Interact with P Nitroglycerin

Interactants	Effect and Significance	Nursing Management
acetylcysteine	Enhanced hypotension and nitroglycerin-induced headache when both are concurrently administered intravenously	Monitor blood pressure carefully if both therapies are indicated. Warn patient about risk of headache.
alteplase, recombinant	Possibly less coronary artery reperfusion, longer time to reperfusion, and more coronary artery reocclusion	Concomitant use of nitroglycerin and alteplase should be avoided if possible. If coadministration is necessary, the lowest effective dose of nitroglycerin should be used. Be aware that alteplase efficacy may be decreased and the risk of reocclusion may be increased.
alcohol, CNS depressants, antihypertensives	Severe hypotension and cardiovascular collapse	Ensure patient does not consume alcohol. Educate patient about risks of interaction. Monitor blood pressure if coadministration is necessary.
aspirin	Increase in nitroglycerin concentrations and additive platelet function depression	Use this interaction therapeutically to benefit patients with acute myocardial infarction. In patients taking analgesic doses of aspirin, monitor for an exaggerated response to nitroglycerin, as evidenced by headache and syncope. Teach patients to use another analgesic.
dihydroergotamine	Induction of dihydroergotamine toxicity (peripheral ischemia, paresthesias, nausea, vomiting) related to decreased metabolism; induction of angina	Monitor patient for signs of ergotism or loss of antianginal efficacy of nitroglycerin. Dose reductions of the ergot preparation may be needed. Ergonovine, ergotamine, or methylergonovine may be less susceptible to major fluctuations in metabolism and could be considered as substitutionary ergot preparations.
heparin	Possibly decreased pharmacologic effects of heparin	Monitor for therapeutic effect of heparin.
pancuronium	Increase in pancuronium duration of action	Concurrent administration of nitroglycerin and pancuronium is not recommended. If concurrent use cannot be avoided, carefully titrate the dose of the neuromuscular blocking agent and monitor for increased or prolonged respiratory depression or paralysis (apnea).
sildenafil, tadalafil, vardenafil	Potentiation of vasodilation from nitrates, resulting in significant hypotension	Educate patients not to use these drugs for erectile dysfunction

use. Nitroglycerin may interfere with the Zlatkis-Zak color reaction, causing a false report of decreased serum cholesterol levels.

Assessment of Relevant Core Patient Variables

Health Status

Ascertain whether the patient has acute angina or chronic recurrent angina. Assess the patient's pulse rate and blood pressure. Determine whether the patient has any of the following conditions, which are contraindications to nitroglycerin use: severe anemia, constrictive pericarditis, increased intracranial pressure, pericardial tamponade, restrictive cardiomyopathy, or symptomatic hypotension. If hepatic or severe renal disease exists, caution must be used with IV administration. Assess for use of the following drugs, as these will have additive hypotensive effects with nitroglycerin: erectile dysfunction drugs such as sildenafil, other CNS depressants, anti-hypertensives, or other drugs that can cause hypotension.

Life Span and Gender

Older adults may have a more pronounced venous dilation from nitroglycerin than younger adults and may experience more hypotension from the drug. Nitroglycerin is in pregnancy category C, so determine whether the patient

CRITICAL THINKING SCENARIO

NITROGLYCERIN

Peter Riley, age 4 years, is staying at his grandparents' house for the weekend. He finds his grandfather's nitroglycerin ointment in the bathroom. He squeezes some out and spreads it over his entire left arm. When his grandparents realize what he has done, they call the Advice Nurse hotline for their HMO.

1. If you were the Advice Nurse, what would you tell the grandparents to do?
2. What is the major risk to Peter?

is pregnant. Assess whether the patient is breast-feeding, because cautious use is advised in that case. Safety and efficacy in children have not been established. Note the age and sex of the patient (Box 30.1). Assess men for use of erectile dysfunction drugs.

Lifestyle, Diet, and Habits

If the patient has chronic stable angina, it is important to determine how much or what type of activity precipitates an anginal attack, or if angina occurs at rest, which may indicate unstable angina. In patients who smoke cigarettes, smoking constricts the blood vessels and may cause angina. Patients whose diet is high in cholesterol or saturated fats risk developing fatty deposits within the vessels, which contribute to narrowing the vessels. Monitor for use of alcohol, as this may increase the hypotensive effect.

Environment

Be aware of the environment in which the drug will be administered. Nitroglycerin can be administered in any environment, with the exception of IV nitroglycerin, which is administered in the hospital with continuous monitoring for blood pressure and heart rate. Sublingual tablets are likely to lose effectiveness if exposed to light, excessive heat, or moisture. Assess how patients store their medication at home.

Nursing Diagnoses and Outcomes

- Acute Pain, Chest, related to cardiac disease
  Desired outcome: *Acute chest pain will be resolved with the use of drug therapy without injury to the heart occurring.*
- Decreased Cardiac Output related to therapeutic effects of drug
  Desired outcome: *Patient's blood pressure will decrease to therapeutic levels but will not decrease to the level of hypotension.*
- Risk for Injury, related to orthostatic hypotension and dizziness secondary to adverse effects of drug therapy
  Desired outcome: *Patient will not sustain injury because of orthostatic hypotension and dizziness.*
- Acute Pain, Headache, related to adverse effects of drug therapy
  Desired outcome: *Patient's headache, if it occurs, will be managed successfully by analgesics so that patient will adhere to drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

SUBLINGUAL TABLETS

Place one tablet under the patient's tongue, where it should be allowed to dissolve. It is important to administer a tablet every 5 minutes, up to three in 15 minutes if necessary, to achieve full therapeutic effect. Have the patient sit or lie down to allow for rest and decrease the oxygen needs of the heart.

It is a good idea to keep tablets in the original dark bottle and keep the lid on when not in use to prevent deterioration and loss of efficacy. Avoid exposure of tablets to high temperatures.

TOPICAL OINTMENT AND TRANSDERMAL PATCHES

Apply to areas that do not have excessive hair, to promote absorption. Apply to the chest, upper arm, or upper thigh to promote absorption and increase onset of systemic action. Do not apply to distal parts of extremities (i.e., near the hands or feet).

BOX 30.1 FOCUS ON RESEARCH

Symptoms Across the Continuum of Acute Coronary Syndromes: Differences Between Women and Men

DeVon, H. A., Ryan, C. J., Ochs, A. L., & Shapiro, M. (2008). *Am J Crit Care*, 17(1):14–24.

The Study

This study set out to "detect differences between women and men in the type, severity, location, and quality of symptoms across the three clinical diagnostic categories of acute coronary syndromes (unstable angina, myocardial infarction without ST-segment elevation, and myocardial infarction with ST-segment elevation). "The authors controlled the following variables: age, diabetes, functional status, anxiety, and depression. The patients were from two urban teaching hospitals in the Midwest; a convenience sample of 112 women and 144 men admitted through the emergency department and hospitalized for acute coronary syndromes were enrolled in the study. These patients were interviewed using a structured interview tool. The authors assessed forty-eight symptom descriptors. Demographic characteristics, health history, functional status, anxiety, and depression levels also were measured. Regardless of their final exact diagnosis, women in the study were more likely to experience indigestion, palpitations, nausea, numbness in the hands, and unusual fatigue. Both sexes experienced chest pain as a symptoms, but more than twice as many women as men (21% versus 10%) did not have chest pain. In this particular study, the differences between the sexes was not significant.

Nursing Implications

Although this study did not show any significant differences among men and women in terms of their symptoms of angina or MI, the sample size and selection most likely account for this, as larger epidemiological studies have found significant differences. The study does emphasize that patients may present with symptoms other than substernal chest pain when they are experiencing unstable angina or an MI. Many of these symptoms are somewhat vague and nonspecific. It is important to assess for these other symptoms and to recognize that taken together, they may help confirm the diagnosis of acute coronary syndrome (ACS) as opposed to representing other disease entities or pathological problems. Failure to recognize these symptoms as ACS can lead to delayed diagnosis, treatment, and potentially death for the patient if they are not diagnosed in a time effective manner.

TRANSLINGUAL SPRAY

Spray nitroglycerin onto or under the tongue to promote absorption. Do not allow the patient to inhale the drug. If used to treat acute angina, spray one or two metered doses. The dose may be repeated but not more than three times in 15 minutes. If used prophylactically, administer one metered dose 5 to 10 minutes before onset of activity that may precipitate angina.

INTRAVENOUS

Proper reconstitution and administration technique will increase the dose delivered. Between 40% and 80% of the IV nitroglycerin dose migrates into many plastics. Therefore, dilute the drug only into glass parenteral solution bottles, and administer using IV tubing not made from polyvinyl chloride (PVC), which is provided by the drug manufacturer. Use an IV pump to control the infusion rate.

Minimizing Adverse Effects

ALL ROUTES

Assess the patient's pulse and blood pressure before administering drug therapy. It also is important to monitor for orthostatic hypotension and to assist the patient to a standing position gradually when arising. Treat any headache that develops with aspirin or acetaminophen until tolerance to this adverse effect occurs. When withdrawing nitroglycerin as a treatment for angina, it is important to reduce the dosage gradually to prevent withdrawal reactions.

SUBLINGUAL

Do not give more than three tablets—one every 5 minutes—to relieve acute angina. If three tablets do not alleviate angina, the patient is considered to be having an acute MI, and it is urgent to obtain emergency help immediately.

TRANSDERMAL

This route is not appropriate for acute angina. Do not apply the drug to broken or irritated skin. It is important to remove the patch for 10 to 12 hours every 24 hours to prevent nitrate tolerance from developing. If anginal symptoms develop at night, the use of a beta blocker or calcium channel blocker should be considered. Patients who normally have angina only during daytime hours are not at substantial risk for developing nighttime angina with a nightly nitrate-free period.

Do not discharge a cardioversion or defibrillation paddle through a transdermal system. Arcing may develop, which may concentrate local current, damaging the paddles and burning the patient. Remove the patches before the patient receives an MRI, as the metal on the patch may allow the patient to be burned.

INTRAVENOUS

Monitor the patient's blood pressure and heart rate while IV therapy continues. It is important to assess for alcohol intoxication if giving high doses for a prolonged period. Use an IV pump to regulate the infusion rate.

Providing Patient and Family Education

Nurses may be asked to teach community groups about emergency care for someone with chest pain. In this circumstance the person offering emergency assistance will not know the patient's medical history. Early recognition of a heart attack and seeking emergency medical assistance for these patients helps to save lives (Box 30.2).

ALL ROUTES

- Explain the purpose and adverse effects of nitroglycerin.
- Instruct patients to sit or lie down when experiencing angina.
- Explain that postural hypotension may occur (especially if standing still after a dose). If feelings of dizziness, weakness, or fainting occur, patients should lie down or place the head in a low position (if sitting) and take deep breaths.

SUBLINGUAL TABLETS

- Teach patients to place a sublingual tablet under the tongue at the first sign of an anginal attack, and not to wait for the pain to become severe.
- Explain that if angina is not relieved, up to two more tablets may be taken; one 5 minutes after the first tablet and the other 5 minutes after the second tablet. Instruct the patient to go the nearest emergency department if angina is not relieved after the above measures are taken.
- Teach patients to keep the sublingual tablets in their original bottle and to keep the cap on the bottle. It also is important to explain the importance of not storing the bottle in the sun.

TRANSLINGUAL SPRAY

- Instruct patients on proper administration—spraying it onto or under the tongue, not inhaling it.

BOX 30.2 COMMUNITY BASED CONCERNS

Chest Pain or Heart Attack?

Many community groups request health education topics for their members. Nurses are often the health care professionals who respond to these requests. If called on to discuss public response to chest pain, be sure to include the following points when teaching families and the public how to respond appropriately when someone is experiencing an angina attack:

- Instruct them to have the person rest (sit or lie down).
- If the person is known to take nitroglycerin tablets, give one and have the person place it under the tongue.
- Repeat in 5 minutes and again in another 5 minutes if chest pain does not go away.

If after three tablets of nitroglycerin the pain does not go away, the person should be considered to be having a heart attack. Call the emergency medical number, and get the person to the nearest hospital.

OR

If the person with chest pain does not take nitroglycerin, have him or her sit or lie down. If the pain does not go away within 5 minutes, assume that the person is having a heart attack. Call the emergency medical number and get the person to the nearest hospital.

- Explain that the drug may be used prophylactically or to treat the onset of angina.

TRANSMUCOSAL TABLETS

- Instruct patients on the proper placement of the tablet—under the upper lip, between the lip and gum above the incisor, or in the pouch between the cheek and gum. It is important to explain that it will dissolve slowly over a 3- to 5-hour period.
- Emphasize the importance of not chewing or swallowing the tablet.
- Explain that the rate of dissolution may be increased by touching the tablet with the tongue or by drinking hot fluids.

SUSTAINED-RELEASE TABLETS

- Instruct patients to swallow these tablets, not to chew them or place them sublingually, because doing so alters onset of the drug effects.

OINTMENTS

- Explain that ointments do not provide immediate relief of acute angina pain and should be used only prophylactically.
- Instruct patients to use an applicator or dose-measuring papers, not the hands, to measure and apply the prescribed amount of nitroglycerin ointment.
- Instruct patients not to rub the drug into the skin.
- Teach patients to choose a different area on the skin when applying a new dose. Tell patients to use a tissue to remove any old ointment left on the skin before applying a new dose.
- Instruct patients to wipe off any ointment that gets on the outside of the tube to prevent it from getting on the hands, and to recap the tube securely.

TRANSDERMAL PATCHES

- Teach patients to apply the patch to as hairless a skin area as possible. Typically the chest or upper arm is used; avoid placing the patch in the distal portion of the extremities.
- Instruct patients to remove the patch for 10 to 12 hours as prescribed.
- Explain the importance of avoiding saunas and other environments that increase the external temperature.
- If the adhesive becomes loose during the "on" period, instruct patients to place additional tape over the patch to guarantee contact with the skin.
- A discarded patch still contains active nitroglycerin, which can be a hazard for children and pets. Therefore, it is important to advise patients to flush used patches down the toilet.

Ongoing Assessment and Evaluation

Monitor the patient's blood pressure and heart rate throughout nitroglycerin therapy. If given intravenously, this monitoring should be continuous. Assess for relief of angina or control of chronic angina. Therapy is effective when angina is controlled or prevented without the development of hypotension or damage to the heart.

MEMORY CHIP

P Nitroglycerin

- Used in treating angina; IV route is used to decrease blood pressure (BP)
- Usually given sublingually or topically, sometimes IV in acute care setting
- Relaxes smooth muscles and dilates vascular beds
- Most common adverse effect: headache followed by hypotension
- Most serious adverse effect: can be hypotension
- Maximizing therapeutic effects: Keep tablets out of sunlight (keep in original dark bottle), moisture (keep cap sealed tightly when drug not in use), and excessive heat; give one tablet every 5 minutes, up to 3 in 15 minutes; and have patient rest or lie down during anginal attacks.
- Minimizing adverse effects: Take BP before and during therapy; to prevent orthostatic hypotension, keep the patient lying down during therapy.
- Most important patient education: If three sublingual tablets do not alleviate pain, seek immediate emergency medical treatment; use prophylactic doses before activities that may precipitate angina; and remove patches or ointment for 10 or 12 hours out of every 24 to prevent tolerance.
- **Patient safety alert: avoid using drugs to treat erectile dysfunction (e.g., sildenafil) as severe hypotension can occur.**

Drugs Closely Related to P Nitroglycerin

Isosorbide (Isordil) is a nitrate, like nitroglycerin, and is used for treating and preventing angina. It is not used to treat hypertension. Isosorbide is given sublingually or orally. Sublingual isosorbide has a slower onset and a longer duration of action compared with sublingual nitroglycerin. Because sublingual isosorbide does not relieve chest pain as rapidly as nitroglycerin, isosorbide is limited to treating acute angina in patients intolerant of or unresponsive to sublingual nitroglycerin. Oral preparations include tablets, sustained-release tablets, and chewable tablets. Oral sustained-relief routes of isosorbide also have a slower onset and longer duration than comparable forms of nitroglycerin. Although nitroglycerin may be used occasionally with adequate monitoring during the early phases of an acute MI, isosorbide should never be used, because of its greater sustained effects.

Amyl nitrate is another nitrate that can be used to treat angina, however it is seldom used for this now, as nitroglycerin sublingual is the standard treatment. It is available only as a capsule that is crushed, releasing vapors that are inhaled. To administer the drug, wave the crushed capsule under the patient's nose for two to six inhalations. Therapeutic effects occur within 30 seconds and last for 3 to 5 minutes. Unlike nitroglycerin, amyl nitrate has no effect on the coronary arteries, but it systemically decreases afterload by causing peripheral vasodilation. It is also the initial treatment for cyanide poisoning and is administered prior to an intravenous

infusion of sodium nitrite. Amyl nitrate is a highly flammable substance; therefore, it must not be exposed to heat or flame. Amyl nitrate is otherwise similar to nitroglycerin.

Drug Significantly Different From Nitroglycerin

Ranolazine (Ranexa), a new antianginal drug, is used in the treatment of chronic angina. Ranolazine has been found to be effective in reducing angina in a broad group of patients with angina (Wilson, Scirica, Braunwald, et al., 2009). Because it can cause prolongation of the QT interval on an ECG (a potentially dangerous alteration), it should be used only in patients whose angina has not been controlled using standard therapy. The effect on the QT interval is dose dependent. Ranolazine should be used only in combination with other antianginal therapy (either nitrates, beta blockers (metoprolol or atenolol), or amlodipine, a calcium channel blocker. It does not achieve its effects by lowering the heart rate or the blood pressure. It should be added on when other therapy has not controlled angina effectively (Rodriguez-Ospina L, Montano-Soto, L, 2008).

Management of Chronic Stable Angina Pectoris

Exactly how ranolazine works is unknown. Ranolazine is not a nitrate but is a piperazine derivative with chemical structure similar to several groups of drugs such as antidepressants, antipsychotics, and antihistamines. At therapeutic levels, ranolazine allows more activation of the sodium current, but precisely how this relates to anginal symptoms is not clear. Ranolazine also prolongs the ventricular action potential. It has been hypothesized that ranolazine can change cardiac muscle metabolism from using fatty acids to using carbohydrates. The antianginal and anti-ischemic effects of the drug are more pronounced in men than in women. When combined with amlodipine, ranolazine has been found to decrease the frequency of angina and the need for nitroglycerin use significantly. A large clinical trial (Metabolic Efficiency with Ranolazine for Less Ischemia in Non-ST elevation Acute Coronary Syndromes or MERLIN-TIMI 36 Trial), found that when ranolazine was added to standard therapy of aspirin, statins,, and beta blockers it minimized the worsening of angina and the need for more intense antinational medication, and it increased exercise duration at 8 months. Ranolazine did not decrease mortality from cardiovascular or events or IM, however (Wilson, Scirica, Braunwald, 2009).

Ranolazine is taken orally twice a day. Food has no effect on absorption. It is extensively metabolized in the gut and the liver, mostly by P-450 3A and to a lesser extent by P-450 2D6. Steady state is considered to be reached in 3 days of twice-daily dosing. The drug and metabolites are primarily eliminated renally; about 25% of elimination occurs through the GI tract.

Cardiovascular changes from ranolazine are normally minimal. The mean changes in pulse rate are less than 2 beats per minute. The systolic blood pressure increases less than 3 mm Hg, and the diastolic blood pressure normally increases only a few points in most patients. However, for patients with severe renal dysfunction, systolic blood pressure may rise 10 to 15 mm Hg. Mild to moderate hepatic dysfunction increases circulating ranolazine levels significantly and creates wider QT intervals than those seen in patients with normal liver function. The QT-widening effect in liver impairment can be 3 times as much as that with normal renal function.

Because of the pharmacokinetic and pharmacodynamic effects of ranolazine, it has the following contraindications: pre-existing QT prolongation; use of drugs that prolong the QT interval (e.g., Class Ia or Class III antiarrhythmics, erythromycin, and some antipsychotics [thioridazine, ziprasidone]); hepatic impairment (mild, moderate, or severe); and current use of drugs that are potent or moderately potent CYP 3A inhibitors (e.g., ketoconazole, HIV protease inhibitors, macrolide antibiotics, diltiazem, verapamil, or grapefruit juice, which all increase serum levels of ranolazine). Ranolazine is a pregnancy category C drug. Whether it is excreted in breast milk is not known. The drug has not been tested in children.

Ranolazine has several drug interactions. Many of the drug interactions are related to changes in the P-450 system. Drugs that inhibit the 3A pathway, which is responsible for metabolism of ranolazine, will increase the circulating level of ranolazine. Because ranolazine inhibits the 2D6 pathway, drugs that are metabolized by this route will have higher circulating levels. Many drugs are metabolized by one of these pathways, so the nurse should always consult a source listing drug interactions with ranolazine prior to administering it. Two drug interactions of special note occur with coadministration of ranolazine with digoxin or simvastatin. Ranolazine greatly increases the circulating levels of each of these drugs, which may produce serious adverse effects.

The most common adverse effects from ranolazine are dizziness, headache, constipation, and nausea. Small, reversible elevations in serum creatinine and blood urea nitrogen have been observed, but they are not associated with renal toxicity. The most serious adverse effect is prolongation of the QT interval. Patients receiving other drugs that prolong the QT interval are likely to develop a form of ventricular tachycardia called torsades de pointes.

To minimize adverse effects of ranolazine, it is necessary to confirm that the patient has previously received other therapy for angina prior to starting ranolazine; the patient should currently be receiving nitrates, beta blockers, or amlodipine when ranolazine is started. The dose should not exceed the maximum recommended amount of 1,000 mg twice a day. The patient should be assessed for evidence of any liver disease. Baseline and follow-up ECGs are necessary to evaluate the effects on the QT interval. Coadministration of drugs that prolong the QT interval or that are inhibitors of P3A isoenzyme should be avoided. Patients also receiving either digoxin or simvastatin may need a decreased dose of those drugs, depending on their serum

levels. Blood pressure of patients with renal dysfunction should be monitored while they are taking ranolazine. Patients should be taught to avoid grapefruit juice or grapefruit in their diets. They may take the drug either with or without food as long as it is swallowed whole and not crushed, broken, or chewed.

CHAPTER SUMMARY

- Nitroglycerin is used to treat angina and to prevent angina. When given intravenously, it also is used to reduce hypertension.
- Nitroglycerin relaxes vascular smooth muscle and dilates both arterial and venous beds. Dilation of veins is more predominant than dilation of arteries, resulting in peripheral pooling of blood and decreased preload.
- Blood pressure decreases as a result of venous dilation. Reflex tachycardia may follow the drop in blood pressure. Thus, the patient's blood pressure is assessed before each dose and during drug therapy with nitroglycerin, and the pulse should be assessed during therapy.
- Arteriolar dilation reduces systemic vascular resistance and arterial pressure, thus reducing afterload. Reduced afterload decreases the work the heart must perform to eject blood from the left ventricle and thereby decreases the oxygen needs of the heart.
- The most common adverse effect of nitroglycerin is headache.
- When nitroglycerin is given intravenously because of elevated blood pressure, the patient must be continually monitored in an intensive care setting. For safety, the drug should be administered by pump.

QUESTIONS FOR STUDY AND REVIEW

1. If the patient is taking nitroglycerin through a transdermal patch to prevent recurrent angina, why should he or she wear the patch only 12 to 14 hours a day?
2. How often should a tablet of sublingual nitroglycerin be administered to treat an episode of angina? How many tablets can be administered?
3. Why should you take the patient's blood pressure before administering a dose of nitroglycerin ointment topically?
4. When measuring the dose of nitroglycerin ointment, you get some on your hands. Later, you experience a throbbing headache. What is the explanation for this headache?
5. How does nitroglycerin decrease anginal pain?

Drugs Affecting Cardiac Rhythm

Learning Objectives

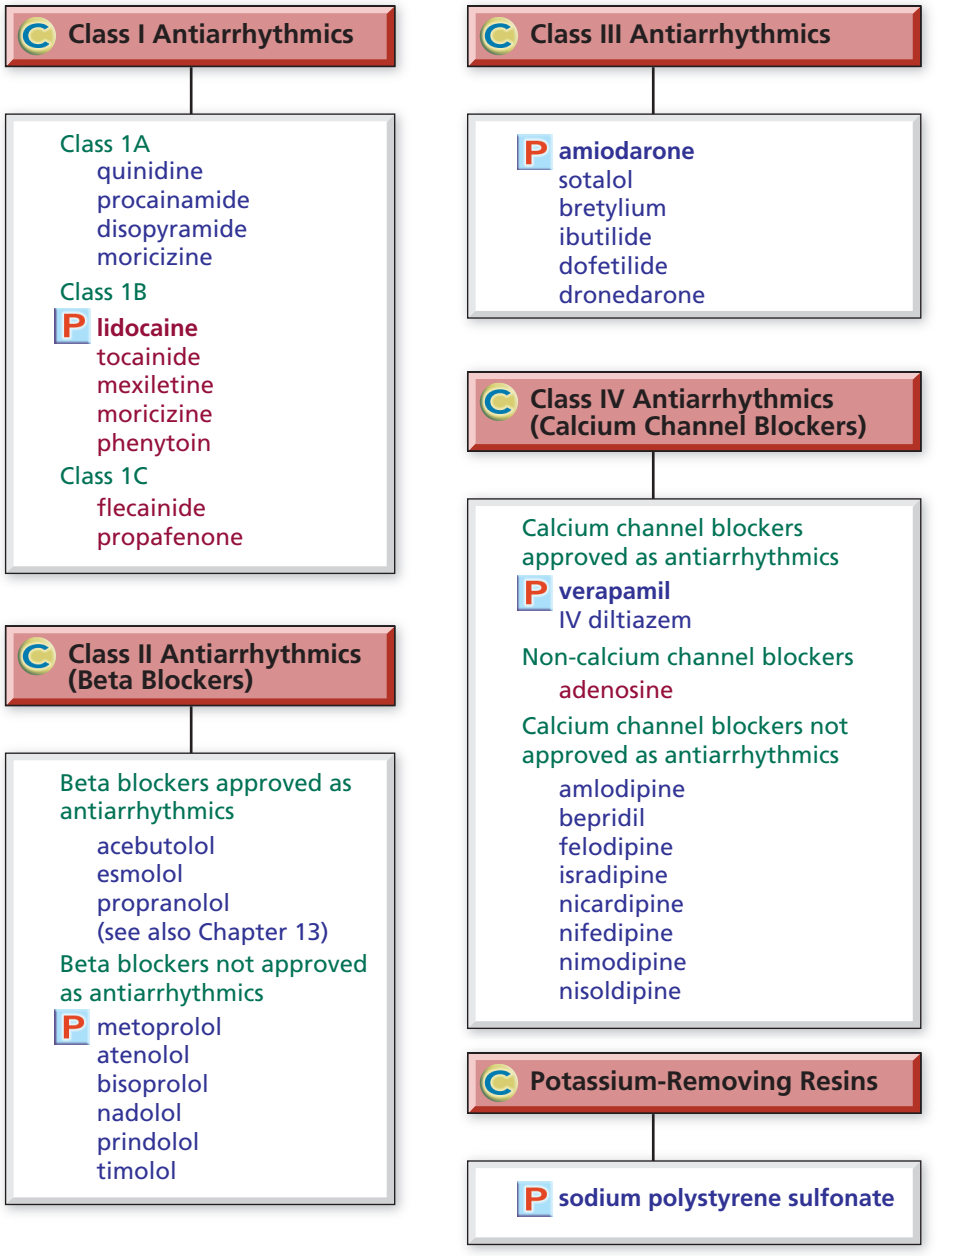
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect cardiac rhythm.
2. Identify core patient variables relevant to drugs that affect cardiac rhythm.
3. Relate the interaction of core drug knowledge to core patient variables for drugs that affect cardiac rhythm.
4. Differentiate Class I, II, III, and IV antiarrhythmic drugs.
5. Describe the varied therapeutic effects of beta blockers and calcium channel blockers.
6. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect cardiac function.
7. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect cardiac rhythm.
8. Determine key points for patient and family education for drugs that affect cardiac rhythm.
9. Differentiate the three main sources of data used in assessment of core drug variables.

Key Terms

action potential
arrhythmia
atrial fibrillation
atrial flutter
automaticity
depolarization
dysrhythmia
ectopic foci
electrocardiogram
proarrhythmia
re-entry phenomenon
refractory period
repolarization
resting membrane potential
transmembrane potential
ventricular fibrillation
ventricular tachycardia

Drugs Affecting Cardiac Rhythm



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

The heart is the muscle responsible for pumping blood through the circulatory system. The contraction of the heart depends on changes in electrical stimulation in cardiac muscle cells. These changes in electrical activity occur at regular, set intervals. These set interval patterns establish a normal rhythm for the beating heart. When pathologic processes interfere with these normal changes in electrical stimulation, the rhythm of the heart is altered. Arrhythmia is the term used to describe these alterations. **Arrhythmia,** meaning "no rhythm," occurs any time the normal rate or rhythm of the heart is altered. The heart continues to beat, but not in the expected pattern or manner. The term **dysrhythmia,** meaning "abnormal rhythm," is used interchangeably with arrhythmia and is preferred by many clinicians. This chapter identifies drugs that are used to treat alterations in the rhythm of the heart.

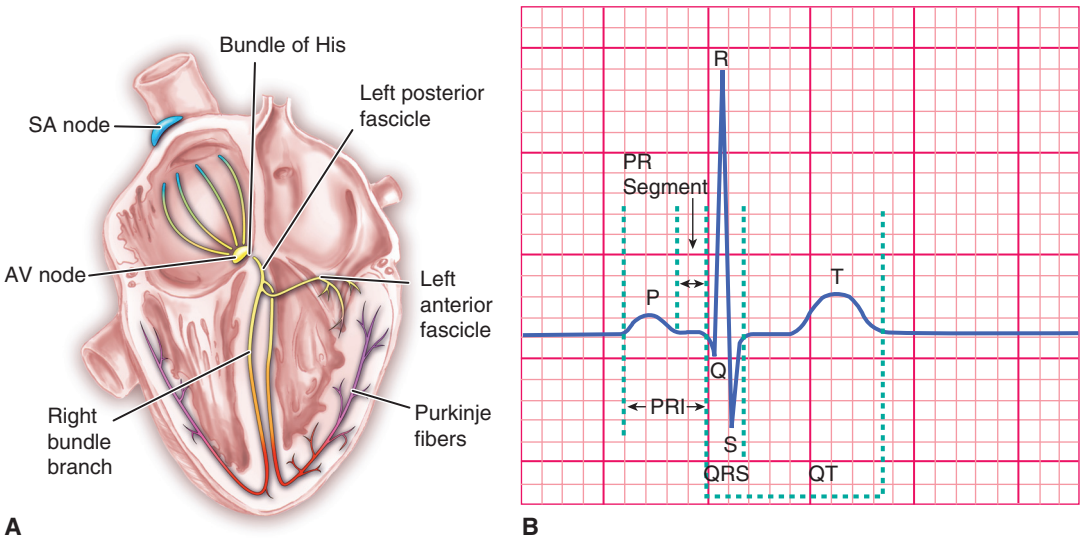
Drugs to treat cardiac arrhythmias are grouped by class: I, II, III, and IV. Class 1 antiarrhythmics, primarily sodium-channel blockers, have three subclasses, A, B, and C. The prototype Class IB antiarrhythmic is lidocaine. Class II antiarrhythmics are the beta blockers. The prototype beta blocker is metoprolol, and it is discussed fully in Chapter 13. Of the other numerous drugs in this class, only acebutolol, esmolol, and propranolol are approved as Class II antiarrhythmics. Any of the other beta blockers may be used, although these are off-label indications, based on the clinical judgment of the physician. Class III antiarrhythmics, primarily potassium channel blockers, include the prototype amiodarone (Cordarone). Class IV antiarrhythmics, the calcium channel blockers, include the prototype verapamil (Calan).

Because hyperkalemia is an electrolyte imbalance that may cause potentially lethal arrhythmias, drugs to prevent arrhythmias are the potassium-removing resins. The prototype potassium-removing resin is sodium polystyrene sulfonate (Kayexalate).

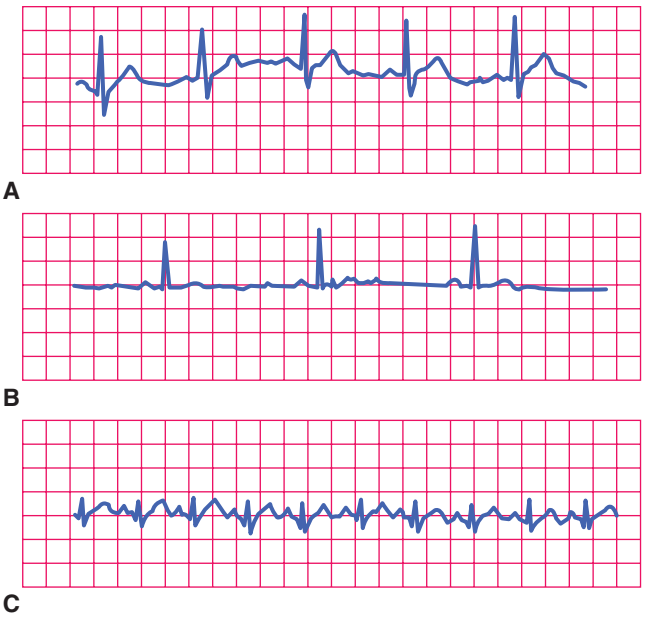
PHYSIOLOGY

Contractions of the heart are dependent on the unique electrical conduction system of the cardiac muscle. The conduction system connects to highly specialized cardiac cells that allow the heart to beat predictably and rhythmically. The system is composed of the sinoatrial (SA) node, the atrioventricular (AV) node, the bundle of His, the bundle branches, and the Purkinje fibers. The SA node, influenced by both the sympathetic and the parasympathetic nervous systems, is known as the pacemaker of the heart. The progression of the electrical impulse that produces the heartbeat starts in the SA node. This electrical impulse leaves the SA node, travels through the atria through the internodal pathways and causes them to contract. The impulse then travels through the bundle of His to the bundle branches and then through the Purkinje fibers (Figure 31.1A). This electrical activity of depolarization causing contraction and repolarization causing relaxation, is captured on an electrocardiogram (ECG or EKG) (see Figure 31.1B). During each phase of the cardiac cycle, a distinct wave pattern is produced on the ECG.

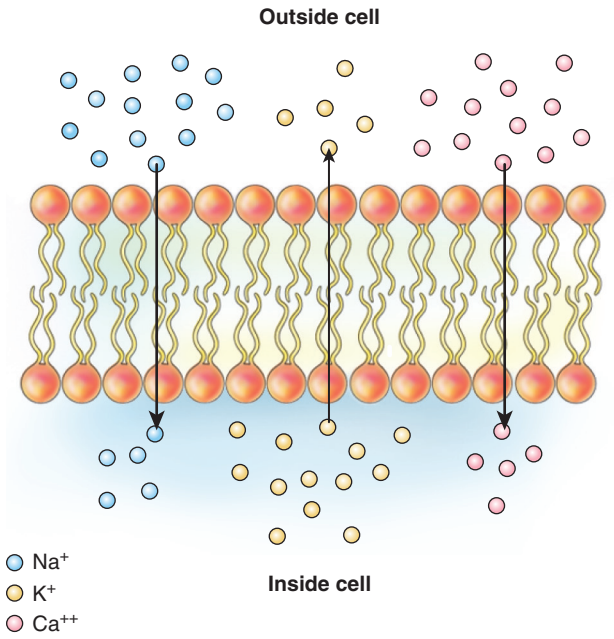
The first wave seen is the P wave, which represents atrial depolarization. After the impulse leaves the atria, it is slowed



• FIGURE 31.1 Cardiac conduction. (**A**) The heart's electrical circuitry has a profound effect on efficient blood flow to the tissues. An electrical impulse from the sinoatrial (SA) node travels over the internodal pathways to produce atrial contraction. The impulse slows slightly as it nears the ventricles at the atrioventricular (AV) node (the AV junction). After passing through the bundle of His, the impulse descends along the left and right bundle branches to the Purkinje fibers, stimulating ventricular contraction and proceeding on to the SA node to continue the cycle. The efficiency of the conduction system has a major influence on cardiac rhythm and output reflected by blood flow. (**B**) This is the pattern of one cardiac cycle on an EKG. Note the components of the complex including the waves and intervals. P wave, PR interval, PR segment; Q,R and S waves, QRS complex; ST segment, QT interval.



• FIGURE 31.2 (**A**) Normal sinus rhythm, ECG. (**B**) Bradycardia, slow heart rate. (**C**) Tachycardia, fast heart rate.



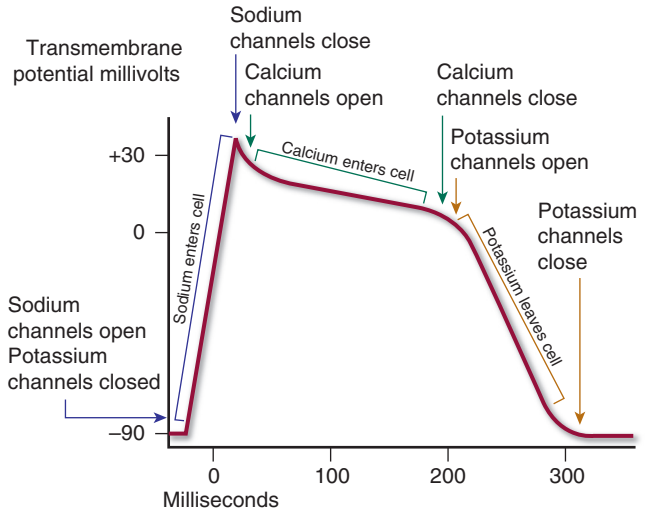
• FIGURE 31.3 Intracellular and extracellular ions. Potassium is the predominant intracellular ion. It will move to the outside of the cell, following its concentration gradient. Sodium and calcium are predominantly extracellular ions; they will move into the cell.

at the AV node to allow the ventricles to fill and to ensure that the atria and the ventricles do not contract simultaneously. On the ECG, this slowing is translated into a period of inactivity called the PR segment: a straight line between the end of the P wave and the start of the first deflection of the next wave. All of the electrical activity in the heart that takes place before the impulse reaches the ventricles is seen in the PR interval, which includes the P wave and the PR segment. The ventricular depolarization is shown by a large complex of three waves: The Q, the R, and the S, called the QRS complex. After the ventricles depolarize, they begin the repolarization phase, which results in another wave on the ECG called the T wave. The atria also repolarize, but their repolarization usually occurs at the same time as ventricular depolarization; thus, the atrial repolarization wave is usually hidden in the QRS complex.

Figure 31.2A shows a normal-rate ECG. Compare this normal rate to the slow heart rate (bradycardia: a resting heart rate less than 60 beats per minute [bpm]) shown in Figure 31.2B and to the fast heart rate (tachycardia: a resting heart rate greater than 100 bpm) shown in Figure 31.2C.

To best comprehend this unique conduction system, it is important to understand how the movement of potassium, sodium, and calcium ions bring about electrical changes in the cardiac cells to stimulate contraction. Potassium is predominantly an intracellular (within the cell) ion, and sodium and calcium are predominantly extracellular (outside the cell) ions (Figure 31.3). Calcium is also stored in sarcoplasmic reticulum within the cell, but it is not active as long as it is stored.

These ions (potassium, sodium, and calcium) all flow following the normal concentration gradient (moving from areas of high concentration to areas of low concentration). Because of the different concentrations of intracellular and extracellular ions, an electrical gradient exists across the membrane of the cell. This electrical gradient is called the **transmembrane potential.** All changes that occur in the transmembrane potential during an entire cycle of contraction and relaxation are, as a unit, called the **action potential.** At rest, the electrical charge of the transmembrane potential, also known as the **resting membrane potential,** is –90 millivolts (mV). This means that there is a 90-mV difference between the electrical charge inside and outside of the cell, and that the charge is negative inside the cell. As sodium moves into the cell, **depolarization** occurs. At this point, the transmembrane potential changes from negative to positive. Depolarization occurs rapidly and is called phase 0 of the action potential. During this rapid depolarization, the sodium channels open quickly for only a brief period. While these "fast channels" are open, sodium rushes into the cell. The influx of sodium ions into the cell increases the transmembrane potential to about +30 (meaning that the charge is now positive inside the cell relative to outside the cell). As soon as this positive charge is achieved, the voltage-regulated sodium channels close, and the cell begins to return to a negative state. This movement of the transmembrane potential away from a positive value and toward the negative resting potential is called **repolarization.** The initial downward movement toward zero is phase 1 of the action potential. As the charge reaches 0 mV, a plateau occurs. This plateau is what differentiates the action potential of cardiac muscle from the action potential of skeletal muscle. In this plateau phase, called phase 2, the calcium channels open slowly. These "slow channels" allow calcium ions to enter the cell. The positively charged calcium channels



• FIGURE 31.4 Movement of electrolytes during the action potential. As sodium enters the cell, rapid depolarization occurs. Once sodium channels close, the process of repolarization slowly begins. When calcium enters the cell, a plateau occurs. When the calcium channels close and potassium channels open, rapid repolarization occurs.

close, potassium channels open, and potassium moves out of the cell. The cell then begins a rapid acceleration of repolarization: phase 3 of the action potential. When full polarization is achieved once more, the cell is in phase 4 of the action potential; sodium and potassium have gradually returned to their original locations (sodium outside of the cell, and potassium inside the cell). The cell remains polarized until stimulated again to depolarize. In other words, the cycle will start over (Figure 31.4).

After the cell depolarizes, and until it restores its normal electrical charge, it cannot be stimulated to fire again. This interval is termed the **refractory period.** Initially after depolarization, the cell cannot be stimulated to fire, no matter how great the stimulus. This state is the absolute refractory period. As repolarization continues, the cell eventually responds, even though it is not at the resting state. However, the intensity of the stimulus needed to depolarize the cell is greater than when the cell is in the resting state. This ability to respond, but only to a larger than normal stimulus, is termed the relative refractory period.

In addition to its role in the propagation of the action potential, calcium is also required for the mechanical contraction of the heart. In contracting cells of the heart, calcium links excitation (from polarization) to contraction. The contraction of cardiac and vascular smooth-muscle tissues is dependent on the movement of extracellular calcium into these cells. However, the influx of calcium is only approximately 20% of the calcium needed to initiate a contraction. The calcium that enters the cell stimulates the release of calcium that is stored inside the sarcoplasmic reticulum. This process is called calcium-induced calcium release. The process occurs during the plateau phase of the action potential. This release of additional calcium is what actually induces a contraction.

The plateau phase is unique to the cardiac muscle. In contrast, repolarization of skeletal muscle occurs rapidly after depolarization, allowing the muscle to be stimulated to contract again almost immediately. Tetany, or constant contractions, may occur in skeletal muscles. This process would be life threatening if it occurred in the heart because no effective contractions would be present. Thus, this plateau phase can be considered a protective mechanism of the heart muscles to promote effective contractions (Figure 31.5). Imbalances of the electrolytes involved in the action potential, either greater than or less than normal serum levels, may produce changes in the action potential and cause various cardiac arrhythmias. Contractility of the heart is also affected by the concentration of catecholamines in the heart muscle—the more catecholamines, the greater the rate of contraction and the greater the force of contraction will be.

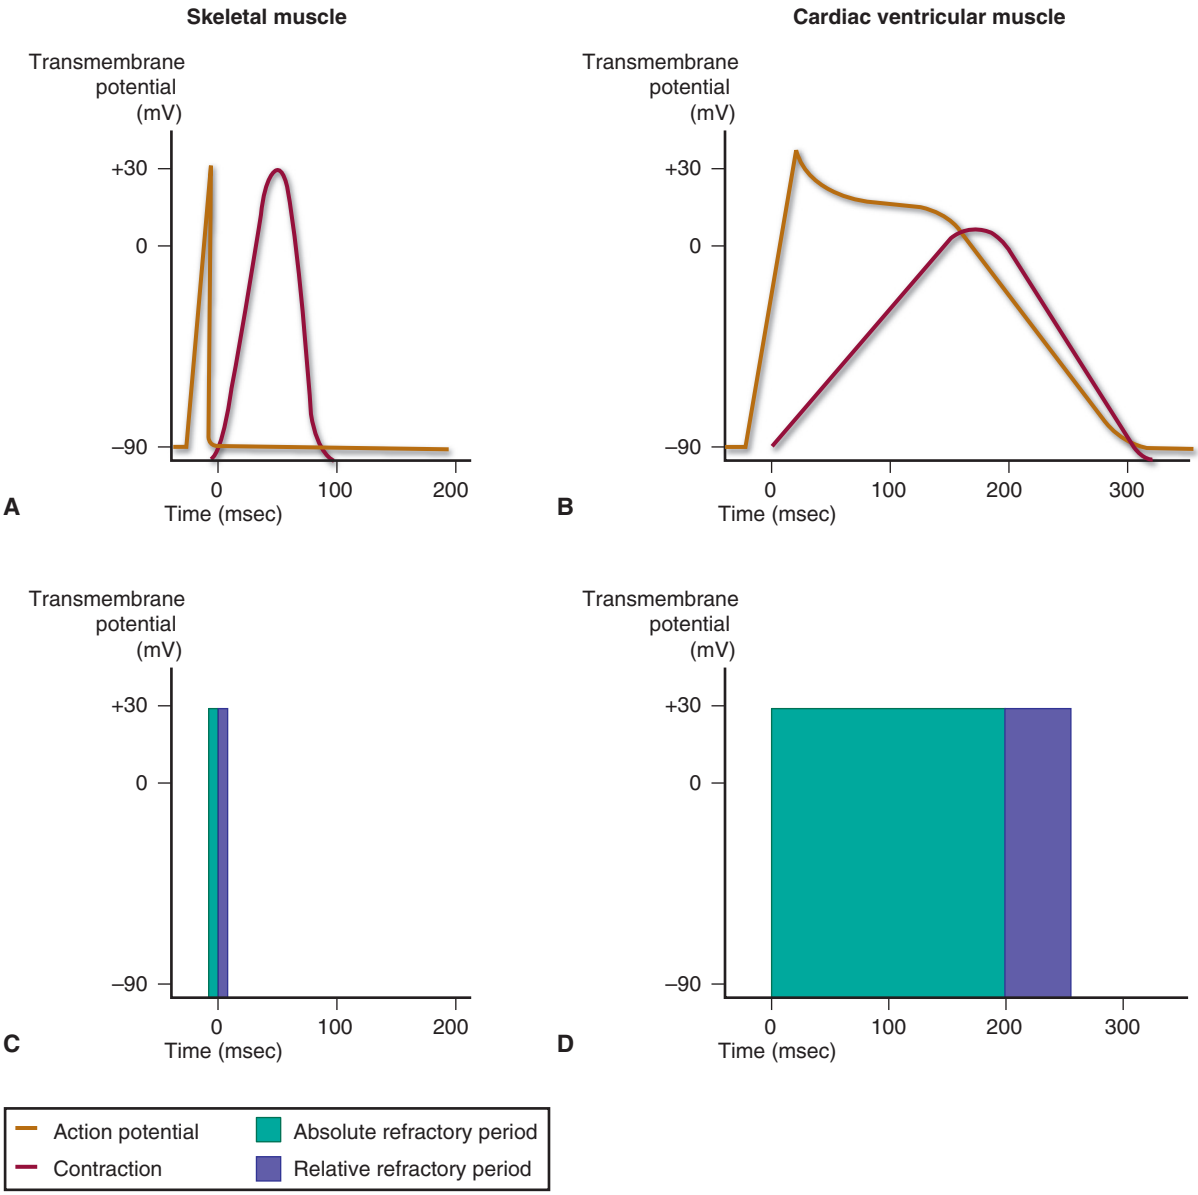
PATHOPHYSIOLOGY

Arrhythmias, also called dysrhythmias, are a disturbance in the electrical activity of the heart. Some arrhythmias are insignificant and do not create any problems for the patient. Others disrupt the function of the heart, increase the oxygen demand of the heart, and interfere with cardiac output. Some are considered life threatening or lethal.

Changes in the ionic currents through ion channels of the myocardial cell membrane are the main cause of cardiac arrhythmia. The ions are sodium, potassium, and calcium. These ionic changes allow arrhythmias to develop in one of three ways: through a disorder with impulse formation, through a disorder of the impulse conduction system, or through a combination of both. When a disorder of impulse formation is present, the rate of SA nodal discharges is altered, allowing changes in the **automaticity** (ability to generate an impulse spontaneously) of the heart. Decreased automaticity results in sinus bradycardia; increased automaticity results in sinus tachycardia. These changes may be the result of drug toxicity, such as from digoxin, or of excessive sympathetic activity. Eliminating the contributing factor controls the arrhythmia. A different problem with automaticity occurs when the SA nodal rate decreases excessively and other excitable heart tissue reaches the threshold potential earlier than the SA node, thus generating an impulse. These abnormal sites of impulse formation are **ectopic foci.** These ectopic pacemakers may result from hypokalemia, myocardial ischemia, emotional stress, or hypoxia. Ectopic foci may arise in atrial, nodal, Purkinje, or ventricular muscle.

Disorders of impulse conduction may result from an alteration in either the rate or the pathway of impulse conduction. When conduction of the impulses through the AV node is delayed, heart block occurs.

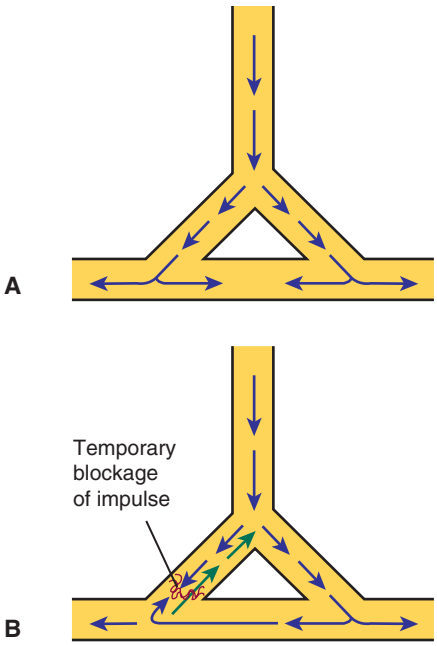
Re-entry phenomenon is a more common source of alterations of impulse formation. Electrical impulses normally travel along a Purkinje fiber and divide at the small branch points in the fiber. When they meet each other in the connecting



• FIGURE 31.5 Comparisons of action potential, contraction, and refractory periods in skeletal and cardiac muscle.

branch, they normally extinguish each other. However, where there is a temporary block in one of the branches because of an alteration in nerve impulse conduction, the impulse cannot continue to travel in its normal forward path, canceling itself out in the common branch. Instead, the impulse is carried through the unopposed side and re-enters the branch from the opposite direction. Re-entry, or the **re-entry phenomenon**, causes repetitive cardiac stimulation, firing, and arrhythmias (Figure 31.6).

Arrhythmias can occur in the atria or in the ventricles. **Atrial flutter** (Figure 31.7A) is an arrhythmia originating in the atria: rapid atrial beating (approximately 240 to 320 bpm) but a slower, regular or irregular, ventricular beating (120 to 160 bpm; usually about 150 bpm). The slower ventricular rate results because atrial flutter commonly occurs with a 2:1 AV block, meaning that the ventricle is protected from excessive stimulation; only half of the impulses pass through the AV node. The ECG pattern shows a sawtooth pattern for atrial activation with a normal QRS complex. **Atrial fibrillation** (AF or Afib) (see Figure 31.7*B*) is the most commonly seen arrhythmia in clinical practice. This arrhythmia is caused by rapid, irregular discharges from multiple atrial ectopic foci. The result is quivering of the atria without the occurrence of a true diastole or atrial contraction. Impulses are transmitted irregularly through the AV node, producing an irregular ventricular response, which is often rapid. Atrial fibrillation is a supraventricular tachyarrhythmia characterized by uncoordinated atrial activation, resulting in a loss of effective atrial contractions. The ECG pattern shows an absence of a normal P wave, which is replaced by rapid oscillating waves of various amplitudes, shapes, and timing. The exact response of the ventricles depends on several factors: the



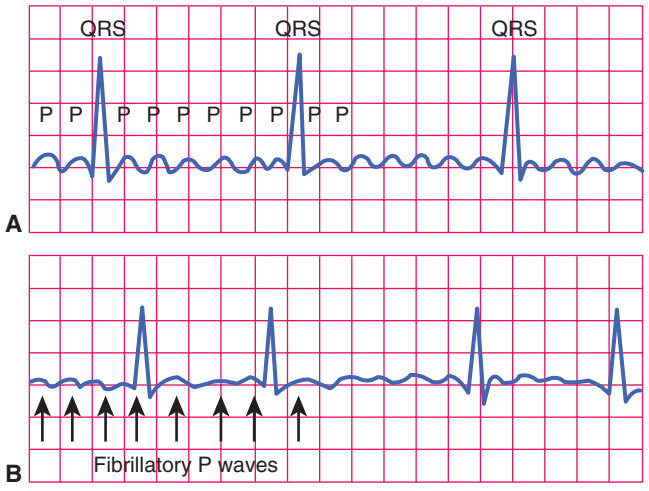
• FIGURE 31.6 Re-entry phenomenon. In normal cardiac conduction (**A**), electrical impulses cancel each other out. In re-entry phenomenon, conduction is altered by a temporarily blocked impulse (**B**), allowing the impulse coming from the other direction to recycle and stimulate the Purkinje fibers to contract again. The result is a disturbance in cardiac rhythm. Antiarrhythmic drugs are used to treat these disturbances.

electrophysiological properties of the AV node and other conducting tissues, the level of vagal and sympathetic tone, and the presence or absence of accessory conduction pathways. Atrial flutter may become A fib and vice versa.

The incidence of A Fib is increasing; it produces a great deal of morbidity and some mortality, although it is not directly life threatening. The American College of Cardiology (ACC), the American Heart Association (AHA), and the European Society of Cardiology (ESC) have defined the following classifications of atrial fibrillation:

- *First detected AFib,* which may or may not be symptomatic or self-limited.
- *Recurrent AFib,* which is characterized by two or more documented episodes of AFib. Recurrent AFib is subdivided based on its clinical presentation:
  - Paroxysmal—the AFib terminates spontaneously
  - Persistent—the AFib is sustained beyond 7 days
- *Permanent AFib,* which has not responded to attempts at cardioversion or cardioversion has not been attempted. This definition may be arbitrary (Fuster, Ryden, Cannom, et al., 2006).

Management of AFib involves two main therapeutic strategies. The first is rhythm control, which is cardioversion followed by maintenance of sinus rhythm with arrhythmic drugs. The second is rate control, which is use of AV nodal blockers plus anticoagulation. In the past, the goal of atrial fibrillation treatment was to correct the rhythm. However, clinical trials such as AFFIRM and RACE (Wyse, Waldo, DiMarco, et al., 2002; Van Gelder, Hagens, Bosker, et al., 2002) found no advantage from correcting rhythm. Rate control is the currently accepted practice and is preferred for most patients (Box 31.1). There are two rationales for using rate control (controlling rapid ventricular rate) in patients with AFib. First, controlling ventricular rate avoids hemodynamic instability and/or symptoms such as palpitations, heart failure, light-headedness, and poor exercise tolerance.



• FIGURE 31.7 (**A**) Atrial flutter. Note rapid flutter waves with occasional QRS complexes. (**B**) Atrial fibrillation. Note small, irregular waves. QRS complexes can be at an irregular rate but appear normal.

BOX 31.1 FOCUS ON RESEARCH

Treatment Options with Atrial Fibrillation

Schneider, M. P., Hua, T. A., Böhm, M., Wachtell, K., Kjeldsen, S. E., Schmieder, R. E. (2010). Prevention of atrial fibrillation by renin-angiotensin system inhibition a meta-analysis. *Journal of American College of Cardiology,* 55(21):2299–2307.

The Study

This meta-analysis reviewed 23 randomized controlled studies focusing on the treatment of atrial fibrillation (AF), both primary and secondary prevention, with renin-angiotensin system (RAS) inhibition. A total of 87,048 patients were included in the review. Both angiotensin converting enzyme and receptor blocker drugs were considered.

Results were variable based partly on the heterogeneity between the studies but it was concluded that RAS inhibition does have a role in the treatment of atrial fibrillation. More controlled studies are necessary.

Nursing Implications

This study is important because successful treatment of atrial fibrillation is hard to accomplish. A clear option has not been identified. Treatment with antiarrhymic drugs has limitations. At present, treatment options with antiarrhythmics lean more toward controlling rate rather than converting to sinus rhythm. This analysis demonstrated the possibility of preventing the occurrence or reoccurrence of AF with RAS inhibition. These studies will be ongoing. The nurse must be aware of new findings that will affect practice. Also, as with any drug therapy, patient education is a must. The patient must understand the dosage, side effects, and when to contact the prescriber.

Second, controlling ventricular rate has the long-term benefit of preventing a tachycardia-induced cardiomyopathy. Treatment of patients with AF should always include anticoagulant therapy, stroke risk assessment, and close follow-up if anticoagulation is discontinued.

Ventricular tachycardia is rapid ventricular beating (greater than 100 bpm; usually 150 to 200 bpm) arising from ventricular ectopic foci. The ECG from ventricular tachycardia consists of wide bizarre QRS complexes that can be regular or of varying shape and amplitude. **Ventricular fibrillation** is quivering of the ventricle without a systolic beat. If not terminated rapidly (2 to 3 minutes) with defibrillation, brain damage occurs because the brain is not receiving oxygen. The ECG from ventricular fibrillation shows rapid, oscillating waves of various amplitudes, shapes, and timing; it is varied and chaotic, with no discernible complexes.

Ventricular tachycardia and ventricular fibrillation are serious and potentially life-threatening arrhythmias. They may occur after an acute myocardial infarction (MI). These arrhythmias must be corrected quickly or the patient may die due to inadequate ventricular filling leading to a greatly reduced or nonexistent cardiac output. Once the patient has been converted by defibrillation to a normal rhythm, there may be a tendency to revert to ventricular tachycardia or ventricular fibrillation later. Patients who are deemed most at risk for reverting may be placed on long-term drug therapy, receive an implantable cardioverter defibrillator (ICD), or both.

DRUGS AND OTHER THERAPIES TO TREAT ARRHYTHMIAS

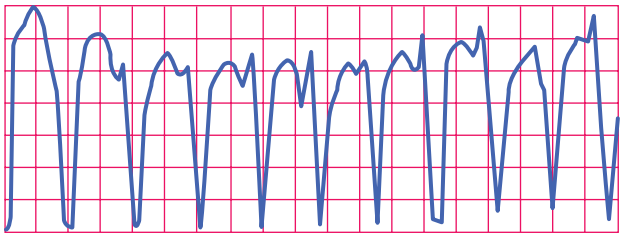
Drug therapy previously was the mainstay for treating arrhythmias; however, the latest research studies show it has become possible to prevent the recurrence of some arrhythmias with the use of ICDs. ICDs have an established and definitive role in preventing sudden cardiac death; technologic innovations and refinements in therapeutic capabilities of these devices have widened the spectrum of patients who can benefit from ICD. This therapy can improve myocardial function with physiologic AV sequential pacing, treat life-threatening ventricular tachyarrhythmias with electrical therapies, and prevent bradycardia with support pacing. Concomitant use of drug therapy with ICDs is often the rule for chronic AFib.

Other arrhythmias can be treated by catheter ablation. Catheter ablation is being used to treat supraventricular arrhythmias and is a highly successful and often curative intervention. The ablative procedure is performed in an electrophysiology laboratory with electrode catheters positioned in the area of the AV node to apply radiofrequency energy to the slow conducting pathway. The slow pathway is ablated, and the patient's conduction then uses the fast pathway, as it should with normal rhythm.

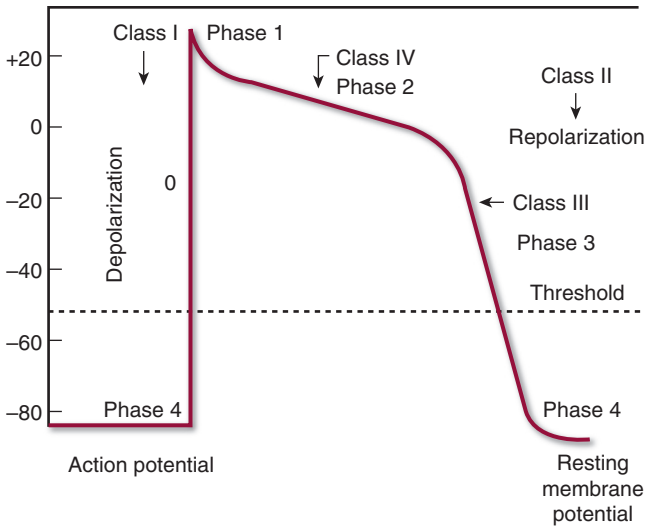
Antiarrhythmics are agents used to prevent, suppress, or treat a disturbance in cardiac rhythm. The primary outcomes are to decrease automaticity, decrease speed of conduction, and decrease re-entry. Clinical trials are providing new information on the effectiveness of different drugs in treating various arrhythmias. Selection of an antiarrhythmic drug is based on outcomes from these clinical trials, such as the AFFIRM study, not solely on the electrophysiologic changes related to the drug class. One problem with all antiarrhythmics is that, because of their ability to modify the rhythm of the heart, they can cause a new arrhythmia or exacerbate the arrhythmia that they are treating. This adverse effect is termed **proarrhythmia.** Such effects range from an increase in frequency of premature ventricular contractions (PVCs) to the development of more severe ventricular tachycardia, ventricular fibrillation, or torsades de pointes. The latter is a rapid, unstable form of tachycardia in which the QRS complexes appear to twist around the axis line. It is usually associated with a prolonged Q-T interval (Figure 31.8), which may lead to death.

When antiarrhythmic drugs were developed, a system of classification was sought in an attempt to organize the complex information in a conceptually meaningful fashion. The classification system developed was fairly comprehensive and was grouped by the drugs' actions (not by the drugs, per se). Class I antiarrhythmic drugs block sodium channels. Several subtypes of sodium channels have been discovered, which depend on the kinetics of their sodium-channel properties (i.e., very fast, very slow, and intermediate). Class IA antiarrhythmic agents are intermediate. Class IB antiarrhythmic agents are very fast. Class IC antiarrhythmic agents are very slow; and Class IA antiarrhythmic agents are also known to suppress sodium-channel activity in all cardiac tissues, whereas Class IB antiarrhythmic agents suppress sodium-channel action only in diseased or depolarized tissue.

Class II antiarrhythmic drugs block adrenergic receptors (beta blockers), producing antisympathetic effects that slow the heart rate, lengthen the time needed for conduction, and increase the force of contraction. The effect seen with Class II antiarrhythmic drugs is depression of phase 4 of depolarization. Beta blockers are the most effective drugs that provide rate control for AF (Olshansky, Rosenfeld, Warner, et al., 2004). Class III antiarrhythmic drugs, or potassium channel blockers, lengthen the duration of the action potential, which prolongs phase 3 of repolarization. Class IV antiarrhythmic drugs block calcium channels, which depresses phase 4 of depolarization and lengthens phases 1 and 2 of repolarization



• FIGURE 31.8 Torsade de pointes. A rapid, unstable form of tachycardia where the amplitude and morphology of the QRS complexes are randomly varied. They appear to twist around the isoelectic line thus the name torsades. It is usually associated with a prolonged QT interval.



• FIGURE 31.9 Action potential and antiarrhythmic drugs. The change in the charge of the myocardial cell that occurs when sodium (Na+) and calcium (Ca++) flow into the cell and potassium (K+) flows out is called the action potential. Different antiarrhythmic drugs act at different phases of polarization and repolarization. Class I drugs (lidocaine) act during depolarization, class II drugs (propranolol) act during the resting period of repolarization, class III drugs (amiodarone) act during rapid repolarization, and class IV drugs (verapamil) act during early repolarization.

(Figure 31.9). Class IV antiarrhythmic drugs are effective in the control of rhythm in AF as well as in serious ventricular arrhythmias.

Although this classification system is widely used, it has substantial limitations. Some drugs have characteristics of more than one class; other drugs (such as digoxin and adenosine) used in specific types of arrhythmias do not fit in any of the classes. Despite these limitations, the antiarrhythmics discussed in this chapter are presented in the traditional groupings of Class I, II, III, and IV.

The major goals of antiarrhythmic therapy are to alleviate symptoms (e.g., palpitations, light-headedness, shortness of breath), improve quality of life, and prolong survival in patients with cardiac arrhythmias. The relief of symptoms in most patients can be achieved either by slowing the rate or by preventing recurrence. However, relief of the arrhythmia is not always associated with decreases in mortality.

CLASS I ANTIARRHYTHMIC DRUGS

Class I antiarrhythmics are local anesthetics or membrane- stabilizing agents that depress phase 0 in depolarization. The drugs in subgroups of A, B, and C are not interchangeable because they have different pharmacotherapeutics. Class IA antiarrhythmics include quinidine, procainamide, disopyramide, and moricizine. These currently have limited use. Class IB drugs, which are utilized most frequently, include the prototype lidocaine, tocainide, mexiletine, moricizine, and phenytoin. Class IC drugs include flecainide and propafenone. Table 31.1 presents a summary of selected Class IA antiarrhythmic drugs.

Nursing Management of the Patient Receiving P Lidocaine

Core Drug Knowledge

Pharmacotherapeutics

Lidocaine (Xylocaine) may be used with all acute ventricular arrhythmias because these may be life threatening. In other strengths and routes, lidocaine also is used as a local and topical anesthetic.

Pharmacokinetics

Lidocaine is usually administered intravenously because it is ineffective orally. Under certain circumstances, it may be administered intramuscularly. Single intramuscular doses are justified in the following exceptional circumstances: lack of availability of ECG equipment to verify diagnosis (but the potential benefits must outweigh the possible risk) and when the facilities for IV administration are not readily available. When given intramuscularly, higher and more rapid serum levels are achieved by injection into the deltoid muscle over the gluteus or vastus lateralis. However, lidocaine given intramuscularly may increase creatine phosphokinase (CPK) levels. CPK is an enzyme used as a diagnostic test for acute MI. Lidocaine is about 50% protein bound. Lidocaine is metabolized extensively in the liver into at least two active metabolites. These metabolites have both antiarrhythmic and convulsant (inducing convulsions) effects. Metabolism of this drug is impaired substantially by any condition that impairs liver function. Although renal elimination processes only about 10% of the dose given, it is highly involved in the excretion of the metabolites. Accumulation of one of the metabolites (known as GX) because of renal disease or impaired renal function contributes to lidocaine toxicity.

Lidocaine has a biphasic half-life. The half-life involved with the distribution phase is less than 10 minutes. This brevity accounts for the short duration of action when an IV bolus is given. Because of the drug's very short half-life, repeated boluses may be required to quickly achieve therapeutic level when a continuous IV infusion is needed to maintain the therapeutic effects (see Table 31.1 for dosing information). The elimination half-life is 1.5 to 2 hours. It may be 3 hours or more if the lidocaine infusion has lasted longer than 24 hours.

Pharmacodynamics

Lidocaine, used to treat arrhythmias, in therapeutic levels, weakens phase 4 diastolic depolarization, decreases the automaticity, and decreases or causes no change in the excitability and membrane responsiveness. Additionally, it decreases the action potential duration and the effective refractory period of Purkinje fibers and ventricular muscle. However, the ratio of the effective refractory period to the action potential duration is increased. The effective refractory period of the AV node may increase, decrease, or remain unchanged; the atrial effective refractory period remains unchanged. Lidocaine raises the ventricular

TABLE 31.1 Summary of Selected Class I Antiarrhythmics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
quinidine (Quinaglute Dura-Tabs) Class 1A	Premature atrial and ventricular contractions Paroxysmal supraventricular tachycardias Atrial flutter	*Adult:* PO, 200–300 mg three or four times daily *Child:* PO, 30 mg/kg/24 h or 900 mg/m^2/24 h in five divided doses *Adult:* F 400–600 mg every 2 or 3 h until the paroxysm is terminated; administer after digitalization; dosage individualized *Child:* PO, 30 mg/kg/24 h or 900 mg/m^2/24 h in five divided doses *Adult:* After digitalization, dosage is individualized	*Onset:* PO, 1–3 h; IM; 30–90 min; IV, rapid *Duration:* 6–8 h $t_{1/2}$: 6–7 h
procainamide (Procan SR) Class 1A	Ventricular arrhythmias	*Adult:* PO, initially 50 mg/kg/d in divided doses every 3 h; PO, maintenance, 50 mg/kg/d in divided doses q6h; IV, loading (initial), 1 mL/min of 20 mg/mL solution or 100 mg every 5 min direct IV, up to 1 g total; maintenance, 1–3 mL/min of 2 mg/mL solution *Child:* PO, 15–50 mg/kg/d divided every 3–6 h; max of 4 g/d; IV, initial 3–6 mg/kg/dose over 5 min; maintenance, 20–80 mg/kg/min continuous infusion; maximum, 100 mg/dose or 2 g/d	*Onset:* PO, 30 min; IM, 10–30 min; IV, immediate *Duration:* 3–4 h $t_{1/2}$: 2.5–4.7 h
P lidocaine (Xylocaine HCl IV for cardiac arrhythmias) Class 1B	Ventricular arrhythmias	*Adult:* Initial IV bolus 50–100 mg at rate of 25–50 mg/min; one-third to one-half the initial dose may be given after 5 min; do not exceed 200–300 mg in 1 h. Continuous infusion, 20–50 mg/kg/min *Child:* AHA recommends bolus of 1 mg/kg IV, followed by 30 mg/kg/min w/caution	*Onset:* IM, 5–10 min; IV, immediate *Duration:* IM; 2 h; IV, 10–20 min $t_{1/2}$: 10 min, then 1.5–3 h
flecainide (Tambocor) Class 1C	PSVT and PAF Sustained ventricular tachycardia	*Adult:* Starting dose of 50 mg every 12 h; increase in 50-mg increments twice a day every fourth day until efficacy is achieved. Max dose is 300 mg/d. *Child:* Not recommended *Adult:* 100 mg every 12 h; increase in 50-mg increments twice a day every fourth day until efficacy is achieved. Max dose is 400 mg/d. *Child:* Not recommended.	*Onset:* 30–60 min *Duration:* 24 h $t_{1/2}$: 20 h

PSVT, paroxysmal supraventricular tachycardia; PAF, paroxysmal atrial flutter.

fibrillation threshold, which is why it is effective in treating ventricular fibrillation.

Clinical electrophysiologic studies have demonstrated no change in sinus node recovery time, sinoatrial conduction time, and His-Purkinje fiber conduction time. AV node conduction time is unchanged or may be shortened. Lidocaine does increase the electrical stimulation threshold of the ventricle during diastole. This increase enables a longer diastole because the ventricle requires a longer time before it can be receptive to depolarization and contract again. This effect is helpful in treating ventricular arrhythmias. In therapeutic doses (serum levels of 1.5 to 6 mcg/mL), lidocaine has no effect on the contractility of the heart, blood pressure, or the absolute refractory period.

Contraindications and Precautions

Lidocaine is a pregnancy category B drug. However, caution should be used because no adequate and well-controlled studies have been done in pregnant women. Although safety and efficacy in children have not been established from clinical studies, the American Heart Association's Standards and Guidelines recommend using lidocaine when needed in children (see Table 31.1). Caution should be used, and lower doses are recommended, for patients who have CHF, reduced cardiac output, digitalis toxicity accompanied by AV block, hypovolemia, and shock; in all forms of heart block; and when used in older adults.

Adverse Effects

Adverse effects of lidocaine are seen particularly in the CV system and CNS. CV effects are related to serum levels, with the most severe cardiac depression coinciding with toxic levels of lidocaine. The most common CV effects are cardiac arrhythmias and hypotension. Other effects include bradycardia and CV collapse, which may lead to cardiac arrest. CNS adverse effects also are related to blood concentrations of lidocaine. The most common CNS effects are dizziness, light-headedness, fatigue, and drowsiness. These common, mild effects are seen with low blood levels of lidocaine and resolve rapidly. As blood levels of lidocaine rise, nervousness, confusion, mood changes, hallucinations, euphoria, tinnitus, blurred or double vision, and a sensation of heat, cold, or numbness may occur. In common health care jargon, these CNS effects

are referred to as the "lidocaine crazies." With excessively high serum levels of lidocaine (greater than 6 mcg/mL), toxicity is present, and the patient develops seizures and loses consciousness.

It is very important to continually monitor the ECG of the patient receiving IV lidocaine. Emergency resuscitative equipment and drug therapy should be on hand in case the patient develops serious adverse effects. As soon as the patient is clinically stable, she or he should be switched to another antiarrhythmic that can be given orally.

Drug Interactions

Lidocaine interacts with many classes of drugs such as beta blockers, antimicrobials, protease inhibitors and other antiarrhythmics Typical effects are additive cardiac effects or decreasing metabolism with puts patients at risk for toxicity. Table 31.2 lists drugs that have a probable interaction with lidocaine.

Assessment of Relevant Core Patient Variables

Health Status

Before emergent use, the health care team must determine whether the patient has a type of ventricular arrhythmia that is an indication for therapy. It also is important to determine whether the patient has a sensitivity to lidocaine which would be a contraindication to therapy. Before initiating continuous therapy, it must be determined whether the patient is on any drugs which will interact with lidocaine.

Also, because lidocaine is largely metabolized in the liver and excreted through the kidneys, renal and liver status should be established. The patient with renal or hepatic disease may be at greater risk for toxicity. The patient with cardiac insufficiency will also be at risk for toxicity due to a decrease in hepatic blood flow. Conversely, the patient without heart disease and thus adequate cardiac output will have increased clearance of lidocaine, increasing the chance of recurrence of the arrhythmias.

Life Span and Gender

As stated earlier, lidocaine has not been linked to adverse effects in either pregnancy or breast-feeding but limited studies have been done. Caution is suggested. Dosage in children should be adjusted by weight.

Environment

Lidocaine should be given in a hospital or emergency setting where continuous ECG monitoring is possible.

Nursing Diagnoses and Outcomes

- Decreased Cardiac Output related to cardiac changes secondary to adverse effects of drug therapy

TABLE 31.2 Agents That Interact with P Lidocaine

Interactants	Effect and Significance	Nursing Management
Amiodarone	May decrease metabolism	Monitor levels
Phenytoin	May increase metabolism; potential for increased cardiac effects	Avoid concomitant use
Propofol	Unknown mechanism, decreases dose necessary for desired effect of propofol	May need to decrease propofol dose
Arbutamine	Increased risk of life threatening arrhythmias due to additive cardiac effects	Avoid concomitant use
cimetidine	Rapid Increas in serum levels and risk of lidocaine toxicity	Monitor serum levels of lidocaine Assess for signs of adverse effects. Consider alternate GI prophylaxis
beta blockers ((propanolol, nadolol, penbutolol, metoprolol)	decrease in metabolism.	Monitor levels and adjust dosage as necessary.
Protease inhibitors (amprenavir, atazanavir, lopinavir)	Inhibition of P-450 3A metabolism of lidocaine.	Avoid concomitant use.
succinylcholine	Snergistic effect; may causeprolonged neuromuscular blockade	Monitor drug levels, and attempt to stagger doses.
St John's Wart	Unknown mechanism; prolonged anesthesia recovery time	Discontinue St John's wort at least 5 d prior to anesthesia
Dalfopristin/Quinupristin	Inhibition of P-450 3A metabolism of lidocaine.	Monitor for lidocaine toxicity; adjust dose as necessary

Desired outcome: *The patient will not develop deleterious cardiac changes that alter cardiac output.*

- Risk for Injury, such as hepatic toxicity, related to adverse effects of drug therapy
  Desired outcome: *The patient will not incur hepatic toxicity while on drug therapy.*
- Change in level of consciousness related to CNS changes secondary to adverse effects of drug therapy
  Desired outcome: *The patient will not experience dangerous CNS changes while on therapy*

Planning and Intervention

Maximizing Therapeutic Effects

To maximize the therapeutic effects of lidocaine, after an initial (or several) IV push dose of 50 to 100 mg, a continuous drip of 1 to 4 mg/min may be started.

Minimizing Adverse Effects

It is necessary to connect the patient to a cardiac monitor and monitor rhythm continuously

Notify the prescriber immediately if any of the following events occurs:

Prolongation of PR or QRS interval

- Sinus node dysfunstion
- Aggravation of the arrhythmia
- CNS depression or irritability
- Liver and kidney function tests. Reveal elevated values.

Providing Patient and Family Education

- Explain the purpose of the drug and the potential adverse effects.
- Explain the rationale for ECG monitoring and frequent blood testing, which is that these are methods used to detect early onset of adverse effects.

Ongoing Assessment and Evaluation

Monitor the patient's ECG and pulse throughout therapy. Check lidocaine blood levels to ensure that they are therapeutic, not toxic. Periodically, monitor liver enzymes, renal function, and complete blood counts. Drug therapy is considered effective if the ventricular arrhythmia is controlled without the patient developing serious adverse effect.

Drugs Closely Related to P Lidocaine

Other Class 1B antiarrhythics include tocainide, mexiletine, and phenytoin.

Tocainide (Tonocard) is used to treat life-threatening ventricular arrhythmias. As a Class IB antiarrhythmic, it is similar to lidocaine, producing dose-dependent decreases in sodium and potassium conduction and thereby decreasing the excitability of the cardiac cells. Most patients who respond to lidocaine respond to tocainide, and failure to respond to lidocaine usually indicates that the patient will not respond to tocainide, either. The electrophysiologic effects of tocainide are similar to those seen with lidocaine. Tocainide does not prolong the QRS duration or QT intervals. Tocainide slightly depresses the left ventricular function and left ventricular end-diastolic pressure. Usually, this effect produces no changes in the cardiac output. It does slightly, but significantly, increase aortic and pulmonary arterial pressures. This effect is most likely related to increases in vascular resistance. Tocainide has been used safely in patients with acute MI, post-MI, and various degrees of CHF.

Tocainide is given orally because it does not have the high metabolism of lidocaine. Bioavailability of tocainide is nearly 100%; peak serum levels are reached in 0.5 to 2 hours after oral dosing. Protein binding is very low, at 10% to 20%. It is inactivated by conjugation in the liver. About 40% of the drug is excreted in the urine unchanged. Half-life is increased in severe renal dysfunction.

It is important to use tocainide cautiously in patients with known heart failure or minimal cardiac reserve, or when beginning or continuing antiarrhythmic therapy in the presence of signs of increasing depression of cardiac conductivity. Like all antiarrhythmics, tocainide can be proarrhythmic. The most common adverse effects are dizziness, vertigo, nausea, paresthesia, and tremor. These reactions are generally mild, transient, and dose related; they are reversible by reducing the dose, by taking the drug with food, or by discontinuing the therapy. The most serious adverse effect, although not common (less than 1% of patients), is the occurrence of blood dyscrasias (e.g., agranulocytosis, depressed bone marrow function, leukopenia, neutropenia, aplastic or hypoplastic anemia, and thrombocytopenia). Tocainide carries a Black Box warning about these potential blood dyscrasias. These effects, which usually occur during the first 12 weeks of therapy, can be fatal in about one fourth of patients who experience them. Monitor blood work weekly during this period

MEMORY CHIP

P Lidocaine

- Class I B antiarrhythmic used in treating ventricular arrhythmias, such as PVCs or ventricular tachycardia
- Decreases automaticity, excitability and membrane responsivesness,
- Increases stimulation threshold for the ventricule during diastole
- Major contraindications: sensitivity to lidocaine. Precaution should be used in patients with CHF, digitalis toxicity, and heart block
- Most common adverse effects: hypotension, bradyarrhythmias, dizziness,
- Most serious adverse effect: heart block, cardiac arrest, seizures
- Maximizing therapeutic effects: After bolus dose(s) is given, a continuous drip of 1–4 mg/min may be started
- Minimizing adverse effects: Always use an infusion pump with a continuous drip. Monitor electrocardiogram continuously
- Most important patient education: Explain purpose of drug and monitoring. Explain potential adverse effects.

for signs of any of these effects. If any of these disorders is diagnosed, discontinue the tocainide immediately. Blood work should return to normal within 1 month.

Fatalities also have occurred with patients who develop severe pulmonary disorders (such as pulmonary fibrosis, interstitial pneumonitis, fibrosing alveolitis, pulmonary edema, and pneumonia). Tocainide also carries a Black Box warning about the pulmonary fibrosis. Instruct patients to report immediately any pulmonary symptoms, such as shortness of breath on exertion, cough, or wheezing. Discontinue tocainide if any of these disorders develop.

Other potential adverse effects of tocainide include:

- CV: ventricular fibrillation, extension of acute MI, cardiogenic shock, angina, AV block, hypertension, increased QRS duration, pericarditis, prolonged QT interval, right bundle branch block, syncope, vasovagal episodes, cardiomegaly, sinus arrest, vasculitis, and orthostatic hypotension
- CNS: coma, convulsions/seizures, depression, psychosis, agitation, decreased mental acuity, dysarthria, impaired memory, increased stuttering, slurred speech, insomnia, sleep disturbances, local anesthesia, dream abnormalities, myasthenia gravis, and malaise
- Dermatologic: Stevens-Johnson syndrome, exfoliative dermatitis, erythema multiforme, urticaria, alopecia, pruritus, and pallor or flushed face
- GI: abdominal pain, constipation, stomatitis, dysphagia, dyspepsia, thirst, and dry mouth
- Hepatic: hepatitis and jaundice
- Respiratory: respiratory arrest and pulmonary edema or embolism

Mexiletine

Mexiletine (Mexitil) is another Class IB drug. It also is used in life-threatening ventricular arrhythmias and, like all antiarrhythmics, may produce arrhythmias. It is administered only orally. It has pharmacologic and electrophysiologic properties similar to those of lidocaine.

Phenytoin

Although treatment of arrhythmias is not a labeled use of phenytoin (Dilantin), an antiepileptic, it is used commonly in treating digitalis-induced arrhythmias. Like other Class IB drugs, it depresses phase 0 slightly and may shorten the action potential. A full discussion of phenytoin and its use in treating seizures can be found in Chapter 21.

Drugs Significantly Different From Lidocaine

Class IA Antiarrhythmics

The Class IA drugs are similar to lidocaine (Class IB) and Class IC drugs because they depress phase 0 (although not as much)of the action potential. Also similar, these drugs may cause arrhythmias in addition to treating them. Unlike lidocaine, they prolong the effective refractory period, increasing conduction time. Also unlike lidocaine their use in treating life-threatening ventricular arrhythmias has not been shown to improve survival, (see Table 31.1). The most important of these drugs are discussed below.

Quinidine

Quinidine is used primarily to treat atrial arrhythmias, including premature atrial, AV junctional, and paroxysmal atrial (supraventricular) tachycardia, paroxysmal AV junctional rhythm, atrial flutter, and paroxysmal and chronic AFib, but has decreased in use during the past decade for maintaining sinus rhythm and is being replaced by amiodarone (Fang, Stafford, Ruskin, et al., 2004). This Class IA antiarrhythmic can be used as maintenance therapy after electrical conversion of atrial fibrillation or flutter, but again, it is being replaced by amiodarone. Other uses include treating premature ventricular contractions (PVCs) and paroxysmal ventricular tachycardia not associated with complete heart block. Quinidine is also used in treating life-threatening ventricular arrhythmias; however, it is not used commonly for this purpose, because although it may correct the arrhythmia, it has not been shown to improve survival. Quinidine is available as two different salts: quinidine sulfate and quinidine gluconate. A noncardiac use of quinidine (quinidine gluconate only) is in treating life-threatening *Plasmodium falciparum*.

Quinidine is rapidly absorbed from the gastrointestinal (GI) tract. Normally given orally, quinidine gluconate may be given parenterally when oral therapy is not possible or when more rapid therapeutic effects are required, such as for cardioversion (see Table 31.1). Quinidine sulfate is given only orally. The concentration of quinidine varies among the different quinidine salts. Quinidine gluconate contains 62% active quinidine, whereas quinidine polygalacturonate contains 80% active quinidine, and quinidine sulfate contains 83% active quinidine. Quinidine distributes to all body tissues except the brain. It is fairly highly protein bound at 80% to 90% and is metabolized by the liver and excreted unchanged by the kidneys. The influence of renal dysfunction on the disposition of quinidine is controversial; volume of distribution and renal clearance may be reduced. Acid urine promotes elimination of quinidine. In patients with cirrhosis, quinidine may have a prolonged half-life and an increased volume of distribution. In chronic heart failure (CHF), total clearance and volume of distribution are decreased. In elderly patients, elimination half-life may be increased.

Quinidine depresses myocardial excitability, conduction velocity, and contractility. The effective refractory period is prolonged, increasing conduction time. Re-entry phenomenon is therefore prevented. Quinidine also exerts an indirect anticholinergic effect; it decreases vagal tone and may promote conduction in the AV junction.

Quinidine is contraindicated in the presence of hypersensitivity or a history of idiosyncratic reaction to quinidine or other cinchona derivatives. Hypersensitivity and idiosyncratic reaction are manifested by thrombocytopenia, skin eruption, or fever. The drug carries the Black Box warning that when

it is used to prevent or defer recurrence of atrial flutter or fibrillation, it is associated with increased mortality, which appears to be greater than the risk of mortality from other antiarrhythmics. Therefore, quinidine is contraindicated in the following cardiovascular (CV) conditions:

- Digitalis intoxication manifested by arrhythmias or AV conduction disorders
- Complete heart block
- Left bundle branch block or other severe intraventricular conduction defects exhibiting marked QRS widening or bizarre ECG complexes
- Complete AV block with an AV nodal or idioventricular pacemaker
- Aberrant ectopic impulses and abnormal rhythms due to escape mechanisms
- Drug-induced torsades de pointes (ventricular tachycardia associated with QT prolongation)
- Long QT syndrome

Also, quinidine is contraindicated in myasthenia gravis

Extreme caution should be used when giving quinidine to patients with incomplete AV block because complete block may develop. Care also must be taken when administering quinidine to patients with:

- Digitalis toxicity, because unpredictable arrhythmias may result.
- Partial bundle branch block, severe CHF, and hypotension, because quinidine will further depress myocardial contractility and arterial pressure.
- Patients with renal, hepatic, or cardiac insufficiency, because toxicity is more likely to occur.

Quinidine crosses the placenta and achieves fetal serum levels similar to maternal levels. It is in pregnancy category C, indicating that safety has not been established. Quinidine also is excreted in breast milk. Milk-to-serum ratios have been found to be 0.71. Although safe use during breast-feeding has not been established clearly, the American Academy of Pediatrics considers the drug compatible with breast-feeding. Safety and efficacy in children have not been established.

The most common adverse effects involve the GI system and include nausea, vomiting, abdominal pain, diarrhea, and anorexia. These may occur after a fever. Arrhythmias also occur commonly, but most are not life threatening. Other common cardiovascular effects include hypotension and syncope. Another common adverse effect is a syndrome of cinchonism, related to the tree bark source of quinidine, usually associated with chronic toxicity but also described after a brief exposure to a moderate dose in sensitive patients. The symptoms of cinchonism include tinnitus, high-frequency hearing loss, deafness, headache, nausea, dizziness, vertigo, lightheadedness, and disturbed vision. Additionally, some dermatologic adverse effects (dermatitis, photosensitivity, rash) are fairly common.

The most serious adverse effect, although not common, is cardiotoxicity, which is manifested by increased PR and QT intervals, 50% widening of the QRS complex, ventricular tachyarrhythmias (including ventricular tachycardia, fibrillation, and torsades de pointes), frequent ventricular ectopic beats, or tachycardia. If signs of cardiotoxicity are present, quinidine should be discontinued at once, and the ECG of the patient should be monitored closely.

Other CV adverse effects include cardiac asystole, arterial embolism, ventricular extrasystole occurring at the rate of one or more for every six normal beats, complete AV block, ventricular flutter, and serious hypotension. Although large oral doses cause peripheral vasodilation that decreases blood pressure, the most serious hypotension is more likely to occur when quinidine is given intravenously.

Hepatic toxicity can occur, including granulomatous hepatitis. This reaction is believed to be the result of quinidine hypersensitivity. Fever occurs, and liver enzymes are elevated. Other hypersensitivity reactions, which are rare but may occur, are angioedema, acute asthma, vascular collapse, respiratory arrest, and purpura vasculitis.

Quinidine overdosage may be associated with depressed mental function even if the patient is hemodynamically stable. In addition, CNS symptoms (e.g., lethargy, confusion, coma, respiratory depression or arrest, seizures, headache, paresthesia, and vertigo) may occur after the onset of CV toxicity. GI effects include vomiting, abdominal pain, diarrhea, and nausea. The CV effects are tachyarrhythmias, depressed automaticity and conduction, hypotension, syncope, and heart failure.

Some of the adverse effects of quinidine may be similar to reasons the drug is prescribed. For this reason, it is important to monitor blood levels to determine whether the drug is in therapeutic range or is elevated excessively.

Drugs Closely Related to P Quinidine

The other Class IA antiarrhythmics are procainamide (Procan SR), disopyramide (Norpace). Like the prototype quinidine, they carry Black Box warnings that they may increase mortality, especially in patients with non–life-threatening ventricular arrhythmias and in post-MI patients. Procainamide has an additional Black Box warning; it may cause blood dyscrasia and development of a positive antinuclear antibody titer, with or without the development of lupus erythematosus–like syndrome. These three drugs have characteristics that make them similar to quinidine. However, unlike quinidine, these other Class IA drugs are labeled only for use in life-threatening ventricular arrhythmias; procainamide can also be used for AFib (off-label use).

Class IC Antiarrhythmics

Class IC drugs are flecainide (Tambocor) , propafenone (Rythmol), and moricizine (see Table 31.1). These drugs depress phase 0 considerably. In addition, they have a slight effect on repolarization and decrease conduction substantially. They are given orally. These drugs are labeled for use in atrial fibrillation and flutter but because of their strong proarrhythmic effects, their use is limited to patients with life-threatening arrhythmias.

One last note on Class 1 Antiarrhythmics:It is important to examine the relationship of Class I antiarrhythmics to mortality. In patients without structural heart disease, the use of Class I drugs rarely causes proarrhythmia serious enough to be life threatening. However, in studies of patients with ventricular tachycardia and ventricular fibrillation, no controlled study has produced decisive evidence demonstrating that Class I antiarrhythmics have the potential for prolonging survival of patients at high risk for dying suddenly. In fact, data from meta-analysis of several studies show that most, if not all, Class I antiarrhythmics are inclined to increase mortality. Thus, drugs that prolong the action potential only (Class I) are not the answer for decreasing mortality in patients with arrhythmias and structural heart disease. Class I agents are still widely used to decrease the number of shocks that patients with implantable cardioversion defibrillators receive. The efficacy for this use is unknown.

CLASS II ANTIARRHYTHMIC DRUGS

Antiarrhythmic Class II drugs (beta blockers) depress phase 4 depolarization. Beta blockers slow heart rate by suppressing the SA node, slow the speed of conduction through the AV node, and decrease the force of contraction. They effectively reduce mortality in patients who have had a recent MI, those with symptomatic heart failure, and those with congenital long-QT syndrome. The prototype Class II drug metaprolol is discussed fully in Chapter 13. However, only acebutolol, esmolol, and propranolol are labeled as antiarrhythmics. Researchers have found that beta blockers are the most effective drugs for controlling the ventricular rate in AFib (Olshansky, Rosenfeld, Warner, et al., 2004). It is important to keep in mind that only some of the beta blockers are approved for use as antiarrhythmics. A brief discussion of their use as antiarrhythmics follows. Other uses of beta blockers relevant to CV function are found in Chapters 28, 29, and 30.

Propranolol

Propranolol (Inderal) is used for treating cardiac arrhythmias, specifically ventricular arrhythmias post-MI, tachyarrhythmias secondary to digoxin toxicity, and SVT (atrial fibrillation or flutter). Like other beta blockers, propranolol is used in AFib because it effectively slows ventricular rate and protects the heart from excessive ventricular contractions. It may be used either intravenously for acute control or orally for long-term chronic AFib. Propranolol, like other beta blockers, is especially helpful in controlling exercise-induced increases in ventricular rate, exercise-induced angina, acute MI, or heart failure, because it provides treatment for all these problems. The drug is also used to treat hypertension (Fuster, Ryden, Cannom, et al., 2006).

Propranolol blocks the beta-adrenergic receptor sites, which means it is a beta blocker. This blockage of the receptor sites occurs as the drug competes with beta-adrenergic agonists for available beta receptor sites. Propranolol blocks both the beta-1 sites, which are located chiefly in the cardiac muscle, and beta-2 receptors, which are located chiefly in the bronchial and vascular musculature. Propranolol also has a membrane-stabilizing effect, like that of anesthetics, which depresses the cardiac action potential, causing the antiarrhythmic response.

Several mechanisms have been proposed to explain how propranolol achieves its various effects on the CV system. First, propranolol competitively blocks catecholamines at non-CNS adrenergic neuron sites, especially in the heart, thereby leading to decreased cardiac output. Second, propranolol has a central effect, resulting in reduced sympathetic outflow to the periphery. Third, because stimulation of beta receptors is responsible for the release of renin from the kidneys, beta blockade with propranolol prevents the release of renin. Total peripheral resistance initially increases slightly because of these mechanisms. However, it readjusts to the pretreatment level or lower with chronic use. Because the decrease in cardiac output is greater than the increase in peripheral resistance, blood pressure is lowered.

Propranolol is contraindicated in sinus bradycardia, greater than first-degree heart block, cardiogenic shock, CHF (unless secondary to a tachyarrhythmia treatable with beta blockers), overt cardiac failure, diabetes, bronchial asthma or bronchospasm, severe chronic obstructive pulmonary disease, and hypersensitivity to beta blockers.

Propranolol carries a black box warning regarding discontinuation of therapy. If discontinued abruptly, angina and myocardial infarction may be exacerbated. Dosages should be gradually decreased. Important patient teaching should include a warning about abruptly stopping therapy.

Acebutolol and Esmolol

Acebutolol (Monitan) differs from propranolol in that it is selective in beta-1 receptors and has little effect on beta-2 receptors. It is approved for use in hypertension and to treat ventricular arrhythmias. In terms of use in arrhythmias it has similar actions to propranolol. It is only administered orally.

Esmolol (Brevibloc) is approved for use in intraoperative and postoperative hypertension, as well as for supraventricular arrhythmia. Off-label uses include treatment of acute MI and as preinduction for rapid sequence intubation. Esmolol is administered only intravenously. It is relatively selective for beta-1 receptors, although it also can inhibit beta-2 receptors at high doses. It has a very short half-life of 9 minutes. Actions in treating arrhythmias are similar to those of propranolol.

CLASS III ANTIARRHYTHMIC DRUGS

Class III antiarrhythmics produce a prolongation of phase 3 (repolarization). Action potential duration and refractory periods are prolonged, leading to reduction in membrane

TABLE 31.3 Summary of Selected C Class III Antiarrhythmics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P amiodarone (Cordarone)	Ventricular fibrillation	*Adult:* PO, 800–1,600 mg/d in divided doses for 1–3 wk; reduce to 600–800 mg/d in divided doses for 1 mo *Child:* Not established	*Onset:* 2–3 q *Duration:* 6–8 h $t_{1/2}$: 2.5–10 d, then 40–55 d
sotalol (Betapace; *Canadian:* Sotacor)	Ventricular arrhythmias	*Adult:* PO, 80 mg bid; adjust gradually q2–3d; may require 240–320 mg/d	*Onset:* Varies *Duration and* $t_{1/2}$: 12 h *Duration:* IV, 24 h $t_{1/2}$: 6.9–8.1 h
ibutilide (Corvert)	Atrial fibrillation Atrial flutter	*Adult: (=60 kg):* IV, 1 mg infused over 10 min (<60 kg): 0.01 mg/kg infused over 10 min; may repeat 1×	*Onset:* Within 10 min *Duration:* Variable $t_{1/2}$: 2–12 h

excitability of all myocardial tissue. The drugs in this class include the prototype amiodarone (Cordarone, Pacerone), sotalol, bretylium, ibutilide, dofetilide and dronedarone. Table 31.3 presents a summary of selected drugs in this class.

Nursing Management of the Patient Receiving P Amiodarone

Core Drug Knowledge

Pharmacotherapeutics

Because of severe and potentially lethal adverse effects, amiodarone is approved for use only in life-threatening arrhythmias. Orally, amiodarone is used in treating only the following documented life-threatening ventricular arrhythmias that do not respond to documented adequate doses of other antiarrhythmics or when alternative agents are not tolerated:

- Recurrent ventricular fibrillation
- Recurrent, hemodynamically unstable ventricular tachycardia

If the patient is nonresponsive to other therapy, intravenous amiodarone is used in the initiation of treatment and as prophylaxis for frequently recurring ventricular fibrillation and hemodynamically unstable ventricular tachycardia. IV amiodarone also can be used in patients who meet the requirements for oral amiodarone but who cannot take oral medication.

Amiodarone is often used in patients with an ICD to reduce the frequency of arrhythmias and decrease the need for future shocks; it appears to be more effective for this purpose when combined with a beta blocker (UpToDate, 2007). Amiodarone is also used as preventive therapy in patients who have survived sudden cardiac death who are not candidates for an ICD.

Although amiodarone is not specifically approved for treating AFib, it has been found to be effective in patients with paroxysmal or persistent AFib (VerNooy & Mounsey, 2004). For chronic maintenance therapy of AFib, research has established that amiodarone is the antiarrhythmic with the highest efficacy (VerNooy & Mounsey, 2004). The drug is used to control rhythm in AFib. One study showed amiodarone was more effective at 1 year than either sotalol or Class I agents for maintaining sinus rhythm without cardioversion (AFFIRM First Antiarrhythmic Drug Substudy Investigators, 2003). Another small study showed that it was effective in maintaining normal sinus rhythm in patients with chronic AFib, even if the AFib was of long enough duration to have induced electrical atrial remodeling (Komatsu, Tachibana, Sato, et al., 2007). Despite these findings that demonstrate effectiveness, many authorities consider using amiodarone for AFib controversial, because it has many significant adverse effects (Fuster, Ryden, Cannom, et al., 2006; UpToDate, 2007).

Pharmacokinetics

With oral administration, amiodarone is absorbed slowly, and the absorption is highly variable. The bioavailability of a single dose of the drug (oral or IV) is about 50% of the dose given, although it can range from 35% to 65%. Some researchers suggest that the incomplete bioavailability is caused by incomplete absorption related to amiodarone's high lipid solubility. Incomplete bioavailability has ramifications for dosing when the patient is being switched from oral to IV (or vice versa). The patient may require a smaller IV dose than the oral dose.

Amiodarone is widely distributed throughout the body, with much variability. It is extensively distributed in some sites, such as adipose tissue and highly perfused organs (e.g., liver, lung, and spleen). Variability in distribution contributes to variability in response to drug therapy, which is exhibited by the patient. The drug is highly protein bound (96%). This high protein binding also complicates the distribution of amiodarone. Individual variability in protein levels may cause some of the variability of drug action. Free drug levels are difficult to measure in extensive protein binding. Because of its high lipid solubility, amiodarone and its metabolite are thought to concentrate in cell membranes, especially of the liver, heart, and fat cells.

Research supports the idea that the slow distribution of amiodarone into tissue sites is an important component of the drug's unusual pharmacokinetic and pharmacodynamic activities.

Metabolism occurs in the liver, apparently by cytochrome P-450 3A4, forming an active metabolite, diethanolamine (DEA), which accumulates in most tissues to an even greater extent than the parent. DEA has pharmacologic properties similar to amiodarone; DEA is highly protein bound, although its distribution is concentrated in the heart.

The actual route of amiodarone elimination is not well understood. Amiodarone has a biphasic elimination with an initial one-half reduction of plasma levels after 2.5 to 107 days. A much slower terminal plasma elimination has a mean half-life of 53 days for amiodarone and 61 days for DEA. Thus, it takes almost a year for the drug to reach steady state with chronic oral administration. Because of this, a loading regimen of the drug is needed to achieve an initial pharmacologic effect. With prolonged administration, serum concentrations of amiodarone and DEA are similar. The main route of excretion is hepatic, into the bile. Some enterohepatic recirculation may occur.

Pharmacodynamics

Although amiodarone produces electrophysiologic changes characteristic of all four antiarrhythmic classes, it predominantly has Class III effects. Amiodarone has two major properties: prolongation of the refractory period, and noncompetitive alpha- and beta-adrenergic inhibition. It also modulates thyroid function (one molecule of amiodarone contains two iodine atoms, and amiodarone shares some structural similarities with thyroid hormones), phospholipid metabolism, and production of certain cytokines (extracellular factors that are important in controlling the inflammatory response).

Like Class I antiarrhythmic drugs, amiodarone blocks the fast sodium channel. It may do this when the channel is in the inactivated state. Unlike Class I antiarrhythmic drugs, amiodarone also blocks potassium channels. These activities contribute to the slowing of conduction and increased refractory period. Amiodarone blocks multiple potassium channels, including inward and outward currents. Like Class II antiarrhythmic drugs, amiodarone has a noncompetitive antisympathetic action. Like Class IV antiarrhythmic drugs, it has a negative chronotropic effect (slowing heart rate) from blocking the slow calcium channel. All these actions (blocking sodium, potassium, and calcium channels, and inhibition of sympathetic action) have an effect on slowing conduction (negative dromotropic effect) at the SA node and on slowing conduction and increasing the refractory period at the AV node. Amiodarone does have some vasodilating effects, which decrease the oxygen needs of the heart.

The effect on sodium channels appears to be limited to acute dosing (by IV) and is not present in chronic dosing. The effect on calcium and potassium channels may be both acute and chronic. However, unlike oral dosing, IV dosing has little or no effect on the length of the sinus cycle, the refractoriness of the right atrium or right ventricle, repolarization, intraventricular conduction, and infranodal (below or beneath the nodes) conduction. These differences suggest that the initial acute effects of amiodarone IV are focused predominantly on the AV node (because of sodium channel blockade).

Several electrophysiologic effects occur with the administration of amiodarone. An increased cardiac refractory period occurs, usually without influencing the resting membrane potential. Sinus rate decreases by 15% to 20%. The PR and QT intervals increase by about 10%. U waves appear, and T waves are altered. These changes do not usually require discontinuation of amiodarone, although marked sinus bradycardia or sinus arrest and heart block can occur. QT prolongation can be associated with worsening of the arrhythmia, but this event is rare.

After IV dosing, amiodarone relaxes the vascular smooth muscle, reduces peripheral vascular resistance (decreasing afterload), and slightly increases the cardiac index (ratio of cardiac output per minute to the body surface area). With oral dosing, amiodarone produces no appreciable change in left ventricular ejection fraction. After acute IV dosing, amiodarone may have a mild negative inotropic effect on left ventricular ejection fraction, decreasing the force of contractility. Oral dosing, however, produces no meaningful change in left ventricular ejection fraction.

Because of its ability to lengthen repolarization and refractoriness in atria and ventricles, while also blocking adrenergic stimulation, amiodarone is a potentially valuable drug in treating AFib. One reason that amiodarone's use in AFib is attractive to researchers is its ability to increase the duration of the action potential in atrial and ventricular tissues following chronic drug administration, while producing lesser effects in Purkinje fibers and M cells (special cardiac cells). Additionally, its effect on repolarization is not influenced by heart rate. Despite producing marked slowing of the heart rate and substantial increases in the QT interval, the drug only seldom produces torsades de pointes (see Adverse Effects). Amiodarone is known to be effective in maintaining normal sinus rhythm, which is now considered crucial in treating atrial fibrillation. Low doses of amiodarone have been found to maintain sinus rhythm in patients with paroxysmal or chronic AFib who were previously nonresponsive to other drug therapies. Furthermore, amiodarone has been found to effectively treat and prevent AFib in patients who have CHF. Few other drugs have this benefit, yet almost 40% of patients with CHF develop atrial fibrillation.

Contraindications and Precautions

Contraindications for giving the drug orally include severe sinus-node dysfunction producing marked sinus bradycardia, second- and third-degree AV block, and a history of episodes of bradycardia that have caused syncope (unless

the drug is used with a pacemaker). Contraindications for giving the drug intravenously are similar and include marked sinus bradycardia, second- and third-degree AV block (unless the patient has a functioning pacemaker), and cardiogenic shock. Additionally, if patients have a known hypersensitivity response to the drug, it should be avoided. Amiodarone carries a Black Box warning regarding the difficulty of using the drug safely because of its long half-life, P-450 effects, variability in effects, and frequent drug interactions.

Amiodarone inhibits peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3), prompting increased T_4 levels, increased levels of inactive reverse T_3, and decreased levels of T_3. It also is a potential source of large amounts of inorganic iodine. Because it releases inorganic iodine, and perhaps for other unknown reasons, amiodarone can cause hypothyroidism or hyperthyroidism. Because of the slow elimination of amiodarone and its metabolite, high plasma iodide levels, altered thyroid function, and abnormal thyroid function tests may persist for several weeks or months after the drug is discontinued.

Amiodarone is in pregnancy category D. It can cause congenital goiter/hypothyroidism or hyperthyroidism. Amiodarone is excreted into breast milk. In animal studies, nursing offspring are less viable and have reduced body weight gains.

Adverse Effects

Amiodarone has several adverse effects that are potentially fatal. Pulmonary toxicity is the most important of these serious adverse effects. The frequency of pulmonary toxicity with amiodarone is between 2% and 17%. About 10% of the patients who develop pulmonary toxicity die. The syndrome, seen frequently with oral dosing, is cough, progressive dyspnea, and test findings (e.g., radiographic, gallium scan, or pulmonary function tests) consistent with pulmonary toxicity. Phospholipidosis (foamy cells, foamy macrophages) is present in most cases of amiodarone-induced pulmonary toxicity. However, this finding is not a specific marker for amiodarone toxicity; these changes are also present in about 50% of patients taking the drug.

Any new changes in the respiratory system warrant reexamining the patient to determine whether pulmonary toxicity is present. Amiodarone is prescribed to patients with life-threatening arrhythmias. Therefore, the drug must be discontinued cautiously if pulmonary toxicity is suspected, because more patients die from sudden cardiac death (the most common cause of death in these patients) than from pulmonary toxicity. Before discontinuing amiodarone because of suspected pulmonary toxicity, other causes of respiratory impairment (e.g., infection) should be ruled out.

Another potentially fatal adverse effect of amiodarone is exacerbation of the arrhythmia it is treating. It also may make the arrhythmia more difficult to reverse. This event occurs in about 2% to 5% of patients treated. The risk for exacerbation is increased if more than one type of arrhythmia is present. Exacerbation can include new ventricular fibrillation, incessant ventricular tachycardia, increased resistance to cardioversion, and polymorphic (more than one form) ventricular tachycardia associated with QT prolongation (torsades de pointes). Amiodarone also has caused symptomatic bradycardia, heart block, and sinus arrest with suppression of escape foci (ectopic foci picking up as pacemaker when SA is not functioning to maintain a heartbeat) in 2% to 4% of patients. Drug-related bradycardia does not appear to be dose related.

A final potentially lethal adverse effect is liver disease. However, this effect is very rare. Some liver injury, evidenced only by elevated liver enzyme levels, is common with amiodarone, but such injury is normally mild and not serious.

Amiodarone carries a Black Box warning related to the three serious adverse effects just described: pulmonary toxicity, fatal arrhythmia, and hepatotoxicity.

Optic neuritis or optic neuropathy, although not a fatal adverse effect, can be potentially serious because visual impairment can occur and may result in permanent blindness. However, this adverse effect is rare.

Other adverse effects include common CNS effects (e.g., malaise, dizziness, paresthesia, tremor, headache, and insomnia). These can occur in 20% to 40% of patients. The effects are not serious, rarely require discontinuing the drug, and often are alleviated with dosage reduction or dividing the dose. GI complaints (e.g., nausea, vomiting, constipation, anorexia, and abdominal pain) also are common; about 25% of patients have these complaints. The drug rarely needs to be discontinued because of these effects. The GI effects are seen mostly with high doses and usually are alleviated with dose reduction or divided doses.

Photosensitivity is a problem for about 10% of patients taking amiodarone. With long-term treatment, a blue-gray discoloration of the exposed skin may be seen. The risk, which may be increased in patients with fair complexions or excessive sun exposure, may be related to cumulative dose and the duration of therapy. It reverses slowly after the drug is discontinued, although sometimes it is irreversible. Hypothyroidism or hyperthyroidism may occur, as may edema, coagulation abnormalities, flushing, epididymitis, vasculitis, pseudotumor cerebri, thrombocytopenia, and angioedema.

When amiodarone is given intravenously, hypotension is its most frequent adverse effect, although it is not normally serious. Clinically significant hypotension occurs in the first few hours of drug administration and appears to be related to the rate of infusion, not the drug concentration. Blood pressure should return to normal if the rate is slowed down.

Drug Interactions

Amiodarone increases the plasma concentration of digoxin. This effect is believed to be caused by amiodarone's inhibition of P-glycoprotein. P-glycoprotein pumps drugs

entering the enterocyte back into the intestinal lumen. It also is active on the tubular side of the renal epithelium and the biliary side of hepatocytes and serves to promote drug excretion at these sites. By inhibiting P-glycoprotein excretion, the elimination of digoxin is decreased, increasing blood levels of this drug.

Amiodarone also decreases the clearance of many other drugs, including flecainide and warfarin. Most likely, multiple mechanisms underlie these effects. Amiodarone's impairment of flecainide elimination appears to be mostly renal. Its impairment of warfarin clearance is most likely related to amiodarone being an inhibitor of CYP2C9 (another major isoenzyme of metabolism); warfarin relies solely on CYP2C9 for metabolism. Research on amiodarone's effects on metabolism and elimination of other drugs is continuing. Table 31.4 provides additional information on drug interactions. Amiodarone also interferes with laboratory tests. It alters thyroid function tests because of its effects on T_3 and T_4 and also may alter liver function tests (alanine aminotransferase and aspartate aminotransferase).

Assessment of Relevant Core Patient Variables

Health Status

Determine the patient's cardiac status using an ECG. This verifies whether the patient has an arrhythmia that is responsive to amiodarone and ensures that none of the pathologic conditions that contraindicate amiodarone's use is present.

TABLE 31.4 Agents That Interact with P Amiodarone

Interactants	Effect and Significance	Nursing Management
anticoagulants	Potentiation of anticoagulant response; prothrombin may be increased	Dose decrease usually needed; monitor prothrombin
beta blockers	May increase risk of bradycardia and hypotension from additive effect	Monitor pulse and blood pressure
calcium channel blockers	Increased risk of atrioventricular block or hypotension	Monitor for electrocardiographic (ECG) changes; monitor blood pressure
cyclosporine	Increased plasma levels of cyclosporine, resulting in elevated creatinine	Reduce dose; monitor creatinine levels
dextromethorphan	Impairs metabolism of dextromethorphan	Assess for adverse effects
digoxin	Increased digoxin serum levels	Monitor digoxin levels; decrease dose of digoxin; consider stopping digoxin
disopyramide	Increases QT prolongation; may cause arrhythmias	Monitor for ECG changes
fentanyl	Increases effect of fentanyl and may cause hypotension and bradycardia	Monitor blood pressure and pulse
flecainide	Increases the effect of flecainide	Decrease the dose of flecainide; therapeutic levels will be maintained
hydantoins	Impairs metabolism of hydantoins; elevated serum levels of hydantoins may occur; amiodarone level also may be decreased	Monitor blood levels; assess for adverse effects
lidocaine	Increased levels of lidocaine	Monitor blood pressure (rare complications)
methotrexate	Impairs metabolism of methotrexate	Assess for adverse effects
procainamide	Increased procainamide serum levels may occur	Monitor for adverse effects
quinidine	Increased quinidine levels; potential for fatal arrhythmias	Assess ECG for changes
theophylline	Increased theophylline levels with toxicity	Monitor levels; assess for adverse effects
cholestyramine	Increased enterohepatic elimination of amiodarone; reduced serum levels and half-life may occur	Monitor for therapeutic effects
cimetidine	Increased serum levels of amiodarone may occur	Assess for adverse effects
ritonavir	Large increases in amiodarone blood levels may occur, increasing the risk of adverse effects	Assess for adverse effects; monitor ECG

Also, obtain baseline results of thyroid function tests and liver function tests. It is important to assess respiratory status through chest x-ray, pulmonary function studies (including diffusion capacity), and auscultation of breath sounds before treatment.

Life Span and Gender

Determine the patient's age because safety and efficacy have not been established in children. The benzyl alcohol that is contained in some of these products as a preservative has been associated with a fatal "gasping syndrome" in premature infants. In older adults, amiodarone has a lower clearance rate and an increased half-life. It also is important to determine whether the patient is pregnant because amiodarone is a pregnancy category D drug. The drug should be used only if the potential benefits outweigh the substantial risks to the fetus. If the patient is breastfeeding, she should be advised to discontinue nursing while on amiodarone.

Environment

Be aware of the setting in which amiodarone is administered. IV amiodarone is given in an intensive care unit, where the patient can receive continuous cardiac monitoring. Oral doses can be given in any environment, except when giving a loading dose; during this time, the patient needs to be hospitalized. While the patient is taking oral doses, assess the patient's exposure to sunlight because photosensitivity can occur.

Culture and Inherited Traits

Variations in response to amiodarone may be genetically related. However, little is yet known about this genetic variation.

Nursing Diagnoses and Outcomes

- Decreased Cardiac Output related to cardiac arrhythmia.
  Desired outcome: *Cardiac rhythm will return to normal, allowing for normal cardiac output.*
- Risk for Injury related to adverse effects of drug therapy
  Desired outcome: *The patient will not suffer permanent injury or death as a result of drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

To maximize the therapeutic effect of amiodarone, administer the prescribed loading doses. When giving amiodarone intravenously, mix the drug in glass bottles or polyolefin bags of 5% dextrose in water (D_5W). Although some of the amiodarone dose is lost during administration because it is absorbed by polyvinyl chloride (PVC) tubing, this tubing should be used because the clinical trials that established dosage used this particular type of tubing, and recommended doses account for this loss. Surface properties of solutions of amiodarone are altered so that drop size may be reduced. This size reduction can account for an underdosage of up to 30%. Use a volumetric infusion pump to prevent underdosage.

Minimizing Adverse Effects

ORAL AND INTRAVENOUS DOSES

It is important to correct electrolyte disturbances before beginning therapy. Hypokalemia and hypomagnesemia can exaggerate the degree of QT prolongation and increase the potential for torsades de pointes. Assess for proarrhythmic changes. Use pulse oximetry or arterial blood gases to assess for changes in respiratory function, including breath sounds, dyspnea, and oxygen delivery to the tissues. If changes occur, it is important to repeat the chest x-ray physical examination, gallium scan, and pulmonary function tests to rule out pulmonary toxicity.

Assess for symptoms of visual impairment. Regular eye examinations are recommended throughout therapy. Ophthalmic examination should be sought immediately if impairment occurs. It also is important to assess T_3 and T_4 levels to determine thyroid function. Assess for signs of hyperthyroidism or hypothyroidism. Liver function studies also should be monitored.

ORAL DOSES

Monitor the patient closely during the loading phase until the risk for recurrent ventricular tachycardia or fibrillation has abated. It is important to attempt to discontinue prior antiarrhythmic drugs gradually. Reduce the dose of these other drugs by 30% to 50% several days after initiating amiodarone, when arrhythmias should be suppressed.

In patients whose arrhythmias are not well controlled on amiodarone alone, introduce other agents, using half of the usual recommended dosage. It is a good idea to divide the dose or give amiodarone with food to minimize or prevent nausea, vomiting, and other GI effects.

INTRAVENOUS DOSES

Adjust the starting dose to suppress life-threatening arrhythmias based on individual response to therapy. Monitor the patient continuously during therapy, using a cardiac monitor. It is important to monitor blood pressure carefully because hypotension is most likely to occur in the early period, and to reduce the infusion rate if hypotension occurs.

Avoid administering amiodarone with aminophylline, cefamandole, cefazolin, mezlocillin, heparin, and sodium bicarbonate because these agents are incompatible with amiodarone and form precipitates. If possible, administer amiodarone using a central venous catheter to prevent phlebitis.

Use an in-line filter. It is important to use IV therapy until the ventricular arrhythmia is stabilized. Transfer the patient to oral therapy either during or after IV treatment, and adjust the IV dose to a new, lower oral dose. If the patient is treated with IV infusion for less than 1 week, give an oral dose of 800 to 1,600 mg/d initially. If the patient is treated with IV for 1 to 3 weeks, give an oral dose of 600 to 800 mg/d initially. If the patient is treated with IV for longer than 3 weeks, give an oral dose of 400 mg/d initially. When adequate arrhythmia control is achieved, decrease to

600 to 800 mg/d (orally) in one to two doses for 1 month; the maintenance dose is 400 mg/d.

Providing Patient and Family Education

- Explain the purpose of the drug and possible adverse effects of the drug.
- Emphasize the importance of returning for follow-up blood work and ECGs.
- Teach patients to use appropriate protection when out in the sun and to limit sun exposure.
- Instruct the patient to notify the physician for new onset of cough, shortness of breath, and changes in visual acuity.

Ongoing Assessment and Evaluation

The patient's ECG should be monitored intermittently throughout therapy and after the initial stabilization and loading dose period for new arrhythmias or worsening of the current arrhythmia being treated. Make recurrent assessments of respiratory function, visual acuity, thyroid function, and liver function. Amiodarone therapy is considered effective if the arrhythmia is corrected and the patient does not develop serious adverse effects.

MEMORY CHIP

P Amiodarone

- Class III antiarrhythmic used to treat life-threatening ventricular arrhythmias and prevent their recurrence
- Produces prolonged phase of repolarization (phase 3)
- Has properties of Classes I, II, and IV
- Has extremely long half-life and great variability in pharmacodynamics and pharmacokinetics
- Major contraindications: severe sinus bradycardia and second- or third-degree atrioventricular heart block
- Most common adverse effects: central nervous system effects (e.g., malaise, dizziness, paresthesia, tremor, headache, and insomnia); GI effects (e.g., nausea and vomiting); photosensitivity; and hypotension (IV use)
- Most serious adverse effects: pulmonary toxicity and cardiac arrhythmias
- **Life span alert: Drug is in pregnancy category D; use only if benefit outweighs risk.**
- Maximizing therapeutic effects: Use a loading dose.
- Minimizing adverse effects: Correct pre-existing electrolyte imbalances before giving the drug; adjust IV dose to control ventricular arrhythmia; monitor blood pressure (IV dosing); monitor electrocardiogram for changes; and assess for respiratory changes.
- Most important patient education: Take with food to minimize GI distress and notify the physician if cough or shortness of breath develops.

Drugs Closely Related to P Amiodarone

Sotalol

Like amiodarone, sotalol (Betapace) prolongs repolarization (phase 3). These Class III effects are seen in doses greater than 160 mg/d. Additionally, like amiodarone, sotalol decreases automaticity at the SA node and ectopic pacemakers. It also decreases conduction velocity at the AV node, although unlike amiodarone, it does not decrease it at the atrium, bundle of His, or Purkinje fibers. ECG changes are similar except that sotalol does not lengthen the QT interval. Although sotalol and amiodarone both have antiadrenergic effects, they work by different mechanisms. Sotalol is actually a beta blocker, blocking both beta-1 and beta-2 sites. However, it is not considered a Class II antiarrhythmic like the other beta blockers, because it also has Class IC and Class III effects.

Sotalol is used in treating life-threatening ventricular arrhythmias. It is also approved for treating atrial arrhythmias. Sotalol has been shown to maintain sinus rhythm in about 50% of patients with AFib after cardioversion to their normal rhythm. When sotalol is used in patients with an implanted cardioverter-defibrillator, patients are less likely to require a shock (Bollmann, Husser, & Cannom, 2005). Like all other antiarrhythmics, sotalol may induce arrhythmias as well as treat them. Torsades de pointes, although possible, is not likely to occur if the dose is controlled, if the patient has normal renal function, and if the patient does not have severe CHF. Sotalol is administered only orally, so it is started after the patient has been on IV antiarrhythmics for ventricular arrhythmias. The other antiarrhythmic should have been withdrawn for at least two to three half-lives before starting sotalol.

Sotalol should be initiated in a facility that can provide cardiac resuscitation, continuous ECG monitoring, and creatinine clearance values. Patients should be cared for by health care providers who are familiar with managing serious ventricular arrhythmias. Patients should continue to be monitored for a minimum of 3 days on the maintenance dose and should not be discharged within 12 hours of electrical or pharmacologic conversion to normal sinus rhythm.

CRITICAL THINKING SCENARIO

AMIODARONE THERAPY

Mr. Bowen is 74 years old. He was brought to the hospital emergency department by ambulance. He was diagnosed with myocardial infarction and was in ventricular fibrillation. He is successfully defibrillated and converted to sinus rhythm. He is started on amiodarone by IV infusion. When he is transferred to the intensive care unit, his blood pressure drops to 88/50 mm Hg. The intensive care unit nurse examines Mr. Bowen's laboratory results; the only unexpected finding is that he has a low serum albumin level.

1. What possible causes may account for Mr. Bowen's hypotension?
2. What action should you take to manage the hypotension?
3. If you are unable to correct the hypotension, what might you do next?

Ibutilide

Ibutilide (Corvert) is a new drug in the category termed the "pure" Class III antiarrhythmics. It is not as multifaceted as amiodarone. The goal of developing these new Class III drugs was to find a drug as effective as amiodarone but without its adverse effects.

Ibutilide was the first of the pure Class III drugs approved for use in the United States. It is approved only for IV use to convert atrial flutter and fibrillation to normal sinus rhythm. It is about twice as effective in converting atrial flutter as AFib. Ibutilide increases the atrial effective refractory period and prolongs the QT interval. This effect on the QT interval is dose dependent. Ibutilide also causes some blockade of potassium channels. As a result, duration of the action potential in the ventricles is also prolonged somewhat. For these reasons, ibutilide should be used with caution in patients with bradycardia, CHF or low ejection fraction, hypokalemia or hypomagnesemia, recent MI, or significantly prolonged QT intervals prior to treatment, or in those who are taking other Class I or III antiarrhythmics (within 4 hours of ibutilide transfusion) or other drugs that prolong QT intervals. Patients who have had AF for more than 3 days must be anticoagulated for at least 2 weeks prior to starting ibutilide.

Ibutilide is metabolized extensively in the liver; its high first-pass effect is the reason it must be given intravenously. Unlike amiodarone, ibutilide has a short half-life of 4 to 8 hours; its metabolites have a similar half-life. Ibutilide distributes rapidly to a large volume, and its electrophysiologic effects decrease quickly after IV administration. Proarrhythmia effects are therefore greatest within the first hour of administration. Ibutilide use is associated with an estimated 8% risk for torsades de pointes. When it occurs, it often is transient. However, if ibutilide is given concurrently with beta blockers or calcium channel blockers, torsades de pointes is more likely to occur.

Dofetilide

Dofetilide (Tikosyn) is another new "pure" Class III drug, like ibutilide. It can be given IV or PO. Similarly, it has more limited effects than amiodarone. Dofetilide is used to convert patients in atrial fibrillation to normal sinus rhythm and maintain them in sinus rhythm. The drug delays repolarization by lengthening the effective refractory period in the atria, ventricles, and Purkinje fibers by blocking some of the potassium channels. It has no effect on sodium or calcium channels and thus little effect on conduction velocity, force of contraction, and systemic hemodynamics. Dofetilide also has no effect on alpha or beta receptors. It is not approved for managing ventricular arrhythmias, and its efficacy for these arrhythmias is under investigation (Khan, 2004). It increases repolarization and refractoriness in both atrial and ventricular tissue, although the predominant effect is on the atrial tissue. It is administered orally and is well absorbed with a bioavailability of more than 90%. Most of the drug is excreted unchanged in the urine, and the rest is metabolized in the liver via the CYP 3A4 pathway. Systemic half-life is 10 hours. Because dofetilide is mostly excreted unchanged, it is important to monitor for kidney function, as decreasing function will make the patient more at risk of adverse effects.

Dofetilide has a reverse use-dependent effect, and at slow rates it has the tendency to increase the QT interval. Dofetilide is not likely to cause torsades de pointes. It carries the Black Box warning, relative to its risk of inducing arrhythmias, that a patient beginning dofetilide should be placed for a minimum of 3 days in a facility that can provide calculations of creatinine clearance, continuous ECG monitoring, and cardiac resuscitation. Dofetilide is available only to hospitals and prescribers who have received appropriate dofetilide dosing and treatment initiation education. Unlike other antiarrhythmics, dofetilide does not increase mortality in patients with a recent MI or CHF (Roukoz & Saliba, 2007). Common adverse effects include chest pain, dizziness, headache, dyspnea, respiratory tract infection, and GI problems. It is a pregnancy class C drug.

Dronedarone

Dronedarone is another new Class III antiarrhythmic. It was recently approved by the FDA for use in treating atrial fibrillation or flutter. It can be given PO. It is a synthetic analog of amiodarone, missing the iodine component. Similar to amiodarone, it has sodium, potassium, and calcium channel blocking properties as well as being a adrenergic receptor antagonist. Differences from amiodarone include: a shorter half life, quicker achievement of therapeutic drug levels, and fewer adverse effects primarily due to the missing iodine component (Cheng, 2010).

Dronedarone carries a Black Box warning related to its use in patients with class IV heart failure or class II or III decompensating heart failure. A study has shown a doubling of mortality when used in those patients. In addition to being contraindicated in those heart failure patients, it is also contraindicated in patients with bradycardia of less than 50, severe hepatitis, second or third degree block without a pacemaker, patients on other QT prolonging drugs, and patients who are pregnant or nursing.

Dronedarone is metabolized in the liver. Care must be taken to monitor liver function. In addition to nausea, vomiting, diarrhea, an increased serum creatinine, other adverse effects include a prolonged QT interval or heart failure. Patients should be taught to take this drug with meals and to avoid any form of grapefruit.

Bretylium

Bretylium (bretylium tosylate), a Class III antiarrhythmic also has adrenergic blocking properties. It was used for the treatment of life-threatening ventricular arrhythmias. It is no longer recommended by the AHA due to the frequent occurrence of adverse effects and the accessibility of other more effective alternatives such as amiodarone (AHA guidelines). There were also issues with the drug's availability. In 1999 the drug was not available due to limited quantities of the raw

materials necessary for manufacture. There is a recent effort to evaluate the current ACLS guidelines specifically looking at the use of bretylium during resuscitation. Bretylium's ability to produce chemical defibrillation by prolonging the QT interval and blocking re-entery pathways is being examined. By raising the threshold for ventricular fibrillation, it may be considered a safer, more effective alternative to excessive doses of epinephrine and electrical defibrillation (Bacaner, Dembo, 2009).

C CLASS IV ANTIARRHYTHMIC DRUGS

Class IV antiarrhythmics depress phase 4 depolarization and lengthen phases 1 and 2 of repolarization (see Figure 31.6). This class is the calcium channel blockers, but only two have been approved specifically as antiarrhythmics: verapamil (Calan) and diltiazem (Cardizem). Table 31.5 presents a summary of selected Class IV antiarrhythmics and other calcium channel blockers. The prototype Class IV antiarrhythmic calcium channel blocker is verapamil.

Calcium channel blockers prescribed for other purposes include amlodipine (Norvasc), bepridil (Vascor), felodipine (Plendil), isradipine (Dyna Circ), nimodipine (Nimotop), nisoldipine (Sular), nicardipine (Cardene), and nifedipine (Procardia, Adalat). Other uses of calcium channel blockers are described in Chapters 28 and 30.

Nursing Management of the Patient Receiving P Verapamil

Core Drug Knowledge

Pharmacotherapeutics

Verapamil is used as an antiarrhythmic. Verapamil, used alone or in conjunction with digoxin, controls ventricular rate in chronic atrial flutter or fibrillation. However, calcium channel blockers are not as effective as beta blockers for this purpose (Olshansky, Rosenfeld, Warner, et al., 2004). It also can be used prophylactically for repetitive paroxysmal SVT. IV verapamil also is used to treat supraventricular tachyarrhythmias, while the oral form may be used to sustain normal rhythm. The antiarrhythmic effects seem similar in adults and children.

Verapamil also is used in treating angina (including Prinzmetal angina) and hypertension. An unlabeled use is preventing migraine headache.

Pharmacokinetics

Well absorbed after oral administration, verapamil undergoes a substantial first-pass effect, resulting in considerably less bioavailability. Verapamil is excreted by the kidneys. It crosses the placenta and appears in breast milk. When sustained-release verapamil is administered with food, it takes longer to reach maximum plasma levels. However, bioavailability is not affected appreciably; hence, verapamil may be administered without regard to meals.

TABLE 31.5 Summary of Selected C Class IV Antiarrhythmics and Selected Other Calcium Channel Blocker

Drugs (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P verapamil (Calan, Isoptin)	Angina pectoris Supraventricular tachyarrhythmias	*Adult:* PO, 80–120 mg tid, increase q1–2d as needed *Adult:* IV, 5–10 mg over 2 min; may repeat dose of 10 mg 30 min after first dose. Give dose over 3 min for elderly. *Child:* IV, >1 y, 0.1–0.2 mg/kg over 2 min; 1–15 y, 0.1–0.3 mg/kg over 2 min; do not exceed 5 mg; repeat after 30 min, if necessary.	*Onset:* PO, 30 min; IV, rapid *Duration:* PO, 3–7 h; IV, 2 h $t_{1/2}$: 3–7 h
	Hypertension	*Adult:* PO, 240 mg qd; sustained-release form in morning; 80 mg tid. May need to individualize dose by titration.	
diltiazem (Cardizem, Tiazac)	Angina pectoris Essential hypertension Atrial fibrillation or flutter (IV only)	*Adult:* PO, 30 mg qid before meals and hs, increase gradually at 1–2 d intervals to 180–360 mg in three to four divided doses; SR, cardizem CD, 180–240 mg/d PO for hypertension; 120–180 mg/d PO for angina IV, 0.25 mg/kg over 2 min; second bolus of 0.35 mg/kg given over 2 min IV infusion: 5–15 mg/h for up to 24 h *Child:* Safety and efficacy not established	*Onset:* PO and SR, 30–60 min; IV, immediate *Duration:* Unknown $t_{1/2}$: $3_{1/2}$–6 h; SR, 5–7 h
Non-Antiarrhythmic Calcium Channel Blockers			
amlodipine (Norvasc)	Angina pectoris Essential hypertension	*Adult:* PO, 5 mg qd, may increase over 10–14 d to a max dose of 10 mg/d *Child:* Safety and efficacy not established	*Onset:* PO, unknown *Duration:* Unknown $t_{1/2}$: 30–50 h
nicardipine (Cardene)	Stable angina	*Adult:* PO, 20 mg tid; range, 20–40 mg tid; allow 3 d before increasing dosage *Child:* Safety and efficacy not established	*Onset:* 20 min *Duration:* Unknown $t_{1/2}$: 2–4 h
	Hypertension	*Adult:* PO, 20 mg tid; range 20–40 mg tid. Adjust dosage based on BP response; allow 3 d before increasing *Child:* Safety and efficacy not established	

Pharmacodynamics

Verapamil acts by inhibiting the movement of calcium ions across the cardiac and arterial muscle cell membrane. It works preferentially in "slow response" myocardial tissue, such as the SA and AV nodes. Calcium currents through these tissues generate the slowly propagating action potentials. Verapamil slows phase 4 depolarization. Blocking calcium movement results in slowing conduction through the AV node (conduction velocity), prolonging the effective refractory phase (automaticity), depressing myocardial contractility, and producing dilation of both coronary arteries and peripheral arterioles. Verapamil interrupts re-entry at the AV node and thus can restore normal sinus rhythm in paroxysmal SVT. When calcium channel blockers such as verapamil cause peripheral vasodilation, they can induce reflex activation of the sympathetic nervous system, causing reflex tachycardia. This prevents a drop in cardiac output. Other outcomes of verapamil therapy are decreased oxygen demand, decreased cardiac effort, and increased oxygen to the myocardium.

Contraindications and Precautions

Verapamil is contraindicated in sick sinus syndrome or second- or third-degree heart block (except with a functioning pacemaker), hypotension (systolic pressure less than 90 mm Hg), cardiogenic shock, and severe CHF. Precaution should be used in severe left ventricular dysfunction (ejection fraction less than 30%). Verapamil may cause a greater hypotensive effect in elderly patients than in younger ones; thus, it should be administered cautiously to older patients. Caution should also be used in patients with cirrhosis of the liver (the half-life is greatly increased) and with renal disease. Caution should be used if the patient has Duchenne muscular dystrophy because verapamil may decrease neuromuscular transmission. IV verapamil can induce respiratory muscle failure in these patients.

Verapamil is in pregnancy category C.

Adverse Effects

The most common adverse effect of verapamil is constipation. Other common adverse effects include dizziness, headache, nausea, hypotension, and peripheral edema. Verapamil may produce potentially lethal ventricular arrhythmias and, rarely, MI.

Drug Interactions

Several drugs interact with verapamil (see Table 31.6). Ranolazine and dofetilide are both contraindicated

TABLE 31.6 Agents That Interact with P Verapami

Interactants	Effect and Significance	Nursing Management
barbiturates	Clearance of verapamil possibly increased and bioavailability decreased	Monitor pulse, blood pressure, and respiration carefully. Monitor patient responses and blood levels.
calcium salts	Antagonism of effects of verapamil with calcium	Administer 2 h apart.
hydantoins	Serum verapamil levels possibly decreased	Monitor for therapeutic effect.
quinidine	Hypotension bradycardia, ventricular tachycardia, atrioventricular (AV) block, and pulmonary edema possible	Use concomitantly only when no other alternatives exist.
rifampin	Possible loss of clinical effectiveness of oral verapamil	Use of IV verapamil may circumvent the interaction.
vitamin D	Therapeutic efficacy of verapamil possibly reduced	Stagger dosage and monitor vital signs.
beta blockers	Coadministration, potential increased adverse effects due to depressant effects on myocardial contractility of AV conduction	Concurrent use normally avoided.
cardiac glycosides (digoxin)	Possible increased digoxin levels	Monitor for adverse effects of cardiac glycoside.
dofetilide	Coadministration of dofetilide and verapamil results in a significant increase in peak plasma levels of dofetilide, thus increasing the risk of serious ventricular arrhythmias associated with QT interval prolongation, including torsades de pointes.	Concurrent administration is contraindicated.
ranolazine	Verapamil inhibits the metabolism of ranolazine by the cytochrome P450-3A enzymes, increasing serum levels of ranolazine, which then increases the risk of QT prolongation.	Coadministration is contraindicated.

when taken in combination with verapamil, because coadministration increases the risk of QT prolongation. Verapamil may elevate serum transaminases, with and without concomitant elevations in alkaline phosphatase and bilirubin. Usually, the elevations are transient, although several cases of hepatocellular injury have occurred.

Verapamil forms a crystalline precipitate if administered into an infusion line containing 0.45% sodium chloride solution with sodium bicarbonate. A milky white precipitate forms when it is given as an IV push into the same line being used for nafcillin infusion.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient has chronic atrial flutter or fibrillation, which is causing elevated ventricular rate, or chronic repetitive paroxysmal SVTs, both of which pose a need for therapy. Also, determine whether the patient has any of the following conditions, because they are contraindications to treatment with verapamil: sick sinus syndrome or second- or third-degree heart block (except with a functioning pacemaker), hypotension (with systolic pressure less than 90 mm Hg), severe left ventricular dysfunction, cardiogenic shock, or severe CHF. It also is important to determine whether the patient has renal or liver impairment or Duchenne muscular dystrophy, because verapamil must be used with caution in these patients.

Life Span and Gender

Determine whether the patient is pregnant, because verapamil is in pregnancy category C and must be used cautiously during pregnancy. Also, note the patient's age before administering verapamil: the safety and efficacy of oral verapamil have not been established in children, but experience has shown that treatment results in children are similar to those for adults. IV verapamil is contraindicated in neonates and infants, but only when given to treat SVT, because of a high risk for electromechanical dissociation. In children older than 5 years and in adolescents, IV verapamil may be administered with the same restrictions as in adults (a wide QRS complex tachycardia or substantial hemodynamic compromise). Verapamil may have greater hypotensive effects on older adults.

Lifestyle, Diet, and Habits

Assess whether patients drink alcohol, as caution is required if there is cirrhosis of the liver. Assess for intake of grapefruit and grapefruit juice because these foods affect the verapamil level. Assess diet for normal intake of fiber.

Environment

Know the setting in which verapamil may be administered. IV verapamil is administered only in the hospital, where the patient is monitored constantly using ECG and blood pressure measurements. Oral verapamil can be administered in any setting.

Nursing Diagnoses and Outcomes

- Risk for Constipation related to adverse effects of the drug
  Desired outcome: *The patient will prevent or minimize constipation by increasing fluid intake and adding fruit and fiber to the diet.*
- Decreased Cardiac Output related to decreased rate and force of contraction and return to normal rhythm related to therapeutic effects of drug
  Desired outcome: *The patient's decreased cardiac output will reduce symptoms of cardiac alterations without developing adverse cardiac effects from drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Verify that the IV line is patent before IV administration. Digoxin may be given with verapamil to achieve the additive effect of slowing at the AV node.

Minimizing Adverse Effects

When administering verapamil by an IV route, do not dilute it with a sodium lactate injection in PVC bags, which may not be stable. It is important to administer IV slowly (bolus, 5 to 10 mg over 2 minutes; infusion, 5 mg/h) and to use an IV pump to regulate the drip rate.

Do not administer IV verapamil simultaneously with (or within a few hours of) IV beta blockers, because both drugs suppress contractility and AV conduction. Monitor the patient's ECG and blood pressure constantly during IV therapy. Throughout oral therapy too, monitor for ECG changes and hypotension. Encourage patients on oral verapamil therapy to increase fluid intake and include fresh fruit and fiber in their diets to help prevent constipation.

Providing Patient and Family Education

- Explain the purpose of the drug and its adverse effects.
- Stress the importance of adequate fluid intake and dietary fruit and fiber to help prevent constipation.
- Teach patients how to take the pulse daily while on oral verapamil, instructing them to notify the prescriber if irregular beating (arrhythmia) occurs.
- Teach patients how to take their own blood pressure, urging them to monitor their blood pressure on a regular basis. If the blood pressure falls below 90/60 mm Hg or any other parameter set by the prescriber, instruct patients to contact a member of the health care team.
- Emphasize the importance of scheduling follow-up visits and blood studies.

Ongoing Assessment and Evaluation

Monitor the patient's ECG and blood pressure throughout therapy with verapamil. It is important to monitor liver function periodically to detect elevated serum drug levels. Therapy is effective when normal rhythm is re-established without onset of new arrhythmias, hypotension, or other clinically important adverse effects.

MEMORY CHIP

P Verapamil

- Class IV antiarrhythmic and a calcium channel blocker; may be given intravenously, orally, or sublingually
- Inhibits movement of calcium ions across the cardiac and arterial muscle cell membrane
- Slows conduction, depresses automaticity, depresses myocardial contractility, and dilates coronary arteries and peripheral arterioles
- Antiarrhythmic uses: controls ventricular rate in chronic atrial flutter or fibrillation; used prophylactically with digoxin for repetitive paroxysmal supraventricular tachycardia; used to treat supraventricular tachyarrhythmias (IV administration)
- Also used in angina and hypertension
- Major contraindications: significantly depressed cardiac function, including second- or third-degree heart block, severe hypotension, severe left ventricular dysfunction, severe chronic heart failure, or cardiogenic shock
- Most common adverse effect: constipation
- Most serious adverse effect: ventricular arrhythmias
- **Life span alert: IV routes are contraindicated in neonates and infants, and older adults are more sensitive to hypotensive effects.**
- Maximizing therapeutic effects: Shield drug solution from light; give with digoxin for additive effect of slowing at the atrioventricular node.
- Minimizing adverse effects: Monitor electrocardiogram and blood pressure constantly while on IV, and monitor periodically throughout oral therapy.
- Most important patient education: techniques to prevent constipation

Drug Closely Related to P Verapamil

Diltiazem is another calcium channel blocker like verapamil. It is indicated for rate control in atrial fibrillation, flutter, or paroxysmal supraventricular tachycardia. It is also used to treat stable chronic angina. It has similar actions and averse effects as verapimil. Unlike verapamil, it is not approved for use in children.

Drug Significantly Different From P Verapamil

Adenosine, unlike verapamil, is not a calcium channel blocker. Adenosine is not related chemically to verapamil or any other antiarrhythmic. It is an endogenous nucleoside occurring in all cells of the body. Adenosine, like verapamil, decreases automaticity, decreases conduction velocity at the AV node, and increases the refractory period at the AV node. It may produce first-, second-, or third-degree heart block of short duration. Unlike verapamil, it increases heart rate. It is used in the conversion of paroxysmal SVT to normal sinus rhythm and is given only as a rapid IV bolus. The IV boluses should be administered directly into the vein, or in an IV as proximally to the vein as possible, and followed by a rapid saline flush. The bolus may be repeated if necessary.

Adenosine is removed from the circulatory system very rapidly. It is taken up by erythrocytes and vascular endothelial cells. Its half-life is estimated to be less than 10 seconds. Adenosine is metabolized primarily to inosine and adenosine monophosphate. Conversion to normal sinus rhythm frequently occurs within 1 minute after dosing.

Adenosine is contraindicated in second- or third-degree AV block, sick sinus syndrome (unless a previously inserted pacemaker is functional), atrial flutter, AFib, and ventricular tachycardia, because the drug does not convert these arrhythmias.

The most common adverse effects of adenosine are facial flushing and shortness of breath and dyspnea. Other adverse effects that may occur include:

- CV: sweating, palpitations, chest pain, hypotension (rare), prolonged systole, ventricular fibrillation, ventricular tachycardia, and transient increase in blood pressure
- CNS: headache, light-headedness, dizziness, tingling in arms, numbness, apprehension, blurred vision, burning sensation, heaviness in arms, and pain in neck or back
- GI: nausea, metallic taste, tightness in throat, pressure in groin (rare)
- Respiratory: chest pressure, hyperventilation, and head pressure (rare)

C POTASSIUM-REMOVING RESINS TO PREVENT ARRHYTHMIAS

Because hyperkalemia may lead to cardiac arrhythmias, potassium-removing resins are drugs used to prevent arrhythmias from occurring. These resins bind with potassium and allow it to be excreted. The prototype and sole drug in this class is sodium polystyrene sulfonate (Kayexalate).

Nursing Management of the Patient Receiving P Sodium Polystyrene Sulfonate

Core Drug Knowledge

Pharmacotherapeutics

Sodium polystyrene sulfonate is a potassium-removing resin used in treating hyperkalemia. Because of its slow onset of action, it may not be appropriate to use if the potassium levels are severely elevated (see Pharmacokinetics below). It can be given orally or as an enema. Table 31.7 presents a summary of information about this drug.

Pharmacokinetics

The exchange of potassium ions after administration of sodium polystyrene sulfonate occurs in the large intestine. The drug is not absorbed systemically and is excreted through the GI tract. The onset of action after oral administration is 2 to 12 hours; after rectal administration, onset of action takes more time, although exact numbers are unknown.

TABLE 31.7 Potassium-Removing Resin

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P sodium polystyrene sulfonate (Kayexalate)	Treatment of hyperkalemia	*Adult:* PO, 15 g 1–4×/d *Child:* PO, 1 g/kg q6h *Adult:* Enema, 30–50 g q6h	*Onset:* PO, 2–12 h Enema, >12 h *Duration:* Unknown $t_{1/2}$: Unknown

Pharmacodynamics

As sodium polystyrene sulfonate moves through the intestine or is maintained in the intestine, it releases sodium ions that are replaced with potassium ions. The efficiency of this process is limited and unpredictable. The ion exchange capacity is approximately 1 mEq potassium per 1 g of drug. Small amounts of calcium and magnesium also can be lost during the exchange process. Effective lowering of serum potassium may take several hours or days.

Contraindications and Precautions

Caution must be used when giving this drug to anyone who cannot tolerate a small increase in sodium intake, such as patients with severe CHF, hypertension, or marked edema. Because therapeutic effects are slow, this should not be the only drug used to treat patients with severe hyperkalemia, in whom the hyperkalemia poses a medical emergency.

Adverse Effects

Hypokalemia may result from therapy and is the most serious adverse effect. Other electrolyte imbalances that may result include hypocalcemia and hypernatremia. Common adverse GI-related effects include gastric irritation, anorexia, nausea, vomiting, and constipation. The constipation occasionally may be severe and cause fecal impaction. Diarrhea occurs occasionally.

Drug Interactions

When administered with nonabsorbable cation-donating antacids and laxatives, such as magnesium hydroxide and aluminum carbonate, systemic alkalosis can occur.

Assessment of Relevant Core Patient Variables

Health Status

Monitor the patient's serum potassium level, and if it is severely elevated, the patient's total physiologic condition and ECG should be reviewed. Also, determine whether the patient has been receiving potassium supplements or replacements in IV fluids.

Life Span and Gender

Note the patient's age before administering sodium polystyrene sulfonate. Large doses of sodium polystyrene sulfonate can cause fecal impaction in elderly patients.

Lifestyle, Diet, and Habits

It is important to investigate the patient's dietary history and preferences, particularly if the patient normally consumes a potassium-rich diet.

Environment

Be aware that sodium polystyrene sulfonate is administered in the hospital.

Nursing Diagnoses and Outcomes

- Risk for Constipation related to adverse effects of drug therapy
  Desired outcome: *Constipation will be prevented by administering sorbitol, orally or rectally, if warranted.*
- Potential complication: hypokalemia.
  Desired outcome: *The patient's potassium level will be lowered only to the normal range.*

Planning and Intervention

Maximizing Therapeutic Effects

Clear the GI tract with a cleansing enema before administering the drug by enema. For adults, insert a soft, large (28-French) rubber tube about 20 cm into the rectum. Mix the resin in an aqueous vehicle, such as 100 mL sorbitol or 20% dextrose, to make a suspension; infuse the drug by gravity. During infusion, it is important to stir the fluid to keep the particles in suspension.

After the fluid has run into the patient, flush the tube with 50 to 100 mL of fluid to make a total of 150 to 200 mL of fluid as infused. It is important to clamp the tube and leave it in place for at least 30 to 60 minutes, preferably several hours (keeping the solution in the colon allows the resin to work; the longer the resin is in the colon, the more ion exchange can occur).

If back-leakage develops, elevate the patient's hips on pillows or have the patient assume a knee-chest position temporarily. These positions help keep the solution in the sigmoid colon.

Irrigate the colon using a Y-tube connection with approximately 2 L of a nonsodium flushing solution at body temperature to remove the resin. The Y-tube allows the returns to drain as the colon is being irrigated.

When the drug is administered orally, create a suspension of the powdered formula with water or syrup for greater palatability.

MEMORY CHIP

P Sodium Polystyrene Sulfonate

- Used to lower serum potassium levels
- Given orally or as enema
- Major contraindication: extremely high potassium levels
- Most common adverse effects: related to GI system
- Most serious adverse effect: hypokalemia
- Maximizing therapeutic effects: Give a cleansing enema first (if drug is given as enema), and leave resin in place at least 30 minutes after administering as enema.
- Minimizing adverse effects: Monitor serum electrolytes and electrocardiogram.

Minimizing Adverse Effects

If the potassium serum level is severely elevated, use other methods to reduce potassium. Sodium polystyrene sulfonate alone may be insufficient to correct an imbalance before a medical emergency occurs. Other methods include the use of IV calcium to antagonize the effect of hyperkalemia on the heart; IV sodium bicarbonate, glucose and insulin together to cause an intracellular shift of potassium (without causing hypoglycemia); the definitive treatment for severe hyperkalemia is dialysis.

Monitor serum electrolytes for changes in potassium and other electrolytes. It also is important to monitor the ECG for changes indicative of hypokalemia (lengthened QT interval; widening, flattening, or inversion of the T wave; prominent U waves; or arrhythmias).

Monitor the pulse rate for arrhythmias and irregularities. It is a good idea to administer sorbitol, orally or rectally, to prevent constipation if warranted.

Providing Patient and Family Education

- Explain the therapeutic and possible adverse effects of the drug.
- It is important to emphasize the importance of repeated blood work to monitor blood electrolyte concentrations.

Ongoing Assessment and Evaluation

Monitor serum electrolytes throughout therapy. Assess for signs of hypokalemia and monitor the patient's pulse and ECG periodically throughout sodium polystyrene sulfonate therapy. Therapy is considered effective in patients whose serum potassium levels return to normal and who do not develop cardiac arrhythmias from hyperkalemia, hypokalemia, or other electrolyte imbalances.

CHAPTER SUMMARY

- Antiarrhythmics restore normal rhythm and rate by varied mechanisms.
- All drugs given to treat an arrhythmia also may cause an arrhythmia.
- Class I drugs block the influx of sodium in the myocardial membrane. They are local anesthetics or membrane stabilizing agents that depress phase 0 of the action potential.
- Quinidine, a Class I antiarrhythmic, is used for treating atrial fibrillation and flutter. Quinidine depresses myocardial excitability, conduction velocity, and contractility. The effective refractory period is prolonged, increasing conduction time. Re-entry phenomenon is therefore prevented. Quinidine also exerts an indirect anticholinergic effect; it decreases vagal tone and may promote conduction in the AV junction.
- Potassium enhances the effect of quinidine, and hypokalemia reduces the effectiveness.
- Class IB antiarrhythmics depress phase 0 of the action potential, but not as much as Class IA drugs. They also suppress automaticity. Like quinidine, these drugs may also cause arrhythmias, in addition to treating them. Unlike quinidine, they are used primarily with ventricular arrhythmias, and they may shorten the action potential duration. Lidocaine is a Class IB drug; it may be used with all acute ventricular arrhythmias that occur in association with cardiac surgery or acute MI.
- Class IC antiarrhythmics also depress phase 0 but markedly so. In addition, they have a slight effect on repolarization and decrease conduction substantially. They have been found to increase mortality significantly when used in patients who have had an MI.
- All Class I antiarrhythmics have the potential to increase mortality; none have been proved to decrease mortality.
- Class II antiarrhythmics block the beta-1 and beta-2 adrenergic receptors and stabilize the cardiac cell membranes. They depress phase 4 depolarization.
- Propranolol, a beta blocker and Class II antiarrhythmic, is used to treat supraventricular, ventricular, and tachyarrhythmias secondary to digoxin toxicity or arising from excessive catecholamine action during anesthesia.
- Propranolol slows the sinus heart rate, depresses AV conduction, decreases cardiac output, reduces systolic and diastolic blood pressure at rest and on exercise, and reduces supine and standing blood pressure.
- Class II antiarrhythmics are the only antiarrhythmics that have been shown to decrease mortality.
- Class III drugs slow heart action by prolonging the action potential or myocardial repolarization (prolonged phase 3).
- Amiodarone, a Class III antiarrhythmic, is used to treat life-threatening ventricular arrhythmias. It also has actions from other classifications. These diverse actions of amiodarone are why the drug is being considered as potentially appropriate for treating atrial fibrillation as well.
- Amiodarone has unusual pharmacokinetic and pharmacodynamic properties. These unique effects include incomplete bioavailability, distribution to multiple tissue sites, extreme lipid solubility, biotransformation to an active metabolite, and extremely slow elimination of amiodarone and its metabolite. These effects may be attributable to genetic variations, although this possibility is not yet confirmed. Because of these unique effects, the effect on patients is variable.

- Adverse effects of amiodarone can be serious and potentially fatal. The patient needs to be monitored closely while on amiodarone therapy.
- Class IV drugs alter the action potential, decrease AV conduction, and prolong repolarization by inhibiting the influx of calcium in cardiac muscle cells. A few calcium channel blocker drugs are in this class.
- Verapamil, a calcium channel blocker and Class IV antiarrhythmic, controls ventricular rate in chronic atrial flutter or fibrillation (used in conjunction with digoxin). It is also used prophylactically for repetitive paroxysmal SVT. IV verapamil is used to treat SVT.
- Verapamil also is used in treating angina (including Prinzmetal angina) and hypertension.
- Sodium polystyrene sulfonate is a potassium-removing resin used in treating hyperkalemia. Because hyperkalemia may lead to cardiac arrhythmias, this drug prevents arrhythmias from occurring.
- Sodium polystyrene sulfonate is given orally or as an enema.
- Although sodium polystyrene sulfonate is in the GI tract, sodium ions are exchanged for potassium ions, which are then excreted in the stool. Onset is slow and unpredictable. Therefore, if the serum potassium level is quite elevated, other mechanisms of lowering the potassium level should be used.

QUESTIONS FOR STUDY AND REVIEW

1. Why are ventricular arrhythmias considered potentially life-threatening?
2. What is meant by proarrhythmia?
3. Why do all antiarrhythmics have proarrhythmic qualities?
4. Describe the phase of the action potential affected by Class I, Class II, Class III, and Class IV antiarrhythmics.
5. Amiodarone, a Class III drug, is used to treat which type of arrhythmias?
6. What changes in the ECG do you commonly see with amiodarone?
7. Why is a loading dose (or doses) necessary to administer when using the Class III drug amiodarone?
8. What suggestions can you give to a patient taking verapamil, a Class IV antiarrhythmic, to prevent constipation?

Drugs Affecting Coagulation

Learning Objectives

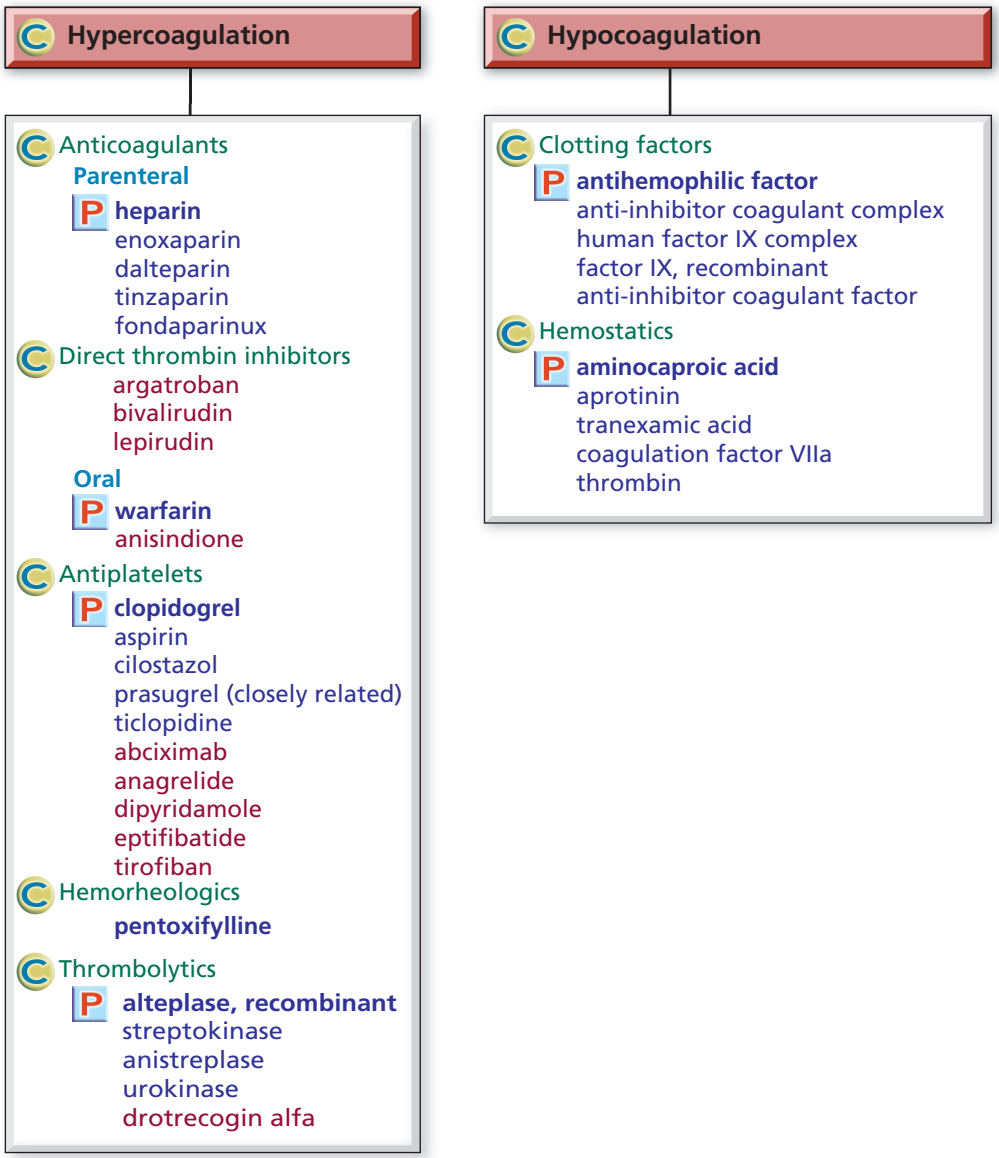
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs affecting coagulation.
2. Differentiate between the anticoagulants heparin and warfarin.
3. Understand the differences between anticoagulants and thrombolytics.
4. Differentiate antiplatelet drugs from hemorrheologic drugs.
5. Differentiate clotting factors from hemostatic agents.
6. Identify core patient variables relevant to drugs affecting coagulation.
7. Relate the interaction of core drug knowledge to core patient variables for drugs affecting coagulation.
8. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs affecting coagulation.
9. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs affecting coagulation.
10. Determine key points for patient and family education for drugs affecting coagulation.

Key Terms

anticoagulants
clotting cascade
clotting factors
coagulation
embolus
fibrin
fibrinolysis
hemophilia
hemostasis
International Normalized Ratio (INR)
plasmin
platelets
thrombin
thromboembolus
thrombus

Drugs Affecting Coagulation



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

This chapter examines drugs used to treat **coagulation** (blood aggregation, or clotting) disorders. Disturbances in the coagulation balance cause abnormalities in the body's ability to transport blood through the vessels to the cells or to form blood clots. Pathophysiologic effects may result from an excess of or a deficit in coagulation factors. When the body begins bleeding, a series of events occurs to slow blood flow, stop blood loss at the injury site, and prevent extensive blood loss. This process is known as **hemostasis.** Excessive coagulation, or hypercoagulation, will result in a **thrombus** (blood clot).

Several drug classes that are used to treat hypercoagulation disorders are discussed in this chapter. The first class is **anticoagulants** (substances that keep blood from clotting). Existing naturally and in drug form, anticoagulants prevent thrombus formation and the extension of existing thrombi. There are two types of anticoagulants—those that are given parenterally and those that are given orally. The prototype parenteral anticoagulant is heparin (Lipo-Hepin, Hep-Lock). The prototype oral anticoagulant is warfarin (Coumadin).

Other drug classes used to treat hypercoagulability include the antiplatelet agents, the hemorheologics, and the thrombolytics. Antiplatelet agents interfere with platelet membrane function and platelet aggregation. The prototype antiplatelet is clopidogrel (Plavix).

Hemorheologics reduce blood viscosity, increase the flexibility of red blood cells (RBCs), and decrease platelet aggregation. The prototype hemorheologic is pentoxifylline (Trental).

Thrombolytics, unlike anticoagulants and other drugs used to treat hypercoagulation, actually dissolve existing clots. They are used to treat medical emergencies resulting from thrombus formations' blocking of blood flow to the heart, lung, or deep veins of the legs. The prototype thrombolytic is alteplase, recombinant (Activase).

This chapter also describes drug classes used when hypocoagulation, or subnormal coagulation, is a problem. These drug classes include clotting factors and hemostatic agents. Clotting factors are replacements for genetic deficiencies of normal clotting factors, which lead to **hemophilia** (uncontrollable bleeding). The prototype drug is antihemophilic factor (AHF, factor VIII). Hemostatics inhibit **fibrinolysis,** the process of breaking down a formed clot. They are either systemic or topical. The prototype systemic hemostatic drug is aminocaproic acid (Amicar). Topical hemostatics are used to control minor bleeding, usually after surgery. The various agents work differently. No prototype is identifiable for topical hemostatics.

PHYSIOLOGY OF COAGULATION

Normal circulation requires blood to circulate freely through large and small blood vessels. However, blood must also be able to form clots to prevent excessive blood loss from injuries. To perform both of these functions requires the body's ability to balance coagulation and anticoagulation.

Blood Components and Balanced Blood Flow

Blood is composed of various cells and substances, each with a specific purpose that assists in maintaining a balance of coagulation and anticoagulation. Present in blood are **platelets** (also called thrombocytes), which are fragmented cells that assist in blood clotting and clot formation. In addition, the blood contains a number of other substances that promote coagulation but are inactive. These substances are the procoagulants (precursors to clotting factors) and **clotting factors,** which are plasma proteins that cause blood clotting. The clotting factors are inactive in the blood until an injury mobilizes them.

Circulating in an active form are the anticoagulants, which dominate the procoagulants, unless an injury to a blood vessel occurs that disrupts the dominance of the anticoagulants.

When a blood vessel is injured initially, the vessel goes into spasm (vasoconstriction), which decreases blood flow and limits blood loss. Because platelets have a surface composed of glycoprotein, they adhere to the endothelial surface of the damaged blood vessel. Next, with the help of enzymatic action, the platelets release a substance called adenosine diphosphate, which in turn is converted to thromboxane A_2. This activity attracts other platelets to the damage site. Together, the platelets form a temporary plug that seals the injured vessel. Normally, this plug is effective because it is stabilized with **fibrin,** an insoluble protein.

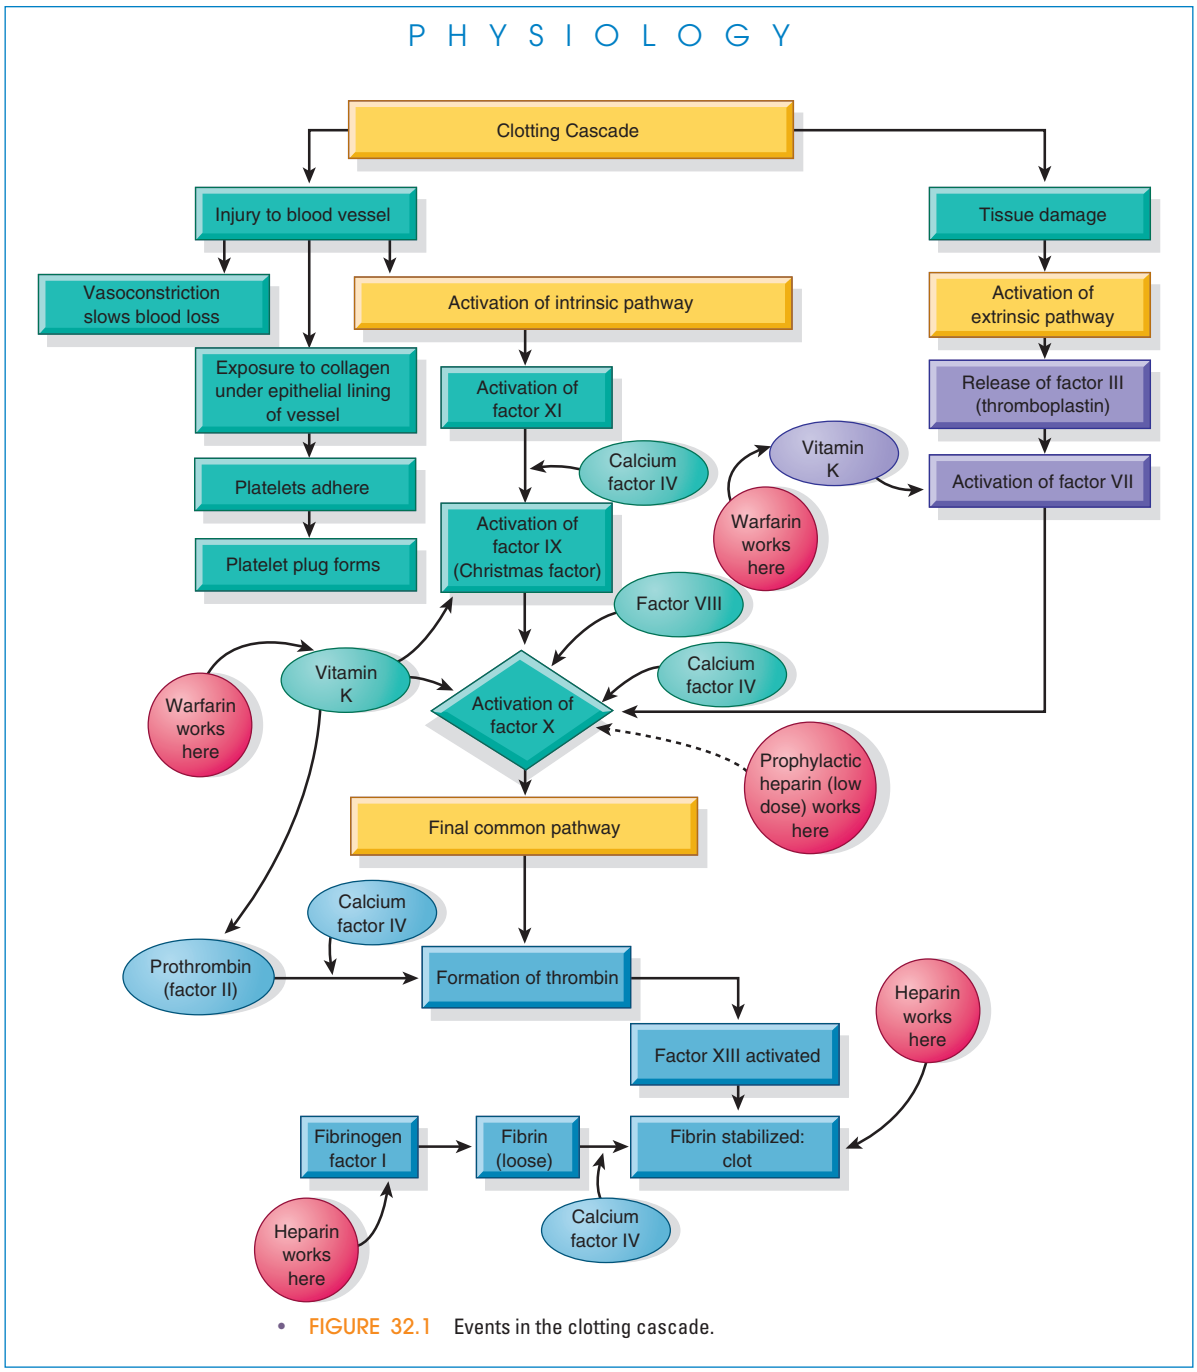
Clotting Cascade

Fibrin is a product of the **clotting cascade.** The cascade is initiated by the tissue damage and platelet activation, which mobilize the clotting factors circulating in the blood. Once active, these clotting factors work with calcium to form fibrin. At this point, blood coagulation is completed and blood loss stops.

The clotting cascade occurs over two pathways, intrinsic and extrinsic, to achieve hemostasis. The intrinsic pathway—so named because all of the clotting factors are present in the blood—is activated by damage to the blood vessel. In the extrinsic pathway, the clotting factors are activated by the damaged tissue. One or both pathways may be activated in response to injury. Figure 32.1 depicts the intrinsic and extrinsic pathways in the clotting cascade.

Intrinsic Pathway

Activity in the intrinsic pathway begins with an enzyme reaction that modifies factor XII from its inactive to active form. In turn, factor XII helps modify factor XI so that it can activate factor IX. Factor IX acts on factor VIII, and factor VIII activates factor X. Activated factor X affects factor V and promotes the conversion of prothrombin (factor II) to **thrombin.** Thrombin in turn converts factor I (fibrinogen) to fibrin. Thrombin also activates factor XIII, a fibrin-stabilizing factor. The fibrin threads that are produced trap the clotting



• FIGURE 32.1 Events in the clotting cascade.

factors that remain in the injured area, preventing the extension of the blood clot beyond the injury. The cascade thus ends in the formation of a stable blood clot.

Extrinsic Pathway

Activity in the extrinsic pathway begins with the activation of factor III, followed by the activation of factor VII. Tissue factor is a cellular receptor for this activated factor, or factor VIIa. The initiation of a clot in arteries or veins is triggered by tissue factor; factor VIIa has little or no enzymatic activity until it is bound to tissue factor. Factor VIIa then activates factor X. The remaining steps in the extrinsic pathway follow those of the intrinsic pathway and are referred to as the final common pathway. The prevention of clot extension, which occurs at the end of the clotting cascade, is assisted by the release of heparin. Heparin, a naturally occurring anticoagulant normally found in small amounts in the blood, is released from mast cells at the time of the initial injury.

Coagulation Inhibitors

The key inhibitors of coagulation are tissue factor pathway inhibitor (TFPI), antithrombin, and the protein C pathway.

TFPI inhibits the complex made from tissue factor and clotting factor VIIa. TFPI first joins with activated factor X to inactivate it. Once joined to now-inactive factor X, TFPI then works on factor VIIa attached to tissue factor to inactivate factor VIIa. This delay allows for some active factor X to create a clot. Antithrombin (formerly referred to as antithrombin III) inhibits thrombin, activated factor X, and other activated clotting factors. The action of antithrombin is very slow unless heparin is present; heparin increases the rate of inhibition by a factor of 1,000. Thrombin is also inhibited by binding to thrombomodulin, a thrombin receptor found on the endothelium. Binding to thrombomodulin allows thrombin to change from a procoagulant enzyme into a potent activator of protein C, a vitamin K–dependent protein (not to be confused with c-peptide [connecting peptide involved in insulin production] or C-reactive protein [protein in the blood that rises with levels of inflammation], or protein kinase C [PKC: one of a group of enzymes involved in signal transmission]). Protein C inactivates factors Va and VIIIa, and protein C may also limit thrombin-induced inflammatory responses. In other words, protein C has anticoagulant properties because it prevents processes that are involved in creating stable clots.

Hemolysis

After a blood clot forms, the blood has a removal system that begins to lyse (decompose or break down) the fibrin in a clot about 1 to 2 days after bleeding stops. This process is called **fibrinolysis.** Plasma protein contains a substance known as plasminogen, which, along with other plasma proteins, is trapped in the blood clot. The damaged tissue releases tissue plasminogen activators. The two distinct plasminogen activators found in the blood are tissue-type plasminogen activator and urokinase-type plasminogen activator. Both are synthesized and released from endothelial cells. These activators change plasminogen to its active form, **plasmin.** Activated plasmin is the substance that lyses the blood clot.

PATHOPHYSIOLOGY

Hypercoagulation

When blood flow is impeded and slowed in an area, coagulation occurs, leading to formation of a thrombus. Any excessive action from the coagulating factors may also produce a thrombus that obstructs blood flow. A thrombus can form anywhere in the cardiovascular system. The components of a thrombus vary, depending on whether the thrombus is arterial (formed under high flow conditions) or venous (formed from stasis). Arterial thrombi consist mostly of platelet aggregates held together with thin fibrin strands, whereas venous thrombi are mostly red cells, a large amount of fibrin, and only a few platelets. An **embolism (embolus)** is any undissolved matter carried in a blood or lymph vessel to another location where it lodges and occludes the vessel. When a portion of a thrombus breaks off, the fragment may travel through the bloodstream and lodge in a vessel (**thromboembolus**), again occluding blood flow. When the thromboembolus is lodged in a coronary vessel, a myocardial infarction (MI) occurs. When it is lodged in the brain, a stroke, or cerebrovascular accident (CVA), occurs. When the thromboembolus is lodged in the pulmonary vessels it is called a pulmonary **embolus.** When a thromboembolus lodges in a blood vessel, blood flow through the vessel decreases or stops, depending on the size and position of the thromboembolus and the degree of obstruction. With decreased blood flow, tissues and cells do not receive necessary oxygen and nutrients, and necrosis (cell death) occurs. Arterial and venous thrombosis result from different pathologies and create different complications for the patient.

Arterial thrombosis, the most common cause of MI, stroke, and limb gangrene, is usually a consequence of spontaneous or mechanical rupturing of an arthrosclerotic plaque. When the plaque ruptures, the thrombogenic material in the lipid-rich core of the plaque is exposed to the blood. The resulting thrombi extend both into the plaque and into the vessel lumen. If the thrombus adheres to the vessel, then platelets and fibrin attach to it to such a degree that the thrombus becomes occlusive. If the thrombus does not initially attach, it may float and lodge elsewhere. Arterial thrombi produce negative effects on blood flow either from directly obstructing blood flow or by producing embolisms that lodge in the microcirculation.

Venous thrombosis, a result of natural procoagulant stimuli overwhelming natural protective mechanisms, leads to pulmonary embolism (PE) and postphlebitic syndrome (a syndrome occurring within 1 year after a deep vein thrombosis [DVT], with chronic, potentially disabling leg swelling, pain, venous dilation, and skin induration). The procoagulant stimuli include excessive activation of coagulation, vessel wall damage (e.g., after major hip or knee surgery), or stasis. Inflammatory cytokines generated after trauma, surgery, or medical illness contribute to the procoagulant state and inherited deficiencies, of naturally anticoagulant pathways may also produce a thrombus. Venous stasis creates a situation of localized hypoxemia in the vein. This hypoxia triggers tissue factor expression in the valve cusps of the vein. Once factor VIIa becomes bound and activated, it sets off a series of clotting events that ends with the conversion of prothrombin to fibrin.

Venous thrombi most often occur in the deep vessels of the lower limbs (referred to as deep vein thrombosis, or DVT) and produce serious effects from inflaming the vessel wall, from direct obstruction of blood flow, or through pulmonary embolism. DVT may be secondary to surgery or trauma (as previously stated), as well as malignancy, hereditary thrombotic disorders, stroke, spinal cord injury, or unexplained causes. Trauma to the vein can result from central venous catheters; this can cause DVT of an upper extremity.

A relationship between cancer and thrombosis has been identified. The exact mechanism of the relationship between cancer and thrombosis is not known. It is known that cancer patients have an increased risk of developing thrombosis (this is possibly related to chemotherapy). The opposite is also true, in that patients who present with thromboembolism of unknown causes have a higher risk for developing cancer. It

has been hypothesized that early presymptomatic cancer may be present in these people and may be producing hypercoagulability. It is also possible that because the patient hospitalized with a blood clot has many tests performed to determine the cause of the clot that the cancer is found serendipitously during this screening. At this time, no extensive screening is recommended to detect cancer in patients with thrombosis. Routine accepted tests for cancer screening (such as Pap smears, mammography, and prostate screening) may be done at the time of hospitalization if they have not been done recently.

Acute coronary syndromes are also related to thrombus. Acute coronary syndromes include unstable angina, non–ST-elevation MI, and ST-elevation MI. All of these conditions have an underlying pathology of unstable coronary plaque on a coronary vessel, with an overlying intracoronary thrombus. Thrombus formation can also be a problem in atrial fibrillation. In this condition, the blood is not moving, which may lead to coagulation of the blood into clots.

Some conditions of hypercoagulability result from increased platelet activity. Constriction of, or fatty deposits in, a blood vessel narrows its lumen, leading to decreased or slowed blood flow through the vessel. The decreased flow causes stasis, which results in blood coagulation. Platelet activity is responsible for the formation of the blood clot. This is a particular problem for patients with chronic, obstructive vascular disease because blood clots further impair or entirely block an already diminished blood flow, thereby posing a risk for tissue death from lack of oxygen and nutrients.

In peripheral vascular disease, the blood vessels in the extremities, particularly the legs, are narrowed. This narrowing prevents the flow of oxygenated blood to the tissues. Lack of oxygenation causes pain, especially with use of the extremity. This condition is known as intermittent claudication. Rest relieves the pain because it decreases the oxygen needed by the tissue. With the impaired circulation, venous stasis occurs, which in turn leads to platelet aggregation and thrombus formation. This thrombus further impairs circulation through the vessel to the tissue.

Hypocoagulation

When clotting factors are deficient, blood clotting does not occur in a timely manner. A minor injury or trauma can cause prolonged bleeding, or hemorrhage, either internally or externally. Bleeding may occur into a joint, such as the elbow or knee, and cause serious damage.

Inherited deficiencies of specific clotting factors produce three major hemophilic conditions: hemophilia A (classic hemophilia), hemophilia B (Christmas disease), and von Willebrand disease. Hemophilia A results from lack of factor VIII. Hemophilia B results from lack of factor IX. Hemophilias A and B are transmitted on recessive, sex-linked genes. The genes are carried by women and transmitted to male children. von Willebrand disease results from deficiency of factor VIII, factor VIII antigen, and von Willebrand factor. It is transmitted by an autosomal dominant gene and inherited by both sexes.

Decreased synthesis of clotting factors is characteristic of diseases that affect the liver, such as cirrhosis and hepatitis, because most clotting factors are produced in the liver. A second cause of decreased synthesis is an absence of vitamin K, which is necessary for the formation of four of the clotting factors: II (prothrombin), VII, IX, and X.

Fibrinolysis normally occurs in balance with blood coagulation. A clot forms to prevent extensive blood loss. When the vessel heals, the clot is broken down (fibrinolysis) by activating plasminogen so that it becomes plasmin. Plasmin breaks down fibrin, fibrinogen, and other plasma proteins. When fibrinolysis is not in balance with the other phases of coagulation (i.e., an excess of plasmin exists), excessive bleeding occurs because the body cannot form a stable clot in response to injury.

DRUG THERAPY FOR HYPERCOAGULATION

In general, disorders of hypercoagulability result from either an increase in platelets or an increase in the activity of the clotting system, or combinations of both. Treatment is aimed at interfering with the clotting cascade. The desired goals of drug therapy are to lengthen the time necessary for blood to clot, to alter platelet aggregation preventing clotting, or both. Anticoagulant drug therapy is used to prevent new clots from forming, to avoid extension of the thrombus, or to deter a thromboembolus. Antiplatelet therapy decreases the ability of platelets to stick together. Therapy to block platelet function is used primarily for arterial thrombi, because these clots consist of platelet aggregates held together by small amounts of fibrin; however, treatment often also includes some anticoagulant drugs to prevent deposits of fibrin. Anticoagulant therapy is the preferred choice for treatment or prevention of venous thrombi, which are mostly composed of fibrin.

When an existing clot may be fatal to the patient because of blocked blood flow to vital organs, thrombolytic agents are used to break it up. When the clot or obstruction blocks a coronary artery, the heart is affected; damage to the heart from an MI can be permanent or fatal. When the clot blocks the pulmonary artery, the blood supply to the lungs is altered; this alteration in turn decreases the oxygenation of blood to be circulated. This is a life-threatening condition. If the clot is in the brain, ischemia of the tissue results in brain cell death with loss of brain function and permanent neurologic deficits or disabilities in the patient. If the injury is severe or an extensive portion of the brain is affected, death can result. Because brain cells are highly dependent on sufficient oxygen for survival, rapid treatment to break apart a thrombus and relieve hypoxia is crucial. When the thrombus is large and blocks the great veins in the legs, circulation is impaired in the limb. If the circulatory impairment is severe enough, the patient may risk losing the limb as a result of tissue death. This event also is considered a medical emergency. Thrombolytic agents are indicated in these emergency situations to prevent severe damage to the body or death.

TABLE 32.1 Summary of Selected Drugs for Hypercoagulability

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P heparin	Anticoagulation	*Adult:* IV, 5,000 U bolus (or 35–70 U/kg) followed by 20,000–40,000 U/24 h or 15–25 U/kg/h *Child:* IV, 50 U/kg bolus, followed by 100 U/kg/4 h or 20,000 U/m2/24 h	*Onset:* Immediate *Duration:* 2–6 h $t_{1/2}$: 30–180 min
	Prophylaxis	*Adult:* SC, 5,000 U q8–12h	*Onset:* 20–60 min *Duration:* 8–12 h
enoxaparin (Lovenox)	Prophylaxis	*Adult:* SC, 30 mg, bid or 40 mg/d	*Onset:* 20–60 min *Duration:* 12 h $t_{1/2}$: 4.5 h
P warfarin (Coumadin)	Prophylaxis and treatment	*Adult:* PO, 5–10 mg/d for 2–4 d, then adjust according to results of PT or INR values	*Onset:* 24 h *Duration:* 2–5 d $t_{1/2}$: 1–2.5 d
P clopidogrel (Plavix)	Reduction of atherosclerotic events	*Adult:* PO, 75 mg/d	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 8 h
aspirin (Bayer)	Prophylaxis for MI Decrease risk of TIA in men	*Adult:* PO, 300–325 mg/d *Adult:* PO, 1,300 mg/d divided into two to four doses	*Onset:* 5–30 min *Duration:* Varies $t_{1/2}$: 15–20 min
P pentoxifylline (Trental)	Intermittent claudication	*Adult:* PO, 400 mg tid	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 0.4–0.8 h
P alteplase, recombinant (Activase)	Acute MI	*Adult* (>67 kg): 100 mg total: 15 mg bolus, 50 mg infusion over 30 min, then 35 mg infusion over 60 min	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Unknown
	Acute ischemic stroke	*Adult:* IV, 0.9 mg/kg (max 90 mg) 10% given as bolus over 1 min, 90% infused over 60 min	
	Pulmonary embolism (PE)	*Adult:* IV, 100 mg infusion over 2 h	

When the patient has a less urgent need for therapy, has a high risk of developing arterial thrombi, or requires additional treatment after the use of thrombolytic drugs, antiplatelet drugs are used. Antiplatelets decrease clumping or aggregating of platelets. Platelet aggregation is also affected by hemorheologic drugs. In addition, the hemorheologics increase the flexibility of RBCs and decrease the blood viscosity.

Table 32.1 presents a summary of selected drugs used to treat hypercoagulability.

C ANTICOAGULANT DRUGS

Heparin, a naturally occurring anticoagulant, is produced by mast cells located in connective tissue throughout the body. The blood cells known as basophils produce a small amount as well. The areas that produce the largest amount of heparin are the lungs and, to a lesser degree, the liver. This fact reflects a natural protective mechanism of the body because these two areas receive the smallest emboli.

All anticoagulants interfere with the clotting cascade and prolong blood clotting time. They vary by their route and their method of action. There are two types of anticoagulants: those that can be administered only parenterally and those that can be administered only orally. The parenteral anticoagulants work by preventing the conversion of fibrinogen to fibrin. The oral anticoagulants work by preventing the synthesis of factors dependent on vitamin K for synthesis: factors II (prothrombin), VII, VIII, IX, and X. Two different laboratory tests, one for drugs administered orally and one for those administered parenterally, are therefore used to measure the therapeutic effects of these anticoagulants.

The prototype parenteral anticoagulant is heparin, which is unfractionated (containing both low-molecular and high-molecular weights). Most heparin is available as generic heparin sodium; lower concentrations may be labeled heparin lock flush.

Nursing Management of the Patient Receiving P Heparin

Core Drug Knowledge

Pharmacotherapeutics

Heparin is the prototype parenteral anticoagulant. It interferes with the final steps of the clotting cascade. It is used to prevent the extension of a blood clot, particularly in patients with DVT or PE. It is also used prophylactically in patients

with short-term increased risk of thrombus formation, such as in the postoperative period after a total hip replacement. When used for treating disseminated intravascular coagulation (DIC), heparin prevents further clotting in the microcirculation, leaving the procoagulants available to work at other sites in the body. In addition, heparin is also used to maintain the patency of venous access devices. It has several off-label uses: in the treatment of acute coronary syndrome or acute MI and with peritoneal dialysis

The heparin dosage is tailored to the patient and the severity of the condition. Continuous intravenous (IV) infusion of heparin is used to achieve full anticoagulation. In adults, a heparin IV drip is usually started by giving an IV bolus of the drug, followed by continuous infusion. Standardized heparin administration protocols are frequently used to prevent medication error and to improve achieving full therapeutic response. These protocols may be based on a standard therapy of units per hour or patient weight. The weight-based nomograms have been found to achieve a therapeutic range more rapidly than methods of estimating the appropriate dose using clinical experience alone or any dose-based protocol. Other methods to achieve the full anticoagulating effects from heparin include intermittent IV boluses or subcutaneous injections of heparin, although these methods are not frequently used today. In adults, subcutaneous administration of heparin may also prevent thromboembolic events. Recently, the potency of U.S. heparin solutions was decreased 10% to match international standards. This decrease should not significantly alter the dose needed for most patients to receive the therapeutic effect; dosing recommendations on the label have not been modified. The FDA does not recommend that practitioners routinely adjust the dose initially prescribed for all patients based on this change in potency. Dosing as always is individually titrated to achieve the therapeutic effect as measured by blood tests (FDA, 2009).

The duration of anticoagulation therapy for venous thromboembolism is based on the patient's risk of thrombosis if anticoagulation is stopped, as well as the patient's risk of bleeding if drug therapy is continued. Risk of recurrent thrombosis is considered low if it was precipitated by a reversible factor, such as surgery (because the surgery and the postoperative period are past, so that risk is no longer present). Risk of recurrence is high if the thromboembolism occurred with no apparent risk factors, or if the patient has persistent risk factors (e.g., cancer). Patients at low risk of recurrence should receive anticoagulation therapy for 3 months. Those at higher risk should receive anticoagulation therapy for 6 months to indefinitely, depending on the patient's variables. Initially, treatment involves heparin for at least 5 days but then continues with the oral anticoagulant warfarin.

Pharmacokinetics

Heparin is not absorbed from the gastrointestinal (GI) tract because it is destroyed by gastric acid; hence, it must be administered parenterally. When administered intravenously, heparin has an immediate onset of action. When administered subcutaneously, its onset of action is 20 to 60 minutes. After administration, the drug is widely distributed in the body, although it does not cross the placenta, and it is not found in breast milk. Heparin metabolism occurs in the liver, where it is inactivated. It is eliminated from the body in the urine.

Pharmacodynamics

Heparin, along with antithrombin, rapidly promotes the inactivation of factor X, which, in turn, prevents the conversion of prothrombin to thrombin. Heparin also has an effect on fibrin, limiting the formation of a stable clot. In blood tests measuring activated partial thromboplastin time (aPTT or APTT), heparin prolongs the clotting time. Low-dose heparin therapy, which is prophylactic dosing, deactivates factor X but has minimal effect on already produced thrombin; thus, it does not normally alter aPTT levels. However, full anticoagulation effects can occur in some individuals. Heparin has no effect on blood clots that have already formed. Therapeutic doses of heparin release TFPI that was bound to the endothelial wall surface. It is not certain whether released TFPI contributes to the anticoagulant properties of heparin (Weitz, Hirsh, & Samama, 2008). A less important action of heparin is that it binds directly to platelets.

Contraindications and Precautions

Heparin is contraindicated in patients who are hypersensitive to beef or pork because some heparin products are derived from the intestinal mucosa of pigs and others from beef lung. Heparin is also contraindicated in patients with thrombocytopenia, bleeding disorders, and active bleeding other than DIC.

This drug should be used with caution in patients with the potential for hemorrhage (e.g., immediately after surgery, with peptic ulcer disease and liver disease).

Adverse Effects

The most common adverse effect of heparin is bleeding. Although heparin-induced thrombocytopenia (HIT) occurs rarely, it is potentially life threatening. Treatment for HIT is discussed under the section Minimizing Adverse Effects below. Other adverse effects of heparin, although uncommon, include hepatitis, rashes, urticaria, hypersensitivity, and fever. In addition, treatment with heparin for more than 6 months may lead to the development of osteoporosis; this is related to bone demineralization.

If a patient receives an overdose of heparin or shows signs of bleeding, then protamine sulfate, the antagonist for heparin, may be administered. Protamine sulfate, a strong base, reacts with heparin, a strong acid, to form a stable salt, thereby neutralizing the anticoagulant effects of heparin. The protamine sulfate dose is based on the heparin dose: 1 mg of protamine sulfate per 100 units of heparin,

or 0.5 mg of protamine sulfate per 100 units of heparin if the heparin was administered more than 30 minutes before the protamine sulfate. No more than 100 mg of protamine sulfate should be given within a 2-hour period, because this drug can cause anticoagulation in its own right. Administering protamine sulfate too rapidly may result in hypotension, bradycardia, dyspnea, and anaphylaxis. Hypersensitivity reactions may occur in some patients because of the fish base of protamine sulfate. Symptoms include flushing and feelings of warmth.

If the patient is not actively bleeding after heparin overdosage, the patient is usually monitored closely, and the protamine sulfate is not administered because heparin has a short half-life. The patient will recover from the overdosage without the added risk of complications from the protamine sulfate.

Drug Interactions

Several different drugs affect the action of heparin. Table 32.2 identifies these drugs and the significance of the reactions.

Assessment of Relevant Core Patient Variables

Health Status

Before administering the first dose of heparin, review the patient's record for evidence of allergy or a pre-existing prolonged bleeding time that would contraindicate administering heparin. A baseline aPTT and platelet count should be obtained. Assess the patient's renal function, because if the creatinine clearance is less than 25 mL/min, heparin is preferred over low-molecular-weight heparins for treatment of venous thrombosis.

Life Span and Gender

Be aware that heparin is safe for pregnant women, although it places other patients at risk for injury, particularly those who are confused, cognitively impaired, unable to modify behavior to prevent injuries, or incapable of complying with requests to modify behavior.

Lifestyle, Diet, and Habits

Because heparin prolongs both internal and external bleeding, slight injuries may potentially cause serious adverse effects. Ask patients about their activity level. Patients who normally engage in active behaviors in which bumping or body injuries frequently occur are more at risk for injury when receiving subcutaneous heparin therapy at home. Assess hospitalized patients for falls; consider such factors as a recent history of falls, impaired mobility, and other known risk factors.

Environment

Be aware of the environment in which the drug will be administered. Heparin is normally administered in an acute care setting.

Nursing Diagnoses and Outcomes

- Risk for Injury, Hemorrhage, related to heparin therapy
  Desired outcome: *Hemorrhage will not occur.*
- Risk for Injury, Heparin-induced thrombocytopenia, related to heparin therapy
  Desired outcome: *Heparin-induced thrombocytopenia will not occur.*

Planning and Intervention

Maximizing Therapeutic Effects

Monitor laboratory values (e.g., the aPTT) to confirm that a therapeutic lengthening of the clotting time has been achieved. The therapeutic lengthening of the clotting time is generally measured as one and one half to two times the control aPTT. Because control times vary from laboratory to laboratory, depending on the test equipment used, the difference between the two times is used to measure effectiveness. To determine the therapeutic range, multiply the control by 1.5 and then by 2; the therapeutic range is between these two products. For example, if the aPTT control time is 30 seconds, a therapeutic level for the patient would be 45 to 60 seconds ($30 \times 1.5 = 45$; $30 \times 2 = 60$). If the laboratory uses a

TABLE 32.2 Agents That Interact with P Heparin

Interactants	Effect and Significance	Nursing Management
cephalosporins	Additive effect with heparin is possible, which increases risk of bleeding.	Monitor for signs of bleeding. Monitor activated partial thromboplastin time carefully. Use drug cautiously when it is required.
nitroglycerin	Information is conflicting, but effect of heparin may be increased, increasing risk of bleeding.	Same as above.
penicillins	Parenteral administration can alter platelet aggregation and coagulation test findings. They may have additive effect with heparin to increase the risk of bleeding.	Same as above.
salicylate	Antiplatelet effect increases risk of bleeding.	Concurrent use is normally avoided.

standard range for aPTT rather than a control (where the range can vary), then the heparin dose should be 1.5 to two times the upper limit of the normal aPTT range. It is important that patients reach the minimum of 1.5 times the control or upper normal range within the first 24 hours of therapy. Failure to promptly achieve this therapeutic level in patients with a clot increases the risk of developing additional clots.

Heparin levels should be allowed to reach steady state before measuring aPTT, usually 6 to 8 hours after the infusion starts. If the aPTT is less than one and one half to two times the control, contact the prescriber to seek new drug therapy orders. If the aPTT is below the desired therapeutic range, the dosage needs to be increased. Repeated testing is needed after each dosage change has reached steady state (6–8 hours after the dosage change). In institutions with established protocols for adjusting heparin infusion rates to meet therapeutic levels, the rate may be changed by a registered nurse. If aPTT values deviate from the protocol limits, the prescriber must be notified.

Do not interrupt IV heparin therapy, because this lowers the blood levels of heparin and affects the therapeutic response. If occlusion or infiltration necessitates changing the IV site, insert the new IV line as soon as possible to minimize the disruption of the infusion.

Doses of SC heparin should not be missed; they should be administered at the regularly prescribed times to maintain blood levels.

Minimizing Adverse Effects

Before initiating therapy, review such laboratory values as aPTT, hematocrit, and platelet count. These tests provide baseline information regarding clotting abilities and identify patients with conditions that contraindicate heparin therapy. However, these tests are not usually performed for prophylactic heparin use.

If the aPTT during treatment exceeds the desired range, the dosage should be decreased. Contact the prescriber to seek new drug therapy orders, or act on the standard protocol (if one is used).

Use an IV controller or pump for continuous IV drip heparin to promote a steady rate of delivery and prevent rapid overdosage, which may occur when IV flow rates are regulated by gravity. Use of a pump is a standard safety precaution. When selecting a vial of heparin, either to mix in a bag of fluid for infusion for SC use or to flush a venous catheter, confirm that the appropriate concentration of the heparin has been selected. Heparin comes in a wide variety of concentrations, from 10 units per mL to 10,000 units per mL. Selection of the wrong concentration is a medication error that can lead to serious adverse effects, especially hemorrhage.

Do not interrupt administration of IV heparin to give another drug. Doing so increases the risk of thrombus formation because therapeutic levels may not be maintained. Do not administer other drugs through the same tubing as heparin because heparin is incompatible with many other drugs and fluids. Instead, use an additional peripheral IV line or a multilumen central venous catheter.

To minimize the risk of heparin-induced thrombocytopenia (HIT), the American College of Chest Physicians recommends that the platelet count be monitored every day for 14 days or until the heparin is discontinued (whichever comes first). When the heparin is administered to prevent a clot, the platelet count should be monitored every 2 to 3 days from day 4 to 14, or until it is stopped (whichever comes first). Patients who have received heparin therapy in the past 100 days and are starting treatment again with heparin are at risk for accelerated thrombocytopenia, so a baseline platelet count should be obtained and then repeated within 24 hours. If patients are receiving heparin just as a flush for a venous catheter, they do not require platelet count monitoring (Hirsh, Albers, & Schunemann, 2008). HIT should be suspected if the patient is receiving heparin or has received heparin within the last 2 weeks and there is a 50% or more drop in the platelet count. Nurses should work jointly with the physician in monitoring the platelet count and bring changes in the platelet count to the physician's attention.

If the patient is determined to have HIT, the treatment includes discontinuing heparin, allowing the platelet count to return to normal, and treating any thrombosis with a nonheparin anticoagulant (such as danaparoid, lepirudin, argatroban, fondaparinux, or bivalirudin, which are discussed below in the section Drugs Significantly Different From Heparin) over further use of unfractioned heparin or low molecular weight heparin..

Monitor patients for bleeding from the gums, nose, vagina, or wounds. Examine urine and stools to detect blood as well. Inspect the skin for ecchymoses or hematomas that indicate bleeding into the tissues. If the patient develops active bleeding from an orifice or a wound, notify the prescriber immediately. Protamine sulfate is administered if significant active bleeding occurs.

Place pressure on IV sites when removing the line until bleeding stops. Use a 25-gauge or finer needle for SC administration (Box 32.1). Do not aspirate or massage the area after SC administration. Avoid intramuscular (IM) injections to prevent bleeding into the muscle.

To protect the patient from injury or falls, use standard fall precaution measures. Raise or pad the top side rails, particularly if the patient is confused, disoriented, restless, or unable to comprehend or follow activity restrictions during therapy.

Providing Patient and Family Education

- Before heparin therapy begins, inform patients why the drug is needed and what it is expected to accomplish. Heparin should be described as an anticoagulant, not a blood thinner. Although this is a common description, it is not correct.

Box 32.1 RESEARCH-BASED SUBCUTANEOUS ADMINISTRATION TECHNIQUES FOR HEPARIN

Traditionally, the abdomen, 2 inches from the umbilicus, was the preferred site for injection because it was believed that this site carried less risk for developing hematoma. The limited research done to date has shown, however, that site selection of the arm or thigh, as opposed to the abdomen, does not increase bruising or alter aPTT (Fahs & Kinney, 1991). Research further indicates that technique affects hematoma formation. As early as 1988, Wooldridge found that changing the needle after drawing the drug into the syringe, having an air bubble in the syringe to follow the dose and lock the drug into the subcutaneous space, injecting at a 90-degree angle, and avoiding aspiration and massage after injection helped to prevent hematoma formation. The use of a 3-cc syringe rather than a 1-mL syringe has been found to cause smaller bruises when administering heparin (Hadley, Chang, & Rogers, 1996).

- Explain that frequent blood samples will need to be analyzed to measure patients' clotting time and determine whether they are receiving a safe amount of heparin.
- Instruct patients to report any blood in urine or stools and any bleeding from the gums, nose, vagina, or wounds.
- Educate patients to use a soft toothbrush and an electric razor during therapy to prevent bleeding and to follow activity restrictions to prevent bruising and internal bleeding from injuries.

Ongoing Assessment and Evaluation

Throughout therapy, monitor for signs of bleeding and review aPTT values to maintain heparin levels in the therapeutic range. Monitor platelet counts at appropriate intervals. Drug therapy is considered effective when a thrombus or extension of an existing thrombus is avoided and adverse effects are prevented or minimized.

Drugs Closely Related to P Heparin

Low-molecular-weight heparin is derived from standard heparin through either chemical or enzymatic depolymerization (breakdown of polymers into monomers, their basic building block). Whereas standard heparin has a molecular weight of 5,000 to 30,000 daltons, low-molecular-weight heparin ranges from 1,000 to 10,000 daltons, resulting in properties that are distinct from those of traditional heparin. Low-molecular-weight heparin binds to protein (although less strongly than traditional heparin), has enhanced bioavailability, interacts less with platelets, and yields a very predictable dose response, eliminating the need to monitor the aPTT. Low-molecular-weight heparin, like standard heparin, binds to antithrombin; however, low-molecular-weight heparin also inhibits thrombin to a lesser degree (and actual factor X to a greater degree) than standard heparin.

Low-molecular-weight heparins also have prolonged half-lives compared with unfractionated heparin (standard heparin that has not been depolymerized). This characteristic, in combination with the increased bioavailability, allows once-daily SC dosing. Such dosing enables treatment for stabilized patients in their own homes, while they are followed as outpatients.

Low-molecular-weight heparins cause less bleeding when given in therapeutic doses, compared with unfractionated heparin, as well as less heparin-induced thrombocytopenia and osteoporosis. Traditional heparin is recommended when patients have severe renal insufficiency, as evidenced by a creatinine clearance less than 30 mL/min; if low-molecular-weight heparin is used, the dose should be decreased by 50% (Hirsh, Albers, & Schünemann, 2008). Obese patients are recommended to be dosed with LMWH based on body weight (Hirsh, Albers, & Schünemann, 2008).

Low-molecular-weight heparins are now used successfully for several therapeutic purposes. In multiple clinical trials and in meta-analyses of trials, these heparins have been found to be at least as safe and effective as unfractionated heparin in treatment of pulmonary embolism, as prophylaxis for venous thromboembolism, and in treatment of DVT; in many cases these drugs have replaced traditional heparin (Weitz, Hirsh & Samama, 2008; van Dongen, van den Belt, Prins, et al., 2004). They are also as effective as heparin in preventing thromboembolism prior to long-term anticoagulation after a mechanical heart valve replacement and in patients with a mechanical valve who have a contraindication to oral anticoagulation. In addition, a 14-day course of therapy of low-molecular-weight heparin may be used in patients who are at high risk for stent thrombosis.Patients who have major orthopedic surgery, particularly hip surgery, remain at risk for clinically important

MEMORY CHIP

P Heparin

- Anticoagulant that prevents formation or extensions of blood clots
- Has no effect on existing blood clots
- Parenteral administration (IV or SC)
- Major contraindications: thrombocytopenia, bleeding disorders, and active bleeding other than DIC
- Most common adverse effect: bleeding (antidote for heparin overdose is protamine sulfate)
- Most serious adverse effect: thrombocytopenia
- **Life span alert: Heparin is the anticoagulant that can be used during pregnancy.**
- **Patient safety alert: Check concentration of heparin carefully. Use of the wrong concentration for the route of administration is a common medication error with serious/potentially life-threatening ramifications.**
- Maximizing therapeutic effects: Monitor APTT for therapeutic range; adjust dose until therapeutic range achieved.
- Minimizing adverse effects: Use IV pump; assess for signs of bleeding.
- Most important patient education: Instruct patients to report any blood in urine or stools or bleeding from gums, nose, vagina, or wounds.

venous thrombosis for at least 4 weeks after the surgery; this risk is significantly reduced if they continue to receive a low-molecular-weight heparin, fondaparinux, or warfarin during this period (Hirsh, Albers & Schünemann, 2008). Low-molecular-weight heparins are currently being studied for their use in preventing thromboembolism in patients with cancer (Box 32.2).

All low-molecular-weight heparins have a Black Box warning regarding the use of epidural/spinal anesthesia or spinal puncture. Patients who either have received or will receive a low-molecular-weight heparin are at increased risk for the development of an epidural or spinal hematoma, which can result in long-term permanent paralysis. The risk of these events is increased by the use of indwelling epidural catheters for administration of analgesia or by the concomitant use of drugs affecting hemostasis, such as nonsteroidal anti-inflammatory drugs (NSAIDs), platelet inhibitors, or other anticoagulants. The risk also appears to be increased by traumatic or repeated epidural or spinal puncture. Other anticoagulants should be used for patients in these situations.

Commercially available low-molecular-weight heparins differ in their method of production, molecular weight, and degree of sulfation. They also differ somewhat in terms of pharmacokinetics. These differences may or may not have any clinical significance. Three low-molecular-weight heparins are used in the United States: enoxaparin, dalteparin, and tinzaparin. Another drug, fondaparinux, has a slightly different composition and is not in the same class but will be considered with these drugs.

Enoxaparin

Enoxaparin (Lovenox), which is considered safer than and equally effective as heparin, has an effect on activated factor X and has limited effect on thrombin. Thus, its effect on aPTT is decreased. Enoxaparin also affects clotting factor C and antithrombin. Most enoxaparin is absorbed after SC administration and is widely distributed. Enoxaparin has been found to be superior to unfractionated heparin in reducing death, MI, and emergency revascularization in patients with Q-wave MI. Enoxaparin and other LMWHs are considered the preferred treatment for deep venous thrombosis over traditional non-fractionated heparin. Enoxaparin is also approved to be used to prevent ischemia that may result from non-Q-wave myocardial infarction or unstable angina.

Enoxaparin appears to have greater efficacy but similar safety as unfractionated heparin when used to treat ST-segment-elevation myocardial infarction. Low-molecular- weight heparins, like enoxaparin, appear to be safe and effective for treating acute coronary syndrome when combined with platelet glycoprotein IIB/IIIa inhibitors (Ferguson, Antman, Bates, et al., 2003). When given to patients with a creatinine clearance of 30 mL/min or less, enoxaparin results in elevated levels of antiactivated factor X, and patients have an increased risk of bleeding. Dosage adjustments may be warranted (Lim, Dentali, Eikelboom, et al., 2006). Enoxaparin is a pregnancy category B drug.

Patients who are to receive enoxaparin by SC injection after discharge should be taught how to administer the drug to themselves (Box 32.3). It is important that they understand the reason for therapy, the necessity of taking the drug on time, and the importance of following a regular dosage schedule and having follow-up blood analyses done as recommended. They should also be advised about scheduling and keeping appointments with the prescriber.

Other important teaching points focus on safety (e.g., clearing pathways, removing loose scatter rugs, wearing nonskid

BOX 32.2 FOCUS ON RESEARCH

Low-Molecular-Weight Heparins and Cancer Patients

Hull, R. D., Pineo, G. F., Brant, R. F., et al. (2006). Long-term low-molecular-weight heparin versus usual care in proximal vein thrombosis patients with cancer. *The American Journal of Medicine,* 119(12):1062–1072.

Deitcher, S. R., Kessler, C. M., Merli, G., et al. (2006). Secondary prevention of venous thromboembolic events in patients with active cancer: Enoxaparin alone versus initial enoxaparin followed by warfarin for a 180-day period. *Clinical and Applied Thrombosis/ Hemostasis: Official Journal of the International Academy of Clinical and Applied Thrombosis/Hemostasis,* 12(4):389–396.

The Study

Although patients with cancer are known to be at increased risk of thromboembolism, anticoagulant trials have not frequently included these patients. Recently, two small trials examined patients with cancer and thromboembolism and evaluated their response to low-molecular-weight heparin. Patients with cancer frequently experience myelosuppression secondary to chemotherapy. With decreased platelets, they are at increased risk of bleeding, although they are also at increased risk of clotting. Warfarin may additionally increase the risk of bleeding.

The first study examined the effectiveness of a low-molecular-weight heparin, tinzaparin, compared with warfarin. Patients received one of these drugs for 3 months. Tinzaparin was found to be more effective than warfarin in preventing recurrent venous thromboembolism in patients with cancer and proximal venous thrombosis.

The second study compared the incidence of bleeding from a low-molecular-weight heparin, enoxaparin, with warfarin. Patients were treated for 6 months. No significant differences in the incidence of major or minor bleeding were found between the two groups.

Nursing Implications

Patients with cancer and a thromboembolism have needs that are unique from those of other patients with clots. Because these patients have an increased risk of both clotting and bleeding, the use of anticoagulant therapy can be challenging. These two small studies show that low-molecular-weight heparins are more effective and cause no more bleeding effects than traditional warfarin. Because the low-molecular-weight heparins are administered subcutaneously, this may be an advantage for patients with cancer who have nausea, vomiting, or difficulty swallowing due to myositis. Nurses should discuss with the other members of the health care team the possibility of using low-molecular-weight heparins in appropriate patients.

BOX 32.3 COMMUNITY BASED CONCERNS

Enoxaparin at Home

Patients receiving subcutaneous injections of enoxaparin at home are typically responsible for self-administering the medication. These patients need information on the following topics:

- Locating appropriate injection sites and rotating injection sites
- Performing subcutaneous injections using appropriate technique
- Disposing of used syringes and needles in an impervious container, such as a plastic milk jug or a coffee can. The lid should be taped shut before placing the container in the regular home trash.
- Recapping needles: Patients may recap their own used needle. If a family member is administering the medication, the needle and syringe should be placed in the container uncapped. The product may come in a self re-capping syringe to prevent accidental needle stick injuries.

footwear, obtaining adequate lighting, and using handrails on stairways in bathtubs). Additional teaching and management concerns are similar to those for heparin therapy.

Dalteparin

Dalteparin (Fragmin), another low-molecular-weight heparin, is used to prevent DVT. It is also used in treating unstable angina and non–Q-wave MI for preventing ischemic complication in patients on concurrent aspirin therapy. A unique feature of dalteparin is that the multiple-dose vial contains benzyl alcohol as a preservative; benzyl alcohol has been associated with "fatal gasping" syndrome in premature infants. Because of this possibility, dalteparin should not be used in infants or in pregnant women (because it crosses the placenta). Other characteristics of dalteparin are similar to those of enoxaparin.

Tinzaparin

Tinzaparin (Innohep) is very similar to enoxaparin. Its major difference is that it is approved for use only in treating DVT in conjunction with warfarin. It is administered subcutaneously for 6 days, at least, until the patient is adequately anticoagulated with warfarin (the patient should have an International Normalized Ratio [INR] of 2 for at least 2 days).

Fondaparinux

Like heparin, fondaparinux (Arixtra) is an anticoagulant. However, fondaparinux works differently. A synthetic polysaccharide that inhibits antithrombin, it is thus a direct inhibitor of activated factor X. Neutralization of activated factor X disrupts the blood coagulation cascade, inhibiting thrombin formation and thrombus development. However, fondaparinux has no direct effect against thrombin. It is administered subcutaneously.

Like heparin, fondaparinux is used to prevent postoperative DVT from hip, knee, or abdominal surgery. It is also used to treat DVT and PE in conjunction with warfarin. Research indicates that fondaparinux may be more effective than enoxaparin in preventing DVT, especially in high-risk orthopedic patients (Weitz, Hirsh, & Samama, 2008). Although it may have a place in the treatment of acute coronary syndrome, more research is required to confirm this.

Like the low-molecular-weight heparins, fondaparinux carries a Black Box warning about a serious interaction that can occur if given before or after spinal or epidural anesthesia. A disadvantage of fondaparinux is that it cannot be reversed by protamine sulfate.

Like heparin, fondaparinux can cause bleeding, but unlike heparin it does not cause HIT with thrombosis. It can also cause anemia.

Drugs Significantly Different From P Heparin

A new group of drugs are the direct thrombin inhibitors. This group includes argatroban, bivalirudin, and lepirudin. The direct thrombin inhibitors bind to the active thrombin site and inhibit both free and clot-bound thrombin. Thus, unlike heparin, they inactivate fibrin-bound as well as circulating thrombin (Weitz, Hirsh, & Samama, 2008). Because direct thrombin inhibitors do not bind to plasma proteins, they produce a more predictable anticoagulant response.

Argatroban and lepirudin (Refludan) are direct thrombin inhibitors that are both labeled for use in heparin-induced thrombocytopenia-thrombotic disorder. Argatroban may be used for both treatment and prophylaxis, whereas lepirudin may be used for prophylaxis only. Off-label uses for argatroban include stroke and MI, and off-label uses for lepirudin include prevention of MI. Argatroban has a slightly shorter half-life. Both these drugs are administered intravenously.

Both argatroban and lepirudin can cause serious bleeding (including hematuria, intracranial bleeding, GI bleeding, and hemoptysis), cardiovascular (CV) effects, pneumonia, and sepsis. Precise CV adverse effects differ; argatroban causes angina, cardiac arrest, hypotension, and ventricular arrhythmias, whereas lepirudin causes heart failure. The overall adverse effect profile of these two drugs differs. Argatroban can commonly cause the following adverse effects: GI (abdominal pain, diarrhea, nausea, and vomiting), neurologic (headache, pain), renal (urinary tract infections), respiratory (cough), as well as fever and infectious diseases. Lepirudin can commonly cause adverse effects such as anemia, fever, and cutaneous hypersensitivity. In addition, lepirudin also produces abnormal liver function tests, renal failure, and extrinsic allergic respiratory disease. Both argatroban and lepirudin are pregnancy category B drugs, and their effect in children is unknown.

Bivalirudin (Angiomax) is also a direct thrombin inhibitor. Unlike the other drugs, it is labeled only for use during percutaneous coronary intervention (PCI) in conjuncture with a glycoprotein IIb/IIIa inhibitor and during percutaneous transluminal coronary angioplasty for unstable angina. Its systemic half-life is short: 25 minutes. It is administered intravenously. The most frequent adverse effects of bivalirudin are back pain, headache, and hypotension. Serious adverse effects include bleeding and hemorrhage that requires transfusion. Like argatroban and lepirudin, bivalirudin is a pregnancy category B drug.

Nursing Management of the Patient Receiving P Warfarin

Core Drug Knowledge

Pharmacotherapeutics

Warfarin (Coumadin) is an oral anticoagulant. It is administered after heparin therapy for 3 to 6 months to complete treating a thrombus or embolism. Warfarin is also used prophylactically for patients with a long-term risk for thrombus formation (e.g., when the mitral valve has been replaced or when hypercoagulability is a chronic concern related to venous stasis). It is also used prophylactically in patients with atrial fibrillation who are at high risk for a cardioembolic stroke; about one third of patients with atrial fibrillation are at such risk. Women with atrial fibrillation especially seem to benefit from preventative treatment (Hart, Halperin, Pearce, et al., 2003).

The American College of Chest Physicians' clinical guidelines suggest that the starting dose should be 5 to 10 mg initially for the first 1 to 2 days, and then adjusted based on the clinical response achieved based on changes to the International Normalized Ratio (INR) (Hirsh, Albers, & Schünemann, 2008). INR has been developed to measure therapeutic levels of warfarin. The INR is determined by a mathematical equation and reflects the patient's prothrombin time (PT) compared with the standardized PT value. The INR has essentially replaced the more traditional PT in which the patient's PT is measured against a control PT. In the traditional PT test, the control times vary with laboratory test methods and equipment, so the effectiveness of the drug therapy is determined by completing a math equation; the patient should take longer to clot than the control. The use of the INR is simpler, as the lab results are standardized; all computation is reflected in the reported lab value. The INR is reported as a number; INRs of 1 indicate that the patient and the control are identical. For treatment or prophylaxis of a thrombus or embolus, the INR should be equal to 2 to 3; the patient's PT should be 1.4 to 1.6 times the control time. For prophylaxis in patients with mechanical heart valves, the PT should be 1.5 to 1.7 times the control, or the INR should be 2.5 to 3.5. While INR is considered the new standard, some institutions still utilize the traditional PT lab value to assess warfarin's effectiveness; others may still report both INR and PT.

After absorption, warfarin is bound to albumin in the plasma. The drug action peaks in 1 to 9 hours; however, the anticoagulant effects do not begin for 24 hours. Maximum effect occurs 3 to 4 days after dosing starts, which is the time required for the drug to reach a steady state in the blood. The time factor is related to previously activated factors that are still circulating in the blood. Each time the dose changes, another 3 to 4 days are needed for the drug to reach its full effect. The effects of warfarin persist for 4 to 5 days after discontinuation (see Table 32.1). The drug crosses the placenta but is not present in breast milk. It is metabolized in the liver and excreted in the bile.

Patients receiving heparin therapy begin taking warfarin before they discontinue heparin. This overlap allows the warfarin to reach a therapeutic level before heparin is discontinued. The practice is safe because the two drugs affect different clotting factors.

Pharmacodynamics

Warfarin works by competitively blocking vitamin K at its sites of action. Thus, it prevents the activation of factors II (prothrombin), VII, IX, and X. It has no effect on factors that have already been activated. Because of this action, the full therapeutic response to a warfarin dose cannot be measured until after 3 days of therapy. In practice however, even though the drug is not at steady state, most of the clinical effects can be seen after 2 days of treatment, so INR can be measured after 2 to 3 days of treatment (Hirsh, Albers, & Schünemann, 2008). For this reason, warfarin therapy is started while patients are still receiving heparin therapy for blood clots. The heparin can be discontinued once the INR is between 2 and 3 for 2 days in a row.

Contraindications and Precautions

Warfarin is contraindicated for patients with active bleeding, open wounds or ulcerations of the GI tract, or bleeding disorders, such as hemophilia or thrombocytopenia. It is not recommended for use in patients with subacute endocarditis, pericarditis, or pericardial effusions. Warfarin is also contraindicated for patients who are undergoing surgery in which hemorrhage is possible (spinal, eye, GI, cranial, and arterial bypass grafting). Usually, the drug is discontinued 7 days before elective surgery.

Cautious use is recommended in patients with renal and hepatic impairment. Warfarin use is primarily determined by comparing the risks of the drug with the benefits to the patient.

Adverse Effects

The most frequent adverse effects of warfarin are bleeding and hemorrhage. Nausea, vomiting, diarrhea, and abdominal cramps can occur as well. Tissue necrosis is a rare adverse effect. A fetal warfarin syndrome has been identified when warfarin is given to pregnant women. (See discussion under Life Span and Gender.)

Drug Interactions

Several drug–drug and drug–food interactions must be considered when a patient begins warfarin therapy (Table 32.3). Many of these drug interactions may be related to effects on the P-450 system. Many herbal preparations also interact with warfarin (Table 32.4). Because drug and herbal interactions are numerous, a complete assessment of all other drug therapies should be conducted when starting a patient on warfarin. Dose adjustments for warfarin may be indicated, depending on other required drug therapy for comorbidities.

TABLE 32.3 Agents That Interact with P Warfarin

Interactants	Effect and Significance	Nursing Management
acetaminophen, androgens, beta blockers, clofibrate, corticosteroids, cyclophosphamide, dextrothyroxine, disulfiram, erythromycin, fluconazole, gemfibrozil, glucagon, hydantoins, influenza virus vaccine, isoniazid, ketoconazole, miconazole, moricizine, propoxyphene, quinolones, sulfonamides, tamoxifen, thioamines, thyroid hormones, urokinase	They may increase the effect of warfarin by unknown or complicated mechanism, increasing risk of bleeding.	Monitor for bleeding carefully. Monitor PT or INR carefully. Anticipate dose adjustments of warfarin if these drugs are started after titrating the dose of warfarin.
amiodarone, chloramphenicol, cimetidine, ifosfamide, lovastatin, metronidazole, omeprazole, phenylbutazones, propafenone, quinidine, quinine, sulfamethoxazole-trimethoprim (SMZ-TMP), sulfinpyrazone	The effect of warfarin may be increased by inhibiting its metabolism, increasing the risk of bleeding.	Same as above.
chloral hydrate, loop diuretics, nalidixic acid	The effect of warfarin may be increased because of displacement from binding sites, increasing the risk of bleeding.	Same as above.
aminoglycosides, mineral oil, tetracyclines, vitamin E	The effect of warfarin may be increased because of interference with vitamin K, increasing the risk of bleeding.	Same as above.
cephalosporins, diflunisal, NSAIDs, penicillins, salicylate	The effect of warfarin may be increased because of effects on platelets and GI irritation (from NSAIDs), increasing the risk of bleeding.	Avoid administering NSAIDs and salicylates if possible. Other considerations are the same as above.
ascorbic acid, dicloxacillin, ethanol, ethchlorvynol, griseofulvin, nafcillin, sucralfate, trazodone	The effect of warfarin may be decreased by an unknown action.	Be aware that dose of warfarin may need to be adjusted to be in therapeutic range. Monitor PT or INR to assess drug effectiveness.
aminoglutethimide, barbiturates, etretinate, carbamazepine, glutethimide, rifampin	The effect of warfarin may be decreased by induction of the anticoagulant's hepatic microsomal enzymes.	Avoid variation in vitamin K–rich food after titrating warfarin dose. Vitamin K is considered an antidote to warfarin. Otherwise nursing considerations are the same as above.
cholestyramine, contraceptives, oral estrogens, thiazide diuretics, thiopurines, spironolactone, vitamin K	The effect of warfarin may be decreased by various mechanisms.	Same as above.

Assessment of Relevant Core Patient Variables

Health Status

Because deficiencies of vitamin K increase the bleeding risk in patients receiving warfarin, assess the availability of vitamin K. Patients with vitamin K deficiency experience decreased synthesis of normal clotting factors and are at greater risk for hemorrhage if they receive warfarin. Besides the body's production of vitamin K in the GI tract, one source of vitamin K is food. Vitamin K is a fat-soluble vitamin and depends on the absorption of fat for its own absorption. Bile is necessary for fats to be digested and absorbed. A patient with decreased available bile (e.g., from obstructed bile ducts) absorbs less vitamin K. Patients with poor dietary intake of vitamin K are also deficient in the vitamin. Vitamin K deficiency may also occur in adults whose normal GI flora has been affected by long-term antibiotic therapy or whose dietary intake consists of parenteral nutrition without vitamin K supplements.

Life Span and Gender

Consider the patient's age before therapy begins. Because vitamin K is continually produced in the GI tract, deficiencies are rare in healthy adults. However, newborns may have a vitamin K deficiency because intestinal flora is not active at birth. In addition, bleeding complications with anticoagulant drugs appear to occur more frequently in older adults (those older than 75 years) than in younger adults. Older adults also have an increased sensitivity to the effects of warfarin, in both the early induction phase and the maintenance phase of drug therapy.

It is important to determine the stage of the reproductive cycle for women. Warfarin should not be used during pregnancy and is in pregnancy category X because it is associated with a described syndrome of fetal defects.

Lifestyle, Diet, and Habits

Obtain information about the patient's dietary habits. Because vitamin K competes with warfarin, high vitamin

TABLE 32.4 Interactions of Herbs and Warfarin*

Effect	Herbs
Increase the effects of warfarin	Boldo, bromelains, dan shen, dong quai (*Angelica sinensis*), garlic, ginkgo (*Ginkgo biloba*), *Lycium barbarum* L
Decrease the effects of warfarin	Coenzyme Q_{10}, green tea, ginseng (*Panax*), St. John's wort
Additive bleeding effects with warfarin	Herbs with potential anticoagulant effects: Alfalfa, dong quai (*Angelica sinensis*), aniseed, arnica, asafoetida, bladder wrack (*Fucus*), bogbean, boldo, buchu, capsicum, cassia, celery, chamomile (German and Roman), dandelion, fenugreek, horse chestnut, horseradish, licorice, meadowsweet, nettle, parsley, passion flower, pau d'arco, prickly ash (Northern), quassia, red clover, sweet clover, sweet woodruff, tonka beans, wild carrot, wild lettuce Herbs that contain salicylate or have antiplatelet properties: Agrimony, aloe gel, aspen, black cohosh, black haw, bogbean, cassia, clove, dandelion, feverfew, garlic, German sarsaparilla, ginger, ginkgo (*Ginkgo biloba*), ginseng (*Panax*), licorice, meadowsweet, onion, policosanol, poplar, senega, tamarind, willow, wintergreen Herbs with fibrinolytic properties: Bromelains, capsicum, garlic, ginseng (*Panax*), inositol nicotinate, onion
May decrease the effectiveness of warfarin	Herbs with coagulant properties: Agrimony, goldenseal, mistletoe, yarrow

*Other herbal interactions are possible.

K levels decrease the effectiveness of warfarin. Diets rich in vitamin K, therefore, should be avoided. If the diet was normally rich in vitamin K when the warfarin dosage was adjusted, restricting these foods is not as important. However, if the patient's diet does not normally include vitamin K–rich foods, these foods should be avoided. Consider lifestyle behaviors that place the patient taking heparin at increased risk for falls and injuries for the patient taking warfarin, as well. Many herbal medications interact with warfarin: assess for their use.

Environment

Be aware that warfarin therapy may be started in the hospital, but most treatment is self-administered by the patient at home. Explore with the patient potential risks in the home environment.

Culture and Inherited Traits

Because warfarin is metabolized via the P-450 system, inherited variations of this system may alter drug response. Variations in this system are believed to be responsible for the difficulty in finding a dose for some patients that is therapeutic but does not cause adverse effects. At this time, there is no way to determine which patients have inherited traits that will cause these problems.

Nursing Diagnosis and Outcome

- Risk for Injury, Bleeding, related to adverse effects of warfarin

  Desired outcome: *The patient will not experience bleeding.*

Planning and Intervention

Maximizing Therapeutic Effects

Warfarin dosage should be individualized until PT or the INR is in therapeutic range. An initial loading dose is given to attain a rapid therapeutic level. This dose is then followed by a maintenance dose. Doses are usually given in the evening, at 6:00 PM. This timing allows for early morning blood draws for PT or INR by hospital laboratory personnel.

Minimizing Adverse Effects

Assess the patient's response to warfarin therapy using either the ratio of the patient's PT compared with the control PT, or the INR. Notify the prescriber if the patient's clotting time is greater than the therapeutic level. (See Box 32.4 for guidelines of suggested responses to various INR levels.) Usually, drug dosage is decreased if clotting time exceeds this level. Skipping one dose may be all that is required to lower the PT or INR to the therapeutic level. In case of warfarin overdose where bleeding is present, the antidote, vitamin K (phytonadione), is administered intravenously.

Falls may cause internal bleeding. Assess all patients for fall risk. Ensure that the patient's home is also assessed for factors that may lead to falls. Encourage the use of proper lighting and handrails on stairways, which may help prevent falls.

Providing Patient and Family Education

- Teach patients the signs of bleeding and methods to prevent bleeding (which are the same as for heparin).
- Instruct patients to take the drug at the same time each day because this dosing schedule helps prevent a drop in warfarin blood levels. After the drug level is stabilized and daily PT is not needed, patients may switch to morning dosing. Doing so may increase absorption and improve adherence to drug therapy. Advise patients to return for follow-up blood work.
- Teach patients that skipping a dose of warfarin could alter therapeutic levels. If patients forget a dose, they should take it as soon as they remember. However, they should not double up on the next dose to prevent bleeding.
- Instruct patients that taking aspirin, large doses of acetaminophen, or other over-the-counter drugs with these ingredients can affect warfarin's action.

Box 32.4 CLINICAL GUIDELINE RECOMMENDATIONS FOR NON-THERAPEUTIC INR LEVELS

INR level	Significant Bleeding	Recommendation	Resume warfarin
>3 but <5	no	Omit a dose; monitor more frequently;	When INR has returned to therapeutic range with adjusted dose
≥5 but <9	no	Omit one or two doses; monitor more frequently; OR skip a dose and administer oral vitamin K (1–2.5 mg) if patient at increased risk of bleeding (may give ≤ 5 mg vitamin K if patient requires urgent surgery)	When INR has returned to therapeutic range with adjusted dose
>9	no	Hold warfarin; administer oral vitamin K (2.5–5 mg); monitor INR more frequently; administer additional vitamin K as needed	When INR has returned to therapeutic range with adjusted dose
Any elevation	yes	Hold warfarin therapy; give vitamin K 10 mg by slow IV infusion; supplemented with fresh frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa, depending on the urgency of the situation. Repeat vitamin K administration every 12 h for persistent INR elevation	When INR has returned to therapeutic range with adjusted dose
Any elevation	yes,life threatening	Holding warfarin therapy and administering fresh frozen plasma, prothrombin complex concentrate, or recombinant factor VIIa supplemented with vitamin K, 10 mg by slow IV infusion, repeated, if necessary, depending on the INR	If indicated, when INR has returned to therapeutic range with adjusted dose

Based on American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition) CHEST June 2008 vol. 133 no. 6 suppl 71S-109S.

- Warn women to avoid becoming pregnant while taking this drug.
- Dietary teaching should focus on the need to avoid increased intake of foods rich in vitamin K, primarily green vegetables.
- Emphasize the importance of informing other health care providers (e.g., dentist, podiatrist) that they are taking warfarin. Patients should also be instructed to wear or carry medical identification stating that they are receiving warfarin.

Ongoing Assessment and Evaluation

To determine the therapeutic effects of warfarin, the patient's PT or INR is monitored. Therapy is effective when a thrombus is prevented and bleeding does not occur.

CRITICAL THINKING SCENARIO

SOLVING PROBLEMS RELATED TO ANTICOAGULANT THERAPY

Melanie Graves is diagnosed with a left leg deep vein thrombosis (DVT). She is started on heparin 1,000 U/h by intravenous infusion. After 3 days, she will start taking warfarin in addition to the heparin.

1. Explain the rationale for starting warfarin while the patient is receiving heparin. Three days have passed. The first dose of warfarin (5 mg) is given at 6 PM. The following morning, blood is drawn to evaluate the PT. The control is 30 seconds, Ms. Graves' PT is 30 seconds, and the INR is 1.
2. Discuss the information about the dosage of the warfarin that can be obtained from this initial blood work. Explain how you arrived at this conclusion.
3. Ms. Graves complains that she doesn't like having her blood drawn so frequently. She says she cannot wait to go home so that she does not have to have any more blood work. What elements will you develop in the initial teaching plan for her?

MEMORY CHIP

P Warfarin

- Anticoagulant used to complete treatment with heparin after clot formation; is used prophylactically in patients at high risk of thrombus formation
- Administered orally
- May be given with heparin until therapeutic level of warfarin is obtained
- Major contraindications: active bleeding, ulcerations of the GI tract, or bleeding disorders
- Most common adverse effect: bleeding (vitamin K is the antidote for warfarin toxicity)
- Most serious adverse effect: fetal warfarin syndrome
- **Life span alert: Warfarin is not for use in pregnancy because it causes fetal defects.**
- Maximizing therapeutic effects: Monitor PT for therapeutic range; adjust dosage until therapeutic range is attained.
- Minimizing adverse effects: Monitor for signs of bleeding.
- Most important patient education: Teach patients to monitor for bleeding, to modify behavior to avoid injuries, and to avoid greatly increased vitamin K intake.

Drug Significantly Different From P Warfarin

Anisindione

Anisindione (Miradon) is an oral anticoagulant like warfarin, but it does not work in the same manner. An indanedione, anisindione is a synthetic anticoagulant drug that acts by reducing the prothrombin activity of the blood. Like warfarin, it can be used to treat or prevent PE and venous thrombosis and can be used in atrial fibrillation where there is thrombosis. It is also indicated as adjunct treatment in coronary occlusion. In contrast to warfarin, anisindione commonly has adverse effects, including dermatologic (alopecia, dermatitis, urticaria) and GI (nausea, mouth ulcers, vomiting) conditions. Fever may also occur. Many of the serious adverse effects of anisindione are similar to warfarin: cholesterol embolus syndrome, skin necrosis, hemorrhage, and hepatitis. Like warfarin, anisindione is in pregnancy category X and is contraindicated in pregnant women because of the risk of teratogenic effects. Anisindione should be reserved for patients who cannot tolerate warfarin.

C ANTIPLATELET DRUGS

Drugs that prevent platelet aggregation are called antiplatelet drugs. They are used when overactive platelets pose long-term risks for hypercoagulability. Platelet aggregation is important in hemostasis and is also involved in thrombus formation, particularly in the arterial circulation.

Antiplatelet drugs reduce platelet aggregation and are used to prevent further thromboembolic events in patients who have suffered MI, ischemic stroke or transient ischemic attack (TIAs), or unstable angina, and for primary prevention of a thromboembolic event in patients at risk. Some are also used for the prevention of reocclusion or restenosis following angioplasty and bypass procedures.

Antiplatelet drugs differ in their modes of action and adverse effects. Aspirin is the most widely used and studied; it acts by irreversibly inhibiting platelet cyclo-oxygenase (COX) and thus preventing synthesis of thromboxane A_2. Although aspirin may be the most frequently prescribed antiplatelet drug, it is also used frequently for other clinical reasons. The prototype NSAID is discussed in Chapter 24.

Heparin and the direct-acting thrombin inhibitors, as previously mentioned, have antiplatelet and anticoagulant effects. Glycoprotein IIb/IIIa-receptor antagonists, such as abciximab, eptifibatide, and tirofiban, interfere with the final step in platelet aggregation and are used in unstable angina and as adjuncts in reperfusion and revascularization procedures.

Drugs that interfere with adenosine metabolism have an antiplatelet effect, and those used include the thienopyridines clopidogrel and ticlopidine, which interfere with adenosine diphosphate–mediated platelet activation, and the adenosine reuptake inhibitor dipyridamole. Ticlopidine was previously identified as the prototype antiplatelet drug, but clopidogrel (Plavix) has replaced it because it is associated with fewer adverse effects and is now more widely used.

Nursing Management of the Patient Receiving P Clopidogrel

Core Drug Knowledge

Pharmacotherapeutics

Clopidogrel is used to reduce the occurrence of atherosclerotic events (MI, stroke, and vascular death) in patients who have atherosclerosis and have had a recent MI or stroke, or who risk having one of these events because they have acute coronary syndrome or peripheral arterial disease. Its use in peripheral arterial disease is unique from aspirin

It is also used in patients undergoing PCI where there is a coronary stent implanted or coronary artery bypass graft (CABG). Use of clopidogrel for 1 year after stent implantation significantly reduces the risk of major vascular events. Clopidogrel is administered orally; in some circumstances, a loading dose is used prior to starting the maintenance dose.

Pharmacokinetics

Clopidogrel is rapidly absorbed by the GI tract. At least 50% is absorbed. The bioavailability is not changed from food. The drug is metabolized in the liver via CYP2C19 to an active form and then eliminated by the kidneys and GI tract. The drug and metabolite are both highly protein bound. Steady state occurs between 3 and 7 days with daily dosing. Platelet aggregation and bleeding time gradually return to baseline levels, generally within 5 days after drug therapy is stopped. For more information, see Table 32.1.

Pharmacodynamics

Clopidogrel inhibits the binding of adenosine diphosphate (ADP) to its platelet receptor and the subsequent ADP-mediated activation of the glycoprotein IIb/IIIa complex and thus inhibits platelet aggregation. It thus prolongs the bleeding time. Clopidogrel must be metabolized to an active metabolite to produce this effect, although the active metabolite has not been isolated. Clopidogrel irreversibly modifies the platelet ADP receptor so that platelets exposed to the drug are affected for the remainder of their life span. The inhibition of platelet aggregation is dose dependent, and effects can be seen within 2 hours after a single oral dose of clopidogrel. By the time the drug is at steady state, the average inhibition of platelet aggregation is between 40% and 60% of normal. Clinical studies have identified a wide variation in response to a dose of clopidogrel, with the assumption that some patients are "nonresponders" to clopidogrel therapy. However, because clopidogrel relies on metabolism to its active metabolite to achieve therapeutic effect, it is probable that the decrease in clopidogrel's effectiveness is not due to an inherited trait but rather to a drug interaction from drugs that inhibit either the CYP3A4 or CYP2C19 pathway. Thus, it decreases conversion to an active, antiplatelet form (Lee et al., 2009).

When clopidogrel was added to aspirin therapy in the treatment of acute coronary syndromes with ST-segment elevation, a significant additive effect was found, reducing the number of deaths, reinfarctions, and strokes without

producing significant excess risk of adverse effects. This was seen in all patients, including those who had received fibrinolytic therapy or who were older than 70 years of age (Chen, Jiang, Chen, et al., 2005). Although clopidogrel does not seem to improve early reperfusion when given before fibrinolysis therapy, it does improve late coronary patency and clinical outcomes by preventing reocclusion of open arteries (Scirica, Sabatine, Morrow, et al., 2006).

Contraindications and Precautions

Clopidogrel's black box warning states that poor metabolizers of the drug via CYP2C19 will form less active therapeutic levels. Genotype testing is necessary to determine an appropriate dose. Clopidogrel is contraindicated in patients with hypersensitivity and in those with active bleeding disorders such as peptic ulcers or intracranial hemorrhage. Caution should be used when administering clopidogrel to patients with severe hepatic dysfunction because knowledge regarding the effects on such patients is limited. Caution should be used if the patient is at risk for increased bleeding from trauma, surgery, or other pathologic conditions. Long-term use of a combination of aspirin and clopidogrel in patients with recent TIA or stroke is not recommended, as it has not been found to be more effective than treatment solely with clopidogrel; the combination has been shown to increase major bleeding. To achieve its full therapeutic effect, the length of therapy needs to be adequate; patients who receive clopidogrel post-stent (PCI) are at risk for stent thrombosis, MI, or death if the therapy is prematurely discontinued.

Assigned to pregnancy risk category B, clopidogrel should be used only if absolutely necessary during pregnancy. The drug is not recommended for use in breast-feeding mothers; it is not known whether the drug is excreted in breast milk.

Adverse Effects

Adverse reactions to clopidogrel are similar to those with aspirin. The most common adverse effect is GI distress, which can include abdominal pain, indigestion, diarrhea, nausea. The serious GI problems of bleeding and ulcers occur less frequently with clopidogrel than with aspirin. Clopidogrel is similar in chemical structure to ticlopidine, which is associated with a small (0.8%) risk of severe neutropenia. Clopidogrel appears to have a much smaller risk of producing severe neutropenia, and its incidence of neutropenia may be no greater than that found in the general population. However, the possibility of neutropenia should be considered if the patient develops a fever or other sign of infection while taking the drug.

Drug Interactions

Because clopidogrel is metabolized to an active metabolite by CYP2C19 concurrent use of any drug that inhibits the activity of isoenzyme CYP2C19 can reduce the plasma concentration of activated clopidogrel. Two proton pump inhibitors (PPIs, used in the prevention of excessive gastric acid) are known to decrease the therapeutic effectiveness of clopidogrel via this mechanism. These drugs are omeprazole and pantoprazole. If patients on clopidogrel require restrictions on their gastric acidity they should receive other drug classes than PPIs.

Because clopidogrel increases bleeding risk, especially from GI ulcers, caution should be used if clopidogrel is coadministered with other drugs that can cause GI ulcers and bleeding, such as aspirin or NSAIDs, because additive effects are likely. Coadministraton with warfarin will also increase the risk of bleeding from clopidogrel. While at high concentrations in laboratory studies, clopidogrel inhibits the hepatic isoenzyme P-450 2C9 and warfarin is a substrate of CYP2C9 (meaning it is metabolized by the isoenzyme) substantial impairment of warfarin's metabolism has not been noted when co-administered with clopidogrel in normal doses. So the increased risk of bleeding that occurs from giving the two drugs concurrently does not appear to be related to this pathway. The potential for an adverse reaction exists with warfarin and other drugs that are CYP2C9 substrates, however.

Additionally, clopidogrel may interact with numerous herbs. Patients taking herbal remedies or multiple prescription drugs should be monitored closely for either toxic or subtherapeutic effects of clopidogrel. Agents that interact with clopidogrel are listed in Table 32.5.

Assessment of Relevant Core Patient Variables

Health Status

Review the patient's history and physical examination findings for any contraindications to the use of this drug. The patient should have a baseline complete blood count (CBC) with differential to determine platelet functioning. Liver function studies should also be done. A baseline cardiovascular assessment is indicated when starting therapy. Neurologic status should also be assessed when clopidogrel is given to prevent stroke.

Life Span and Gender

Determine the patient's age before therapy begins. Caution must be used in children younger than 18 years because safety has not been established. The exact effects of clopidogrel on pregnancy and lactation are not known, and caution must be used. In older adults, no differences in platelet aggregation and bleeding time have been noted; thus, no dosage adjustment is needed.

Lifestyle, Diet, and Habits

Assess for lifestyle behaviors that would place the patient at increased risk for bleeding while taking this drug. Because patients take clopidogrel to decrease the risk of atherosclerotic events (such as MI and stroke), assess whether the patient is following a heart-healthy diet that is low in fat and cholesterol. Assess for use of herbs that may interact with clopidogrel.

Environment

Be aware of the environment in which the drug will be administered. Clopidogrel may be administered in the hospital. However, most of the time, it is self-administered by

TABLE 32.5 Agents That Interact with P Clopidogrel

Interactants	Effect and Significance	Nursing Management
anticoagulants; thrombolytics; antiplatelets	Additive anticoagulation effects may increase risk of bleeding.	Concurrent use requires additional monitoring for complications. Observe for external and internal bleeding. Monitor PT, aPTT, platelet counts. Use full precautions to prevent internal injuries and bleeding.
NSAIDs	Decreased platelet function and decreased coagulation can occur, making bleeding, especially GI bleeding, more likely.	Avoid coadministration if possible. Use caution if coadministration is necessary. Monitor closely for GI bleeding.
Proton pump inhibitors (omeprazole, pantoprazole)	Prevents metabolism of clopidogrel to active form via CYP2C19. This significantly decreases therapeutic effect, and increases risk for developing life threatening clots.	Avoid this combination. Use H_2 antagonists or antacids instead of PPIs.
herbs and vitamins: angelica; anise; arnica; astragalus; bilberry; black currant; bladderwrack; bogbean; boldo; borage; capsaicin; cat's claw, celery; clove oil; curcumin; dandelion; evening primrose; feverfew; garlic; ginger; ginkgo; guggul; hawthorn; kava; licorice; meadowsweet; motherwort; skullcap; tan-shen; vitamin A	Increased risk of bleeding	Minimize or avoid coadministration. If coadministered, monitor for signs of bleeding.
drugs metabolized by CYP2C9 (warfarin; fluvastatin; phenytoin; tamoxifen; tolbutamide; torsemide)	Clopidogrel inhibits CYP2C9 in large dose. Less CYP2C9 means less metabolism of drugs via this pathway. Increased risk of adverse effects in these drugs is possible.	Administer together with caution. Monitor for adverse effects of CYP2C9-metabolized drug.
ibritumomab	Severe and prolonged thrombocytopenia that can be an adverse effect from ibritumomab may make patients more likely to bleed if they are taking drugs that interfere with platelet function.	Monitor for thrombocytopenia more frequently when using ibritumomab and antiplatelet agents concomitantly.

the patient at home. Discuss with the patient potential risks in the home environment. Falls and activities that are likely to produce internal or external bleeding should be avoided while taking clopidogrel.

Nursing Diagnoses and Outcomes

- Risk for Injury: Increased Risk for Bleeding related to decreased platelet aggregation from drug therapy
  Desired outcome: *The patient will suffer no injury related to bleeding while on clopidogrel.*
- Risk for Nausea related to adverse effects of clopidogrel.
  Desired outcome: *Nausea and GI distress will not be extreme enough to warrant stopping clopidogrel therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that clopidogrel is administered routinely to achieve its maximum therapeutic effects. Do not co-administer with omeprazole or pantoprazole.

Minimizing Adverse Effects

Have patients take clopidogrel with food to decrease GI problems if they occur. Make sure that the home environment is assessed for safety hazards that may contribute to falls or other accidents. Remember that severe neutropenia is a potential risk, and evaluate the patient's white blood cell count (WBC) if the patient develops signs of infection.

Providing Patient and Family Education

- Inform patients and families about laboratory tests that are needed on a regular basis and the reasons for their frequency.
- Emphasize to patients and families the importance of informing all health care providers (e.g., dentists and other physicians) of the drug regimen. If surgery is needed, and the antiplatelet effect is not desired, drug therapy should be discontinued 7 days before the procedure to prevent excessive bleeding.
- Instruct patients and families to apply pressure on wounds until bleeding stops.
- Emphasize to patients that behaviors that may lead to injury should be avoided (e.g., roller-blading, ice skating, motorcycle riding, use of nonmotorized scooters, walking on icy patches).
- Instruct patients and families to make the home environment more "fall proof" by removing scatter rugs, placing handrails on stairs, and fastening any loose carpet edges.

MEMORY CHIP

P Clopidogrel

- Used to prevent atherosclerotic events in patients who have had myocardial infarction or stroke, or who are at risk for having these events
- Prevents platelet aggregation and prolongs bleeding time
- Major contraindication: active bleeding disorders
- Most common adverse effect: GI distress
- Most serious adverse effect: bleeding
- Maximizing therapeutic effects: Administer regularly.
- Minimizing adverse effects: Take with food to decrease GI distress; assess for risk for falls and injuries.
- Most important patient education: Avoid activities that increase risk for falls or injury, remove scatter rugs or other hazards that may contribute to falls in the home; apply pressure to any bleeding cut.
- **Black box warning: This drug relies on metabolism via CYP2C19 to become active. Loss of therapeutic effect in poor metabolizers. Genetic test required to determine therapeutic dose. Consider alternative therapy in poor metabolizers.**

Ongoing Assessment and Evaluation

Periodic measurement of bleeding time and platelet function is needed throughout clopidogrel therapy. Neutrophil counts should be assessed if the patient develops signs of infection, to rule out severe neutropenia. Therapy is evaluated as effective when the outcomes are achieved and atherosclerotic events have been prevented.

Drugs Closely Related to P Clopidogrel

Prasugrel

Like clopidogrel, prasugrel is an antiplatelet. Its labeled indications are more limited than clopidogrel. It is approved to prevent clots (including stent thrombosis) in patients with acute coronary syndrome who are to be managed with percutaneous coronary intervention. Prasugrel's onset of antiplatelet effect is achieved more quickly than clopidogrel. Prasugrel causes more bleeding than clopidogrel. Prasugrel carries several Black Box warnings. These include:

1) Can cause significant, sometimes fatal, bleeding in patients with active pathologic bleeding or a propensity to bleed, a history of transient ischemic attack or stroke, a body weight of less than 60 kg, or concomitant use of medications that increase the risk of bleeding (e.g., warfarin, heparin, fibrinolytics, chronic use of NSAIDs). Do not use in patients with active pathologic bleeding or a history of transient ischemic attack or stroke.
2) Do not use in patients 75 years of age and older because of the increased risk of fatal and intracranial bleeding with the exception of high-risk situations (patients with diabetes or a history of prior myocardial infarction) where its effect appears to be greater.
3) Do not start prasugrel in patients likely to undergo urgent coronary artery bypass graft surgery (CABG). When possible, discontinue prasugrel at least 7 days prior to any surgery.
4) Suspect bleeding in any patient who is hypotensive and has recently undergone coronary angiography, percutaneous coronary intervention (PCI), CABG, or other surgical procedures in the setting of prasugrel. (FDA label for EFFIENT, 2009).

Patients should be taught to watch for bleeding such as nose bleeds, coughing up blood, black tarry stools from gastrointestinal hemorrhage, and bruising.

Aspirin

Aspirin, a drug used for its antiplatelet properties, has a mechanism of action that differs from that of clopidogrel in that it irreversibly inhibits platelet cyclo-oxygenase (COX) and the subsequent synthesis of thromboxane A_2 for the life of the platelet. Thromboxane A_2 is a vasoconstrictor that facilitates platelet aggregation. Inhibiting its synthesis, therefore, inhibits platelet aggregation. The antiplatelet effects of aspirin, which result from its effect on COX-1 sites, can be achieved with low doses of aspirin, between 50 and 100 mg daily. Aspirin can also act on COX-2 to create anti-inflammatory effects, but a much larger dose and more frequent administration of doses are required (Tourmousoglou, Rokkas, 2008).

As an antiplatelet drug, it is recommended that aspirin be given within 24 to 48 hours of the onset of a stroke. Use of aspirin concurrently or within 24 hours of the use of thrombolytic agents, such as alteplase, is not recommended. Long-term aspirin therapy provides a significant reduction in the risk of MI, stroke, or vascular death in patients who have an intermediate to high risk of vascular complications. These risk factors include chronic stable angina, prior MI, unstable angina, TIA or minor stroke, as well as other high-risk conditions (Grant, Brotman, Jaffer, 2009). Aspirin is also used to decrease the incidence of coronary heart disease in adults who are at increased risk for heart disease.

Patients who should be considered for cardiac preventive therapy with aspirin include men older than 40 years, postmenopausal women, and younger adults with risk factors for coronary heart disease (hypertension, diabetes, smoking, elevated lipid levels, obesity, family history). Aspirin is used prophylactically against thromboembolic complications in cardiovascular disease, including MI and TIA. Aspirin in low doses is recommended after MI to prevent future infarcts and in patients with atrial fibrillation to prevent stroke; however, it is not as effective as warfarin for this purpose (Grant, Brotman, Jaffer, 2009). Aspirin prevents noncardioembolic strokes primarily. In patients with diabetes, low-dose aspirin is a primary prevention therapy if the patient has cardiovascular risk factors (family history of coronary vascular disease, cigarette smoking, hypertension, obesity, albuminuria, elevated lipid levels, and age older than 40 years). Aspirin is a secondary prevention strategy in patients with diabetes with large vessel disease; indications include history of MI, vascular bypass surgery, stroke or

TIAs, peripheral vascular disease, claudication, angina, or any combination of these factors. The American Diabetes Association recommends an aspirin dosage of 75 to 162 mg/d in patients with diabetes (American Diabetes Association, 2004).

A major adverse effect of aspirin is its ability to cause bleeding, especially GI bleeding; GI ulceration is also problematic. GI ulceration caused by overexposure to aspirin or other NSAIDS is a result of systemic inhibition of COX, which is an enzyme in prostaglandin formation that helps produce a protective mucous lining of the stomach and duodenum. Because of this systemic effect, GI complications are related to the use of aspirin no matter what form it is in (UpToDate, 2009b).

These adverse effects may limit the use of aspirin in some patients. Although the antiplatelet effect of aspirin is not dose related, the GI adverse effects are dose related, so administering as low a dose as possible helps minimize the risk of these adverse effects. Aspirin may pose a risk of neutropenia, but compared with clopidogrel, aspirin poses a much smaller risk of this complication.

For more information on aspirin, see Chapter 24.

Cilostazol

Cilostazol (Pletal) is a platelet aggregation inhibitor with vasodilating activity. It is used to treat the symptoms of intermittent claudication, which occur in about one third of patients who have peripheral arterial disease. The drug improves pain-free walking distance. Off-label uses include secondary prevention of repeat CVAs and during percutaneous coronary intervention. In addition to its antiplatelet effects, cilostazol also decreases triglycerides and increases high-density lipoprotein cholesterol. Cilostazol is contraindicated for use in patients with heart failure, hemostatic disorders, or active bleeding. Precaution is necessary in severe renal impairment. Cilostazol is extensively metabolized in the liver by the CYP3A4 and, to a lesser extent, CYP2C9 isoenzymes; thus, potential drug–drug interactions are similar to those of clopidogrel.

Cilostazol is a pregnancy category C drug. Breast-feeding should be ceased during cilostazol therapy, to avoid potential harm to the infant.

Ticlopidine

Ticlopidine works very similarly to clopidogrel with one major exception. Ticlopidine, unlike clopidogrel, can cause life-threatening hematologic adverse reactions, including neutropenia/agranulocytosis, thrombotic thrombocytopenic purpura (TTP) and aplastic anemia. Because of these serious adverse effects, ticlopidine is not frequently used to prevent platelet aggregation.

Drugs Significantly Different From P Clopidogrel

Dipyridamole

Unlike clopidogrel, dipyridamole is primarily a coronary vasodilator that increases functional levels of adenosine, which produces vasodilation and inhibits platelet aggregation. Dipyridamole also inhibits the enzyme phosphodiesterase, which increases cyclic adenosine monophosphate (cAMP) and decreases platelet activation. Data from the literature are conflicting as to whether dipyridamole actually has an antiplatelet effect. Dipyridamole dilates coronary arteries, increasing flow in narrowed vessels. It does not usually produce much systemic vasodilation. A mild positive inotropic effect has also been documented.

Dipyridamole is used with anticoagulants and other antiplatelets in patients after surgery, such as prosthetic heart valve placement and vascular grafting procedures, to prevent thrombus formation. It is used diagnostically during thallium myocardial perfusion imaging. A combination of aspirin and dipyridamole (Aggrenox) appears to increase the antiplatelet effect of aspirin and is approved for use in preventing recurrent thromboembolic stroke.

Dipyridamole is moderately absorbed after oral administration. Its distribution is widespread; it crosses the placenta and enters breast milk. It is metabolized in the liver and excreted by the GI tract. It should be used cautiously in patients with hypotension because some vasodilation occurs.

The most frequent adverse effects of dipyridamole are headache, dizziness, and nausea. After IV administration, MI, arrhythmias, and bronchospasm may occur, although they are uncommon.

Dipyridamole has additive effects on platelet aggregation when given with aspirin. Bleeding risk is increased when dipyridamole is used concurrently with anticoagulants, thrombolytics, NSAIDs, or sulfinpyrazone. Ingesting alcohol increases the risk for hypotension. Theophylline may negate the effects of dipyridamole during diagnostic thallium imaging.

Glycoprotein IIb/IIIa Inhibitors

Tirofiban (Aggrastat), eptifibatide (Integrilin), and abciximab (ReoPro) are all antagonists of the platelet glycoprotein IIb/IIIa receptor, the major platelet surface receptor involved in platelet aggregation. This receptor is found only on platelets and their progenitors. Glycoprotein IIb/IIIa inhibitors block the final common pathway leading to platelet aggregation. Activation of the glycoprotein IIb/IIIa receptors leads to the binding of fibrinogen and von Willebrand factor to platelets and thus to platelet aggregation. American College of Cardiology/American Heart Association guidelines recommend glycoprotein IIb/IIIa inhibitors as an integral component to prevent thromboembolic-induced myocardial ischemia in non-ST-elevation acute coronary syndromes and the ischemic complications of percutaneous coronary intervention.

Both tirofiban and eptifibatide reversibly prevent fibrinogen and von Willebrand factor from binding to the glycoprotein IIb/IIIa receptor, thereby inhibiting platelet aggregation. Eptifibatide has been found to achieve the highest level of consistent platelet inhibition compared with abciximab and tirofiban (Jennings, 2005). Eptifibatide, when combined with the low-molecular-weight heparin enoxaparin, has been found to be safe and effective in the treatment of acute coronary syndrome (unstable angina or non–Q-wave MI)

(Diez, Medina, Cheong, et al., 2009). Both tirofiban and eptifibatide are administered by IV infusion. One difference between these two drugs is their rate of ability to bind with protein in the blood. Tirofiban is moderately protein bound (65%), whereas eptifibatide has low protein binding (25%).

Contraindications for tirofiban and eptifibatide are the same and include active internal bleeding or a history of bleeding within the last 30 days; a history of thrombocytopenia following a prior exposure to tirofiban; history of stroke within 30 days or any history of hemorrhagic stroke; a major surgical procedure or severe physical trauma within the last 30 days; severe hypertension; concomitant use of another parenteral glycoprotein IIb/IIIa inhibitor; any history of intracranial hemorrhage, intracranial neoplasm, arteriovenous malformation, or aneurysm; history, symptoms, or findings suggestive of aortic dissection or acute pericarditis; platelet counts less than 1,000,000/mm^3; a serum creatinine level of 2 mg/dL or higher; or dependency on renal dialysis.

The most frequent adverse effect for both tirofiban and eptifibatide is bleeding, which can be a minor or major event. Nonbleeding adverse effects for tirofiban (when coadministered with heparin) include nausea, fever, and headache. The only nonbleeding adverse effect of eptifibatide is hypotension, which may be serious. Tirofiban may cause bradycardia.

Abciximab is different from the other glycoprotein IIb/ IIIa inhibitors in that it is a chimeric human-murine monoclonal antibody Fab (fragment antigen binding) fragment. It inhibits platelet aggregation by specifically binding to the glycoprotein GPIIb/IIIa receptor. Abciximab is used as an adjunct to percutaneous transluminal coronary angioplasty or atherectomy, to prevent acute cardiac ischemic complications in patients at high risk for abrupt closure of the treated coronary vessel. Off-label uses include treatment of myocardial infarction. It is used with aspirin and heparin. Low-dose, weight-adjusted heparin regimens are recommended to minimize the risk of bleeding. Like tirofiban and eptifibatide, bleeding is the major adverse effect of abciximab. Unlike tirofiban and eptifibatide, abciximab is a pregnancy category C drug.

Anagrelide

Anagrelide (Agrylin) is a platelet-reducing agent that is significantly different from clopidogrel. It is used in treating essential thrombocytosis, secondary to myeloproliferative disorders, to decrease the elevated platelet count and the risk of thrombosis and to reduce the associated symptoms of the disorder. Anagrelide hydrochloride, a phosphodiesterase III inhibitor, inhibits cAMP and reduces blood platelet production. WBCs and other coagulation factors are not affected. RBC counts may be altered, but these alterations are not clinically important. The most common adverse effects of anagrelide are headache, diarrhea, edema, palpitations, and abdominal pain. Serious potential adverse effects, none of which are common, include chronic heart failure, MI, cardiomyopathy, cardiomegaly, complete heart block, atrial fibrillation, CVA, pericarditis, pulmonary infiltrates, pulmonary fibrosis, pulmonary hypertension, pancreatitis, gastric or duodenal ulcers, and seizures.

HEMORHEOLOGIC DRUGS

The hemorheologic drugs differ from the antiplatelet drugs in that they act on RBCs to reduce blood viscosity and increase the flexibility of RBCs. This effect helps prevent thrombus formation and allows the RBCs to enter the microcirculation, thereby increasing oxygenation at the cellular level. These effects are helpful in treating peripheral vascular disease. The prototype hemorheologic drug is pentoxifylline (Trental).

Nursing Management of the Patient Receiving P Pentoxifylline

Core Drug Knowledge

Pharmacotherapeutics

Pentoxifylline is used to manage the symptoms of intermittent claudication from peripheral vascular disease. Using this drug improves the patient's ability to walk for longer distances without pain. It has also been used to treat acute and chronic cerebral vascular disease because it improves the psychopathologic symptoms. Unlabeled uses include treating diabetic angiopathies, neuropathies, TIAs, chronic leg ulcers, Raynaud disease, and disorders of the circulation of the eye (see Table 32.1). Although an off-label use, the American College of Chest Physicians recommends that pentoxifylline, 400 mg po tid, be part of the treatment for venous leg ulcers (Hirsh, Albers, & Schünemann, 2008).

Pharmacokinetics

Pentoxifylline is absorbed readily from the GI tract. It undergoes first-pass effect in the liver with about 50% of the drug remaining. It is widely distributed. Onset of therapeutic effects takes 2 to 4 weeks. However, full therapeutic effects are not evident until 4 to 8 weeks after therapy starts. The drug is metabolized by RBCs and the liver and is excreted in urine.

Pharmacodynamics

Pentoxifylline increases the flexibility of RBCs by increasing cAMP levels. In turn, this effect decreases platelet aggregation and promotes vasodilation. Blood fibrinogen concentration is lowered. In addition, the drug increases cellular adenosine triphosphate levels, which stabilizes the cell membrane and reduces the RBC aggregation, thus lowering blood viscosity.

Contraindications and Precautions

Because pentoxifylline is derived from the methylxanthines (caffeine and theophylline), it is contraindicated in patients who have an intolerance to it or to the methylxanthines. Patients with impaired renal function may require a reduced dose to prevent toxicity. Caution is also necessary when administering pentoxifylline to patients with coronary artery or cardiovascular disease, such as angina, arrhythmias, or severe hypotension. Pentoxifylline should be used with care in pregnant or nursing women. The drug is in pregnancy risk category C and is excreted in breast milk. Caution should also be used for children younger than 18 years, because safety in this age group has not been established.

Adverse Effects

Pentoxifylline's adverse effects occur primarily in the central nervous, CV, and GI systems. The effects on these systems may result from this drug's similarity to caffeine and theophylline.

Headache, dizziness, tremor, dyspepsia, nausea, and vomiting are all common adverse effects. Other adverse effects can occur occasionally. These effects include agitation, nervousness, insomnia, angina, chest pain, arrhythmia, tachycardia, edema, hypotension, abdominal discomfort, bloating, belching, flatus, diarrhea, blurred vision, epistaxis, bad taste, rash, urticaria, pruritus, and brittle fingernails.

Drug Interactions

Pentoxifylline may interact with a few drugs, which are listed in Table 32.6.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient is hypersensitive to the drug or to methylxanthines before beginning therapy. Assess the patient's baseline walking tolerance, circulation, and pulses in the affected extremities. Ask the patient to describe any pain experienced with activity and the effect of rest on the pain.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding.

Lifestyle, Diet, and Habits

Find out whether the patient smokes tobacco. Usual patterns of exercise and activity should be compared with desired level of exercise and activity.

Environment

Be aware that pentoxifylline is generally self-administered in the home, although it may also be administered in the hospital. Discuss potential risks in the home environment with the patient.

Nursing Diagnosis and Outcome

- Risk for Injury related to adverse pentoxifylline effects (dizziness, drowsiness, blurred vision)
  Desired outcome: *The patient will remain injury free while on pentoxifylline.*

Planning and Intervention

Maximizing Therapeutic Effects

Pentoxifylline must be taken for several weeks before the full therapeutic effects are evident. Therefore, confirm that a patient discharged on this medication has a prescription for continued use.

Minimizing Adverse Effects

Give pentoxifylline with food to minimize GI upset.

Providing Patient and Family Education

- Inform patients that pentoxifylline does not have an immediate effect and that they should not stop taking the drug before the therapeutic effects are achieved.
- Instruct patients to avoid driving or operating machinery until it is known whether dizziness or blurred vision will occur from the drug. If these problems continue after the initial phase of drug therapy, the prescriber should be contacted in case the dosage needs to be decreased.
- Advise patients not to smoke because smoking constricts the blood vessels.
- Instruct patients to keep all follow-up visits with the prescriber.

Ongoing Assessment and Evaluation

Peripheral circulation should be reassessed periodically to measure improvement. Throughout pentoxifylline therapy, the patient's exercise tolerance should be assessed, with improvement being noted over time if therapy is effective. For patients also taking antihypertensive drugs, monitor blood pressure throughout therapy.

TABLE 32.6 Agents That Interact with P Pentoxifylline

Interactants	Effect and Significance	Nursing Management
cimetidine	Cimetidine decreases hepatic metabolism of pentoxifylline, which can lead to adverse effects from pentoxifylline.	Monitor for pentoxifylline toxicity (e.g., flushing, hypotension, or seizures) and adjust the dose accordingly. Suggest switching to another H_2-antagonist (e.g., ranitidine or famotidine), which has less potential to alter metabolism of pentoxifylline.
dicumarol	Hypoprothrombinemic effect of dicumarol may be increased, increasing the risk of bleeding.	Monitor PT and INR frequently; lower dose of pentoxifylline if necessary.
insulin glulisine; inhaled human insulin	The blood glucose–lowering effect of insulin may be increased, and hypoglycemia may result.	Monitor blood glucose levels closely if adding or subtracting pentoxifylline from insulin therapy.
theophylline	Overdoses of pentoxifylline can interfere with theophylline assay levels and falsely elevate the levels of theophylline when EMIT assay test is used.	Alternate assay tests can be used if large doses of pentoxifylline are indicated.

MEMORY CHIP

P Pentoxifylline

- Hemorheologic agent that reduces blood viscosity and increases flexibility of red blood cells
- Used to manage symptoms of intermittent claudication
- Needs to be taken for several weeks before full therapeutic effect is seen
- Major contraindication: sensitivity to methylxanthines
- Most common adverse effects: headache, dizziness, tremor, dyspepsia, nausea, and vomiting
- Most serious adverse effect: tachycardia

C THROMBOLYTIC DRUGS

Thrombolytic drugs assist in breaking down formed blood clots. These drugs are used for patients who are diagnosed with an evolving, acute MI; a PE; or acute ischemic stroke. They may also be given to unclog central venous catheters. These drugs may be given systemically or directly at the site of the blood clot. Although these drugs are given during emergency situations and can save lives, their adverse effects can be life threatening. Therefore, these drugs should be administered by clinicians who are familiar with them and skilled in using them. Patients receiving these drugs need to be monitored carefully for adverse effects. The prototype of the thrombolytic drugs, also known as the tissue plasminogen activators(tPA), is alteplase, recombinant (Activase; Cathflo Activase). Drugs closely related to alteplase, recombinant, are reteplase, recombinant; tenecteplase (TNKase); streptokinase; and urokinase. A significantly different drug is drotrecogin alfa (activated).

Nursing Management of the Patient Receiving P Alteplase, Recombinant

Core Drug Knowledge

Pharmacotherapeutics

Alteplase, recombinant (Activase) is indicated in a number of thromboembolic conditions considered medical emergencies (e.g., acute evolving MI from an acute coronary artery thrombus). Therapy for this condition is most effective when it is initiated as soon as possible after the onset of symptoms (within 3 hours after the onset of symptoms is preferred; Hirsh, Albers, & Schünemann, 2008). Alteplase, recombinant is also indicated for acute ischemic stroke; it is the only drug therapy approved for treating ischemic stroke. Treatment has shown to be safe and effective if initiated within 3 hours after the onset of stroke and after intracranial bleeding (hemorrhagic stroke) has been ruled out by a computed tomography (CT) scan (Hacke, 2008; Matthews, 2009). Box 32.5 describes management of patients who are receiving alteplase, recombinant, for ischemic stroke. Patients should be at least 18 years of age and have a clinical diagnosis of ischemic stroke with clinically meaningful neurologic deficit.

Box 32.5 MANAGEMENT OF PATIENTS RECEIVING ALTEPLASE, RECOMBINANT, FOR TREATMENT OF ISCHEMIC STROKE

- Infuse 0.9 mg/kg (maximum, 90 mg) over 60 minutes with 10% of the dose given as a bolus over 1 minute.
- Admit the patient to an intensive care unit or stroke unit for monitoring.
- Perform neurologic assessment every 15 minutes during infusion, every 30 minutes for the next 6 hours, and then every hour until 24 hours from treatment.
- Delay placing nasogastric tubes, indwelling bladder catheters, or intra-arterial pressure catheters.
- If the patient develops severe headache, acute hypertension, nausea, or vomiting, discontinue infusion (if still being administered), and obtain computed tomography scan of brain immediately.
- Monitor blood pressure every 15 minutes for the first 2 hours, every 30 minutes for the next 6 hours, and then every hour until 24 hours after treatment.
- Increase frequency of blood pressure monitoring if systolic is equal to or greater than 180 mm Hg or diastolic is equal to or greater than 105 mm Hg. Administer antihypertensive drug therapy to maintain blood pressure below these levels.
- If diastolic is 105 to 140 mm Hg or systolic is 180 mm Hg or greater, give IV labetalol, 10 mg over 1 to 2 minutes. Repeat or double the dose every 10 to 20 minutes to a maximum dose of 300 mg. Or, give initial bolus of labetalol followed by continuous IV infusion of 2 to 8 mg/min. If this approach does not control blood pressure and diastolic is 121 to 140 mm Hg or systolic is greater than 230 mm Hg, consider starting nitroprusside infusion.
- If diastolic is greater than 140 mm Hg, start nitroprusside infusion at 0.5 mg/kg/min.

From Adams, H. P., Adams, R. J., Brott, T., et al. (2003). Guidelines for the early management of patients with ischemic stroke: a scientific statement from the Stroke Council of the American Stroke Association. *Stroke,* 34(4):1056–1083. Available: *http://stroke.ahajournals.org/cgi/content/full/ 34/4/1056.*

Alteplase, recombinant is also indicated to treat massive pulmonary embolism. However, this use of alteplase, as well as other thrombolytics, is somewhat controversial. Although thrombolytics accelerate clot lysis and are associated with short-term physiologic benefits, current research does not clearly show that thrombolytics decrease mortality better than heparin (UpToDate, 2009a; Wan, Quinlan, Agnelli, et al., 2004; Dong, Jirong, Liu, et al., 2009). Persistent hypotension due to PE is the most accepted indication for the use of thrombolytics. Because thrombolytics have potential serious adverse effects, it has been recommended that their use be limited to confirmed PE or DVT. For these uses, alteplase, recombinant is administered by IV infusion.

A form of alteplase is designed and approved for clearing clots that have formed in central venous catheters (Cathflo Activase); this is a labeled use for the drug in patients 2 years or older. Unlabeled uses for alteplase, recombinant include managing peripheral arterial thromboemboli and treatment of massive proximal lower extremity or iliofemoral

DVT associated with severe symptomatic swelling or limb-threatening ischemia (see Table 32.1).

Pharmacokinetics

Alteplase is infused intravenously so that distribution begins immediately. Steady state is higher if accelerated infusion of alteplase is used. Alteplase is rapidly cleared from the plasma, primarily by the liver. About 80% of the drug is cleared within 10 minutes after the infusion has completed.

Pharmacodynamics

Alteplase, recombinant is a tissue plasminogen activator (tPA) synthesized by recombinant DNA technology. It acts in the same way as endogenous tPA. Alteplase, recombinant is actually an enzyme that, when fibrin is present, converts plasminogen to plasmin. It has limited effect if fibrin is not present. When administered, alteplase, recombinant binds to the fibrin in a clot and converts the trapped plasminogen to plasmin. Fibrinolysis, or breakdown of the clot, then occurs.

Contraindications and Precautions

Alteplase, recombinant should be used only in clinical settings in which hematologic function and clinical response can be adequately monitored. It should be administered by a clinician with experience and knowledge in treating the thromboembolic disorders.

Contraindications to the use of alteplase are numerous and include hypersensitivity to alteplase; active internal bleeding; evidence of intracranial bleeding (ischemic stroke) on pretreatment evaluation; history of intracranial bleeding; suspicion of subarachnoid hemorrhage; recent (within the past 2 months) stroke; recent intracranial or intraspinal surgery or severe head trauma (within 3 months); intracranial neoplasm; seizure at onset of stroke; conditions (including other prescribed drug therapy) that make the patient likely to bleed; severe uncontrolled hypertension (systolic blood pressure ≥180 mm Hg or diastolic blood pressure ≥110 mm Hg); platelet count less than 100,000/mm^3 (ischemic stroke); and administration of heparin 48 hours preceding the onset of stroke and an elevated active partial thromboplastin time (aPTT) at presentation (ischemic stroke).

Risks of alteplase, recombinant when used to treat acute ischemic stroke may be increased if the patient has severe neurologic deficits or major early infarct signs visible in the CT scan (e.g., substantial edema, mass effect of midline shift). Several studies have looked at the risk for intracerebral hemorrhage following thrombolytic therapy for actue ischemic stroke, as it is associated with a high rate of morbidity and mortality. Risk factors include: hyperglycemia, history of diabetes, stroke severity, advanced age, increased time to treatment, high blood pressure, low platelets, early CT changes, large baseline diffusion lesion volume, a history of congestive heart failure and low plasminogen activator inhibitor levels (Lansberg, Albers, & Wijman, 2007; Derex & Nighoghossian, 2008).Certain conditions may increase the risk of bleeding from alteplase, recombinant. If any of the following are present, the benefits must be weighed against this increased risk:

- Recent (≤10 days) major surgery (e.g., CABG, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels such as internal jugular)
- Cerebrovascular disease
- Recent (≤10 days) GI or genitourinary (GU) bleeding
- Recent (≤10 days) trauma
- Hypertension (systolic blood pressure ≥180 mm Hg; diastolic blood pressure ≥110 mm Hg)
- Likelihood of left heart thrombus (e.g., mitral stenosis with atrial fibrillation)
- Acute pericarditis
- Subacute bacterial endocarditis
- Hemostatic defects, including secondary to severe hepatic or renal disease
- Serious liver dysfunction
- Pregnancy
- Diabetic hemorrhagic retinopathy or other ophthalmic hemorrhaging
- Septic thrombophlebitis or occluded arteriovenous cannula at seriously infected site
- Older adult (greater than 75 years)
- Currently receiving oral anticoagulants
- Any other condition in which bleeding would pose a major hazard or would be very difficult to manage because of its location

Adverse Effects

Bleeding is the most frequently occurring adverse effect. It can be internal, involving GI, GU, or respiratory tracts or the retroperitoneal or intracranial areas. On the other hand, it can be surface or superficial bleeding at puncture sites (e.g., IV sites or arterial punctures) or surgical incisions. Predictors of major hemorrhage after alteplase administration for acute PE include receiving a catecholamine to increase blood pressure, cancer, diabetes, and elevated INR before fibrinolysis (Fiumara, Kucher, Fanikos, et al., 2006). Nausea, vomiting, hypotension, and fever can occur with alteplase use; however, these are common sequelae after an MI and therefore may not be related to drug therapy. Other possible adverse effects, although not common, include occasional, mild hypersensitivity reactions; urticaria; fat embolism (which can occur with any thrombolytic); cerebral edema with fatal brain herniation (if administered when ≥3 hours have elapsed since onset of ischemic stroke); and CV complications (bradycardia, cardiogenic shock, arrhythmias, pulmonary edema, heart failure, cardiac arrest, recurrent ischemic reinfarction, myocardial rupture, mitral regurgitation, pericardial effusion, pericarditis, cardiac tamponade, venous thrombosis and embolism, and electromechanical dissociation).

Drug Interactions

For a complete list of the drugs that interact with alteplase, recombinant, see Table 32.7. Anticoagulant therapy with heparin should be discontinued before starting to infuse alteplase. When the alteplase infusion is complete, heparin can be resumed when the aPTT is less than twice the upper limit of normal. Heparin, or other anticoagulants, and alteplase together may increase the risk of bleeding; however, heparin is used to help prevent additional clots. Many herbs may also increase the risk of bleeding. Drugs that alter platelet function (e.g., aspirin, dipyridamole, and abciximab) may potentially increase the risk of bleeding if administered prior to or after alteplase therapy.

Antiplatelet therapy, such as aspirin, is often indicated post-thrombus, especially post-MI, and is given after alteplase infusion; however, large doses may increase the risk of bleeding. Aminocaproic acid and other antifibrinolytic agents decrease the effects of alteplase, because they have the opposite effect on blood clotting. The use of nitroglycerin should be avoided during alteplase therapy because it may decrease antithrombotic effects.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for conditions that contraindicate or are precautions for administering alteplase. If the patient has an acute ischemic stroke, confirm that the onset was less than 3 hours ago, because this is the recommended time frame for starting alteplase therapy. Laboratory values, such as hematocrit, hemoglobin level, platelet count, PT, and aPTT, can provide baseline clotting information. Assess the patient's skin for old puncture sites or incisions from which bleeding may likely occur during alteplase therapy. Determine whether the patient is receiving or will be receiving other drug therapy that increases the risk for bleeding from alteplase treatment. If the patient has a pulmonary embolism, assess whether the patient has received a catecholamine to increase blood pressure, has cancer or diabetes, or has an elevated baseline INR. If any of these are present, the patient is more likely to suffer severe hemorrhage from alteplase therapy.

Life Span and Gender

Determine the patient's age and whether pregnancy is an issue. If the patient is currently pregnant or has delivered a child within 10 days, the risk of bleeding with alteplase is increased. Alteplase is a pregnancy category C drug. Assess whether the woman is breast-feeding, because it is not known whether alteplase is secreted in breast milk. Safety and efficacy in children have not been established. Although increasing age (greater than 76 years) decreases the benefits received from alteplase therapy, treatment is still effective in reducing death rates from these cardiovascular events. Older adults have an increased risk of intracranial bleeding when they are treated for acute ischemic stroke, but treatment is still beneficial and should be provided. Accelerated infusion of alteplase (within 90 minutes) slightly increases the risk of stroke in older adults.

Environment

Be aware of the environment in which the drug will be administered. Alteplase must be administered in an acute care setting because the patient needs close monitoring.

TABLE 32.7 Agents That Interact with P Alteplase

Interactants	Effect and Significance	Nursing Management
Drugs: anticoagulants; antithrombin; antiplatelets; other thrombolytics	May increase the risk of bleeding.	Use with caution if both must be used. Assess for signs of bleeding.
Herbs: angelica; anise; arnica; asafetida; astragalus; bilberry; black currant; bladderwrack; bogbean; boldo; borage; bromelains; buchu; capsaicin; cat's claw; celery; certoparin; chaparral; cilostazol; clove oil; curcumin; dandelion; dong quai; evening primrose; fenugreek; feverfew; garlic; ginger; ginkgo; guggul; kava; licorice; meadowsweet; motherwort; red clover; skullcap; tan-shen	May increase the risk of bleeding. Risk is considered theoretical.	Use with caution if both must be used. Assess for signs of bleeding.
nitroglycerin	By increasing hepatic blood flow, nitroglycerin infusions may increase the clearance of alteplase, resulting in decreased alteplase plasma concentrations. Reduced alteplase plasma concentrations may be associated with reocclusion of the coronary arteries, less coronary artery reperfusion, and longer time to reperfusion.	Concomitant use of nitroglycerin and alteplase should be avoided if possible. If coadministration is necessary, the lowest effective dose of nitroglycerin should be used. Be aware that alteplase efficacy may be decreased and the risk of reocclusion may be increased.

Nursing Diagnosis and Outcome

- Risk for Injury related to drug-induced bleeding from alteplase
  Desired outcome: *The patient will not suffer injury from alteplase.*

Planning and Intervention

Maximizing Therapeutic Effects

Reconstitute alteplase, recombinant in sterile water for injection without preservatives. Do not use bacteriostatic water. The reconstituted solution is colorless to pale yellow and transparent. Dilute the 50-mg vial using a large-bore (e.g., 18-gauge) needle. Direct the sterile water without preservatives at the dry drug. The 100-mg vial does not have a vacuum, unlike the 50-mg vial. Use the transfer device provided to reconstitute the alteplase. Mix the drug and diluent by gentle swirling; avoid shaking or excessive agitation. Once reconstituted, it may be administered intravenously, or it may be further diluted in either 0.9% normal saline or 5% dextrose for IV infusion. The drug may be infused either by accelerated infusion, over 90 minutes (current recommended method), or by a 3-hour infusion. Make yourself familiar with the protocol of the institution regarding which method is to be used or ensure that the order specifies the preferred administration technique. With both methods, more of the dose is administered in the first part of the infusion. Check the manufacturer's instructions for exact information about drug administration.

Minimizing Adverse Effects

Throughout the time the drug is administered, closely and continually monitor vital signs and observe for signs of active bleeding. Frank bleeding may occur at access sites, such as old IM injection or arterial puncture sites; or from orifices such as the vagina or rectum. Internal bleeding may be signaled by abdominal pain with coffee grounds–like emesis; black, tarry stools; joint pain; and changes in level of consciousness.

Closely assess for possible bleeding throughout therapy. If it is necessary to perform an arterial puncture during therapy, the site chosen should be one in which external pressure can be applied, such as the femoral artery. A pressure dressing should be applied to the site and checked carefully for evidence of bleeding. Venipuncture, if it must be done, should be done carefully to prevent bleeding. IM injections and unnecessary handling of patients should be avoided to prevent internal injury while they are receiving alteplase. If bleeding occurs and is not controllable with pressure, stop the infusion and notify the prescriber.

Multiple IV lines are usually indicated to enable administration of the alteplase and other drugs and to provide a route for obtaining blood samples during therapy. Start these lines before initiating alteplase therapy.

The patient should be connected to a cardiac monitor, both during the treatment and afterward, if alteplase is given as treatment for an MI. Arrhythmias may occur, especially after the clot has dissolved and the heart has been reperfused. Antiarrhythmic therapy should be on hand when starting alteplase therapy. Notify the prescriber if substantial arrhythmias occur.

When therapy is given to treat a PE, monitor respiratory status carefully. Note respiratory rate, dyspnea, pulse oximetry, and arterial blood gas findings in addition to all the assessments described previously.

When alteplase is given to treat acute ischemic stroke, monitor the blood pressure closely during therapy. Avoid starting alteplase if 3 hours or more have elapsed from the onset of the stroke, because the benefits of treatment during this time frame are not known, and this timing increases the risk of cerebral edema with fatal brain herniation and may increase the risk of cerebral hemorrhage.

Providing Patient and Family Education

- Emphasize to patients and families the need for frequent assessment, pressure dressings, and activity limitations.
- Instruct patients to notify their nurse if they experience signs of adverse reactions.

Ongoing Assessment and Evaluation

Vital signs, evidence of bleeding, and laboratory test results should be assessed throughout therapy with alteplase, recombinant as described previously. Therapy is judged effective if the patient sustains no injury or adverse effects of the drug, the clot dissolves, and circulation is restored.

MEMORY CHIP

P Alteplase, Recombinant

- Used to break up blood clots posing acute medical emergencies such as acute myocardial infarctions, acute ischemic strokes, and pulmonary embolus
- Works by binding to the fibrin in a clot and converting the trapped plasminogen to plasmin. Fibrinolysis then occurs.
- Major contraindications: current internal bleeding, especially intracranial; recent surgeries or medical events in which patient bled or which put patient at increased risk for bleeding now; seizure at onset of stroke; or severe uncontrolled hypertension
- Most common adverse effect: bleeding
- Most serious adverse effect: bleeding
- **Life span alert: Current pregnancy or delivery of a child within the last 10 days increases risk for bleeding; older adults are more likely to have intracranial bleeding.**
- Maximizing therapeutic effects: Avoid vigorous shaking or agitation when reconstituting; administer IV over 90 minutes to 3 hours.
- Minimizing adverse effects: Monitor for bleeding; avoid venipuncture and arterial puncture if possible, use pressure dressings when needed; handle patient gently; when treating ischemic stroke, give within 3 hours of onset of symptoms.
- Most important patient education: need for frequent assessment and limitations on activity

Drugs Closely Related to P Alteplase, Recombinant

Thrombolytic Enzymes: Streptokinase, Urokinase, and Anistreplase

Streptokinase (Streptase) is used in treating acute evolving MI, pulmonary embolism DVT, arterial thrombosis, or embolism, and to open occluded arteriovenous cannulas. Unlike alteplase, which works by attaching to the fibrin in a thrombus and converting the trapped plasminogen to plasmin, streptokinase works indirectly to activate plasminogen. Streptokinase acts with plasminogen to produce an "activator complex" that converts plasminogen to plasmin. Because fibrin is not necessary for streptokinase to activate plasminogen, streptokinase can produce more systemic bleeding than alteplase, recombinant. Allergic reactions are more common in streptokinase than with alteplase because it is not produced from DNA recombinant technology. Fever and chills are the common allergic reactions. Hypotension is also more common in streptokinase and may be severe. Because adverse effects are more common with streptokinase, its use has become more limited, and alteplase, recombinant is the drug most frequently used.

Urokinase (Abbokinase) is used in treating pulmonary embolism, lysis of coronary artery thrombi, and re-establishing patency of occluded IV catheters. Anistreplase (Eminase) is used in treating acute MI. It has a longer half-life than streptokinase or urokinase but otherwise possesses similar characteristics.

Drug Significantly Different From P Alteplase, Recombinant

Drotrecogin Alfa (Activated)

Drotrecogin alfa, activated (Xigris) is an anticoagulant and profibrinolytic drug. Unlike alteplase, recombinant, drotrecogin alfa is used to reduce mortality in adults with severe sepsis who are at high risk for death. Very specific criteria must be met for the patient to be a candidate for use of this drug, because it is appropriate only if the patient is likely to die from the sepsis.

Drotrecogin alfa rapidly increases protein C and antithrombin levels, and it normalizes levels of plasminogen. Remember that protein C inactivates factors V and VII and may also limit thrombin-induced inflammatory responses. In other words, protein C prevents processes that are involved in creating stable clots. As an agent that increases the level of active protein C, drotrecogin alfa also has anti-inflammatory effects. As with alteplase, recombinant, bleeding is the most common adverse effect of drotrecogin alfa. The drug may prolong aPTT but has minimal effect on PT; the PT should be used to monitor the status of the coagulopathy. Drotrecogin alfa may cause serious hemorrhage. It should be discontinued 2 hours before procedures with an inherent risk of bleeding.

DRUG THERAPY FOR HYPOCOAGULATION

In addition to preventing blood coagulation, drug therapy may also be used to promote coagulation. Drug classes used to treat hypocoagulation, or subnormal coagulation, are clotting factors and hemostatic agents.

Table 32.8 presents a summary of information about drugs used to treat hypocoagulation.

C CLOTTING FACTORS

Deficiencies of normal blood clotting factors are associated with prolonged bleeding and clot formation times. These deficiencies result from an inherited absence of the factor (hemophilia) or from a decreased synthesis of the factor or factors. Replacement of these factors with clotting factors is the treatment of choice. The prototype clotting factor is antihemophilic factor (AHF). Other drugs in the class include

TABLE 32.8 Summary of Selected Drugs for Hypocoagulation

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P antihemophilic factor (Alphanate, Bioclate, Helixate, Hemofil M, Humate-P, Koate-HP, Kogenate, Monoclate-P, Profilate HP, Recombinate)	Temporarily replaces clotting factors missing because of hemophilia Prevents or corrects bleeding episodes Prophylaxis Mild to severe hemorrhage	*Adult:* administered so that factor VIII level assay is 20%–40% of normal or up to 80%–100% of normal after trauma or major surgery*	*Onset:* Immediate *Duration:* Unknown $t_{1/2}$: 12 h
anti-inhibitor coagulant complex (Autoplex T, FEIBA VH)	Controls bleeding in patients with factor VIII inhibitors Joint hemorrhage	*Adult:* IV, 50–100 U/kg at 12-h intervals (FEIBA VH) 25–100 U/kg, may repeat in 6 h (Autoplex I)	*Onset:* Immediate *Duration:* Unknown $t_{1/2}$: Unknown
P aminocaproic acid (Amicar)	Controls fibrinolysis and stops bleeding	*Adult:* PO or IV, 4–5 g over the first hour followed by 1–1.25 g/h for 8 h	*Onset:* PO, rapid; IV immediate *Duration:* IV, 2–3 h $t_{1/2}$: IV, 3 h

*Dosing is highly individualized to achieve desired results. See manufacturer's instructions.

anti-inhibitor coagulant complex and factor IX complex. AHF is from pooled human blood sources. It is screened for hepatitis antibodies and heated to prevent the transmission of hepatitis. Blood donors are screened for human immunodeficiency virus (HIV) as well, and positive sources are screened again. The chance of disease transmission, therefore, still exists but is quite small.

Nursing Management of the Patient Receiving P Antihemophilic Factor

Core Drug Knowledge

Pharmacotherapeutics

In patients with a demonstrated deficiency of clotting factor VIII, hemophilia A, AHF is used to prevent and control excessive bleeding. The drug effect is short term because the factor is used up in the clotting process (see Table 32.8).

Pharmacokinetics

Administered intravenously, AHF is totally absorbed. It is rapidly removed from the plasma because it is used in the clotting process. Its half-life is from 4 to 24 hours, with a 12-hour average half-life (see Table 32.8).

Pharmacodynamics

Factor VIII is an essential component of blood clotting. It is required for the conversion of prothrombin to thrombin. Patients with factor VIII deficiencies have markedly prolonged bleeding and clotting times.

Contraindications and Precautions

A contraindication to AHF is a hypersensitivity to mouse protein (limited to products that contain monoclonal antibodies). Considered a pregnancy risk category C drug, AHF should be used in pregnancy only if necessary. The pooled blood product may contain minute amounts of blood type A or B. If the patient receives a large quantity of the preparation, a risk of hemolysis from blood type incompatibility exists. In patients who have not previously received multiple infusions of blood or plasma products, signs or symptoms of some viral infections, especially hepatitis C, are likely to develop. These patients, particularly those with mild hemophilia, should receive single-donor products. AHF also carries risk of HIV transmission, although current viral-depleting processes and donor-screening practices have reduced the potential for transmission considerably.

Adverse Effects

Several adverse effects may result from AHF, although none is common. Allergic reactions include anaphylaxis, urticaria, nausea, and chills. Other adverse effects include tachycardia, hypotension, headache, drowsiness, lethargy, vision disturbances, loss of consciousness, vomiting, hepatitis, intravascular hemolysis, back pain, chest constriction, and wheezing.

Drug Interactions

No important interactions are associated with AHF.

Assessment of Relevant Core Patient Variables

Health Status

Important lab values to assess before administration of antihemophilic factor include factor VIII level assays, CBC, direct Coombs test, urinalysis, aPTT, thromboplastin generation test, and prothrombin generation test. These results provide data regarding current clotting times and serve as baseline information to determine whether therapeutic reactions are occurring during therapy. In the physical examination, be alert for signs of active bleeding and extent of the bleeding.

Life Span and Gender

Because the safety of AHF during pregnancy has not been established, determine whether the patient is pregnant.

Lifestyle, Diet, and Habits

During assessment, investigate any patient behaviors likely to result in injury, such as participation in contact sports.

Environment

Be aware that AHF is generally self-administered at home by the patient or family.

Culture and Inherited Traits

Patients with religious views that forbid receiving blood products may be opposed to receiving AHF. Discuss with the patient beliefs that may have an impact on drug therapy.

Nursing Diagnosis and Outcome

- Risk for Injury, Hemorrhage, related to deficiency of clotting factor VIII
  Desired outcome: *The patient will receive enough factor VIII to prevent injury.*

Planning and Intervention

Maximizing Therapeutic Effects

Refrigeration is required for AHF until it is used. Before reconstitution, warm the concentrate and the diluent provided by the manufacturer to room temperature. Add the diluent to the concentrate in the vial, and rotate the vial carefully until the contents dissolve. To help prevent gel formation, the vial should not be shaken. If a gel forms during reconstitution of AHF, notify the pharmacy or blood bank and withhold the AHF. Use only plastic syringes for drawing up the reconstituted drug, because the AHF solution can stick to glass surfaces.

Monitor coagulation studies during therapy to assess the effectiveness of AHF.

Minimizing Adverse Effects

After dilution, administer AHF within 3 hours to prevent bacterial growth. Use only the IV route. Apply pressure to all venipuncture sites for at least 5 minutes. Avoid IM injections to prevent bleeding into the muscle. Other measures include monitoring intake and output ratios and inspecting urine for color. If there is a discrepancy in ratios

or if urine becomes red or orange, a sign of hemolytic reaction, notify the prescriber.

Monitor for decreased hematocrit and increased Coombs test, both of which are indications of hemolytic anemia, and assess for allergic reaction. If present, stop the infusion and notify the prescriber.

Providing Patient and Family Education

- Instruct patients and families to observe for bleeding from gums, skin, urine, stools, or emesis.
- Caution patients to avoid products containing aspirin or ibuprofen because they may further impair clotting.
- Discuss strategies to prevent bleeding, such as using a soft toothbrush, avoiding IM and SC injections, and avoiding behaviors and activities that are likely to cause injury.
- Advise patients to wear medical identification that identifies their disease.
- Emphasize that improved screening factors have decreased the risk of transmission of hepatitis or HIV substantially, although a slight risk of disease transmission remains.

Ongoing Assessment and Evaluation

Blood studies are monitored as previously described when AHF is administered. Therapy is effective when prolonged bleeding is prevented or stopped.

Drugs Closely Related to P Antihemophilic Factor

Anti-inhibitor coagulant complex (Autoplex T; FEIBA-VH Immuno) treats blood coagulation disorders associated with inhibitors of factors VIII, XI, or XII; the drug is used to treat and prevent hemorrhage. It is also used in hemophilia A or B for spontaneous bleeding or to cover surgical interventions. The exact mechanism of action of anti-inhibitor coagulant complex is unknown, although it may be related to one or more of the active clotting factors and their ability to bypass the factor VIII inhibitor. Anti-inhibitor coagulant complex is not used to treat bleeding that results from deficiencies of coagulation factors, in DIC, in fibrinolysis, or if there are normal coagulation mechanisms present; the drug is made from human plasma and may therefore contain infectious agents.

Human factor IX complex is used to treat hemophilia B (Christmas disease), although it is not a substitute for fresh-frozen plasma used in mild factor IX deficiency. The complex contains factors II (prothrombin), VII, IX, and X. Factors II (prothrombin), VII, and X are required for converting prothrombin to thrombin, and factor IX is necessary for prothrombin production. The complex prevents or controls bleeding in hemophilia B, controls bleeding episodes in patients with factor VIII inhibitors, and reverses oral anticoagulant-induced hemorrhage. Human factor IX complex (Konyne 80, Profilnine SD, Proplex T, and AlphaNine SD) has one variant: mononine. Mononine contains factor IX, but after reconstitution, it has undetectable levels of factors II (prothrombin), VII, and X. It also contains histidine, mannitol, and mouse protein. Factor IX is also available in a recombinant form called BeneFix. A Chinese hamster ovary cell line has been genetically engineered to secrete recombinant factor IX into a culture medium that contains no proteins derived from human or animal sources, thus producing this form of the drug.

Factor IX, human contains only factor IX. Human factor IX complex and factor IX are administered intravenously. Dosage depends on the condition of the patient and the manufacturer's instructions, which vary according to the manufacturer. For additional information, refer to Table 32.8.

Anti-Inhibitor Coagulant Factor

Made from pooled human plasma, anti-inhibitor coagulant factor is a concentrate of activated and precursor clotting factors. It differs from AHF in that it is useful in treating patients with hemophilia who have significant levels of factor VIII inhibitors. It therefore allows clotting to occur in patients with hemophilia who are not responsive to AHF (see Table 32.8).

MEMORY CHIP

P Antihemophilic Factor

- Provides factor VIII for those with hemophilia; made from pooled human sources
- Temporarily meets needs for clotting factor to prevent or stop bleeding
- Dosage is individualized to needs of patient
- No common adverse effects
- Most serious adverse effects: slight risk of hemolytic anemia and transmission of hepatitis or HIV
- Minimizing adverse effects: monitor hematocrit and Coombs test result (hemolytic anemia)
- Most important patient education: Teach patients to avoid injury to prevent bleeding, and to carry or wear identification of the disease.

C HEMOSTATIC DRUGS

Hemostatics stop blood loss by enhancing blood coagulation. There are two types of hemostatic agents: systemic and topical. Systemic agents interfere with the breakdown of clots. Topical agents are used to control small amounts of bleeding or oozing, usually following surgery. The prototype systemic hemostatic drug is aminocaproic acid (Amicar). Tranexamic acid is also a hemostatic drug. Additional topical hemostatic drugs are presented in Table 32.9.

TABLE 32.9 Topical Hemostatic Agents

Hemostatic Agent and Action	Indication	Dosage	Contraindications and Adverse Effects	Nursing Management
Topical thrombin (Thrombinar, Thrombogen, Thrombostat) When applied directly on the wound, thrombin converts fibrinogen to fibrin.	Used in oozing wounds after dental surgery, plastic surgery, neurosurgery, epistaxis, and graft procedures Also used with absorbable gelatin sponges for hemostasis during surgery	The amount of bleeding determines the strength of solution, 100 to 2,000 U/mL.	This is included in pregnancy risk category C. The drug may cause a hypersensitivity reaction. If the drug enters the bloodstream, intravascular coagulation occurs and may result in death. Reported adverse effects include febrile episodes and allergic reaction when used to treat epistaxis.	Clean blood from affected area with gauze pads. Apply solution soon after it is reconstituted (within 3 h of reconstitution if it has to be refrigerated). Monitor the application site frequently to detect any recurrence of blood loss.
Microfibrillar collagen hemostat (Avitene Hemostat, Hemotene, Hemoped) Attracts platelets when applied to a bleeding area. Platelet aggregation fills the space with a fibrin clot.	Adjunct in controlling bleeding when traditional methods are not effective or useful	The dose is impregnated into a web or sponge form. The amount used depends on the amount of bleeding.	The drug should not be resterilized after use; its use in infected wounds is not recommended. Its effect during pregnancy is not known. Excess drug should be removed after use to prevent complications. Adverse effects include increase in infection, formation of adhesions, and hypersensitivity.	Avoid handling the substance with wet gloves or instruments, because it will adhere to a wet surface. After application to the wound, apply pressure using a dry gauze sponge. Discard any unused material; this agent may not be resterilized.
Absorbable gelatin sponge (Gelfoam). Product absorbs and holds many times its weight in whole blood. Wound may be closed over sponge, which will dissolve slowly.	Used in dental and oral surgery, neurosurgery, and prostatectomy to control bleeding	It is supplied in several different sizes to match size of the wound and the amount of bleeding.	The preparation should not be resterilized using heat, because heat may alter the product's effectiveness. The sponge should not be used on incisions. It has no indication for use in postpartum bleeding. It should be used sparingly in areas where expansion may be detrimental to surrounding structures. Adverse effects include potential for infection or abscess formation.	Assess wound frequently for bleeding. Apply during surgery as recommended by the surgeon—either dry or saturated in saline solution. Squeeze sponge to remove any air bubbles when the sponge is to be moistened on application. After application, apply pressure with a gauze pad for 10–15 s.
Absorbable gelatin film (Gel- film, Gelfilm Ophthalmic) Cellophane-like material that becomes rubbery when wet and may be implanted into body tissue; will be slowly absorbed.	Used in neurosurgery, thoracic surgery, and ocular surgery	This is supplied in a standard size and cut to fit the area	Using this film in contaminated wounds is contraindicated.	Soak the film in a sterile saline solution until pliable. The surgeon will cut the film to the desired size.
Oxidized cellulose (Oxycel, Surgicel) Exact mechanism of action is unknown but provides hemostasis when applied directly on bleeding area. It does not affect normal blood clotting, but in con- tact with blood, this product forms an artificial clot.	Used to control bleeding when sutures or clipping are not possible Primarily for bleeding from capillaries, venioles, or arterioles Used for oral and dental surgery	This is supplied impregnated into pads, pledgets, and strips. Number used depends on amount of bleeding and size of wound.	This product is contraindicated for use as wound packing. Product should not be used in fractures or spinal surgery because it may interfere with bone regrowth or cause cyst formation. It is not recommended for use in bleeding from large arteries or with serous oozing. This drug product should not be used if it has been autoclaved because this method of sterilization causes it to break down. The product may be left in the wound, but its removal once hemostasis is achieved is recommended. If used during a laminectomy, it must be removed. Adverse effects include nasal burning, encapsulation of fluid, antibody reactions.	Use a surgical clamp to remove substance from its container. Do not wet the product; instead, apply it dry. Monitor wounds of patients using oxidized cellulose for signs of bleeding.

Nursing Management of the Patient Receiving P Aminocaproic Acid

Core Drug Knowledge

Pharmacotherapeutics

Aminocaproic acid treats severe, life-threatening hemorrhage from systemic hyperfibrinolysis or urinary fibrinolysis. Systemic hyperfibrinolysis has occurred with heart surgery, abruptio placentae, cirrhosis of the liver, and neoplastic disorders. Urinary hyperfibrinolysis is associated with severe trauma, shock, prostatectomy, nephrectomy, and renal cancers.

Unapproved uses of aminocaproic acid include: preventing recurrent subarachnoidhemorrhage, to control bleeding in thrombocytopenia or oral bleeding, as well as the prevetion of perioperative bleeding associated with cardiac surgery. Aminocaproic acid is also used to treat overdoses of fibrinolytic drugs, such as streptokinase.

Pharmacokinetics

Aminocaproic acid is administered orally or by IV infusion. After oral administration, the drug is quickly absorbed; through both routes, it is widely distributed. Most of the drug is excreted unchanged in the urine.

Pharmacodynamics

Aminocaproic acid prevents fibrinolysis in two ways. First, it blocks the action of plasminogen activators, thus interfering with the formation of active plasmin. Second, it interferes with the binding of active plasmin to fibrin, thus preventing breakdown of fibrin. The result is stabilization of the blood clot and control of bleeding.

Contraindications and Precautions

Aminocaproic acid should be used only in life-threatening situations and then only when overactivity of the fibrinolytic system is verified by laboratory testing. The drug is not to be used in patients with active intravascular clotting, such as DIC.

Rapid I.V. injection (IVP) of undiluted solution is not recommended due to possible hypotension, bradycardia, and arrhythmia.

This drug is used with caution in patients with uremia or hepatic disease. Cautious use is recommended in patients with upper renal tract bleeding and in those with cardiac, liver, or renal disease. Cautious use is also recommended in pregnancy or lactation because safety has not been established.

Adverse Effects

The most common adverse effect of aminocaproic acid is GI distress (anorexia, nausea). Life-threatening or serious adverse effects are rare; these include convulsions, rhabdomyolysis (acute, sometimes fatal disease with destruction of the skeletal muscle), and renal failure. Other adverse effects that may occur include headache, dizziness, seizures, malaise, thrombophlebitis, hypotension (after IV administration), arrhythmias, tinnitus, nasal congestion, vomiting, abdominal cramps, diarrhea, and diuresis. Symptoms of overdosage include nausea, diarrhea, delirium, hepatic necrosis, and thromboembolism.

Drug Interactions

An increase in clotting factors leading to hypercoagulation may occur if aminocaproic acid is administered concurrently with oral contraceptives or estrogen (Table 32.10).

Assessment of Relevant Core Patient Variables

Health Status

Initially, identify contraindications to the drug by determining clotting factor levels and platelet counts to assess the severity of the patient's condition.

Life Span and Gender

During assessment, evaluate the patient's possible pregnancy or breast-feeding status. If the patient is a child, measure his or her weight so that a correct dosage can be calculated.

Environment

Be aware of the environment in which the drug will be administered. Aminocaproic acid is administered in an acute care setting, such as a hospital.

Nursing Diagnosis and Outcome

- Risk for Altered Cardiovascular Perfusion related to volume loss secondary to uncontrolled bleeding or thrombophlebitis secondary to adverse effects of aminocaproic acid

  Desired outcome: *Adequate perfusion will be maintained as evidenced by presence of pulses, normal skin color and warmth, and capillary refill.*

Planning and Intervention

Minimizing Adverse Effects

Monitor vital signs at start of therapy and throughout therapy at intervals appropriate to the patient's condition. Every

TABLE 32.10 Agents That Interact with P Aminocaproic Acid

Interactants	Effect and Significance	Nursing Management
oral contraceptives	Increase in clotting factors may lead to hypercoagulant state and may possibly increase risk of thrombus formation.	Monitor for signs of thrombus.
estrogens	Same as above.	Same as above.

15 to 30 minutes, assess the patient for bleeding, particularly at incision and old injection sites.

To administer aminocaproic acid, use an IV infusion pump to regulate the flow rate. Assess the IV site and line for patency. Verify that the line is secured to prevent thrombophlebitis. Do not mix aminocaproic acid with other drugs.

Connect the patient to a cardiac monitor to detect arrhythmias, and observe for signs of thromboembolic complications, such as chest pain, dyspnea, changes in skin color and temperature, pain in an extremity, or changes in peripheral pulses. Notify the prescriber if these changes occur.

Additional ways to guard against adverse drug effects include monitoring intake and output and monitoring neurologic status in patients with subarachnoid hemorrhage. Notify the prescriber of major discrepancies or changes.

To combat nausea, encourage patients to eat small, frequent meals.

Providing Patient and Family Education

- Teach patients and families about the role of aminocaproic acid in controlling bleeding. They also must understand the importance of reporting any bleeding or symptoms of thromboembolism immediately.
- Instruct patients to change positions slowly to prevent orthostatic hypotension.

Ongoing Assessment and Evaluation

Monitor the patient throughout treatment and recovery for signs and symptoms of bleeding or embolism or any other untoward event. Drug therapy is effective if bleeding is controlled.

Drugs Closely Related to P Aminocaproic Acid

Tranexamic acid (Cyklokapron) is another systemic hemostatic agent. It competitively inhibits activation of plasminogen. It is used to reduce or prevent hemorrhage during and after tooth extraction in patients with hemophilia. After oral administration, between 30% and 50% of the drug is absorbed. The drug remains in serum for 7 to 8 hours and is excreted from the body in the urine.

Tranexamic acid is contraindicated for patients with subarachnoid hemorrhage. It should be used cautiously in patients with acquired defective color vision because altered color vision is an early sign of visual toxicity. Caution should be used in pregnant or lactating women and in patients with renal insufficiency.

Aprotinin, also a systemic hemostatic agent, is indicated to reduce perioperative blood loss and the need for blood transfusion in patients undergoing cardiopulmonary bypass in the course of CABG surgery. It has also been studied for use in other types of surgery. The exact mechanism by which it reduces bleeding is unclear.

Coagulation factor VIIa (NovoSeven) is used to prevent or treat bleeding related to factor VII deficiency. Factor VIIa is a vitamin K–dependent glycoprotein that is structurally similar to human plasma-derived factor VIIa. Administered intravenously, it promotes hemostasis by complexing with tissue factor and activating coagulation factors IX and X. Activated factor X, when it forms a complex with other factors, converts prothrombin to thrombin and fibrinogen to fibrin to form a hemostatic plug.

Thrombin (Thrombin-JMI; Thrombogen), unlike aminocaproic acid, is applied topically to control hemorrhage. Thrombin is a protein substance of bovine origin that immediately clots the fibrinogen of the blood without the aid of a physiological agent.

MEMORY CHIP

P Aminocaproic Acid

- Used to treat life-threatening bleeding from systemic hyperfibrinolysis or urinary fibrinolysis
- Prevents breakdown of the stable clot and controls bleeding
- Major contraindications: Use only in life-threatening situations and only when the overactivity of the fibrinolytic system is verified by laboratory testing; DIC.
- Most common adverse effect: GI distress
- Most serious adverse effects: renal failure (rare), rhabdomyolysis (rare), thromboembolism, and arrhythmias
- Minimizing adverse effects: Use IV pump, assess for bleeding or signs of thromboembolism, and place patient on cardiac monitor to detect arrhythmias.
- Most important patient education: Teach patients to report symptoms of thromboembolism

CHAPTER SUMMARY

- Anticoagulants do not break down existing clots; they prevent clots from forming.
- The parenteral anticoagulant heparin and the oral anticoagulant warfarin are used in treating thrombus or thromboembolic disorders to prevent extension of the clot or formation of an embolism. They are also used in high-risk patients to prevent formation of an initial clot. Patients may be taking both drugs at the same time during dose regulation of warfarin.
- Low-molecular-weight heparins are administered subcutaneously daily. They have been found to be effective for the same conditions as infusions of heparin. They require less monitoring of blood clotting times, because they have a very predictable effect. Patients can be taught to self-administer the SC injection at home.
- Education for patients taking anticoagulant therapy should include safety measures to prevent bleeding, instructions to be alert for signs of bleeding, and directions for what to do if bleeding occurs.
- Antiplatelet drugs prevent platelet aggregation and thereby prevent thrombus formation. They are used prophylactically to prevent CVAs (also called strokes) and MIs (also

called heart attacks). They are used as part of treatment for ischemic strokes, after thrombolytic therapy.
- Hemorheologic agents promote the flexibility of the RBCs and decrease blood viscosity to prevent thrombus formation.
- Thrombolytic drugs break down existing clots. They are used in acute medical emergencies, such as evolving MI, pulmonary embolism, and acute ischemic stroke. Although they can save lives, these drugs carry a risk for inducing hemorrhage. The patient must be closely monitored during this drug therapy.
- Clotting factors are administered when the patient has a deficiency of clotting factors resulting from heredity or disease. These drugs allow natural clotting to occur and prevent massive blood loss.
- Hemostatics are drugs used to promote blood coagulation. Hemostatics come in systemic and topical forms. Systemic hemostatics also interfere with the breaking down of clots.

QUESTIONS FOR STUDY AND REVIEW

1. Describe how heparin and warfarin differ in their effects on the clotting cycle.
2. What interventions would promote safety while the patient is receiving heparin by continuous IV infusion?
3. Describe which laboratory values need to be monitored if the patient is receiving heparin and warfarin. What criteria do you use to determine whether these drugs are in a therapeutic range?
4. Why is it important to assess the usual vitamin K intake for a patient who will be receiving warfarin, but not for the patient who will be receiving heparin?
5. What assessment should be performed if the patient is receiving the antiplatelet drug clopidogrel and the antilipid drug fluvastatin?
6. What is the difference between an anticoagulant and a thrombolytic drug?
7. What drug therapy would be used for a patient who has hemophilia and who requires an inguinal hernia repair?

Drugs Affecting Hematopoiesis

Learning Objectives

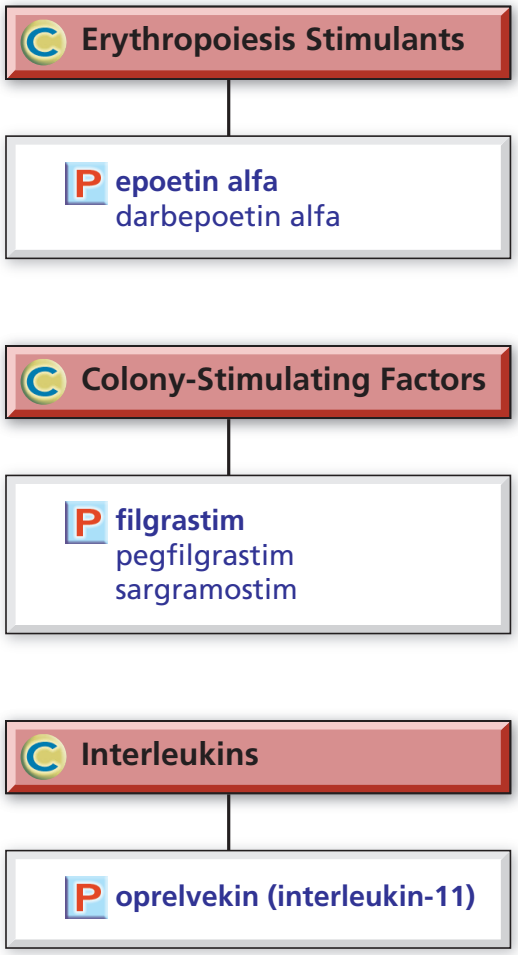
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect hematopoiesis.
2. Identify core patient variables relevant to drugs that affect hematopoiesis.
3. Relate the interaction of core drug knowledge to core patient variables for drugs that affect hematopoiesis.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect hematopoiesis.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect hematopoiesis.
6. Determine key points for patient and family education for drugs that affect hematopoiesis.

Key Terms

anemia
aplastic
erythrocytes
erythropoiesis
erythropoietin
granulocytes
hematopoiesis
leukocytes
lymphocytes
macrophages
monocytes
neutropenia
neutrophils
phagocytosis
platelets
thrombocytopenia
thrombopoietin

Drugs Affecting Hematopoiesis



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Biologic modulators, or biologic modifiers, are a group of biopharmaceuticals that are naturally occurring proteins used to alter the body's hematologic or immunologic responses. These substances are sometimes called biologic therapies. The rapid growth of these therapies over the past decade is attributable to the refinement of recombinant DNA technology, which has enabled researchers to produce large quantities of these substances outside the body. Many agents enhance the body's ability to create new cells. Other agents stimulate immunologic activity to combat specific antigens (substances that induce the formation of antibodies). Similar drugs from this class may also be used to suppress the immune system to prevent rejection of foreign transplanted tissue or to prevent rejection of the body's own tissue, as in autoimmune disease. This chapter deals with drugs that stimulate cell growth. Drugs that stimulate or suppress the immune system are discussed in Chapters 54 and 55.

Hematopoiesis, the production and differentiation of blood cells, normally occurs within bone marrow. Hematopoietic growth factors are substances generated by the body to enhance production of blood cells. Some of these agents are actually classified as hormone substances (e.g., epoetin), whereas others are cytokine growth factors. For this text, epoetin alfa (Epogen, Procrit), a hematopoietic hormone, is the prototype drug for stimulating red blood cell production. The prototype drug for white blood cell production is the colony-stimulating factor filgrastim (Neupogen). The prototype drug for creating platelets is oprelvekin (also known as interleukin-1; brand name, Neumega). See Table 33.1.

PHYSIOLOGY

The immune system is composed of hematopoietic cells and multiple hematologic-immunologic production and storage sites. Hematopoietic tissue is found in the bone marrow, lymph nodes, and lymphatic channels of the body. Stem cells located in the red bone marrow, found in the long bones and vertebral skeleton, produce the three types of functional hematopoietic cells: **erythrocytes** (also called red blood cells [RBCs]), **leukocytes** (also called white blood cells [WBCs]), and **platelets,** which are small cells necessary for blood coagulation. The reticuloendothelial system includes immunologically active tissue and cells found in the lymph system, spleen, liver, lungs, gastrointestinal (GI) tract, and brain. An integrated immune response involving hematopoietic cells and immune tissues provides the body's nonspecific and specific responses to invasion by antigens identified as nonself. The essential components of the immune system are hematopoietic cells, barrier defenses, the nonspecific immune response, the specific immune response, and immunity. Hematopoietic cells are discussed in this chapter; the other components of the immune system are further discussed in Chapter 54.

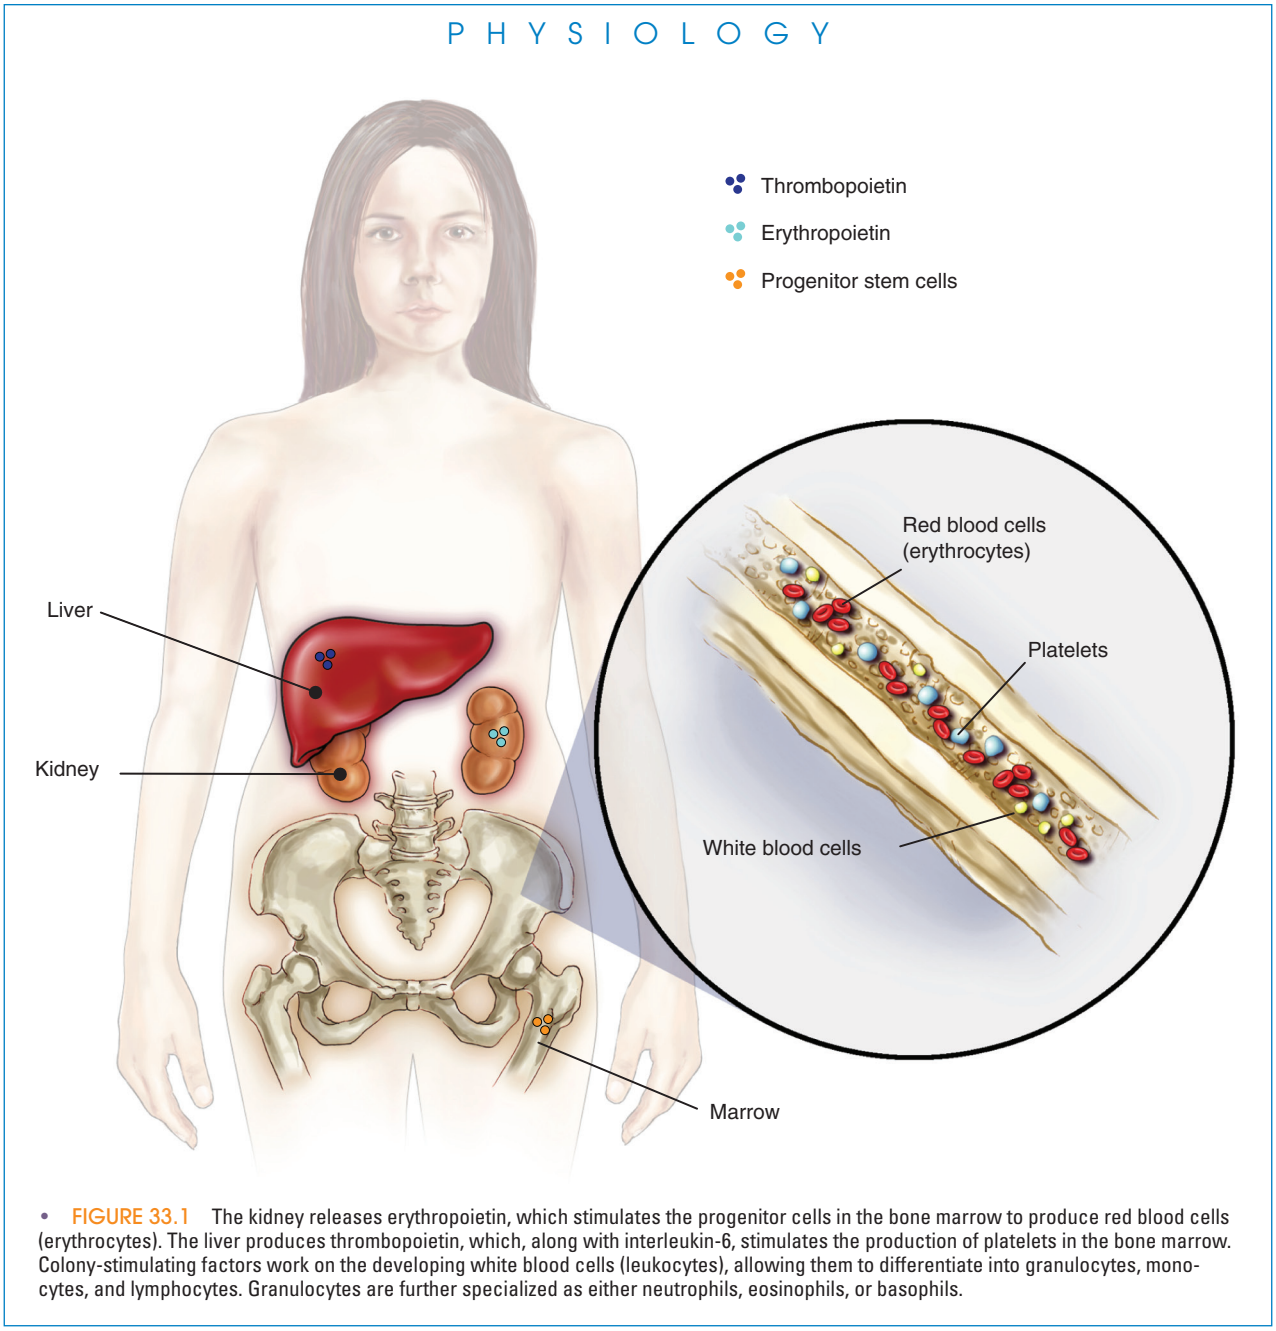
Hematopoietic Cells

Red blood cells (RBCs) are mainly composed of hemoglobin, which enables the cells to carry oxygen to the cells in the body. The biconcave disc shape of the RBCs makes them flexible enough to maneuver through the small capillaries to deliver oxygen to the tissues.

The major peptide hormone, or glycoprotein, that stimulates the production of RBCs (called **erythropoiesis**) is **erythropoietin.** Erythropoietin is produced by the kidneys in response to tissue hypoxia and reduced oxygen-carrying capacity of the red blood cells. Chronic obstructive pulmonary disease (COPD) and anemia, which produce chronic hypoxic states, are examples of disorders that stimulate production of erythropoietin and, consequently, production of RBCs. When hemoglobin levels fall below 12 g/dL (as in anemia), erythropoietin production is stimulated to maintain homeostasis. Erythropoietin in turn stimulates the progenitor stem cells to make RBCs, which live about 120 days. Plasma erythropoietin

TABLE 33.1 Understanding Drug Therapy That Affects Blood Cells

Cell Picture	Cell Type	Drug to Increase Production	Impact of Drug Therapy	Patients may Require this Drug if they have:
<leave blank space for red blood cell figure to come>	RBC	Epoetin alfa	elevates or maintains RBC levels- improves oxygenation to tissues	Anemia HIV kidney disease Cancer, or receiving anti cancer drugs
<leave blank space for white blood cell figure to come>	WBC	Filgrastim	increase neutrophil count- fight infection, decrease risk of infection	Cancer Need fo astem cell harvest Or receiving anti cancer drugs
<leave blank space for platelet blood cell figure to come>	Platelets	Oprelvekin	Increase platelet production, prevent bleeding, allows for clot formation	cancer or patients receiving anti cancer drugs



• FIGURE 33.1 The kidney releases erythropoietin, which stimulates the progenitor cells in the bone marrow to produce red blood cells (erythrocytes). The liver produces thrombopoietin, which, along with interleukin-6, stimulates the production of platelets in the bone marrow. Colony-stimulating factors work on the developing white blood cells (leukocytes), allowing them to differentiate into granulocytes, monocytes, and lymphocytes. Granulocytes are further specialized as either neutrophils, eosinophils, or basophils.

levels vary from 0.01 U/mL to 0.03 U/mL and increase 100- to 1,000-fold during hypoxia or anemia. When hemoglobin levels are elevated, erythropoietin production is halted, ending the stimulation to produce new RBCs.

Iron, the primary ion reversibly bound to oxygen in the heme molecule, is necessary to support erythropoiesis. It is held stable in the ferrous form by the other atoms that are in heme. When iron deficiency exists, the final step in heme synthesis is interrupted.

Platelets are the formed element involved in blood coagulation. Platelets are small cells that arise from the bone marrow precursor cells, called megakaryocytes. Platelet production, although stimulated by many cytokines, is mostly dependent on the action of interleukin-6 and a peptide called **thrombopoietin.** Thrombopoietin is produced in the liver. A low platelet count stimulates the production of thrombopoietin. Platelets are important in normal blood clotting. (For more information on blood clotting, see Chapter 32.)

Leukocytes (white blood cells, or WBCs) are key components of all immune system responses. During maturation in the bone marrow, WBCs differentiate into three main cell types—**granulocytes, monocytes,** and **lymphocytes**—that respond to cell injury or foreign invaders (Figure 33.1). Granulocytes are the most common type of WBC. Production

of granulocytes is regulated by colony-stimulating factors (CSFs), also known as growth factors. Granulocytes are further divided into neutrophils, eosinophils, and basophils. The formation of granulocytes (myelopoiesis) is stimulated by many cytokines. These cells are produced in response to infection, inflammation, and tissue necrosis.

Barrier Defenses

The human body has many physical barrier defense mechanisms to protect it from the outside environment. The skin is the first line of defense. Mucus is another barrier defense, providing protection for the respiratory and genitourinary tracts. A third barrier defense, the GI tract, provides an acid protector that destroys many microorganisms.

Nonspecific Immune Responses

If a pathogen gets past one of the barrier defense mechanisms and injures a cell, the body activates the nonspecific inflammatory reaction, initiating granulocyte, monocyte, and macrophage activities to destroy the invader and repair the damage. **Neutrophils** are the most common granulocyte and are considered the first line of defense against pathogens that gain entry into the body. Neutrophils contain enzymes that kill bacteria in the bloodstream when the bacteria are ingested by the neutrophil. This process of engulfing and destroying bacteria is called endocytosis or **phagocytosis.** The life of the neutrophil is extremely short—only 6 to 8 hours. Normally, when an acute infection is present in the body, the numbers of both mature and immature neutrophils increase, producing neutrophilia. The immature neutrophils are called bands. When large numbers of bands are present in the blood count, it is termed a "shift to the left," and this event usually signals a bacterial infection. When the neutrophil level or count is low (**neutropenia**), infection is likely to occur. Basophils are granulocytes that are not capable of phagocytosis but contain chemical substances important for initiating and maintaining an immune response. These substances include histamine, heparin, and chemicals used in the inflammatory response. Monocytes differentiate into immunologically active cells called **macrophages.** Macrophages can be circulating phagocytes or can be fixed in specific tissues.

Specific Immune Responses

If an invader gets past the barrier and nonspecific immune systems and enters the tissues or bloodstream, a specific immune response involving lymphocytes is initiated.

Bone marrow stem cells develop into two types of lymphocytes: T lymphocytes, or T cells, and B lymphocytes, or B cells. These T and B lymphocytes may also differentiate into specialized cells such as natural killer cells and lymphokine-activated killer cells, which have been identified as the cells that aggressively attack and destroy neoplastic cells. Because research in the area of lymphocyte identification is relatively new and ongoing, other not-yet-identified lymphocytes may be taking part in the immune response. The specific immune response is discussed in detail in Chapter 54.

PATHOPHYSIOLOGY

The pathophysiologic consequence of hematologic failure is inadequate cell production to meet the body's demands for oxygen transportation, blood coagulation, or prevention of infection. Deficient cell production is named by the cell involved; when production of all cells is deficient, it is termed **aplastic.**

Anemia, a condition of reduced circulating RBCs, can be caused by deficient cell production (arising from folic acid deficiency, iron deficiency, insufficient production of erythropoietin, or bone marrow failure) or abnormal hemolysis (as featured in sickle cell anemia and hemolytic anemia), or through loss of blood volume or cells, such as with overt bleeding. Anemia is also a common finding in heart failure, in which it is associated with increased mortality and morbidity (see Chapter 29 for a discussion of chronic heart failure [CHF]). The condition may also be an adverse effect of drug therapy (e.g., with antineoplastic agents, some antibiotics, and some anti-HIV drugs); the drug causes myelosuppression of red blood cell development.

Anemia that results from inadequate levels of the stimulating hormone erythropoietin occurs with chronic kidney disease or bone marrow failure, conditions that cause insufficient production of erythropoietin. As many as 60% to 80% of patients with chronic kidney disease have anemia (Strippoli, Navaneethan, & Craig, 2006). Another source of anemia is chronic disease; this is mediated by inflammatory cytokines that directly suppress erythropoiesis and inhibit erythropoietin production. Affected patients have low serum iron levels, but the bone marrow is replete with iron, indicating that the body is not using the iron it has effectively, as opposed to not having enough iron. This is termed functional iron deficiency. Patients with anemias related to deficiency of erythropoietin have RBCs that are normal in size and color. Those with anemias related to iron deficiency or aluminum overload have smaller RBCs than normal, whereas those with anemias related to vitamin B_{12} or folate deficiency have larger than normal RBCs.

Anemias related to decreased erythropoietin levels can be treated with exogenous erythropoietin (epoetin alfa). In chronic kidney disease, hemoglobin levels that are below 10 g/dL induce the heart to work harder to meet the tissue's needs for oxygen. This phenomenon eventually leads to left ventricular hypertrophy and left ventricular dilation, creating greater morbidity with severely altered quality of life, as well as greater cardiac mortality. Early normalization of the hemoglobin level can prevent development of left ventricular dilation and improve quality of life. Children with chronic kidney disease and anemia have impaired cognitive function, growth retardation, reduced quality of life, and an increased risk of developing left ventricular hypertrophy (National Kidney Foundation, 2006).

To effectively manage early anemia in chronic kidney disease, it should be assumed that an erythropoietin deficiency exists and any iron deficiency that may be contributing to the problem should be ruled out. Assessment and evaluation of the anemia in a patient with chronic renal disease should occur when the hemoglobin (Hb) is less than 13.5 g/dL in men and postmenopausal women, or when it is less than 12 g/dL in women. Anemia for children is defined as less than the 5th percentile of normal Hb when adjusted for age and sex. Therapy with replacement erythropoietin should begin if the evaluation determines that the patient has normal serum iron levels. The target goal for both sexes and all ages is greater than 11 g/dL; this level has been found to increase quality of life without great risk of adverse effects (National Kidney Foundation, 2006). Functional iron deficiency (normal ferritin levels but low transferrin saturation) is a common occurrence in patients who have started epoetin alfa therapy, even if they originally had normal iron levels. This deficiency occurs because stimulation of erythropoiesis increases the demand for iron, and eventually not enough iron is available.

If anemia is related to cancer and its treatment, an Hb of less than 11 g/dL requires erythropoietic therapy, and the optimum maximum treatment goal is 12 g/dL (National Comprehensive Cancer Network, 2009). A relationship between anemia and fatigue, common among patients with cancer, is believed to exist. Cancer-related fatigue is a multifactorial and common problem that decreases quality of life. Treatment of anemia to the desired treatment goal has been shown to improve quality of life in patients with cancer (National Comprehensive Cancer Network, 2009). Raising the hemoglobin level greater than 12 g/dL increases the risk for adverse effects (see below).

Abnormalities in WBC counts are fairly common, although abnormalities of WBC function are rare. Decreased numbers of neutrophils, called neutropenia, are related to two basic causes: decreased marrow activity and decreased neutrophil survival. When neutropenia is related to decreased marrow activity, it may be related to drug therapy (e.g., with antineoplastics, some antibiotics, gold, certain diuretics, antithyroid agents, antihistamines, and antipsychotics). Other causes include radiation exposure, megaloblastic anemia (anemia in which large nucleated abnormal RBCs are present in the blood), cyclic neutropenia (a benign disease), Kostmann (infantile) neutropenia, aplastic anemia (anemia from complete suppression, or loss of function, of the bone marrow), myelodysplastic syndrome, and marrow replacement by tumor.

Because neutrophils are the first line of defense for infection, neutropenia increases the risk of infection. Chemotherapy-induced neutropenia is a major dose-limiting toxicity of systemic cancer chemotherapy; it increases the risk of morbidity, mortality, and the overall cost of treating patients with cancer. Febrile neutropenia may occur, and it often requires hospitalization for evaluation and treatment with antibiotics. Patients with chemotherapy-induced neutropenia are more likely to die from an infection than from cancer.

A low platelet count is termed **thrombocytopenia.** Thrombocytopenia can result from decreased production, shortened survival, or loss of platelets. Decreased production is caused by aplastic anemia (which may be drug induced), marrow infiltration, deficiencies of vitamin B_{12} and folate, radiation, and hereditary factors. Decreased survival of platelets is related to immune-mediated factors (idiopathic, systemic lupus erythematosus, drug induced, neonatal from maternal immunoglobulin G [IgG]); hypersplenism; disseminated intravascular coagulation; thrombotic thrombocytopenic purpura; hemolytic uremic syndrome; and prosthetic valves.

Hematopoietic growth factors are exogenous replacements of endogenous growth factors. They are used when the internal mechanism for producing sufficient blood cells does not meet the body's needs. Drugs that affect hematopoiesis include erythropoiesis stimulants, colony-stimulating factors, and interleukins. Table 33.2 provides a summary of selected hematopoietic agents.

ERYTHROPOIESIS STIMULANTS

The prototype drug used to create RBCs is epoetin alfa (Epogen, Procrit), a 165–amino acid glycoprotein manufactured by recombinant DNA technology. It is recombinant human erythropoietin. The product contains the same amino acid sequence as natural erythropoietin. The human erythropoietin gene is introduced into mammalian cells, which then produce erythropoietin that has the same biologic effects as endogenous erythropoietin.

Nursing Management of the Patient Receiving Epoetin Alfa

Core Drug Knowledge

Pharmacotherapeutics

Epoetin alfa, also referred to as erythropoietin or EPO, is used to treat anemia associated with chronic kidney disease, to elevate or maintain the RBC level (assessed through Hb determinations) and to decrease the need for transfusion (see Table 33.2). Epoetin alfa is also used to treat anemia related to zidovudine therapy in HIV-positive patients. It is used when the endogenous erythropoietin levels are 500 mU/ mL or less and the dose of zidovudine is 4,200 mg/wk or less. Although clinical reviews have found some evidence that supports the use of epoetin alfa to reduce transfusion requirements, increase hemoglobin levels, and improve the quality of life in HIV-infected patients with anemia, the review authors felt this evidence was weak. These authors stated: "There is a need for randomized trials of high methodological quality to evaluate the effect of interventions on anemia in persons infected with human immunodeficiency virus" (Martí-Carvajal & Solà, 2009). It has historically been used to treat chemotherapy-induced anemia in patients with cancer and it may reduce the need for blood transfusions. Improving Hb levels in patients with cancer appears to also decrease the fatigue that often accompanies cancer.

TABLE 33.2 Summary of Selected Hematopoietic Agents

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Erythropoiesis Stimulants			
P epoetin alfa or erythropoietin or EPO (Epogen, Procrit)	Anemia from chronic renal disease (CRD) Anemia related to zidovudine therapy in HIV-associated illness Anemia related to chemotherapy in cancer patients	CRD: 50–100 U/kg 3×/wk IV or SC injection to maintain Hct of 30%–36% HIV: 100 U/kg 3×/wk for 8 wk IV or SC injection Cancer: 150 U/kg 3×/wk SC injection (weekly injections under investigation)	*Onset:* IV, immediate; SC, within 5–24 h *Duration:* IV, = 24 h; SC levels fall slowly after 24 h $t_{1/2}$: 4–13 h
C Colony-Stimulating Factors			
P filgrastim or granulocyte-colony stimulating factor (G-CSF) (Neupogen)	Neutropenia due to chemotherapy, after bone-marrow transplantation (BMT), or severe chronic neutropenia Prior to peripheral blood progenitor cell (PBPC) collection	Chemotherapy: 5 mcg/kg/d SC injection, or infusion, or IV BMT: 10 mcg/kg/d IV or SC infusion Chronic: congenital 6 mcg/kg bid SC injection Idiopathic or cyclic: 5 mcg/kg once/d SC injection PBPC collection: 10 mcg/kg/d SC (injection or infusion) starting at least 4 d prior to procedure	*Onset:* IV, immediate *Duration:* Unknown $t_{1/2}$: 3.5 h
C Interleukins			
P oprelvekin or interleukin-11 (IL-11) (Neumega)	Thrombocytopenia from chemotherapy	*Adult:* 50 mcg/kg/d SC injection *Child:* Safety and efficacy not established	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 6.9 h

However, two recent meta-analyses concluded that erythropoietin treatment shortens survival in cancer patients. It appears that all cancer patients are equally at risk, no matter what cancer treatment they receive or what type of cancer they have (Bohlius, Schmidlin, Brillant, 2009; Lambin, Ramaekers, van Mastrigt, et al., 2009). Finally, epoetin alfa is used in patients with anemia who will be undergoing elective, noncardiac, or nonvascular surgery, and in patients who are at high risk for substantial blood loss during surgery, to reduce their need for postoperative blood transfusions.

Off-label uses of epoetin alfa include treatment of anemia in a variety of other conditions, including critical illness, CHF, anemia due to radiation, anemia during puerperium, hepatitis C (in patients being treated with a combination of ribavirin and interferon alfa or ribavirin and peginterferon alfa), multiple myeloma, myelodysplastic syndrome, myelofibrosis, prematurity, and pre-donation for autologous blood transfusion.

Dosage and frequency of administration of epoetin alfa vary by its intended purpose. Multiple effective regimens have been studied and seem effective, including two or three times per week, weekly, and biweekly. Most protocols recommend that epoetin alfa be administered subcutaneously, but it may also be given intravenously.

Pharmacokinetics

Epoetin alfa can be administered either intravenously or subcutaneously. When epoetin alfa is given intravenously, its circulating half-life is 4 to 13 hours. For chronic renal failure patients, it lasts approximately 20% longer than in healthy adults. Therapeutic levels are maintained for 24 hours or longer. After subcutaneous (SC) administration, peak levels are achieved within 5 to 24 hours and decline slowly afterward. Elimination is through the kidneys. Half-life is not affected by dialysis (see Table 33.2).

Pharmacodynamics

Epoetin alfa has the same effects on the body as endogenous erythropoietin. It stimulates production of RBCs. In patients with chronic kidney disease, the first evidence that epoetin alfa is producing a positive response is an increase in the reticulocyte (immature RBC) count within 10 days. Next seen, within 2 to 6 weeks, is an increase in the RBC count

and Hb level. Once the target Hb level has been reached, it can be maintained by using epoetin alfa. The rate of hemoglobin increase varies among patients and is dose dependent; however, doses over 300 units/kg three times weekly (or 60,000 units once weekly) are unlikely to produce any additional biologic response. Other factors affecting rate and extent of response include the availability of iron stores, baseline hemoglobin, and concurrent illnesses. A recent study showed that erythropoietin (in addition to oral iron) given to patients with CHF and anemia yielded not only a significant increase in their hemoglobin levels but also the following improvements related to their heart failure: an improvement in New York Heart Association functional class; increased exercise endurance (including tolerating longer periods of exercise and an ability to walk greater distances); a significant improvement in oxygen use during exercise; a fall in plasma B–type natriuretic peptide levels; improved renal function (as evidenced by a significant decrease in serum creatinine and an increase in estimated creatinine clearance); and decreased need for hospitalization. Patients who received only the oral iron preparation did not experience these benefits (Palazzuoli, Silverberg, Iovine, et al., 2006). Another small study showed that patients with chronic kidney disease but not receiving dialysis who received epoetin alfa had a significant increase in their high-density lipid cholesterol; this may represent an important cardiovascular benefit of epoetin alfa (Siamopoulos, Gouva, Katopodis, et al., 2006).

Responsiveness of HIV-positive patients to epoetin alfa is based on endogenous erythropoietin levels. Those with levels above 500 mU/mL do not appear to respond to therapy. An increased Hb and a decreased need for transfusion are evidence of a response.

Epoetin alfa is no longer recommended for the treatment of anemia caused by cancer associated with solid tumors or hematologic malignancies other than myelodysplastic syndromes (National Comprehensive Cancer Network, 2009). The use of epoetin alpha in patients receiving myelosuppressive chemotherapy depends on symptoms of anemia and hemoglobin levels. For example, epoetin alfa is an option in someone with symptoms of anemia and a hemoglobin level of less than 11g/dL. In patients with no symptoms of anemia, it should only be considered as an option if hemoglobin levels are less than 10 g/dL and if the patient is at risk of development of symptomatic anemia requiring transfusion. Furthermore, the use of epoetin alfa for cancer-related anemia should be limited to the period during chemotherapy and a short period following (usually 6 weeks). The use of epoetin alfa in cancer-associated anemia must be monitored very closely because recent evidence indicates that there is decreased survival of cancer patients who receive epoetin alfa.

Research has shown that premature infants who are given epoetin alfa to prevent or treat anemia require fewer transfusions than those who did not receive the drug (Ohlsson & Aher, 2006; Haiden, Schwindt, Cardona, et al., 2006).

Contraindications and Precautions

Use of epoetin alfa should be avoided in uncontrolled hypertension and in cases of hypersensitivity to mammalian cell–derived products or human albumin; anaphylaxis can occur. Although epoetin alfa therapy does not appear to have direct vasopressor effects, blood pressure may rise during therapy, especially during the early phase of treatment, when the Hb is rising. An elevation in blood pressure is especially problematic for patients with chronic kidney disease, who typically have hypertension already.

Increasing the Hb to greater than 12 g/dL (in an attempt to raise it to normal levels) appears to increase the risk of cardiovascular complications, including death, myocardial infarction, hospitalization for CHF, or stroke; thus, treatment goals for Hb should be below this level. Hypertensive encephalopathy has also been reported with the use of epoetin alfa, and a reduction or interruption of the dose may be required.

In patients with chronic kidney disease who require correction for severe anemia, epoetin alfa therapy should not be used as a replacement for transfusion. Patients with chronic kidney disease who are taking epoetin alfa may suffer thrombotic events, such as myocardial infarction, transient ischemic attacks, and cerebrovascular accident, or clotting of the artificial kidney during dialysis. Patients receiving hemodialysis may need increased anticoagulation with heparin to prevent their artificial kidneys from clotting. The risk of thrombotic events is greatly increased in patients with ischemic heart disease or CHF when the prescriber is trying to increase the Hb to normal levels with epoetin alfa therapy.

In patients with cancer, epoetin alfa should only be used when anemia is due to concomitant myelosuppressive chemotherapy and should be discontinued when the chemotherapy course is completed. The use of epoetin alfa during cancer may shorten survival and/or increase the risk of tumor progression or recurrence. Patients with cancer are also at risk for serious cardiovascular and thrombovascular events and should use the lowest dose needed to avoid red blood cell transfusions.

Increasing the Hb level too quickly, with a rise of greater than 1 g/dL in any 2-week period, increases the risk of neurologic and cardiovascular events, including seizure, death, myocardial infarction, stroke, CHF, exacerbation of hypertension, and hemodialysis graft occlusion in all patient populations.

Several other patient variables require cautious use of epoetin alfa. Patients with porphyria may experience exacerbations. Patients with underlying hematologic disease (i.e., sickle cell anemia, myelodysplastic syndrome, hemolytic anemia) may have problems with epoetin alfa; the safety and efficacy of the drug in such patients have not been determined. Patients taking epoetin alfa who require surgery may require iron supplementation. Use of epoetin alfa during the peri-surgery period should be monitored due to increased risk of DVT and DVT prophylaxis may

be considered. Epoetin alfa is a pregnancy class C drug. Premature infants are at increased risk of neurologic and sometimes-fatal complications, due to benzyl alcohol contained in the multidose-preserved formulation. Resumption of menses in some postmenopausal female patients has occurred; unplanned pregnancy may result. Also, because small amounts of human albumin are found in epoetin alfa, theoretically the drug may transmit viral illnesses or Creutzfeldt-Jakob disease; however, no known cases have been documented. Lastly, patients with several conditions may fail to respond or maintain a response to epoetin alfa. These include possible iron deficiency, underlying infection, inflammatory, or malignant processes, occult blood loss, underlying hematologic diseases, vitamin deficiencies, hemolysis, aluminum intoxication, osteitis fibrosa cystic, and pure red cell aplasia.

In contrast, there does not seem to be any association between epoetin alfa therapy in HIV-positive patients and exacerbation of hypertension, seizures, or thrombotic events. However, therapy should not be started until blood pressure is controlled. Epoetin alfa should not be used to treat anemia caused by iron or folate deficiencies, hemolysis, or GI bleeding in HIV-positive patients with cancer.

Adverse Effects

Adverse effects occurring during epoetin alfa therapy appear to reflect the patients' underlying disease process or their postoperative state. Although fever, headache, cough, rash, nausea, diarrhea, vomiting, and edema were all noted in the original clinical trials of epoetin alfa prior to Food and Drug Administration approval, these were also found in those patients who did not receive epoetin alfa. It is difficult to determine, then, exactly what the adverse effects of epoetin alfa are. Exacerbation of hypertension may occur in patients with chronic kidney disease who are on dialysis (see Contraindications and Precautions). Seizures have been reported less often; they occur most commonly in patients with renal disease who have lower Hb targets (less than 12 g/dL) (Strippoli, Navaneethan, & Craig, 2006). Porphyria (excretion of nitrogen-containing compounds in the urine) may be exacerbated in patients with chronic kidney disease, although this effect is rare.

Although it is difficult to determine adverse effects of epoetin alfa per se, there is mounting evidence that raising the hemoglobin level to 13.5 g/dL in patients with chronic kidney disease increases the risk of serious adverse effects such as hypertension, hospitalization for CHF, myocardial infarction, and stroke (Singh, Szczech, Tang, et al., 2006). Whether it increases the risk of death is inconclusive in the literature at this time (Strippoli, Navaneethan, & Craig, 2006). Patients with cancer receiving epoetin alfa have a significant increased risk of thromboembolic events (Bohlius, Wilson, Seidenfeld, et al., 2006).

Premature infants less than 8 days of age who received epoetin alfa experienced an increased risk of retinopathy of prematurity (Ohlsson & Aher, 2006).

Drug Interactions

No drug interactions are known to occur with epoetin alfa.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient has pre-existing uncontrolled hypertension, which is a contraindication for the use of epoetin alfa. Verify that the anemia is not caused by iron or folate deficiency, hemolysis, or GI bleeding, because these anemias should be treated differently. Determine whether the patient has pre-existing vascular disease, because it may increase the patient's risk for developing thrombotic adverse effects. Before and during therapy, assess the patient's iron status, including transferrin saturation (serum iron divided by iron-binding capacity) and serum ferritin (the iron-phosphorous-protein complex that is the form in which iron is stored in the tissues). Transferrin saturation should be at least 20%, and ferritin should be at least 100 ng/mL (200 ng/mL if the patient is receiving dialysis). Iron is needed to support erythropoiesis. Absolute or functional iron deficiency may develop during therapy. Functional iron deficiency, in which the ferritin level is normal but the transferrin saturation is low, is believed to be caused by the body's inability to mobilize iron stores rapidly enough to support increased erythropoiesis.

Life Span and Gender

Determine whether the patient is pregnant, because epoetin alfa is a pregnancy category C drug. Adverse effects have occurred in rats given epoetin alfa in doses five times the comparable human dose; however, no adequate studies have been performed in humans. Use caution if administering epoetin alfa to a woman who is breast-feeding, because it is not known whether the drug is excreted in breast milk. Because menstruation may resume in some female patients who take epoetin alfa, discuss birth control strategies.

Safety and efficacy in children are not established. If giving epoetin alfa for unlabeled purposes to premature infants, use the form without the benzyl alcohol (the preservative), because benzyl alcohol has been associated with a fatal "gasping syndrome" in premature infants. Administration of epoetin alfa to premature infants before 8 days of age is not recommended because of the increased risk of retinopathy of prematurity.

Ask the patient's age, which may affect the adverse effects from the drug. Carefully assess the older adult with cancer who is receiving epoetin alfa for adverse effects related to anemia, because these patients are more sensitive to the anemia that results from chemotherapy. Older adults are also likely to experience adverse effects from other, concurrent drug therapy. Some drugs bind to RBCs, and without adequate RBCs, epoetin alfa has no binding sites. In this case, levels of the drug rise, increasing the incidence of adverse effects).

Lifestyle, Diet, and Habits

Verify that patients with chronic kidney disease are continuing the dietary restrictions necessary in this disease. As the hemoglobin rises and patients begin to feel better, they may feel that they no longer need a restrictive diet. Determine whether patients are at risk for iron deficiency; if so, encourage them to consume foods high in iron.

Environment

Be aware of the setting in which epoetin alfa will be administered. The drug is administered in many ambulatory settings as well as in the hospital or dialysis center. For patients who receive home dialysis or intermittent ambulatory treatment (antiretroviral therapy, chemotherapy, or radiation therapy), therapy can be self-administered at home. Assess the patient factors in the home environment that may affect adherence to drug therapy. Be careful to review the reimbursement policies of the patient's health care insurance, because injectable medications are often not reimbursed as a home therapy.

Culture and Inherited Traits

No cultural barriers exist to the use of epoetin alfa. If your assessment reveals that the patient has a religious affiliation (such as the Jehovah Witnesses) in which blood transfusions are forbidden, epoetin alfa may still be administered. Epoetin alfa is not considered a blood component by religious affiliations that object to transfusions and hence offers an excellent alternative to RBC transfusion for those individuals.

Nursing Diagnoses and Outcomes

- Impaired Tissue Oxygenation related to anemia
  Desired outcome: *Tissues will be oxygenated satisfactorily, and hemoglobin will reach desired level with epoetin alfa therapy.*
- Risk for Injury related to adverse effects of epoetin alfa
  Desired outcome: *Adverse effects will be prevented or minimized to prevent injury.*

Planning and Intervention

Maximizing Therapeutic Effects

To maintain the biologic activity of epoetin alfa, do not shake the drug after reconstituting it. Vigorous shaking may denature the glycoprotein, making it biologically inactive. Do not further dilute the drug. Direct intravenous (IV) administration can be performed at the end of dialysis.

Allow time for the Hb level to rise before seeking an order to adjust the dose. An increase in Hb should not exceed 1 g/dL in 2 weeks. The accepted range for target Hb for all patients is 10 to 12 g/dL. When epoetin alfa is given, the time required to elicit a clinically meaningful change is 2 to 6 weeks. After dosage adjustment, measure Hb in patients with chronic kidney disease twice weekly for 2 to 6 weeks, and measure Hb in zidovudine-treated patients with HIV and patients with cancer once weekly until stabilized.

Iron stores (including transferrin saturation and ferritin) should be assessed prior to initiating therapy and periodically during therapy. Supplemental iron should be administered during therapy with epoetin alfa. Although oral iron preparations are most common, parenteral iron preparations are helpful in treating functional iron deficiency and may be more effective. Because allergic responses are possible from IV iron, it is often recommended that patients receive pretreatment with diphenhydramine and acetaminophen to minimize adverse effects.

If response to epoetin alfa is delayed or diminished, assess for other reasons that may cause a low Hb (e.g., functional iron deficiency; underlying infectious, inflammatory, or malignant processes; occult blood loss; underlying hematologic diseases; folic acid or vitamin B_{12} deficiencies; hemolysis; aluminum intoxication; or osteitis fibrosa cystica [overactivity of the parathyroid gland that results in disturbances of calcium and phosphorus metabolism]). Patients who fail to respond to epoetin alfa should be evaluated for these problems.

Minimizing Adverse Effects

Cancer patients should discuss with the physician if they are more at risk from taking epoietin alfa or from blood transfusions, as epoietin alfa appears to increase the rate of mortality from cancer, but blood transfusion also carries some risk to the patient (Bohlius, Schmidlin, Brillant, 2009).

Remember that the single-dose 1-mL vials have no preservative. To prevent contamination, use only one dose per vial, do not re-enter the vial, and discard any unused portion. In contrast, the multidose 2-mL vial has preservative in it. Store it at 2°C to 8°C after initial entry and between doses. Discard the vial 21 days after initial entry to prevent use of a possibly contaminated product. Never use the multidose preparation with preservatives in premature infants; use only the single-use, preservative-free preparations. The preservative has been found to cause potentially lethal adverse effects in premature infants. Although dilution is not generally recommended for adults, it may be done with bacteriostatic normal saline in a 1 to 1 ratio to help relieve injection site discomfort. Always monitor the patient closely after the first dose; anaphylactic reactions have occurred.

Monitor the blood pressure of all patients receiving epoetin alfa throughout therapy to assess for hypertension.

Monitor the Hb level to prevent adverse effects. Dosage adjustments to achieve the desired Hb level are not uncommon. These adjustments, or titrations, may be stated in the original drug order or in a unit or hospital protocol. If neither guideline exists, contact the prescriber for further orders. The nurse is responsible for verifying that the dose being administered is safe, based on the patient's current physiologic status, and does not promote serious adverse effects. Withhold a dose if hemoglobin exceeds 13 g/dL; reinitiate with 25% dose reduction when hemoglobin is less than 12 g/dL; an alternative to this would be to immediately decrease the dose instead of withholding the drug for a period of time. This method may help prevent the hemoglobin level

from falling too greatly. If a very rapid hemoglobin response (increase of more than 1 g/dL in any 2-week period) occurs, the dose should be reduced by 25%. Consult with the prescriber for changes in the prescribed dose.

Assess for the presence of premonitory neurologic symptoms, particularly during the first 90 days of therapy. Assess renal function and fluid and electrolyte balance in patients with chronic renal failure.

Providing Patient and Family Education

- Teach patients and families the purpose of the drug and the need for follow-up blood work to check the Hb.
- Instruct patients to maintain adequate iron intake, which may aid in the effectiveness of epoetin alfa. Foods high in iron include green leafy vegetables, beans, and organ meats. High-iron-content foods or supplements are best absorbed if taken with ascorbic acid, such as that found in citrus drinks.
- If patients are to take an iron supplement, teach them that it is best taken without food or phosphate binders, and that the best time to take it is at bedtime.
- Explain to patients with chronic kidney disease the importance of continuing with diet restrictions and dialysis (if used) while receiving epoetin alfa.
- For patients who will be self-administering epoetin alfa at home, teach proper SC injection technique and safe disposal of used needles and syringes.
- Instruct patients to avoid activities requiring coordination until the drug effects are realized, as epoetin alfa may cause dizziness.
- Teach patients to stop using epoetin alfa when the chemotherapy course is complete.

Ongoing Assessment and Evaluation

Monitor patients' blood pressure and hemoglobin throughout epoetin alfa therapy. Check the hemoglobin twice weekly until the target hemoglobin has been achieved and the dose has been established. Monitor iron levels throughout therapy to verify that enough iron is available to support erythropoiesis. Therapy is effective when the Hb rises to a desired treatment level, the need for transfusions is reduced, and the patient does not have major adverse effects.

CRITICAL THINKING SCENARIO

EPOETIN ALFA AND IRON DEFICIENCY

Ada Greene, 65 years of age, has chronic kidney disease. Her blood work shows that her hemoglobin is 9 g/dL. An anemia evaluation shows that her serum iron levels are normal, and she is started on epoetin alfa. After 3 weeks of epoetin alfa therapy, her hemoglobin count is 10.5 g/dL, and her serum iron levels show normal ferritin levels but low transferrin saturation. She is diagnosed as having functional iron deficiency.

1. What would account for these changes in her iron levels?
2. What treatment would you expect to be ordered for Ms. Greene?

Drug Closely Related to P Epoetin Alfa

Darbepoetin alfa (Aranesp) is in the same class as epoetin alfa. Darbepoetin alfa has a slightly different chemical structure (it contains five N-linked oligosaccharide chains, as compared to three) and a much longer half-life. Approved for use in treating anemia from chronic kidney disease or from chemotherapy, darbepoetin alfa should be avoided in cancer patients with anemia that is not secondary to drug therapy, because it is not effective in reducing the need for blood transfusions and it increases the mortality rate in these patients (FDA MedWatch, 2007). It appears to have a reduced efficacy in renal dialysis. In one study (Papatheofanis, Smith, Mody et al., 2007), short-term measurements of effectiveness (4 to 12 weeks) showed that darbepoetin alfa was not as effective as epoetin alfa; however, by 24 weeks of therapy, target Hb levels had been reached equally in patients receiving therapy with either drug. Darbepoetin alfa was 33% more expensive than epoetin alfa.

MEMORY CHIP

P Epoetin Alfa

- Recombinant human erythropoietin works exactly as endogenous erythropoietin; it stimulates the production of RBCs (erythropoiesis)
- Used to treat anemia in chronic kidney disease, HIV infection (when zidovudine is used), and cancer (when chemotherapy is used), and in preoperative anemic patients (when high blood loss and transfusion are anticipated)
- **Black box warning: Renal failure patients experienced greater risks for death and serious cardiovascular events if hemoglobin level raised too high; treatment goal should be 10 to 12 g/dL only.**
- **Black box warning: Cancer patients may shorten overall survival and/or increased the risk of tumor progression or recurrence; use the lowest ESA dose needed to avoid red blood cell transfusion.**
- **Black box warning: For pre-operative use, administer anticoagulants to prevent DVT.**
- Major contraindication: uncontrolled hypertension
- Difficult to determine true adverse effects, because those reported are also present in disease process or post procedure
- Most common adverse effects: hypertension (in chronic kidney disease (CKD)); fever (all other uses); nausea and vomiting (surgical patients)
- Most serious adverse effects: thrombotic effects (in CKD, and preoperative patients)
- **Patient safety alert: Attempting to raise the Hb level to typical normal levels increases the risk of cardiovascular complication; raising the Hb level too quickly can result in seizures, doses should be individualized and the lowest effective dose should be used.**
- Maximizing therapeutic effects: Consult with prescriber about dose adjustment and verify iron availability; monitor hemoglobin levels in CKD patients; do not shake vial.
- Minimizing adverse effects: Monitor hemoglobin; do not use high target levels for hemoglobin.
- Most important patient education: Advise patients of the need for follow-up blood work and the importance of dietary iron.

C COLONY-STIMULATING FACTORS

Colony-stimulating factors are glycoproteins that assist in the production of blood cells by binding to specific cell-surface receptors and stimulating proliferation, differentiation commitment, and some end-cell functional activation. Filgrastim (Neupogen), a granulocyte colony-stimulating factor (G-CSF), is the prototype drug for stimulating WBC production.

Nursing Management of the Patient Receiving P Filgrastim

Core Drug Knowledge

Pharmacotherapeutics

Filgrastim is licensed for use in both adults and children with cancer to increase their neutrophil count. For patients with cancer who have nonmyeloid malignancies (cancers that are not related to blood cell components) and are receiving myelosuppressive chemotherapy (which suppresses the production of blood cells in the bone marrow), it is used to decrease the incidence of infection, as manifested by febrile neutropenia (Box 33.1). Primary administration of filgrastim or other CSFs as prophylaxis should be reserved for patients expected to experience febrile neutropenia at an incidence equal to or greater than 20% (National Comprehensive Cancer Network, Myeloid Growth Factors, 2009). Filgrastim is used for patients with cancer who receive chemotherapy following bone marrow transplantation to reduce the duration of neutropenia and neutropenia-related clinical sequelae (e.g., febrile neutropenia). In addition, it is used in patients with cancer before leukapheresis (removal of WBCs from blood, which are saved and then later transfused back into the patient). Other uses for filgrastim include severe, chronic neutropenia that is congenital, cyclic, or idiopathic in origin. The goal is to reduce the incidence and duration of sequelae of neutropenia (e.g., fever, infections, and oropharyngeal ulcers).

Off-label uses of filgrastim include treating neutropenia in patients with AIDS, prevention of febrile neutropenia in myeloid malignancies following a bone marrow transplantation, myelodysplastic syndrome, aplastic anemia, hairy cell leukemia, and drug-induced neutropenia.

Filgrastim is administered as a single daily SC injection bolus, by short IV infusion (15 to 30 minutes), or by continuous SC or IV infusion.

Pharmacokinetics

Filgrastim begins to work as soon as it can bind with its receptor sites. Absorption and excretion occur through the kidneys; the elimination half-life is about 3.5 hours (Quirion, 2009).

Pharmacodynamics

Filgrastim is produced by *Escherichia coli* bacteria that have had the human G-CSF gene inserted. G-CSF regulates the production of neutrophils within the bone marrow. Recombinant DNA G-CSF (filgrastim) acts the way that endogenous G-CSF does.

Filgrastim stimulates and mobilizes the cells that are the progenitor cells for neutrophils into the peripheral circulation. When this additional volume of progenitor cells is infused back into the patient by leukophoresis, the neutrophil count rises more rapidly. It also affects some end-cell functional activation, including phagocytic activity, cellular metabolism, and antibody-dependent killing.

Contraindications and Precautions

The only contraindication to administration of this agent is hypersensitivity to *E. coli*–derived proteins, filgrastim, or any of the product components. Caution should be used when a patient has a myeloid malignancy or requires concomitant cytotoxic (destructive to cells) chemotherapy or

BOX 33.1 FOCUS ON RESEARCH

Determining Cost-effective Treatment in Breast Cancer

Lyman, G., Lalla, A., Barron, R., & Dubois, R. (2009). Cost-effectiveness of pegfilgrastim versus filgrastim primary prophylaxis in women with early-stage breast cancer receiving chemotherapy in the United States. *Clinical Therapeutics*, 31(5):1092–1104.

The Study

Filgrastim has been used in women with early stage breast cancer to prevent febrile neutropenia. The newer drug pegfilgrastim has advantages related to the dosing schedule, but is more expensive. This study sought to assess the incremental cost effectiveness of pegfilgrastim versus filgrastim as a prophylaxis for febrile neutropenia in women with early stage breast cancer who have received myelosupressive chemotherapy. The model included the cost of the treatment, other direct medical costs, the costs related to reduced risk for febrile neutropenia, and potential survival benefits associated with reduced risk for febrile neutropenia. The study found that despite an initial higher cost of treatment with pegfilgrastim, it is ultimately more cost effective than either an 11-day or a 6-day treatment with filgrastim. The factors most significant factors in the analysis were: cost of the medication and its administration, base line, and relative risk for febrile neutropenia and febrile neutropenia case fatality rate.

Nursing Implication

Despite the higher cost for the medication with pegfilgrastim, which can be as much as $7,000 per dose (Quirion, 2009), treatment with pegfilgrastim has been found to be over all more cost effective than filgrastim (which is comparatively inexpensive at approximately $150 to 350 per dose). Pegfilgrastim has the additional advantage of being given as a single dose rather than 6 or 11 days of injections needed for treatment with filgrastim. This is much more comfortable and more supportive of patient adherence. Nurses are often consulted by patients regarding both the financial cost and personal impact of treatment options. This study demonstrates that sometimes the most cost-effective regimen is not with the drug that is least expensive. Understanding the true cost of drug therapy allows the nurse to more accurately address patients' concerns over the potential financial burden from drug therapy.

radiotherapy, because the rapidly dividing myeloid cells may be sensitive to these substances.

Filgrastim should not be used from 24 hours before to 24 hours after chemotherapy with cytotoxic substances, because extremely elevated WBC counts have occurred as a result. Although no specific adverse effects have been noted with this use, the WBC count should be monitored closely during therapy. Be careful not to discontinue treatment with filgrastim prematurely. Although a transient increase in neutrophil count occurs 1 to 2 days after starting therapy, this increase should not be mistaken for the full therapeutic effect of drug therapy. This drug should be administered throughout the time when the marrow-suppressing therapy's full nadir (lowest level) of neutrophils should have occurred before therapy is discontinued.

Caution is also recommended if the patient has adult respiratory distress syndrome (specifically, neutropenic patients with sepsis), sickle cell disease, or severe sickle cell crisis. Filgrastim is a pregnancy category C drug and should be used with caution.

Adverse Effects

Determining the adverse effects of filgrastim in patients receiving chemotherapy is difficult because all of the effects recorded during clinical trials with the drug can also be consequences of the malignancy or the cytotoxic chemotherapy. In other words, adverse effects may mimic the disease being treated or the effects of other treatments for the disease. Medullary bone pain (pain within the marrow) is the only consistently observed adverse effect that can be attributed to drug therapy; it is mild to moderate in severity and is reported in 56% of patients taking filgrastim (Quirion, 2009).

In patients receiving intensive chemotherapy or total-body irradiation followed by bone marrow transplantation, few unique adverse effects have been attributable to the G-CSF therapy.

In patients in whom filgrastim is used during collection of peripheral blood progenitor cells, adverse effects have included decreased platelet count (although it usually remains in the normal range), anemia, mild to moderate musculoskeletal symptoms, medullary bone pain, headache, and increases in alkaline phosphatase levels. Patients with severe chronic neutropenia have also experienced mild to moderate bone pain.

Drug Interactions

Drug interactions with filgrastim have not yet been fully evaluated. Drugs such as lithium carbonate that can potentiate the release of neutrophils should be used with caution because a synergistic effect may result; consequently, CBC levels should be taken more than twice per week during treatment. Because cytotoxic treatment may attack the proliferating cells effected by filgrastim, it should not be used concurrently with chemotherapy or during radiation treatment (Amgen Inc., 2007).

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient has nonmyeloid cancer, has neutropenic fevers or severe chronic neutropenia, has had a bone marrow transplantation, or is a candidate for peripheral blood progenitor cell collection, because these states are indications for the use of filgrastim.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding; caution is warranted in these patients because filgrastim is a pregnancy category C drug. Whether the drug is excreted in breast milk is unknown. Ask the patient's age. Filgrastim has been used in pediatric patients aged 4 months to 17 years, and no long-term risks have been identified. However, safety and efficacy in neonatal autoimmune neutropenia have not been established, and long-term effects of this agent have not been evaluated in neonates. Older adults with cancer are especially sensitive to adverse effects from neutropenia; the more severe and the longer the duration of the neutropenia, the more likely the older adult will develop a fatal infection. Neutropenia can also require that a lower dose of chemotherapy be given to older adults, thus making them less likely to receive the full therapeutic effect from chemotherapy. Prophylactic administration of filgrastim or pegfilgrastim (see below) to prevent febrile neutropenia is as effective for older adults as for younger adults in reducing the severity and duration of neutropenia. Administering filgrastim during the first cycle of chemotherapy may be especially valuable for older adults.

Environment

Determine the environment in which filgrastim is to be administered. IV infusions of filgrastim are administered in either a hospital or outpatient setting. SC injections may be administered in the hospital, in an outpatient center, or by the patient at home. Assess whether the patient will be able to return for daily injections or whether he or she has the ability to self-administer the drug. The drug should be kept refrigerated between 2°C and 8°C but not allowed to freeze. Assess whether there is a refrigerator at home if the patient is to self-administer the drug. The drug may be allowed to come to room temperature before administration and is stable at room temperature for up to 24 hours.

Nursing Diagnoses and Outcomes

- Risk for Altered Body Temperature related to neutropenia
  Desired outcome: *Febrile neutropenia will be avoided while receiving filgrastim.*
- Risk for Caregiver Role Strain related to need to bring patient daily to clinic for treatment with filgrastim
  Desired outcome: *Caregiver role strain will not develop.*
- Risk for Infection related to neutropenia
  Desired outcome: *The patient will not develop an infection while receiving filgrastim.*

- Risk for Pain, Medullary Bone, related to adverse effect of filgrastim
  Desired outcome: *Bone pain will not develop or will not be unmanageable if it develops while the patient is taking filgrastim.*
- Management of Individual, Effective Therapeutic Regimen, as evidenced by using correct technique daily to administer filgrastim subcutaneously and returning for all follow-up appointments
  Desired outcome: *Patient will be adept at self-administering filgrastim before discharge home and will be able to demonstrate technique when he or she returns for first follow-up appointment.*

Planning and Intervention

Maximizing Therapeutic Effects

To achieve the maximum therapeutic effect from the filgrastim, take the following actions:

- Keep it refrigerated. Allow the drug to reach room temperature before administering it.
- If giving the drug intravenously, dilute it in 5% dextrose solution with albumin added, to prevent absorption by plastic materials.
- Do not dilute the drug in saline, because it may precipitate.
- Avoid shaking the drug, which can damage the protein.
- Administer filgrastim with the first cycle of chemotherapy for those at high risk for febrile neutropenia, including older adults.
- Administer filgrastim within 24 hours of the completion of chemotherapy.

Minimizing Adverse Effects

To prevent adverse effects, be careful not to decrease the dose prematurely (before the expected neutrophil nadir, or lowest point, is expected). Additionally, discard any vial that has been at room temperature for more than 24 hours, use only one dose per vial, and never re-enter a used vial. Because filgrastim is preservative free, these actions guard against bacterial growth. If the absolute neutrophil count remains above 1,000/mm^3 for 3 consecutive days, discontinue filgrastim to prevent excessively high neutrophil counts. Patients should be monitored with biweekly CBCs during treatment because the increased blood viscosity caused by overproduction of white blood cells can lead to acute respiratory distress or sickle-cell crisis (Quirion, 2009).

Providing Patient and Family Education

Patients with neutropenia are at increased risk for contracting an infection. When providing patient education, instruct the patient and those in contact with the patient to wash their hands frequently, avoid crowds, and avoid people with illnesses (Box 33.2).

Ongoing Assessment and Evaluation

Monitor the patient's temperature closely (at least daily) throughout therapy for fever indicating infection. Monitor the WBC count throughout filgrastim therapy, two to three times per week. The WBC count should rise and return to a normal level but should not become unduly elevated. If patients must use drugs that potentiate neutrophil release, monitoring the WBC is especially important, because a synergistic effect may occur. Once the absolute neutrophil count remains above 1,000/mm^3 for 3 consecutive days, discontinue filgrastim. The other components of a complete blood count (CBC) should also be monitored to detect any adverse effects from filgrastim. Filgrastim therapy is effective when infection is avoided (or is minimal if it occurs) and the WBC count rises to a normal level.

BOX 33.2 COMMUNITY BASED CONCERNS

Keeping Neutropenic Patients Infection Free

Patients who are neutropenic are at increased risk if they contract an infection, because they cannot defend themselves against the infecting organism. The infection may become severe or even life threatening. This is true for even "common" infections, which most people can overcome fairly easily on their own. Patients who are immunocompromised by either disease or drug therapy should be taught how to minimize their risk of becoming sick with an infection, as follows:

- Wash hands frequently. Family members and others in the household should also wash their hands frequently.
- Avoid people with acute illnesses.
- Avoid going out in crowds, especially during cold and flu season. This precaution would include such places as malls, movie theaters, and worship services.
- Handle food safely. Cook meats to an appropriately high temperature to kill bacteria. Clean thoroughly all surfaces that have come into contact with raw food products. Refrigerate leftover food as soon as possible.

Drugs Closely Related to P Filgrastim

Pegfilgrastim

Pegfilgrastim (Neulasta) is produced by recombinant DNA technology. Like filgrastim, pegfilgrastim is used in myelosuppressive chemotherapy to decrease the incidence of infection manifested as febrile neutropenia in patients who have nonmyeloid cancer and are receiving chemotherapy that suppresses the WBC count. However, unlike the prototype, it should not be used for peripheral blood progenitor cell mobilization. Pegfilgrastim is filgrastim that has been chemically altered by attaching a polyethylene glycol molecule to the filgrastim molecule. Although this change in molecular size does not alter the way the drug acts to increase the WBC count, it does have substantial effects on the pharmacokinetics and thus on the dosing of the drug. Pegfilgrastim, unlike filgrastim, has poor renal excretion. Its sole mechanism of elimination is related to binding on receptors of neutrophils (Quirion, 2009). When mature neutrophil counts remain low (as a result of myelosuppression from chemotherapy), unbound, circulating levels of pegfilgrastim remain high, stimulating more neutrophil development. Once the mature

MEMORY CHIP

P Filgrastim

- Used in patients with cancer to increase their neutrophil counts and to support stem cell harvest
- A DNA recombinant granulocyte colony-stimulating factor (G-CSF) that stimulates white blood cell development just as endogenous G-CSF does
- Administered by IV infusion or daily SC injections
- Most common adverse effect: medullary bone pain; nausea and vomiting
- Most serious adverse effects: none
- **Life span alert: Older adults are more at risk from complications with neutropenia; prophylactic use of G-CSF is usually appropriate.**
- **Patient safety alert: Patients have a high risk of infection until neutropenia is corrected.**
- Maximizing therapeutic effects: Do not dilute in saline use D5W; avoid shaking; do not use 24 hours pre- or post-chemotherapy; administer with the first cycle of chemotherapy in those at high risk for febrile neutropenia, including older adults.
- Minimizing adverse effects: Do not decrease the dose before the expected neutrophil nadir; keep refrigerated and use aseptic technique to minimize risk of bacterial growth.
- Most important patient education: how to decrease risk of infection

neutrophil cell count has increased sufficiently, receptors are present to enable binding and elimination of the pegfilgrastim. The elimination half-life of pegfilgrastim is much longer than for filgrastim: 15 to 80 hours instead of 3.5 hours. The advantage of this pharmacokinetic difference is that pegfilgrastim has to be given only once per chemotherapy cycle, instead of daily. Although the current labeling of pegfilgrastim states not to administer the drug between 14 days prior to and 24 hours after the administration of chemotherapy, one study showed that pegfilgrastim could be safely given simultaneously with chemotherapy in weekly chemotherapy schedules (Lokich, 2005). This difference may increase patients' adherence to therapy because they do not need to return daily for injections as they do with filgrastim. Patients may also prefer this therapy because they receive fewer injections.

Effectiveness, contraindications, precautions, drug interactions, and adverse effects of pegfilgrastim are similar to those of filgrastim. Pegfilgrastim, which is administered subcutaneously, comes in prefilled syringes that should be protected from light. Although it is kept refrigerated, it should be allowed to come to room temperature before administration. Like filgrastim, it should not be shaken. Because the solution is preservative free, only one injection should be administered per syringe; any remaining medication should be discarded. Pegfilgrastim should not be administered to patients weighing less than 45 kg (Quirion, 2009).

As with filgrastim, the patient's CBC with differential must be monitored after pegfilgrastim therapy. However, because patients are not seen as frequently when they receive pegfilgrastim as when they receive filgrastim, it is especially important that they are taught the signs of infection and know when to contact the clinic or the prescriber.

Sargramostim

Sargramostim (Leukine), a granulocyte-macrophage colony-stimulating factor (GM-CSF), is produced by recombinant DNA technology in a yeast expression system. This 127-amino-acid glycoprotein has an amino acid sequence that differs from the natural human GM-CSF by substitution of leucine at position 23; the carbohydrate portion may also be different than in the native protein. Unlike G-CSF (filgrastim), which induces production only of granulocytes, specifically neutrophils, GM-CSF induces partially committed progenitor cells to divide and differentiate into the granulocyte and the macrophage pathways. Sargramostim increases the cytotoxicity of monocytes toward certain neoplastic cell lines and activates neutrophils to inhibit the growth of pathogens or tumor cells.

Sargramostim is used to treat patients with non-Hodgkin lymphoma, acute lymphoblastic leukemia, and Hodgkin disease who are undergoing autologous bone marrow transplantation (transplantation of their own bone marrow that was previously collected). It accelerates myeloid recovery in these patients. Sargramostim is also used in bone marrow transplant failure or when engraftment delays occur. It can be used after the induction of chemotherapy in older adults with acute myelogenous leukemia to shorten their neutrophil recovery time and reduce severe, life-threatening infections. Sargramostim can also be used to mobilize the hematopoietic progenitor cells into the peripheral circulation, where they can be collected by leukapheresis. The additional progenitor cells are later returned after chemotherapy, enabling more rapid engraftment and decreasing the need for supportive care. The drug is administered after collection and transplantation of peripheral blood progenitors, to rapidly increase monocyte production. Sargramostim is also used after allogenic (from a matched donor) bone marrow transplantation to accelerate the myeloid recovery.

Unlabeled uses of sargramostim include increasing WBC counts in patients with myelodysplastic syndromes and in patients with AIDS who are receiving zidovudine; limiting the duration of leukopenia secondary to myelosuppressive chemotherapy and decreasing myelosuppression in preleukemic patients; correcting neutropenia in aplastic anemia; and decreasing transplantation-associated organ system damage, particularly liver and kidney disease (neutropenia correlates with organ system injury). Sargramostim is administered by IV infusion for most applications. It may be given subcutaneously when used after peripheral blood progenitor cell transplantation.

Contraindications to sargramostim use include presence of excess leukemic myeloid blasts in the bone marrow or peripheral blood, known hypersensitivity to the drug, simultaneous administration of chemotherapy or radiotherapy, or administration of sargramostim 24 hours preceding or following chemotherapy or radiotherapy. Like filgrastim, sargramostim is a

pregnancy category C drug. Whether it is excreted into breast milk is unknown. It does not appear to produce any greater toxicity in children than in adults.

Although most of the adverse effects that occur with sargramostim can also be attributed to the disease process or the chemotherapy used to treat it, it is necessary to be alert for unique events that may occur with sargramostim. Bone pain can occur, as with filgrastim. Sargramostim should be administered in the evening to minimize this problem; administration of acetaminophen 20 to 30 minutes before injection is also helpful. Site reactions are possible. Special attention to injection technique, as recommended by Buchsel and colleagues (2002), minimizes site pain. These steps include:

- Allowing enough time for the drug to come to room temperature before administration
- Choosing a short (⅝-inch), fine-gauge (25–27) needle
- Icing the injection site before and after injection
- Avoiding pinching the skin if possible
- Injecting no more than 2 mL into any injection site
- Injecting the medication slowly into the SC space, avoiding IM injections
- Not rubbing after injection
- Rotating injection sites among the upper arms, abdomen, and thighs

Occasional transient supraventricular arrhythmias may occur during administration of sargramostim, especially if the patient has a history of cardiac arrhythmias. These arrhythmias are reversible when the drug is discontinued. Trapping of granulocytes in the pulmonary circulation has occurred following sargramostim infusion, sometimes producing dyspnea. The recommended treatment for patients who become dyspneic is to reduce the rate of infusion by half. In patients with pre-existing pleural and pericardial effusions, sargramostim may aggravate fluid retention. This condition is usually reversible with dose interruption or reduction, although occasionally a diuretic is needed.

A first-dose effect has occurred rarely following the first dose of sargramostim. In this syndrome, respiratory distress, hypoxia, flushing, hypotension, syncope, or tachycardia occurs. The patient should be monitored for these problems for the first 20 minutes after the first injection, and the first dose should be administered in a clinical setting where the patient can be observed. The syndrome should be treated by stopping the infusion and treating the patient according to symptoms. Oxygen, methylprednisone, and diphenhydramine may be indicated. When symptoms have resolved, the infusion is resumed at half the rate. These effects do not usually happen again with future doses.

Excessively high WBC counts have sometimes rapidly occurred with sargramostim therapy (absolute neutrophil count [ANC] above 20,000 cells/mm^3 or platelet count above 500,000/mm^3). If this effect occurs, the dose should be reduced or temporarily stopped.

In some patients with pre-existing renal or hepatic dysfunction, sargramostim has induced elevation of serum creatinine or bilirubin and hepatic enzymes.

INTERLEUKINS

Unlike other interleukins, oprelvekin (Neumega)—also known as interleukin-11—primarily alters hematopoietic activity and stimulates the production of platelets. Other interleukins are presented in Chapter 54. Interleukin-11, the sole drug in this class, is by necessity also the prototype.

Nursing Management of the Patient Receiving P Oprelvekin

Core Drug Knowledge

Pharmacotherapeutics

Oprelvekin is used to prevent severe thrombocytopenia and to reduce the need for platelet transfusions following myelosuppressive chemotherapy in adult patients with nonmyeloid malignancies who are at high risk for severe thrombocytopenia. It is administered as an SC dose once daily.

Pharmacokinetics

The peak serum level of oprelvekin is reached 3.2 hours after it is given subcutaneously. Although the drug is thought to be metabolized, the exact mechanism is not known. It is eliminated by the kidney.

Pharmacodynamics

Oprelvekin is produced in *E. coli* by recombinant DNA technology. The resultant polypeptide is 177 amino acids long and differs from the 178-amino-acid length of endogenous interleukin-11 by a missing amino-terminal proline residue. Bone-forming and bone-resorbing cells are potential targets of interleukin-11. Its primary hematopoietic activity is to directly stimulate the production of megakaryocyte progenitor cells and thrombopoietin. This action stimulates production of platelets that are structurally and functionally the same as those platelets produced by endogenous interleukin-11. Platelet counts begin to rise 5 to 9 days after starting drug therapy with oprelvekin. When treatment with oprelvekin is stopped, platelet levels continue to rise for about 7 days; they fall toward baseline in about 14 days.

Contraindications and Precautions

Oprelvekin is contraindicated only if the patient has hypersensitivity to the drug or any of its components. Caution should be used if oprelvekin is used in patients with preexisting cardiomyopathy or CHF, because fluid retention is a common effect of therapy. Use caution if the patient has a history of atrial arrhythmia, which may increase the risk of developing an atrial arrhythmia from oprelvekin use. Do not use this drug with or immediately following cytotoxic chemotherapy. Oprelvekin is a pregnancy category C drug and has caused increased rates of fetal death in animal studies.

Adverse Effects

Nausea and vomiting are the most common adverse effects from oprelvekin, occurring in about 77% of patients. Fluid retention with weight gain is the next most common adverse effect, occurring in 59% of patients; this is a potentially very serious adverse effect. This condition may be evidenced by peripheral edema, dyspnea on exertion, an increase in pleural effusion (if effusion was present before therapy), pulmonary edema, and decreases of about 10% to 15% in hemoglobin concentration, hematocrit, and RBCs (dilutional anemia caused by an increase in plasma volume). The cardiovascular adverse effects of oprelvekin may also be related to fluid retention (tachycardia, vasodilation, palpitations, syncope, and atrial fibrillation and flutter). Other fairly common adverse effects include headache, fatigue, dizziness, rash, bone pain, and febrile neutropenia. Transient, mild blurred vision, conjunctival fluid, and papilledema have been reported. Papilledema, conjunctival fluid, and tachycardia are more common when oprelvekin is administered to children; the drug is not approved for use in children Anaphylaxis is possible, although not common.

Drug Interactions

There are no known drug interactions with oprelvekin.

Assessment of Relevant Core Patient Variables

Health Status

Assess for CHF, pleural or pericardial effusion, or susceptibility to developing CHF, because fluid retention is possible from oprelvekin. Also assess for a history of atrial fibrillation or flutter, other cardiac disorders, or cardiac medications, because these factors may increase the risk of atrial arrhythmia during drug therapy. Determine that at least 6 hours have elapsed after the completion of chemotherapy before starting oprelvekin. The patient should not have received myeloablative therapy (therapy in which myelocytes are destroyed), because this therapy is not an indication for oprelvekin use.

Life Span and Gender

Determine whether the patient is pregnant, because oprelvekin is a pregnancy category C drug. Ask the patient's age and whether she is breast-feeding. Whether oprelvekin crosses into breast milk is unknown, and the safety and efficacy for children under 12 years of age also are not known. Older adults may be more likely to develop atrial arrhythmias while taking oprelvekin.

Lifestyle, Diet, and Habits

Assess for poor potassium intake, as hypokalemia may increase the risk of atrial arrhythmias.

Environment

Find out whether refrigeration is available for storing oprelvekin. Oprelvekin must be kept refrigerated because neither it nor its diluent contains preservatives. The drug is also sensitive to light and must be stored accordingly.

Nursing Diagnoses and Outcomes

- Risk for Injury related to bleeding secondary to low platelet counts
  Desired outcome: *Injury will not occur while treating low platelet counts with oprelvekin.*
- Risk for Fluid Volume Excess related to adverse effects of oprelvekin
  Desired outcome: *Retention of fluid will not occur or will be controllable while on oprelvekin therapy.*
- Risk for Infection related to lack of medical asepsis in storage, preparation, and administration of subcutaneous oprelvekin
  Desired outcome: *The patient will remain free of infection.*
- Risk for Caregiver Role Strain related to the need to bring patient daily to clinic for treatment with oprelvekin
  Desired outcome: *Caregiver role strain will not occur.*

Planning and Intervention

Maximizing Therapeutic Effects

Store the powdered drug and the diluent in the refrigerator but do not freeze it. Keep the drug out of direct light. Reconstitute oprelvekin with the sterile water for injection (without preservative) that is provided with the medication. When injecting the sterile water into the vial, direct the spray of fluid toward the glass wall. To prevent excessive agitation, do not aim it directly into the powdered drug. Do not shake or excessively agitate the vial, which can denature the protein. To fully reconstitute the powder, gently swirl the vial.

Administration of oprelvekin should begin 6 to 24 hours after chemotherapy is completed. Continue until the post-nadir platelet count is greater than or equal to 50,000 cells/mm^3. Clinical trials showed the need to dose for 10 to 21 days; the effect of giving oprelvekin for more than 21 days is not known. Discontinue oprelvekin treatment at least 2 days before starting the next round of chemotherapy.

Minimizing Adverse Effects

Because neither oprelvekin nor the sterile water used to dilute it contains preservatives, take care to maintain aseptic technique when reconstituting and drawing up the medication. Do not re-enter or reuse the single-dose vial. Be certain to use the reconstituted drug within 3 hours of reconstitution.

Monitor fluid intake and output carefully. Diuretics may be indicated if the patient is experiencing fluid retention from oprelvekin therapy.

Providing Patient and Family Education

If the patient will self-administer at home, teach the patient how to administer the drug safely and correctly into the subcutaneous tissue. Patient education should emphasize the importance of telling the physician or nurse when fluid retention occurs and should also emphasize the need to avoid activities that may cause bleeding until platelet counts are in the normal range.

MEMORY CHIP

P Oprelvekin (Interleukin-11)

- Used to prevent severe thrombocytopenia in cancer patients
- A recombinant DNA polypeptide that stimulates production of platelets in the same way that endogenous interleukin-11 does
- Administered daily by SC injection
- Major contraindication: Do not use with or immediately following cytotoxic chemotherapy.
- Most common adverse effects: nausea and vomiting, fluid retention, febrile neutropenia
- Most serious adverse effects: CHF or pulmonary edema from fluid retention; atrial arrhythmias
- **Life span alert: Older adults may be more likely to develop atrial arrhythmias.**
- Maximizing therapeutic effects: Do not shake or excessively agitate the vial; begin administration 6 to 24 hours after the completion of chemotherapy; continue until the postnadir platelet count is greater than or equal to 50,000 cells/mm^3; discontinue 2 days prior to next chemotherapy.
- Minimizing adverse effects: Monitor fluid intake and output; maintain aseptic technique.
- Most important patient education: Contact prescriber if fluid retention occurs; avoid activities that increase risk for bleeding.

Ongoing Assessment and Evaluation

Monitor the patient's platelet count throughout oprelvekin therapy. Continue with therapy until the post-nadir platelet count is greater than or equal to 50,000 cells/mm^3. Also, monitor the other components of the CBC to detect any adverse effects. Until the platelet count is adequate, monitor the patient for bleeding. Therapy with oprelvekin is effective if the platelet count rises to normal and severe bleeding is prevented.

CHAPTER SUMMARY

- The immune system is a complex system of cells and chemical mediators that prevents foreign pathogens or cells from invading the body.
- The mature blood cells differ in structure and function, but all develop from a common progenitor cell, or stem cell, from within the bone marrow.
- Blood cell components may be altered because of pathophysiology or drug therapy to treat a disease process.
- Drugs that stimulate the immune system to produce blood cells are hematopoietic growth factors. Drugs that stimulate production of RBCs are erythropoietics, those that produce WBCs are colony-stimulating factors, and those that increase platelets include a special interleukin. These drugs perform the same function as their endogenous counterparts.
- Recombinant human erythropoietin, also known as epoetin alfa, is used to treat anemias that result from decreased production of RBCs (erythropoiesis). Tissue oxygenation cannot occur optimally with anemia. Anemia is common in chronic kidney disease, in CHF, and after some types of drug therapy.
- Iron is also needed to form RBCs. Epoetin alfa therapy that is not effective or has a diminished effect is likely attributable to iron deficiency, which may be absolute or functional. Most patients who receive epoetin alfa therapy need iron supplementation at some time for RBCs to be produced.
- The colony-stimulating factors are the granulocyte colony-stimulating factors (G-CSF) and the granulocyte-macrophage colony-stimulating factors (GM-CSF). They stimulate WBC production. Neutropenia and other suppression of the WBC count frequently occur after chemotherapy and use of some other types of drugs. Low WBC counts, especially low neutrophil counts, place the patient at increased risk for contracting an infection.
- Unlike other interleukins, interleukin-11 (oprelvekin) has hematopoietic properties and stimulates the production of platelets. Without an adequate number of platelets, proper blood clotting cannot take place. The patient is at risk for excessive bleeding (internal or external).
- Drugs that promote production of blood cells should not be given at the same time as chemotherapy because the rapidly producing cells are likely to be killed by the drug therapy.

QUESTIONS FOR STUDY AND REVIEW

1. What are the principal polypeptides and glycoproteins involved in hematopoiesis?
2. Why are people with chronic kidney disease anemic?
3. What is the major risk to people who are neutropenic after chemotherapy?
4. How are platelets produced?
5. Why do patients with CHF require close monitoring of their intake and output of fluids when they are started on oprelvekin?
6. Your patient has CHF and chronic kidney disease and is receiving epoetin alfa. Why should the target range for hemoglobin be set lower than what is usually considered "normal"?

UNIT 8
Respiratory System Drugs

34

Drugs Affecting the Upper Respiratory System

Learning Objectives

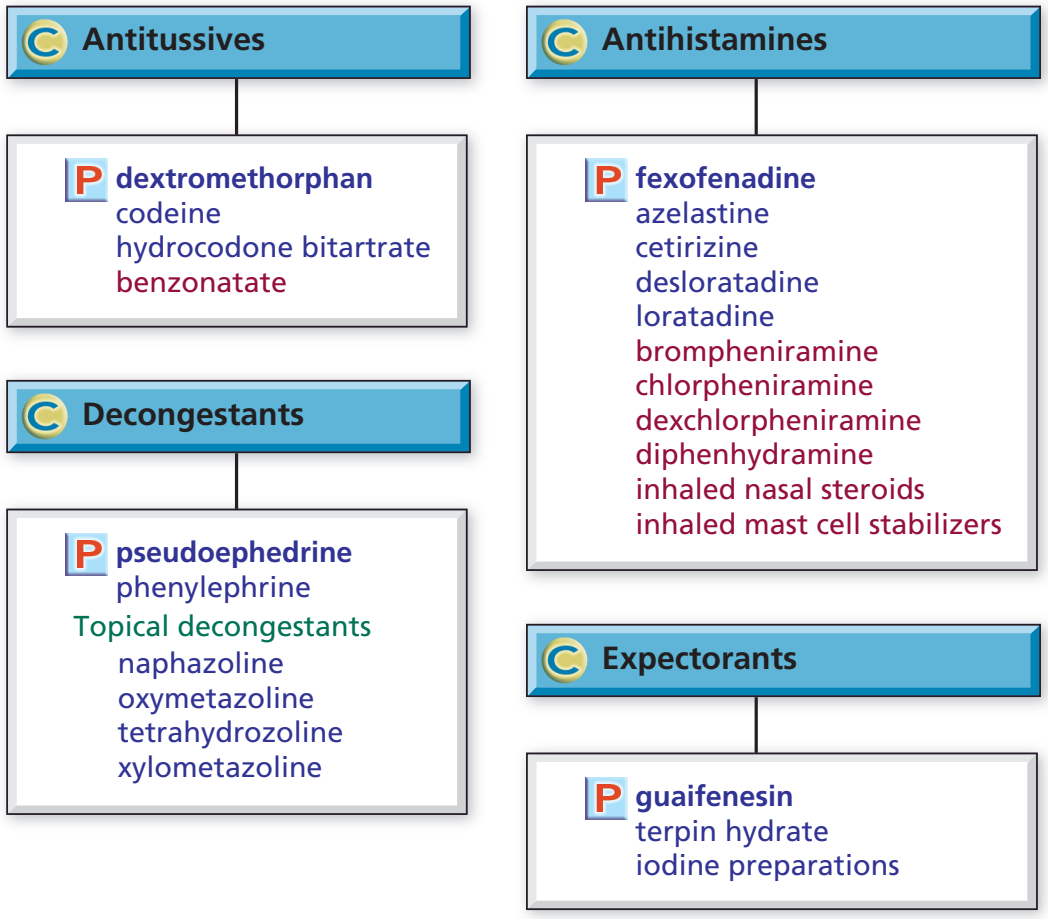
At the completion of this chapter the student will:

1. Describe the anatomy and physiology of the upper respiratory system.
2. Identify core drug knowledge pertaining to drugs that affect the upper respiratory system.
3. Identify core patient variables pertaining to drugs that affect the upper respiratory system.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that affect the upper respiratory system.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect the upper respiratory system.
6. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect the upper respiratory system.
7. Determine key points for patient and family education for drugs that affect the upper respiratory system.

Key Terms

angioedema
antihistamines
antitussives
common cold
decongestants
expectorants
enantiomer
histamine
influenza
laryngitis
pharyngitis
rebound congestion
rhinitis
sinusitis
urticaria

Drugs Affecting the Upper Respiratory System



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

This chapter discusses drugs that affect the upper respiratory system. The upper respiratory system is essential for bringing oxygen into the body and body tissues. The classes of drugs that affect the upper respiratory system work to keep the airways open. The following drug classes are discussed in this chapter:

- **Antitussives**—drugs that block the cough reflex
- **Decongestants**—drugs that decrease the blood flow to an area and thus decrease overproduction of secretions
- **Antihistamines**—drugs that block the release or action of **histamine,** a chemical released during inflammation, which increases secretions and narrows airways
- **Expectorants**—drugs that increase productive cough to clear the airways

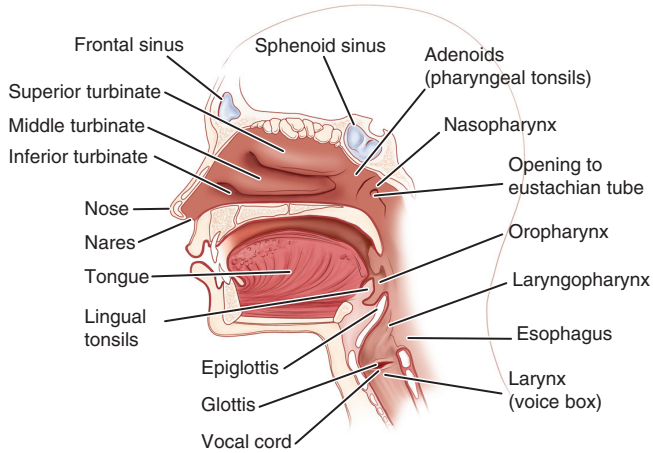
PHYSIOLOGY

The respiratory system is composed of the upper and lower respiratory systems. The upper respiratory system, or conducting airway, is composed of the nose, mouth, pharynx, larynx, trachea, and the bronchial tree (Figure 34.1). Air moves from the nasal cavity through the pharynx and into the larynx. The larynx contains the vocal chords and the epiglottis, the latter of which closes during swallowing to protect the lower respiratory tract from any foreign particles. From the larynx, air proceeds to the trachea, the main conducting airway into the lungs.

Air Filtration

Air usually moves into the nasal cavity through the nose. Nasal hairs catch and filter foreign substances, and the air is warmed and humidified as it passes by blood vessels close to the surface of the epithelial lining in the nasal passage. This epithelial lining contains goblet cells that produce mucus, which traps dust, microorganisms, pollen, and other foreign substances. These actions help purify the air and increase the efficiency of gas diffusion when the air reaches the lower respiratory tract.

The cells of the epithelial lining also contain cilia, microscopic hair-like projections of the cell membrane. The cilia are in constant motion, moving the mucus and any trapped substances toward the throat, where they are swallowed and destroyed. Three pairs of sinuses (air-filled passages through the skull) open into the nasal passage. The epithelial lining of the nose is continuous with the lining of the sinuses, and the mucus produced in the sinuses drains into the nasal cavity. The mucus drains into the throat, is swallowed, and proceeds to the gastrointestinal (GI) tract, where foreign materials are destroyed by the stomach acids.



• FIGURE 34.1 Structures of the upper airway.

Other Air-Purifying Mechanisms

The walls of the nasal cavity are sensitive to irritation. When receptors in these walls are stimulated, a central nervous system (CNS) reflex is initiated, and a sneeze results. The sneeze causes air to push through the nasal cavity under tremendous pressure, cleaning out any foreign irritant and opening the passages for more efficient flow of air. Throughout the airways, many macrophage scavengers are free to move throughout the epithelium and destroy invaders. Mast cells are present in abundance and release histamine, serotonin, adenosine triphosphate, and other chemicals to ensure a rapid and intense inflammatory reaction to any cell injury.

PATHOPHYSIOLOGY

The most common conditions that affect the upper respiratory system can be classified as inflammatory responses. For example, the rhinovirus and adenovirus are two types of common cold viruses that invade the tissues of the upper respiratory tract, initiating the release of histamine and prostaglandins and causing an inflammatory response.

Common Cold

The **common cold** is a viral infection that starts in the upper respiratory tract, sometimes spreads to the lower structures, and may contribute to secondary infections in the eyes or middle ears. The main differences between the common cold and other respiratory infections are the absence of fever and the relative mildness of the symptoms. Cold symptoms vary from person to person. Manifestations may include sneezing, headaches, fatigue, chills, sore throat, inflammation of the nose (**rhinitis**), and nasal discharge. Usually, there is no fever. The secretions are generally watery and clear. Pathologic changes occurring in the mucous membrane that lines the nose, the nasal sinuses, the nasopharynx, and other upper respiratory passages may include tissue swelling, congestion of blood, and oozing of fluids.

Allergic or Seasonal Rhinitis

A condition similar to the common cold that afflicts many people is called allergic or seasonal rhinitis. This inflammation

of the nasal cavity also is commonly called hay fever. It occurs when the upper airways respond to a specific allergen (e.g., pollen, mold, or dust) with a vigorous inflammatory response, resulting in nasal congestion, sneezing, stuffiness, and watery eyes. Other areas of the upper respiratory tract can become irritated or infected, resulting in inflammation.

Sinusitis

Sinusitis occurs when the epithelial lining of the sinus cavities becomes inflamed. It can be caused by bacteria or viruses. The resultant swelling often causes severe pain because the bony cavity cannot stretch and the swollen tissue pushes against the bone and blocks the sinus passages. The danger of a sinus infection is that if it is untreated, the causative microorganisms can move up the sinus passages and into brain tissue.

Pharyngitis

Pharyngitis is an inflammation or infection of the pharynx (throat) caused by bacteria or viruses. The symptoms of pharyngitis caused by bacteria are generally redness and swelling of the throat, a pustulant fluid on the tonsils or discharged from the mouth, extreme soreness of the throat that is felt during swallowing, swelling of lymph nodes, and a slight fever. Viral pharyngitis infections produce raised whitish to yellow lesions in the pharynx that are surrounded by reddened tissue. They also cause fever, headache, and sore throat that last for 4 to 14 days. Lymphatic tissue in the pharynx also may become involved.

Laryngitis

Laryngitis is an inflammation of the larynx or voice box, caused by chemical or mechanical irritation, viral infections, or bacterial infections. Simple laryngitis usually is associated with the common cold or similar infections. Usually, the mucous membrane lining the larynx is the primary site of infection; it becomes swollen and filled with blood, secretes a thick mucous substance, and contains many inflammatory cells.

When the epiglottis, which closes the larynx during swallowing, becomes swollen and infected by influenza viruses, the larynx can become obstructed, and suffocation may result. Excessive smoking, alcoholism, or overuse of the vocal cords may cause chronic laryngitis. The mucous membrane becomes dry and covered with polyps, small lumps of tissue that project from the surface. In addition, the wall of the larynx may thicken and become inflamed. Additional causes of laryngitis include diphtheria, tuberculosis, and syphilis—serious infections that require aggressive treatment.

Influenza

Influenza is an infection caused by any of several strains of myxoviruses, categorized as types A, B, and C. Influenza is transmitted from person to person through the respiratory tract by inhalation of infected droplets ejected by coughing and sneezing. As the virus particles gain entrance to the body, they selectively attack and destroy the ciliated epithelial cells that line the upper respiratory tract, bronchial tubes, and trachea. The onset of symptoms is abrupt, with sudden and distinct chills, fatigue, and high temperature. A diffuse headache and severe muscular aches throughout the body are experienced and often are accompanied by irritation or a sense of rawness in the throat. Symptoms associated with other respiratory tract infections, such as coughing and nasal discharge, also may occur.

C ANTITUSSIVE DRUGS

Antitussives are drugs that suppress the cough reflex. Many disorders of the upper and lower respiratory tracts, including the common cold, sinusitis, pharyngitis, and pneumonia, are accompanied by an uncomfortable, nonproductive cough. Coughing normally is a protective mechanism that forces foreign irritants out of the respiratory system, opening it for more efficient flow of air. However, persistent coughing can be exhausting, cause muscle strain, and further irritate the respiratory tract. A cough that occurs without an active disease process or that persists after treatment may be a symptom of another disease process and should be investigated before any drug is given to alleviate it. Antitussive drugs include dextromethorphan, codeine, and hydrocodone bitartrate. Dextromethorphan (Robitussin, PediaCare, Vicks 44, Benylin Pediatric) is selected as the prototype antitussive. Table 34.1 presents a summary of antitussive drugs.

Nursing Management of the Patient Receiving P Dextromethorphan

Core Drug Knowledge

Pharmacotherapeutics

Dextromethorphan is used in treating nonproductive cough. It is available widely in a variety of nonprescription forms, such as capsules, lozenges, syrups, extended-release oral suspension, and chewable tablets.

Pharmacokinetics

Dextromethorphan is absorbed rapidly from the GI tract, with antitussive activity occurring within 15 to 30 minutes. It undergoes extensive hepatic metabolism. Excretion is mainly renal, with some drug eliminated unchanged but most eliminated as metabolites.

Pharmacodynamics

Dextromethorphan is related chemically to the opiate agonists and can suppress coughing as effectively as narcotics. Cough suppression occurs by several mechanisms, but mainly the drug directly affects the cough center in the medulla. Therapeutic doses do not affect ciliary activity.

TABLE 34.1 Summary of Selected C Antitussives

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P dextromethorphan (Benylin, Delsym, Robitussin Maximum Strength Cough, Robitussin Cough Calmers, Sucrets Cough Control Formula, Vicks 44 Cough)	Cough suppression	*Adult and adolescent:* PO, regular-release formulation: 10–20 mg PO every 4 h; or 30 mg every 6–8 h; Max: 120 mg/d *Child 6–11 y:* PO, 5–10 mg every 4 h; or 15 mg every 6–8 h; Max: 60 mg/d *Child 2–5 y:* 2.5–5 mg every 4 h; or 7.5 mg every 6–8 h; Max: 30 mg/d *Child <2 y:* Safe and effective usage is not established. Extended-release formulation: *Adult and adolescent:* 10 mL every 12 h; Max: 20 mL/d *Child 6–11 y:* 5 mL every 12 h; Max: 10 mL/d *Child 2–5 y:* 2.5 mL every 12 h; Max: 5 mL/d *Child <2 y:* Safe and effective usage is not established.	*Onset:* 15–30 min *Duration:* 5–6 h $t_{1/2}$: 11 h
benzonatate (Tessalon Perles)	Cough suppression	*Adult and child >10 y:* PO, 100 mg 3∞/d or every 4 h; Max: 600 mg/day *Child <10 y:* Safe and effective usage is not established.	*Onset:* 15–20 min *Duration:* 3–8 h $t_{1/2}$: Unknown
codeine	Cough suppression	*Adult:* PO, 10–20 mg every 4–6 h; Max: 120 mg/24 h *Elderly:* May require reduced doses *Child 6–12 y:* 5–10 mg every 4–6 h; Max: 60 mg/d *Child 2–5 y:* 2.5–5 mg every 4–6 h; Max: 30 mg/d *Child and infant <2 y:* Safe dosage has not been established.	*Onset:* 15–20 min *Duration:* 4–6 h $t_{1/2}$: 1.5–4 h
hydrocodone bitartrate (Hycodan, Hydromet, Hydropane, Mycodone, Tussigon)	Cough suppression	*Adult:* PO, 5–10 mg every 4–6 h; Max single dose: 15 mg *Adolescent >12 y:* PO, 0.6 mg/kg/d in 3–4 divided doses; Max single dose: 10 mg *Child 2–11 y:* 0.6 mg/kg/d in 3–4 divided doses; Max single dose: 5 mg	*Onset:* 10–20 min *Duration:* 3–6 h $t_{1/2}$: 3–8 h

Contraindications and Precautions

Dextromethorphan is contraindicated for treating chronic coughs resulting from emphysema and asthma. Because of its extensive hepatic metabolism, dextromethorphan is used with caution in patients with hepatic impairment. It also is used with caution during pregnancy. Although teratogenic effects have not been demonstrated, dextromethorphan is in pregnancy category C.

Adverse Effects

Although adverse effects are generally rare, dextromethorphan toxicity can occur and is characterized by nausea and vomiting, drowsiness, dizziness, irritability, and restlessness. In excessive doses, dextromethorphan poisoning may occur and induce symptoms similar to those associated with phencyclidine (Box 34.1).

Drug Interactions

Dextromethorphan may potentiate sedation when used with other CNS depressants. It may interact with monoamine oxidase inhibitors (MAOIs), resulting in serotonin syndrome, a dangerous condition that consists of nausea, hypotension, excitation, hyperpyrexia, and possible coma. It also may interact with fluoxetine, quinidine, and sibutramine.Table 34.2 lists drugs that interact with dextromethorphan.

Box34.1 DEXTROMETHORPHAN POISONING

In excessive amounts, dextromethorphan (DMX) may induce euphoric, stimulant, and dissociative effects in children and adolescents. Neurobehavioral effects begin in as little as 30 minutes and can last up to 6 hours. In 2008, 5 teenage deaths were attributed to DMX poisoning.

	Dose	Effect
First Plateau	100–200 mg 1.5 mg/kg	Mild stimulation
Second Plateau	200–400 mg 2.5–7.5 mg/kg	Euphoria and hallucinations
Third Plateau	300–600 mg 7.5–15 mg/kg	Dissociate state
Fourth Plateau	> 600 mg >15 mg/kg	Complete dissociation with unresponsiveness

TABLE 34.2 Agents That Interact with P Dextromethorphan

Interactants	Effect and Significance	Nursing Management
juice: grapefruit, orange	Grapefruit and orange juice inhibit metabolism and intestinal efflux of dextromethorphan, resulting in increased risk of pharmacologic and adverse effects that last for several days.	Avoid administration of dextromethorphan with grapefruit or orange juice. Monitor for adverse effects.
monoamine oxidase inhibitors	Dextromethorphan can block neuronal uptake of serotonin and may produce serotonin syndrome.	Maintain interval of at least 2 wk between administration of these drugs.
Sibutramine	Coadministration of these agents may have additive serotonergic effects.	Avoid coadministration if possible. Monitor for CNS irritability, motor weakness, shivering, myoclonus, and altered consciousness. Ensure safety.

Assessment of Relevant Core Patient Variables

Health Status

Before administering dextromethorphan, review the patient's record to determine whether dextromethorphan may be administered safely. This drug is contraindicated for patients with emphysema or asthma. If coughing is suppressed in these patients, they may retain secretions that exacerbate their disease. It is also necessary to review the patient's record for drugs that may interact with dextromethorphan, especially antidepressants. Also, evaluate the patient for a history of hepatic insufficiency, because dextromethorphan is processed by the liver. Finally, perform a baseline evaluation of the head, eyes, ears, nose, and throat in addition to a complete lung assessment.

Life Span and Gender

Determine whether the patient is pregnant. Dextromethorphan, a pregnancy category C drug, should be used with caution during pregnancy. Dextromethorphan is not indicated for use in children younger than 2 years old. With adolescent patients, assess the potential for abuse. Dextromethorphan abuse is a growing problem in high schools.

Lifestyle, Diet, and Habits

Investigate the patient's need to drive or operate potentially dangerous equipment and advise the patient to refrain from these activities until the sedative effects of dextromethorphan use are known. It is important to assess the patient's typical intake of alcohol. Caution the patient about the potentially additive effects of dextromethorphan when used with alcohol, because both are CNS depressants. Assess the frequency of grapefruit or orange juice ingestion, because these juices can substantially increase the concentration of dextromethorphan.

Environment

Dextromethorphan is used commonly in over-the-counter (OTC) cough and cold preparations, and prescribed dextromethorphan is just as commonly self-administered by patients at home. Therefore, caution patients to read labels of all drugs they are taking to avoid a possible overdose.

Nursing Diagnoses and Outcomes

- Risk for Injury related to sensory-perceptual alteration from drug-induced drowsiness and sedation
  Desired outcome: *The patient will remain free from injury related to sedation and drowsiness.*
- Risk for Ineffective Airway Clearance related to suppression of cough reflex
  Desired outcome: *The patient will maintain his or her baseline respiratory function.*

Planning and Intervention

Maximizing Therapeutic Effects

In acute or long-term care settings, administer dextromethorphan at evenly spaced intervals to maintain blood levels of the drug at steady state. Provide environmental controls, including appropriate lighting, reduced noise, and comfortable temperature, to ease sensory-perceptual alteration and aid relaxation.

Minimizing Adverse Effects

During therapy, ensure that safety precautions are used, such as side rails and ambulation assistance. Assess respiratory status and movement of air periodically during drug use. Refrain from administering dextromethorphan with grapefruit or orange juice.

Providing Patient and Family Education

- Explain to patients and their families that taking dextromethorphan will help quiet a cough.
- Emphasize that sedation, drowsiness, and impaired orientation can occur. Because it can be sedating, tell patients to take dextromethorphan only as directed and not to drive or perform other tasks that require alertness. Some patients may require assistance walking if they react strongly to dextromethorphan.
- Explain to patients that they should not take dextromethorphan if they have ever had a reaction to it, are pregnant or breast-feeding, or have a history of liver problems.

- Caution patients who are taking certain antidepressants or drugs for obesity about the potential for serious drug–drug interactions.
- Alert patients not to take any OTC drugs or consume alcohol while taking dextromethorphan because doing so could increase sedation.
- Caution patients to keep dextromethorphan out of the reach of children.
- Tell patients to report immediately any chest tightness, difficulty breathing, noisy breathing, or shortness of breath. These symptoms may indicate that the drug is not working, or that a patient is having a reaction to the drug.
- Caution parents about the potential for abuse of dextromethorphan.

Ongoing Assessment and Evaluation

Monitor the effect of dextromethorphan on the patient's motor control, sedation, and respiratory status. By the end of therapy, the patient should remain free of injury related to sedation and have cough relief.

Drugs Closely Related to P Dextromethorphan

Codeine

Codeine is a controlled substance used in treating cough. Like dextromethorphan, it works directly on the medullary center to suppress the cough reflex. Codeine is more sedating than dextromethorphan and also may induce respiratory depression. It is contraindicated for patients who must cough to maintain a patent airway (e.g., postoperative patients). Codeine is used with caution in patients who are pregnant or breast-feeding and in patients with head injuries. It also is used cautiously in patients with chronic cough (e.g., that caused by emphysema or asthma) or in patients with a history of drug addiction. Adverse effects include sedation, dry mouth, nausea, vomiting, and constipation. Codeine also is discussed in Chapter 23.

MEMORY CHIP

P Dextromethorphan

- Used to manage nonproductive cough
- Major contraindication: cough resulting from emphysema or asthma
- Most common adverse effects: nausea, vomiting, and irritability
- Most serious adverse effects: drowsiness and dizziness
- Maximizing therapeutic effects: Administer at evenly spaced intervals throughout the day.
- Minimizing adverse effects: Institute precautions to ensure safety during potential drowsiness or dizziness.
- Most important patient education: Advise the patient to seek medical attention if cough does not resolve.

Hydrocodone Bitartrate

Hydrocodone bitartrate (Hycodan), also a controlled substance, is a derivative of codeine and acts directly on the cough reflex center in the medulla. It is combined with homatropine methylbromide. Hydrocodone is more sedating than codeine and has the same properties, contraindications, and adverse effects.

Drug Significantly Different From P Dextromethorphan

Benzonatate

Benzonatate (Tessalon, Tessalon Perles) is an oral nonnarcotic antitussive agent that is rarely used because it is not as effective as other antitussives. Benzonatate works by anesthetizing the stretch receptors in the respiratory tract, lung tissue, and pleura, interfering with their activity, and thereby reducing the cough reflex. At normal doses, it does not affect the respiratory center.

Benzonatate is used to coat the oropharynx to depress the gag reflex before intubation or endoscopy. The "Perles" are also topically applied to discrete areas of the body, such as a defined lesion or abnormality, before magnetic resonance imaging, because they show up as "markers" for more accurate mapping and measurement. Of course, neither of these uses is approved by the Food and Drug Administration.

C DECONGESTANT DRUGS

Decongestants are drugs taken to decrease nasal congestion related to the common cold, sinusitis, and allergic rhinitis, a condition that is caused by an inflammatory response in the upper respiratory tract. Nasal decongestants work by constricting the nasal arterioles, thereby decreasing the swelling of the nasal membrane. These drugs can be administered orally or topically. When decongestants are taken orally, they are absorbed in the body, thus increasing the chance of adverse effects. When used topically, the drug has the same therapeutic effects; however, the potential for adverse effects is diminished.

Many of the decongestants have abuse potential. Several OTC decongestant drugs have been used to make methamphetamine. In 2006, the Combat Methamphetamine Abuse Act (Box 34.2) was signed into law. This act regulates the sale of pseudoephedrine, ephedrine, and phenylpropanolamine. Although ephedrine and phenylpropanolamine have been removed from the market, pseudoephedrine is still the active ingredient in a number of OTC cough and cold medications.

Pseudoephedrine, which is discussed as the prototype decongestant, is most frequently known by the trade name Sudafed. In accordance with the Combat Methamphetamine Abuse Act, Sudafed and any combination drugs that contain pseudoephedrine have been removed from the shelves of drug stores, *but they have not been taken off the market*

Box34.2 COMBAT METHAMPHETAMINE ACT

The Combat Methamphetamine Act stipulates that merchants who sell pseudoephedrine must:

- Keep a retrievable record of all purchases, identifying the name and address of each party, for two years.
- Require verification of proof of identity of all purchasers.
- Use protection and disclosure methods in the collection of personal information.
- Report to the Attorney General any suspicious payments or disappearances of the regulated products.
- Sell the nonliquid dose form of regulated product only in unit-dose blister packs.
- Sell regulated products behind the counter or in a locked cabinet in such a way as to restrict access.
- Have daily sales of regulated products not exceed 3.6 g, without regard to the number of transactions.
- Have monthly sales not exceed 9 g of pseudoephedrine base in regulated products.
- With mail order purchases, have monthly sales that do not exceed 7.5 g

(Table 34.3). Consumers must purchase drugs containing pseudoephedrine from a pharmacy, despite the fact the drugs do not require a prescription. The amount of pseudoephedrine that may be purchased is regulated by this act, so the medication is kept behind the pharmacy counter. Sudafed PE is the drug on the shelves of drug stores, supermarkets, and other consumer stores. It is not regulated because it does not contain pseudoephedrine. Table 34.4 presents a summary of decongestant drugs.

TABLE 34.3 Over-The-Counter Drugs Available From the Pharmacy

Active Ingredient(s)	Trade Name	Dosage
Pseudoephedrine	Sudafed	pseudoephedrine, 30 mg
pseudoephedrine ER, naproxen	Aleve Cold and Sinus	pseudoephedrine ER, 120 mg naproxen, 220 mg
pseudoephedrine, loratadine	Claritin-D 12-hour Claritin-D 24-h	pseudoephedrine, 120 mg loratadine, 5 mg pseudoephedrine, 240 mg loratadine, 10 mg
pseudoephedrine, chlorpheniramine, Acetaminophen	Coricidin-D	pseudoephedrine, 30 mg chlorpheniramine, 2 mg acetaminophen, 325 mg
pseudoephedrine,	Drixoral	pseudoephedrine, 60 mg dexbrompheniramine, dexbrompheniramine, 3 mg acetaminophen acetaminophen, 500 mg
pseudoephedrine, guaifenesin	Mucinex-D	pseudoephedrine, 30 mg guaifenesin, 600 mg

Nursing Management of the Patient Receiving P Pseudoephedrine

Core Drug Knowledge

Pharmacotherapeutics

Pseudoephedrine can reduce the volume of nasal mucus and is recommended for the temporary relief of nasal congestion related to the common cold, allergic rhinitis, and sinusitis. It also is used to relieve the pressure of otitis media by promoting drainage of the eustachian tubes.

Pharmacokinetics

Pseudoephedrine is an oral drug readily absorbed from the GI tract, with onset of activity occurring within 30 minutes. Duration of action ranges from 4 to 6 hours, in regular formulations, to 8 to 12 hours in extended-release preparations Pseudoephedrine is metabolized by the liver and excreted in the urine. This drug also crosses the placenta and is secreted in breast milk.

Pharmacodynamics

Pseudoephedrine mimics the actions of the sympathetic nervous system and achieves its nasal decongestant effects by causing vasoconstriction in the nasal mucous membranes. This shrinkage decreases membrane size and promotes sinus drainage and improved airflow. Stimulation of other sympathetic receptors while the patient is taking pseudoephedrine can result in cardiovascular stimulation, constriction of renal arterioles, and anxiety.

Contraindications and Precautions

Pseudoephedrine is a pregnancy category C drug and should be used with caution during pregnancy or lactation because of its possible effects on the fetus and neonate. This drug should not be used by patients with severe hypertension and coronary artery disease for a prolonged period because it produces sympathomimetic effects such as increased heart rate and blood pressure. Special caution should be used in patients with diabetes, thyrotoxicosis, coronary artery disease, benign prostatic hypertrophy, and increased intraocular pressure because of the risk for sympathomimetic adverse effects, which could aggravate these conditions.

Adverse Effects

Adverse effects related to pseudoephedrine use are related primarily to its sympathomimetic effects on the CNS and cardiovascular systems. They occur almost immediately and include feelings of tension, anxiety, restlessness, tremor, insomnia, and weakness. Severe CNS reactions have included hallucinations, delusions, and convulsions. Adverse cardiovascular effects include palpitations, tachycardia, hypertension, and arrhythmias. Allergic reactions that have been reported with pseudoephedrine use include skin rashes and urticaria. Extreme dryness of the mucous membranes, resulting in pain and irritation, has been reported in some cases.

When sympathomimetic adverse effects occur, patients with diabetes, thyrotoxicosis, coronary artery disease,

TABLE 34.4 Summary of Selected C Decongestants

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Oral Decongestants			
P pseudoephedrine (Sudafed, PediaCare, Triaminic, Contac)	Nasal decongestion	*Adult and child >12 y:* PO, 60 mg q4–6 h *Child >6 y:* PO, 30 mg q4–6 h *Child <6 y:* PO, 15 mg q4–6 h Sustained release: *Adult and child >12 y:* PO, 120 mg q12 h *Child <12 y:* not recommended Controlled release: *Adult and Child >12 y:* PO, 240 mg q24 h *Child <12 y:* not recommended	*Onset:* 30 min *Duration:* 4–6 h $t_{1/2}$: 7 h
phenylephrine (Sudafed PE, Neo-Synephrine, Neofrin; *Canadian:* Dionephrine)	Nasal decongestion	*Adult and Child >12 y:* PO, 10–20 mg q4 h *Child >6 y:* PO, 10 mg q4 h	*Onset:* 5–10 min *Duration:* 3–4 h $t_{1/2}$: Unknown
Topical Decongestants			
naphazoline (Albalon, Nafazair, Naphcon-A, Opcon-A, Vasocon-A, Visine-A)	Nasal decongestion	Intranasal dosage (0.05% nasal spray): *Adult:* 1–2 sprays in each nostril q4–6 h as needed Intranasal dosage (0.05% nasal drops): *Adult:* 1–2 drops in each nostril q3 h as needed *Child:* not recommended	Minimal systemic absorption
oxymetazoline (Afrin 12 Hour Nasal, Dristan 12 Hr Nasal, Visine, Ocu-Clear plus many others)	Nasal decongestion	Nasal dosage: *Adult and Child >6 y:* 1–2 drops or sprays of 0.05% solution in each nostril 2∞/d or as required, but no more frequently than q6 h *Child <6 y:* not recommended	Minimal systemic absorption
phenylephrine (Neo-Synephrine)	Nasal decongestion	*Adult and Child >12 y:* 2–3 drops or 2–3 sprays of 0.25%–1% solution in each nostril q4 h as needed *Child 6–12 y:* 2–3 drops of 0.25% solution in each nostril q4 h as needed *Child <6 y:* not recommended	Minimal systemic absorption
tetrahydrozoline (Tyzine)	Nasal decongestion Occular erythema (Visine)	*Adult and Child ε 2 y:* 3–4 sprays of 0.1% nasal solution in each nostril q3 h *Child <6 y:* not recommended *Adult and Child >12 y:* 2–4 drops of 0.1% solution q3 h *Child <6 y:* 2–3 drops of 0.05% solution in each nostril q3 h	Minimal systemic absorption
xylometazoline (Otrivin)	Nasal decongestion	*Adult and Child >12 y:* 1–3 sprays of 0.1% solution in each nostril q8–10 h *Child 2–12 y:* 1 spray of 0.05% solution in each nostril q8–10 h *Adult and Child >12 y:* 2–3 drops of 0.1% solution in each nostril q8–10 h *Child 2–12 y:* 2–3 drops of 0.05% solution in each nostril q8–10 h	Minimal systemic absorption

hypertension, benign prostatic hypertrophy, or increased intraocular pressure should discontinue using pseudoephedrine. Patients without concurrent disease may continue taking the drug, unless the adverse effects create a safety problem.

Drug Interactions

Increased hypertension may occur if pseudoephedrine is taken concurrently with MAOIs, guanethidine, methyldopa, or furazolidone. Instruct the patient to avoid such combinations. The duration of pseudoephedrine's effect may increase if it is taken with any urinary alkalinizer (e.g., potassium citrate, sodium citrate, sodium lactate, tromethamine, sodium acetate, and sodium bicarbonate) because the drug cannot be excreted into alkaline urine. An increased dose of pseudoephedrine may be necessary when giving it with urinary acidifiers, such as ammonium chloride, potassium phosphate, or sodium acid phosphate. Table 34.5 lists drugs that interact with pseudoephedrine.

TABLE 34.5 Agents That Interact with P Pseudoephedrine

Interactants	Effect and Significance	Nursing Management
furazolidone	May increase the pressor sensitivity to mixed and indirect-acting sympathomimetics, such as pseudoephedrine, resulting in hypertension	Avoid coadministration. If used concurrently, monitor for hypertension. If hypertensive crisis results, consider the use of phentolamine.
Guanethidine	Depletes norepinephrine stores, resulting in hypertension	Use an alternative antihypertensive therapy.
monoamine oxidase inhibitors	Increase the amount of norepinephrine available for release by pseudoephedrine, resulting in severe headache, hypertension, and hyperpyrexia; hypertensive crisis possible	Avoid coadministration. If these are used together and hypertension develops, administer phentolamine.
methyldopa	Coadministration of methyldopa and pseudoephedrine may result in an increased pressor response, resulting in hypertension	Monitor the blood pressure during coadministration. Discontinue pseudoephedrine if hypertension occurs.
urinary acidifiers	Tubular reabsorption of pseudoephedrine possibly decreased due to a decreased urinary pH by urinary acidifiers	Monitor possible need for an increased dose of pseudoephedrine to achieve desired results. Acidification of the urine may be useful in the treatment of sympathomimetic intoxication.
urinary alkalinizers	Tubular reabsorption of pseudoephedrine possibly increased due to an increased urinary pH by urinary alkalinizers	Decrease the dose of pseudoephedrine during coadministration of a urinary alkalinizer.

Assessment of Relevant Core Patient Variables

Health Status

Review the patient's health history and perform a physical examination to determine any contraindications to the use of this drug. Contraindications include hypersensitivity to the drug, thyrotoxicosis, diabetes, hypertension, benign prostatic hypertrophy, cardiovascular disorders, pregnancy, and lactation.

Assess the patient's baseline orientation, affect, respiratory rate and sounds, blood pressure, and pulse.

Life Span and Gender

Be aware of the patient's age before administering pseudoephedrine. Pseudoephedrine must be given cautiously to elderly patients because they may experience more serious adverse effects than other patients. Avoid sustained-release preparations and use short-duration preparations in the elderly. Assess female patients for pregnancy. Pseudoephedrine is in pregnancy category C; pregnant women should avoid it unless the benefits outweigh the risks.

Lifestyle, Diet, and Habits

Assess the use of OTC medications. Pseudoephedrine is used in combination with many other agents, including antihistamines. Teach the patient to read ingredient labels carefully.

Environment

Pseudoephedrine is generally taken in the outpatient setting. Because it is an OTC medication and patients have easy access to the drug, caution them about overuse of pseudoephedrine and other decongestants. Frequent, long-term, or excessive use of decongestants induces rebound congestion. **Rebound congestion** occurs when the nasal passages become congested as the drug effect wears off and the body compensates by vasodilating the same nasal arterioles that the drug constricted. When rebound occurs, patients tend to use more of the drug to decrease the congestion, and a vicious cycle of congestion–drug use–congestion develops.

Nursing Diagnoses and Outcomes

- Risk for Injury caused by visual sensory-perceptual alterations (hallucinations) related to drug-induced CNS effects
  Desired outcome: *The patient will be protected from injury related to drug use and will demonstrate safety procedures to use if these effects occur.*
- Ineffective Tissue Perfusion: Cerebral or Cardiopulmonary, related to sympathomimetic effects
  Desired outcome: *The patient will be monitored and dosage adjusted to minimize potential perfusion deficits or CNS effects.*

Planning and Intervention

Maximizing Therapeutic Effects

In conjunction with pseudoephedrine therapy, encourage patients to use a humidifier, drink plenty of fluids, and avoid smoke-filled rooms, because dry air, dry mucous membranes, and airborne irritants may render the drug less effective.

Minimizing Adverse Effects

Provide the patient with appropriate safety measures, such as side rails, adequate lighting, and assistance with movement to avoid injury if CNS effects are experienced.

Providing Patient and Family Education

- Explain to patients that the purpose of pseudoephedrine is to promote breathing and relieve congestion.
- Tell patients not to take pseudoephedrine if they have ever had a reaction to it, have high blood pressure, or are breast-feeding. In addition, instruct patients to take the drug exactly as prescribed. Higher doses may cause nervousness, dizziness, chest pain, or sleeplessness.
- Tell patients not to take pseudoephedrine for more than 4 days. They should contact their health care providers to schedule an appointment if respiratory symptoms do not subside after 4 days.
- Caution patients to avoid using other OTC drugs, many of which also contain pseudoephedrine, because a serious overdose could occur.
- To avoid rebound congestion, teach patients strategies for decreasing the discomfort of nasal congestion and explain why excessive drug use should be avoided.
- Outline safety measures that may be necessary if CNS effects occur, such as getting assistance with ambulation, using adequate lighting, and avoiding driving or other tasks that require alertness.
- Urge patients to report excessive dizziness, weakness, palpitations, and sleeplessness, and to keep pseudoephedrine out of the reach of children.

Ongoing Assessment and Evaluation

Monitor patients receiving pseudoephedrine for rebound congestion, sedation, dizziness, weakness, tremor, urinary retention, and cardiovascular effects. By the end of therapy, the patient should be free from nasal congestion and free from potential CNS or cardiovascular adverse effects.

Drugs Closely Related to P Pseudoephedrine

Phenylephrine

Phenylephrine (Sudafed PE, Neo-Synephrine) is a powerful alpha-adrenergic stimulant that decreases nasal congestion. It is available in oral, spray, and drop formulations. Special caution must be taken to avoid use in abraded nasal membranes, because systemic absorption of this drug can result in severe cardiac, CNS, and urinary effects. As with other decongestants, continuous use may induce rebound congestion.

Topical Decongestant Drugs

Topical decongestants include naphazoline (Naphcon and others), oxymetazoline (Afrin), phenylephrine (Neo-Synephrine), tetrahydrozoline (Tyzine), and xylometazoline (Otrivin). They stimulate alpha-adrenergic receptors in the nasal passages, causing constriction in the nasal arterioles. As a result, the nasal membrane is reduced in size, swelling is limited, and the size of the nostril is increased, allowing for more efficient airflow. Although topical decongestants have the same potential adverse effects as pseudoephedrine, the risks are diminished because their action is localized rather than systemic. In very young children, the vascularity of the nasal membranes, developing nasal passages, and eustachian tubes increases the risk for systemic absorption and adverse effects.

Use of topical decongestants for longer than 5 continuous days can lead to rebound congestion. Patients should be instructed to stop using the drug if rebound congestion occurs.

CRITICAL THINKING SCENARIO

PROLONGED USE OF NASAL DECONGESTANTS

Noah Rightman, age 16 years, comes to the clinic for a recheck of his allergic rhinitis. He uses a nasal decongestant daily. Lately, he has needed to use his nasal decongestant "10 times a day," and asks, "What's wrong with this drug? I want something stronger." Understanding the sympathetic nervous system, how would you respond to Noah?

MEMORY CHIP

P Pseudoephedrine

- Used to relieve nasal congestion
- Major contraindications: severe hypertension, severe cardiac disorders
- Most common adverse effects: tachycardia, palpitations, and nervousness
- Most serious adverse effects: dysrhythmias, hypertension, and coronary vasospasm
- Maximizing therapeutic effects: Use humidifier and increase fluid intake.
- Minimizing adverse effects: Adhere to safety precautions.
- Most important patient education: Take pseudoephedrine exactly as prescribed to avoid rebound congestion.

C ANTIHISTAMINES

Antihistamines are used to relieve symptoms of allergies. These drugs, which block the action of histamine as it is released during the inflammatory response to an antigen, are very effective for allergic rhinitis. Their action restores normal airflow through the upper respiratory system. Because of their OTC availability, these drugs are often misused to treat colds and influenza. Drugs within the antihistamine class can be separated into first-generation and second-generation agents. First-generation antihistamines are also referred to as sedating antihistamines. Second-generation antihistamines are known as nonsedating antihistamines, although a better term might be less-sedating antihistamines. Fexofenadine (Allegra), a second-generation drug, is the prototype antihistamine. Table 48.6 presents a summary of antihistamine drugs.

(*text continues on page 705*)

TABLE 34.6 Summary of Selected Antihistamines

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Second-Generation Antihistamines			
P fexofenadine (Allegra)	Allergy relief	*Adult and Child >12 y:* PO, 60 mg 2×/d or 180 mg daily *Child 6–11 y:* PO, 30 mg 2×/d	*Onset:* 1–2 h *Duration:* 12 h $t_{1/2}$: 14 h
	Chronic idiopathic urticaria	*Child 2–11 y:* Oral suspension, 30 mg (5 mL) 2×/d *Child 2–11 y:* 30 mg (5 mL) 2×/d *Child 6 mo to <2 y:* 15 mg (2.5 mL) 2∞/d	
cetirizine (Zyrtec, Zyrtec-D)	Allergy relief	*Adult and Child >6 y:* PO, tablets, chewable tablets, or oral syrup, 5–10 mg daily *Child 2–5 y:* 2.5 mg (1/2 tsp or 2.5 mL of oral syrup) daily or 5-mg chewable tablet daily *Child 1–2 y:* PO, 2.5 mg (1/2 tsp or 2.5 mL) q12 h *Child 6–11 mo:* PO, 2.5 mg (1/2 tsp or 2.5 mL) daily	*Onset:* 30 min *Duration:* 24 h $t_{1/2}$: 8–11 h
desloratadine (Clarinex)	Allergy relief	*Adult and Child >12 y:* PO, 5 mg daily	*Onset:* 1 h *Duration:* 24 h $t_{1/2}$: 27 h
Levocetirizine (Xyzal)	Allergy relief	*Adult and Child > 12y PO:* 5 mg daily *Child 6–11 y PO:* 2.5 mg daily *Child: 2-6 y PO:* 1.25 mg daily	*Onset:* unk *Duration:* 24 h $t_{1/2}$: 7-8 h
loratadine (Alavert, Claritin)	Allergy relief	*Adult and Child >6 y:* PO, 10 mg daily *Child 2–5 y:* PO, 5 mg (5 mL oral syrup) daily *Child <2 y:* Safe and effective use has not been established.	*Onset:* 1–3 h *Duration:* 24 h $t_{1/2}$: 8.4 h
Inhaled Antihistamine			
azelastine (Astelin)	Allergy relief	*Adult and Child >12 y:* 2 sprays in each nostril 2∞ daily *Child 5–11 y:* 1 spray in each nostril 2∞ daily	Minimal systemic absorption
First Generation Antihistamines			
brompheniramine (Veltane)	Allergy relief	*Adult and Child >12 y:* PO, 4 mg q4–6h *Child 6–11 y:* 2–4 mg q6–8h *Child <6 y:* 0.125 mg/kg q6h	*Onset:* 1 h *Duration:* 9–24 h $t_{1/2}$: 12–34 h
	Anaphylaxis	*Adult and Child >12 y:* IV, IM, SQ, 5–20 mg q6h *Child <12 y:* IV, IM, SQ, 0.5 mg/kg/d	
Clemastine (Tavist Allergy)	Allergy relief	*Adult and Child >12 PO:* 1.34 mg 2×/day *Child 6–12 y PO:* 0.67 mg as syrup 2×/d	*Onset:* 15–30 min *Duration:* 12 h $t_{1/2}$: 3–4 h
	Urticaria	*Adult and Child >12y PO:* 2.68 mg 1–3×/d *Child 6-12 y PO:* 1.34 mg as syrup 2×/d	
chlorpheniramine (Chlor-Trimeton)	Allergy relief	*Adult and Child >12 y:* 4 mg PO q4–6h; max, 24/mg/d Extended-release: 8–12 mg q8–12h *Child 6–11 y:* 2 mg PO q4–6 h; max, 12/mg/d *Child 2–5 y:* 1 mg PO q4–6 h; max, 4/mg/d *Adult:* SC, IM, IV, 5–40 mg single dose; max, 40 mg/d *Child:* SC (only), 87.5 mcg/kg q6 h	*Onset:* 15–30 min *Duration:* 4–12 h $t_{1/2}$: 20–24 h

TABLE 34.6 Summary of Selected C Antihistamines *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
dexchlorpheniramine (Polaramine)	Allergy relief	*Adult:* PO, 2 mg q4–6 h or 4–6 mg timed release at bedtime or q8–10 h *Child 2–5 y:* PO, 0.5 mg q4–6 h (do not use timed release) *Child 6–11 y:* PO, 1 mg q4–6 h or 4 mg timed release at bedtime	*Onset:* 15–30 min *Duration:* Unknown $t_{1/2}$: 12–15 h
diphenhydramine (Benadryl)	Allergy relief	*Adult:* PO, 25–50 mg qid; IV/IM, 10–50 mg; max, 400 mg *Child:* PO, 5 mg/kg/d; max, 300 mg daily; IV/IM, same	*Onset:* 15–30 min *Duration:* 4–8 h $t_{1/2}$: 2.5–7 h
Combination Drugs			
acrivastine and pseudoephedrine (Semprex-D)	Allergy and congestion relief	*Adult and Child >12 y:* PO, 1 capsule (acrivastine 8 mg and pseudoephedrine 60 mg) q4–6 h	See individual components
brompheniramine, dextromethorphan, pseudoephedrine (Bromfed-DM, Myphetane DX)	Allergy and congestion relief	*Adult and Child >12 y:* PO, 10 mL q4 h *Child 6–12 y:* PO, 5 mL q4 h *Child 2–6 y:* PO, 2.5 mL q4 h	See individual components
brompheniramine, pseudoephedrine (Bromfed-PE, Efidac 24)	Allergy and congestion relief	*Adult and Child >12 y:* PO, 1–2 capsules q12 h *Child 6–12 y:* PO, 1 capsule q12 h	See individual components
chlorpheniramine and pseudoephedrine (Allerest Maximum Strength)	Allergy and congestion relief	*Adult and Child >12 y:* PO, 1 tablet q4–6 h *Child 6–12 y:* PO, 1/2 tablet q4–6 h	See individual components
chlorpheniramine pseudoephedrine, ibuprofen (Advil Allergy Sinus)	Allergy and congestion relief	*Adult:* PO, 2 mg chlorpheniramine, 60 mg pseudoephedrine, 200 mg ibuprofen; 1 tablet q4–6 h	See individual components
loratadine and pseudoephedrine (Claritin-D, Claritin-D 12-hour)	Allergy and congestion relief	12-h extended-release tablets: *Adult and Child >12 y:* PO, 1 tablet q12 h 24-h extended-release tablet: *Adult and child >12 y:* PO, 1 tablet q24 h *Child <12 y:* Safe and effective use has not been established.	See individual components
fexofenadine and pseudoephedrine (Allegra-D)	Allergy and congestion relief	*Adult and Adolescent:* PO, 1 tablet 2×/d *Child:* Safe and effective use has not been established.	See individual components
triprolidine pseudoephedrine (Actifed Cold and Allergy)	Allergy and congestion relief	*Adult:* PO, 2.5 mg triprolidine, 60 mg pseudoephedrine q4–6 h	Minimal systemic absorption
Ophthalmic Antihistamine/Mast Cell Stabilizers			
alcaftadine (Lastacaft)	Allergic Conjunctivitis	*Adult and child >2y:* *Instill 1 drop daily*	Minimal systemic absorption
azelastine (Optivar)	Allergic Conjunctivitis	*Adult and child >3y:* Instill 1 drop 2×/d	Minimal systemic absorption
bepotastine (Bepreve)	Allergic Conjunctivitis	*Adult and Child >2y:* Instill 1 drop 2×/d	Minimal systemic absorption
epinastine (Elestat)	Allergic Conjunctivitis	*Adult and Child >3y:* Instill 1 drop every 8–12 h	Minimal systemic absorption
ketotifen (Zaditor, Alaway)	Allergic Conjunctivitis	*Adult and Child >3y:* Instill 1 drop every 8–12 h	Minimal systemic absorption
olopatadine (Pataday, Patanol)	Allergic Conjunctivitis	*Adult and Child >3y:* 0.2% 1 drop daily 0.1% 1 drop 2×/d	Minimal systemic absorption

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Inhaled Nasal Steroids			
beclomethasone (Beconase, Vancenase)	Allergy and congestion relief	**Metered-dose inhalers (42 mcg/spray)** *Adult and Child >12 y:* 1 spray in each nostril 2–4×/d *Child 6–12 y:* 1 spray in each nostril 3×/d **AQ pump nasal sprays (42 mcg/spray)** *Adult and Child >6 y:* 1–2 sprays in each nostril 2×/d **AQ double-strength pump nasal spray (84 mcg/spray)** *Adult and Child >6 y:* 1–2 sprays in each nostril once daily in the morning *Children <6 y:* not recommended	beclomethsone (Beconase, Vancenase)
budesonide (Rhinocort)	Allergy and congestion relief	**Metered-dose inhaler (32 mcg/spray)** *Adult and Child >6 y:* 2 sprays in each nostril in the morning and in the evening, or 4 sprays in each nostril in the morning **AQ pump nasal sprays (32 mcg/spray)** *Adult and Adolescent:* 1 spray in each nostril once daily in the morning; max, 256 mcg/d *Child >6 y:* 1 spray in each nostril once daily in the morning; max, 128 mcg/d	budesonide (Rhinocort)
ciclesonide (Omnaris)	Allergic rhinitis	**AQ pump nasal spray (50 mcg/spray)** *Adult and Child >12 y:* 2 sprays in each nostril daily	ciclesonide (Onmaris)
flunisolide (Nasalide)	Allergy and congestion relief	**AQ pump nasal sprays (25 mcg/spray)** *Adult and Child >14 y:* 2 sprays in each nostril 2×/d; max, 200 mcg in each nostril per day *Child 6–14 y:* 1 spray in each nostril 3×/d, or 2 sprays in each nostril 2×/d; max, 100 mcg in each nostril per day *Child <6 y:* Safe and effective use has not been established.	flunisolide (Nasalide)
fluticasone (Flonase)	Allergy and congestion relief	**AQ pump nasal sprays (50 mcg/spray)** *Adult >18 y:* 2 sprays in each nostril once daily or 1 spray in each nostril 2×/d; max, 200 mcg/d *Child 4–17 y:* 1 spray in each nostril 1×/d *Child <4 y:* Safe and effective dosage has not been established.	fluticasone (Flonase)
mometasone (Nasonex)	Allergy and congestion relief	**AQ pump nasal sprays (50 mcg/spray)** *Adult and Child >11 y:* 2 sprays in each nostril once daily (total daily dose of 200 mcg) *Child 2–11 y:* 1 spray in each nostril once daily (total daily dose of 100 mcg) *Child <2 y:* Safe and effective use has not been established.	mometasone (Nasonex)
triamcinolone (Nasacort)	Allergy and congestion relief	**Metered-dose inhaler (55 mcg/pump)** *Adult and Adolescent >12 y:* 2 sprays in each nostril once daily Max: 440 mcg/d *Child 6–11 y:* 2 sprays in each nostril 1×/d; max, 220 mcg/d **AQ pump nasal sprays (55 mcg/spray)** *Adult and Child >12 y:* 2 sprays in each nostril once daily (total dose of 220 mcg) *Child 6–11 y:* 1–2 sprays in each nostril once daily	triamcinolone (Nasacort)
Inhaled Mast Cell Stabilizers			
cromolyn sodium (NasalCrom)	Allergy and congestion relief	**Metered-dose inhaler (5.2 mg/spray)** *Adult and Child >2 y:* 1 spray in each nostril 3–4×/d	Minimal Systemic Absorption
cromolyn sodium (Opticrom, Crolom)	Allergic conjunctivitis	*Adult and Child >4y:* 1–2 drops 4–6×/d	Minimal Systemic Absorption
lodoxamide (Alomide)	Vernal keratitis, conjunctivitis, and keratoconjunctivitis	*Adult and Child >2y:* 1–2 drops 4×/d for up to 3 months	Minimal Systemic Absorption
nedocromil (Alocril)	Allergic conjunctivitis	*Adult and Child >3y:* 1–2 drops 2×/d	Minimal Systemic Absorption

Nursing Management of the Patient Receiving P Fexofenadine

Core Drug Knowledge

Pharmacotherapeutics

Fexofenadine is used to relieve symptoms associated with seasonal and perennial allergic rhinitis, allergic conjunctivitis, uncomplicated urticaria, and angioedema. It is most effective if used before the onset of symptoms.

Pharmacokinetics

Fexofenadine is taken orally and is absorbed rapidly. The peak drug effect is seen within 2 to 6 hours Fexofenadine is only slightly (5%) metabolized in the liver and is excreted in the feces (80%) and urine (11%).

Pharmacodynamics

Fexofenadine selectively blocks the effects of histamine at H_1-receptor sites, decreasing the allergic response. Fexofenadine also has anticholinergic and antipruritic effects. However, fexofenadine, a second-generation antihistamine, has less of an anticholinergic effect than the first-generation antihistamines because it binds to lung receptors substantially more than it binds to cerebellar receptors, resulting in a reduced sedative potential.

Contraindications and Precautions

Fexofenadine should not be used in a patient with hypersensitivity to fexofenadine or terfenadine or any of their components or in children younger than 2 years of age. This drug is in pregnancy category C; because it crosses the placenta and enters breast milk, it should be avoided or used with caution by pregnant and lactating women. Fexofenadine also should be used with caution in patients with renal impairment, because the drug's half-life is prolonged in these patients. In addition, peak plasma levels in patients with renal impairment are increased.

Adverse Effects

The most common adverse reactions associated with fexofenadine include viral infection (e.g., colds and flu), nausea and vomiting, dysmenorrhea, drowsiness, dyspepsia, and fatigue. Fexofenadine is a metabolite of terfenadine, which has been associated with QT-interval prolongation and ventricular tachycardias and is no longer manufactured. Fexofenadine has not induced QT-interval prolongation, but patients should still be monitored for this adverse effect.

Drug Interactions

Only a few drug interactions are associated with fexofenadine. They are presented in Table 34.7.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient's history for allergy to any antihistamine and for pregnancy, lactation, or renal impairment. Before beginning therapy, assess the patient's respiratory system, orientation and affect, and skin condition. If long-term therapy is anticipated, renal function should be assessed as well.

Life Span and Gender

Note the age of the patient before administering fexofenadine. Use special precautions in elderly patients, who are more likely than others to experience dizziness, sedation, and syncope. Determine whether the patient is pregnant, because fexofenadine should not be used during pregnancy.

Lifestyle, Diet, and Habits

Evaluate how often the patient drinks apple, grapefruit, or orange juice because these juices decrease the absorption of fexofenadine. Teach the patient to avoid these juices for 1 hour before and 2 hours after taking fexofenadine.

Caution patients taking fexofenadine to assess the level of sedation caused by the drug before driving a vehicle or performing tasks that require concentration.

Environment

Fexofenadine usually is administered at home and in the community setting. Caution patients taking fexofenadine to read the labels of nonprescription products to be sure that they are not taking another product that also contains an antihistamine, which could potentiate the effects of both drugs.

Nursing Diagnosis and Outcome

- Risk for Injury caused by drowsiness and fatigue related to drug-induced CNS effects
  Desired outcome: *Safety precautions will prevent injury related to drug-induced CNS effects.*

TABLE 34.7 Agents That Interact with P Fexofenadine

Interactants	Effect and Significance	Nursing Management
Juices Apple Grapefruit Orange	Apple, grapefruit, and orange juice decrease the absorption of fexofenadine.	Monitor for continued allergy symptoms. May require increased dose of fexofenadine.
Rifampin	Rifampin reduces the absorption of fexofenadine.	Monitor for continued allergy symptoms.

Planning and Intervention

Maximizing Therapeutic Effects

Institute measures to prevent dangers associated with thickening of respiratory secretions. Examples of appropriate measures include use of a humidifier, forcing fluids as appropriate, and encouraging the patient to avoid dry or smoke-filled areas.

Minimizing Adverse Effects

Refrain from giving the patient apple, grapefruit, or orange juice with fexofenadine, because these juices decrease its absorption.

Provide safety measures, such as side rails, and assistance with ambulation if CNS effects occur.

Providing Patient and Family Education

- Explain that fexofenadine is formulated to relieve allergy symptoms.
- Caution patients not to take fexofenadine if they have ever had a reaction to it, are pregnant, or are breast-feeding.
- Caution patients to take the drug as prescribed. If they miss a dose, they should take it as soon as they remember, unless it is almost time for the next dose; two doses should not be taken at the same time.
- Tell patients to avoid the use of other OTC drugs, many of which contain similar antihistamines that could cause serious adverse effects if taken concurrently with fexofenadine.
- Inform patients to avoid alcohol while taking fexofenadine and not to drive or perform tasks that require alertness until the drug's effect has been determined.
- Tell patients to take fexofenadine with food if GI upset occurs and to suck on sugarless lozenges if dry mouth is a problem.
- Teach patients to take fexofenadine with a glass of water. Explain why apple, grapefruit, and orange juices should not be taken at the same time as fexofenadine.
- Warn patients to report difficulty breathing, tremors, hallucinations, and palpitations; teach patients and their families about safety measures that may be needed if these CNS effects occur. Caution patients to keep fexofenadine out of the reach of children.
- Encourage patients to use a humidifier, drink fluids, and avoid overly dry spaces and smoke-filled areas to help decrease the problems associated with the drying effects of antihistamines.

Ongoing Assessment and Evaluation

After several days taking fexofenadine, the patient should experience little discomfort associated with the drug's adverse effects. The patient should be free of injury related to the CNS effects of fexofenadine. The patient should not experience respiratory difficulty related to the anticholinergic effects of the drug.

MEMORY CHIP

P Fexofenadine

- Used for allergic disorders
- Major contraindication: use in children younger than 12 years old
- Most common adverse effects: flu-like symptoms, nausea and vomiting, dysmenorrhea, and drowsiness
- Most serious adverse effect: potential for QT-interval prolongation
- Maximizing therapeutic effects: Use a humidifier and increase fluid intake.
- Minimizing adverse effects: Adhere to safety precautions.
- Most important patient education: Use for symptoms related to allergic disorders; do **not** use for symptoms related to common viral illness, such as colds and flu.

Drugs Closely Related to **P** Fexofenadine

Azelastine

Azelastine (Astelin) is a second-generation H_1-receptor antagonist that is administered as a nasal spray. It is approved to treat the symptoms of seasonal allergic rhinitis and vasomotor rhinitis such as rhinorrhea, nasal congestion, sneezing, nasal pruritus, and postnasal drip. It acts by locally antagonizing the effects of histamine at the H_1-receptor sites but does not bind to or inactivate histamine. Adverse effects include drowsiness, dizziness, epistaxis, nasal burning, sneezing, dry mouth, and a bitter taste. A pregnancy category C drug, it is approved for use in children older than 5 years.

Cetirizine

Cetirizine (Zyrtec) is the active metabolite of hydroxyzine; it differs from the parent compound by having greater affinity for the H_1 receptor. Cetirizine is effective in treating chronic idiopathic urticaria, perennial allergic rhinitis, and seasonal allergic rhinitis. It causes more sedation than other second-generation antihistamines such as desloratadine, loratadine, and fexofenadine but much less sedation than first-generation antihistamines. Cetirizine is approved for use in children as young as 6 months of age.

Cetirizine is classified as a pregnancy category B drug. It is excreted in human breast milk; because the concentration of drug in breast milk has not been quantified, the manufacturer recommends against using cetirizine during breast-feeding.

Desloratadine

Desloratadine (Clarinex) is the **enantiomer** (mirror image) of loratadine. It is a potent, long-acting antihistamine. Because it penetrates poorly into the CNS and has low affinity for CNS H_1 receptors, it does not cause intense drowsiness. It is available as regular or rapidly disintegrating tablets. It is approved for use in children older than 12 years.

Desloratadine is a pregnancy category C drug. It enters breast milk and reaches a concentration equal to that in maternal serum. Potential adverse effects in the infant include irritability, disturbed sleeping patterns, drowsiness, hyperexcitability, and excessive crying.

Levocetirizine (Xyzal)

Levocetirizine (Xyzal) is the enantiomer of cetirizine. It is used in the management of idiopathic urticaria, chronic uncomplicated skin manifestations, and both perennial and seasonal allergic rhinitis. It is approved for children as young as 6 months of age. Levocetirizine is contraindicated for patients receiving hemodialysis and those with renal impairment. It is a pregnancy category B drug.

Loratadine

Loratadine (Claritin), like fexofenadine, is a second-generation antihistamine. It has fewer CNS effects than other H_1 receptor blockers and can be administered once a day. It is not indicated for children younger than 2 years of age. Loratadine should be given cautiously to patients with pre-existing hepatic dysfunction. To minimize the risk of hepatotoxicity, these patients should take loratadine on an every-other-day regimen. Loratadine is most effective when taken on an empty stomach.

Loratadine is a pregnancy category C drug. Like desloratadine, it enters breast milk in a concentration equal to that in maternal serum.

Drugs Significantly Different From P Fexofenadine

Brompheniramine, Chlorpheniramine, and Dexchlorpheniramine

Brompheniramine (Veltane), chlorpheniramine (Chlor-Trimeton), clemastine (Tavist Allergy), and dexchlorpheniramine (Polaramine) are antihistamines which also may be used in conjunction with decongestants. They are nonselective H_1 blockers (first-generation antihistamines) and thus have sedative effects. These drugs are given to treat allergies such as hay fever, allergic conjunctivitis, **urticaria** (hives), and **angioedema** (allergic swelling). They reduce sneezing, runny nose, and itching eyes in hay fever. In addition, they have a mild anticholinergic action that suppresses mucus secretion. Their advantage is that they are relatively inexpensive. The major detriment is that they must be taken every 4 to 6 hours.

Brompheniramine causes less sedation than other first-generation antihistamine agents. A pregnancy category C drug, it is contraindicated during the first trimester of pregnancy and should be avoided during the following trimesters. If brompheniramine must be used during pregnancy, extended-release products should be avoided to limit fetal exposure. Chlorpheniramine is a pregnancy category B drug, although it also should be avoided during pregnancy. Clemastine is another less sedating first generation antihistamine. It is frequently used for pruritus. Clemastine is a pregnancy category B drug. Dexchlorpheniramine is the predominant active isomer of chlorpheniramine and is approximately twice as active. It has the same indications and precautions as brompheniramine and chlorpheniramine. Like chlorpheniramine, it is a pregnancy category B drug.

Diphenhydramine

Diphenhydramine (Benadryl) is a first-generation antihistamine known as an ethanolamine. Ethanolamine antihistamines have substantial antimuscarinic activity and produce marked sedation in most patients. In general, GI effects are minimal. In addition to treating allergic symptoms, diphenhydramine is effective in relieving nausea, vomiting, and vertigo associated with motion sickness. Because of its sedating effects, it is frequently used to induce sleep. It also is used commonly to treat drug-induced extrapyramidal symptoms and mild cases of Parkinson disease.

Diphendydramine is a pregnancy category B drug. Although the use of H_1 antagonists is discouraged during pregnancy, diphenhydramine is the parenteral antihistamine of choice for managing acute or severe allergic reactions in pregnant patients. First-generation H_1 antagonists are not used during breast-feeding because they may inhibit lactation. In addition, they may induce paradoxical CNS stimulation in neonates or seizures in premature infants.

Ophthalmic Antihistamines and Mast Cell Stabilizers

The drugs in this class include alcaftadine (Lastacaft), azelastine (Optivar), bepotastine (Bepreve), epinastine (Elestat), ketotifen (Alaway, Zaditor), and olopatadine (Patanol, Pataday). As antihistamines, they reversibly block H-1 receptors in the conjunctiva and eyelid. As mast cell stabilizers, they inhibit the first step of the allergic cascade by inhibiting mast cell degranulation. The combination of these effects is more efficacious than utilizing antihistamines or mast cell stabilizers as a single topical agent. Common adverse effects include eye irritation, nasopharyngitis, bitter taste, and headache. Emedastine (Emadine) is an H-1 antihistamine. It does not have mast cell stabilizing effects.

Inhaled Nasal Steroids

Inhaled nasal steroidal preparations are used to treat seasonal or perennial allergic rhinitis. Drugs in this class include beclomethasone (Beconase), budesonide (Rhinocort), ciclesonide (Omnaris), flunisolide (Nasalide), fluticasone (Flonase), mometasone (Nasonex), and triamcinolone (Nasacort). Studies have shown that they are superior to oral antihistamines for alleviating nasal, eye, and global allergy symptoms.

Two types of inhaled nasal steroids are available: aqueous sprays that spray a liquid from a bottle through a nozzle fixed at the top of the unit, and metered-dose nasal inhalers that deliver the drug from a pressurized canister through a nozzle on the side near the bottom of the unit. Aqueous sprays are less irritating than those delivered by metered-dose inhaler.

Common adverse effects of inhaled nasal steroids include a burning or itching sensation and a drying effect on the nasal mucosa. By delivering steroids directly to the nasal passage, inhaled nasal steroids maximize the beneficial therapeutic effects of corticosteroids while minimizing their potential systemic adverse effects, although systemic adverse effects may still occur during long-term or high-dose therapy.

Despite these drugs' reduced risk for systemic adverse effects, children receiving inhaled nasal steroids should be evaluated routinely for possible growth retardation, although the risk is extremely small.

Inhaled Mast Cell Stabilizer

Cromolyn sodium (NasalCrom Nasal Spray) is available OTC. Cromolyn sodium provides a protective layer that shields mast cells lining the nasal passage and prevents them from breaking down and releasing histamines. Common adverse effects include irritation inside of the nose, flushing, and an increase in sneezing. Cromolyn sodium has been approved for adults and children older than 2 years. For best results, cromolyn sodium should be taken for 1 full week before coming in contact with allergens and should then be taken three to four times daily.

Ophthalmic Mast Cell Stabilizers

Cromolyn sodium (Opticrom), lodoxamide (Alomide), nedocromil (Alocril), and pemirolast (Alamast) are mast cell stabilizers for allergic conjunctivitis. They are not used for acute symptoms because their onset of action is 5 to 14 days. These drugs are generally used for patients who experience only mild to moderate symptoms. They require more frequent dosing than the combination antihistamine/mast cell stabilizer formulation.

C EXPECTORANT DRUGS

Expectorants are drugs that liquefy lower respiratory tract secretions. This effect decreases the viscosity of the secretions (which makes it easier for the patient to cough them up) and improves airflow. Expectorants are available in many OTC preparations, making them widely available to the patient without advice from a health care provider. Guaifenesin (Robitussin) is the prototype expectorant drug. Table 48.8 presents a summary of selected expectorant drugs.

Nursing Management of the Patient Receiving P Guaifenesin

Core Drug Knowledge

Pharmacotherapeutics

Guaifenesin is used to relieve the symptoms of respiratory conditions characterized by a dry, nonproductive cough. These disorders include the common cold, acute bronchitis, and influenza. Guaifenesin is often found in combination with antihistamines and decongestants (see Table 34.8).

Pharmacokinetics

Guaifenesin is taken orally and is absorbed readily from the GI tract, with an onset of action of 30 minutes. The duration of action is 4 to 6 hours.

Pharmacodynamics

Guaifenesin enhances the output of respiratory tract fluids by reducing the adhesiveness and surface tension of the fluids, thus allowing easier movement of the less viscous secretions. Thinned secretions result in a more productive cough. With a more productive cough, the frequency of coughing should decrease.

Contraindications and Precautions

The only known contraindication to guaifenesin is a known allergy to the drug. The most important consideration in the use of this drug is discovering the cause of the underlying cough. Prolonged use of the OTC preparation could result in masking important symptoms of a serious underlying disorder. The drug should not be used for more than a week; if the cough persists, encourage the patient to visit the prescriber.

Guaifenesin is a pregnancy category C drug.

Adverse Effects

The most common adverse effects of guaifenesin use are GI symptoms, including nausea, vomiting, and anorexia.

TABLE 34.8 Summary of Selected C Expectorants

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P guaifenesin (Robitussin, Scot-Tussin, Mytussin, Fenesin, and many more)	Relief of conditions characterized by dry, nonproductive cough Presence of mucus in the respiratory tract	*Adult:* PO, 100–400 mg q4 h, not to exceed 2.4 g/d *Child >12 y:* PO, adult dosage *6–12 y:* PO, 100–200 mg q4 h, not to exceed 1.2 g/d *2–6 y:* PO, 50–100 mg q4 h, not to exceed 600 mg/d	*Onset:* 30 min *Duration:* 4–6 h $t_{1/2}$: Unknown
terpin hydrate (various)	Symptomatic relief of dry, nonproductive cough	*Adult:* PO, 85–170 mg tid–qid *Child:* Do not give unless prescribed *10–12 y:* 85 mg tid–qid *5–9 y:* 40 mg tid–qid *1–4 y:* 20 mg tid–qid	*Onset:* 30–60 min *Duration:* Unknown $t_{1/2}$: Unknown
iodine preparations (SSKI, potassium iodide)	Symptomatic treatment of COPD diseases in which tenacious mucus complicates the problem	*Adult:* PO, 300–1,000 mg after meals bid–tid *Child:* PO, 150–500 mg after meals bid–tid	*Onset:* 30 min *Duration:* Unknown $t_{1/2}$: Unknown

Some patients experience headache or dizziness, and an occasional person will develop a mild rash.

Drug Interactions

Guaifenesin has no important drug–drug interactions. However, it may interfere with colorimetric tests and give false results with urinary catecholamine determinations.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for any past hypersensitivity to guaifenesin; history of persistent cough for more than 1 week; cough caused by smoking, asthma, or emphysema; or a very productive cough. In addition, perform a physical assessment, which should include an examination of the patient's skin condition (as a baseline if a rash develops), temperature (to monitor for underlying problems), respiratory status, and adventitious breath sounds.

Life Span and Gender

Determine whether the patient is pregnant. Guaifenesin is a pregnancy category C drug and should be used very cautiously by pregnant patients.

Lifestyle, Diet, and Habits

It is important to assess the patient's smoking habits and typical alcohol intake. Smokers do not benefit from the action of guaifenesin because the etiology of their cough is irritation. When using guaifenesin, the patient should take care not to drink alcohol or use other drugs containing alcohol. Although guaifenesin and alcohol do not interact, both cause drowsiness; therefore, they should not be taken together.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to GI symptoms of nausea and vomiting
  Desired outcome: *The patient will maintain baseline weight and nutritional status.*
- Ineffective Airway Clearance related to increased viscosity of secretions
  Desired outcome: *The patient will demonstrate effective coughing technique and make use of several methods to increase airway clearance.*

Planning and Intervention

Maximizing Therapeutic Effects

Teach the patient about good pulmonary hygiene, which includes coughing, deep breathing, drinking plenty of fluids, and using a humidifier. Show the patient how to perform effective coughing technique. Family members may assist with percussion and postural drainage as appropriate.

Minimizing Adverse Effects

Suggest that the patient eat small, frequent meals to alleviate GI upset. Additionally, give the drug with meals if symptoms become intolerable.

Providing Patient and Family Education

- Explain to patients that guaifenesin will help make it easier to cough up secretions from the lungs.
- Warn patients not to take guaifenesin if they have ever had a reaction to it, if their cough is caused by smoking, or if their cough is chronic (unless use of the drug is approved by their provider).
- Tell patients not to use guaifenesin for longer than 1 week, and that if the cough persists after that time, or if fever or rash develops, they should consult with their prescriber.
- Caution patients taking guaifenesin not to take any other drugs without their provider's approval and not to drink alcohol while taking this drug.
- Tell patients that if a dose is missed, it should be taken as soon as remembered unless it is time for the next dose. Two doses should never be taken at the same time.
- Teach patients ways to augment guaifenesin therapy, such as drinking a glass of water with each dose. Lots of water helps the body thin the secretions in the lungs and helps guaifenesin work more efficiently. Other ways to augment drug therapy include use of a humidifier, deep breathing, chest percussion, and positional drainage if needed. In addition, teach patients good coughing technique and encourage patients to use the technique regularly.

Ongoing Assessment and Evaluation

Monitor the patient's reaction to guaifenesin carefully; fever, rash, or persistent cough may indicate a more serious underlying medical problem, and appropriate follow-up should be arranged. The patient should tolerate drug adverse effects through use of small, frequent meals and proper timing of dosage. Within 1 week, the patient should exhibit an increasingly productive cough and good movement of respiratory secretions, as demonstrated by productive cough and clearing breath sounds.

Drugs Closely Related to P Guaifenesin

Terpin Hydrate

Terpin hydrate stimulates the glands of the respiratory tract to increase the amount of fluid secreted. Actions

MEMORY CHIP

P Guaifenesin

- Used to manage dry cough
- Major contraindication: hypersensitivity
- Most common adverse effects: nausea, vomiting, and anorexia
- Maximizing therapeutic effects: good pulmonary hygiene
- Minimizing adverse effects: small, frequent meals to decrease GI distress
- Most important patient education: Seek medical attention if cough does not resolve.

and management related to this drug are very similar to those for guaifenesin. However, terpin hydrate contains about 42% alcohol, which crosses the placenta and may result in congenital abnormalities. The alcohol in terpin hydrate also is excreted in breast milk and can be harmful to infants.

Iodine Preparations

These drugs have been used for many years to stimulate an increase in the fluid produced by the lungs. They are used in treating chronic obstructive pulmonary disease and as adjunctive treatment in respiratory tract conditions, such as cystic fibrosis and chronic sinusitis, and after surgery to prevent atelectasis. These drugs tend to have a bitter flavor, which limits their popularity. They must be used with caution in many conditions because of the effect of iodine on the thyroid gland. Iodine preparations are assigned to pregnancy category X because of potential damage to the fetal thyroid.

CHAPTER SUMMARY

- The upper respiratory system is composed of upper or conducting airways, including the nares, nasal sinus, pharynx, larynx, and trachea.
- Disorders of the upper respiratory system include inflammation and irritation of the upper airways.
- Antitussives, such as dextromethorphan, are drugs used to suppress the cough reflex when dry, nonproductive coughing is tiring and irritating to the respiratory system.
- Decongestants, such as pseudoephedrine, are drugs used to decrease the swelling and blood flow to the mucosa of the respiratory tract. Oral decongestants have greater potential than topical decongestants, which are applied directly to the mucosa, to cause systemic adverse effects. However, the topical decongestants are more likely to cause rebound congestion if used longer than 5 consecutive days.
- Antihistamines are classified as first- or second-generation drugs. First-generation antihistamines are more sedating than second- generation drugs.
- Antihistamines, such as fexofenadine, are used to block the action of histamine as it is released in response to an inflammatory reaction. These drugs block the swelling and congestion that follow histamine release.
- Antihistamines may be taken orally or by nasal or topical administration.
- Topical antihistamines with both antihistamine and mast cell stabilizing effects are most effective for allergic conjunctivitis.
- Inhaled nasal steroids are also used to manage allergic rhinitis and vasomotor rhinitis.
- Expectorants, such as guaifenesin, are drugs used to increase the viscosity and volume of the respiratory tract secretions, which helps patients to clear the lower respiratory tract of tenacious secretions.

QUESTIONS FOR STUDY AND REVIEW

1. What is the difference between dextromethorphan and narcotic antitussive agents?
2. Why are antihistamines inappropriate for treating the common viral cold?
3. What property of fexofenadine makes it an excellent antihistamine?
4. What are the advantages of inhaled antihistamine or steroid drugs over oral formulations?
5. How does guaifenesin assist in controlling cough?

Drugs Affecting the Lower Respiratory System

Learning Objectives

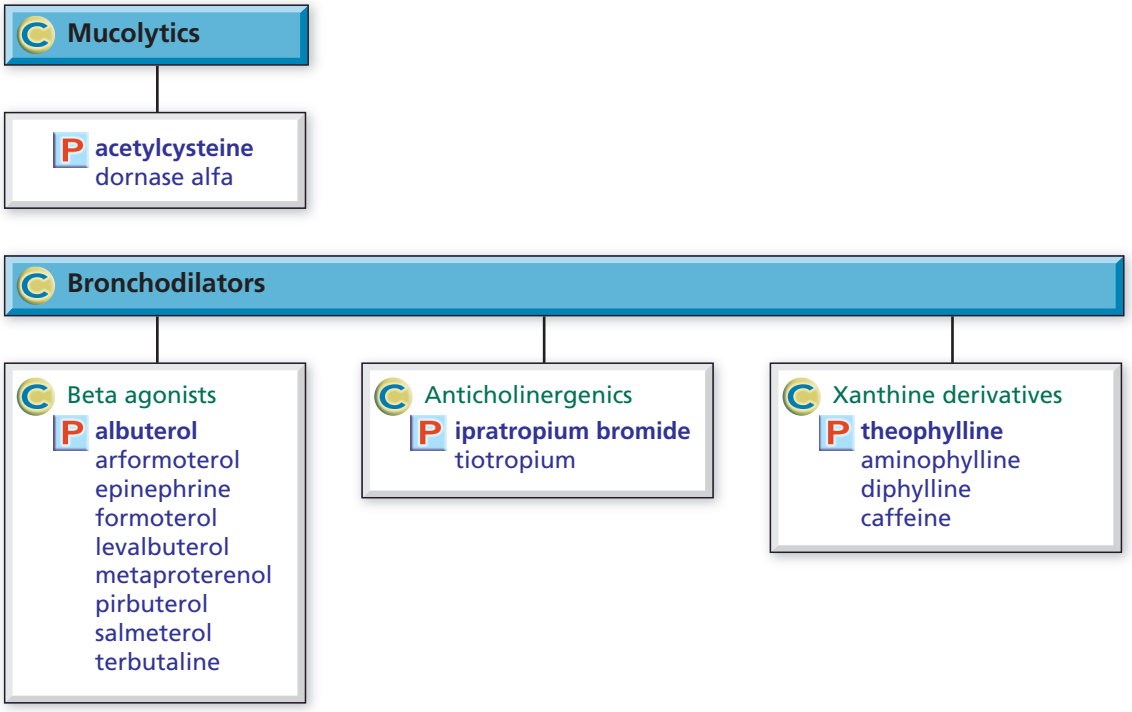
At the completion of this chapter the student will:

1. Describe the anatomy and physiology of the lower respiratory system.
2. Identify core drug knowledge pertaining to drugs that affect the lower respiratory system.
3. Identify core patient variables pertaining to drugs that affect the lower respiratory system.
4. Relate the interaction of core drug knowledge to core patient variables for drugs that affect the lower respiratory system.
5. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect the lower respiratory system.
6. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs that affect the lower respiratory system.
7. Determine key points for patient and family education for drugs that affect the lower respiratory system.
8. Compare and contrast drugs used for maintenance treatment of lower respiratory disorders with those used to manage acute exacerbations of lower respiratory disorders.

Key Terms

bronchodilators
bronchospasm
chemoreceptors
chronic airway limitation (CAL)
chronic obstructive pulmonary disease (COPD)
mucolytics
perfusion
respiration
status asthmaticus
ventilation

Drugs Affecting the Lower Respiratory System



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

This chapter discusses drugs that affect the lower respiratory system. The lower respiratory system is affected by many serious conditions, which all, to some extent, affect the ability to move air in and out of the lungs. Examples of these conditions include pneumonia, bronchitis, chronic obstructive pulmonary diseases, and cystic fibrosis.

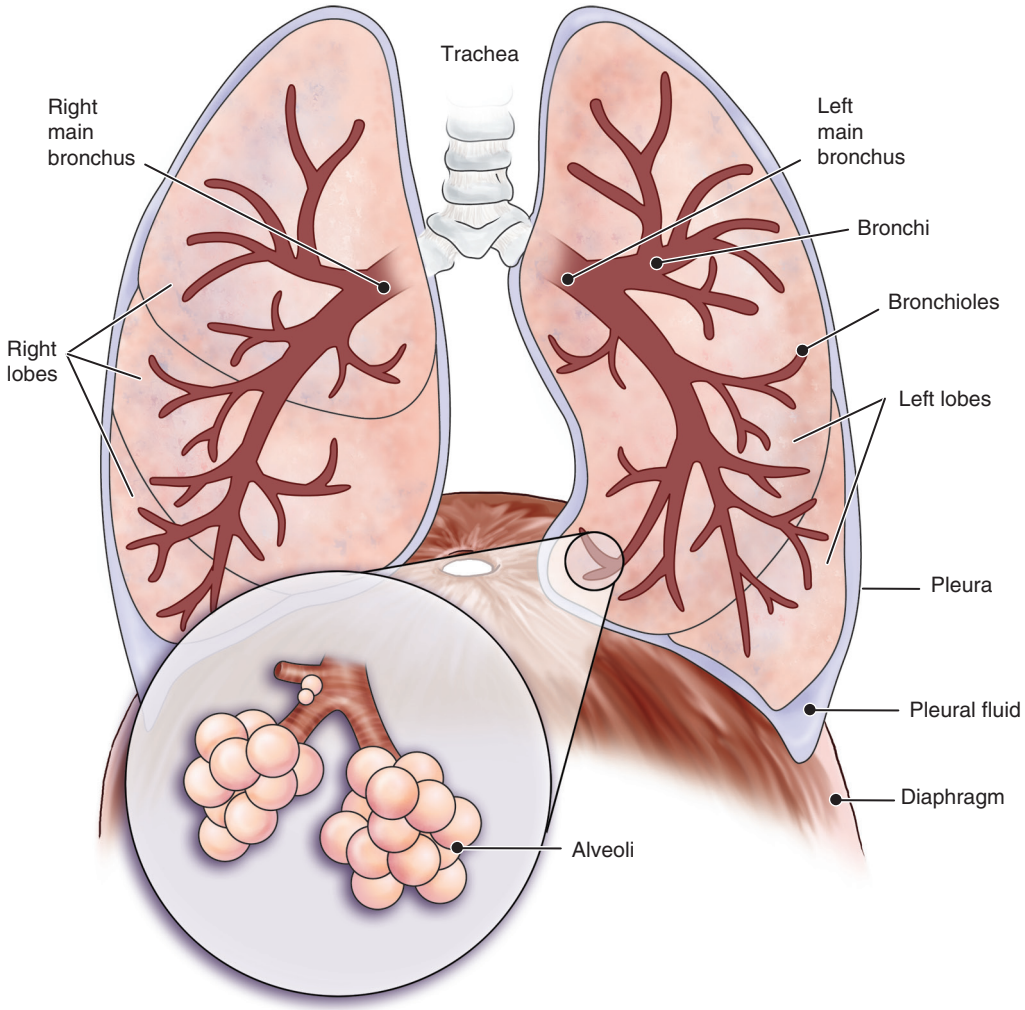
Drugs used to manage lower respiratory system disorders include mucolytics such as acetylcysteine; bronchodilators, which include several subclasses, such as sympathomimetics (respiratory beta agonists), anticholinergics, and xanthines; and anti-inflammatory drugs, which also have several subclasses, including glucocorticoids, mast cell stabilizers, monoclonal antibodies, and leukotriene receptor antagonists.

PHYSIOLOGY

The lower respiratory tract is virtually sterile because of the various defense mechanisms in the upper respiratory system. The lower respiratory system, or the bronchial tree, begins at the trachea, which is surrounded by cartilaginous C-shaped rings that reinforce it and maintain its patency. The trachea bifurcates into two bronchi at a segment called the carina. The right main stem bronchus is wider, shorter, and more vertical. It divides into the upper, middle, and lower lobar bronchi, which then divide into 10 segmental (tertiary) bronchi. The left main stem bronchus is narrower, longer, and more horizontal. It divides into two lobar bronchi, which then divide into 8 to 10 segmental bronchi. Segmental bronchi supply the bronchopulmonary segments, which are the functional units of the lung. Within each bronchopulmonary segment, the segmental bronchi branch 6 to 18 times, producing 50 to 70 respiratory bronchioles that oxygenate the alveolar sacs composed of alveoli (Figure 35.1).

Protective Mechanisms

The bronchial tubes have three layers: cartilage, muscle, and epithelial cells. The cartilage keeps the tube open and becomes progressively less abundant as the bronchi divide and get smaller. The muscles also help to keep the bronchi open, and they too become smaller and less abundant, with only a few muscle fibers remaining in the terminal bronchi and alveoli.



• FIGURE 35.1 Lower respiratory system.

All the tubes in the lower airway contain goblet cells, which secrete mucus to entrap any particles that may have escaped the upper airway protective mechanisms. In addition, during the passage through the bronchi, microorganisms and other foreign bodies are removed from the air by tiny hair-like structures called cilia, which project from the cells that line the bronchial wall. With a wave-like motion, these cilia sweep the foreign material and mucus upward toward the trachea and larynx. The walls of the trachea and the conducting bronchi are very sensitive to irritation. Foreign material and mucus stimulate nerve endings in the bronchial wall and initiate the cough reflex. Coughing completes the expulsion of the foreign material and mucus from the bronchial tree.

Gas Exchange, Perfusion, and Respiration

Lung tissue receives its blood supply from the bronchial artery, which branches directly off the thoracic aorta. The alveoli receive unoxygenated blood from the right ventricle by way of the pulmonary artery. Blood delivery to the alveoli is referred to as **perfusion.** In the alveoli, gas exchange occurs; carbon dioxide is removed from the blood, while oxygen from inhaled air diffuses into the blood. This exchange of gases at the alveolar level is called **respiration.** The alveolar sac stays open even during exhalation because the nitrogen and oxygen gases it contains exert outward pressure and because the lungs produce a lipoprotein surfactant that decreases the surface tension of the alveolar walls, preventing alveolar collapse. Oxygenated blood is returned from the lungs to the left atrium through the pulmonary veins. From there, it is pumped throughout the body to deliver oxygen and pick up waste products.

Ventilation

Ventilation, or the act of breathing, is controlled by the central nervous system (CNS). The inspiratory muscles (the diaphragm and the external intercostal and abdominal muscles) are stimulated to contract by the respiratory center in the medulla. The medulla receives input from **chemoreceptors** (neuroreceptors in the medulla, aorta, and carotid arteries that are sensitive to carbon dioxide and acid levels) and increases the rate or depth of respiration to maintain homeostasis in the body. The vagus nerve, a predominantly parasympathetic nerve, plays a key role in stimulating the diaphragm to contract, causing inspiration. Vagal stimulation also leads to bronchoconstriction (tightening of the bronchi). The sympathetic system also innervates the respiratory system. Stimulation of the sympathetic system leads to increased rate and depth of respiration and dilates the bronchi to allow freer airflow through the system. During a physical examination, nurses document vital signs as temperature, pulse, and respirations. To be accurate, they actually are assessing the ventilatory rate, not the respiratory rate. However, the authors of this text do not recommend changing the long-standing method of charting vital signs.

PATHOPHYSIOLOGY

Acute Bronchitis

Acute bronchitis is caused most frequently by viruses. Therefore, it may be a sequela to the common cold, influenza, whooping cough, and measles. Bacteria such as streptococci and staphylococci also may cause acute bronchitis. Furthermore, bronchitis can be precipitated by a variety of physical and chemical agents, such as fumes of strong acids, ammonia, or organic solvents. Symptoms of acute bronchitis include fever, a productive cough, and purulent mucus. Inflammation often narrows or obstructs a person's airway, making bronchitis a potentially serious condition. Treatment includes bronchodilators and expectorants, plus antibiotic therapy if there is a bacterial infection. The course of the disease is commonly short: 2 to 4 days. However, untreated acute bronchitis may develop into chronic bronchitis.

Asthma

Asthma is a disorder characterized by recurrent episodes of **bronchospasm,** bronchial muscle spasm that leads to narrowed or obstructed airways. Asthma has been classified as either intrinsic or extrinsic. Intrinsic asthma has no identifiable cause but has been associated with exercise and emotional stress. Extrinsic asthma occurs as a result of an allergic reaction to an environmental allergen. Exposure to the antigen causes a rapid and intense inflammatory reaction with the release of histamine, serotonin, and leukotrienes. These chemicals cause severe bronchoconstriction and increased mucus production. In addition, as airway obstruction increases pressure in the respiratory system, fluid moves into the tissues and results in further obstruction. This reaction usually occurs within 5 to 30 minutes after exposure to the allergen. An extreme type of asthma called **status asthmaticus,** is a life-threatening bronchospasm, which occludes airflow into the lungs and requires emergency treatment. Asthma is divided into classifications (Box 35.1). Pharmacotherapy for asthma is dependent on the current classification because the patient may fluctuate between classifications, depending on his or her response to medication as well as daily environmental, psychological, and physical stressors (Box 35.2).

Chronic Airway Limitation

Chronic airway limitation (CAL) is an umbrella term that describes gradually progressive, degenerative diseases, such as chronic bronchitis, emphysema, or repeated, severe asthma attacks. Other terms used for the same conditions are **chronic obstructive pulmonary disease (COPD),** chronic obstructive respiratory disease (CORD), chronic obstructive airway disease (COAD), and chronic obstructive lung disease (COLD). The term CAL is used in this chapter.

In CAL, the bronchioles become thick and edematous, the upper respiratory defense mechanisms are destroyed, and constant irritation and inflammation of the lower respiratory tract are present. With time, the fragile alveoli enlarge and collapse

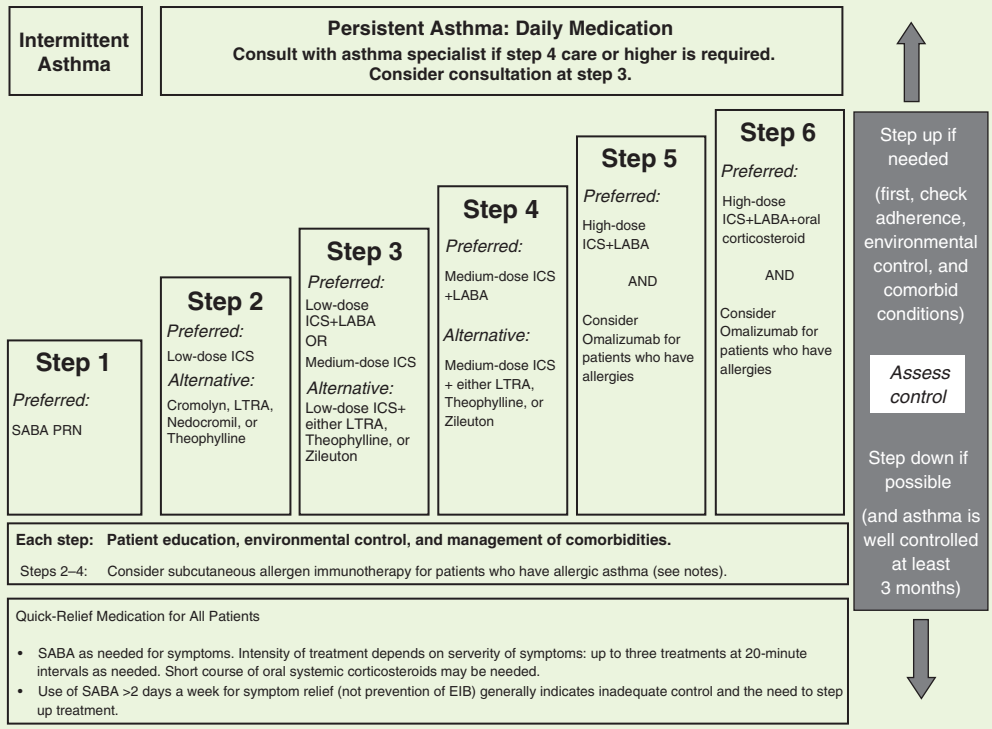
Box 35.1 CLASSIFICATION OF ASTHMA SEVERITY

Components of Severity		Classification of Asthma Severity ≥12 years of age			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	Often 7x/week
	Short-acting $beta_2$-agnoist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily, and not more than 1x on any day	Daily	Several times per day
Normal FEV_1/FVC: **8–19 yr 85%** **20–39 yr 80%** **40–59 yr 75%** **60–80 yr 70%**	Interferance with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV_1 between exacerbations • FEV_1 >80% predicted • FEV_1/FVC normal	• FEV_1 >80% predicted • FEV_1/FVC normal	• FEV_1 >60% but <80% predicted • FEV_1/FVC reduced 5%	• FEV_1 <60% predicted • FEV_1/FVC reduced >5%

Adapted from Expert Panel Report-3: Guidelines for the Diagnosis and Management of Asthma

Box 35.2 STEPWISE APPROACH TO ASTHMA THERAPY

STEPWISE APPROACH FOR MANAGING ASTHMA IN YOUTHS ≥12 YEARS OF AGE AND ADULTS



Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** EIB, excercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, long-acting inhaled $beta_2$-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting $beta_2$-agonist

or fuse. Air is trapped in the lungs as the elastic fibers are lost, and increasing amounts of energy are required to try to move the air through the narrowed bronchial tubes. The lungs overinflate and the efficiency of gas exchange is lost. The person suffering from CAL complains of dyspnea and shortness of breath. A barrel chest develops as the lungs overinflate. The person is fatigued from the poor oxygenation of the blood and from the increased expenditure of energy required for breathing.

Chronic Bronchitis

Chronic bronchitis is long-standing, largely irreversible inflammation of the bronchial tree. The continuous inflammatory injury to the lining of the bronchial tree has destroyed many of the cells, the cilia are absent, and the defense mechanism against invading foreign material is lost. The bronchial tubes are narrow, rigid, and distorted. Viscous mucous materials are hypersecreted, resulting in a chronic, deep, productive cough. The cough is difficult to suppress and in fact should not be, because the abundant secretions must be eliminated to avoid the danger of severe superimposed infection.

Excessive and prolonged tobacco smoking can cause chronic bronchitis and is certainly one of its most aggravating factors. Infections of the sinus cavities also provide a reservoir of microorganisms that can continually reinfect the lungs. Damaged bronchi are ideal sites for harboring infections and for accumulation of excess fluids and secreted mucus. Episodes of acute bronchitis and pneumonia are frequent because the respiratory tract is more susceptible to invasion by pathogenic microorganisms.

Emphysema

Emphysema is an abnormal distention of the lungs with air, characterized by loss or degeneration of elastic tissue, disappearance of capillary walls, and breakdown of the alveolar walls. The alveoli first stretch and then tend to disintegrate. The lungs become filled with large pools of air, and loss of elastic support around small airways, or loss of the small airways themselves, severely interferes with expiration. As with chronic bronchitis, smoking is the main cause of emphysema. Symptoms include severe breathlessness on exertion, weight loss, and swelling in the extremities. The skin takes on a bluish color from lack of sufficient gas exchange, there is tightness in the chest, and the affected person wheezes.

Bullous emphysema is a variety of emphysema in which the distended alveoli form large air cysts on one or both of the lungs and occasionally rupture, causing lung collapse.

Pneumonia

Pneumonia is an inflammation of the lungs. It can be caused by bacterial or viral invasion of the tissue or by aspiration of foreign substances into the lower respiratory tract. The lung tissue progresses through an inflammatory reaction that produces symptoms of difficulty breathing, fever, productive cough, shortness of breath, and sometimes chest pain. Pneumonia is more frequently seen when a person's immune system is compromised or when the person has an upper respiratory disorder that causes the normal protective mechanisms to be inefficient. Its etiology can be challenging to pinpoint.

Cystic Fibrosis

Cystic fibrosis is a hereditary disease that affects the functioning of the body's exocrine glands: the mucus-secreting and sweat glands. In persons with this disease, a protein is produced that lacks the amino acid phenylalanine. This flawed protein distorts the movement of salt and water across the membranes that line the lungs and gut, resulting in dehydration of the mucus that normally coats these surfaces. Thus, the normal mucous secretions in the respiratory and digestive systems become abnormally thick, sticky, and concentrated. The thick, sticky mucus accumulates in the lungs, plugging the bronchi and making breathing difficult. This condition results in chronic respiratory infections, often bacterial. Chronic cough, recurrent pneumonia, and progressive loss of lung function are the major manifestations of this disease. The goals of treatment are to keep the secretions fluid and moving and to maintain airway patency as much as possible. Because the disease increases tenacious mucous secretions, acetylcysteine, a mucolytic drug, is the drug of choice.

MUCOLYTIC DRUGS

Mucolytics break down mucus and help the high-risk respiratory patient cough up thick, tenacious secretions to improve breathing and airflow. The drugs can be administered by a nebulizer or by direct instillation into the trachea through an endotracheal tube or tracheostomy. Mucolytics usually are reserved for patients who have major difficulty mobilizing and coughing up secretions. Acetylcysteine (Mucomyst) is the prototype mucolytic agent Table 35.1 presents a summary of selected mucolytic agents.

Nursing Management of the Patient Receiving P Acetylcysteine

Core Drug Knowledge

Pharmacotherapeutics

Acetylcysteine is used to liquefy the thick, tenacious secretions of patients whose respiratory disorders make it difficult to mobilize and cough up these secretions. These disorders include CAL, cystic fibrosis, pneumonia, and tuberculosis. Acetylcysteine also is indicated for patients who develop atelectasis (collapse of the alveoli) because of thick mucous secretions. It can be used during diagnostic bronchoscopy to clear the airway, to facilitate the removal of secretions postoperatively, and to facilitate airway clearance and suctioning in patients with tracheostomies. Other uses for acetylcysteine include treating acetaminophen overdose, hepatorenal syndrome, and toxic renal effects caused by cisplatin therapy. It is also used to prevent contrast-induced renal complications in high-risk patients receiving contrast agents for diagnostic imaging tests.

TABLE 35.1 Summary of Selected C Mucolytics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P acetylcysteine (Mucomyst)	Mucolytic adjuvant therapy for abnormal or viscous mucous secretions in acute and chronic bronchopulmonary disease Diagnostic bronchial studies Acetaminophen antidote Contrast-induced nephropathy prophylaxis	Nebulization with face mask, mouthpiece, tracheostomy; 1–10 mL of 20% solution or 2–20 mL of 10% solution q2–6 h Nebulization with tent, croupette: up to 300 mL per treatment Instillation: Direct or by tracheostomy, 1–2 mL of a 10%–20% solution q1–4 h Diagnostic bronchogram: Before the procedure, give two to three administrations of 1–2 mL of a 20% solution or 2–4 mL of a 10% solution by nebulization or intratracheal instillation Acetaminophen antidote: PO, 140 mg/kg loading dose followed by 17 maintenance doses of 70 mg/kg starting 4 h after the loading dose Prevention of contrast-induced nephropathy: PO 600 mg 2×/d	*Onset:* Instillation and inhalation, 1 min *Duration:* 2–3 h $t_{1/2}$: 6–25 h
dornase alfa (Pulmozyme)	Management of respiratory symptoms associated with cystic fibrosis	*Adult:* Inhaled, 2.5 mg qid through nebulizer *Child* >5 y: Inhaled, adult dosage	*Onset*: Slow *Duration*: 1 wk $t_{1/2}$: Unknown

Pharmacokinetics

Acetylcysteine is delivered directly to the respiratory system by nebulizer (inhalation) or direct instillation. Onset of effect occurs within 1 minute, with a peak effect occurring within 5 to 10 minutes. The drug is metabolized in the liver and is excreted in the urine.

Pharmacodynamics

Acetylcysteine affects the mucoproteins in the respiratory secretions. It splits disulfide bonds that are responsible for holding the mucous material together. The result is a decrease in the tenacity and viscosity of the secretions. This drug also protects liver cells from being damaged during episodes of acetaminophen toxicity. For best results, acetylcysteine is given within 8 to 10 hours after ingestion of acetaminophen. It has this effect because it normalizes hepatic glutathione levels and binds with a reactive hepatotoxic metabolite of acetaminophen. In its role in preventing contrast-induced nephropathy, acetylcysteine acts as an antioxidant and vasodilator. Antioxidants prevent oxygen free radicals from bonding with other unbound radicals and thus reduce cell damage.

Contraindications and Precautions

Acetylcysteine is contraindicated in patients who are hypersensitive to the drug. It should be used with caution in patients with a history of respiratory compromise. For example, acetylcysteine should be used with caution in any condition that compromises the patient's ability to cough, because the increased volume of secretions can compromise the airway if it is not cleared. It should also be used with caution in patients who have asthma because bronchospasm can occur.

Intravenous (IV) acetylcysteine is used with caution in patients with serious hepatic disease because these patients may have higher serum concentrations of acetylcysteine than other patients do. Oral acetylcysteine may induce vomiting; thus, it should be given cautiously to patients with esophageal varices or peptic ulcer disease because vomiting can result in acute bleeding.

Acetylcysteine is a pregnancy category B drug.

Adverse Effects

Inhaled acetylcysteine may induce bronchospasm, bronchoconstriction, chest tightness, a burning feeling in the upper airway, and rhinorrhea. Some patients report stomatitis as well. Less common adverse effects are fever, chills, drowsiness, and clammy skin.

IV acetylcysteine may induce anaphylactoid reactions such as angioedema, chest tightness, rash, hypotension, and tachycardia. Both IV and oral acetylcysteine may cause nausea and vomiting.

Drug Interactions

No important drug interactions have been reported for acetylcysteine.

Assessment of Relevant Core Patient Variables

Health Status

Before initiating therapy, perform a physical examination to establish baselines. This examination should include temperature, skin evaluation, respiratory evaluation (including adventitious sounds and ability to cough), and an abdominal assessment for potential hepatomegaly.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding, because acetylcysteine should be avoided during pregnancy and lactation unless the benefit to the mother outweighs the potential risk to the fetus or child.

Environment

Inhaled acetylcysteine usually is administered under the supervision of a respiratory therapist or specially trained nurse, although some patients or caregivers trained to administer it may give it at home.

Patients receiving acetylcysteine for contrast-induced nephrotoxicity or acetaminophen overdose must be closely monitored; thus, acetylcysteine given for these purposes is administered in the acute care hospital.

Nursing Diagnoses and Outcomes

- Ineffective Airway Clearance related to drug effect or bronchospasm
  Desired outcome: *The patient's airway will be maintained without increased difficulty breathing.*
- Disturbed Sensory Perception, Olfactory, related to odor of drug and route of administration
  Desired outcome: *The patient will remain comfortable and able to tolerate drug therapy.*
- Imbalanced Nutrition: Less than Body Requirements, related to nausea and vomiting.
  Desired outcome: *The patient will maintain nutritional balance throughout therapy.*
- Risk for Injury related to anaphylactoid reaction
  Desired outcome: *Potential anaphylactoid reactions will be recognized and treated appropriately.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer an inhaled beta agonist before administering acetylcysteine, to dilate the bronchial tree and enable the drug to permeate the entire tree. Read the instructions for using the inhalation mask before administering inhaled acetylcysteine. Monitor the nebulizer for any buildup of the drug in the mask from evaporation. Dilute oral acetylcysteine with any kind of diet soda to mask the taste.

Minimizing Adverse Effects

Inform the patient that nebulization may produce an initially disagreeable odor, but that this odor is transient. Remove residual drug from the patient's face after administration by face mask; the drug may irritate the face and will make it feel sticky and uncomfortable. Establish a routine for pulmonary hygiene to eliminate secretions as efficiently as possible; keep suction equipment available.

Carefully monitor the patient receiving IV acetylcysteine for signs of anaphylactoid reaction. If the patient's face becomes flushed, slow the administration of acetylcysteine and administer diphenhydramine as ordered.

Providing Patient and Family Education

- Explain the rationale for receiving acetylcysteine.
- Instruct patients to report all adverse effects, including difficulty breathing, severe nausea, and dizziness.
- Explain to patients that inhaled acetylcysteine will help to get rid of mucus in the lungs.
- Inform patients that they must not take this drug without the assistance of a respiratory therapist or other health care provider unless they have been taught how to prepare the drug and how to use the nebulizer for administration.
- Warn patients not to take any other drugs without their provider's approval and not to drink alcohol while taking this drug.
- Teach patients and their family members all aspects of pulmonary hygiene, including drainage, cupping, coughing, and deep-breathing exercises. Encourage other methods of keeping secretions loose: drinking plenty of fluids, using a humidifier, and avoiding dry or smoke-filled areas.
- Inform patients that nebulization may produce a disagreeable odor, but that this odor is transient. In addition, explain the need to wipe the face with water to remove residual drug after administration by face mask because the drug may irritate the face and make it feel uncomfortable. These patient education tips help increase adherence to drug therapy.

Ongoing Assessment and Evaluation

For the patient receiving acetylcysteine for acetaminophen overdose, monitor for anaphylactoid reactions and schedule serial liver function tests. For the patient receiving acetylcysteine to prevent contrast-induced nephrotoxicity, monitor kidney function tests, urinalysis, and intake and output of food and fluids. For the patient receiving acetylcysteine for its mucolytic effects, assess the patient for proper techniques of pulmonary hygiene and respiratory status.

Determinants of successful therapy depend on the pharmacotherapeutic use of acetylcysteine. In managing acetaminophen overdose, the patient recovers without permanent hepatic dysfunction. The patient receiving acetylcysteine before contrast imaging maintains his/her baseline renal function. The patient receiving acetylcysteine for its respiratory effects tolerates the procedure without breathing difficulty, maintains his/her respiratory status, and continues with drug therapy. There is evidence, by history and breath sounds, that secretions are loosening and the patient is having success coughing and moving secretions.

Drug Closely Related to P Acetylcysteine

Dornase alfa (Pulmozyme) is a mucolytic agent prepared by techniques that use recombinant deoxyribonucleic acid

MEMORY CHIP

P Acetylcysteine

- Used to liquefy thick, tenacious secretions
- Major contraindication: hypersensitivity
- Most common adverse effects: nausea, vomiting, and rhinorrhea
- Most serious adverse effects: bronchospasm and bronchoconstriction
- Maximizing therapeutic effects: Refrigerate the solution and use it within 96 hours.
- Minimizing adverse effects: Keep suction equipment close by.
- Most important patient education: correct use of special equipment

(DNA). The mucus of people with cystic fibrosis contains excess DNA. The drug selectively breaks down respiratory tract mucus by separating this extracellular DNA from proteins. This drug is used as adjunctive therapy to relieve the buildup of secretions in cystic fibrosis. It does not replace any other therapy for cystic fibrosis, but it does help keep the airways open and functioning longer. Caution must be used in anyone with a history of hypersensitivity to hamster protein because the drug is manufactured using Chinese hamster ovary cells. It is not yet approved for use in children younger than 5 years old. Adverse effects can include hoarseness and sore throat related to nebulizer use, skin rash, and conjunctivitis.

C BRONCHODILATORS

Bronchodilators are drugs used to facilitate respiration by dilating the airways. Sympathomimetics (beta-2 adrenergic agonists), such as albuterol; anticholinergics, such as ipratropium bromide; and xanthine derivatives, such as theophylline, are bronchodilators commonly used to treat respiratory diseases. Bronchodilators may be administered orally, parenterally, or by inhalation. Inhalation is the most frequent method using metered-dose inhalers (MDIs) or dry-powder inhalers (DPIs). Table 35.2 presents a summary of selected bronchodilators.

• C Beta Agonists (Sympathomimetics)

As discussed in Chapter 13, sympathomimetics are drugs that mimic the effects of the sympathetic nervous system. As a quick review, the body has two subtypes of beta receptors: beta-1 and beta-2. Drugs that stimulate these receptors may be nonspecific or selective to either beta-1 or beta-2 receptors. Beta-2 receptors are more predominant in the lungs, whereas beta-1 receptors are more predominant in the heart. One of the actions of beta stimulation in the sympathetic nervous system is dilation of the bronchi and increased rate and depth of respiration. For respiratory disorders, the drugs of choice would be those that are beta-2 selective. Albuterol (Proventil, Ventolin) is the prototypical beta-agonist agent

Nursing Management of the Patient Receiving P Albuterol

Core Drug Knowledge

Pharmacotherapeutics

Albuterol is used as a bronchodilator in managing CAL and asthma

Pharmacokinetics

Albuterol may be administered orally in tablet or liquid form and by inhalation. Oral inhalation is by MDI, or nebulizer (Box 35.3). Following oral inhalation, bronchodilation occurs in 5 to 15 minutes, after which albuterol is absorbed over several hours from the respiratory tract. The kidneys excrete 80% to 100% of a dose within 72 hours, whereas 10% may be eliminated in feces.

When albuterol is administered orally in tablet or liquid form, bronchodilation occurs within 30 minutes. The kidneys excrete 75% of a dose within 72 hours as metabolites, and 4% may be found in feces.

Pharmacodynamics

Albuterol is a moderately selective beta-2 agonist. It selectively stimulates receptors of smooth muscle in the lungs, the uterus, and the vasculature that supplies skeletal muscle. The main result of albuterol binding to beta-2 receptors in the lungs is relaxation of bronchial smooth muscles. This relaxation of bronchial smooth muscle relieves bronchospasm, reduces airway resistance, facilitates mucus drainage, and increases vital capacity. Figure 35.2 shows where albuterol and other asthma medications exert their effects.

Contraindications and Precautions

The only absolute contraindication to albuterol is hypersensitivity to the drug or any components of the delivery system, such as fluorocarbons.

Precautions of albuterol use include hypertension, cardiac disease, cardiac arrhythmias, ischemic heart disease, hyperthyroidism, diabetes mellitus, and seizures. Selectivity is relative; therefore, potential beta-1 stimulation may exacerbate these conditions.

Albuterol, a pregnancy category C drug; should be used cautiously in pregnancy because beta-2 agonists may interfere with uterine contractility. This effect occurs more frequently when albuterol is administered orally than when it is inhaled.

Adverse Effects

Adverse effects to albuterol are related to its sympathomimetic action and occur more frequently when the drug is administered orally than when it is inhaled. The most common adverse effects of inhaled albuterol include throat irritation, palpitations, sinus tachycardia, anxiety, tremor, and increased blood pressure. Rarely, serious adverse effects such as bronchospasm, urticaria, or angioedema may occur.

Frequent adverse effects of oral albuterol include tachycardia or palpitations, anxiety, tremors, headache, insomnia,

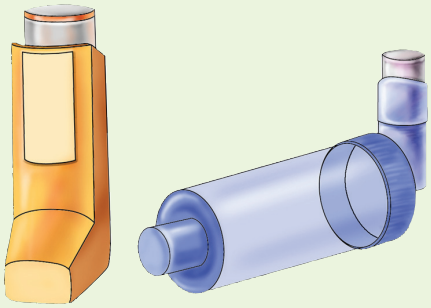
Box 35.3 TYPES OF INHALATION DEVICES

Metered-dose inhaler (MDI)

- A small, hand-held device that delivers a set amount of drug with each activation
- Requires coordination to inhale medication correctly
- Optimally, approximately 10% of drug reaches the lung
- Important to wait at least 1 minute between puffs
- May be used with a "spacer" to increase amount of drug delivered to the lungs



MDI MDI with spacer

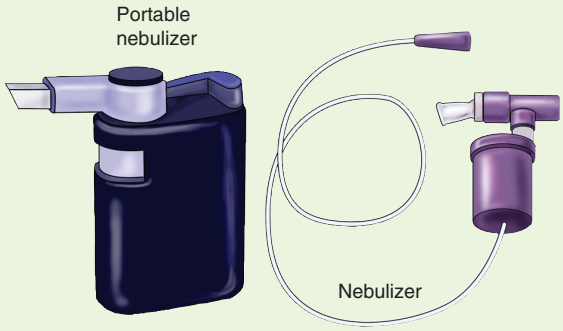
Dry-powder inhaler (DPI)

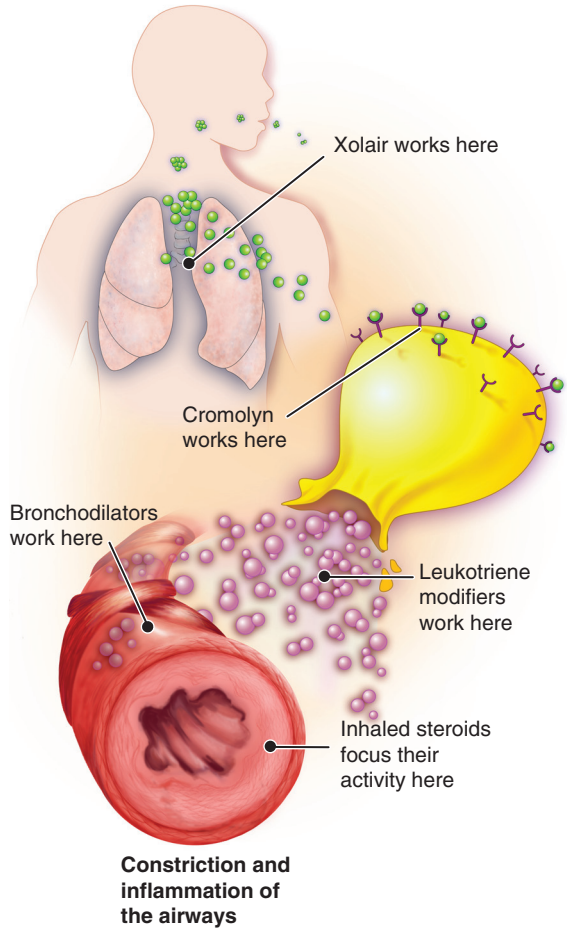
- A small, hand-held device that delivers a dry, micronized powder with each inhalation
- Does not require coordination
- Optimally, approximately 20% of drug reaches the lung
- Important to wait at least 1 minute between inhalations

Dry-powder inhaler

Nebulizer

- A small machine that delivers misted droplets of drug into the lungs
- Delivered through a mouthpiece or mask
- Takes longer time to deliver medication to the lungs than MDIs or DPIs
- More effective for some patients than MDIs or DPIs





• FIGURE 35.2 Sites of action of drugs used in controlling asthma.

muscle cramps, and gastrointestinal (GI) symptoms such as dyspepsia, nausea, and vomiting.

Overuse of albuterol may induce rebound bronchoconstriction, regardless of the method of administration.

Drug Interactions

Albuterol may interact with other sympathomimetic agents, beta-adrenergic blocking agents, digoxin, antidepressants such as monoamine oxidase inhibitors (MAOIs) or tricyclic antidepressants, and potassium-losing diuretics. Table 35.3 presents these potential drug–drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

Evaluate the patient for potential medical conditions or other drug therapy that contraindicates using albuterol or requires close patient monitoring. Any positive findings should be communicated to the health care provider.

Perform a baseline physical examination, concentrating on the cardiac and respiratory systems. Document the baseline findings for later comparison to evaluate efficacy of treatment or potential adverse effects.

TABLE 35.3 Agents That Interact with P Albuterol

Interactants	Effect and Significance	Nursing Management
sympathomimetics	Additive effects may occur when albuterol is administered in combination with other sympathomimetic drugs. This increases risk of cardiovascular adverse effects.	Monitor vital signs frequently. Monitor neurologic status.
beta-adrenergic blocking agents	Albuterol has exact opposite effect on body as beta-adrenergic blocking agents. Additionally, beta blockers may induce bronchospasm.	Monitor for bronchospasm.
digoxin	Albuterol may decrease serum digoxin levels.	Monitor for therapeutic effects of digoxin. Monitor serum digoxin levels. Discuss adjustment of digoxin dose with health care provider.
diuretics	Beta agonist may worsen ECG changes or hypokalemia that may be induced by loop or thiazide diuretics.	Monitor potassium levels. Monitor for signs of hypokalemia. Monitor for ECG changes.
MAOI or tricyclic antidepressants	MAOI and tricyclic antidepressants potentiate albuterol's effect on peripheral vasculature. This may result in severe hypotension.	Monitor blood pressure. Ensure safety.

Life Span and Gender

Evaluate the pregnancy status of female patients. Albuterol is classified as a pregnancy class C drug because it can interfere with uterine contractility as a result of its beta-adrenergic– mediated relaxant effects on smooth muscle.

Determine the age of a pediatric patient before administering albuterol. Oral albuterol tablets and extended-release tablets are not recommended for children younger than 6 years of age, and liquid albuterol is not recommended for children younger than 2 years of age.

Lifestyle, Diet, and Habits

Assess the patient's intake of caffeine, including coffee, tea, soda, cocoa, candy, and chocolate. Caffeine has sympathomimetic effects that may increase the risk for adverse effects. Also, assess for use of over-the-counter (OTC) medications such as pain relievers, appetite suppressants, and cold medicines because they frequently contain caffeine.

Environment

Albuterol is most frequently used in the home environment. It is also the drug of choice for patients in the emergency department experiencing an acute asthma attack.

Nursing Diagnoses and Outcomes

- Anxiety related to sympathomimetic effects of albuterol administration
  Desired outcome: *The patient will engage in interventions that decrease anxiety.*
- Ineffective Tissue Perfusion: Cardiopulmonary, related to rebound bronchoconstriction caused by overuse of albuterol
  Desired outcome: *The patient will use albuterol as prescribed by the health care provider and contact that person if symptoms do not abate.*

Planning and Intervention

Maximizing Therapeutic Effects

To obtain the correct dose of albuterol, prime the device by releasing 2 test sprays when using a new MDI or if the MDI has not been used in more than 3 days. Because albuterol is most commonly administered by inhalation, it is important to supervise the patient's ability to use the MDIor nebulizer appropriately (Box 35.4).

Minimizing Adverse Effects

Patients who self-administer albuterol may use their MDIs more frequently than recommended. This practice can result in rebound bronchoconstriction, which may motivate the patient to increase MDI use, stimulating the cycle of rebound congestion. Explain the need to adhere to the recommended frequency of administration. The patient should be encouraged to contact the health care provider to obtain adjunctive medications if symptoms persist, rather than increase the frequency of albuterol use.

Providing Patient and Family Education

- Teach patients that inhaled albuterol is called a "rescue drug" and should be the *first drug* to use when symptoms of an acute attack occur.
- Teach patients how to use an MDI. Include the correct procedure for administering medication, methods of keeping the equipment clean, and how to assess when to change the canister (Box 35.5).
- Explain the importance of using the drug as prescribed and encourage patients to communicate with the health care provider if the symptoms do not abate with the recommended therapy.
- Explain the importance of limiting caffeine intake.
- Explain the importance of refraining from use of OTC drugs without the health care provider's knowledge.

BOX 35.4 COMMUNITY BASED CONCERNS

How to Use an Inhaler

When a patient is first diagnosed with asthma and prescribed inhalation therapy, he or she may need to learn how to use the inhaler that will deliver drug therapy. The nurse may be the health care provider who supplies instructions such as these:

Metered-Dose Inhaler (MDI)

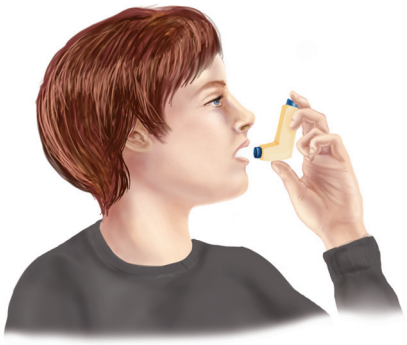
1. When using a new inhaler, or one that has not been used in several days, point the inhaler away from you and prime the inhaler 1–2 times.
2. Hold the device upright and shake it.
3. Tilt the head back slightly.
4. Exhale and open mouth.
5. Position the inhaler in one of three ways:
   - Held 1 to 2 inches from the mouth (this is preferred)
   - Using a spacer
   - With the inhaler between the lips
6. Start to inhale slowly and press down on the inhaler to release the medication.
7. Breathe in for 3 to 5 seconds.
8. Hold your breath for 10 seconds to allow the drug to reach deep into the lungs.
9. Repeat for the ordered number of puffs, allowing 1 minute between each puff.

Spacers are recommended for children, older adults, and anyone who has difficulty using a nebulizer alone. Spacers are indicated when using inhaled steroids.

Dry-Powder Inhaler (DPI)

1. Prepare the medication for inhalation.
2. Place the mouthpiece to the lips.
3. Inhale quickly.
4. Hold your breath for 10 seconds to allow the drug to reach deep into the lungs.
5. Capsules for inhalation (such as those used in the Foradil Aerolizer or Spiriva HandiHaler) must not be swallowed.
6. Do not place your device in water.

When the patient is prescribed more than one type of inhaler, instruct the patient to use the bronchodilator first to open air passages, and then use other prescribed medications.



Ongoing Assessment and Evaluation

Evaluate for the symptoms of asthma or CAL in patients using albuterol. Evaluate for CNS symptoms, such as anxiety, tremors, insomnia, or CNS disturbances. Determine the frequency of use and refer the patient to the health care provider if albuterol is needed more frequently than prescribed.

BOX 35.5 COMMUNITY BASED CONCERNS

How to Care for Your Inhaler

- Keep the inhaler clean.
- Once a week, remove the medication canister from the plastic casing and wash the casing in warm, soapy water. When the casing is dry, replace the medication canister and place the cap on the mouthpiece. Ensure that the hole is clear.
- Check the expiration date.
- Keep a log of doses used to know when medication should be replaced.

Drugs Closely Related to P Albuterol

Several other beta-agonist agents are used as bronchodilators. The pharmacodynamics and pharmacokinetics of all of these drugs are very similar; slight variations or different vehicles make them the drugs of choice for different patients. A patient may need to try several of these before finding the one that works most effectively. In addition, combination inhalers, with beta agonists combined with either anticholinergic drugs or inhaled steroids, are available.

Short-Acting Beta-2 Agonists

Epinephrine

Epinephrine is the active ingredient in OTC inhalers such as Primatene Mist. It is a nonselective adrenergic agonist; therefore, it stimulates alpha-1, alpha-2, beta-1, and beta-2. For that reason, it is prone to induce multiple adverse reactions, especially tachycardia, hypertension, chest palpitations, and anxiety.

MEMORY CHIP

P Albuterol

- Used for acute and chronic management of CAL and asthma
- Major contraindication: hypersensitivity
- Most common adverse effects: throat irritation, palpitations, tachycardia, anxiety, tremors, and increased blood pressure
- Most serious adverse effects: bronchospasm, urticaria, and angioedema
- Maximizing therapeutic effects: Ensure correct use of inhalation device.
- Minimizing adverse effects: Do not use more than prescribed.
- Most important patient education: This rescue drug should be used first for all acute symptoms of shortness of breath or wheezing.

Levalbuterol

Levalbuterol (Xopenex) is the R-isomer of albuterol and has approximately twofold greater binding affinity than racemic albuterol and approximately 100-fold greater binding affinity than the S-isomer of albuterol. It is available as a solution for nebulization and as an MDI.

Pirbuterol

Pirbuterol (Maxair) is structurally very similar to albuterol. It is used to interrupt an acute asthmatic event or to prevent bronchospasm associated with asthma, exercise-induced bronchospasm, bronchitis, emphysema, and bronchiectasis.

Terbutaline

Terbutaline (Brethine) is shorter acting than albuterol or salmeterol. Its main pharmacotherapeutic use is the prevention of bronchospasm, but it is also used clinically to abort premature labor.

Long-Acting Beta-2 Agonists

Arformoterol

Arformoterol tartrate (Brovana) is a long-acting beta-2 agonist bronchodilator for nebulization. It is the isomer of formoterol specifically developed for maintenance of chronic obstructive disorders such as chronic bronchitis and emphysema. Arformoterol is used cautiously in patients being treated with MAOIs, tricyclic antidepressants, or other drugs known to prolong the QTC interval because these agents may potentiate the action of adrenergic agonists on the cardiovascular system. It should not be used in conjunction with other long-acting beta-2 agonists, or with any other medications that contain long-acting beta-2 agonists.

The most common adverse effects of arformoterol are back and chest pain, diarrhea, and sinusitis. A Black Box warning states that long-acting beta-2–adrenergic agonists such as arformoterol may increase the risk of asthma-related death. Data from a large placebo-controlled U.S. study comparing the safety of another long-acting beta-2–adrenergic agonist (salmeterol) or placebo added to usual asthma therapy showed an increase in asthma-related deaths of patients receiving salmeterol.

Instruct the patient who is making the transition from short-acting beta-2 agonists to stop routine use when starting arformoterol. Should acute symptoms occur, use a short-acting beta-2 agonist.

Formoterol

Formoterol (Foradil) is a highly selective long-acting beta-2 agonist administered as a DPI. The drug does not work fast enough to be used for an acute asthma attack. It is used primarily to prevent exercise- induced asthma, although it approved for use in patients with asthma, bronchospasm, and CAL. Formoterol has the same Black Box warning as arformoterol. Formoterol fumate (Performist) is an inhalation solution, approved for long-term maintenance, for emphysema and chronic bronchitis.

Salmeterol

Salmeterol (Serevent Diskus) is another highly selective long-acting beta-2 agonist with the same indications as formoterol. Like formoterol, it has a slow onset, which makes it useful for the prevention of attacks but not for an acute attack. Salmeterol also carries a Black Box warning because the Salmeterol Multicenter Asthma Research Trial (SMART) showed an increase in asthma-related deaths in patients receiving salmeterol (13 deaths among 13,176 patients treated for 28 weeks on salmeterol, versus 3 deaths among 13,179 patients on placebo).

• C Respiratory Anticholinergic Agents

Inhaled anticholinergic drugs are considered first-line treatment for patients with CAL whose symptoms have become persistent. Anticholinergic agents diminish the effect of acetylcholine, the terminal neurotransmitter in the parasympathetic nervous system. In the respiratory system, use of inhaled anticholinergic drugs stops the bronchoconstriction that is caused by stimulation of the parasympathetic nervous system. Ipratropium bromide (Atrovent) is the prototype respiratory anticholinergic agent (Table 35.4).

Nursing Management of the Patient Receiving P Ipratropium Bromide

Core Drug Knowledge

Pharmacotherapeutics

Ipratropium bromide is used for maintenance treatment of bronchospasm associated with asthma, bronchitis, or pulmonary emphysema.

Pharmacokinetics

Ipratropium bromide is administered by oral inhalation (MDI or nebulizer) or intranasal spray. Following oral inhalation, onset of action occurs between 15 and 30 minutes; action peaks in 1 to 2 hours and lasts 4 to 5 hours. Ipratropium bromide is not readily absorbed into the systemic circulation after inhalation either from the surface of the lung or from the

TABLE 35.4 Summary of Selected Anticholinergic Agents

P ipratropium (Atrovent HFA) MDI; 17 mcg/spray	Bronchospasm maintenance Asthma and COPD	*Adult:* HFA, 2 puffs 4×/d *Adult:* NEB, 0.25 mg every 6 h Max: 12 puffs/d	*Onset:* 15 min *Duration:* 3–4 h $t_{1/2}$: 2–3 h
tiotropium (Spiriva) 18 mcg/inhalation DPI	Bronchospasm maintenance	*Adult:* DPI, 1 inhalation every day *Child:* Safety not established	*Onset:* 5 min *Duration:* 24 h $t_{1/2}$: 5–6 d

GI tract. Approximately 50% of the absorbed drug is excreted unchanged in the urine. After intranasal dosing, less than 20% of an ipratropium dose is absorbed from the nasal mucosa into the systemic circulation. The metabolism of intranasal ipratropium bromide is the same as that of the inhaled drug.

Pharmacodynamics

Ipratropium antagonizes the action of acetylcholine by blocking muscarinic cholinergic receptors. Blockade of these cholinergic receptors decreases the formation of cyclic guanosine monophosphate, resulting in decreased contractility of smooth muscle and thereby reducing bronchospasm.

Contraindications and Precautions

Ipratropium aerosol inhalation is contraindicated in patients with sensitivity to ipratropium and atropine or any of its derivatives.

Because of its anticholinergic effects, ipratropium should be used with caution in patients with bladder obstruction, prostatic hypertrophy, or closed-angle glaucoma. Ipratropium may precipitate urinary retention in patients with pre-existing bladder obstruction or prostatic hypertrophy. It may increase intraocular pressure and aqueous outflow resistance in patients with closed-angle glaucoma, especially if the medication gets into the eyes.

Ipratropium is a pregnancy category B drug.

Adverse Effects

Ipratropium aerosols can produce a paradoxic acute bronchospasm that can be life threatening in some patients. This rare problem, when it occurs, is usually seen with the first inhalation from a newly opened MDI. Like a new albuterol MDI, a new ipratropium MDI should be primed with 2 sprays before use. Another serious, but rare, adverse effect is an anaphylactoid reaction. Symptoms include urticaria; angioedema of the tongue, lips, and face; maculopapular rash; bronchospasm; laryngospasm; pruritus; and oropharyngeal edema. This reaction may occur when a patient has an unknown allergy to soybeans, legumes, or soya lecithin.

More commonly, ipratropium may induce cough, hoarseness, throat irritation, or dysgeusia. The classic anticholinergic adverse effects—dry mouth, constipation, urinary retention, and blurred vision—may also occur, but not as frequently or intensely as with systemic anticholinergic drugs.

Nasal administration of ipratropium may induce epistaxis, headache, rhinitis, nasal congestion, rhinorrhea, and general nasal irritation.

Temporary ocular irritation, ocular pain, mydriasis, cycloplegia, blurred vision, conjunctivitis, or visual impairment may result from spraying ipratropium products inadvertently into the eyes.

Drug Interactions

No serious drug–drug interactions are associated with ipratropium. Ipratropium inhalation solution forms a precipitate with cromolyn sodium inhalation solution if they are mixed together in a nebulizer. Theoretically, potential exists for ipratropium to have additive anticholinergic effects when administered with other antimuscarinics.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for potential medical conditions or other drug therapy that contraindicates using ipratropium or requires close patient monitoring. Perform a baseline respiratory examination and document the findings. This baseline assessment will be used to evaluate the efficacy of treatment.

Life Span and Gender

Evaluate the pregnancy status of the patient, as needed. Ipratropium is classified as a pregnancy category B drug. However, human studies have not been performed. Therefore, ipratropium should be used during pregnancy only when the benefits to the mother outweigh the possible risk to the fetus. Minimal amounts of inhaled ipratropium reach breast milk; therefore, the potential risk to the breastfeeding infant is negligible. Safety and effectiveness of ipratropium have not been established in infants or in children younger than 5 years.

Lifestyle, Diet, and Habits

Determine whether the patient smokes. Smoking causes vasoconstriction, the opposite of the action of ipratropium.

Environment

Ipratropium is most frequently self-administered in the home environment. It is used on a daily basis, regardless of the presence or absence of symptoms. Although beta-agonist drugs, such as albuterol, are the drugs of choice for acute symptoms, ipratropium may still be delivered during exacerbations of asthma.

Nursing Diagnoses and Outcomes

- Risk for Injury (bronchospasm) related to use of new canister of ipratropium
  Desired outcome: *The patient will "test-spray" a new canister three times before inhaling the medication.*
- Risk for Injury (anaphylactoid reactions) related to allergies to soybeans, legumes, or soya lecithin.
  Desired outcome: *The patient will review past allergic responses to assess whether any of the causative foods may have been responsible.*

Planning and Intervention

Maximizing Therapeutic Effects

Explain the importance of taking ipratropium daily, despite the absence of symptoms. Watch the patient demonstrate the correct use of the MDI.

Minimizing Adverse Effects

Explain the importance of using the MDI as prescribed to avoid systemic absorption that leads to an increased risk of adverse effects.

Providing Patient and Family Education

- Advise patients that ipratropium is used prophylactically to reduce the frequency and severity of future asthma attacks. It will not abort an asthma attack in progress.
- Advise patients to avoid using ipratropium if they have a history of allergy to soybeans, legumes, or soya lecithin.
- Remind patients that ipratropium must be taken daily, despite the absence of symptoms of asthma.
- Remind patients that overuse of ipratropium may induce adverse effects or increase their intensity.
- Teach patients to use an MDI. Include the correct procedure for administering the medication, keeping the equipment clean, and assessing when to change the canister.

Ongoing Assessment and Evaluation

Assess the patient's need for beta-agonist drugs in addition to ipratropium. If the patient continues to need beta agonists more than twice a week, refer the patient to the health care provider for additional assessment.

Drug Closely Related to P Ipratropium Bromide

Tiotropium

Tiotropium (Spiriva), administered as a DPI, is structurally close to ipratropium but pharmacodynamically different. It is selective for muscarinic receptors 1 to 3; however, it dissociates from them much slower than ipratropium does. This slow dissociation gives tiotropium a long duration of action and enables once-daily dosing. Another advantage is that tiotropium is minimally absorbed, which decreases the risk for systemic adverse effects.

Tiotropium should be used with caution in the elderly because they may experience anticholinergic effects such as blurred vision, constipation, urinary retention, and dry mouth despite the drug's minimal systemic absorption. It should also be used with caution in pregnant women. Tiotropium is a pregnancy category C drug; whether it crosses into breast milk is unknown.

As with ipratropium, there is potential for additive anticholinergic effects when tiotropium is administered with other antimuscarinics.

MEMORY CHIP

P Ipratropium Bromide

- Used for maintenance therapy of CAL or asthma
- Major contraindications: hypersensitivity to fluorocarbons or legumes, such as soybeans or peanuts
- Most common adverse effects: cough, hoarseness, throat irritation, dysgeusia, and anticholinergic effects
- Most serious adverse effects: bronchospasm and anaphylaxis
- Maximizing therapeutic effects: Administer the medication daily, despite the absence of symptoms.
- Minimizing adverse effects: Use only as directed to decrease potential systemic absorption.
- Most important patient education: This drug will not abort an acute asthma attack.

• C Xanthine Derivatives

The xanthine derivatives, including theophylline, aminophylline, dyphylline, and caffeine, come from a variety of naturally occurring sources. They are excellent bronchodilators but do not work as rapidly as beta-adrenergic agonist drugs. Theophylline (Elixophyllin, Theo24, Uniphyl) is the prototype xanthine derivative bronchodilator (Table 35.5).

Nursing Management of the Patient Receiving P Theophylline

Core Drug Knowledge

Pharmacotherapeutics

Theophylline is indicated for the symptomatic relief or prevention of bronchial asthma and reversal of bronchospasm associated with CAL. An off-label use is treatment of apnea and bradycardia in premature infants.

Pharmacokinetics

Theophylline is given orally or intravenously. When given orally, it is well absorbed, with peak effects in 2 hours; it lasts from 4 to 8 hours. The drug is metabolized in the liver and excreted in the urine.

TABLE 35.5 Summary of Selected Xanthine Derivatives

P theophylline (Elixophyllin, Theo24, Uniphyl) 100, 200, 300, 400 ER	Acute asthma/CAL/COPD	*Adult child and infant loading dose:* IV, 5.7 mg/kg of lean body weight *Adult and child 16 to 60 y, nonsmokers IV (after loading dose):* 0.4 mg/kg/h *Adult >60 IV:* 0.3 mg/kg/h *Child IV (after loading dose):* Neonates up to 24 days, 1 mg/kg every 12 h Neonates over 24 days, 1.5 mg/kg IV every 12 h Infants 6 to 52 wk, mg/kg/h = (0.008) × (age in wk) + 0.21 IV 1–9 y, initial 0.8 mg/kg/h 9–12 y, 0.7 mg/kg/h 12–16 y, smokers, 0.7 mg/kg/h 12–16 y, nonsmokers, 0.5 mg/kg/h	*Onset:* PO, varies; peak: 2 h *Duration:* 2–3 d $t_{1/2}$: 3–5 h for nonsmoker; 4–5 h for smoker

dyphylline (Lufyllin)		*Adult:* PO, 15/mg/kg qid; IM, 250–500 mg q6h *Child:* Safety not established	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: Unknown

Pharmacodynamics

Theophylline has a direct effect on the smooth muscles of the respiratory tract, both those in the bronchi and those in the blood vessels. Although the exact mechanism of action is not fully understood, it is believed that bronchodilation is caused by inhibiting phosphodiesterase (PDEs III and IV). Nonbronchodilation occurs through other molecular mechanisms. Theophylline also increases the force of contraction of diaphragmatic muscles to draw more air into the lungs.

Contraindications and Precautions

Theophylline is contraindicated in patients with hypersensitivity to any xanthines, in those with status asthmaticus, or in those with a peptic ulcer. Many diseases and disorders decrease the clearance of theophylline, including acute pulmonary edema, chronic heart failure, cor pulmonale, hypothyroidism, sepsis with multiorgan failure, and shock, resulting in an increased risk of toxicity. Theophylline should be used with caution with any patient with cardiovascular

problems such as an arrhythmia or hypertension because of the drug's stimulatory effects. In addition, care also should be taken when theophylline is used in patients with renal or hepatic disease, because the drug is metabolized in the liver and excreted through the kidneys.

Theophylline is a pregnancy category C drug. It should be used with caution in pregnancy because it crosses the placenta and may enter breast milk.

Adverse Effects

Adverse effects related to theophylline use are related directly to serum levels of the drug. At serum levels less than 20 mcg/ mL, adverse effects are uncommon. At serum levels of 20 to 25 mcg/mL, the most common adverse effects are GI symptoms of nausea, vomiting, and diarrhea and CNS effects of headache, insomnia, and irritability. At serum levels exceeding 30 mcg/mL, adverse effects such as hyperglycemia, hypotension, arrhythmias, seizures, brain damage, and even death may occur. Even at therapeutic doses, theophylline may cause CNS effects, such as irritability (especially in children), restlessness, and muscle twitching. It also may cause GI effects, such as loss of appetite, hematemesis, and gastroesophageal reflux. Potential cardiovascular effects include palpitations, tachycardia, and circulatory failure. In the respiratory system, theophylline may cause tachypnea. Possible genitourinary effects include urinary retention in men with prostate enlargement and diuresis. Generalized effects, such as fever, flushing, rash, and elevated liver enzymes, also have occurred.

Drug Interactions

Theophylline may have a substantial interaction with a multitude of drugs (Table 35.6). These drugs decrease the clearance of theophylline, resulting in an increased risk of adverse effects and toxicity. Theophylline may also induce the metabolism of other drugs, resulting in decreased efficacy of those drugs. Many of these interactions require a dose adjustment of theophylline or the interactant drug. Potential dosage adjustments should be discussed with the health care provider.

Assessment of Relevant Core Patient Variables

Health Status

When taking the patient history before starting theophylline therapy, screen the patient for any hypersensitivity to xanthines and for peptic ulcer, active gastritis, coronary artery disease, hypothyroidism, renal or hepatic disorders, pregnancy, and lactation.

Patients with cardiac disease should be monitored closely during theophylline therapy because the drug may cause cardiovascular effects, such as palpitations, tachycardia, and elevated blood pressure.

Perform a baseline physical examination, including skin color, texture, and lesions; reflexes, orientation, and affect; and heart rate. Assess the respiratory system for breathing rate, adventitious sounds, and the patient's forced expiratory volume in 1 second (FEV_1). For patients on long-term therapy, obtain baseline thyroid, liver, and kidney function test results.

Life Span and Gender

Assess the patient for pregnancy and lactation because theophylline is contraindicated during pregnancy; newborns of mothers who used theophylline exhibit tachycardia, jitteriness, and withdrawal apnea. Assess older men carefully for possible enlargement of the prostate gland, because special precautions should be taken when administering theophylline to these patients: they should be monitored closely for any prostate changes.

Lifestyle, Diet, and Habits

Determine whether the patient smokes. Smoking cigarettes may decrease serum theophylline levels. In fact, some patients who smoke require an increase in theophylline dosage of up to 50%. Monitor patients who smoke for any change in smoking habits. It also is important to assess the diet of patients taking theophylline. Theophylline elimination is increased by a low-carbohydrate, high-protein diet and by charcoal-broiled beef. Theophylline elimination is decreased by a high-carbohydrate, low-protein diet. The effects of theophylline can be increased by foods containing xanthines, particularly caffeine. Caffeine is found in many beverages, such as coffee, tea, and cola, and in chocolate. OTC drug preparations also frequently contain caffeine.

Environment

Oral theophylline may be administered in any environment. IV theophylline is administered in an acute care setting.

Nursing Diagnoses and Outcomes

- Disturbed Sensory Perception: Kinesthetic, related to CNS effects of irritability, insomnia, and dizziness
  Desired outcome: *The patient will be protected from injury caused by CNS effects, such as dizziness and loss of balance.*
- Ineffective Tissue Perfusion: Cardiopulmonary, related to cardiac effects of drug
  Desired outcome: *Adverse effects will be limited by proper administration and monitoring of drug serum levels.*
- Risk for Injury related to headache, GI effects, and CNS effects
  Desired outcome: *The patient will develop strategies to be able to tolerate the drug and remain injury free during drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

If serum levels of theophylline have not been stabilized, screen the patient's diet, other drugs taken (including OTC

Acyclovir cimetadine diltiazem disulfiram fluvoxamine fluoroquinolone hormonal contraceptives mexiletine ticlopidine zileuton	Coadministration decreases clearance of theophylline, resulting in increased risk of adverse effects and toxicity.	Monitor for headache, insomnia, irritability, nausea, vomiting, arrhythmias, and seizures. Monitor theophylline levels.
activated charcoal	Can reduce absorption of theophylline and remove it from systemic circulation, resulting in subtherapeutic levels of theophylline	Monitor for efficacy of theophylline.
adenosine	Mechanism of action unclear; theophylline may decrease effectiveness of adenosine.	Monitor heart rate. Monitor blood pressure.
barbiturates	May induce cytochrome P-450, stimulating theophylline metabolism and increasing clearance, resulting in subtherapeutic levels of theophylline	Monitor for efficacy of theophylline.
benzodiazepines	Possible antagonistic action by competitive binding to intracerebral adenosine receptors, resulting in decreased sedative effects of benzodiazepines	Monitor sedation level. Monitor for anxiety.
beta blockers	May reduce N-demethylation of theophylline, resulting in decreased effect of one or both agents	Monitor efficacy of both drugs.
halothane	Catecholamine-induced arrhythmias possible when halothane is administered after theophylline	Document theophylline use clearly on front of chart for patients scheduled for surgery.
hydantoins	Phenytoin and theophylline metabolism increased, resulting in subtherapeutic levels of both drugs	Monitor plasma levels of both drugs.
isoniazid	Isoniazid may induce and inhibit hepatic enzymes responsible for theophylline metabolism.	Monitor for both decreased efficacy and increased adverse effects of theophylline.
ketamine	Mechanism is unknown. Coadministration may increase risk of seizures.	Monitor for seizure activity. Ensure safety.
ketoconazole	Ketoconazole may decrease absorption of theophylline.	Monitor for theophylline efficacy.
macrolide antibiotics	Inhibit metabolism of theophylline; theophylline reduces bioavailability and increases renal clearance of oral erythromycin, resulting in theophylline toxicity and macrolide ineffectivity.	Monitor drug levels of both drugs.
non-depolarizing muscle relaxants	Antagonistic activity between theophylline and nondepolarizing muscle relaxants—nontherapeutic effects of muscle relaxants	Document theophylline use clearly on front of chart for patients scheduled for surgery.
rifampin	Appears to induce hepatic metabolism of theophylline, resulting in subtherapeutic levels	Monitor theophylline efficacy.
thyroid hormones and preparations	Direct correlation between plasma thyroid hormones/preparations and theophylline clearance; hypothyroid or hyperthyroid patients, alteration in theophylline clearance	Monitor theophylline levels closely. Achieving euthyroid state is critical in controlling theophylline clearance.

BOX 35.6 COMMUNITY BASED CONCERNS

Using a Peak Flow Meter

Patients receiving inhaled bronchodilators at home can monitor the effectiveness of drug therapy and lung function by using a peak flow meter to monitor peak expiratory flow rates (PEFR). These devices are inexpensive and may be available from the health care provider or by prescription from the pharmacist.

Peak flow values are a way to quantify and evaluate lung function. Daily monitoring helps detect trends and subtle changes in lung function, sometimes even before the patient experiences symptoms. Daily monitoring also permits early and prompt intervention before the patient experiences a setback and needs to seek emergency care.

The peak flow meter consists of a mouthpiece connected to a sealed measuring device. The patient inhales as deeply as possible and then places the mouthpiece in the mouth, making a tight seal. Next, the patient blows out as hard and as fast as possible. The exhaled air propels an indicator up a scale to a number. This number, signifying liters of air per minute, represents the peak flow rate. After consulting with the provider, the patient can determine his or her normal PEFR. The patient can then keep a record of the readings and report any changes in PEFR to the health care provider.

drugs), smoking habits, and adherence to prescribed regimen. In the hospital setting, administer theophylline at a rate of 20 mg/minute. If patients have frequent exacerbations of CAL, determine the patient's ability to use a peak flow meter in the home environment to assess the need for additional bronchodilation (Box 35.6).

Minimizing Adverse Effects

Monitor serum theophylline levels carefully and discuss dosage adjustment with the health care provider to keep serum levels at 10 to 20 mcg/mL, which is the optimal therapeutic level. Never infuse theophylline rapidly; rapid infusion may cause hypotension, arrhythmias, syncope, or even death.

Administer immediate-release preparations with a meal to decrease GI distress. Administer sustained-release preparations on an empty stomach, 1 hour before or 2 hours after meals. To prevent injuries, be prepared to institute safety precautions if CNS effects occur. Additionally, provide environmental control—including adjusting lighting, heat, and noise—if irritability, restlessness, or insomnia occurs.

Providing Patient and Family Education

- Explain that theophylline will help make breathing easier.
- Caution patients not to take theophylline if they are allergic to it, if they have reactions to caffeine, or if they are breast-feeding.
- Make sure that patients report to their health care providers the names of all drugs they are currently taking.
- Explain the importance of taking theophylline exactly as prescribed and instruct patients to make a list of things that can interfere with their drug concentrations (e.g., diet, OTC drugs, and smoking). Make sure that patients and their families are aware of precautions they should take and know when to contact the health care provider if they change their diets, use OTC drugs, or change their smoking habits.
- Teach patients never to chew or crush time-release capsules; they should be swallowed whole. In addition, time-release capsules should always be taken on an empty stomach, 1 hour before or 2 hours after meals. If patients are using a solution, it should be shaken well before use. Encourage patients to take immediate-release and liquid preparations of the drug with food if GI upset occurs.
- Caution patients not to change the drug dosage without consulting the health care provider and to schedule regular checkups or blood tests so that progress can be evaluated.
- Instruct patients to take the drug around the clock; if a dose is missed, it should be taken as soon as it is remembered unless it is almost time for the next dose. However, two doses should never be taken at the same time.
- Instruct patients to avoid consuming large quantities of caffeine-containing foods (e.g., chocolates) or beverages (e.g., coffee, cola, and tea) while taking theophylline and to contact their health care provider if they change their consumption substantially. In addition, alert patients to check the ingredients of any OTC drug for caffeine before using it.
- Advise patients to ingest small, frequent meals if GI distress occurs.

CRITICAL THINKING SCENARIO

THINKING ABOUT THEOPHYLLINE AND OTHER ASTHMA THERAPIES

Martin Kell is a 12-year-old boy with a history of allergic asthma. Skin testing has revealed allergies to trees, molds, and dust. His mother, Mrs. Kell, is bringing him to the clinic for sensitization treatment. She reports that Martin has had a stuffy nose, dry cough, and occasional wheezing. On examination, scattered wheezes are noted throughout the lung fields. The physician orders the following:

Theophylline, 200 mg bid
Albuterol inhaler, 2 puffs bid
Beclomethasone inhaler, 2 puffs bid

You review all of the medications with Martin's mother, who exclaims, "All these medicines! How is he ever going to be able to take them all?"

1. Prioritize concerns to be discussed with Mrs. Kell.
2. Explain the rationale for using both inhalers.
3. Construct written instructions about using the inhalers to give to Mrs. Kell.
4. Consider what adaptations may be necessary with Martin to help ensure therapeutic adherence and effective drug therapy.
5. Propose some assessments that you can plan to make during the next visit to evaluate the effectiveness of therapy.

- Advise a quiet environment or exercise to decrease agitation or insomnia from theophylline therapy.
- Caution against using oral theophylline for an acute asthma attack because its onset is not quick enough to subdue an acute attack. IV theophylline may be used for an acute attack.
- Urge patients to report such adverse effects as headaches, insomnia, restlessness, muscle twitching, nausea, vomiting, severe GI pain, palpitation, and convulsions.

Ongoing Assessment and Evaluation

Monitor the patient taking theophylline for potential CNS and cardiovascular adverse effects. The patient's serum theophylline level should be maintained between 10 and 20 mcg/mL for optimal therapeutic effects and minimal adverse effects. After 1 to 2 weeks on theophylline, the patient should report no more than minimal discomfort from adverse effects and continue to adhere to the therapy prescribed.

Drugs Closely Related to P Theophylline

Aminophylline

Aminophylline, a theophylline salt, is pharmacologically identical to theophylline. It is more soluble than theophylline; thus, it is preferred when IV administration is needed. It is important to administer IV aminophylline at a rate not to exceed 25 mg/min. Aminophylline also can be administered as a rectal suppository (Truphylline).

Dyphylline

Dyphylline (Lufyllin) is structurally similar to theophylline. Dyphylline works by direct stimulation of the bronchial smooth muscles but is not converted into theophylline to achieve its action. It is approximately one tenth as potent as theophylline, and therefore it induces fewer adverse effects.

Caffeine

Caffeine is a naturally occurring xanthine derivative used as a CNS and respiratory stimulant, or as a mild diuretic. Caffeine often is combined with analgesics or with ergot alkaloids to treat migraine and other types of headache. Caffeine also is sold without a prescription in products marketed to treat drowsiness, or in products used for mild water-weight gain.

Caffeine is administered both orally and parenterally as a respiratory stimulant in neonates with apnea of prematurity. It reduces the frequency of apneic episodes by 30% to 50% within 24 hours of administration. Caffeine is an excellent drug for neonates because of its once-daily administration, reliable oral absorption, and wide therapeutic margin.

MEMORY CHIP

P Theophylline

- Used for symptomatic relief of bronchoconstriction and bronchospasm
- Major contraindications: status asthmaticus and peptic ulcer
- Most common adverse effects: nausea, vomiting, headache, and insomnia
- Most serious adverse effects: seizures and arrhythmias
- Maximizing therapeutic effects: Evaluate patient care variables if serum concentration not stable.
- Minimizing adverse effects: Monitor serum theophylline levels periodically.
- Most important patient education: Take the drug exactly as prescribed to avoid adverse effects.

C ANTI-INFLAMMATORY AGENTS

In addition to bronchodilators, anti-inflammatory agents are used to manage respiratory disorders, especially asthma. These agents include glucocorticoid steroids, mast cell stabilizers, and leukotriene receptor antagonists.

• C Inhaled Glucocorticoid Steroids

Glucocorticoid steroids are the most effective anti- inflammatory drugs available for managing respiratory disorders. They can be given orally, parenterally, or by inhalation. Oral and parenteral agents (discussed in Chapter 48) are the most potent and are reserved for an exacerbation of CAL or asthma that occurs despite the use of inhaled steroids. Inhaled corticosteroid (ICS) agents have become the first-line treatment for persistent asthma. Although there may be regional preferences, the prototype ICS in this chapter is flunisolide (AeroBid). Table 35.7 provides a summary of selected inhaled glucocorticosteroids.

Nursing Management of the Patient Receiving P Flunisolide

Core Drug Knowledge

Pharmacotherapeutics

Inhaled flunisolide is used to prevent bronchospasm associated with asthma, CAL, and other respiratory disorders. A maintenance drug, it is not helpful during an acute attack. Intranasal flunisolide is used to treat allergic rhinitis.

Pharmacokinetics

As with the anticholinergic ipratropium bromide, flunisolide obtains its peak effect only after 1 to 2 weeks of regular use. Despite flunisolide being an inhaled drug, systemic absorption does occur. During inhalation, especially when a spacer is not used, flunisolide is deposited in the mouth and pharynx, where some of the drug is swallowed. Also, ICS deposited in the lungs is not inactivated; therefore, any portion of the inhaled drug not used by the lungs eventually becomes systemically absorbed.

Pharmacodynamics

Inhaled glucocorticoid steroids such as flunisolide have several actions. They inhibit the production of leukotrienes and prostaglandins through interference with arachidonic acid metabolism, reduce migration and activity of the

TABLE 35.7 Summary of Selected C Inhaled Steroids

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P flunisolide (AeroBid), 250 mcg/spray; (AeroSpan), 80 mcg/spray	Asthma prophylaxis	*Adult and child >15 y:* INH, 2 puffs 2×/d Max: 8 puffs/d *Child 6–15 y:* INH, 2 puffs 2×/d Max: 4 puffs/d	Not systemically absorbed
beclomethasone HFA (QVAR), 40, 80 mcg/puff INH	Asthma prophylaxis	*Adult and child >12 y: INH, 40–160 mcg 2×/d* *Max: 320 mcg 2×/d* *Child 4–11 y: INH, 40–80 mcg 2×/d* *Max: 160 mcg/d*	Not systemically absorbed
budesonide DPI (Pulmicort Flexhaler), 90, 180 mcg/actuation INH	Asthma prophylaxis	*Adult: INH, 180–360 mcg/ 2×/d* *Child >6y: INH 180–360 mcg 2×/d Max: 720 mcg/d* *Max: 1 mg/d*	Not systemically absorbed
budesonide (Pulmicort Respules), 0.25, 0.5 mg/2 mL INH solution	Asthma prophylaxis	*Adult: Not recommended* *Child 1–8 y: INH via nebulizer, 0.25–0.5 mg 1–4×/d; max: 0.5 mg/d*	Onset: PO, 30 min Inhalation: Immediate Duration: 8–12 h $t_{1/2}$: PO, 2–3.6 h; inhalation, 2.8 h
ciclesonide (Alvesco) 80, 160 mcg/puff	Asthma prophylaxis	*Adult and Child >12 y: INH 80–160 mcg 2×/d*	Not systemically absorbed
fluticasone (Flovent HFA), 44, 110, 220 mcg/spray	Asthma prophylaxis	*Adult: INH, 88–440 mcg 2×/d; max: 880 mcg 2×/d* *Child: INH, 88 mcg 2×/d; max 176 mcg*	Not systemically absorbed
fluticasone (Flovent Diskus), 50 mcg DPI	Asthma prophylaxis	*Adult and child >12 y: INH, 100–500 mcg 2×/d; max 1000 mcg* *Child 4–11 y: INH, 50–100 mcg 2×/d; max: 100 mcg 2×/d*	Not systemically absorbed
mometasone (Asmanex Twisthaler) 110, 200 mcg/activation	Asthma prophylaxis	*Adult and child >12 y: INH, 220–440 mcg 1–2×/d* *Child 4–11y: INH 110 mcg/d*	Not systemically absorbed

inflammatory cells, increase the number of beta receptors, enhance the responsiveness of beta receptors in airway smooth muscle, and decrease the production of mucus.

Contraindications and Precautions

Flunisolide is contraindicated for use in patients with an active systemic fungal infection. It should be used with caution in patients with active infection of the respiratory tract; untreated systemic fungal, bacterial, parasitic or viral infections; or ocular herpes simplex because it depresses the immune response, an effect that could result in serious illness.

Flunisolide, a pregnancy category C drug, should be used during pregnancy only if the benefits outweigh the risks to the fetus, because animal studies have shown teratogenic and fetotoxic effects.

Adverse Effects

Adverse effects are limited with flunisolide because of the route of administration. Sore throat, hoarseness, coughing, dry mouth, and pharyngeal and laryngeal fungal infections are the most common adverse effects. Dysphonia and oropharyngeal *Candida albicans* infection are common adverse effects associated with daily use of ICS. In children, long-term use of ICS may delay growth patterns. Suppression of the hypothalamic-pituitary-adrenal (HPA) axis is possible, but this effect is very rare.

Drug Interactions

Because of the route of administration, no important drug–drug interactions occur with flunisolide.

Assessment of Relevant Core Patient Variables

Health Status

Assess for signs of an active lung infection because flunisolide may exacerbate the infection. Contact the prescriber if you suspect that the patient has a systemic fungal infection. Assess for recent oral corticoid steroid use. Patients making the transition from oral corticoid steroids to ICS have an increased risk of adrenal insufficiency if they experience trauma, surgery, or infections, particularly gastroenteritis.

To accurately assess for delayed growth patterns during flunisolide therapy, obtain baseline height and weight of children.

Life Span and Gender

Flunisolide is approved for use in children older than 6 years. Schedule periodic clinic visits for children to monitor for possible adverse effects on growth patterns. Assess whether women of childbearing age are pregnant. Flunisolide is a pregnancy category C drug and should be used during pregnancy only if the benefits outweigh the risks to the fetus. It is not known whether flunisolide enters breast milk.

Lifestyle, Diet and Habits

Caution the patient to avoid cigarette smoking because smoking will decrease the efficacy of flunisolide.

Environment

Flunisolide is used primarily in the home care setting. Evaluate the patient's inhalation technique during each outpatient visit to ensure proper drug administration at home.

Nursing Diagnoses and Outcomes

- Impaired Verbal Communication related to dysphonia and cough
  Desired outcome: *The patient will report symptoms to the health care provider.*
- Risk for Infection related to immunosuppression
  Desired outcome: *The patient will remain free of infection throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Instruct the patient to take flunisolide every day, regardless of how well she or he feels. As a maintenance drug, flunisolide must be taken twice daily in order to affect its maximal response. Using a beta-2 agonist before flunisolide dilates the bronchial tree and allows the drug to be dispersed throughout the lungs. The use of a spacer may also help increase the intrapulmonary delivery of the drug if the patient's inhalation technique is poor.

Minimizing Adverse Effects

Spacers may help alleviate dysphonia by filtering larger aerosol particles that ordinarily deposit in the oropharynx and extrathoracic airways (this precaution also reduces the risk of oropharyngeal candidiasis). Spacers also help decrease systemic absorption because less flunisolide is swallowed. Rinsing the mouth after use decreases the potential for thrush as well as decreases the amount of drug swallowed, thus reducing the potential for systemic effects. With children, be especially vigilant for signs of HPA axis suppression, even in children with normal growth patterns, because growth is not a reliable predictor of HPA axis suppression. Monitor patients making the transition from oral corticosteroid to ICS frequently. Monitor for signs of adrenal insufficiency, especially if the patient is experiencing additional stressors such as infection.

Providing Patient and Family Education

Patient education is important for inhaled steroid therapy. Include the following topics in patient education:

- Good oral hygiene
- Proper use of MDI
- Signs and symptoms of oropharyngeal candidiasis (e.g., mouth ulcers, white spots on oral mucous membranes, and painful swallowing)
- Importance of rinsing the mouth after each administration to decrease the potential for fungal infections of the mouth
- Importance of daily use, regardless of the absence of symptoms, and of using a short-acting sympathomimetic inhaler for acute symptoms
- Symptoms of HPA suppression. Advise the patient to resume taking oral steroids if symptoms of HPA suppression occur.

Ongoing Assessment and Evaluation

Assess for a decreased incidence of acute asthma attacks. Evaluate the correct use of the MDI or DPI at each visit. Although the risk for developing HPA suppression is very low with inhaled flunisolide, monitor for this possibility at each visit. In children, document growth patterns at each visit.

Drugs Closely Related to P Flunisolide

Beclomethasone

Beclomethasone (Qvar) is used to treat steroid-dependent asthma, prevent allergic or nonallergic rhinitis, and prevent recurrent nasal polyps after removal. It is available for both nasal and oral inhalation for use in patients older than 5 years. It is a pregnancy category C drug.

Budesonide

Budesonide is available as intranasal inhalation (Rhinocort), oral inhalation (Pulmicort DPI, Pulmicort Respules), or orally (Entocort EC). It is also available as a combination MDI

MEMORY CHIP

P Flunisolide

- Used for maintenance treatment of CAL and asthma
- Major contraindication: active respiratory infection
- Most common adverse effects: dry mouth, dysphonia
- Most serious adverse effects: oral candidiasis, systemic absorption
- Maximizing therapeutic effects: Administer the drug daily, despite the absence of symptoms.
- Minimizing adverse effects: Use a spacer device.
- Most important patient education: This drug will not abort an acute attack.

with the long-acting beta-2 agonist formoterol (Symbicort). Budesonide is used to manage symptoms associated with allergic rhinitis, asthma, ulcerative colitis, or Crohn disease. Given as an oral inhaled drug, it is approved for use in children older than 6 years of age. Given by nebulizer, it may be given to children 1 to 8 years of age. Budesonide is a pregnancy category C drug.

Ciclesonide

Ciclesonide (Alvesco) is the same steroid used in the nasal spray Omnaris. It has a smaller particle size that, theoretically, should be able to disperse into smaller airways. As a prodrug, it is activated in the lungs. This decreases the potential for oral or esophageal candidiasis. Ciclesonide is indicated for adults and children over the age of 12. It is a pregnancy category C drug.

Fluticasone

Fluticasone is also used in managing rhinitis, asthma, and CAL. It is available for nasal inhalation (Flonase), for oral inhalation (Flovent HFA, Flovent Diskus), and in combination with salmeterol (Advair Diskus). High-dose fluticasone is associated with suppression of the HPA axis. It is approved for use in children older than 4 years of age. It is a pregnancy category C drug.

Mometasone

Mometasone DPI (Asmanex Twisthaler) is the same steroid as the nasal spray Nasonex. It is approved for the management of asthma, but not bronchospasm. Studies have demonstrated better compliance with mometasone due to its once-daily administration. Better compliance may decrease the frequency of exacerbations and the need for short-acting beta agonist rescue drugs. Instruct the patient to discard when the counter reaches "00" or 45 days after it was removed from its foil package.

Triamcinolone

Triamcinolone (Azmacort) was the first ICS on the market. It is used to manage rhinitis, asthma, and CAL. It is available for nasal inhalation (Nasacort) and oral inhalation (Azmacort). It is approved for use in children older than 6 years. Like other ICS drugs, it is a pregnancy category C drug.

• C Mast Cell Stabilizers

Vasoactive substances such as histamine, serotonin, bradykinin, and leukotrienes are located within the mast cell. When the mast cell ruptures, these substances cause an inflammatory response, such as bronchial constriction, which accounts for the symptoms of an acute asthma attack. The prototype mast cell stabilizer is cromolyn sodium (Table 35.8).

Nursing Management of the Patient Receiving P Cromolyn Sodium

Core Drug Knowledge

Pharmacotherapeutics

Cromolyn sodium is used as a prophylactic agent in treating mild to moderate asthma (Intal) and acute bronchospasm induced by exercise, environmental pollutants, and known antigens. The drug also is used as a nasal inhaler

TABLE 35.8 Summary of Selected C Mast Cell Stabilizers

P cromolyn sodium (Intal)	Asthma prophylaxis	Oral inhalation (800 mcg/spray): *Adult and child >5 y:* 2 puffs qid until stabilized, then 2 puffs bid Exercise-induced asthma: 2 puffs 10–60 min before exercise *Child 2–4 y:* 20 mg Spinhaler qid until stabilized, then bid	*Onset:* 15 min *Duration:* Unknown $t_{1/2}$: 80–90 min
(NasalCrom)	Allergic rhinitis	Nasal inhalation (40 mg/mL): *Adult and child >6 y:* 1 spray each nostril, 3–4/d	
(Crolom)	Allergic conjunctivitis	Ophthalmic (4% drops): *Adult and child >4 y:* 1–2 drops each eye, 4–6/d	
nedocromil ophthalmic (Alocril)	Allergic conjunctivitis	Ophthalmic (2%) drops) Adult and child > 3 y: 1–2 drops each eye 2×/d	
omalizumab (Xolair)	Allergic asthma	*Adult and child >12 y:* SC, 150–375 mg q2–4 wk	*Onset:* Slow *Duration:* Unknown $t_{1/2}$: 26 d

(NasalCrom) to treat seasonal allergic rhinitis, as an ophthalmic solution (Crolom) to treat allergic conjunctivitis, and orally (Gastrocrom) to treat systemic mastocytosis (a rare disease characterized by an abnormal increase in mast cells in various body organs and tissues) and ulcerative colitis. Off-label uses include refractory forms of chronic urticaria/ angioedema, treatment of food allergies, and mucosal and serosal eosinophilic gastroenteritis.

Pharmacokinetics

Cromolyn sodium may be administered orally for a systemic effect to treat mastocytosis. There is no systemic absorption when used by either intranasal or ophthalmic administration. Approximately 10% of inhaled cromolyn reaches the lungs, but this percentage may be decreased by the degree of bronchoconstriction present. About 98% of the drug is eliminated unchanged in feces. Minimal amounts of the drug cross the placenta or enter the breast milk. Improvement of symptoms requires several weeks of therapy.

Pharmacodynamics

Cromolyn sodium is an anti-inflammatory agent that works at the surface of the mast cell to inhibit mast cell rupture and degranulation after contact with an antigen. This action, in turn, prevents the release of histamine and SRS-A, mediators of type I allergic reactions. Cromolyn also may reduce the release of inflammatory leukotrienes. Although its exact mechanism of action is unclear, it is thought to produce these effects by inhibiting calcium influx.

Contraindications and Precautions

Cromolyn sodium is absolutely contraindicated in patients with a demonstrated hypersensitivity because anaphylaxis can occur. Cromolyn sodium is not a bronchodilator. Therefore, it is contraindicated for treating acute bronchospasm or status asthmaticus. The aerosol preparation of cromolyn sodium is contraindicated in patients with coronary artery disease or cardiac dysrhythmias because the aerosol contains fluorocarbon as a propellant, and fluorocarbons irritate cardiac cells.

Precautions include patients with lactose intolerance because oral preparations contain lactose. Patients who wear soft contact lenses should use ophthalmic cromolyn sodium cautiously because it contains benzalkonium chloride, which can cause ocular irritation.

Cromolyn sodium is a pregnancy category B drug.

Adverse Effects

In general, cromolyn is well tolerated. When it is administered by oral inhalation, the most common adverse effects are bronchospasm, throat irritation, and cough. Because preparations for oral inhalation can contain lactose, patients with lactose intolerance may experience nausea and vomiting, bloating, abdominal cramps, and flatulence.

Intranasal cromolyn spray can produce sneezing and nasal irritation, but these are generally transient effects following application. Ocular cromolyn ophthalmic drops may produce ocular irritation, especially in patients with soft contact lenses. The most frequent adverse effects from cromolyn powder for oral solution are headache and diarrhea.

Drug Interactions

No clinically important drug interactions are known with cromolyn sodium.

Assessment of Relevant Core Patient Variables

Health Status

Evaluate for previous adverse effects to cromolyn sodium before administration. Perform a baseline physical assessment, including the head, eyes, ears, nose, throat, and lung sounds.

Life Span and Gender

Cromolyn sodium can be administered to both adults and children. Note whether the patient is pregnant or lactating. Cromolyn sodium is classified as a pregnancy category B drug because only a minimal amount of the drug crosses the placenta or enters the breast milk.

Lifestyle, Diet, and Habits

Monitor patients with lactose intolerance for adverse effects to oral cromolyn sodium. Advise patients who experience exercise-induced bronchospasm to take cromolyn sodium 15 to 20 minutes before exercise.

Environment

Cromolyn sodium can be administered in any setting. If it will be administered at home, remind the patient to administer it before engaging in an activity that causes bronchospasm.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to nausea and vomiting, bloating, abdominal cramps, and flatulence
  Desired outcome: *The patient will maintain body weight throughout therapy.*
- Ineffective Breathing Pattern related to bronchospasm and cough
  Desired outcome: *The patient will have a patent airway throughout therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Cromolyn sodium is available in a variety of administration vehicles, such as a nebulizer, an MDI, or an oral tablet. Evaluate the patient's ability to correctly use these devices (see Box 35.4). Cromolyn sodium is used for long-term management of respiratory disorders. Except in the case of

exercise-induced asthma, the patient should take the medication daily, even when symptoms are absent.

Minimizing Adverse Effects

Caution patients who have a known intolerance to lactose or who experience symptoms of lactose intolerance (nausea and vomiting, bloating, abdominal cramps, and flatulence) while taking oral cromolyn sodium. Changing to a different route of administration may be necessary to avoid losing weight from GI effects.

Providing Patient and Family Education

- Stress that cromolyn sodium should not be taken by anyone who has a hypersensitivity to this drug.
- Emphasize that cromolyn sodium is not useful for managing acute symptoms and that it is used for prophylaxis only. Patients should use a sympathomimetic drug for acute symptoms of respiratory distress.
- Demonstrate the correct use of administration devices and then have patients demonstrate it while you watch.
- Be sure that patients understand that cromolyn sodium must be taken daily, whether or not symptoms are present, except for exercise-induced asthma.
- Instruct patients to use cromolyn sodium 15 to 20 minutes before engaging in any activity, such as exercise, that is known to induce bronchospasm in that patient.
- Teach patients how to use a peak flow meter to monitor his or her personal respiratory status.

Ongoing Assessment and Evaluation

Evaluate the effectiveness of cromolyn sodium, demonstrated by a decrease in the frequency and severity of symptoms. For example, the patient should remain free from symptoms such as itchy and watery eyes, nasal congestion, or respiratory distress. Monitor for potential adverse effects in patients with lactose intolerance and in those who wear soft contact lenses, as previously mentioned.

MEMORY CHIP

P Cromolyn Sodium

- Used for prophylaxis of allergic symptoms, including asthma
- Major contraindications: hypersensitivity and acute symptoms
- Most common adverse effects: dry throat, cough, and wheezing
- Most serious adverse effects: bronchospasm and anaphylaxis
- Maximizing therapeutic effects: Teach use of delivery systems.
- Minimizing adverse effects: Use only as directed.
- Most important patient education: Take the medication daily, despite the absence of symptoms; the drug is to be used only for prophylaxis and not as a "rescue" drug.

Drug Significantly Different From P Cromolyn Sodium

Omalizumab (Xolair) is the first monoclonal antibody directed against immunoglobulin E (IgE) and the first biologic therapy developed to treat asthma. It is used to manage asthma in patients with moderate to severe persistent asthma and a positive skin test for perennial allergens that inhaled corticosteroids do not control. Omalizumab is also being studied for use in other IgE-related conditions, including allergic rhinitis, peanut allergy, latex sensitivity, atopic dermatitis, chronic urticaria, and allergic bronchopulmonary aspergillosis. Omalizumab is a subcutaneous injection. Reconstituting this medication correctly is important, and you must be sure to wait 20 minutes to ensure that the powder dissolves.

Omalizumab binds to mast cells, preventing mast cell rupture and degranulation. In addition to binding mast cells, it binds to receptors on monocytes, eosinophils, dendritic cells, epithelial cells, and platelets, thereby interfering with release of inflammatory mediators and cytokines.

The only contraindication to the use of omalizumab is hypersensitivity to hamster protein because it is derived from this source. Omalizumab is used cautiously in patients with pre-existing neoplasm because it has induced several types of malignancy.

Omalizumab may induce anaphylaxis in susceptible patients. Anaphylaxis can occur at any time, even with the first dose. It occurs most frequently within the first 2 hours after administration; however, delayed reactions of up to 24 hours have been reported. More common adverse effects include injection-site reaction, viral infections (including upper respiratory tract infections), sinusitis, headache, and pharyngitis.

Monitor the patient for a minimum of 2 hours after administering the injection. Teach the patient the signs and symptoms of anaphylaxis and the importance of obtaining immediate medical care, such as calling 911 for assistance should any symptoms occur. Omalizumab is a pregnancy category B drug; whether it enters breast milk is not known. It is not approved for use in children younger than 12 years of age.

• C Leukotriene Receptor Antagonists

Leukotrienes are inflammatory mediators that are powerful bronchoconstrictors and vasodilators. Within the past decade, leukotrienes have been identified as important mediators in the pathology and symptomatology of asthma, both acute and chronic. Even patients with mild asthma show airway inflammation, including infiltration of the mucosa and epithelium with activated T cells, mast cells, and eosinophils. T cells and mast cells release the cytokines leukotriene, histamine, bradykinin, and serotonin, which increase microvascular permeability, disrupt the epithelium, and stimulate neural reflexes and mucus-secreting glands. The result is airway hyperreactivity, bronchoconstriction, and hypersecretion, manifested by wheezing, coughing, and dyspnea. Leukotriene receptor antagonists include zafirlukast, montelukast, and zileuton. Zafirlukast (Accolate) is the prototype leukotriene receptor antagonist (Table 35.9).

TABLE 35.9 Summary of Selected C Leukotriene Receptor Antagonists

P zafirlukast (Accolate) 10, 20 mg	Asthma maintenance	*Adult and child >12:* PO, 20 mg bid *Child 5–11 y:* PO, 10 mg bid	*Onset:* Rapid *Duration:* 12–24 h $t_{1/2}$: 10 h
montelukast (Singulair) 4, 5 mg chewable; 10 mg; 4-mg granule packet	Asthma maintenance	*Adult and child >15 y:* PO, 10 mg in the evening *Child 6–14 y:* PO, 5 mg in the evening *Child 2–5 y:* 4 mg in the evening *Child 12–24 mo:* 4-mg granule	*Onset:* Rapid *Duration:* 12–24 h $t_{1/2}$: 5.5 h
zileuton (Zyflo CR) 600 mg	Asthma maintenance	*Adult and child >12 y:* 1,200 mg bid *Child <12 y:* Not recommended	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 2.5 h

Nursing Management of the Patient Receiving P Zafirlukast

Core Drug Knowledge

Pharmacotherapeutics

Zafirlukast is used as prophylaxis or for treating chronic asthma. It is not indicated for symptoms of an acute attack. Off-label uses of zafirlukast are chronic idiopathic urticaria and dermatographism.

Pharmacokinetics

Zafirlukast is administered orally. It is distributed to tissues to some degree, but it distributes across the blood–brain barrier only minimally. In treating asthma, the peak action is noted as early as day 1 of therapy but more commonly takes up to 2 weeks. For that reason, it is not useful for managing an acute asthma attack.

Food reduces the bioavailability of zafirlukast by approximately 40%; therefore, this drug should be taken either 1 hour before or 2 hours after meals. Zafirlukast is metabolized extensively through the P-450 (CYP3A4 and CYP2C9) system. Elimination is primarily in feces, with approximately 10% excreted in urine.

Pharmacodynamics

Several kinds of leukotrienes have been identified. Zafirlukast blocks receptors for the leukotrienes bound to the amino acid cysteine. The cysteinyl leukotrienes are potent bronchoconstrictors, approximately 100 to 1,000 times more potent than histamine. By blocking their receptors, which mediate bronchoconstriction, vascular permeability, and mucous secretion, zafirlukast substantially improves the wheezing, coughing, and dyspneic symptoms of asthma.

Contraindications and Precautions

Zafirlukast is contraindicated in any patient with a known hypersensitivity to zafirlukast or to povidone, lactose, titanium dioxide, or cellulose derivatives, which are all inactive ingredients in the tablet. The drug is a pregnancy category B drug and is contraindicated for use in women who breastfeed because it is not approved for use in children younger than 6 years. Finally, zafirlukast is contraindicated for use against acute symptoms of wheezing, shortness of breath, or bronchospasm.

Zafirlukast should be given cautiously to patients with hepatic disease or those older than 65 years of age because clearance of the drug is decreased in these patients. It also is used cautiously in patients taking warfarin because both drugs use the same P-450 metabolism pathway.

Adverse Effects

The most common adverse effects of zafirlukast are headache, gastritis, pharyngitis, and rhinitis. Other reported adverse effects include dizziness, nausea and vomiting, diarrhea, abdominal pain, arthralgia, myalgia, fever, and back pain.

Serious adverse effects include asymptomatic elevated hepatic enzymes, symptomatic hepatitis with hyperbilirubinemia or jaundice, and, rarely, hepatic failure.

In patients taking zafirlukast at the same time that systemic steroids are being withdrawn, Churg-Strauss syndrome (CSS), a form of vasculitis with migratory lung infiltrates and eosinophilia, may occur. In patients in whom this event has occurred, it has been unclear whether CSS is caused by the use of zafirlukast or is already present but masked by the use of glucocorticosteroids.

Drug Interactions

Zafirlukast interacts with theophyllines, warfarin, and macrolides such as erythromycin and clarithromycin.. Table 35.10 presents these potential drug–drug interactions. Food decreases the bioavailability of zafirlukast by approximately 40%.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for potential medical conditions, such as hepatic insufficiency or drug therapy, that contraindicate using zafirlukast or require close patient monitoring. Assessing the patient for use of theophylline, aspirin, warfarin, or other drugs that use the P-450 metabolism pathway

TABLE 35.10 Agents That Interact with P Zafirlukast

Interactants	Effect and Significance	Nursing Management
erythromycin and clarithromycin	In asthmatic patients, erythromycin decreases bioavailability of zafirlukast by approximately 40%.	Monitor for efficacy of antibiotic therapy.
theophylline	Zafirlukast may increase serum concentration of theophylline resulting in an increased risk for pharmacologic and toxic effects. Zafirlukast levels may decrease.	Monitor serum theophylline levels. Monitor for signs and symptoms of theophylline toxicity. Monitor for efficacy of zafirlukast therapy.
warfarin	Zafirlukast increases elimination half-life of S-warfarin by ~36% and prolongs prothrombin time by 35%.	Prothrombin times and international normalized ratios should be carefully monitored in patients on warfarin therapy. Anticoagulant dosage should be adjusted as indicated.

is especially important. Assess for hypersensitivity to povidone, lactose, titanium dioxide, and cellulose derivatives, all of which are ingredients in zafirlukast tablets. Finally, evaluate the plan of care to see whether the patient is being withdrawn from glucocorticoid steroid therapy. Communicate any positive findings to the health care provider. Perform a baseline respiratory assessment and document the findings. The baseline data will be used to evaluate the efficacy of zafirlukast therapy.

Life Span and Gender

Evaluate the pregnancy status of the patient, as needed. Zafirlukast is a pregnancy category B drug, but human studies have not been performed. Zafirlukast should be administered during pregnancy only when the benefits to the mother outweigh the risk to the fetus. The drug enters breast milk. Therefore, it should not be administered to women who breast-feed because it is not approved for use in children younger than 5 years.

Note the age of the patient taking zafirlukast. Arrange for frequent follow-up appointments for patients older than 65 years of age. Elderly patients may experience decreased clearance of zafirlukast, which increases the risk of adverse effects and toxicity.

Lifestyle, Diet, and Habits

Assess the patient's understanding that zafirlukast must be taken on an empty stomach. Remind the patient that food decreases the bioavailability of zafirlukast.

Environment

Zafirlukast generally is administered in the home environment.

Nursing Diagnoses and Outcomes

- Risk for Injury (poisoning) related to interaction between drugs metabolized by the P-450 enzyme system
  Desired outcome: *The patient will adhere to dosage adjustment of medications, undergo serial laboratory testing, and report adverse effects immediately to the health care provider.*
- Diarrhea related to drug therapy
  Desired outcome: *The patient will remain well hydrated throughout therapy.*
- Acute Pain related to drug therapy
  Desired outcome: *The patient will take nonnarcotic analgesics if headache occurs.*

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that the patient takes zafirlukast twice daily despite the absence of symptoms. Remind the patient to take zafirlukast 1 hour before or 2 hours after a meal to increase the bioavailability of the drug.

Minimizing Adverse Effects

Ensure that the patient takes the medication only as prescribed. Assess for potential need to change CAL or asthma therapy when zafirlukast is added, especially if the patient is taking systemic glucocorticoid steroid medications. Carefully review the patient's medications to establish whether he or she is taking other medications that use the P-450 metabolism pathway.

Providing Patient and Family Education

- Explain that zafirlukast is used in maintenance therapy for CAL and asthma and should not be used if acute shortness of breath or wheezing occurs.
- Advise patients to report symptoms such as abdominal pain, jaundice, nausea, vomiting, or dark urine immediately, because these symptoms may indicate hepatic injury.
- Encourage patients to take nonnarcotic analgesics if headache occurs and to drink plenty of fluids if they experience diarrhea while taking zafirlukast. Patients also should report these adverse effects to the health care provider.
- Caution patients not to stop or decrease systemic glucocorticoid steroid therapy without speaking with the health care provider first.
- Emphasize the importance of contacting the primary health care provider if any new medications are prescribed by any other member of the health care team.

Ongoing Assessment and Evaluation

Assess whether the patient needs beta-agonist drugs in addition to zafirlukast. If the patient continues to need beta-agonist drugs more than twice weekly, refer the patient to the health care provider for additional assessment.

Assess the patient for symptoms that may reflect hepatic injury. If the patient takes other medications that are metabolized by the P-450 enzyme system, evaluate the patient for potential adverse effects or toxicities of these drugs.

Drugs Closely Related to P Zafirlukast

Montelukast

Montelukast (Singulair) is similar to zafirlukast in its mechanism of action. It has the advantage of once-daily dosing, and it is also approved for use in children 2 years of age and older. Unlike zafirlukast, montelukast does not inhibit specific hepatic cytochrome isozymes. Therefore, it is not expected to affect the hepatic clearance of drugs metabolized by these enzymes.

Zileuton

Zileuton (Zyflo) inhibits the first enzyme in the lipoxygenase pathway, thus preventing the formation of potent leukotrienes. Although this mechanism of action may be beneficial in other disorders, such as rheumatoid arthritis and ulcerative colitis, at this time, zileuton is approved only for managing asthma.

In animal studies, zileuton produced developmental defects. Therefore, it is assigned to pregnancy category C. During pregnancy, zileuton should be used only if the potential benefit to the mother outweighs the potential risks to the fetus. It is not known whether zileuton is excreted in human milk, and therefore, it should be avoided by women who breast-feed.

Most adverse effects attributed to zileuton therapy have been mild and self-limited. Adverse effects include flu-like syndrome, headache, dizziness, dyspepsia, drowsiness, abdominal pain, and insomnia. In rare cases, hepatotoxicity and neutropenia have occurred.

MEMORY CHIP

P Zafirlukast

- Used for maintenance treatment of CAL and asthma
- Major contraindications: hypersensitivity to povidone, lactose, titanium dioxide, and cellulose; breast-feeding
- Most common adverse effects: headache, gastritis, pharyngitis, and rhinitis
- Most serious adverse effects: hepatic failure and Churg-Strauss syndrome
- Maximizing therapeutic effects: Administer the drug daily, despite the absence of symptoms.
- Minimizing adverse effects: Take the drug only as prescribed.
- Most important patient education: This drug will not abort an acute attack.

Administer the extended release formula within 1 hour after morning and evening meals. Document the patient's baseline liver function tests prior to initiation of treat-ment. Instruct the patient to return for repeat liver function tests monthly for 3 months, then every 3 months thereafter.

CHAPTER SUMMARY

- Mucolytics, such as acetylcysteine, are drugs designed to break up the mucus produced in the respiratory tract, leading to thinner secretions that are more easily moved.
- Acetylcysteine is also used to manage acetaminophen overdose and in patients having contrast imaging to reduce the risk for contrast-induced nephrotoxicity.
- Drugs used to manage CAL (COPD) are generally grouped into two categories: bronchodilators and anti-inflammatory agents.
- Bronchodilators are composed of several different subclasses, such as sympathomimetics, anticholinergics, and xanthine derivatives.
- Short-acting beta-agonist drugs are the only types of inhaled drug that help during acute episodes of asthma or exacerbations of CAL. They are known as "rescue drugs."
- Inhaled anticholinergics are used for maintenance treatment for asthma and CAL and are not used for acute symptoms.
- Xanthine derivatives are most frequently used as maintenance drugs; however, they may be given intravenously during an acute exacerbation of CAL or asthma.
- Anti-inflammatory drugs are composed of several different subclasses, including inhaled glucocorticoids, such as beclomethasone, mast cell stabilizers, and leukotriene receptor antagonists.
- Anti-inflammatory drugs are used as maintenance therapy, not for an acute exacerbation of CAL or asthma.
- The glucocorticoids are the most effective anti-inflammatory drugs available for managing respiratory disorders.
- The mast cell stabilizer cromolyn sodium works by stabilizing mast cells and preventing rupture when these cells are exposed to an antigen. This action stops the release of histamine, serotonin, bradykinin, and leukotriene, all of which induce bronchoconstriction.
- The leukotriene receptor antagonist zafirlukast works by inhibiting the bronchoconstrictive properties of leukotrienes.

QUESTIONS FOR STUDY AND REVIEW

1. In managing lower respiratory tract disorders, which main classes of drugs are used?
2. Compare and contrast the pharmacodynamics of the different types of bronchodilators.
3. In a patient with acute respiratory distress, which of the bronchodilators would be most effective?
4. Which of the anti-inflammatory agents is the most effective?

5. What is the difference between glucocorticoid steroids given orally and by inhalation?
6. Compare and contrast the pharmacodynamics of the different types of antiinflammatory agents.
7. If a patient is taking inhaled steroids, an anticholinergic inhaler, and a beta-adrenergic agonist inhaler, which inhaler would you tell the patient to use first?

UNIT 9
Gastrointestinal Tract Drugs

36

Drugs Affecting the Upper Gastrointestinal Tract

Learning Objectives

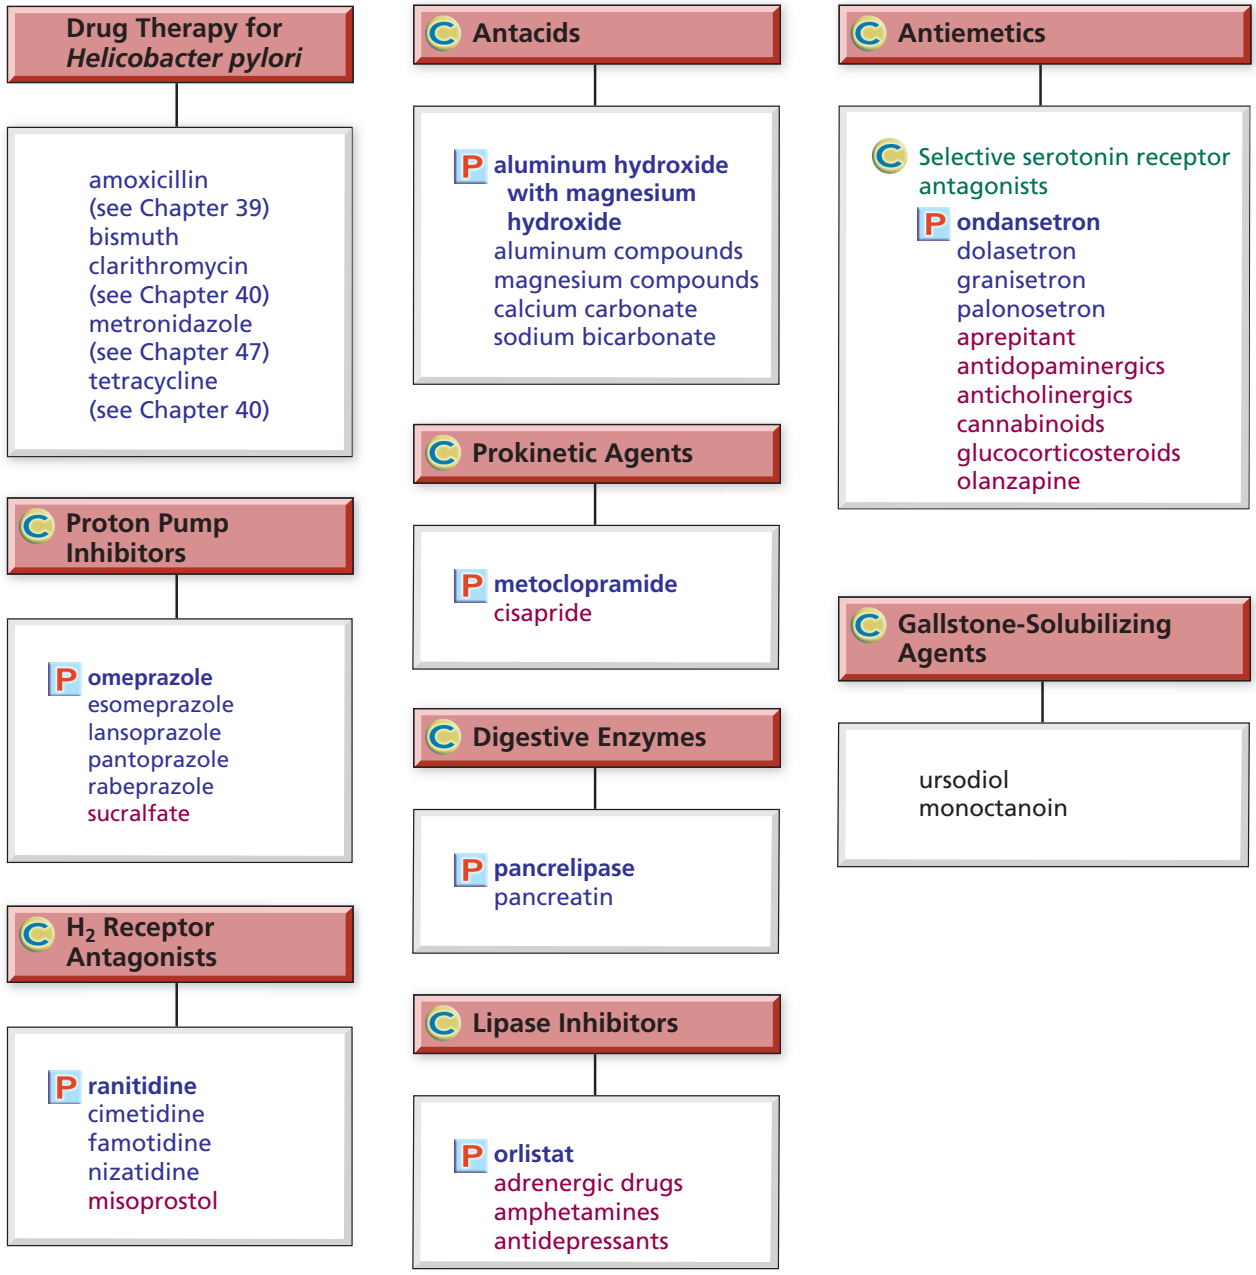
At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect the upper gastrointestinal (GI) tract.
2. Differentiate the drugs and drug classes used to treat peptic ulcer disease.
3. Differentiate histamine-1 (H_1) receptor antagonists from histamine-2 (H_2) receptor antagonists.
4. Identify core patient variables related to drugs that affect the upper GI tract.
5. Relate the interaction of core drug knowledge to core patient variables for drugs that affect the upper GI tract.
6. Generate a nursing plan of care from the interactions between core drug knowledge and the core patient variable for drugs that affect the upper GI tract.
7. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect the upper GI tract.
8. Determine key points for patient and family education for drugs that affect the upper GI tract.

Key Terms

antiemetics
chemoreceptor trigger zone
digestive enzymes
duodenum
dysphagia
emetics
gastroesophageal reflux disease
heartburn
Helicobacter pylori
hematemesis
melena
peptic ulcer
peristalsis
prokinetic agent
reflux
regurgitation
stress ulcer
vomit center
waterbrash

Drugs Affecting the Upper Gastrointestinal Tract



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Numerous prescription drugs and over-the-counter (OTC) preparations are used to treat or prevent disorders of the upper gastrointestinal (GI) tract, such as gastroesophageal reflux disease, hiatal hernia, peptic ulcer disease, digestive problems, nausea, and vomiting. These problems may be caused by innate physiologic problems, such as poor organ functioning or excessive acid production, or they may be secondary to therapeutic treatment, such as surgery or other drug therapy.

Many of these drugs have a local effect in the GI tract and can interfere with the absorption of other drugs that are administered orally. Other GI drugs act systemically and can produce interactions with other drugs. Because many of the drugs used to treat these disorders are available OTC, the potential for self-diagnosis and self-medication is great. Patients might not consider OTC drugs to be part of their drug therapy and therefore might not mention using these agents unless questioned directly. Therefore, it is important for the nurse to specifically ask about these preparations.

This chapter discusses the most common drug classes used to treat disorders of the upper GI tract, including:

- Drugs to treat *Helicobacter pylori* infection
- Proton pump inhibitors (PPIs)
- Histamine-2 receptor antagonists (H_2RAs)
- Antacids
- Prokinetic agents
- Digestive enzymes
- Lipase inhibitors
- Antiemetics
- Gallstone-solubilizing agents. These drugs are mentioned briefly in this chapter, but a prototype is not presented.

PHYSIOLOGY

The upper GI tract consists of the mouth, oropharynx, esophagus, stomach, and duodenum (small intestine). The **duodenum,** which is responsible for most digestive functions, is composed of four layers—the mucosa, submucosa, muscularis externa, and serosa. The mucosa is a mucous membrane covering the entire inner surface of the GI tract. In the duodenum, where some of the glands necessary for digestion and absorption are located, the mucosa forms folds and projections that increase the surface area of the intestine. The submucosa is composed of loose connective tissue containing blood, lymphatic vessels, and nerves. The blood vessels provide nutrients and oxygen to the tissues and remove the products of digestion. The muscularis externa is composed of two layers of smooth muscle. One layer encircles and constricts the tract; the other layer consists of longitudinal muscle fibers that contract to decrease the length of the tract. The serosa, which covers the outside of the GI tract, contains secretory cells that keep the outer surface of the tract moist and lubricated.

Digestion begins in the mouth, where food is chewed into fine particles, and salivary glands secrete substances that begin breaking down the food. The salivary glands consist of two types of secretory cells—serous and mucous. The serous cells contain amylase, an enzyme that splits the starch and glycogen contained in carbohydrates into disaccharides. This process is the first step of digestion. The mucous cells secrete mucus, which binds the food and facilitates swallowing. The tongue mixes food with the salivary gland secretions and moves the food toward the pharynx for swallowing.

Swallowing is a complex reflex that requires coordination of several muscle groups. After the bolus of food is moved toward the pharynx by the tongue, stimulated sensory nerves in the pharyngeal area trigger the swallowing reflex. Swallowing begins when the soft palate rises, preventing food from entering the nasal cavity. The epiglottis moves down over the trachea, preventing food from entering the lungs. Next, muscles in the lower pharynx relax, enabling food to move into the esophagus. **Peristalsis,** a rhythmic movement of contraction and expansion of the smooth muscle, propels the food toward the stomach.

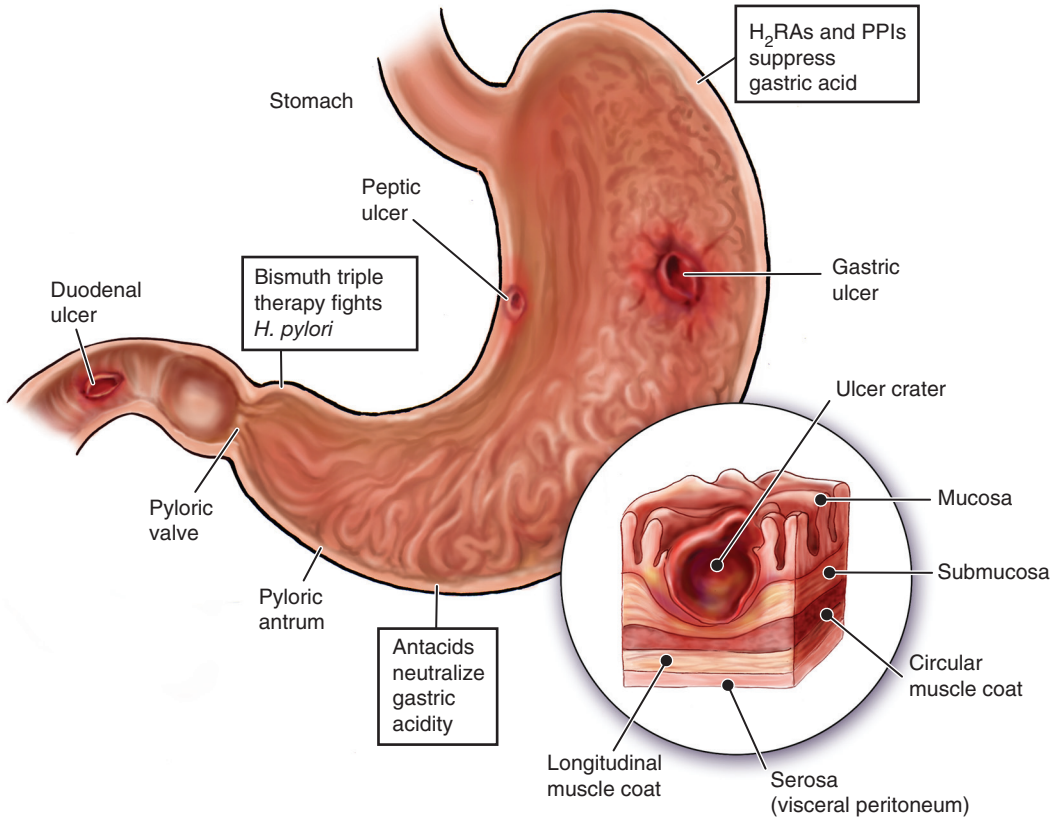
The esophagus, a long, hollow tube that connects the mouth to the stomach, passes through the diaphragm and joins the stomach in the abdomen. The lower esophageal sphincter (LES) contains circular muscle fibers that contract to prevent regurgitation of gastric contents into the esophagus. Peristalsis causes these muscles to relax and allows food to enter the esophagus.

The stomach, which is situated between the esophagus and the duodenum, is a temporary storage and mixing site for food undergoing digestion. Three types of cells—mucous, chief, and parietal—secrete fluids commonly referred to as gastric juice. Chief cells in the stomach release pepsinogen, which is activated to form the digestive enzyme pepsin by hydrochloric acid (secreted from parietal cells). Pepsin begins the process of protein digestion. The mucus secreted by mucous cells in the stomach protects against pepsin and hydrochloric acid, which can help form or aggravate peptic ulcers (Figure 36.1).

Gastric secretions are regulated primarily by the parasympathetic nervous system. The sight, smell, or thought of food stimulate parasympathetic nerve impulses that trigger the release of the hormone gastrin, which stimulates production of gastric juice (chyme). The movement of food mixed with chymeinto the duodenum inhibits further secretion of gastric juice. Fat-rich, acidic chyme entering the duodenum triggers the release of cholecystokinin, a hormone produced in the intestinal wall that decreases gastric motility.

The acid in chyme also triggers release of secretin, another hormone. Secretin and cholecystokinin stimulate the release of pancreatic juice that contains bicarbonate, which buffers the effects of gastric acid, and **digestive enzymes.** The digestive enzymes, which break down chyme into nutrients the body can absorb, are secreted by the pancreas in inactive forms and changed to their active forms in the duodenum. The duodenum also produces some digestive enzymes.

PHYSIOLOGY



• FIGURE 36.1 Drugs used in treating peptic ulcer disease need to retard further ulceration and promote healing. Lesions known as peptic ulcers are those that affect the mucosa of the stomach (gastric ulcer) or the duodenum (duodenal ulcer). With an advanced duodenal ulcer, gastric acid burrows through the gastric mucosa, submucosa, and muscle layers and perforates the peritoneum. As the illustration indicates, antacids neutralize excess acidity, H_2 receptor antagonists suppress gastric acid production; and bismuth triple therapy treats ulcers caused by *H. pylori*.

The pancreatic enzymes include amylase (which splits starch and glycogen into disaccharides), lipase (which hydrolyzes fats to fatty acids), and trypsin, chymotrypsin, and carboxypeptidase (which split proteins into amino acids).

Vomiting of GI contents is controlled by the **vomit center** (VC) in the medulla of the brain. The GI tract contains sensory receptors that send nerve impulses to the brain in response to abdominal distention or irritation. Inflammation, spasms, and ischemia can also irritate nerve endings and activate the VC. These impulses are transmitted to the VC, which returns impulses that trigger abdominal contractions and reverse peristalsis, thereby inducing vomiting. The VC can also be directly stimulated through the cortical pathway by unpleasant olfactory and visual stimuli, pain, emotional factors, increased intracranial pressure, migraine headaches, or vestibular (inner ear) disturbances.

Additionally, the VC can be stimulated when the **chemoreceptor trigger zone** (CTZ) is stimulated. Located near the VC, the CTZ is stimulated by drugs, chemicals, toxins, radiation, hormonal changes, some disease states, and altered metabolic states. It also is stimulated by vestibular mechanisms. When the CTZ is stimulated, it acts on the VC to maintain a state of excitability to other incoming vestibular impulses.

PATHOPHYSIOLOGY

Gastroesophageal Reflux Disease

The esophagus normally is not exposed to much gastric acid because the LES prevents **reflux** (upward movement of gastric juices into the esophagus). This condition is known as **gastroesophageal reflux disease** (GERD) or acid reflux disease. In patients with GERD, the LES opens either more frequently or at the wrong time, allowing stomach acid to back up into the esophagus. When gastric acids reflux into the esophagus over a long period of time, a portion of the esophagus can become "raw." This change in the esophagus, which is called erosive esophagitis, can lead to serious medical problems such as scarring, bleeding, and ulcers. Chronic GERD may result in a disorder called Barrett's esophagus, which is characterized

by an abnormal lining of the esophagus; affected patients have an increased risk of cancer of the esophagus.

Although GERD frequently occurs alone, it may also result from a hiatal hernia, a condition in which the cardiac portion of the stomach moves up through an opening in a weakened diaphragm. The movement of the stomach through the diaphragm decreases the pressure of the LES, so that the acid easily moves into the esophagus.

Four major symptoms are characteristic of GERD: heartburn, regurgitation, dysphagia, and waterbrash. **Heartburn,** the most common symptom, is a burning sensation that rises from the stomach up the chest toward the neck. It can be quite painful. **Regurgitation** occurs when stomach acid washes through the esophagus into the mouth, causing a bitter or sour taste. **Dysphagia** is difficulty swallowing. **Waterbrash** is the sudden appearance of a slightly sour or salty fluid in the mouth that occurs when the salivary glands are stimulated by acid reflux.

There are four treatment options for GERD, depending on the severity of the symptoms: antacids, promotility agents, antisecretory agents, or mucosal protective agents may be used. Each of these drug classes has a different mechanism by which it decreases either the amount of acid in the stomach or inhibits damage to the GI tract.

Helicobacter pylori Infection

Helicobacter pylori (*H. pylori*) infection, the most common chronic bacterial infection worldwide, is found in more than half of the human population. The natural history of *H. pylori* infection and its transmission is still unknown. Current theories of transmission include the fecal–oral, oral–oral, and gastric–oral routes.

H. pylori is a gram-negative, spiral bacterium that weakens the protective mucous lining of the stomach and duodenum, allowing gastric acid to reach the sensitive lining of the GI tract. Both the bacterium and gastric acid irritate this sensitive lining, resulting in ulceration. *H. pylori* is not destroyed by gastric acid because it secretes enzymes that neutralize the acid. Infection with the bacterium is the major cause of gastritis and the gastritis-associated diseases: gastric ulcer, duodenal ulcer, gastric cancer, and primary gastric B-cell lymphoma (MALToma). *H. pylori* has been identified in 90% to 95% of patients with duodenal ulcers, 50% to 80% of patients with gastric ulcers, and almost 100% of patients with chronic active gastritis. Chronic *H. pylori* infection, particularly when acquired in early childhood, increases the risk of gastric cancer. *H. pylori* is not a causative factor in the development of GERD.

Diagnosis of *H. pylori* infection is determined by a blood test, stool test, urea breath test, or biopsy of an endoscopically obtained sample. It is possible to identify antibodies attached to the *H. pylori* bacteria in blood or the antigen in a stool sample. If the result of either test is positive, the patient is currently infected or has had an infection within the past 3 years. The only way to establish the definitive existence of a current infection is by a urea breath test, which indirectly detects the presence of *H. pylori*–associated urease by measuring CO_2 in the patient's breath. The patient ingests urea labeled with a naturally occurring, nonradioactive carbon isotope. *H. pylori*–associated urease degrades the urea, producing ammonia and CO_2. The resultant CO_2 is absorbed in the blood, exhaled, and measured. An increased amount of labeled CO_2 indicates the presence of *H. pylori*–associated urease. To produce an accurate breath test, the patient must not have taken bismuth or antibiotics for 1 month, PPIs for 1 week, or H_2RAs for 24 hours, and should fast for 1 hour prior to the test.

Eliminating *H. pylori* from the GI tract improves healing and decreases the recurrence of ulcers. Once the infection has been eradicated, reinfection rates are less than 0.5% per year; ulcer recurrence rates also decline dramatically. The cure rate from the various treatment options ranges from about 70% to 90% or higher. Eradication therapy is the standard of care for patients with active or inactive peptic ulcers, including patients who use nonsteroidal anti-inflammatory drugs (NSAIDs).

The current treatment protocol of choice is called sequential therapy and has replaced legacy triple therapy, due primarily to increasing macrolide resistance (Graham, Fischbach, 2010). Classic quadruple therapy (bismuth, a PPI, 1,500 mg of metronidazole, and 1,500 mg of tetracycline) is highly effective and is frequently the regimen of choice. A newer sequential therapy (PPI plus amoxicillin followed by a PPI plus clarithromycin plus metronidazole) has been proposed and is expected to replace legacy therapy (Table 36.1).

Prophylactic and therapeutic vaccines have been developed against *H. pylori* in animals. Research toward developing vaccines against *H. pylori* for use in humans is now under way (Agarwal and Agarwal, 2009).

Peptic Ulcer Disease

Peptic ulcer disease (PUD) is a general term that refers to ulcer formation in the esophagus (esophageal ulcer), stomach (gastric ulcer), or duodenum (duodenal ulcer). Approximately 75% of ulcers, especially duodenal ulcers, are caused by the bacteria *H. pylori;* however, most infected persons do not develop PUD. Other causes of ulcer formation include drugs such as aspirin, NSAIDs, and glucocorticosteroids. Although many practitioners believe that stress may also be a factor in the development of ulcers, there is some controversy about this matter.

Pain is the most common symptom of an ulcer. The pain lasts from a few minutes to hours, may be worse when the stomach is empty, and may flare at night. It may be temporarily relieved when eating foods that buffer the stomach acid or by taking acid-reducing drugs. Severe symptoms that occur less frequently include **hematemesis** (vomiting of blood), **melena** (dark tarry stools), chest pain, unexplained weight loss, and nausea or vomiting.

Timing of the pain in relation to meals may differentiate between gastric and duodenal ulcers. Pain occurs with or just after meals with gastric ulcers because food increases

TABLE 36.1 Therapies for *Helicobacter pylori* Infection Approved by the Food and Drug Administration

Regimen	Side Effect Rating	Cure Rate	Duration of Treatment
Two-Drug Regimen			
amoxicillin + PPI	Low-medium	66%–77%	14 d
clarithromycin + PPI	Low-medium	70%–74%	14–28 d
Three-Drug Regimen (Legacy Therapy)			
*clarithromycin + metronidazole + PPI	Medium	85%–95%	10–14 d
*amoxicillin + clarithromycin + PPI	Low-medium	85%–95%	10–14 d
amoxicillin + metronidazole + PPI	Medium	80%–90%	10–14 d
Four-Drug Regimen			
Bismuth + metronidazole + tetracycline + H_2RA	Medium-high	80%–90%	7–14 d
Bismuth + metronidazole + amoxicillin + H_2RA	Medium-high	70%–90%	7–14 d
†Bismuth + metronidazole + tetracycline + PPI	Medium-high	80%–90%	7–14 d
Bismuth + metronidazole + clarithromycin +	Medium-high	80%–90%	7–14 d
Sequential Therapy			
PPI + amoxicillin followed by PPI + clarithromycin		90%–94%	14 d
PPI			
Combination Drugs			
Helidac + H_2RA	Medium-high	Up to 82%	14 d
Prevpac	Low-medium	81%–92%	14 d

*First-line treatment; †second-line treatment; PPI, proton pump inhibitor; H_2RA, histamine-2 receptor antagonist.

the release of gastric acid. Pain occurs before a meal with duodenal ulcers because acid that is stimulated by hunger passes into the duodenum.

A **stress ulcer** is an ulcer that is caused by acute or chronic stress, especially in burn patients. Stress ulcers occur frequently in critically ill patients. Complications of stress ulcers include bleeding that requires transfusion and bleeding associated with hemodynamic instability. Stress ulcers may have significant impact on morbidity and mortality rates in an intensive care setting.

The gold standard for diagnosing an ulcer is an esophagogastroduodenoscopy (EGD), which is also known as a gastroscopy. An EGD is a minimally invasive test that allows direct visualization of the upper part of the GI tract to the duodenum. In addition, during the EGD the health care provider may obtain tissue for biopsy to rule out gastric carcinoma because it has several symptoms that are similar to PUD.

Treatment for PUD depends on the etiology of the ulcer. Patients with *H. pylori* infection require multiple-drug therapy (see *H. pylori* section). Treatment protocols for patients without *H. pylori* include PPIs, H_2RAs, antacids, or mucosal protective agents.

The most serious complication of PUD is a perforated ulcer. This complication requires immediate surgical repair.

Pancreatitis

The pancreas contributes pancreatic juice and vital digestive enzymes to digestion. Production of these enzymes is reduced or no longer occurs in patients who have chronic pancreatitis or in those who have undergone a pancreatic resection or removal. In pancreatitis, digestive enzymes that normally are maintained in the pancreas in their inactive form become activated, destroying parts of the gland. With time, destruction of the pancreas decreases the amount of enzymes produced because the cells that produce the enzymes have been lost. Chronic pancreatitis generally occurs following repeated attacks of acute pancreatitis, but it may also be triggered by only one acute attack, especially if the pancreatic ducts are damaged.

Symptoms of chronic pancreatitis include abdominal pain that may become worse when eating or drinking, spread to the back, or become constant and disabling. Other symptoms include nausea, vomiting, weight loss, and fatty stools. Weight loss occurs because the body does not secrete enough pancreatic enzymes to break down food, so nutrients are not absorbed. Poor digestion leads to excretion of fat, protein, and sugar into the stool. If the insulin-producing cells of the pancreas (islet cells) have been damaged, diabetes may also develop at this stage.

Treatment for chronic pancreatitis includes replacement of digestive enzymes with pancrelipase.

Obesity

The incidence of overweight and obesity is increasing at an alarming rate, both in the United States and worldwide. Obesity and overweight reflect the extent to which a patient's body mass index (BMI) exceeds the normal range. The BMI is calculated as weight in kilograms divided by the square of height in meters. Normal BMI is 18.5 to 24.9 kg/m^2. The term overweight is used if the patient's BMI is 25 to 29.9 kg/m^2, whereas the term obesity is used if the BMI exceeds 29.9 kg/m^2. Overweight and obesity are the result of a mismatch between energy consumed in calories and energy expended in activities. The lifestyle in industrialized countries is increasingly sedentary. The energy expenditure of the average American worker at the beginning of the 21st century is estimated to be about half of that of the American worker at the start of the 20th century. Additionally, a high-fat diet, common in these countries, also contributes to obesity. High blood pressure, type 2 diabetes, coronary heart disease, elevated blood cholesterol, gallbladder disease, and osteoarthritis are associated with overweight and obesity. High blood pressure is the most common overweight- and obesity-related health condition, and its incidence increases as weight increases. Type 2 diabetes, gallbladder disease, and osteoarthritis also are more prevalent as weight increases. The risk of coronary heart disease, somewhat higher than normal in overweight patients, is substantially elevated if the patient is obese. Elevated blood cholesterol levels are found at all levels of overweight and obesity. Preventing and treating obesity are important to control these lifelong morbidities and the mortality that accompanies them.

Nausea and Vomiting

Disorders of the upper GI tract are often accompanied by nausea and vomiting. Increased activity of neurotransmitters—for example, dopamine in the CTZ and acetylcholine in the VC—appears to play an important role in inducing vomiting. Serotonin also has a role in vomiting, and special serotonin receptors are located in the CTZ. The CTZ is stimulated through peripheral and central pathways. Peripheral stimulation happens when chemotherapy causes damage to the GI mucosa, activating afferent input through the vagus nerve. Serotonin is the neurotransmitter for peripheral stimulation. The neurotransmitter substance P, found in the gut and the central nervous system, is capable of mediating emesis and is responsible for central pathway stimulation. Substance P exerts its antiemetic effect by binding to the tachykinin neurokinin (NK1) receptor, found throughout the central and peripheral systems and in the gut. The release of serotonin from the small intestine during chemotherapy stimulates these receptors and therefore stimulates vomiting. Because different substances are involved in the process of nausea and vomiting, several different classes of drugs may be used for management.

C PROTON PUMP INHIBITORS

The secretion of gastric acid can be suppressed by inhibiting the H^+/K^+ adenosine triphosphatase (ATPase) enzyme system at the secretory surface of the gastric parietal cell. Because this enzyme system is the "acid pump," also known as the "proton pump," within the gastric mucosa, drugs that inhibit this system are known as PPIs. These drugs block the final step of gastric acid production. Their effect is dose related; they inhibit both basal and stimulated acid secretion.

The prototype PPI is omeprazole (Prilosec). Table 36.2 presents a summary of proton pump inhibitors.

Nursing Management of the Patient Receiving P Omeprazole

Core Drug Knowledge

Pharmacotherapeutics

Omeprazole is used for symptomatic treatment of heartburn and other symptoms of GERD. It also is used to treat duodenal ulcers associated with *H. pylori* infection. It is sometimes used for short-term treatment (4 to 8 weeks) of active duodenal and gastric ulcer when *H. pylori* is not present and is also used as short-term treatment for erosive esophagitis, diagnosed by endoscopy, to maintain healing. It can be used long term in chronic hypersecretory conditions, such as Zollinger-Ellison syndrome, multiple endocrine adenomas, and systemic mastocytosis. Off-label uses are treatment of GERD-related laryngitis, and adjunctive treatment to enhance the efficacy of pancreatin in treating steatorrhea (large quantities of fat in stool) in cystic fibrosis.

Pharmacokinetics

Omeprazole, like other PPIs, is unstable in an acid environment and therefore is enteric-coated to protect the drug until it passes through the stomach. It is well absorbed when it reaches the small intestine. An immediate-release formulation of omeprazole (Zegerid) works by adding sodium bicarbonate to protect omeprazole from gastric acid degradation.

Omeprazole is metabolized extensively by the cytochrome P-450 system in the liver, and several metabolites are formed. These metabolites have minimal antisecretory function. The antisecretory effect of omeprazole is long lasting and is not related closely to elimination half-life: its half-life in plasma is less than 2 hours, whereas the antisecretory effect lasts longer than 24 hours. This extended effect is attributed to prolonged binding of the drug to the parietal H^+/K^+ ATPase enzyme. When the drug is discontinued, normal secretory activity returns within 3 to 5 days. Little of the drug is excreted unchanged. The metabolites are excreted mostly in the urine, although about one fourth of them are eliminated in the feces.

Pharmacodynamics

Omeprazole suppresses the last phase of gastric acid production by suppressing the H^+/K^+ ATPase enzyme system. Intragastric pH is therefore elevated, and as a result, blood flow in the antrum, pylorus, and duodenal bulb is

TABLE 36.2 Summary of Selected Proton Pump Inhibitors

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
omeprazole (Prilosec)		*Adult:* PO,	*Onset:* Within 1 h
	Active duodenal ulcer	20–40 mg/d × 4–8 wk	*Duration:* Unknown
	Gastric ulcer	40 mg/d × 4–8 wk	$t_{1/2}$: 30–60 min
	GERD	20 mg/d × 4–8 wk	
	Erosive esophagitis	20–40 mg/d × 4–8 wk	
	Hypersecretory conditions	60 mg once daily (max, 120 mg/d)	
	Helicobacter pylori	20 mg bid (in combination with other therapy) × 10–14 d	
esomeprazole (Nexium)	Erosive esophagitis, GERD	PO, 20–40 mg/d × 4–8 wk	*Onset*: 1–2 h
	H. pylori	IV, 20–40 mg/d up to 10 d	*Duration*: 17 h
	Hypersecretory conditions	PO, 40 mg/d × 10 d	$t_{1/2}$: 1–1.5 h
	Gastric ulcer prophylaxis	PO, 40 mg 2×/d (max, 240 mg/d)	
		PO, 20–40 mg/d	
lansoprazole (Prevacid)	Active duodenal ulcer	PO, 15 mg/d × 4 wk	*Onset*: Unknown
	Erosive esophagitis, GERD	PO, 15–30 mg/d × 8 wk	*Duration*: 24 h
	Hypersecretory conditions	60 mg/d	$t_{1/2}$: 1.5 h
	H. pylori	30 mg/d × 2 wk (in combination with other drug therapy)	
pantoprazole (Protonix)	Erosive esophagitis, GERD	PO, 40 mg 1–2×/d × 8 wk	*Onset*: PO, unknown; IV, 15–30 min
		IV, 40 mg/d × 7–10 d	*Duration*: 24 h
	Hypersecretory conditions	40–120 mg 2×/d	$t_{1/2}$: 1–1.5 h
		IV, 80 mg q8–12 h × 6 d	
	Upper GI bleed	IV, 80-mg bolus ×1, then 8 mg/h × 72 h	
rabeprazole (Aciphex)	GERD	PO, 20 mg/d × 4–8 wk	*Onset*: 1 h
	Erosive esophagitis	20 mg 1–2×/d × 8 wk	*Duration*: >24 h
	Duodenal ulcer	PO, 20 mg/d up to 4 wk	$t_{1/2}$: 1.5 h
	Hypersecretory conditions	60 mg 1–2×/d	
	H. pylori	PO, 20 mg 2×/d × 7 d	

decreased. Omeprazole increases serum pepsinogen levels and decreases pepsin activity. The increases in gastric pH are associated with increased numbers of nitrate-reducing bacteria and elevated nitrate concentrations in gastric juice in patients with gastric ulcers. Serum gastrin levels increase as acid secretion is inhibited. Continued treatment does not provoke serum gastrin levels to rise continually; however; they reach a certain degree of elevation and remain there. Omeprazole also has an antimicrobial affect against *H. pylori*. It inhibits *H. pylori* urease, which is necessary for gastric colonization.

Contraindications and Precautions

Omeprazole is contraindicated for patients who are hypersensitive to the drug or any of its components. It is given cautiously as empiric therapy because it may decrease the symptoms of gastric cancer, thus delaying treatment. Long-term PPI administration in rats has demonstrated an increased rate of gastric cancer. This finding has not been replicated in humans. PPIs do cause hypergastrinemia, which in turn causes diffuse, linear, or micronodular hyperplasia and atrophic gastritis. These changes occur most frequently in patients with *H. pylori* infection and markedly increased gastrin levels. Gastric hyperplasia and atrophic gastritis in combination with *H. pylori* infection increase the risk of gastric cancer, but there are no studies that show a direct correlation between PPI administration and gastric cancer (Ito, et al., 2009).

Omeprazole is a pregnancy category C drug.

Adverse Effects

Omeprazole is generally well tolerated. The most common adverse effects are headache and diarrhea. However, during clinical trials, these effects also were found in patients receiving placebo. Other adverse effects reported in clinical trials include central nervous system (CNS) effects of dizziness and asthenia; GI effects of constipation, abdominal pain, nausea, and vomiting; and miscellaneous effects of upper respiratory infection, cough, rash, and back pain. Pneumonia is another potential adverse effect associated with all PPIs, including omeprazole, because bacterial colonization of the stomach and respiratory tract increases

when gastric acidity is reduced. As people age, gastric pH rises, and omeprazole therapy raises the pH even further. Elevated gastric pH inhibits the dissolution and absorption of calcium, theoretically resulting in an increased risk of fractures. Several recent studies have been unable to validate this concern (Thompson et al., 2010; Gray et al., 2010; Targownik et al., 2010).

Rare adverse effects are numerous and diverse. They include confusion, drowsiness, blurred vision, tachycardia, diaphoresis, flushing, dry mouth, severe generalized skin reactions, blood dyscrasias, elevated liver enzyme levels, and overt hepatic disease. Study findings regarding an increased risk of *Clostridium difficile* diarrhea (Ananthakrishnan, Issa, and Binion, 2010) in patients taking proton pump inhibitors are conflicting.

Overdosage with omeprazole has been reported rarely, and no serious outcomes have been reported from overdosage. In patients who received 16 to 45 times the usual dose, symptoms were transient and included confusion, drowsiness, blurred vision, tachycardia, nausea, diaphoresis, flushing, headache, and dry mouth.

Drug Interactions

Omeprazole can interact with other drugs that also are metabolized through the cytochrome P-450 pathway. Such interactions can produce elevated levels of these other drugs because their metabolism is decreased. Because omeprazole causes prolonged and substantial decreases in gastric acidity, drugs that depend on an acid environment for absorption may not be absorbed optimally. Table 36.3 lists drugs that interact with omeprazole.

Assessment of Relevant Core Patient Variables

Health Status

Determine that the patient has a clinical indication for the use of omeprazole. Hepatic and renal diseases do not require a decreased dosage. For patients on long-term therapy, coordinate testing for *H. pylori* infection.

Life Span and Gender

Note the patient's age. Omeprazole's efficacy and safety in children have not been established. Although bioavailability of the drug may be increased in older adults, no dosage adjustment is needed. Coordinate bone density testing for elderly patients on long-term omeprazole therapy. Omeprazole decreases the dissolution and absorption of calcium, which may increase the risk of hip fracture. Men are more likely to have PPI-associated hip fractures than women.

Assess female patients for pregnancy or breast-feeding. Omeprazole is a pregnancy category C drug; no adequate or well-controlled studies of the drug have been done in pregnant women. Omeprazole should be used during pregnancy only if the potential benefit to the mother justifies the potential risk to the fetus. It is not known whether omeprazole is secreted in breast milk. Animal studies showed decreased weight gain from nursing when the mother received large doses (35 to 365 times the human dose) of omeprazole. Therefore, use in breast-feeding is not recommended.

Lifestyle, Diet, and Habits

Assess the patient's diet and smoking habits. Highly acidic foods, such as tomato juice, and highly spiced foods may worsen the symptoms of GERD or PUD until the ulcer heals. Omeprazole should be taken 30 minutes before eating a meal. Smoking also may aggravate the symptoms of PUD.

Environment

Omeprazole may be given in any environment. Advise elderly patients to clear the home of factors that increase the risk of falling such as loose rugs or highly waxed floors because of the association between PPI administration and hip fractures.

Culture and Inherited Traits

Assess the patient's culture and genetic background before administering omeprazole. The drug has a longer duration of action of omeprazole in Asians than in whites. In addition, Asians can experience elevated serum levels (up to fourfold higher) than whites and thus may need a decreased dose.

Nursing Diagnoses and Outcomes

- Altered Comfort related to symptoms of GERD, peptic ulcer disease, or chronically elevated acid production
  Desired outcome: *Drug therapy will relieve the symptoms from the GI disorder.*
- Imbalanced Nutrition: Less than Body Requirements, related to symptoms of GERD, peptic ulcer disease, or chronically elevated acid production
  Desired outcome: *Drug therapy will allow adequate dietary intake.*
- Collaborative Problem: *H. pylori* infection
  Desired outcome: *Treatment regimen to eradicate* ***H. pylori*** *will be effective, with minimal adverse effects.*

Planning and Intervention

Maximizing Therapeutic Effects

Optimal efficacy requires that omeprazole is taken daily, not just when the patient is symptomatic. Make sure that omeprazole is administered for the recommended time, based on the clinical indication for therapy, usually between 2 and 8 weeks. For chronic pathologic hypersecretory conditions, administer daily for as long as needed. Some patients are known to have received omeprazole for 5 years or longer.

Be sure the patient does not crush or chew the capsule. For patients who cannot swallow the capsule, open it and sprinkle the granules in 1 tablespoon of applesauce, and advise patients to swallow the applesauce without chewing the granules.

TABLE 36.3 Agents That Interact with P Omeprazole

Interactants	Effect and Significance	Nursing Management
azole antifungal agents	Bioavailability of azole antifungal agents may be decreased because of elevated gastric pH induced by omeprazole.	Monitor for antifungal treatment failure.
benzodiazepines	Omeprazole may reduce clearance, prolong $t_{1/2}$, and increase serum levels of certain benzodiazepines.	Ensure safety. Monitor for sedation. Discuss dosage adjustment of benzodiazepine with health care provider.
calcium citrate	Omeprazole may decrease pH-dependent calcium absorption.	Ensure safety, especially of elderly patients. Discuss increasing dose of calcium with health care provider.
cilostazol	Omeprazole inhibits metabolism of cilostazol, resulting in increased therapeutic and pharmacologic activity.	Monitor PT and INR. Monitor for bleeding or bruising. Discuss possible dosage adjustment of cilostazol with health care provider.
clarithromycin	Increases plasma levels of both clarithromycin and omeprazole; this may be beneficial because the two are given as cotherapy to treat *Helicobacter pylori*.	Administer as ordered. Assess for possible adverse effects.
cyclosporine	Omeprazole alters metabolism of cyclosporine, resulting in alterations of serum concentration (may be increased or decreased).	Verify order with health care provider. Monitor renal status. Discuss dosage adjustment of cyclosporine with health care provider as needed.
digoxin	Omeprazole may increase absorption of digoxin.	Monitor digoxin levels. Monitor heart rate. Monitor for anorexia, nausea, or vomiting.
herbal drugs ginkgo biloba St. John's wort	Ginkgo biloba induces metabolism of omeprazole, resulting in decreased serum concentration of omeprazole.	Monitor for efficacy of PPI therapy.
methotrexate	Omeprazole decreases renal clearance of methotrexate.	Monitor CBC. Monitor renal and hepatic function. Monitor for signs of methotrexate toxicity.
phenytoin	Reduced plasma clearance of phenytoin and increased half-life, most likely caused by inhibition of its metabolism.	Monitor phenytoin levels. Monitor for ataxia, difficulty thinking, difficulty speaking.
protease inhibitors (PIs)	Omeprazole may decrease dissolution of certain PIs, resulting in decreased absorption and lower serum concentrations.	Monitor viral load. Monitor T-cell count. Monitor for opportunistic infections.
salicylates	Enteric-coated salicylates may dissolve more rapidly in increased pH environment caused by omeprazole.	Monitor for gastric adverse effects. Advise patients to avoid enteric-coated preparations.
selective serotonin reuptake inhibitors (SSRIs)	Omeprazole may inhibit metabolism of SSRIs, resulting in an increased serum concentration.	Monitor for increased SSRI adverse effects.
sulfonylureas	Omeprazole inhibits metabolism of sulfonylurea drugs, resulting in increased serum concentration of sulfonylureas.	Monitor blood glucose. Monitor for signs of hypoglycemia. Discuss dosage adjustment of sulfonylurea drug with health care provider.
Sucralfate	Delayed absorption and reduced bioavailability of omeprazole (by about 17%) when the two are given at same time; this decreases desired therapeutic effect.	Give omeprazole ≥30 min before sucralfate.

TABLE 36.3 Agents That Interact with P Omeprazole *(continued)*

Interactants	Effect and Significance	Nursing Management
tacrolimus	Omeprazole inhibits metabolism of tacrolimus, resulting in increased therapeutic and pharmacologic activity.	Monitor for CNS effects such as seizures, headache, insomnia, and tremors. Discuss possible dosage adjustment of tacrolimus with health care provider.
theophylline	Omeprazole induces hypochlorhydria that increases peristalsis in the small intestine and antiperistalsis in the proximal colon. This allows increased absorption of sustained-release theophylline formulations.	Monitor for signs of theophylline toxicity.
Warfarin	Omeprazole inhibits metabolism of warfarin, increasing its therapeutic and pharmacologic activity.	Monitor PT and INR. Monitor for bleeding or bruising. Discuss possible dosage adjustment of warfarin with health care provider.

Minimizing Adverse Effects

Daily dosages larger than 80 mg should be given in divided doses. Because the drug is enteric coated, it cannot be crushed before use. Monitor the patient for the development of diarrhea and notify the health care provider should it occur. Suggest calcium citrate supplementation for elderly patients on long-term therapy.

Providing Patient and Family Education

- Teach patients to take omeprazole 1 hour before meals and to continue therapy for the duration prescribed.
- Emphasize that the drug should not be crushed or chewed, because doing so alters absorption and effectiveness.
- Explain the importance of taking the drug daily to ensure an adequate therapeutic response.
- Encourage calcium citrate supplementation for patients on long-term therapy to decrease the potential for PPI-induced hip fracture.
- Discuss potential adverse effects and interventions
- Avoid driving if dizziness occurs.
- Ensure adequate nutrition if nausea, vomiting, or diarrhea occurs. Contact the health care provider if these symptoms are persistent.
- Do not self-medicate for symptoms of an upper respiratory infection because this is a drug effect, not an infection. Contact the health care provider if the symptoms are intolerable.
- Explain that antacids can be used while taking omeprazole if symptoms require additional management.
- Advise patients to contact the health care provider immediately if they experience persistent diarrhea.

Ongoing Assessment and Evaluation

Omeprazole therapy is considered effective when the symptoms of GERD, PUD, or hypersecretory conditions are controlled or the duodenal ulcer is healed.

Drugs Closely Related to P Omeprazole

Four additional PPIs are available in the United States: esomeprazole, lansoprazole, pantoprazole, and rabeprazole. The major difference between these PPIs and omeprazole is that they are all available in both oral and intravenous (IV) forms and none is marketed as a generic drug. Indications, precautions, and adverse effects are similar to omeprazole, including the risk of pneumonia and GI cancer. Most health care providers believe all of the PPIs to be similarly effective.

Esomeprazole

Esomeprazole (Nexium) is the S-isomer of omeprazole. It is metabolized more slowly than omeprazole; therefore, it suppresses gastric acid for a longer period. This finding has not been proven to be clinically significant.

Lansoprazole

Lansoprazole (Prevacid) is very similar to omeprazole. It is available as an orally disintegrating tablet, delayed-release tablet, and enteric-coated granules that form a suspension.

Rabeprazole

Rabeprazole (Aciphex) has a shorter duration of action than omeprazole. However, it also has antibacterial activity that works in conjunction with other antibiotics to eradicate *H. pylori*. Rabeprazole interacts with digoxin and increases its serum concentration. It is necessary to monitor for signs of digoxin toxicity when these drugs are given together.

Pantoprazole

Pantoprazole (Protonix) is also very similar to omeprazole. It is used frequently because it is the least expensive of all the PPIs.

MEMORY CHIP

P Omeprazole

- Used to treat peptic ulcers resulting from *H. pylori,* GERD, erosive esophagitis, and chronic hypersecretory conditions (e.g., Zollinger-Ellison syndrome)
- May interact with other drugs metabolized by CYP 450
- Most common adverse effects: headache and diarrhea
- **Life span alert: use not recommended during breast-feeding**
- Most important patient education: Take omeprazole before meals; do not crush or chew drug.

Drug Significantly Different From P Omeprazole

Sucralfate (Carafate), like omeprazole, is used to treat duodenal ulcers (Table 36.4). Off-label uses of sucralfate include accelerating the healing of gastric ulcers and long-term management of gastric ulcers. Other off-label uses include treating reflux ulcers, reflux and peptic esophagitis, and NSAID-induced GI symptoms (including those caused by aspirin), and preventing stress ulcers and GI bleeding in critically ill patients. Sucralfate suspension also has been used to treat oral and esophageal ulcers caused by radiation, chemotherapy, and sclerotherapy.

Unlike omeprazole, sucralfate is not a PPI and does not prevent the secretion of gastric acid. Sucralfate is an aluminum salt of sulfated sucrose, a polysaccharide with antipeptic activity. In the acidic medium of gastric fluid, the aluminum ion splits off, leaving a highly polar anion. An essentially nonabsorbent paste forms and adheres to the ulcer lesion, protecting the lesion from acid, pepsin, and bile salts. This protection allows the ulcer to heal. The drug also has minimal antacid effects, but these effects do not contribute to ulcer healing.

Sucralfate should be used cautiously during pregnancy (pregnancy category B) and breast-feeding because it is not known whether the drug is secreted in breast milk. Safety and efficacy in children have not been established. In dialysis patients and others with chronic renal failure, sucralfate given concurrently with aluminum antacids increases the risk of aluminum toxicity because small amounts of aluminum, given off by sucralfate, are absorbed from the GI tract. This toxicity is not a potential problem for patients with normal renal function.

Adverse effects from sucralfate are usually mild. The drug rarely had to be discontinued during clinical trials. The most common adverse effect was constipation, which occurred in only 2% of patients. Sucralfate may decrease the effectiveness of anticoagulants, digoxin, hydantoins, ketoconazole, quinidine, and the quinolones.

Patients should be taught to take sucralfate at least 1 hour before meals and at bedtime to maximize the therapeutic effect. Sucralfate may block the absorption of other drugs; therefore, it should be taken 1 hour before or after other drugs are administered. Antacids should be taken 30 minutes before or after sucralfate.

C HISTAMINE-2 RECEPTOR ANTAGONISTS

Various terms are used to describe the H_2 receptor antagonists, including H_2RAs, H_2 receptor blockers, H_2 antagonists, H_2 blockers, and histamine blockers. H_2RAs block the effect of histamine at H_2 receptors, particularly those in the parietal cells of the stomach. Antihistamines that block histamine-1 (H_1) receptors, the most frequent site of action for antihistamines, do not affect H_2 receptor sites, and H_2RAs do not block H_1 sites; they also are not anticholinergic.

By blocking histamine at the parietal cells, these drugs inhibit gastric acid secretion in all phases, and other secretions caused by histamine, muscarinic agonists, and gastrin are also inhibited. H_2RAs also inhibit the fasting secretions that occur during the night, as well as secretions stimulated by food, insulin, caffeine, pentagastrin, and betazole. These drugs also reduce the volume of, and the hydrogen ion concentration in, gastric secretions.

Although cimetidine was the first drug in this class, it is not used frequently because of its numerous drug interactions that are not found with other H_2RA drugs. The prototype H_2RA is ranitidine (Zantac). Table 36.5 presents a summary of H_2RAs.

Nursing Management of the Patient Receiving P Ranitidine

Core Drug Knowledge

Pharmacotherapeutics

Ranitidine is used to treat patients with active duodenal or benign gastric ulcers and (at reduced dosage) in maintenance therapy after acute ulcers have healed. It is also used to treat pathologic hypersecretory conditions, such as

TABLE 36.4 Summary of Miscellaneous Drugs Used to Treat Ulcers

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
misoprostol (Cytotec)	Prevention of NSAID-induced gastric ulcers	PO, 200 mcg qid with food; if not well tolerated, may use 100 mcg/dose	*Onset*: Rapid *Duration*: 3 h $t_{1/2}$: 20–40 min
sucralfate (Carafate)	Duodenal ulcer	PO, 1 g qid 1 h before meals and at bedtime for 4–8 wk	*Onset*: 30 min *Duration*: 5 h $t_{1/2}$: 6–20 h

TABLE 36.5 Summary of Selected Histamine-2 Receptor Antagonists

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P ranitidine (Zantac, EFFERdose, Zantac 75 [OTC]; Zantac 150 [OTC];	Duodenal and gastric ulcers	PO, 150 mg bid, or 300 mg at bedtime (for duodenal) as short-term use for active ulcers; maintenance dose, 150 mg at bedtime Parenteral (any use): IM, 50 mg (2 mL premixed) q6–8h; IV push, 50 mg (2 mL) diluted with 0.09% NaCl solution (normal saline) to make 20 mL, over 5 min or more; intermittent IV, 50 mg diluted in 100 mL dextrose 5% in water (D_5W) or other compatible solution, run over 15–20 min, q6–8h, not to exceed 400 mg/d	*Onset:* PO, varies; IM, rapid; IV, immediate *Duration:* 8–12 h $t_{1/2}$: 2–3 h
	GERD	PO, 150 mg bid	
	Pathologic hypersecretory conditions (i.e., Zollinger-Ellison syndrome)	PO, 150 mg bid (max, 6 g/d); continuous IV infusion (dilute in compatible solution to no more than 2.5 mg/mL), run at 1 mg/kg/h; after 4 h may be adjusted upward in 0.5-mg/kg/h increments up to 2.5 mg/kg/h	
	Erosive esophagitis	PO, 150 mg qid; maintenance, 150 mg bid	
cimetidine (Tagamet [DSC], Tagamet HB 200 [OTC])	Duodenal and gastric ulcers	PO, 800 mg at bedtime, or 300 mg qid with meals and at bedtime for 4–6 wk (duodenal) or 8 wk (gastric); IV or IM, 300 mg q6–8 h, not to exceed 2,400 mg/d	*Onset*: PO, varies; IV, rapid *Duration*: 4–13 h (depending on dose and regimen) $t_{1/2}$: 2 h
	Prevention of upper GI bleeding	IV, infusion at 50 mg/h	
	Erosive GERD	PO, 1,600 mg/d divided into 2 or 4 doses for 12 wk; IV or IM, dosing and regimen not established	
	Pathologic hypersecretory conditions	PO, 300 mg qid with meals and at bedtime, not to exceed 240 mg/d, given as long as clinically needed	
	Heartburn/acid indigestion	PO, OTC, 200 mg twice daily; continuous IV infusion, 300 mg q6–8 h	
famotidine (Pepcid, Pepcid AC, Pepcid RPD, Fluxid)	Same as ranitidine, for ulcers and related conditions	PO (acute duodenal ulcer), 40 mg/d at bedtime or 20 mg bid for 6–8 wk; maintenance, 20 mg/d at bedtime or (for acute benign gastric ulcer) 40 mg/d at bedtime; IV (patient NPO), 20 mg q12 h (dilute 2 mL, or 20 mg, in 5 or 10 mL normal saline or other compatible solution, and inject over at least 2 min); intermittent IV, 20 mg (dilute in 100 mL D5W or other compatible solution; infuse over 15–30 min)	*Onset*: PO, ≤1 h; IV, rapid *Duration*: 10–12 h $t_{1/2}$: 2.5–3.5 h
	Hypersecretory conditions	PO (individualize), 20 mg q6 h to start, up to 160 mg q6 h; continue as long as needed	
	GERD	PO, 20 mg bid up to 6 wk	
	Esophagitis due to GERD	PO, 20 or 40 mg bid up to 12 wk	
	Heartburn, acid indigestion	PO, OTC, 10 mg (1 tablet); prevention, 1 h before eating a meal expected to cause GI distress; up to 2 tablets in 24 h	
nizatidine (Axid, Axid AR [OTC])	Duodenal ulcer, benign active gastric ulcer	PO (for active ulcer), 300 mg once daily at bed-time or 150 mg bid (less for patients with renal insufficiency); maintenance, 150 mg once daily at bedtime	*Onset*: Varies *Duration*: 3–10 h $t_{1/2}$: 1–2 h
	GERD	*Adult*: PO, 150 mg bid	

Zollinger-Ellison syndrome. It is used to treat GERD and endoscopically diagnosed erosive esophagitis and as maintenance therapy to promote healing of erosive esophagitis.

Pharmacokinetics

Ranitidine is a competitive, reversible inhibitor of the action of histamine at the H_2 receptors, including receptors on the gastric cells. The drug is 50% absorbed after oral administration. It is metabolized by the liver to N-oxide, S-oxide, and desmethyl ranitidine.

The drug's principal route of excretion is in the urine, with approximately 30% of the orally administered dose collected in the urine as unchanged drug in 24 hours. The elimination half-life is 2.5 to 3 hours.

Pharmacodynamics

Ranitidine inhibits both daytime and nocturnal basal gastric acid secretions as well as gastric acid secretion stimulated by food, betazole, and pentagastrin. Ranitidine does not affect pepsin secretion. It has little or no effect on fasting or postprandial serum gastrin secretion. It has no effect on prolactin levels, gonadotropins, thyroid-stimulating hormone, growth hormone, cortisol, aldosterone, androgen or estrogen levels, or sperm count.

Contraindications and Precautions

Ranitidine is contraindicated in patients who are hypersensitive to the drug. It is a pregnancy category B drug; no adequate, well-controlled studies of this drug have been performed in pregnant women. It also is not recommended for use by nursing mothers because it has been found in breast milk. The safety and effectiveness of ranitidine have been established in patients 1 month to 16 years of age.

Ranitidine should be used cautiously in patients with hepatic or renal impairment because the drug is metabolized by the liver and excreted by the kidneys. Patients with gastric ulcers should be monitored closely when using ranitidine because the drug can mask symptoms of GI cancer temporarily. Such patients should be evaluated thoroughly to rule out cancer. Ranitidine is also used cautiously in elderly patients, in patients with chronic obstructive pulmonary disease, and in those who are immunocompromised because of an increased risk of community-acquired pneumonia. In geriatric populations, as compared with younger subjects, no overall differences in safety or effectiveness have been observed. However, greater sensitivity of some older individuals to the drug cannot be ruled out.

Adverse Effects

Ranitidine generally is well tolerated. Headache, sometimes severe, seems to be related to drug administration. Blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred. These effects are usually reversible. Rash has been reported. GI effects include constipation, diarrhea, nausea and vomiting, and abdominal discomfort or pain; pancreatitis has also been reported, but rarely. Hepatocellular, cholestatic, or mixed hepatitis, with or without jaundice, occurs occasionally. CNS, cardiovascular, musculoskeletal, integumentary, and other effects such as hypersensitivity are rare.

IV ranitidine may cause increased liver function enzymes when given for a prolonged period. Rapid IV infusion may induce bradyarrhythmias. Low-weight neonates who receive IV ranitidine have an increased risk of necrotizing enterocolitis.

Drug Interactions

Ranitidine has a favorable drug interaction profile because it does not inhibit the cytochrome P-450 system. Table 36.6 presents drug interactions with ranitidine.

Assessment of Relevant Core Patient Variables

Health Status

Before administering ranitidine, assess the patient for epigastric, abdominal, and esophageal pain, commonly described as heartburn or a burning sensation that occurs after eating. Also, explore complaints of dyspepsia; nausea and vomiting; dark, tarry stools; hepatic dysfunction; and

TABLE 36.6 Agents That Interact with P Ranitidine

Interactants	Effect and Significance	Nursing Management
alcohol	Ranitidine may increase absorption and decrease gastric first-pass metabolism of alcohol by inhibiting gastric alcohol dehydrogenase activity.	Advise patients to avoid alcohol.
azole antifungal agents	Ranitidine increases gastric pH, which results in decreased dissolution and absorption of itraconazole and ketoconazole.	Monitor for azole antifungal efficacy.
cephalosporins	Ranitidine increases gastric pH, which results in decreased absorption of cephalosporins.	Monitor for cephalosporin efficacy.
Diltiazem	Ranitidine may increase the bioavailability of diltiazem.	Monitor for diltiazem toxicity.
phenytoin	Ranitidine inhibits metabolism of phenytoin, resulting in an increased serum concentration.	Monitor phenytoin levels. Monitor for ataxia, difficulty thinking, difficulty speaking.
Procainamide	Ranitidine may alter bioavailability and renal clearance of procainamide.	Monitor for procainamide toxicity.
Sulfonylureas	Ranitidine inhibits metabolism of sulfonylureas, resulting in an increased serum concentration.	Monitor glucose. Monitor for signs of hypoglycemia.

renal impairment. If the patient has a nasogastric tube in place, inspect for frank or occult bleeding.

The drug history should include the prescription and OTC drugs the patient is taking currently because many drugs, including aspirin, other NSAIDs, and corticosteroids, can cause gastric irritation. Additional drug history involves determining whether the patient is taking any OTC H_2RA drugs and asking how long and why the patient has been using these drugs.

Ensure that a baseline complete blood count as well as liver and renal functions tests are obtained when long-term therapy is anticipated or patients have a history of hematopoietic, renal, or liver dysfunction.

Life Span and Gender

Assess whether the patient is pregnant or breast-feeding because pregnant and breast-feeding patients should take ranitidine only if necessary. Ranitidine is a pregnancy category B drug. Determine the patient's age. Elderly patients should be assessed carefully for decreased renal and hepatic function. Monitor low-birth-weight neonates carefully for signs of necrotizing enterocolitis.

Lifestyle, Diet, and Habits

Assess the patient's diet and smoking habits. Caffeine, alcohol, and certain foods may aggravate gastric symptoms from GERD, PUD, and hypersecretory conditions. Assess for meals that frequently include spices, onion, citrus, tomato, and pepper. Evaluate the use of peppermint, chocolate, or carbonated beverages. Decreasing the intake of these foods may decrease the severity of GERD symptoms. Smoking reverses the drug-induced inhibition of nocturnal gastric acid production and hinders ulcer healing. Cigarette smoking also is related closely to ulcer recurrence.

Question the patient about napping and sleep patterns. Lying down within 3 hours of eating increases the risk of acid reflux.

Environment

Ranitidine can be administered in any setting. The oral form is self-administered easily. Administration through the IV route is done most commonly in an inpatient setting.

Culture and Inherited Traits

Cultural influences on dietary patterns must be considered if the patient normally eats a diet consisting of highly spiced foods, such as jalapeño peppers, Thai curries, or Szechwan cuisine.

Nursing Diagnoses and Outcomes

- Chronic Pain related to alteration in the gastric mucosa, ulceration, or irritation
  Desired outcome: *The patient will report decreased pain while receiving drug therapy.*
- Acute Pain related to adverse drug effects, such as headache
  Desired outcome: *The patient will not experience adverse effects while taking ranitidine.*
- Risk for Injury related to drug-induced somnolence, dizziness, confusion, or hallucinations
  Desired outcome: *The patient will not suffer injury from adverse effects of drug therapy.*
- Diarrhea related to adverse effects of drug therapy
  Desired outcome: *The patient will remain well hydrated and elimination patterns will remain within normal parameters.*

Planning and Intervention

Maximizing Therapeutic Effects

If both ranitidine and antacids are prescribed, give them at least 2 hours apart to prevent decreased absorption of ranitidine. If administration is intramuscular, inject undiluted ranitidine into a large muscle.

Minimizing Adverse Effects

Monitor serum trough levels in patients with renal or hepatic impairment because CNS effects are more likely to occur when serum levels are elevated above the therapeutic level. Drug therapy may have to be discontinued if serious adverse effects occur.

Administer IV ranitidine slowly to prevent hypotension and cardiac arrhythmias. It is important to administer single IV push doses, diluted in 20 mL of normal saline or other compatible solution, over at least 2 minutes. Intermittent IV infusions of 300 mg in at least 50 mL of D_5W or other compatible solution should be administered over at least 15 minutes or 20 minutes. Give a continuous IV infusion at a rate of 37.5 mg/h.

Providing Patient and Family Education

- Instruct patients to take the drug exactly as directed for the entire course of therapy, even if symptoms disappear (it usually takes 4 to 6 weeks for an ulcer to heal but less time for the symptoms to subside).
- Caution patients not to take a double dose if a dose is missed.
- Counsel patients on smoking cessation. OTC or prescription smoking cessation aids may be recommended, if appropriate.
- Explain that alcohol, caffeine, spicy foods, products containing aspirin or ibuprofen, and smoking all contribute to gastric irritation and slow healing of the ulcer.
- Discuss potential adverse effects and interventions.
  - Avoid driving if dizziness occurs.
  - Ensure adequate nutrition if nausea, vomiting, or diarrhea occurs. Contact the health care provider if these symptoms are persistent.
  - Adjust lights or temperature, and avoid noise if headache occurs. Contact the health care provider if the symptoms are intolerable.
- Caution patients not to substitute OTC ranitidine for prescribed ranitidine because these products have different potencies (Box 36.1).

BOX 36.1 COMMUNITY BASED CONCERNS

Using Over-the-Counter (OTC) Gastrointestinal Drugs Responsibly

Various antacids, such as Maalox and Mylanta, and histamine-2 receptor antagonists (H_2RAs) such as cimetidine (Tagamet HB), ranitidine (Zantac HB), famotidine (Pepcid AC), and nizatidine (Axid AR), are available OTC. Nurses who provide home care or who treat patients on an outpatient basis need to be aware that many patients self-medicate with these preparations. They may use them alone, as an adjunct to prescribed therapy, or in place of their prescribed drug. The following guidelines may help nurses help such patients use these drugs responsibly:

- Assess specifically for OTC antacid and H_2RA use. The patient may not think of OTC products as "real drugs" and so fail to identify them during the drug history.
- Advise the patient taking a prescribed H_2RA to take only that drug and not to substitute any OTC preparation for it. Explain that the dosages and drug formulations may be different.
- Caution the patient not to take any OTC H_2RA in addition to the prescribed drug. In such cases, "more is not better."
- If a particular antacid has been prescribed for a patient, warn the patient not to switch brands or type of antacid without consulting the prescriber. Some forms of antacids are contraindicated in certain medical conditions (e.g., chronic heart failure, renal failure, and hypertension).
- Urge the patient to consult his or her own health care provider before taking antacids in conjunction with an H_2RA.

- Teach patients to stagger ranitidine and antacid dosing schedules to allow at least 2 hours between doses.
- Advise patients to contact the health care provider immediately if they experience:
  - Sharp, sudden or persistent stomach pain
  - Bloody or black stools
  - Bloody vomit or vomit that looks like coffee grounds
  - Sore throat, fever, unusual bruising, confusion, hallucinations, severe headache, or severe muscle or joint pain.

Ongoing Assessment and Evaluation

During long-term ranitidine therapy, the patient's blood count should be monitored to detect changes from baseline. Drug therapy is effective when epigastric pain decreases, peptic ulcers heal, hypersecretion of gastric acid declines, or GI bleeding is prevented without adverse effects.

Drugs Closely Related to P Ranitidine

Cimetidine

Cimetidine (Tagamet) was the first H_2RA on the market. It is available as a prescription and OTC drug. Unlike ranitidine, cimetidine is a potent inhibitor of P-450 drugs. For this reason, cimetidine use is decreasing, and ranitidine, famotidine, and nizatidine have become the drugs of first choice.

Cimetidine has the same indications as ranitidine. It has two additional indications: acute upper GI hemorrhage and systemic mast cell disease (mastocytosis). Mastocytosis is a rare disorder characterized by abnormal accumulations of mast cells in skin, bone marrow, and internal organs such as the liver, spleen, and lymph nodes.

MEMORY CHIP

P Ranitidine

- Blocks histamine competitively at histamine-2 (H_2) receptors in the gastric parietal cells; these receptors are not affected by H_1 antagonists.
- Inhibits all phases of gastric acid secretion
- Used for gastroesophageal reflux disease, duodenal ulcer, gastric ulcer, pathologic hypersecretory conditions; to prevent upper GI bleeding; and for heartburn and acid indigestion (OTC strength only)
- Interacts with numerous other drugs, many by decreasing their hepatic metabolism
- Most serious adverse effects (all rare): neutropenia, agranulocytosis, thrombocytopenia, autoimmune hemolytic or aplastic anemia
- Maximizing therapeutic effects: Give ranitidine at least 2 hours apart from antacids.
- Most important patient education: Do not substitute OTC drug for prescription drug nor add OTC drug to prescribed drug therapy.

Famotidine

Famotidine (Pepcid), another frequently used H_2RA, is also available as a prescription and OTC drug. It has the same indications as ranitidine with two additions: esophagitis and common indigestion. The most common adverse effect of famotidine is dizziness. Patients with moderate to severe renal dysfunction may experience increased CNS effects and longer elimination half-life than other patients.

Nizatidine

Nizatidine (Axid), another H_2RA, is also available OTC and has the same indications as ranitidine. Nizatidine is used with caution in patients who are immunocompromised because of an increased risk of strongyloidosis (tapeworm infection). The most common adverse effects are abdominal pain, headache, and GI symptoms.

Drug Significantly Different From P Ranitidine

Misoprostol (Cytotec), unlike ranitidine, is not an H_2 antagonist. It is a synthetic form of prostaglandin E and is used to prevent NSAID-induced gastric ulcers in high-risk patients, such as older adults, patients with other debilitating diseases, and patients with a history of gastric ulcers (see Table 36.4). An off-label use is treating duodenal ulcers. Misoprostol may be useful in treating duodenal ulcers refractory to treatment with H_2 receptor antagonists. Although misoprostol does not prevent duodenal ulcers, it is effective in decreasing the incidence of gastric ulcers associated with the use of NSAIDs.

NSAIDs inhibit prostaglandin synthesis, causing diminished bicarbonate and mucus secretion in the gastric mucosa. Misoprostol binds at the prostaglandin receptors

and can increase bicarbonate and mucus secretion, thereby protecting the stomach lining. This action results in decreased peptic ulcer formation in patients taking NSAIDs. Misoprostol decreases pepsin concentration moderately during basal conditions but not during histamine stimulation. It has no significant effect on gastrin levels, either before or after meals. Misoprostol does decrease normal daytime and nocturnal gastric acid secretion. It also decreases the gastric acid that is produced in response to stimuli, including meals, histamine, pentagastrin, and coffee. Activity of the drug begins within 30 minutes of administration and lasts for 3 hours or more.

Misoprostol is classified as a pregnancy category X drug because it has abortifacient properties. The drug causes uterine contractions and miscarriage. Women of childbearing potential must receive written and oral warnings about the hazards of misoprostol, be able to adhere to effective contraceptive measures, and have had a negative serum pregnancy test result in the 2 weeks before beginning therapy. Therapy should be started on the second or third day of the next normal menstrual cycle. It is not known whether the drug enters breast milk; thus, its use by nursing mothers is not recommended. Efficacy and safe use in children have not been established. Additionally, elderly patients may not be able to tolerate the usual dose. Cautious use is recommended for patients with renal failure. However, a dosage reduction is not normally necessary.

The most common adverse effect of misoprostol therapy is diarrhea; the next most common is abdominal pain. Other adverse effects are nausea and vomiting, dyspepsia, flatulence, constipation, and headache. Possible gynecologic problems include spotting, cramps, and menstrual disorders.

When antacids are administered with misoprostol, the availability of misoprostol is reduced, but this effect does not appear to be important clinically. Although food decreases plasma concentrations of misoprostol, the specific receptors for misoprostol in the GI tract are still activated, and a therapeutic response is evident. The effect of misoprostol is topical, rather than systemic. Patients should take misoprostol with food. If diarrhea is a problem, it can be diminished if the drug is taken after the meal.

C ANTACIDS

Antacids are drugs that increase the gastric pH, thereby neutralizing gastric acidity. These preparations are used for various upper GI disorders, including symptoms of GERD (heartburn, indigestion, and upset stomach), esophagitis, hiatal hernia, gastritis, and PUD. Antacids are composed of inorganic salts of aluminum, magnesium, calcium, or sodium used alone or in various combinations. Antacids include aluminum hydroxide with magnesium hydroxide, aluminum, magnesium, calcium, and sodium bicarbonate. The prototype antacid is aluminum hydroxide with magnesium hydroxide (Maalox, Mylanta). Table 36.7 presents a summary of antacid drugs.

Nursing Management of the Patient Receiving P Aluminum Hydroxide with Magnesium Hydroxide

Core Drug Knowledge

Pharmacotherapeutics

The combination drug aluminum hydroxide with magnesium hydroxide is used in conditions of hypersensitivity to relieve the symptoms of upset stomach, heartburn, gastric reflux, and sour stomach associated with GERD, and the discomfort from peptic ulcers. Off-label uses include treatment and maintenance therapy for duodenal ulcer.

Pharmacokinetics

A single oral dose of an aluminum and magnesium–based antacid typically results in minimal absorption from the GI tract. Patients taking this type of drug for a prolonged period may absorb between 5% and 20% of the magnesium and very little of the aluminum. The small amounts of magnesium and aluminum that are absorbed are distributed widely throughout the body. Small amounts of the drugs are found in breast milk. Aluminum hydroxide with magnesium hydroxide is eliminated in the feces.

The onset of action is rapid. Duration of action varies according to when the drug was taken in relation to meals. If it is taken on an empty stomach, the duration is 20 to 60 minutes; if it is taken following a meal, the duration is 3 hours.

Pharmacodynamics

Antacids do not coat the lining of the stomach, despite what is commonly believed. Aluminum hydroxide with magnesium hydroxide raises the gastric pH in the stomach and duodenal bulb above 4, which inhibits pepsin's proteolytic activity and increases the tone of the lower esophageal sphincter. Antacids, in general, may have a local astringent effect. The aluminum in this drug, and in other aluminum antacids, inhibits gastric emptying by inhibiting contraction of the smooth muscle of the stomach. The aluminum in the drug binds with phosphate in the GI tract and can lower phosphate levels effectively.

Antacids have different acid-neutralizing capacities (ANCs). The ANC is expressed in mEq/mL. The definition is the milliequivalent (mEq) of HCl required to keep the antacid suspension at a pH of 3.5 for 10 minutes, in vitro (in the laboratory). To be an antacid, a substance must neutralize 5 mEq/dose or more. Antacids with high ANCs are usually more effective in vivo (in the patient). Of the various forms of antacids available, suspensions have the greatest neutralizing capacity.

Contraindications and Precautions

Aluminum hydroxide with magnesium hydroxide may cause hypophosphatemia, especially if dietary intake of phosphorus is inadequate. Patients with renal insufficiency should use magnesium-containing antacids with caution because a small amount of magnesium is absorbed systemically, and hypermagnesemia is possible, especially if the

TABLE 36.7 Summary of Selected Antacids

Drug (Trade) Name	Selected Indications	Route and Dosage Range*	Pharmacokinetics
P aluminum hydroxide with magnesium hydroxide (Maalox)	Hyperacidity; prevention of stress ulcer bleeding; treatment and maintenance of duodenal and gastric ulcers; initially for GERD	PO, 15–30 mL up to 4×/d	*Onset:* Immediate *Duration:* 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Not systemically absorbed
magnesium hydroxide (Milk of Magnesia, MOM)	Hyperacidity; bleeding; treatment and maintenance of duodenal and gastric ulcers; initially for GERD	PO, liquid, 5–15 mL up to 4×/d; liquid concentrate, 2.5–7.5 mL up to 4×/d; tablets, 622–1,244 mg up to 4×/d	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Not systemically absorbed
aluminum hydroxide (Amphojel, LternaGEL)	Hyperacidity; prevention of stress ulcer bleeding; treatment and maintenance of duodenal and gastric ulcers; initially for GERD; reduction of phosphate absorption in hyperphosphatemia in chronic renal failure	PO, suspension, 5–30 mL as needed after meals and at bedtime; tablets/capsules, 500–1,500 mg 3–6×/d, between meals and at bedtime	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Not systemically absorbed
calcium carbonate (Tums, Caltrate 600, Nephro-Calci)	Hyperacidity (occasional use); calcium replacement	PO, tablets, 0.5–1.5 g as needed	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Unknown
magnesium oxide (Mag-Ox, Mag-Caps, MagGel)	Hyperacidity; magnesium replacement	PO, capsules, 140 mg tid–qid; tablets, 400–800 mg/d	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Not systemically absorbed
magaldrate/simethicone (Riopan Plus)	Hyperacidity; treatment and maintenance of duodenal and gastric ulcers; initially for GERD	PO, suspension liquid, 5–10 mL between meals and at bedtime	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Not systemically absorbed
sodium bicarbonate (Bell/ans)	Hyperacidity (occasional use)	PO, tablets, 0.3–2 g up to qid	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Unknown
sodium citrate and citric acid (Bicitra, Oracit)	Hyperacidity (occasional use)	*Adult*: PO, liquid, 10–30 mL diluted in water, up to 4×/d *Child*: PO, liquid, 5–15 mL diluted in water, up to 4×/d	*Onset*: Immediate *Duration*: 20–40 min on empty stomach; 3 h if 1 h after meals $t_{1/2}$: Unknown

patient takes more than 50 mEq daily. Aluminum hydroxide with magnesium hydroxide is a pregnancy category B drug; pregnant or breast-feeding patients should consult the prescriber before taking this medication.

Aluminum hydroxide with magnesium hydroxide should be used cautiously in patients who have recently experienced massive upper GI bleeding.

Adverse Effects

Antacids that contain aluminum alone can cause constipation, whereas antacids that contain magnesium alone can cause diarrhea. Aluminum and magnesium are combined to balance the constipating effects of aluminum with the diarrheal effects of magnesium. Other possible adverse effects include hypermagnesemia (in patients with renal failure) and hypophosphatemia. Less common adverse effects are accumulation of aluminum in serum, bone, and the CNS (with large doses); osteomalacia; and encephalopathy. Acid rebound may occur, although this effect may not be important clinically because the buffers in the antacid may neutralize any elevation in acidity.

Drug Interactions

Magnesium and aluminum affect the action of many orally administered drugs (Table 36.8). This interaction may stem from decreased acidity of gastric juices, which affects absorption; absorption or binding by the magnesium and aluminum to the surface of drugs, which decreases their

TABLE 36.8 Agents That Interact with Antacids

Interactants	Effect and Significance	Nursing Management
allopurinol	Decreased effect with aluminum salts	Monitor for drug effectiveness. Separate administration of drugs by 2 h. Discuss possible dosage adjustment with health care provider.

bioavailability; or increased urine alkalinity, which changes the rate of drug elimination (slowing the excretion of basic drugs and speeding the elimination of acidic drugs).

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient has symptoms that warrant the use of aluminum hydroxide with magnesium hydroxide. Assess for GI bleeding; coffee grounds–like emesis indicates GI bleeding, as do dark, tarry stools if the patient is not taking iron supplements. Assess for a history of recent upper GI bleeding. Patients who have had massive upper GI bleeding should use caution when taking products that contain aluminum. Also assess for renal insufficiency. Patients with a history of renal insufficiency should not receive aluminum hydroxide with magnesium hydroxide. Although antacids that are solely aluminum based are used to decrease elevated phosphate levels found in renal failure, aluminum in combination with magnesium hydroxide should be avoided because these patients do not excrete magnesium at the normal rate. The additional magnesium that can be absorbed from this product and all magnesium-containing antacids may be sufficient to cause hypermagnesemia in the patient with renal failure. Also, determine the patient's serum phosphate level because aluminum binds with phosphate.

Ask the patient about use of OTC drugs because the patient may not consider these agents important to mention during the drug history. Assess which type of drugs the patient uses and determine why they are being used, to detect possible drug interactions.

Lifestyle, Diet, and Habits

Evaluate the patient's normal dietary, alcohol, and smoking habits. Caffeine, alcohol, spicy food, and smoking may contribute to the severity of symptoms experienced.

Environment

Aluminum hydroxide with magnesium hydroxide is easily self-administered. It may be used in any care setting, including the home (see Box 36.1).

Nursing Diagnoses and Outcomes

- Chronic Pain related to alteration in the gastric mucosa, ulceration, or irritation
  Desired outcome: *The patient will report that pain has decreased while on drug therapy.*
- Potential Complication: Electrolyte Imbalance related to hypophosphatemia, hypermagnesemia, or hyperalbuminemia secondary to drug therapy
  Desired outcome: *The patient's electrolyte levels will remain within normal limits.*
- Diarrhea or Constipation secondary to drug therapy
  Desired outcome: *The patient's elimination patterns will remain within normal parameters.*

Planning and Intervention

Maximizing Therapeutic Effects

Liquid preparations are usually preferred, because of their rapid action. Shake suspensions well before use to disperse the drug evenly. If tablets are used, they must be chewed thoroughly before swallowing and followed with a glass of water. Tablets should be administered 1 to 3 hours after meals and at bedtime for the best therapeutic effects.

Minimizing Adverse Effects

Administer or teach the patient to administer aluminum hydroxide and magnesium hydroxide 2 hours after other drugs to prevent drug interactions. Assess for use of antacids and other OTC preparations during drug history; patients might not consider these to be drugs and might fail to mention them unless asked.

Monitor for signs of acid rebound, such as increased GI pain and complaints of acid reflux. Monitor serum

phosphorus and magnesium levels in patients receiving high doses of aluminum hydroxide and magnesium hydroxide (the maximum dosage for more than 2 weeks) or in patients on long-term therapy or with renal impairment. Monitor for signs of aluminum deposits in serum, bone, and CNS and for dialysis encephalopathy and osteomalacia syndromes when high doses are given to patients with renal failure.

Providing Patient and Family Education

- Teach patients to take the antacid 2 hours after other drugs and 1 hour after meals and at bedtime.
- Caution patients not to take the maximum dose for longer than 2 weeks unless directed by the prescriber.
- Instruct patients not to substitute this drug for prescription drugs to treat PUD.
- Urge patients to contact the prescriber if diarrhea or constipation occurs, if abdominal pain does not diminish, or if black, tarry stools, or coffee grounds–like emesis is seen.
- Teach patients to shake liquid forms well and measure the proper dose; they should not just drink some undetermined amount.
- Instruct patients to chew the tablet form thoroughly and then drink water.

Ongoing Assessment and Evaluation

Therapy using aluminum hydroxide with magnesium hydroxide is considered effective if the patient's pain is decreased or eliminated, electrolytes remain at normal levels, elimination patterns remain normal, and GI symptoms are controlled.

MEMORY CHIP

P Aluminum Hydroxide with Magnesium Hydroxide

- Treats hyperacidity and its symptoms in GERD and peptic ulcers; prevents stress ulcer bleeding
- Interacts with many other drugs by increasing the pH (i.e., increasing alkalinity), which alters absorption, adsorption, or binding with drugs; or by increasing urinary pH (i.e., affecting drug elimination rate)
- Major contraindication: Avoid use in chronic renal failure (multiple doses).
- Most common adverse effects: constipation (aluminum antacids) and diarrhea (magnesium antacids); combination usually negates the adverse effect of each, although either may occur
- Most serious adverse effect: potential electrolyte imbalance
- Minimizing adverse effects: Administer 2 hours after other drugs to prevent drug interactions.
- Most important patient education: Do not substitute this drug for prescription drugs to treat peptic ulcer disease.

Drugs Closely Related to P Aluminum Hydroxide with Magnesium Hydroxide

All antacid preparations are related closely and are used in various combinations to produce the desired results. In addition to the prototype aluminum hydroxide with magnesium hydroxide, aluminum preparations and magnesium preparations may be used individually. Additionally, sodium bicarbonate and calcium carbonate are used as antacids, either alone or in combination with other antacids. Various combinations of aluminum salts, magnesium salts, calcium carbonate, and sodium bicarbonate are useful. The aluminum salts used in antacids include aluminum carbonate, aluminum hydroxide, aluminum phosphate, and dihydroxy-aluminum aminoacetate. The magnesium salts include magnesium carbonate, magnesium hydroxide, magnesium oxide, and magnesium trisilicate. The calcium salt *calcium carbonate* is often given with simethicone (an antiflatulent), magnesium carbonate, magnesium hydroxide, or aluminum hydroxide. However, it can be used alone.

The pharmacotherapeutics of the antacids vary. Unlike aluminum or magnesium preparations, neither calcium carbonate nor sodium bicarbonate is recommended for long-term use, such as in treating PUD. Aluminum hydroxide is used to treat hyperphosphatemia associated with chronic renal failure. Aluminum carbonate can be used to treat, control, or manage hyperphosphatemia. It can also be used with low-phosphate diets to prevent phosphate-based renal calculi (kidney stones) from developing. Calcium carbonate is used in treating hypocalcemia. Magnesium sulfate is used to treat hypomagnesemia.

The pharmacokinetics of the antacids varies slightly because sodium bicarbonate and calcium carbonate undergo much more systemic absorption than the aluminum or magnesium preparations.

The main variation in pharmacodynamics is in the ANC of the antacids.

Sodium bicarbonate and calcium carbonate have the greatest ANC. Suspension forms of antacids have greater ANC than tablets. Box 36.2 lists selected antacids according to their acid-neutralizing ability.

Box 36.2 ACID-NEUTRALIZING CAPACITY OF ANTACIDS

The antacids listed below appear in descending order of their acid-neutralizing capacity (e.g., sodium bicarbonate most effective). Aluminum phosphate has the lowest acid-neutralizing effect.

- sodium bicarbonate
- calcium carbonate
- magnesium hydroxide
- magnesium and aluminum hydroxide mixtures
- magaldrate
- magnesium trisilate
- aluminum hydroxide
- aluminum phosphate

Sodium bicarbonate and calcium carbonate can cause metabolic alkalosis and acid rebound because of their systemic absorption, especially with large doses and frequent use. When given together in large doses, they may cause milk alkali syndrome. Milk alkali syndrome can be acute (with symptoms of weakness, headache, nausea, and irritability) or chronic (with alkalosis, hypercalcemia, and possible renal impairment).

The major core patient variable that must be considered for the different forms of antacids is health status. It is necessary to bear in mind the following points:

- Aluminum hydroxide may be used therapeutically in patients with renal failure.
- Multiple doses of magnesium oxide are avoided in renal failure because of the risk of magnesium toxicity.
- Sodium bicarbonate should not be given to people on low-sodium diets or those who have underlying pathologies that make sodium restrictions necessary, such as hypertension, chronic heart failure, or renal failure because of its high sodium content.
- Neither sodium bicarbonate nor calcium carbonate is recommended for PUD.

C PROKINETIC AGENTS

The **prokinetic agents** increase the effect of acetylcholine on the GI system. Acetylcholine is responsible for normal GI function. Prokinetic agents increase peristalsis and gastric emptying. The prototype prokinetic agent is metoclopramide (Reglan). Table 36.9 presents an overview of metoclopromide.

Nursing Management of the Patient Receiving P Metoclopramide

Core Drug Knowledge

Pharmacotherapeutics

Metoclopramide is used to relieve symptoms of diabetic gastroparesis, also known as diabetic gastric stasis. Symptoms of this disorder include nausea, vomiting, heartburn, persistent fullness after meals, and anorexia. Metoclopramide also is used short-term to treat GERD in patients who do not respond to usual therapy. It is used parenterally to prevent nausea and vomiting associated with postoperative states, opioid administration, and cancer chemotherapy or radiation therapy. It may be administered as a single dose before small bowel intubation, especially in instances in which the tube does not pass through the pylorus easily. It may be used to promote the transit of barium through the GI tract after a diagnostic procedure if the delayed passage of barium interferes with further radiographic diagnostic procedures in the stomach and small intestine.

Off-label uses of metoclopramide include improving lactation (it can increase milk production by elevating serum prolactin levels); minimizing nausea and vomiting in a variety of conditions, including during pregnancy and labor; treating gastric ulcers and anorexia nervosa; improving response to ergotamine, analgesics, and sedatives used in migraine headache; treating postoperative gastric bezoars (boluses of food that have hardened and remain in the stomach); treating diabetic atonic bladder; and treating esophageal variceal bleeding.

Pharmacokinetics

Metoclopramide is given orally and is absorbed readily from the GI tract. The drug is distributed widely throughout the body; it crosses the blood–brain barrier and placenta and is found in breast milk. The drug is not highly protein bound (30%).

A small amount of the drug is metabolized by the liver, and most is excreted in the urine. Patients with renal insufficiency may require a dosage reduction.

Pharmacodynamics

Metoclopramide's mechanism of action is unclear. However, it appears to sensitize tissues to the effect of acetylcholine. It has the cholinergic-like effect on the upper GI tract of stimulating motility but does not stimulate gastric, pancreatic, or gallbladder secretions. Metoclopramide increases peristalsis of the duodenum and jejunum, thus shortening the transit time through the stomach and small intestine. It also increases the tone of the lower esophageal sphincter, increases gastric contractions, and relaxes the pyloric sphincter.

TABLE 36.9 Overview of Metoclopromide

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P metoclopramide (Reglan, Octamide, Metozolv ODT)	Diabetic gastroparesis, GERD, prevention of postoperative nausea and vomiting, prevention of chemotherapy-induced vomiting	*Adult:* PO, 10 mg 30 min before each meal and at bedtime for 2–8 wk; IM, 10–20 mg near end of surgery; IV, infuse over at least 15 min, 30 min before chemotherapy, repeat every 2 h for two doses, then every 3 h for three doses; for highly emetogenic drugs, such as cisplatin and dacarbazine, give 2 mg/kg for first two doses; for less emetogenic drugs, give 1 mg/kg Metozolv ODT is an orally disintegrating tablet that usually dissolves within 1 minute.	*Onset:* PO, 30–60 min; IM, 10–15 min; IV, 1–3 min *Duration:* PO, IM, IV, 1–2 h $t_{1/2}$: PO, IM, IV, 5–6 h

Dopamine and serotonin produce nausea and vomiting by stimulating the medullary CTZ. Metoclopramide blocks these receptors, inducing an antiemetic effect directly on the CTZ. It is believed to lessen the sensitivity of visceral nerves to stimuli that induce nausea and vomiting.

Contraindications and Precautions

Metoclopramide is contraindicated when stimulation of GI motility may be dangerous, as in GI hemorrhage, perforation, or mechanical obstruction. Other contraindications include hypersensitivity to the drug; pheochromocytoma (the drug may cause a hypertensive crisis that probably results from a release of catecholamines from the tumor); history of seizure disorders (seizure activity may increase with this drug); and concomitant use of drugs that produce extrapyramidal effects (because these effects may increase).

Depression, from mild to severe, including suicidal ideation, has occurred in patients with and without a history of depression. Use caution in giving metoclopramide to patients with a history of depression; it should be given only if the benefits of the drug outweigh the potential risks from depression. Metoclopramide should be given very cautiously, if at all, to patients with Parkinson disease because they may experience an exacerbation of symptoms. Use caution if giving this drug to patients with hypertension. Theoretically, metoclopramide may increase the pressure on a suture line following a gut anastomosis or closure. Although this effect has not been reported in the literature, use some caution when giving this drug to postoperative patients. Elevated prolactin levels will persist during chronic administration of metoclopramide. One third of human breast cancers are prolactin dependent in vitro. Therefore, use caution if the patient has previously detected breast cancer. Studies have not, however, shown a definite link between elevated prolactin levels and breast cancer in animals or in humans.

Metoclopramide is a pregnancy category B drug.

Adverse Effects

Approximately 20% to 30% of patients receiving metoclopramide experience adverse effects of the drug. The adverse effects are usually mild, transient, and reversible after discontinuing the drug. Incidence correlates with dose and duration of therapy. Effects on the CNS are common and include restlessness, drowsiness, fatigue, insomnia, headache, dizziness, confusion, anxiety, dystonia, mental depression (even in patients who had never experienced clinical depression before) with suicidal ideation and suicide, convulsive seizures, and hallucinations. Extrapyramidal symptoms, Parkinson-like reactions, tardive dyskinesia, and akathisia also may occur. Extrapyramidal symptoms are manifested primarily as acute dystonic reactions. They occur more commonly in children and young adults during the first 24 to 48 hours of treatment. They occur even more frequently when metoclopramide is used in high doses to control vomiting caused by chemotherapy. Tardive dyskinesia, potentially irreversible, occurs most often in the elderly, particularly older women and is identified as a black box warning. Additional adverse effects are nausea, diarrhea, and transient hypertension.

Drug Interactions

Metoclopramide interacts with several drugs because it increases gastric motility, thereby altering absorption. The most important drug interactions are with levodopa, anticholinergics, and narcotics. Levodopa and metoclopramide have opposite effects on dopamine receptors. Metoclopramide's effects on GI motility are antagonized by anticholinergics and narcotics. Table 36.10 presents agents that interact with metoclopramide.

Assessment of Relevant Core Patient Variables

Health Status

Before beginning therapy with metoclopramide, assess the patient indications for metoclopramide use, such as diabetic gastroparesis, GERD, cancer that requires chemotherapy or radiation therapy, postoperative status, or opioid administration. Also, assess for depression, Parkinson disease, seizures, or hypertension because these conditions are precautions to its use. In addition, assess the patient's drug history; it should not include current use of levodopa, anticholinergics, or narcotics. Any renal or hepatic impairment should be noted because the dosage may need to be adjusted.

Life Span and Gender

Determine whether the patient is pregnant. Metoclopramide is classified as a pregnancy category B drug. Several case reports show no adverse effects on the fetus with the use of metoclopramide; however, no adequate and well-controlled studies exist. Although metoclopramide is excreted into breast milk, the levels are well below the maximum therapeutic infant dose. Therefore, there appears to be no contraindication to breast-feeding if the mother receives no more than 45 mg/d of metoclopramide. Note the patient's age and gender because older adults, especially older women, are more likely than others to develop the adverse effect of tardive dyskinesia.

Environment

Oral metoclopramide can be given in any setting and can be self-administered. IV administration of metoclopramide is performed in an acute care setting or an outpatient center.

Nursing Diagnoses and Outcomes

- Risk for Self-Directed Violence secondary to adverse effects of drug therapy
  Desired outcome: *The patient will do no self-harm related to depression from drug therapy.*

TABLE 36.10 Agents That Interact with P Metoclopramide

Interactants	Effect and Significance	Nursing Management
alcohol	Increases the rate of absorption, raising blood levels more quickly	Advise patient to avoid alcohol while on drug therapy.
Anticholinergics	Antagonize effects of metoclopramide on GI motility	Monitor for therapeutic effects.
cyclosporine	Faster gastric emptying, which may allow for increased absorption, possibly increasing immunosuppression and adverse effects from cyclosporine	Monitor CBC. Monitor for other adverse effects, such as tremor, hypertension, and renal dysfunction.
digoxin	Absorption, plasma levels, and therapeutic response may be decreased; capsule, elixir, and tablets with a high dissolution rate least affected	Monitor digoxin level. Monitor efficacy of digoxin therapy. Discuss dosage adjustment of digoxin with health care provider.
levodopa	Has opposite effect on dopamine receptors; bioavailability of levodopa may be increased; may decrease effect of metoclopramide on gastric emptying and lower esophageal pressure	Monitor for therapeutic and adverse effects of both. Administration of metoclopramide to patients with Parkinson disease is relatively contraindicated.
mefloquine	Increased gastric emptying could increase rate of mefloquine absorption in small intestine.	Monitor for GI, CNS, and cardiovascular adverse effects of mefloquine.
selective serotonin reuptake inhibitors	Increased risk of serotonin syndrome. Mechanism unknown.	Monitor for irritability, increased muscle tone, shivering, myoclonus, and altered consciousness.
succinylcholine	Metoclopramide inhibits plasma cholinesterase, may increase neuromuscular blocking effects of succinylcholine.	Monitor respiratory function.
Tacrolimus	Increased gastric emptying could increase rate of tacrolimus absorption in small intestine.	Monitor for signs of tacrolimus toxicity.

- Powerlessness related to extrapyramidal effects, Parkinson-like symptoms, or tardive dyskinesia secondary to adverse effect of drug therapy
  Desired outcome: *The patient will make decisions regarding own care, treatment, and future (when possible) while on drug therapy.*
- Risk for Injury related to drowsiness, fatigue, insomnia, confusion, and hallucination secondary to adverse effects of drug therapy
  Desired outcome: *The patient will not suffer injury while on drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Give oral doses 30 minutes before each meal to allow for onset of action and give an intramuscular injection near the end of surgery to prevent postoperative nausea and vomiting. Administer IV metoclopramide over at least 15 minutes, 30 minutes before the start of chemotherapy, to prevent chemotherapy-induced vomiting. Repeat every 2 hours for two doses, then every 3 hours for three doses. Do not administer metoclopramide concurrently with anticholinergic drugs.

Minimizing Adverse Effects

Monitor for evidence of depression and report positive findings to the prescriber. Institute interventions to protect the patient if he or she expresses suicidal ideas. If extrapyramidal symptoms (e.g., involuntary movements of the limbs, facial grimacing, and rhythmic protrusion of the tongue) occur, especially during the first 48 hours of therapy, withhold the metoclopramide dose, notify the health care provider, and seek orders for diphenhydramine (Benadryl), 50 mg intramuscularly, or benztropine (Cogentin), 1 to 2 mg intramuscularly. Either of these drugs usually reverses the symptoms.

Withhold the dose and notify the prescriber if Parkinson-like symptoms (e.g., bradykinesia, tremor, cog-wheel motions, and mask-like faces) occur, particularly in the first 6 months of therapy. Effects usually subside gradually within 2 to 3 months after drug discontinuation. Contact the prescriber regarding discontinuing the drug if signs of tardive dyskinesia (involuntary movements of the face, tongue, mouth, or jaw and sometimes involuntary movements of trunk or extremities) occur because tardive dyskinesia may be irreversible.

Providing Patient and Family Education

- Tell patients to take metoclopramide 30 minutes before meals.
- Caution patients to prevent injury by avoiding activities that require mental alertness, coordination, or physical dexterity (e.g., operating motor vehicles or other heavy machinery) until the effects of the drug are known.
- Caution patients to avoid alcoholic beverages, sedatives, and other CNS depressants during metoclopramide therapy because these substances may cause additive sedation.
- Explain to patients how to recognize any involuntary movements of the eyes, face, or limbs, such as tremors or cogwheel motion of the arms; depression; or serious diarrhea, and report these to the prescriber at once. In such cases, the patient should not take any more of the drug without discussing these signs and symptoms with the prescriber.

Ongoing Assessment and Evaluation

With careful monitoring and follow-up assessments, nursing care and metoclopramide therapy can be considered successful if the patient's GI complaints diminish and the patient does not experience depression or other adverse effects, such as nausea or Parkinson-like symptoms.

Drug Significantly Different From P Metoclopramide

Cisapride

Cisapride (Propulsid) is a prokinetic agent that was removed from the U.S. market because of its potential to induce fatal cardiac arrhythmias. It is now available through a limited access program—to be used only as a last resort—to treat refractory GERD, gastroparesis, severe chronic constipation, and pseudo-GI obstruction. Cisapride promotes the release of acetylcholine from neurons of the myenteric plexus, resulting in increased tone and motility of GI smooth muscle. It is contraindicated for patients with a risk of cardiac arrhythmias. This includes those with heart failure, ischemic heart disease, prolonged QT interval, sinus node dysfunction, second- or third-degree atrioventricular block, and a history of ventricular arrhythmias or torsades de pointes. Cisapride interacts with many drugs that increase the risk of cardiac arrhythmias. Certain drugs that inhibit CYP3A4, loop and thiazide diuretics, and class 1 and 2 antidysrhythmic drugs are contraindicated for use with cisapride.

MEMORY CHIP

P Metoclopramide

- Used as a GI stimulant in diabetic gastric stasis, and GERD; as an antiemetic postsurgery and with chemotherapy for cancer
- Major contraindication: when stimulation of GI motility might be dangerous
- Most common adverse effects: CNS complaints
- Most serious adverse effects: tardive dyskinesia and severe depression
- **Life span alert: Older women are more likely to experience tardive dyskinesia as an adverse effect.**
- Maximizing therapeutic effects: Give metoclopramide 30 min before meals or chemotherapy.
- Minimizing adverse effects: Monitor for depression, Parkinson-like symptoms, extrapyramidal effects, and tardive dyskinesia; hold further drug administration and contact the prescriber if noted.
- Most important patient education: Teach patient to recognize signs of serious adverse effects; to call prescriber at once when noted.
- **Black box warning: May cause tardive dyskinesia in the elderly, especially in women.**

C DIGESTIVE ENZYMES

Digestive enzymes are responsible for breaking down food into forms that can be absorbed easily in the GI tract. The digestive process normally begins in the mouth with digestive enzymes in salivary secretions and then continues in the stomach with the action of gastric acid and pepsin. It is completed in the duodenum with the release of the pancreatic enzymes that change protein, carbohydrate, and fat into absorbable forms.

Replacement of many of these enzymes is not necessary or truly useful, because rarely does a deficiency of endogenous enzymes actually cause GI problems. Many of the drug preparations of digestive enzymes are combinations of various enzymes, frequently paired with anticholinergics, barbiturates, or antacids. In those few situations in which an endogenous deficit does exist, it is nearly impossible to correct the deficit adequately with these combinations. In addition, combination therapy increases the risk of adverse effects from the other drug entities in the compound.

Pancreatic enzymes comprise one group of digestive enzymes that is an exception. Replacement of these enzymes is indicated. The prototype pancreatic digestive enzyme is pancrelipase (Pancrease MT, Viokase, Creon, Lipram, Pancrecarb, Panocaps). Table 36.11 presents a summary of selected digestive enzymes.

Nursing Management of the Patient Receiving P Pancrelipase

Core Drug Knowledge

Pharmacotherapeutics

Pancrelipase is enzymatic replacement therapy for patients with deficient exocrine pancreatic secretions; cystic fibrosis; chronic pancreatitis; ductal obstructions caused by cancer of the pancreas or common bile duct; pancreatic insufficiency; or steatorrhea from malabsorption syndrome; and after pancreatectomy, gastrectomy, or post-GI surgery, such as Billroth II gastroenterostomy. Pancrelipase also can be used as a presumptive test to evaluate pancreatic function. Pancrelipase is administered orally.

TABLE 36.11 Summary of Selected Digestive Enzymes

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P pancrelipase (Pancrease, Ku-Zyme, Viokase, Ilozyme, Zymase, Ultrase)	Deficient exocrine pancreatic secretions Pancreatic insufficiency, steatorrhea from malabsorption syndrome and post-gastrectomy, or post-GI surgery, Billroth II gastroenterostomy	Adjust dosage until steatorrhea minimizes and good nutritional status is maintained *Adult:* PO, 4,000 to 50,000 U with each meal and with snacks; severe deficiencies, increase to 64,000–88,000 U with each meal or increase hourly if tolerated *Child <6 mo:* PO, dose not established; *6–12 mo,* 2,000 U with each meal; *1–6 y,* 4,000–8,000 U with each meal and 4,000 U with each snack; *7–12 y,* 4,000–12,000 U with each meal and snack	Unknown
	Postpancreatectomy, ductal obstructions caused by cancer of the pancreas or common bile duct	*Adult:* PO, 8,000–16,000 U at 2-h intervals, or as prescribed	
	Cystic fibrosis	Use powder form: 0.7 g with meals	
pancreatin (Dizymes, Entozyme, Donnazyme, Hi-Vegi-Lip, Creon)	Same as above	*Adult*: PO, 1 or 2 tablets with meals and snacks; adjust according to individual meals *Child*: Dosage not established	Unknown

Pharmacokinetics

Absorption, distribution, metabolism, and excretion of this drug are unknown. The onset, peak, and duration are also unknown. Because pancrelipase is affected by gastric acid, the drug is enteric coated. However, this formulation may decrease absorption in the duodenum. The site of metabolism and route of elimination from the body are unknown.

Pharmacodynamics

Pancrelipase contains the enzymes lipase, protease, and amylase, which are responsible for the final phase of digestion. During this phase, fats are hydrolyzed to fatty acids, proteins to proteoses and derived substances, and starches to sugars and dextrins so that they can be absorbed in the small intestine. Pancreatic enzymes normally exert their effects in the duodenum and in the first part of the jejunum.

Contraindications and Precautions

Pancrelipase is contraindicated in patients who are hypersensitive to pork protein or enzymes, because the drug is derived from pork. It should not be used by patients with acute pancreatitis or acute exacerbations of chronic pancreatitis. Pancrelipase is a pregnancy category C drug and should be used only if necessary. It is not known whether it crosses into breast milk; therefore, it should be administered with caution to nursing mothers.

Caution must be used not to spill the powder on one's hands because it may irritate the skin. Inhaling the powder irritates the nasal mucosa and the respiratory tract, triggering an asthma attack in those susceptible.

Adverse Effects

Caution must be used with large doses because they may cause nausea, abdominal cramps, and diarrhea. Hyperuricosuria and hyperuricemia have occurred with extremely high doses. Less often, allergic reactions have occurred.

Drug Interactions

The antacids calcium carbonate and magnesium hydroxide can interfere with the beneficial effects of pancrelipase. Serum iron response to oral iron supplements may be decreased by concurrent dosing of pancrelipase. Table 36.12 lists agents that interact with pancrelipase.

TABLE 36.12 Agents That Interact with Pancrelipase

Interactants	Effect and Significance	Nursing Management
calcium carbonate, magnesium hydroxide	May negate effect of enzymes	Administer 2 h apart. Monitor for therapeutic effect.
Iron	Serum levels may not increase as expected with oral supplements	Monitor blood iron levels. Seek order to adjust dose if iron levels are significantly affected.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient's health history for chronic pancreatitis, cystic fibrosis, ductal obstructions from cancer, pancreatic insufficiency, pancreatectomy, gastrectomy, or other GI surgery. Results of laboratory studies to review include serum amylase and lipase levels to determine pancreatic functioning and findings of steatorrhea. Foul-smelling, frothy stools are a sign of steatorrhea. Assess the patient's nutritional status because deficiency of pancreatic enzymes prevents the absorption of fats, proteins, and starches and may leave the patient malnourished. Also, determine whether the patient is allergic to pork, because pancrelipase is derived from pork.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding. Because pancrelipase is in pregnancy category C, it should be given only if clearly necessary. Caution should be used when administering pancrelipase to a breast-feeding woman. The drug can be given to children, but the dosage for children younger than 6 months old has not been established.

Environment

Pancrelipase can be administered in any setting, including the home.

Culture and Inherited Traits

Consider the religious affiliation of patients taking pancrelipase. Some religious groups, such as Muslims and Orthodox Jews, forbid the consumption of pork products in any form, and pancrelipase is pork based. Therefore, these patients may not accept this drug therapy.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to impaired digestion secondary to insufficient pancreatic enzymes
  Desired outcome: *The patient's nutrient absorption will be adequate to meet body needs while on drug therapy.*
- Risk for Pain, acute abdominal, secondary to adverse effects of drug therapy
  Desired outcome: *The patient will not develop pain as an adverse effect of drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Brands of pancrelipase should not be changed without consulting the prescriber because the various brands do not have equal bioavailability. Administer antacids or H_2 receptor antagonists, if prescribed, to maintain the patient's gastric pH within an alkaline range. An alkaline pH prevents pancrelipase tablets from dissolving in the stomach and becoming inactivated.

Minimizing Adverse Effects

Be sure to administer or make sure the patient is administering pancrelipase exactly as prescribed to prevent excessive dosing.

Providing Patient and Family Education

- Explain to patients and families the need to learn about the role of the digestive enzyme in digesting and absorbing food. Insufficient amounts of enzyme result in weight loss and steatorrhea (foul-smelling and frothy stools). Although it is not usually possible to dose pancrelipase to eradicate steatorrhea completely, pancrelipase should greatly decrease steatorrhea.
- Tell patients to take the drug every time they eat, either before or with meals and snacks.
- Caution patients not to crush or chew pancrelipase because doing so will destroy the enzyme by exposing it to gastric acid.
- Urge patients to notify the prescriber of any abdominal pain, diarrhea, nausea, or return of steatorrhea.
- If the form of pancrelipase is a capsule that is to be opened and mixed with food, caution patients to avoid getting the powder on the hands or sniffing the powder contained in the capsules. Asthma attacks can occur in susceptible patients who inhale pancrelipase powder.

Ongoing Assessment and Evaluation

Assess patients taking pancrelipase for decreased steatorrhea, weight gain, and improved nutritional status. Drug therapy is considered successful if digestion and nutritional status improve without the occurrence of adverse effects.

Drug Closely Related to P Pancrelipase

Pancreatin (Dygase, Hi-Vegi-Lip, Ku-Zyme, Kutrase, Lapase) is a digestive enzyme that has the same action and indication for use as pancrelipase. This agent is not as concentrated as pancrelipase and therefore may not control steatorrhea as well. Pancreatin may be from beef or pork sources.

DRUGS FOR WEIGHT MANAGEMENT

Lipase inhibitors and anorexiants are Food and Drug Administration (FDA)–approved drug classes for the management of obesity. Other drug classes used for weight

MEMORY CHIP

P Pancrelipase

- Used as enzyme replacement therapy for patients deficient in this pancreatic enzyme
- Most common adverse effects: nausea, abdominal cramps, and diarrhea at large doses
- Most important patient education: Do not crush or chew tablets; take before or with meals; avoid breathing powder and skin contact.

TABLE 36.13 Summary of Selected Drugs for Weight Management

Drug (Trade) Name	Indication	Dosage Range	Pharmacokinetics
P orlistat (Xenical)	Obesity	*Adult:* PO, 120 mg tid with meals that contain fat	*Onset:* Immediate *Duration:* Unknown $t_{1/2}$: Not absorbed
benzphentermine (Didrex)	Obesity	*Adult and child* >12 y: PO, 25–50 mg daily; maximum, 50 mg 3×/d	*Onset*: Unknown *Duration*: Unknown $t_{1/2}$: Unknown
diethylpropion (Tenuate)	Obesity	*Adult and child* >16 y: PO, Immediate release: 25 mg 3×/d Controlled release: 75 mg/d	*Onset*: Rapid *Duration*: Immediate release, 4 h; controlled release, 12 h $t_{1/2}$: 4–8 h
phendimetrazine (Bontril)	Obesity	*Adult and child* >12 y: PO, Immediate release: 35 mg 2–3×/d Sustained release: 105 mg/d	*Onset*: Immediate release, rapid; controlled release, 1–2 h *Duration*: Unknown $t_{1/2}$: 2–4 h
phentermine (Adipex-P)	Obesity	*Adult and child* >16 y: PO, 37.5 mg/d; may be divided	*Onset*: 1–2 wk *Duration*: 12 wk $t_{1/2}$: 20 h

management include amphetamines and some antidepressant drugs, but they are not approved for this use (Table 36.13).

• C Lipase Inhibitors

Lipase inhibitors are used specifically for long-term weight reduction in patients with an initial BMI of 30 kg/m^2 or more, or a BMI of 27 kg/m^2 or more in those who have other cardiovascular risk factors (e.g., hypertension, diabetes, or dyslipidemia). The prototype lipase inhibitor is orlistat (Xenical).

Nursing Management of the Patient Receiving P Orlistat

Core Drug Knowledge

Pharmacotherapeutics

Orlistat with the trade name Xenical is a prescription drug used to manage obesity by promoting weight loss and weight maintenance. Orlistat with the trade name Alli is also available as an OTC drug. It is used in conjunction with a weight-loss diet and exercise program as well to reduce the risk of regaining weight after weight loss.

Pharmacokinetics

Very little orlistat is absorbed into the systemic circulation after oral administration; most of its effect is from its local action in the GI tract. In laboratory studies, orlistat was more than 99% protein bound. Metabolism appears to occur predominantly within the GI wall. Two metabolites are formed, but they do not seem to be pharmacologically important. Fecal excretion is the main route of elimination.

Pharmacodynamics

Orlistat is a reversible lipase inhibitor. By inhibiting the action of lipase, it decreases the absorption of dietary fats. Its therapeutic effect occurs in the lumen of the stomach and small intestine, where it prevents the formation of active gastric and pancreatic lipases. The inactivated enzymes are unable to hydrolyze dietary fat, in the form of triglycerides, into absorbable free fatty acids and monoglycerides. Undigested triglycerides are not absorbed, and therefore fewer calories are absorbed. This reduced caloric intake enables weight loss. At the recommended therapeutic dose of 120 mg three times a day, orlistat inhibits dietary fat absorption by about 30%.

Contraindications and Precautions

Orlistat is contraindicated if the patient has chronic malabsorption syndrome or cholestasis. It also is contraindicated if the patient is hypersensitive to the drug or any of its elements. Organic causes of obesity, such as hypothyroidism, should be ruled out before prescribing orlistat.

Some patients may develop increased levels of urinary oxalate following treatment. Caution should be used if the patient has a history of hyperoxaluria or calcium oxalate nephrolithiasis. The weight loss brought about by orlistat use may improve metabolic control in diabetic patients. They may require a reduced dose of oral hypoglycemic medication or insulin. Orlistat is a pregnancy category B drug.

Adverse Effects

The adverse effects of orlistat are extensions of its treatment effects. GI symptoms, the most common adverse effects, are related to the pharmacodynamics of the drug. These adverse effects are generally mild and transient, although for some patients, they may last for 6 months or longer and be severe enough to warrant discontinuing the drug. These GI symptoms are oily spotting, flatus with discharge of stool, fecal urgency, fatty or oily stool, oily evacuation, increased defecation, and fecal incontinence.

Other adverse effects that can occur, but are not common, include:

- CNS: anxiety, depression, dizziness, and headache
- Dermatologic: dry skin and rash
- GI: abdominal pain, gingival disorder, infectious diarrhea, nausea, rectal pain or discomfort, tooth disorders, and vomiting
- Musculoskeletal: arthritis, back pain, joint disorders, myalgia, tendonitis, and pain in the lower extremities
- Reproductive, female: menstrual irregularity and vaginitis
- Respiratory: ear, nose, and throat symptoms, influenza, lower respiratory tract infection, and upper respiratory tract infection
- Miscellaneous: fatigue, otitis, pedal edema, sleep disorder, and urinary tract infection

No adverse effects related to overdose are known to have occurred. If necessary, stop the drug and observe the patient for 24 hours. The systemic effects attributable to lipase inhibition should be rapidly reversible.

Drug Interactions

Because orlistat impairs fat absorption, the absorption of fat-soluble vitamins (A, D, E, beta-carotene) decreases. A few other known drug interactions are listed in Table 36.14.

Assessment of Relevant Core Patient Variables

Health Status

Verify that the patient does not have a physiologic cause for obesity before starting orlistat. Assess for a history of hepatic dysfunction. Assess for thyroid disease, diabetes mellitus, and anticoagulant therapy. Patients with these conditions require direct supervision by a health care provider when taking orlistat (Xenical) rather than the OTC formulation (Alli).

Life Span and Gender

Assess the pregnancy status of female patients. Orlistat is a pregnancy category B drug, which poses a risk to the fetus. Suggest use of barrier contraceptives while taking orlistat. It is not known whether orlistat is excreted in breast milk; therefore, its use is not recommended during breast-feeding. Determine the patient's age because safety and efficacy have not been established in children.

Lifestyle, Diet, and Habits

Take a dietary history to determine how many calories in the patient's diet, and what percentage of the calories, come from fat. The patient should eat a nutritionally balanced, reduced-calorie diet; no more than 30% of the patient's caloric intake should come from fat while he or she receives orlistat. Assess the patient's exercise pattern. Weight loss is accomplished best when a diet and exercise plan are used together.

Environment

Orlistat is normally self-administered in the patient's home.

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: More than Body Requirements
  Desired outcome: *The patient will lose weight during drug therapy.*
- Risk for Imbalanced Nutrition: Less than Body Requirements, related to impaired absorption of fat-soluble vitamins during drug therapy

TABLE 36.14 Agents That Interact with P Orlistat

Interactants	Effect and Significance	Nursing Management
Amiodarone	Orlistat may decrease absorption of amiodarone.	Monitor for arrhythmias.
cyclosporine	Exact clinical effect is unknown. Changes in cyclosporine absorption have been reported with variations in dietary intake.	Monitor immunosuppressive effects of cyclosporine.
fat-soluble vitamins	Decreased absorption rate of fat-soluble vitamins; 30% decrease in beta-carotene and about 60% reduction in vitamin E absorption have been shown. Decreases in other vitamin levels not known exactly; vitamin deficiency may result.	Teach patient to take multivitamin that includes fat-soluble vitamins to prevent deficiencies.
Warfarin	Possible decrease in vitamin K absorption. No known effect on pharmacokinetics or pharmacodynamics of warfarin currently.	Monitor PT/INR. Monitor for bruising or bleeding.

Desired outcome: *The patient will not have serious vitamin deficiencies while taking drug therapy.*

- Risk for Bowel Incontinence related to adverse effects of drug therapy
  Desired outcome: *Bowel incontinence will not occur or will be minimal and transient.*
- Risk for Diarrhea related to adverse effects of drug therapy
  Desired outcome: *Diarrhea will not occur or will be minimal and transient.*

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that the patient takes orlistat with all meals that contain fat and that he or she limits dietary fat to 30% of calories. Omit the dose of orlistat if the meal does not contain fat. The patient should also be encouraged to participate in exercise while on drug therapy.

Minimizing Adverse Effects

Advise the patient to take a multivitamin that contains fat-soluble vitamins to prevent imbalances from drug therapy. Separate the administration of orlistat and multivitamins by 2 hours.

GI symptoms are more pronounced when the fat content of a meal is high. Emphasize the need to alter fat ingestion.

Providing Patient and Family Education

- Teach patients to limit dietary fat. Calories from fat should be no more than 30% of daily calories. This percentage promotes weight loss and prevents and minimizes GI adverse effects.
- Instruct patients to divide daily fat intake equally between meals and to take the drug with each meal containing fat (during or up to 1 hour after eating). Patients should skip a dose if the meal has no fat or if the meal is missed.
- Encourage patients to take a vitamin supplement that includes fat-soluble vitamins. Remind patients to separate these drugs by at least 2 hours.
- Discuss possible adverse effects and potential interventions:
  - Suck sugarless lozenges and perform frequent mouth care for dry mouth
  - Decrease the amount of fat in meals for continued loose stools

Ongoing Assessment and Evaluation

Orlistat therapy is considered effective if weight loss occurs without major GI adverse effects or vitamin deficiency arising.

Drugs Significantly Different From P Orlistat

Adrenergic Drugs

The adrenergic drugs benzphetamine (Didrex), diethylpropion (Tenuate, Dospan), phentermine (Adipex-P, Ionamin), and phendimetrazine (Bontril) are used for weight control. They decrease the appetite by stimulating the CNS. They also effects similar to those of amphetamines, such as tachycardia, hypertension, nervousness, and anxiety. Although they are safer than amphetamines, they still have an abuse potential; thus, they are scheduled drugs. They are not useful for long-term management of obesity because tolerance develops in 6 to 12 weeks. They are contraindicated during pregnancy because of an increased risk of cleft palate and congenital heart defects.

Amphetamines

Amphetamines work by decreasing the appetite. Although they are effective, the risk of abuse outweighs the benefit of weight loss. Some health care providers do prescribe these drugs; however, they are not approved for use in weight management.

Antidepressant Drugs

Bupropion (Wellbutrin), fluoxetine (Prozac), venlafaxine (Effexor), and sertraline (Zoloft) are antidepressant drugs. None are approved for weight loss. Bupropion blocks reuptake of norepinephrine and dopamine, while fluoxetine, venlafaxine, and sertraline block the reuptake of serotonin. All of these drugs are discussed in Chapter 16.

CRITICAL THINKING SCENARIO

ADVERSE EFFECTS FROM ORLISTAT

Ms. Benson has been taking orlistat, a lipase inhibitor, to promote weight loss for 1 month. She returns to the clinic for follow-up. You, the nurse, ask her how she is tolerating the medication. She tells you that initially she only had some problems with "needing to go to the bathroom a couple of times a day." However, she says that in the last few days she has been bothered by "real oily poop." She tells you that she has to run to the bathroom "like mad, `cause I can't hold it. Sometimes I can't get there fast enough and spot my panties with that stuff."

What questions should you ask Ms. Benson to assess her problem thoroughly?

MEMORY CHIP

P Orlistat

- Used to promote weight loss in obesity; prevents absorption of dietary fat
- Major contraindication: chronic malabsorption syndrome or cholestasis
- Most common adverse effects: GI (oily spotting, flatus with stool, and fecal urgency)
- Most important patient education: Take with all meals containing fat; limit dietary fat to 30% of calories; take a multivitamin with fat-soluble vitamins.

C ANTIEMETICS

Nausea and vomiting related to oncologic therapy are frequently difficult to manage. The American Society of Clinical Oncology (ASCO) categorizes their antiemetic guidelines according to type of emesis: acute, delayed, anticipatory, special emetic problems, and radiation emesis. The special emetic problems category includes emesis in pediatric oncology, high-dose chemotherapy, and nausea and vomiting despite prophylaxis, also referred to as refractory or breakthrough emesis.

Antiemetics, which suppress stimulation of the CTZ and the VC, are used to treat nausea and vomiting. Antiemetic drugs are primarily from three main drug classifications—selective serotonin receptor antagonists, antidopaminergic drugs, and anticholinergic drugs. Other classes of drugs that may be used include glucocorticoids, cannabinoids, and benzodiazepines (Table 36.15).

• C Selective Serotonin Receptor Antagonists

The selective serotonin receptor antagonists, also known as the 5-HT_3 receptor antagonists, prevent the stimulation of type 3 serotonin receptors in the CTZ. The prototype selective serotonin receptor antagonist is ondansetron (Zofran).

Nursing Management of the Patient Receiving P Ondansetron

Core Drug Knowledge

Pharmacotherapeutics

Ondansetron is used to prevent nausea and vomiting associated with cancer chemotherapy and radiotherapy, and in postoperative states when expectation is high that nausea or vomiting will occur or when nausea and vomiting must be avoided (Box 36.3).

Off-label uses of ondansetron include treating nausea and vomiting associated with acetaminophen poisoning; hyperemesis gravidarum; and treatment of early-onset alcoholism. Alcoholism that occurs relatively early in life is associated with serotonergic abnormality and antisocial behaviors. Ondansetron appears to be effective treatment for these patients, presumably by relieving an underlying abnormality in serotonin stimulation.

Pharmacokinetics

Ondansetron is metabolized by the liver. It is moderately protein bound (about 75%). It crosses the placenta, may enter breast milk, and is excreted in the urine.

Pharmacodynamics

Serotonin receptors of the 5-HT_3 type are located peripherally on the vagal nerve terminal and centrally in the CTZ. During chemotherapy, special mucosal cells in the small intestine release serotonin, which stimulates these receptors. Ondansetron blocks these receptor sites, thus preventing nausea and vomiting.

Contraindications and Precautions

Ondansetron is contraindicated in patients with hypersensitivity to the drug or its components. Ondansetron is a pregnancy category B drug.

Adverse Effects

The most common adverse effects of ondansetron are headache, constipation, and malaise. Potentially serious adverse effects are arrhythmias, hypotension, and extrapyramidal effects (e.g., Parkinson-like symptoms). Other adverse effects that can occur include:

- Cardiovascular: hypertension
- CNS: anxiety, dizziness, drowsiness, and chills or shivering
- GI: abdominal pain, diarrhea, and xerostomia
- Miscellaneous: wound problems, musculoskeletal pain, cold sensation, fever, gynecologic disorders, hypoxia, injection-site reaction, paresthesia, pruritus, urinary retention, weakness, increases in aspartate transaminase and alanine aminotransferase, and pain.

Drug Interactions

Because ondansetron is metabolized by the cytochrome P-450 enzymes, drug interactions may occur with other drugs that are metabolized by these enzymes or those that inhibit P-450 metabolism. However, no dosage adjustment has been recommended based on available data regarding this finding. Table 36.16 presents drugs that interact with ondansetron.

Assessment of Relevant Core Patient Variables

Health Status

Verify that the patient has clinical indications for receiving ondansetron and is not known to have a hypersensitivity to it. Assess baseline skin color and texture and urinary output. Perform an abdominal examination.

Life Span and Gender

Assess whether the patient is pregnant. Ondansetron is a pregnancy category B drug. Therefore, it should be used only if the potential benefit to the mother justifies potential risks to the fetus. Determine the patient's age. Ondansetron is used to prevent nausea and vomiting associated with cancer chemotherapy in children. However, dosage information for children 3 years of age or younger is limited. Dosage adjustment is not needed in older adults.

Environment

Ondansetron normally is administered in an acute care setting. Oral ondansetron is frequently self-administered in the home environment.

TABLE 36.15 Summary of Selected C Antiemetics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C 5-HT3 Receptor Antagonists			
P ondansetron	Prevention and treatment of chemotherapy-induced nausea and vomiting; prevention and treatment of postoperative nausea and vomiting; prevention of radiation-induced nausea and vomiting	*Adult:* PO, 8 mg 30 min before chemotherapy; repeat 8 h later, then q12 h for 1–2 d; increase to 8 mg 3×/d for radiotherapy *Adult:* IV, 0.15 mg/kg infused over 15 min, beginning 30 min before chemotherapy; repeat 4 and 8 h later	*Onset:* PO, 30–60 min; IV, immediate *Duration:* Unknown $t_{1/2}$: 3.5–6 h
dolasetron (Anzemet)	Prevention of chemotherapy-induced nausea and vomiting; prevention and treatment of postoperative nausea and vomiting	*Adult*: PO, 100 mg 1 h before chemotherapy or 2 h before surgery *Child* 2–16 y: PO, 1.8 mg/kg 1 h before chemotherapy; 1.2 mg/kg 2 h before surgery *Adult*: IV, 1.8 mg/kg 30 min before chemotherapy; 12.5 mg 15 min prior to stopping anesthesia *Child*: IV, 1.8 mg/kg 30 min before chemotherapy; 0.35 mg/kg 15 min before stopping anesthesia	*Onset*: PO, rapid; IV, immediate *Duration*: Unknown $t_{1/2}$: 3.5–5 h
granisetron (Kytril)	Prevention and treatment of chemotherapy-induced nausea and vomiting; prevention and treatment of postoperative nausea and vomiting; prevention and treatment of radiation-induced nausea and vomiting	*Adult and child* >2 y: PO, 1 mg 2×/d or 2 mg/d. Start 1 h before chemotherapy and give second dose 12 h later. IV, 10 mcg/kg over 5 min, starting within 30 min of chemotherapy	*Onset*: PO, moderate; IV, rapid *Duration*: 24 h $t_{1/2}$: 3–14 h
palonosetron (Aloxi)	Prevention of acute and delayed nausea and vomiting associated with chemotherapy	*Adult*: IV, 0.25 mg over 30 s, 30 min before start of chemotherapy. Do not repeat use for 7 d.	*Onset*: IV, immediate *Duration*: Unknown $t_{1/2}$: 40 h
C Substance P/NK1 Receptor Antagonist			
aprepritant (Emend)	Prevention of chemotherapy-induced nausea and vomiting; prevention and treatment of postoperative nausea and vomiting	*Adult*: PO, 125 mg 1 h before chemo on day 1, then 80 mg on day 2–3; *Postop*: 40 mg within 3 h of anesthesia induction.	*Onset*: unknown *Duration*: unknown $t_{1/2}$: 9–14 h
C Anticholinergic Drugs			
dimenhydrinate	Nausea and vomiting, vertigo, motion sickness	*Adult*: PO/IM/IV, 50–100 mg q4–6 h	*Onset*: 15–30 min *Duration*: 3–6 h $t_{1/2}$: Unknown
diphenhydramine (Benadryl)	Nausea and vomiting, motion sickness	*Adult*: PO/IM/IV, 10–50 mg q4–6 h	*Onset*: 15–30 min *Duration*: 4–8 h $t_{1/2}$: 2.5–7 h
hydroxyzine (Vistaril)	Nausea and vomiting	*Adult*: PO/IM, 25–100 mg q6 h *Child* >6 y: PO, 50–100 mg/d in divided doses *Child* <6 y: PO, 50 mg/d in divided doses	*Onset*: 15–30 min *Duration*: 4–6 h $t_{1/2}$: 3 h
meclizine (Antivert)	Nausea and vomiting, vertigo Motion sickness	*Adult*: PO, 25–100 mg daily in divided doses *Adult*: PO, 25–50 mg 1 h before travel; may repeat q24 h	*Onset*: 1 h *Duration*: 12–24 h $t_{1/2}$: 6 h
scopolamine (Transderm Scop)	Nausea and vomiting, motion sickness	*Adult*: Transdermal patch, 0.5 mg q72 h *Child*: Not recommended	*Onset*: 4–5 h *Duration*: 72 h $t_{1/2}$: 8 h
C Antidopaminergic Drugs			
chlorpromazine (Thorazine)	Nausea and vomiting	*Adult and child* >12 y: rectal suppository, 0.5 mg/lb q6–8 h *Child* >6 mo: rectal suppository, 1 mg/kg q6–8 h	*Onset*: 1 h *Duration*: 3–4 h $t_{1/2}$: 20–24 h

TABLE 36.15 Summary of Selected C Antiemetics *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
droperidol (Inapsine)	Nausea and vomiting	*Adult*: IM/IV, 2.5–5 mg q4–6 h *Child* 2–12 y: IM/IV, 0.1 mg/kg	*Onset*: 3–10 min *Duration*: 2–12 h $t_{1/2}$: 2 h
haloperidol (Haldol)	Nausea and vomiting	*Adult*: PO/IM/IV, 1–5 mg q12 h *Child*: Not recommended	*Onset*: 1 h *Duration*: Unknown $t_{1/2}$: 21–24 h
prochlorperazine (Compazine)	Nausea and vomiting	*Adult*: PO/IM/IV/rectal, 5–10 mg 3–4×/d *Child* >2 y: PO/rectal suppository 20–29 lb: 2.5 mg 1–2×/d 30–39 lb: 2.5 mg 2–3×/d 40–85 lb: 2.5 mg 3×/d or 5 mg 2×/d	*Onset*: 30–40 min *Duration*: 3–4 h $t_{1/2}$: 6.8–9 h
promethazine (Phenergan)	Nausea and vomiting, vertigo, motion sickness	*Adult*: PO/IM/IV/rectal, 12.5–25 mg q4–6 h *Child* >2 y: PO/rectal, 1.1 mg/kg q4–6 h	*Onset*: PO/IM, 20 min; IV, 3–5 min *Duration*: 12 h $t_{1/2}$: 7–15 h
thiethylperazine (Torecan)	Nausea and vomiting	*Adult and child* >12 y: PO, 10 mg 3×/d *Child* <12 y: Not recommended	*Onset*: 30 min *Duration*: 4 h $t_{1/2}$: Unknown
C Cannabinoids			
dronabinol (Marinol)	Nausea and vomiting not responsive to other antiemetics	*Adult*: PO, 5–7.5 mg/m^2 q24 h *Child*: PO, 5 mg/m^2 1–3 h before chemotherapy, 5 mg/m^2 q2–4 h after chemotherapy for a total of 4–6 doses/d	*Onset*: 30–60 min *Duration*: 4–6 h $t_{1/2}$: 25–36 h
nabilone (Cesamet)	Nausea and vomiting not responsive to other antiemetics	*Adult*: PO, 1–2 mg 1–3 h before chemotherapy; may be administered 2–3× during course of therapy, up to 48 h after last dose of chemotherapy	*Onset*: 60–90 min *Duration*: 8–12 h $t_{1/2}$: 2 h

Nursing Diagnoses and Outcomes

- Imbalanced Nutrition: Less than Body Requirements, related to severe nausea and vomiting
  Desired outcome: *Nutritional needs will be met, and ondansetron therapy will prevent severe nausea and vomiting.*
- Risk for Altered Comfort related to severe nausea and vomiting
  Desired outcome: *Comfort will be maintained, and ondansetron therapy will prevent severe nausea and vomiting.*

BOX 36.3 FOCUS ON RESEARCH

Control of Stress-Related Gastrointestinal Bleeding in the Critical Care Setting

Lin, P. C., Chang, C. H., Hsu, P. I., Tseng, P. L., & Huang, Y. B. (2010). The efficacy and safety of proton pump inhibitors vs histamine-2 receptor antagonists for stress ulcer bleeding prophylaxis among critical care patients: A meta analysis. *Critical Care Medicine,* 38(4):1197–1205.

The Study

A meta-anlysis was conducted to compare the efficacy and safety of proton pump inhibitors and histamine-2 receptor antagonists in the management of stress related bleeding in critical care patients. A search for randomized, controlled studies that compared these two therapies was completed and resulted in the identification of seven randomized, controlled trials with a total of 936 patients. Results demonstrated no significant difference in stress bleeding prophylaxis, pneumonia, or mortality between the two treatment options. Recommendations included more well-designed and powered randomized, clinical trials to be conducted.

Nursing Implications

Stress-related gastrointestinal disease and bleeding are associated with increased mortality and morbidity. While gastrointestinal prophylaxis is routine care in most critical care units, there is a need to better manage these patients. According to Lin et al. (2010), there is a 48.5% mortality rate in patients with stress-related gastrointestinal bleeding as compared to 9.1% in those without bleeding.

TABLE 36.16 Drugs that Interact with P Ondansetron

Interactants	Effect and Significance	Nursing Management
cisplatin	Ondansetron may decrease cisplatin levels, resulting in subtherapeutic effect.	Monitor for efficacy of cisplatin therapy. Discuss possible dosage adjustment with health care provider.
cyclophosphamide	Ondansetron may decrease cyclophosphamide levels, resulting in subtherapeutic effect.	Monitor for efficacy of cyclophosphamide therapy. Discuss possible dosage adjustment with health care provider.
Rifamycins	Rifamycins may decrease serum ondansetron levels.	Monitor for continued nausea or vomiting. Discuss alternative antiemetic therapy with health care provider.

- Potential Complication: Altered Cardiac Output related to adverse effects of ondansetron
  Desired outcome: *Cardiac output will not be affected adversely by possible hypotension and arrhythmias from ondansetron.*

Planning and Intervention

Maximizing Therapeutic Effects

Administer ondansetron 30 minutes before the start of chemotherapy. Infusions should be given over 15 minutes. Additional doses are used after chemotherapy. When used for postoperative nausea and vomiting, ondansetron should be given immediately before induction into anesthesia. If ondansetron is used with radiation therapy, the dose should be given orally, 1 to 2 hours before treatment. Oral disintegrating tablets should be removed from the pack by peeling back the foil, not by pushing the drug tablet through the foil. Place ondansetron on the patient's tongue and have the patient swallow it. The drug does not have to be administered with a fluid.

Minimizing Adverse Effects

For IV administration, dilute ondansetron in 50 mL of 5% dextrose or 0.9% sodium chloride. Do not mix with alkaline solutions. Administer slowly over 15 minutes. Undiluted ondansetron may be given by IV push over 2 to 5 minutes.

Providing Patient and Family Education

- Explain the purpose of the drug.
- Advise patients to take ondansetron every 8 hours for 1 to 2 days after chemotherapy or radiation therapy to maximize prevention of nausea and vomiting.
- Teach patients to change positions slowly to avoid weakness or dizziness.
- Advise patients to refrain from driving or performing tasks that require alertness until the effects of ondansetron are assessed.
- Teach patients to report any tremor, gait problems, or other Parkinson-like symptoms.

Ongoing Assessment and Evaluation

Ondansetron therapy is considered effective if nausea and vomiting are controlled and adverse effects are controlled or do not occur.

Drugs Closely Related to P Ondansetron

Dolasetron

Dolasetron (Anzemet) is available as an oral and parenteral drug. It is approved for treatment of acute nausea and vomiting associated with emetogenic chemotherapy and prevention and treatment of postoperative nausea and vomiting. Off-label uses include the treatment and prevention of radiation therapy–induced nausea and vomiting. The drug is also used cautiously in patients with atrioventricular block or in those who are at risk for developing prolongation of cardiac conduction intervals.

Granisetron

Granisetron (Kytril) is very similar to ondansetron with the same indications, precautions, and adverse effects. The most common adverse effect is headache.

Palonosetron

Palonosetron (Aloxi), the newest drug in this class, is available only for parenteral administration. It has the same indications as ondansetron. In comparison with other selective serotonin receptor antagonists, palonosetron has a prolonged half-life, which makes it an excellent drug for delayed emesis from chemotherapy.

Drugs Significantly Different From P Ondansetron

Aprepitant

A new drug, aprepitant (Emend), is a substance P/NK1 receptor antagonist that has been approved for preventing delayed

MEMORY CHIP

P Ondansetron

- Used to prevent nausea and vomiting associated with cancer chemotherapy, radiation, and certain postoperative states
- Most common adverse effects: headache, constipation, and malaise
- Most serious adverse effects: arrhythmias, hypotension, and extrapyramidal effects
- Maximizing therapeutic effects: Administer 30 minutes before treatment.
- Most important patient education: Notify the nurse if any adverse effects occur

emesis from chemotherapy. It has little or no affinity for serotonin (5-HT), dopamine, and corticosteroid receptors, the targets of other antiemetics. Aprepitant is highly protein bound at 95%. The drug is extensively metabolized by the P-450 system, primarily by CYP3A4. Aprepitant is also a moderate inhibitor of CYP3A4. Minor metabolism occurs through CYP1A2 and CYP2C19. Metabolism is the route of elimination; aprepitant is not renally excreted. The half-life is 9 to 13 hours. No clinically statistical pharmacokinetic differences in aprepitant use exist among men and women, older and younger adults, and Hispanics, blacks, and whites. No dosage adjustments are indicated for any of these groups. Aprepitant has not been studied in children younger than 18 years.

Studies show that, given orally once a day for 3 days (the day of therapy, and then 2 days afterward) 1 hour before administration of chemotherapy, this drug decreased delayed emesis by 30% over placebo. Aprepitant is used in combination with ondansetron and dexamethasone as a standardized regimen. It is not used alone. The aprepitant regimen prevents acute and delayed nausea and vomiting associated with highly emetogenic drugs, including high doses of cisplatin. Aprepitant is not effective in treating current conditions of nausea.

Aprepitant is generally well tolerated and in clinical trials had an adverse effect pattern similar to that of placebo. The most common adverse effects were tiredness, hiccups, constipation, diarrhea, and loss of appetite.

A major difference between aprepitant and ondansetron is the potential for drug interactions. Aprepitant must be used with extreme caution in patients who also receive other drugs that are primarily metabolized through CYP3A4, and elevations of their plasma levels are likely to occur. It should not be used at all concurrently with pimozide, cisapride, terfenadine, or astemizole, because inhibition of CYP3A4 in these drugs and the elevated plasma concentrations of these drugs can potentially cause serious or life-threatening reactions. Several chemotherapy drugs are metabolized by CYP3A4, including docetaxel, paclitaxel, etoposide, vinblastine, vincristine, irinotecan, ifosfamide, and imatinib. During clinical trials, aprepitant was commonly coadministered with etoposide, vinorelbine, or paclitaxel. These drugs did not require dosage adjustments. Use of the other chemotherapeutic CYP3A4 substrates has not been studied, and they may require downward dosage adjustments if coadministered with the aprepitant regimen. Aprepitant also interacts substantially with warfarin, which may result in a clinically significant decrease in the International Normalized Ratio (INR), leading to a risk of clotting. Patients need to have their INR monitored for 14 days, especially between days 7 and 10, following initiation of the 3-day aprepitant regimen. The efficacy of oral contraceptives may also be reduced by aprepitant. A backup method of contraception should be used.

Antidopaminergic Drugs

The antidopaminergic drugs (also referred to as phenothiazines) block the action of dopamine, a neurotransmitter found in both the GI tract and the CTZ. Used for nausea and vomiting, they also have sedative properties. Drugs in this class include chlorpromazine (Thorazine), prochlorperazine (Compazine), promethazine (Phenergan), and thiethylperazine (Torecan). In addition to nausea and vomiting, chlorpromazine is used for intractable hiccups. Other drugs that affect dopamine receptors, but are not phenothiazines, include the butyrophenones droperidol (Inapsine) and haloperidol (Haldol), and the dopamine-2 antagonist metoclopramide (Reglan).

These drugs have limited use in children with prolonged vomiting because of their possible adverse effects. Drowsiness should be anticipated, and patient safety should be a priority. Patients should be advised not to drive or perform activities requiring mental alertness until the effects of the drug are known. Patients should be taught to avoid alcohol and other CNS depressants because of possible additive effects. Additional information regarding the phenothiazines and butyrophenones is found in Chapter 17.

Anticholinergic Drugs

The anticholinergic antiemetics block the action of acetylcholine in the VC. They prevent motion sickness by reducing the sensitivity of the labyrinthine apparatus, thus inhibiting vestibular input to the CNS. This process decreases stimulation of the CTZ and the VC. The anticholinergics are used to treat nausea, vomiting, and motion sickness, and some of these agents, such as meclizine (Antivert) and dimenhydrinate, are used to treat vertigo. Other drugs in this class that are used as antiemetics include scopolamine (Transderm-Scop), diphenhydramine (Benadryl), hydroxyzine (Vistaril), and trimethobenzamide (Tigan).

Anticholinergic drugs are used with caution in patients with glaucoma, obstructive diseases of the GI or GU tract, and elderly men with possible prostatic hypertrophy. Like antidopaminergic drugs, anticholinergic drugs may cause significant sedation. It is necessary to caution patients about possible additive effects with alcohol and other CNS depressants. Patients should be taught to wash their hands after handling scopolamine transdermal patches, because temporary dilation of the pupil and blurred vision are possible if the drug comes in contact with the eyes.

Cannabinoids

Dronabinol (Marinol) and nabilone (Cesamet) are used for nausea and vomiting associated with cancer chemotherapy that does not respond to other antiemetic drugs. Also used for its psychoactive activity in marijuana, dronabinol is also known as tetrahydrocannabinol (THC). Its use is also approved by the FDA for the treatment of anorexia in patients who are HIV antibody positive. As an antiemetic, the exact mechanism of action of dronabinol is unknown, but it is thought to work by inhibiting the vomiting control mechanism in the medulla oblongata. Dronabinol is a schedule III drug because of its abuse potential. It may induce CNS effects such as ataxia, confusion, problems with coordination,

TABLE 36.17 Summary of Selected Gallstone-Solubilizing Agents

Drug (Trade) Name	Selected Indications	Contraindications and Precautions	Adverse Effects	Route and Dosage Range
ursodiol (Actigall)	Dissolution of radiolucent, noncalcified, smaller than 20-mm gallstones in patients who are not candidates for surgery due to age, disease states, or idiosyncratic reactions to anesthesia	Will not dissolve calcified, radiopaque, or radiolucent bile pigment stones in patients with compelling needs for cholecystectomy	Nausea, vomiting, dyspepsia	*Adult:* PO, 8–20 mg/kg/d in two to three doses, for 1 y or more (if partial or full dissolution does not occur in 1 y, likelihood of success is reduced)
monoctanoin (Moctanin)	Dissolution of radiolucent gallstones retained in biliary tract after cholecystectomy when other means have failed or cannot be used	Impaired hepatic function, significant biliary tract infection, recent history of duodenal ulcer or duodenitis, portosystemic shunting, acute pancreatitis, or any life-threatening problem that would be complicated by biliary tract infusion	Abdominal pain, nausea, vomiting, diarrhea, anorexia, indigestion, fever	*Adult* (direct infusion into biliary tract only after a catheter has been placed endoscopically as close to the stones as possible): Dilute 120-mL vial with 13 mL of sterile water; perfuse stone 3–5 mL/h for 2–10 d

dizziness, somnolence, and vertigo. Psychiatric adverse effects such as delusion of persecution, depersonalization, depression, disturbance in thinking, and euphoria may occur. Potential cardiovascular adverse effects include hypertension or hypotension, palpitations, tachyarrhythmia, and vasodilatation. Because of these potential effects, dronabinol is used cautiously in patients with a history of substance abuse, psychiatric disorders, and cardiovascular disorders.

Nabilone is a schedule II drug. Precautions are similar to those for dronabinol. In addition, nabilone is used cautiously in patients with hepatic dysfunction. It has a high incidence of adverse effects such as asthenia, ataxia, drowsiness, dizziness, dry mouth, headache, poor concentration, somnolence, vertigo, and hypotension. Orthostatic hypotension, euphoria, dysphoria, depression, visual hallucinations, and psychosis can occur, especially in older patients.

Patients should be taught to take these drugs exactly as prescribed. Because of the potential adverse effects, a responsible adult should be with the patient while taking these drugs. Patients taking cannabinoids should be advised not to drive or perform activities that require concentration. Patients should refrain from alcohol or other CNS depressants. It is important to reporting symptoms such as bizarre thoughts, uncontrollable behavior or thought processes, fainting, dizziness, or irregular heartbeat to the health care provider immediately. In the acute care setting, it is necessary to ensure the safety of the patient.

Glucocorticoid Steroids

Dexamethasone (Decadron) and methylprednisolone (Depo-Medrol) are used for cancer-induced nausea and vomiting, although this is not a FDA-approved indication. The ASCO recommends the use of glucocorticoids for every type of cancer-induced emesis. The drugs are administered intravenously just prior to chemotherapy. Adverse effects are rare due to the short duration of treatment.

Olanzapine

Olanzapine (Zyprexa) is actually a drug for schizophrenia and bipolar mania. Olanzapine blocks multiple neurotransmitters, including D_1, D_2, and D_4 receptors; the serotonin receptors 5-HT_{2a}, 5-HT_{2c}, and 5-HT_3; alpha-1 adrenergic receptors; acetylcholine; and histamine-1 receptors. Because many of these receptors have a role in nausea and vomiting, olanzapine may be effective for its management. It is hypothesized that olanzapine decreases nausea and vomiting because of its antagonism of D_2 receptors and its blockade of 5-HT_3 receptors. Olanzapine is also discussed in Chapter 17.

GALLSTONE-SOLUBILIZING AGENTS

Gallstone-solubilizing agents, including ursodiol (Actigall) and monoctanoin (Moctanin), work to dissolve gallstones. They are used only under specific circumstances and are summarized in Table 36.17.

CHAPTER SUMMARY

- Drug therapy for the upper GI tract is related to problems from bacterial infection, acid production, digestion, and nausea and vomiting.
- Dietary factors can influence symptoms experienced from the disease process; can contribute to the effectiveness of the therapy; and can contribute to adverse effects from therapy. Current dietary habits should be explored, and additional dietary teaching provided as indicated, with all patients requiring drug therapy for upper GI problems.
- *Helicobacter pylori* causes a bacterial infection that is a causative factor in peptic ulcers and gastric cancer. When

H. pylori is eradicated, an ulcer rarely reoccurs. Treatment involves various drug choices but optimally includes the combination of antibiotics (usually two) and a proton pump inhibitor. A bismuth salicylate may be added as well. H_2 receptor antagonists sometimes are used instead of a proton pump inhibitor.

- PPIs, such as omeprazole, decrease gastric acid production. They are used to manage the symptoms of GERD and peptic ulcers and to treat hypersecretory conditions.
- H_2RAs, such as ranitidine, block histamine at parietal cells, thus reducing the hydrogen ion concentration and the volume of gastric acid. Common uses of H_2RAs include treating PUD, GERD, and hypersecretory conditions and preventing stress ulcers. OTC H_2RAs are used for heartburn and indigestion.
- Antacids are basic salts that increase the gastric pH, thereby neutralizing gastric acidity. These preparations are used for upper GI disorders such as gastroesophageal reflux esophagitis, hiatal hernia, gastritis, and PUD. Antacids do not cure these conditions but help manage the symptoms and discomfort associated with them. All antacids are closely related and are used in various combinations to produce the desired effects and to minimize adverse effects.
- Two antacids are absorbed systemically: sodium bicarbonate and calcium carbonate. In large doses, they can cause metabolic alkalosis. Sodium bicarbonate contains large quantities of sodium. It should not be given to patients who have pathologies that require salt restriction.
- Magnesium antacids should not be given to patients with chronic renal failure because these drugs increase the risk of developing magnesium toxicity in such patients. Aluminum carbonate is used in patients with chronic renal failure because it binds with phosphorus, reducing serum phosphate levels.
- Sucralfate, although an aluminum salt, is not an antacid. When it dissolves in the stomach, it forms a sticky paste that adheres to ulcerated areas, preventing gastric acids from touching the ulcer and allowing healing to occur.
- The GI stimulants, such as metoclopramide, are used in diabetic gastroparesis and with symptomatic gastroesophageal reflux. They increase GI motility, apparently by sensitizing the tissues to acetylcholine. Metoclopramide, because of its dopamine antagonist characteristics, also is used as an antiemetic postoperatively and during chemotherapy.
- Digestive enzymes are a replacement for the body's intrinsic enzymes when the body does not produce enough to meet the needs for digestion. The enzymes that are replaced most frequently and with the greatest therapeutic effects are the pancreatic enzymes. They should be taken with meals and with snacks.
- Orlistat, a lipase inhibitor, prevents the absorption of dietary fat. It is used in obesity to promote and maintain weight loss.
- Antiemetics prevent nausea and vomiting; they prevent stimulation of the CTZ and the VC by interfering with neurotransmitter receptors. They are primarily selective serotonin receptor antagonists, antidopaminergics, or anticholinergics.
- Selective serotonin receptor antagonists, such as ondansetron, are used to prevent the nausea and vomiting associated with cancer chemotherapy and radiation therapy, and after some types of surgery.

QUESTIONS FOR STUDY AND REVIEW

1. If a patient is treated for active peptic ulcer disease solely with an antisecretory drug, such as the proton pump inhibitor (PPI) omeprazole or an H_2 receptor antagonist (H_2RA) such as ranitidine, is it likely that the ulcer will recur?
2. Your patient is receiving the PPI omeprazole for GERD. Explain how dietary factors may interact with the therapeutic action of omeprazole.
3. Why is it important to assess the pharmacokinetics of other drugs that a patient is receiving when you plan to start the patient on omeprazole therapy?
4. How do H_1 receptor antagonists (H_1RAs) differ from H_2 receptor antagonists (H_2RAs)?
5. What is the advantage of combining aluminum hydroxide with magnesium hydroxide as an antacid?
6. Why are aluminum antacids given to patients with chronic renal failure?
7. What are the main adverse effects of orlistat, a lipase inhibitor used in treating obesity?
8. Why is ondansetron especially helpful in preventing nausea and vomiting caused by cancer chemotherapy?

Drugs Affecting the Lower Gastrointestinal Tract

Learning Objectives

At the completion of this chapter the student will:

1. Identify core drug knowledge about drugs that affect the lower gastrointestinal (GI) tract.
2. Identify core patient variables related to drugs that affect the lower GI tract.
3. Relate the interaction of core drug knowledge to core patient variables for drugs that affect the lower GI tract.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs that affect the lower GI tract.
5. Describe nursing interventions to maximize therapeutic effects and minimize adverse effects for drugs that affect the lower GI tract.
6. Determine key points for patient and family education for drugs that affect the lower GI tract.

Key Terms

constipation
Crohn disease
diarrhea
fecal impaction
flatus
inflammatory bowel disease (IBD)
irritable bowel syndrome (IBS)
peristalsis
ulcerative colitis

Drugs Affecting the Lower Gastrointestinal Tract

Antiflatulents

- **simethicone** (P)
- charcoal

Antidiarrheals

- **diphenoxylate HCl with atropine sulfate** (P)
- loperamide
- bismuth subsalicylate
- kaolin and pectin

Drugs Used to Treat Irritable Bowel Syndrome

- **alosetron** (P)
- dicyclomine
- lubiprostone
- tegaserod
- tricyclic antidepressants

Drugs Used to Treat Inflammatory Bowel Disease

- 5-ASA preparations (C)
  - **mesalamine** (P)
  - balsalazide
  - olsalazine
  - sulfasalazine
  - infliximab

Laxatives

- Saline laxatives (C)
  - **magnesium hydroxide** (P)
  - magnesium sulfate
  - magnesium citrate
  - sodium phosphate
- Hyperosmotic laxatives (C)
  - glycerin suppository
  - lactulose
- Stimulant laxatives (C)
  - bisacodyl
  - cascara sagrada
  - castor oil
  - senna
- Bulk-forming laxatives (C)
  - methylcellulose
  - polycarbophil
  - psyllium
- Stool softeners (C)
  - docusate calcium
  - docusate sodium
- Lubricant laxative (C)
  - mineral oil
- Bowel evacuants (C)
  - polyethylene glycol-electrolyte solution

The symbol (C) indicates the drug class.
Drugs in **bold type** marked with the symbol (P) are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

This chapter discusses drugs used to treat the most common alterations of the lower gastrointestinal (GI) tract, including flatus (gas), diarrhea, constipation, irritable bowel syndrome, and irritable bowel disease. All are digestive disorders. Their occurrence may be mild and episodic or severe, debilitating, and chronic. Patients may self-treat these problems with over-the-counter (OTC) medications, or they may seek medical attention. These problems may be related to other drug therapy, diet, emotions, or changes in activity. The drug classes used to treat flatus, diarrhea, and constipation are called antiflatulents, antidiarrheals, and laxatives, respectively. In addition, drugs used to treat irritable bowel syndrome and inflammatory bowel disease (including ulcerative colitis and Crohn disease) are presented.

Some drugs begin acting in the lower GI tract. However, their therapeutic uses are for alterations of other systems. These drugs include potassium-removing resins, such as sodium polystyrene sulfonate (Kayexalate), and a lipid-lowering agent, such as cholestyramine (Questran). These drugs are discussed in Chapters 26 and 31, respectively.

PHYSIOLOGY

The large intestine is approximately 5 feet long (1.5 m) and 2.5 inches (6.5 cm) in diameter. The longitudinal muscle fibers on the outer surface of the large intestine are in three layers and do not cover the entire colon uniformly. This arrangement of the muscle exerts a tension on the wall of the intestine, drawing it up and giving it a puckered appearance.

The large intestine is composed of the cecum, colon, rectum, and anal canal. The cecum, located on the right side of the abdomen, is a small pouch-like structure. The appendix is a blind tube of lymphoid tissue attached to the cecum. The colon has four sections—ascending, transverse, descending, and sigmoid. The area immediately after the sigmoid colon is the rectum, which is followed by the anal canal. The anal canal has two sphincters—the internal and the external.

The contents from the small intestine enter the cecum through the ileocecal valve. **Peristalsis,** wave-like muscular contractions and squeezing of the intestines, moves the contents through the small and large intestines. The movement of fecal material into the rectum triggers defecation. The distended rectum activates the defecation reflex, relaxing both the internal and external anal sphincters. As peristaltic action increases, the diaphragm lowers, and the abdominal muscles contract, forcing the feces out of the body through the anus. Defecation is controlled in the healthy person by maintaining a contracted external anal sphincter. The normally brown color of fecal material is caused by the breakdown of bilirubin. The normal content of fecal matter includes dead bacteria, fat, inorganic matter, protein, dried digestive juices, and indigestible components of food.

Large amounts of mucus are secreted by goblet cells in the epithelial layer of the large intestine. This mucus protects the epithelial surface from abrasive fecal material and aids in holding the fecal material together. Certain bacteria normally present in the large intestine produce some needed vitamins, including vitamin K, vitamin B_{12}, riboflavin, and thiamine. The bacteria produce gases that contribute to the formation of flatus.

During the movement of stomach contents through the large intestine, water and some electrolytes are reabsorbed. Absorption of fluid and electrolytes occurs primarily in the proximal colon. The longer the contents remain in the large intestine, the greater the amount of water that is reabsorbed (Figure 37.1).

PATHOPHYSIOLOGY

Flatus

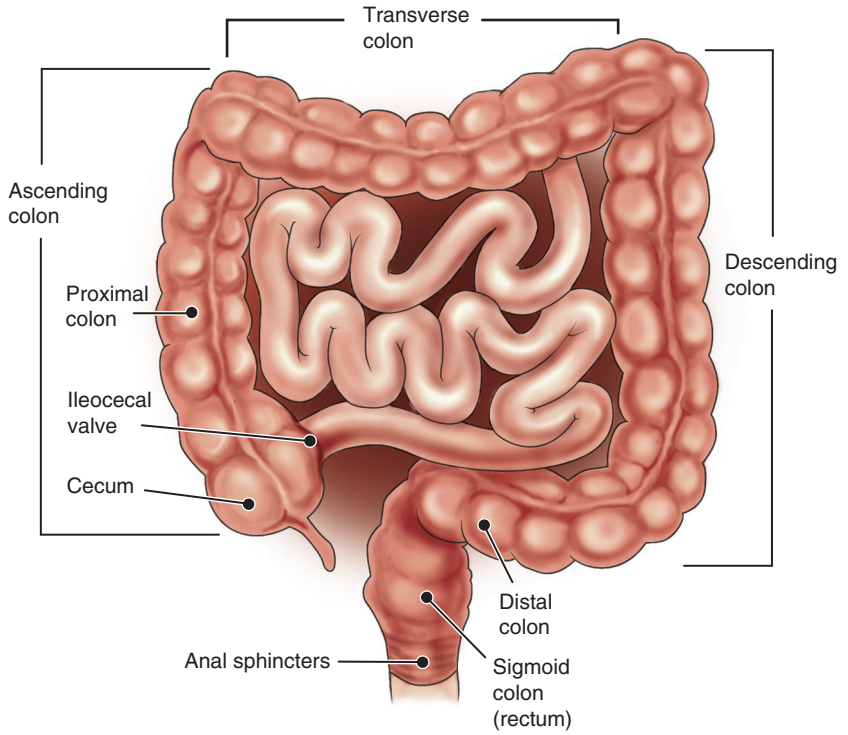
Flatus is a normal by-product of digestion. Flatus becomes problematic, causing discomfort or pain from excessive production (caused by ingesting gas-producing foods) or from an inability to pass the gas through the large intestine (a disruption of peristalsis, such as occurs temporarily after surgery).

Diarrhea

Diarrhea is the frequent passage of loose or liquid stools. It is a symptom rather than a disease. Causes include decreased fluid absorption, increased fluid secretion, or motility disturbances. Decreased fluid absorption may result from malabsorption syndrome, lactulose intolerance, osmotic diarrhea, or mucosal injury due to celiac disease, Crohn disease, radiation injury, ulcerative colitis, or ischemic bowel disease. Increased fluid secretion most frequently results from infectious bacterial endotoxins such as *Vibrio cholerae, Escherichia coli, Shigella, Salmonella, Staphylococcus,* and *Clostridium difficile,* as well as viral agents such as rotavirus and parasites such as *Giardia lamblia*. Other causes of increased fluid secretion include gastrin secretion from Zollinger-Ellison syndrome, calcitonin secretion from carcinoma of the thyroid, and polypeptide secretion from adenoma of the pancreas. The motility disturbance that most frequently causes diarrhea is irritable bowel syndrome. Patients with a previous gastrectomy may experience "dumping syndrome" that leads to increased motility and diarrhea.

Diarrhea may be acute or chronic. Acute diarrhea is usually self-limiting or responds to treatment within 48 hours. It is generally associated with bacterial or viral infections. Symptoms include explosive diarrhea, tenesmus (spasmodic contraction of the anal sphincter with pain and persistent desire to defecate), and abdominal cramping. Anal skin irritation frequently occurs because of the frequency of liquid stool. In contrast, chronic diarrhea lasts more than 4 weeks. It is associated with chronic disease states. Chronic diarrhea can be life-threatening due to electrolyte imbalance, acid-base imbalance, or dehydration. Malabsorption and malnutrition are other complications. Children and the

PHYSIOLOGY



• FIGURE 37.1 Moving through the lower gastrointestinal tract. Once the contents of the small intestine enter the cecum through the ileocecal valve, they are transported through the large intestine by peristalsis (wave-like propulsion of gastric contents). The three segments of the large intestine are termed the ascending colon, the transverse colon, and the descending colon. When the contents leave the distal colon and enter the sigmoid colon (rectum), the distended rectum activates the defecation reflex, which causes the internal and external anal sphincters to relax. As peristaltic activity increases, the diaphragm lowers and the abdominal muscles contract, forcing the feces out of the body through the anus. Certain bacteria normally present in the intestine produce gases that are commonly known as flatus. Absorption of fluid and electrolytes occurs primarily in the proximal colon, although some absorption occurs throughout the length of the large intestine. The longer the contents remain in the large intestine, the more water is absorbed.

elderly are most vulnerable. Treatment of the underlying disease usually eliminates the diarrhea. However, when diarrhea becomes chronic, antidiarrheal drug therapy may be needed for an extended period.

Constipation and Fecal Impaction

Constipation is infrequent or incomplete passage of hard stools resulting from a decrease in peristaltic activity and slow movement of fecal material through the colon. This slow movement through the colon allows more water to be absorbed from the feces, resulting in hard, dry stools. The hard, dry fecal material is more difficult to pass and can cause painful defecation. Other symptoms associated with constipation include abdominal distention or bloating, increased flatulence, increased rectal pressure, straining, and tenesmus. Box 37.1 presents possible causes of constipation.

Normal bowel frequency varies substantially among individuals. "Normal" may range from a bowel movement 3 times a day to one every 3 days. For this reason, an individual's definition may not reflect the actual slowed movement through the colon and the resultant dry, hard stools.

Prolonged constipation may lead to **fecal impaction,** in which the patient is unable to pass the hardened mass of feces. Fecal impaction may be resistant to pharmacotherapy, and digital stool removal may be required.

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a common disorder of the intestines characterized by altered bowel habits and abnormal sensations (discomfort or pain) in the absence of specific organic pathology. In the United States, IBS is the most common GI diagnosis made by gastroenterologists, affecting 10% to 20% of the general population.

IBS is a complex syndrome with a varying clinical presentation. For some people, the primary problem is diarrhea; for some, it is constipation; and for others, it is alternating diarrhea and constipation. No definitive test exists for IBS; thus, a clear diagnosis is difficult. A consensus panel of gastroenterologists has developed a set of conditions for the diagnosis

Box 37.1 CAUSES OF CONSTIPATION

Colonic Disorders

- IBS
- Diverticular disease
- Inflammatory strictures
- Luminal obstruction
- Rectocele

Metabolic/Endocrine Systemic Disorders

- Hypothyroidism
- Diabetes mellitus
- Hypokalemia
- Pheochromocytoma
- Pregnancy

Neurologic Disorders

- Multiple sclerosis
- Parkinson disease
- Spinal cord lesions
- Cerebrovascular accident
- Autonomic neuropathy

Drug Induced

- Laxative abuse
- Opioids
- Anticholinergics
- Antihypertensives
- Antidepressants
- Antacids (calcium and aluminum)
- Calcium and iron supplements

Box 37.2 ROME III CRITERIA USED IN THE DIAGNOSIS OF IRRITABLE BOWEL SYNDROME

The patient must have recurrent abdominal pain or discomfort at least 3 d/mo during the previous 3 months that is associated with two or more of the following:

- Improvement with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool

Supporting symptoms include the following:

- Altered stool frequency
- Altered stool form
- Altered stool passage (straining and/or urgency)
- Mucorrhea
- Abdominal bloating or subjective distention

of IBS known as the Rome III Criteria (Box 37.2). There are four subtypes of IBS: IBS-D (diarrhea predominant), IBS-C (constipation predominant), IBS-A (alternating diarrhea and constipation), and IBS-M (mixed diarrhea and constipation).

IBS is called a functional disorder because no evidence of disease is seen when the colon is examined. It does not lead to any serious, organic diseases, and it does not cause cancer of the bowel. IBS has not been linked to inflammatory bowel diseases such as Crohn disease or ulcerative colitis. However, IBS is a chronic disorder that can be very painful, limiting the ability of a person to fully participate in life, diminishing quality of life, and incurring substantial cost.

The symptoms of IBS are painful diarrhea or constipation, or diarrhea that alternates with constipation. Other symptoms are crampy abdominal pain, bloating, gas pain, excessive flatulence, increased belching, mucus in the stool, small stools ("rabbit-like pellets"), or flat "ribbon" stools. Bleeding, fever, weight loss, and persistent severe pain are not symptoms of IBS and may indicate other problems. IBS symptoms negatively affect general health, vitality, social functioning, bodily pain, diet, sexual function, and sleep, and they also contribute to time lost from work.

For individuals with IBS, the symptoms of spastic contractions may be triggered by stress because the bowel is controlled partly by the nervous system. However, IBS is not related to a personality disorder; it is a disorder of digestion. Stress management or use of stress-reduction techniques may help relieve some of the symptoms or make them less severe. Diet also can trigger flares of IBS. An increase in peristalsis is normal after eating. For people with IBS, strong contractions of the colon may come sooner after eating than usual, accompanied by cramps and diarrhea. Because fat is a strong stimulus for colonic contractions, eating a high-fat meal induces contractions in some people that may be stronger or more violent than usual. Large meals also can cause cramping and diarrhea in people with IBS. Lack of fiber may potentiate constipation in IBS. Finally, women with IBS experience more symptoms when they have their menstrual period, which is hypothesized to be related to female sex hormones increasing the susceptibility of the colon to spasm.

The exact cause of IBS is not known. The theory of IBS pathogenesis includes altered GI motility and visceral hyperalgesia. In IBS, the bowel is hypersensitive and overreacts to mild stimulation. The normal distention of the bowel that can occur with food intake, gas, or a high-fiber diet can be enough to trigger IBS. Thus, patients with IBS exhibit pain and discomfort at lower volumes of gastric distention than occur in patients who do not have IBS. Some researchers also believe that psychopathology may contribute to IBS. Whether psychopathology induces the development of IBS or IBS induces the development of psychopathology is unclear.

It is not unusual for the symptoms of one subtype of IBS to change to those of another; therefore, treatment of IBS focuses on the symptoms the patient is currently experiencing. Although antidiarrheals, antispasmodics, and laxatives are commonly used, some patients require drugs that either stimulate or block serotonin ($5\text{-}HT_3$) receptors. Serotonin is a primary neurotransmitter affecting the enteric tract, and it plays a role in visceral sensation and the normal functioning of the tract, including secretion and motility. Abnormalities in motility and visceral sensation correspond to the pathology of many of the symptoms of IBS. Although seven serotonin

receptor sites have been identified, 5-HT_3 and 5 HT_4 receptors are the most important sites in IBS.

Lifestyle modification may also be used in the treatment of patients with IBS. However, research has not shown that stress reduction or dietary modification is helpful or effective in all patients with IBS. Even in patients who experience a positive effect, these lifestyle modifications may not replace the need for drug therapy.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a general term that includes both ulcerative colitis and Crohn disease. **Ulcerative colitis** is an inflammatory disease of the large intestine in which ulcers form in the mucosa of the colon or rectum. Diarrhea, blood, and pus may result. **Crohn disease** is an inflammation extending into the deeper layers of the intestinal wall. It is most often found in the ileum and the cecum. However, Crohn disease can develop anywhere along the intestines. It may cause ulcers along the entire colon, form a string of ulcers in one part of the colon, or cause multiple scattered clusters of ulcers in the colon. The main symptom of IBD is diarrhea, which may, especially in ulcerative colitis, contain blood. Constipation also may develop during active flare-ups. Cramps and intestinal pain may occur. Fever, fatigue, loss of appetite, and weight loss also may occur.

Approximately 1 to 2 million Americans have IBD (the wide variation is because of the difficulty of diagnosing IBD and because people may have long remissions and not be identified as having IBD). Men and women seem to be affected equally. IBD most often is diagnosed between 15 and 40 years of age. Jewish Americans of European descent have a risk for IBD that is five times that of the general population. IBD is more common among city dwellers than country dwellers and is more prevalent in developed countries.

Although the exact cause is not known, genetic factors have been implicated. Up to 25% of people with IBD have family members with the disease. Genetic abnormalities linked to the two disorders may share locations on chromosomes 1, 3, 4, 7, 12, and 16. Some researchers believe that the disease develops in people who have a genetic susceptibility that allows an agent, such as a virus or bacterium, to trigger an abnormal immune response. When an organism injures the lining of the intestine in a normal, healthy person, the immune system reduces the inflammation and injury by producing suppressor T cells. In people with IBD, however, when an organism injures the lining of the intestine, the immune system produces helper T cells. Helper T cells produce a protein called a cytokine. Cytokines cause intestinal inflammation and damage, which attract even more helper T cells to the area. Because IBD is more prevalent in industrialized countries, environmental factors, such as diet, are believed to also play a role in producing IBD. No clear insight into this phenomenon is yet available from research.

Post-operative Ileus

Post-operative ileus is a temporary decrease in gastrointestinal motility observed in patients after undergoing gastrointestinal, as well as other procedures requiring general anesthesia (Bream-Rouwnehorst and Cantrell, 2009). Opiate receptors are located in the gastrointestinal tract and play a role in gastrointestinal motility, secretion, and transportation of electrolytes. Secondary to surgical manipulation or trauma, inhibitory sympathetic neural reflexes are triggered in the gut, resulting in decreased gastrointestinal mobility. Post-operative ileus is most often associated with bowel manipulation or surgical trauma, and usually resolves within 24 to 72 hours.

C ANTIFLATULENTS

Antiflatulents decrease gas production, coalesce gas bubbles, and facilitate the passage of gas through belching and expelling flatus. Antiflatulents include simethicone and charcoal. The prototype antiflatulent is simethicone (Mylicon) Table 37.1. It is available alone or combined with antacids and digestants (see Chapter 36).

Nursing Management of the Patient Receiving P Simethicone

Core Drug Knowledge

Pharmacotherapeutics

Antiflatulents are drugs used to relieve the discomfort of excess gas in the GI tract caused by swallowing air, postoperative gas distention, peptic ulcer, spastic or irritable colon, or diverticulitis. These drugs relieve pain and discomfort by promoting belching and the passing of flatus.

Pharmacokinetics

Simethicone is inert and is not absorbed from the GI tract. Because the drug is inactive, it is excreted unchanged in feces and does not interfere with absorption of water

TABLE 37.1 Summary of Selected C Antiflatulent Drugs

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P simethicone (Mylanta Gas, Gas Relief, Gas-X, Major-Con, Phazyme, Flatulex, Mylicon)	Relief of symptoms and pressure from excess gas in intestinal tract	*Adult:* PO, 125-mg capsules qid with meals; 40–125-mg tablets qid with meals; 40–80-mg drops qid up to 500 mg/d *Child <2 y:* PO, 20 mg qid up to 240 mg/d *Child 2–12 y:* 40 mg qid	*Onset:* Not absorbed systemically *Duration:* None $t_{1/2}$: None

or nutrients or the secretion of mucus in the GI tract. Simethicone is not distributed systemically in the body and is excreted unchanged in the feces. It begins to act immediately in the GI tract and has a duration of approximately 3 hours. Its peak and half-life are unknown.

Pharmacodynamics

Simethicone has a defoaming action that alters the surface tension of gas bubbles. As the surface tension is changed, gas bubbles unite, forming larger gas bubbles that are eliminated more easily by belching or expulsion as flatus. It also is combined with antacids to decrease flatulence, but it has no antacid properties. An off-label use is treating the symptoms of infant colic.

Contraindications and Precautions

Simethicone has no contraindications or precautions.

Adverse Effects

No substantial adverse reactions have been reported with the use of simethicone.

Drug Interactions

No drug interactions with simethicone are known.

Assessment of Relevant Core Patient Variables

Health Status

Before administering simethicone, assess for abdominal pain, distention, and bowel sounds.

Lifestyle, Diet, and Habits

Assess the patient's dietary choices for gas-producing foods such as cucumbers, cabbage, onions, beans, and radishes.

Environment

Simethicone is easily self-administered and can be given in any setting. Some preparations are available OTC.

Nursing Diagnosis and Outcome

- Acute Pain related to the presence of flatus
  Desired outcome: *Within 2 to 3 hours of using simethicone, the patient will experience a decrease in abdominal pain and distention.*

Planning and Intervention

Maximizing Therapeutic Effects

Simethicone should be given after meals and at bedtime to increase its effectiveness. Have the patient chew tablets thoroughly or allow them to dissolve in the mouth to promote dispersion. The suspension form of the drug must be shaken to ensure that the active ingredients are well dispersed.

To ensure accuracy of dosing liquid forms of the drug, use or teach the patient to use a calibrated dropper. When administering to infants, simethicone should be mixed with 30 mL of a suitable liquid, preferably formula or cool water.

Providing Patient and Family Education

- Teach patients to take simethicone after each meal and at bedtime, to chew tablets thoroughly before swallowing, and to shake the liquid suspension form well before measuring a dose.
- Tell patients to expect to pass gas and have increased belching after taking this drug.
- Caution patients not to increase the dosage unless instructed to do so by the prescriber.
- Instruct patients to avoid gas-producing foods. A high-fiber diet increases peristalsis, and a low-fat diet decreases production of carbon dioxide gas.

Ongoing Assessment and Evaluation

Assess abdominal pain and distention periodically throughout simethicone therapy to monitor the effectiveness of the drug. It is effective if abdominal distention is decreased and the patient reports feeling more comfortable. If effectiveness is not observed, the dose may need to be increased. Verify that the patient does not have any increase in abdominal pain, nausea, vomiting, or fever because these findings are not symptoms of excessive flatus and may indicate that the patient requires medical attention.

Drug Closely Related to P Simethicone

Charcoal is an absorbing, detoxifying, and soothing agent. The drug relieves gas and cramping by absorbing toxins and gas on the surfaces of its carbon particles. Like simethicone, it is useful for the relief of gas, diarrhea, and GI distress associated with indigestion and cramping.

Unlike simethicone, charcoal is used as an antidote in poisonings from drug overdose because it reduces absorption of certain drugs and chemicals and can actually remove them from the systemic circulation. Charcoal also is used for preventing nonspecific pruritus associated with kidney dialysis. It should not be given to children younger than 3 years of age. Charcoal can be combined with simethicone to treat gas pains; the charcoal decreases the amount of gas produced, and the simethicone promotes elimination of gas.

MEMORY CHIP

P Simethicone

- Relieves the pain of excess gas in the GI tract; antifoaming action changes surface tension of gas bubbles, causing them to coalesce and pass more easily
- Most important patient education: Chew tablets to promote effectiveness; take after meals and at bedtime.

C ANTIDIARRHEALS

Antidiarrheals slow intestinal motility, allowing time for fluid reabsorption and better stool formation. The most effective antidiarrheal drugs include opiate derivatives, the opiates themselves, and loperamide, a drug related to the antipsychotic drug haloperidol. These drugs act systemically to reduce intestinal motility and slow peristalsis. Several locally acting drugs are available OTC and are effective in mild cases of diarrhea The prototype antidiarrheal drug is diphenoxylate HCl with atropine sulfate (Lomotil, Lonox) (Table 37.2).

Nursing Management of the Patient Receiving P Diphenoxylate HCl with Atropine Sulfate

Core Drug Knowledge

Pharmacotherapeutics

Diphenoxylate HCl with atropine sulfate is used as an adjunct in treating diarrhea.

Pharmacokinetics

Diphenoxylate HCl with atropine sulfate is absorbed readily in the GI tract. When the tablet form is used instead of the solution, bioavailability is decreased by approximately 10%. Diphenoxylate HCl with atropine sulfate is found in breast milk; however, the distribution is unknown. The drug is metabolized in the liver to difenoxin, which is an active metabolite that produces the desired therapeutic effects. It leaves the liver as bile and is excreted in feces. A tiny amount is excreted unchanged in the urine.

Pharmacodynamics

Diphenoxylate HCl with atropine sulfate is a synthetic narcotic similar in structure to meperidine, and it is classified as a schedule V drug. The dosage used in treating diarrhea is not high enough to provide pain relief. The drug acts on the smooth muscle of the intestine to slow intestinal motility and prolong intestinal transit time, allowing for the reabsorption of fluid. This preparation is very effective in treating diarrhea. A small amount of atropine sulfate is combined with diphenoxylate to discourage deliberate abuse. When excessive dosages are taken, the adverse reactions of atropine sulfate, which include dry mouth and tachycardia, are particularly unpleasant.

Contraindications and Precautions

Hypersensitivity to diphenoxylate HCl with atropine sulfate or to atropine sulfate alone is a contraindication. Use is contraindicated for diarrhea caused by GI organisms that penetrate the gastric mucosa (e.g., *Shigella, Salmonella,* and some toxic strains of *E. coli*) because the drug slows peristalsis and may aggravate and prolong the diarrhea. The drug is contraindicated in patients with pseudomembranous colitis that occurs with broad-spectrum antibiotic therapy because it may worsen and prolong diarrhea. It also is contraindicated in patients

TABLE 37.2 Summary of Selected C Antidiarrheal Drugs

P diphenoxylate HCl with atropine sulfate (Lomotil, Lonox, Logen, Lomanate)	Acute diarrhea	*Adult:* PO, 5 mg qid *Child 2–12 y:* 0.3–0.4 mg/kg/d in 4 doses	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 12–14 h
bismuth subsalicylate (Pepto-Bismol, Bismatrol, Kao-Tin, Kaopectate)	Indigestion, nausea, diarrhea (including traveler's diarrhea), abdominal cramps	*Adult:* PO, 2 tablets or 30 mL every 30 min to 1 h as needed, up to 8 doses in 24 h *Child 9–12 y:* PO, 1 tablet or 15 mL *Child 6–9 y:* ⅔ tablet or 10 mL *Child 3–6 y:* ⅓ tablet or 5 mL, same dosing schedule as for adults	bismuth subsalicylate (Pepto-Bismol, Bismatrol, Pink Bismuth, Kaopectate)
loperamide (Imodium, Kaopectate II Caplets, Pepto Diarrhea Control)	Acute and chronic diarrhea	*Adult (acute):* PO, 4 mg initially, then 2 mg after each loose stool, not to exceed 16 mg/d; *Adult (chronic):* 4 mg initially, then 2 mg after each loose stool until diarrhea controlled *Child (acute):* PO, first day, 13–20 kg weight, 1 mg tid; 20–30 kg, 2 mg bid; >30 kg, 2 mg tid; after first day, 1 mg/10 kg after loose stools (not to exceed first-day recommended doses) *Child (chronic):* not established	loperamide (Imodium, Kaopectate II Caplets, Pepto Diarrhea Control)
	OTC: traveler's diarrhea (acute diarrhea)	*Adult:* PO, 4 mg initially, then 2 mg after each loose stool, no more than 8 mg/d for no more than 2 d *Child 9–11 y:* PO, 2 mg initially, then 1 mg after each loose stool up to 6 mg/d for no more than 2 d *Child 6–8 y:* 1 mg initially and after each loose stool up to 4 mg/d for up to 2 d	

with obstructive jaundice caused by hepatic impairment. Diphenoxylate HCl with atropine sulfate is contraindicated in children younger than 2 years of age. The drug is a pregnancy category C drug.

Caution is used when administering diphenoxylate HCl with atropine sulfate to patients with advanced hepatic and renal disease because of the risk of hepatic coma, to those with ulcerative colitis because of the risk of inducing toxic megacolon, and to those with severe dehydration because it may cause variability of drug response that may predispose to delayed diphenoxylate intoxication. Caution should be used in lactating women and in children because adverse effects from the atropine sulfate are more likely to occur in these patients. Children with Down syndrome are at special risk of atropine sulfate toxicity when taking diphenoxylate, even if it is taken in recommended doses. Although diphenoxylate HCl with atropine sulfate does not produce morphine-like effects or addiction in recommended dosages, at high doses, addiction can occur.

Adverse Effects

The most common adverse effects of diphenoxylate HCl with atropine sulfate are drowsiness and dizziness related to the drug's chemical similarity to meperidine, an opioid. Dry mouth and other anticholinergic effects (e.g., flushing, tachycardia, hyperthermia, and urinary retention) from the atropine in the drug are not common in adults receiving normal, therapeutic doses of diphenoxylate HCl, although the risk of these effects is greater in children. Diphenoxylate HCl with atropine sulfate also may have the following adverse effects:

- GI: nausea, vomiting, abdominal discomfort, paralytic ileus, toxic megacolon, and pancreatitis
- Central nervous system (CNS): sedation, headache, malaise, lethargy, restlessness, euphoria, depression, and numbness of extremities
- Allergic: pruritus, swelling of gums, angioneurotic edema, urticaria, and anaphylaxis

Drug Interactions

When diphenoxylate HCl with atropine sulfate is given to patients taking monoamine oxidase inhibitors (MAOIs), the combination of the two drugs could precipitate a hypertensive crisis because diphenoxylate is similar chemically to meperidine. The antidiarrheal drug may potentiate the depressive effects of alcohol, barbiturates, and tranquilizers. Table 37.3 lists drugs that interact with diphenoxylate HCl with atropine sulfate.

Assessment of Relevant Core Patient Variables

Health Status

Before administering diphenoxylate HCl with atropine sulfate, assess the patient for abdominal pain and distention to have a baseline for monitoring therapy. Auscultate bowel sounds. Patients with diarrhea usually have frequent, high-pitched bowel sounds. Assess the condition of mucous membranes and the skin for signs of dehydration. It is necessary to assess and document pertinent information about stools; this includes frequency, color, consistency, and odor. Examine laboratory reports of stool specimens and do not administer diphenoxylate HCl with atropine sulfate if stool cultures are positive for *E. coli, Salmonella, Shigella,* or *C. difficile*. Determine whether the patient has a diagnosis of hepatic impairment, obstructive jaundice, pseudomembranous colitis, or ulcerative colitis. While taking a drug history, determine whether the patient is receiving MAOIs. Report any positive findings to the health care provider. If the patient is a child, observe for Down syndrome.

Life Span and Gender

Determine whether the patient is pregnant or breast-feeding because diphenoxylate HCl with atropine sulfate is a pregnancy category C drug. If the patient is a child, verify that he or she is older than 2 years of age. In children aged 2 to 12 years, liquid diphenoxylate is recommended. Monitor children and elderly patients closely because they have an increased risk of atropine toxicity.

Lifestyle, Diet, and Habits

Determine whether the patient has a history of substance abuse because it may make the patient more likely to use diphenoxylate HCl with atropine sulfate inappropriately. Assess the patient's use of alcohol. Encourage the patient to refrain from alcohol while taking diphenoxylate.

TABLE 37.3 Agents That Interact with P Diphenoxylate HCl with Atropine Sulfate

Interactants	Effect and Significance	Nursing Management
monoamine oxidase inhibitors	Chemical structure of diphenoxylate similar to meperidine—hypertensive crisis possible	Administer together cautiously. Monitor blood pressure.
barbiturates, tranquilizers, and alcohol	Depressant effect on central nervous system may be potentiated, leading to respiratory depression or sedation	Monitor for sedation. Monitor vital signs. Ensure safety.

Environment

Although diphenoxylate HCl with atropine sulfate requires a prescription, oral doses are easily self-administered and can be given in any setting.

Culture and Inherited Traits

Cultural and social variations exist regarding how regular bowel movements and diarrhea are defined. Determine the patient's perception of normal elimination and diarrhea.

Nursing Diagnoses and Outcomes

- Diarrhea related to the causative factor (if identified)
  Desired outcome: *Diarrhea will be controlled through use of diphenoxylate HCl with atropine sulfate.*
- Risk for Injury related to drowsiness and dizziness secondary to drug therapy
  Desired outcome: *The patient will not sustain injury from drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

To maximize the therapeutic effect, administer diphenoxylate HCl with atropine sulfate as ordered, four times daily, to obtain therapeutic results. Use the dropper provided when administering liquid preparations to ensure the correct dose.

Minimizing Adverse Effects

Decrease the dosage of diphenoxylate HCl with atropine sulfate when the number of stools decreases. The recommended dosage should not be exceeded. If the patient's condition does not improve with the maximum daily dose for 10 days, diarrhea symptoms are unlikely to be controlled with further use of the drug. In such cases, assess for adverse effects. Assess for toxic megacolon (abdominal distention and pain are possible indications). Because the massive dilation and atony of the colon from toxic megacolon can result in serious complications, signs of abdominal distention should be reported immediately.

Assess for and report signs of atropine sulfate toxicity (e.g., dry mouth, flushing, hypothermia, tachycardia, and urinary retention) because this condition requires immediate treatment. Children must be assessed very carefully because they are especially susceptible to atropine sulfate toxicity.

Providing Patient and Family Education

- Teach patients not to exceed the prescribed dosage and to lower the dosage as instructed as soon as symptoms of diarrhea are controlled. Furthermore, if a dose is missed, instruct the patient not to take two doses.
- Instruct patients to notify the prescriber if diarrhea persists for more than 2 days.
- Encourage patients to avoid alcohol and other CNS depressants and not to drive or perform tasks that require mental alertness until the effects of diphenoxylate HCl with atropine sulfate on the individual are known.

CRITICAL THINKING SCENARIO

DIPHENOXYLATE IN ANTIDIARRHEAL THERAPY

Mr. Rothberg is 46 years old. He enters the emergency clinic with complaints of acute diarrhea for the last 36 hours. He also complains of abdominal pain and cramping. "Every time I eat," he says, "I have to run to the bathroom. I can't seem to keep anything in."

1. What questions would you ask when assessing Mr. Rothberg's condition?
2. After assessment is completed, Mr. Rothberg is diagnosed as having diarrhea secondary to an acute viral illness of the GI tract. He is given a prescription for diphenoxylate HCl with atropine sulfate. What additional core patient variables need to be assessed to provide patient education geared to Mr. Rothberg's personal learning needs?

- Caution patients to maintain adequate fluid intake during periods of diarrhea to prevent dehydration and electrolyte imbalance.
- Caution patients to store diphenoxylate HCl with atropine sulfate out of the reach of children.
- For liquid forms of diphenoxylate HCl with atropine sulfate, tell patients not to use a household teaspoon to measure doses but rather a specially marked dropper or measuring spoon.
- If dry mouth occurs, recommend that patients suck on hard candy or sip water.

Ongoing Assessment and Evaluation

In patients who take diphenoxylate HCl with atropine sulfate, it is important to assess skin turgor and mucous membranes for loss of moisture because these signs indicate dehydration. Monitoring electrolyte laboratory reports for electrolyte imbalance that may occur with the loss of fluid through diarrhea is also a priority. Weakness, muscular cramping, or dizziness should be reported because they are subjective symptoms of electrolyte imbalance. Any change in amount, color, consistency, or odor of stools should be noted. Drug therapy is considered effective when diarrhea is controlled without any adverse effects.

Drug Closely Related to P Diphenoxylate HCl with Atropine Sulfate

Loperamide

Loperamide (Imodium) is also chemically similar to meperidine. However, it is not a scheduled drug. It comes in prescription and OTC strengths. Unlike diphenoxylate, loperamide may be used for chronic as well as acute diarrhea. Loperamide is contraindicated for diarrhea related to infections and pseudomembranous colitis. It is used cautiously in patients with hepatic impairment because of the risk of encephalopathy. The contraindications and adverse reactions related to atropine sulfate are not applicable because loperamide does not contain the anticholinergic drug atropine sulfate. For this

MEMORY CHIP

P Diphenoxylate HCl with Atropine Sulfate

- Used to treat diarrhea not responsive to symptomatic and supportive treatment
- This drug is related chemically to meperidine, an opioid, but lacks any analgesic effect. Atropine is added to discourage abuse.
- Major contraindications: diarrhea associated with organisms that penetrate intestinal mucosa; pseudomembranous enterocolitis
- Most common adverse effects: drowsiness, dizziness, and dry mouth
- Most serious adverse effects: atropine overdose and toxic megacolon
- **Life span alert: Children are more likely to have adverse effects from atropine, especially if they have Down syndrome; variable response in children; avoid use if patient is less than 2 years old.**
- Minimizing adverse effects: Decrease the dose when diarrhea becomes less frequent; monitor for signs of atropine overdose (in children) and toxic megacolon.
- Most important patient education: Do not exceed the prescribed dose.

reason, it may also be better tolerated than diphenoxylate HCl with atropine sulfate. If no clinical improvement occurs, loperamide is generally discontinued after 48 hours.

Drugs Significantly Different From P Diphenoxylate HCl with Atropine Sulfate

Bismuth Subsalicylate

Bismuth subsalicylate (Pepto-Bismol, Bismatrol, Pink Bismuth, Kaopectate), a locally acting antidiarrheal, is available without a prescription and is used widely as an antidiarrheal agent. The salicylate component of this drug seems to have an antisecretory effect, whereas the bismuth component has a direct antimicrobial effect against bacteria and viral pathogens in the GI tract. Bismuth subsalicylate is used to treat diarrhea, indigestion, heartburn, nausea, and abdominal cramps. Off-label uses include treating chronic infantile diarrhea and the symptoms of Norwalk virus–induced gastroenteritis, as well as preventing traveler's diarrhea. Bismuth subsalicylate is not given to children or adolescents with viral diseases because of the possibility that the salicylate component may cause Reye syndrome.

Kaolin and Pectin

Kaolin and pectin (Kapectolin) are locally acting antidiarrheals frequently used in combination. These drugs are used widely to treat mild diarrhea, even though clinical studies have not firmly established their effectiveness. These drugs act as absorbents; that is, toxins, bacteria, and other irritants in the GI tract bind to them. Commercial products usually contain two or more adsorbents. For example, Kaopectate is a combination of kaolin and pectin. The adsorptive action is not selective and therefore can interfere with normal GI absorption, particularly absorption of other drugs.

C LAXATIVES

Drugs used to treat constipation are referred to as laxatives. Laxatives are drugs that act directly on the intestine to promote peristalsis and evacuation of the bowel. Laxatives are classified as saline, hyperosmotic, stimulant (irritant), and bulk-forming. Table 37.4 presents a summary of laxative drugs. Stool softeners (surfactants) and emollients (lubricants) are also used to promote easy passage of stool, but they are not technically laxatives.

• C Saline Laxatives

Saline laxatives attract or retain water in the intestinal lumen, resulting in an increased intraluminal pressure that stimulates peristalsis. The increased amount of water also softens fecal material for easier evacuation. The prototype saline laxative is magnesium hydroxide (Milk of Magnesia).

Nursing Management of the Patient Receiving P Magnesium Hydroxide

Core Drug Knowledge

Pharmacotherapeutics

Magnesium hydroxide is used for acute or chronic constipation, preoperatively to prepare the bowel for surgery, and to clear the lower bowel tract before or after radiologic and other diagnostic studies. Magnesium hydroxide also is used as an antacid (see Chapter 36).

Pharmacokinetics

Magnesium hydroxide has a local effect in the lower GI tract and is absorbed poorly. Approximately 15% to 30% of the magnesium in magnesium hydroxide is absorbed in the small intestine. Onset of action is 30 minutes to 3 hours after administration. Low-dose administration produces effects in 6 to 12 hours, whereas high-dose administration produces effects in 2 to 6 hours. Excretion occurs in the kidneys and the GI tract.

Pharmacodynamics

Magnesium hydroxide is a salt. It works in the small and large intestines by attracting and retaining water in the intestinal lumen, thereby increasing pressure within the intestine. The retention of fluid in the intestine results in stimulation of the stretch receptors and an increase in peristalsis, which promotes evacuation of the bowel.

Contraindications and Precautions

Magnesium hydroxide should not be used if the patient has abdominal pain or any symptoms that indicate an acute abdomen (nausea, vomiting, or diarrhea). Magnesium salts must be used with caution in patients with renal failure because retention of magnesium could result in magnesium

TABLE 37.4 Summary of Selected C Laxatives

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
C Saline Laxatives			
P magnesium hydroxide (Milk of Magnesia, Dulcolax)	Constipation, preparation for diagnostic tests of lower GI tract, post-GI diagnostic tests	*Adult:* PO, 30–60 mL/d; 15–30 mL/d if concentrated *Child 2–5 y:* PO, 5–15 mL/d *Child 6–11:* PO, 15–30 mL	*Onset:* 0.5–3 h *Duration:* Unknown $t_{1/2}$: None
magnesium sulfate (Epsom salts)	Same as above	*Adult:* PO, 10–15 g in glass of water *Child:* PO, 5–10 g in glass of water	*Onset:* 0.5–3 h *Duration:* Unknown $t_{1/2}$: None
magnesium citrate (Citrate of Magnesia, Citroma;	Same as above	*Adult:* PO, 240 mL *Child:* PO, 120 mL	*Onset:* 0.5–3 h *Duration:* Unknown $t_{1/2}$: None
sodium phosphate (Fleet, Phospho-Soda, sodium phosphates, OsmoPrep;	Same as above	*Adult:* PO, 20–45 mL mixed in half glass of cool water *Child (5–11 y):* PO, 5–20 mL mixed in half glass of cool water	*Onset:* 0.5–3 h *Duration:* Unknown $t_{1/2}$: None
C Hyperosmotic Laxatives			
glycerin (Sani-Supp, Fleet Babylax)	Constipation	*Adult and child:* Rectal, 1 suppository, retain 15 min (sized for adults and children)	*Onset:* 0.25–1 h *Duration:* Unknown $t_{1/2}$: None
lactulose (Cholac, Constilac, Constulose, Enulose, Generiac, Kristalose)	Constipation	*Adult:* PO, 15–30 mL/d up to 60 mL/d if needed *Child (infant):* PO, 2.5–10 mL in divided doses; older children and adolescents, 40–90 mL	*Onset:* 24–48 h *Duration:* Unknown $t_{1/2}$: None
	Prevention and treatment of portal-systemic encephalopathy, including hepatic precoma and coma	*Adult:* PO, 30–45 mL tid or qid; adjust dose every day or two to produce two or three soft but formed stools; may give hourly doses to induce rapid effect initially *Adult:* rectal, 300 mL in 700 mL water or normal saline solution, retain for 30–60 min; repeat every 4–6 h until patient is awake enough to take oral form	
C Stimulant/Irritant Laxatives			
bisacodyl (Bisac-Evac, Bisacodyl Uniserts, Bisco-Lax, Bisalax, Bisco-Lax, Carter's Little Pills, Correctol, Dacodyl, Dulcolax, Durolax, Feen-a-Mint, Modane, Theralax)	Constipation	*Adult and child > 12 y:* PO, 5–15 mg/d, up to 30 mg/d before diagnostic study *Adult and child > 12 y:* PR, 10 mg/d *Child 2–11 y:* PO/PR, 5–10 mg/d *Child 6 mo–2 y:* PR, 5 mg/d	*Onset:* PO, 6–10 h; PR, 0.25–1 h *Duration:* Unknown $t_{1/2}$: Unknown
cascara sagrada (Cascara Sagrada Fluid Extract Aromatic)	Constipation	*Adult:* PO, 325-mg tablet at bedtime or 5 mL *Child < 12 y:* No recommended dosage	*Onset:* 6–8 h *Duration:* Unknown $t_{1/2}$: None
castor oil (Fleet flavored Castor Oil, Purge, Emulsoil)	Constipation Bowel prep	*Adult:* PO, 15–60 mL *Child 2–12 y:* PO, 5–15 mL	*Onset:* 2–6 h *Duration:* Unknown $t_{1/2}$: None
senna (Senokot, Senexon, Ex-Lax, Senna-Gen, SenokotXTRA, Black Draught, Gentlax, Dr. Caldwell Senna Laxative, Fletcher's Castoria)	Same as above	*Adult:* PO, 1 or 2 tablets, 1–2×/d *Child 6–12 y:* PO, 1 tablet once or twice/d	*Onset:* 6–10 h *Duration:* Unknown $t_{1/2}$: None

TABLE 37.4 Summary of Selected Laxatives *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Bulk-Forming Laxatives			
polycarbophil (FiberCon, Equalactin, Mitrolan, Fiber-Lax, Fiberall)	Constipation or diarrhea associated with conditions such as irritable bowel syndrome and diverticulitis; acute nonspecific diarrhea	*Adult:* PO, 1 g/d to qid; not to exceed 4 g/d; severe diarrhea, repeat every 30 min; not to exceed maximum dose *Child 6–12 y:* PO, 500 mg no more than qid; not to exceed 2 g/d	*Onset:* 12–72 h *Duration:* Unknown $t_{1/2}$: None
psyllium (Fiberall, Hydrocil Instant, Konsyl, Metamucil, natural vegetable powder, Reguloid, Serutan, Syllact, Konsyl-D, Modane Bulk, V-Lax)	Constipation, promotion of regularity	*Adult:* PO, 1 rounded tsp in 8 oz water 1–3×/d	*Onset:* 12–72 h *Duration:* Unknown $t_{1/2}$: None
Methylcellulose (Citrucel)	Constipation	*Adult:* PO, 1 heaping tbsp 1–3×/d *Child:* Not recommended	*Onset:* 12–72 h *Duration:* Unknown $t_{1/2}$: None
Stool Softeners/Surfactants			
docusate sodium (Colace, Disonate, DOK, DOS Softgel, D-S-S, Modane Soft, Pro-Sof, Regular SS, Dioeze, Surfak Liquigels, DC Softgels, Pro-Cal-Sof, Sulfalax Calcium, Diolose, Diocto-K, Kasof)	Softens stool to prevent constipation and straining in defecation	*Adult:* PO, 50–300 mg/d *Child 6–12 y:* PO, 40–150 mg/d 2–4×/d *Child 3–6 y:* PO, 20–60 mg/d 2–4×/d *Child <3 y:* PO, 10–40 mg/d 2–4×/d	*Onset:* 12–72 h *Duration:* Unknown $t_{1/2}$: None
Emollient Laxatives			
mineral oil (Fleet Mineral Oil Enema, Kondremul, Liqui-Doss)	Constipation	*Adult:* PO, 15–45 mL/d *Child 6–12 y:* PO, 5–15 mL/d	*Onset:* 6–8 h *Duration:* Unknown $t_{1/2}$: None
Bowel Evacuants			
polyethylene glycol-electrolyte solution (PEG-ES) (Colyte, GoLYTELY, NuLYTELY, TriLyte, MoviPrep;	Bowel prep	*Adult:* PO, 240 mL every 10 min until 4 L consumed or effluent is clear; may be given through nasogastric tube, 20–30 mL/min	*Onset:* 1–2 h *Duration:* About 4 h $t_{1/2}$: None
Peripherally Selective Mu (m) Opioid Receptor Antagonist			
alvimopan (Entereg)	Postoperative ileus	*Adult:* PO, 12 mg 30min-5 h prior to surgery, then 12 mg 2x/d for up to 15 doses	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 10–17 h
methylnaltrexone (Relistor)	Opioid-Induced Constipation	*Adult:* SC <38 kg: 0.15 mg/kg every other day 38–61 kg: 8 mg every other day 62–114 kg: 12 mg every other day >114 kg: 0.15 mg/kg every other day	*Onset:* unknown *Duration:* unknown $t_{1/2}$: 8 h

TABLE 37.5 Agents That Interact with P Magnesium Hydroxide

Interactants	Effect and Significance	Nursing Management
Chloroquine	Magnesium may decrease absorption of chloroquine.	Separate administration of these drugs by 2 h.*
dicumarol	Magnesium may increase anticoagulant activity of dicumarol.	Monitor PT/INR. Monitor for bruising or bleeding.
digoxin	Magnesium may physically absorb digoxin in GI tract.	Monitor serum digoxin levels. Monitor for efficacy of digoxin therapy.
Fluoroquinolones	Magnesium may decrease absorption of fluoroquinolones.	Monitor for efficacy of fluoroquinolone therapy.
Ketoconazole	Magnesium may reduce tablet dissolution of ketoconazole.	Monitor for efficacy of ketoconazole therapy.
levodopa	Magnesium decreases gastric emptying times, allowing for more rapid and complete intestinal levodopa absorption.	Monitor for levodopa toxicity.
nifedipine	Neuromuscular blockade and hypotension have occurred with coadministration of nifedipine and magnesium.	Monitor blood pressure. Ensure safety.
Nitrofurantoin	Magnesium may absorb nitrofurantoin, decreasing its bioavailability.	Monitor for efficacy of nitrofurantoin.
penicillamine	Poor GI absorption of penicillamine may be result of chelation or adsorption with magnesium.	Administer penicillamine on an empty stomach.
Quinidine	Inhibition of excretion of quinidine, possibly leading to increased effect.	Monitor for arrhythmias.
salicylates	Magnesium-induced increase in urinary pH reduces renal reabsorption of salicylates, increasing their clearance.	Monitor for efficacy of salicylate therapy.
Tetracyclines	Binds to surface of tetracycline, preventing absorption, decreasing effect.	Monitor for efficacy of tetracycline therapy.
Ticlopidine	Decreases effect of ticlopidine	Monitor for bruising or bleeding.

*Whenever possible, magnesium hydroxide administration should be separated by 2 hours from that of any other drug in this table.

toxicity. Safe use in children younger than 2 years of age has not been established. Large doses in pregnancy may lead to serious fluid and electrolyte imbalances.

Adverse Effects

Adverse effects can occur with large doses. Overactive bowel (marked by cramps, diarrhea, or nausea) is the primary adverse effect. Fluid and electrolyte imbalance can occur with large doses given frequently.

Drug Interactions

Magnesium hydroxide may decrease or increase the effects of many drugs. Table 37.5 lists agents that interact with magnesium hydroxide.

Assessment of Relevant Core Patient Variables

Health Status

Determine whether the patient receiving magnesium salts has a history of renal insufficiency. Before drug administration, listen for bowel sounds, palpate for abdominal distention, and ask questions about the patient's usual pattern of bowel function. Be sure to determine whether the patient is receiving drug therapy that may interact with magnesium hydroxide.

Life Span and Gender

Determine the patient's age before administering magnesium hydroxide. The patient must be at least 2 years of age to receive magnesium hydroxide. Older adults may have weakened abdominal muscles and decreased peristalsis related to aging. They also may engage in less regular activity and eat fewer foods containing roughage. All of these factors may contribute to constipation.

Lifestyle, Diet, and Habits

Determine whether the patient's normal fluid intake is adequate (at least between 1,000 and 1,500 mL daily); whether the normal diet includes an adequate amount of fruits, vegetables, and roughage; and whether the patient engages in any regular physical activity. Assess whether the patient must frequently ignore the urge to defecate because of lifestyle patterns. These variables can contribute to constipation. In addition, it is important to determine whether the patient uses laxatives regularly because chronic use of laxatives may lead to dependency on the laxative to expel a bowel movement.

Environment

Magnesium hydroxide is sold OTC, and patients frequently self-medicate for constipation. The drug also is used in acute care settings before rectal and colonic examinations, diagnostic tests, or operations. Patients in an inpatient facility frequently are less active than when they are at home, which can contribute to constipation. Thus, magnesium hydroxide also may be used in a hospital setting to prevent constipation.

Culture and Inherited Traits

Cultural and social variations exist regarding how frequently bowel movements should occur for the individual to be considered regular or constipated. Ascertain what the patient means by normal elimination and constipation.

Nursing Diagnosis and Outcome

- Constipation related to dietary factors, fluid restrictions, decreased peristalsis, lack of activity, changes in activity, postoperative state, GI disease or malfunction, or adverse effects from other drug therapy.
  Desired outcome: *The patient will have a bowel movement after taking magnesium hydroxide.*

Planning and Intervention

Maximizing Therapeutic Effects

After taking magnesium hydroxide, the patient should follow with a full glass of water to prevent dehydration and to promote a more rapid effect.

Minimizing Adverse Effects

To prevent fluid and electrolyte imbalance, use of magnesium hydroxide should be limited to short-term treatment of constipation. Administer magnesium hydroxide with caution, if at all, in patients with renal disease. At least 2 hours should pass between administration of magnesium hydroxide and drugs that are known to interact with it.

Providing Patient and Family Education

- Teach patients that magnesium hydroxide should be used for short-term use only and that long-term use may cause electrolyte imbalance and dependency on laxatives (Box 37.3).
- Caution patients not to take magnesium hydroxide within 2 hours of drugs that may interact with it.

Ongoing Assessment and Evaluation

Assess color, consistency, and amount of stool produced to monitor effectiveness of magnesium hydroxide.

Drugs Closely Related to P Magnesium Hydroxide

Other Saline Laxatives

Magnesium sulfate (Epsom salts), magnesium citrate (Citrate of Magnesia), and sodium phosphate (Phospho-Soda) are all saline laxatives similar to magnesium hydroxide. Like magnesium hydroxide, both magnesium sulfate and magnesium citrate are contraindicated for patients with renal dysfunction. Sodium phosphate is contraindicated for patients with disorders that are exacerbated by an increased fluid volume such as chronic heart failure, hypertension, or significant edema. Pharmacologic indications, adverse effects, and patient management are similar to those of magnesium hydroxide.

BOX 37.3 COMMUNITY BASED CONCERNS

Educating Patients in the Community About Laxative Use

Individual misuse of OTC and prescription laxatives is encountered commonly by nurses practicing in the community. Nurses have a vital educational role to play in this area by providing teaching programs for individuals or groups. These programs may focus on general principles of elimination and bowel health so that patients learn to use laxatives responsibly and to avoid laxative abuse. A general teaching program may include the following features:

- Assessing elimination patterns. Teach patients how to assess their own usual habits and daily elimination routines to identify what is a "normal bowel movement" pattern for them.
- Defining normality. Show patients how to analyze their assessment findings and recognize patterns that are normal for the individual. Emphasize that what is normal for one person may not be normal for another.
- Eating to promote regularity. Identify dietary measures that promote peristalsis and regular bowel movement. Emphasize adequate fluid intake of 1,000 to 2,000 mL/d and fiber-rich foods, such as whole-grain breads, cereals, and vegetables, and fluids, such as pulpy fruit juices.
- Exercising to promote regularity. Assist patients to incorporate regular exercise into their daily activities. Explain how exercise promotes peristalsis and regular bowel movements.
- Dealing with altered elimination patterns. Teach patients to observe for changes in the normal pattern, form, and color of stools. Help them decide when occasional use of laxatives, preferably bulk or stimulant types, may be appropriate and when medical attention may be advisable. Also point out the potential for dependence on laxatives and the disadvantages of dependence.

C Hyperosmotic Laxatives

The hyperosmotics act similarly to the saline laxative magnesium hydroxide. Drugs in this laxative subclass include lactulose (Cephulac, Cholac, Chronulac, Constilac, Constulose, Duphalac, Enulose) and glycerin suppository (Sani-Supp, Colace, Fleet Babylax).

Like the saline laxative magnesium hydroxide, lactulose pulls water into the colon. Unlike magnesium hydroxide, lactulose is a synthetic disaccharide of lactose. In the colon, lactulose is metabolized by bacteria into acids and carbon dioxide. These products increase the oncotic pressure in the colon and draw water into the stool. The acids formed also draw ammonia into the stool for evacuation. Because of this action, lactulose is used to decrease blood ammonia levels in hepatic coma and hepatic encephalopathy in addition to its use for constipation. Lactulose also can be given by enema.

MEMORY CHIP

P Magnesium Hydroxide

- Laxative for short-term use. Works by pulling water into the bowel by distending it and promoting peristalsis.
- Major contraindications: signs of an acute abdomen and renal failure
- Most common adverse effect: overactive GI activity
- Most serious adverse effect: fluid and electrolyte imbalance (large, frequent doses only)
- Maximizing therapeutic effects: Follow administration with a glass of water.
- Most important patient education: Magnesium hydroxide is not for long-term use.

Glycerin suppositories are inserted into the rectum. They pull moisture into the bowel and provide local irritation to stimulate a bowel movement. Glycerin suppositories are considered a very gentle laxative.

Drugs Significantly Different From P Magnesium Hydroxide

Stimulant (Irritant) Laxatives

Stimulant laxatives include bisacodyl (Bisac-Evac, Bisacodyl Uniserts, Bisacolax, Bisalax, Bisco-Lax, Carter's Little Pills, Correctol, Dacodyl, Dulcolax, Durolax, Feen-a-Mint, Modane, Theralax), cascara sagrada (Cascara Aromatic, Aromatic Cascara Fluid Extract), senna (Senokot, Senexon, Ex-Lax, Cenalax, Senna-Gen, Black Draught, Gentlax, Dr. Caldwell Senna Laxative, Fletcher's Castoria), and castor oil (Purge, Emulsoil, and Neoloid). Therapeutic uses are similar to those for magnesium hydroxide. These laxatives have a direct stimulatory effect on the intestinal mucosa or nerve plexus and increase peristalsis. They also alter water and electrolyte secretion. They all work in the colon, with the exception of castor oil, which works in the small intestine. Stimulant laxatives are the most frequently abused type of laxative. Chronic use may induce loss of normal bowel function and laxative dependency. They are contraindicated for use in patients with fecal impaction or obstipation (severe obstruction of fecal flow through the bowels).

C Bulk-Forming Laxatives

Bulk-forming (fiber) laxatives are considered the safest and most physiologic of the laxatives. They include polycarbophil (FiberCon, Equalactin, Mitrolan, Fiber-Norm, and Konsyl Fiber), psyllium (Fiberall, Genfiber, Metamucil, Hydrocil Instant, Konsyl, Natural Fiber Laxative, Reguloid, Serutan, Syllact, Modane Bulk, and Perdiem Fiber Therapy), and methylcellulose (Citrucel). Bulk-forming laxatives pass through the body undigested. The fibers attract water to the large and small intestine, and they absorb the water and swell to form a soft, bulky stool. The bulky mass stimulates the intestinal muscles and increases peristalsis. Their onset of action, normally 12 to 24 hours but rarely up to 72 hours, is more prolonged than that of the saline laxative magnesium hydroxide. Some of these preparations contain sodium and therefore must be used cautiously in patients for whom excess sodium can cause problems (e.g., patients with chronic heart failure or hypertension). Psyllium also appears to be useful in reducing cholesterol levels as an adjunct therapy to dietary control, although this use is off-label. In addition to its laxative use, polycarbophil can be used for diarrhea because it absorbs free fecal water and produces formed stools. Patients should be cautioned to increase fluid intake while taking bulk-forming laxatives. They will not work without increased fluid intake and can complicate constipation.

C Stool Softeners

Docusate is a stool softener (surfactant). It has detergent activity and facilitates the addition of fat and water into the stool to soften it. It does not stimulate peristalsis. It is used prophylactically to prevent constipation in patients who are at risk for developing it, such as elderly patients after orthopedic surgery or patients for whom straining at stool is contraindicated (e.g., after myocardial infarction, eye surgery, or anorectal surgery).

Docusate is available in two formulations, either as docusate sodium (Colace, D-S-S, Modane Soft, Regulax SS, Diocto, Ex-lax Stool Softener, Non Habit Forming Stool Softener, Stool Softener, Genasoft, Phillips Liqui-Gels, Docu, and Silace) or as docusate calcium (Surfak, DC Softgels).

C Emollient (Lubricant) Laxatives

Mineral oil (Fleet Mineral Oil Enema, Kondremul, Liqui-Doss) is an emollient (lubricant) laxative. It is also used as an enema in fecal impaction. Mineral oil lubricates the intestine and retards colonic absorption of water. The stool is thus softened because it contains more water. Because of its coating action, mineral oil may decrease absorption of fat-soluble vitamins. This is especially important for patients receiving warfarin because the patient is at risk of bleeding when decreased vitamin K stores affect the clotting mechanism.

C Bowel Evacuants

Polyethylene Glycol-Electrolyte Solution (PEG-ES) is used not to treat constipation, but rather for bowel cleansing in preparation for GI examinations. PEG-ES is a combination of a nonabsorbable osmotic agent (polyethylene glycol) and an electrolyte solution containing potassium chloride, sodium chloride, sodium sulfate, and sodium bicarbonate. This combination results in practically no net absorption or excretion of ions or water, thus allowing for bowel evacuation while maintaining fluid and electrolyte balance. PEG-ES is used cautiously in patients with ulcerative colitis. Common adverse effects include anal irritation, bloating, epigastric fullness, nausea, stomach cramps, and vomiting.

BOX 37.4 FOCUS ON RESEARCH

Management of Opioid Induced Constipation

Chamberlain, B. H., Cross, K., Winston, J. L., Thomas, J., Wang, W., et al. (2009). Methylnaltrexone treatment of opioid-induced constipation in patients with advanced illness. *Journal of Pain and Symptom Management,* 38(5):683–690.

The Study

Opioid-induced constipation is a frequent complication for patients in the advanced stages of terminal diseases. Researchers conducted a double blind study comparing the effects of methylnaltrexone with placebo in 27 nursing homes. The study included 134 patients, with advanced disease defined as a terminal condition or end stage cancer, who had been on opioids for at least two weeks. Methylnaltrexone was found to induce a bowel movement within four hours of administration, with no effect on pain control. Because this drug has limited effect on the central nervous system, it is an acceptable option for those patients who develop severe constipation secondary to opioid administration.

Nursing Implications

This study provides evidence for management of constipation for patients in the late stages of terminal disease, where palliation and comfort are priorities. The results of this study found that methylnaltrexone was effective in inducing a bowel movement without affecting pain control. This treatment also decreased other uncomfortable procedures often associated with opioid induced constipation, including enemas.

C Peripherally Selective Mu (μ) Opioid Receptor Antagonist

Post-operative ileus and opiate induced bowel dysfunction (OBID) are treated with peripherally selective μ opioid receptor antagonists, such as alvimopan (Entereg) or methylnaltrexone (Relistor). These drugs act by blocking the μ opioid receptors, resulting in improved gastrointestinal motility. Alvimopan should only be administered in a hospital, and be limited to 15 doses. A major advantage of alvimopan is its ability to selectively block opioid receptors in the gastrointestinal system, with little to no effect in the central nervous system (CNS) secondary to its low systemic absorption and limited ability to cross the blood–brain barrier and enter the CNS. The health care provider should be made aware if any of the following side effects occur secondary to the administration of alvimopan: gas, constipation, heartburn, difficulty urinating, or back pain.

Methylnaltrexone (Relistor) was approved by the FDA in 2008 to treat opioid related constipation and ileus, and has been used with patients undergoing palliative therapy (Kyle, 2009). Intended for subcutaneous injection, the dose is based on the weight of the patient. This drug is to be used in combination with more conventional treatments for constipation, including laxatives. Methylnaltrexone must be discontinued when the opiates for pain control are discontinued. Common side effects of this drug include abdominal pain, flatus, nausea, dizziness, and diarrhea. The administration of methylnaltrexone longer than 4 months has not been extensively evaluated (Box 37.4).

DRUGS USED TO TREAT IRRITABLE BOWEL SYNDROME

Serotonin receptors in the bowel play a role in bowel motility and visceral sensations perceived from the bowel. Drugs that work at these receptors can alter symptoms of IBS such as diarrhea, constipation, and abdominal pain. Blockade of serotonin receptor subtype 3 (5-HT_3) decreases the diarrhea associated with IBS. The prototype drug for this group is alosetron (Lotronex). Table 37.6 presents a summary of drugs used to treat IBS.

Nursing Management of the Patient Receiving P Alosetron

Core Drug Knowledge

Pharmacotherapeutics

Alosetron is the only drug approved in the United States for the treatment of women with IBS-D. It is administered orally. Its use is restricted to those with severe symptoms that have not responded to other therapies. It is not used

TABLE 37.6 Summary of Selected Drugs to Treat Irritable Bowel Syndrome

Drug (Trade) Name	Selected Indication	Route and Dosage Range	Pharmacokinetics
P alosetron (Lotronex)	IBS-D	PO, 1 mg daily; may increase to 1 mg bid after 4 wk if needed	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: Elimination, 1.5 h; pharmacodynamic, 6–10 h
dicyclomine (Bentyl)	IBS	*Adult and Child > 12 y:* 20 mg 4×/d *Child 2–12 y:* PO, 10 mg 3×/d *Child 6 mo–2 y:* PO, 5–10 mg 3×/d	*Onset:* 1–2 h *Duration:* 4 h $t_{1/2}$: 9–10 h
lubiprostone (Amitiza)	IBS-C, chronic idiopathic constipation	*Adult:* PO, 24 mcg 2∞/d with food *Child:* Not recommended	*Onset:* Rapid *Duration:* Unknown $t_{1/2}$: 0.9–1.4 h

in patients who have any degree of constipation from IBS. IBS-D is considered severe if it includes diarrhea and one or more of the following: frequent and severe abdominal pain or discomfort, frequent bowel urgency or fecal incontinence, or disability or restriction of daily activities caused by IBS. Less than 5% of IBS cases are considered severe.

Pharmacokinetics

Alosetron is rapidly absorbed. The oral availability of alosetron is about 60%. Absorption is decreased by about 25% when it is taken with food, but the drug can be taken with or without food. The presence of food delays the peak by about 15 minutes. Men achieve a 30% to 50% lower serum concentration than women who receive the same dose. Alosetron is moderately protein bound at 82%. Although the elimination half-life is 1.5 hours, the pharmacodynamic half-life is much longer at 6 to 10 hours. Alosetron is extensively metabolized by the P-450 isoenzymes (predominantly CYP2C9, and to a lesser extent, CYP3A4 and CYP1A2). Most of the drug is excreted as metabolites by the kidneys, and the rest is lost in the stool.

Pharmacodynamics

Alosetron blocks the 5-HT_3 receptor. It alters visceral sensation, decreasing abdominal discomfort and pain. It also lengthens the transit time in the bowel and decreases chloride and water secretion, which help control diarrhea in IBS.

Contraindications and Precautions

Alosetron should not be administered to anyone with IBS-C. Alosetron is also contraindicated for anyone with a history of chronic or severe constipation or with a history of sequelae from constipation; a history of intestinal obstruction, stricture, toxic megacolon, GI perforation, or adhesions; a history of ischemic colitis, impaired intestinal circulation, thrombophlebitis, or hypercoagulable state; a history of or current Crohn disease or ulcerative colitis; or a history of or active diverticulitis. Alosetron is also contraindicated in patients who are unable to understand or comply with the Patient–Physician Agreement or who have a known hypersensitivity to any component of the product.

Alosetron is a pregnancy category B drug. Whether it is excreted into breast milk is unknown; therefore, it must be used with caution. Because alosetron is extensively metabolized in the liver, patients with poor liver function are likely to have increased circulating levels of alosetron. No studies have been done on this phenomenon, but caution is warranted because these patients may be at increased risk for adverse effects.

Adverse Effects

The major adverse effect of alosetron is constipation, occurring in 22% to 39% of patients who received the drug during clinical trials. Most of the time, constipation is mild to moderate and stops either spontaneously or after an interruption in drug therapy. Constipation can be severe in some patients, possibly even necessitating hospitalization or surgery for removal of part or all of the colon (colectomy). Serious complications of constipation include obstruction, perforation, impaction, and toxic megacolon. These patients are also at risk for ischemic colitis, which is a serious complication and potentially fatal, although rare. The signs of ischemic colitis include rectal bleeding, bloody diarrhea, and new or worsening abdominal pain. Alosetron was first approved and originally available in February 2000 but was taken off the market in November 2000 because of reports of eight possible cases of ischemic colitis. Owing to a large and rather unexpected public outcry over the withdrawal of the drug, the Food and Drug Administration (FDA) reviewed additional material and eventually reapproved the drug in June 2002. Use of the drug is now severely restricted because of these potential adverse effects. To prescribe the drug, physicians must have completed an educational training session, use special stickers on prescriptions, fully inform the patient about the potential risks, and obtain a signed consent form from the patient. The incidence of complications from alosetron is somewhat controversial because a large research study conducted after the drug was first put on the market did not find that alosetron users were at greater risk for bowel surgery or hospitalization caused by constipation than those patients not taking alosetron.

Drug Interactions

No important drug interactions with alosetron have been identified. Alosetron does not appear to inhibit the hepatic metabolism of drugs metabolized by the major P-450 enzymes.

Assessment of Relevant Core Patient Variables

Health Status

Assess whether the patient has IBS-D. Patients should not have IBS-C or any bowel problems that are considered contraindications for therapy. Assess whether the patient has liver disease or poor liver function, which may place the patient at increased risk for adverse effects. Assess whether the patient is generally debilitated or taking other medications that may slow GI motility. These factors may also increase the risk of adverse effects from alosetron.

Life Span and Gender

Assess the patient's age. The effectiveness of alosetron has not been established in pediatric patients. Older adults may be at increased risk for constipation. Alosetron is a pregnancy category B drug. Because it is not known whether the drug is excreted in breast milk, if the patient is breastfeeding, the infant should be cautiously monitored for signs of complications. The safety and effectiveness of alosetron cannot be determined in men, because few men were included in the clinical trials for the drug. Women are more likely than men to experience a positive effect from alosetron.

Nursing Diagnosis and Outcome

- Risk for Altered Elimination, Constipation, related to potential adverse effect of alosetron
  Desired outcome: *The patient will not develop serious constipation while on alosetron.*

Planning and Intervention

Maximizing Therapeutic Effects

No specific actions are recommended to maximize the therapeutic effects of alosetron.

Minimizing Adverse Effects

Confirm that the patient has received the Medication Guide from the prescriber before starting therapy and has read it and understands it. Answer any questions the patient may have regarding drug therapy and its potential adverse effects or contact the prescriber to answer patient questions. Confirm that the medical record contains the signed Patient–Physician Agreement and that the patient has a copy of this agreement. If the patient develops any constipation or signs of ischemic colitis, alosetron therapy should be discontinued at once. Although treatment can be resumed under medical direction for patients with constipation, it should not be resumed if the patient develops ischemic colitis.

Providing Patient and Family Education

- Help educate patients about the potential adverse effects of alosetron. If needed, repeat or clarify information that the prescribing physician was required to provide. Provide answers to any additional patient questions.
- Because the contents of the Medication Guide may change, emphasize to patients that they need to read the entire Medication Guide each time they get a prescription for alosetron.
- Instruct patients to report any constipation or signs of ischemic colitis (rectal bleeding, bloody diarrhea, or new or worsening abdominal pain) immediately.
- To help prevent or minimize constipation, encourage patients to drink sufficient fluids daily.

Ongoing Evaluation and Assessment

Assess the patient throughout alosetron therapy for constipation. Drug therapy is considered effective if the symptoms of IBS are decreased and the patient does not develop serious complications.

MEMORY CHIP

P Alosetron

- Used to treat women with severe IBS, diarrhea type
- Works by blocking a specific serotonin receptor (5-HT4) to decrease bowel motility, bowel secretions, and abdominal pain and discomfort
- Major contraindication: constipation
- Most common adverse effect: constipation
- Most serious adverse effects: ischemic colitis, severe constipation
- **Life span alert: effectiveness in men not yet known**
- Minimizing adverse effects: Discontinue drug if patient develops constipation or signs of ischemic colitis; do not resume drug therapy if patient develops ischemic colitis.
- Most important patient education: Read Medication Guide every time a prescription is filled; contact prescriber at once if constipation or signs of ischemic colitis develop.
- **Black box warning: Risk for serious GI adverse effects; only indicated for women with severe diarrhea-predominant IBS without adequate response to conventional therapies; prescribers must enroll in Prometheus Prescribing Program**

Drugs Significantly Different From P Alosetron

Dicyclomine

Dicyclomine (Bentyl) is an antispasmodic that is commonly prescribed for IBS. It works by blocking the action of acetylcholine at parasympathetic sites in secretory glands, smooth muscle, and the CNS. Dicyclomine is contraindicated for patients with obstructive uropathy, myasthenia gravis, glaucoma, GI tract obstruction, paralytic ileus, and toxic megacolon. It is given cautiously to patients with hepatic or renal insufficiency, cardiovascular disease, hyperthyroidism, or hypertension. Dicyclomine may cause sedation, constipation, urinary retention, tachycardia, blurred vision, dry mouth, or dizziness. Children 3 months of age and younger have been reported to experience respiratory distress, seizures, syncope, asphyxia, pulse rate fluctuation, muscular hypotonia, and coma within minutes of ingesting dicyclomine. These effects appear to be a result of local irritation or aspiration rather than the drug itself. However, because of these possible problems, dicyclomine should not be used in infants younger than 3 months of age.

Laxatives and Antidiarrheals

Laxatives, bulk agents, and antidiarrheals are sometimes also prescribed for symptoms of IBS and have already been discussed in this chapter.

Selective Chloride Channel Activator

Lubiprostone (Amitiza) is used in the treatment of chronic idiopathic constipation. It works by activating chloride channels on the apical part of the small bowel epithelium that results in a secretion of chloride ions. Sodium and water passively diffuse into the lumen to maintain isotonicity. The drug is contraindicated for use in patients with a history of mechanical GI obstruction or in those with a suspected obstruction. Common adverse effects include headache, abdominal distention, abdominal cramps, diarrhea, and flatulence. Lubiprostone is a pregnancy category C drug and is not recommended for use in children.

Tricyclic Antidepressants

Imipramine (Tofranil) and amitriptyline (Elavil) are tricyclic antidepressants used to manage IBS. They provide

visceral analgesia by increasing the pain threshold in the GI system, thus reducing abdominal pain, mucorrhea, and stool frequency. The dose used for IBS is subtherapeutic for depression. Imipramine is contraindicated for patients with narrow-angle glaucoma, those in the acute recovery phase following myocardial infarction, and those who started taking MAOIs less than 2 weeks previously. Amitriptyline is also contraindicated for patients taking MAOIs as well as patients with a history of seizures, cardiac arrhythmias, glaucoma, and urinary retention. Both drugs may impair mental or physical abilities required for concentration and performance of hazardous tasks. They may also cause sedation, confusion, constipation, tachycardia, orthostasis, blurred vision, and dry mouth. Tricyclic antidepressants are fully discussed in Chapter 19.

DRUGS USED TO TREAT INFLAMMATORY BOWEL DISEASE

Drug therapy cannot cure IBD, but it is effective in reducing inflammation and symptoms of the disease in up to 80% of patients. The drug groups used to treat IBD include the 5-aminosalicylic acid (5-ASA) preparations, corticosteroids, and drugs that suppress the immune system (Table 37.7). Some antibiotics are also used in mild to moderate disease. Corticosteroids are discussed in Chapter 48, and drugs that suppress the immune system are discussed in Chapter 54. One drug that suppresses the immune system and has a role in treating IBD is infliximab.

• C 5-ASA Preparations

Aminosalicylates (5-ASA) are the anti-inflammatory drugs most commonly prescribed for IBD. A recent review of the literature suggests that this group of drugs offers some protection against the development of colon cancer in patients with IBD. This finding is a positive one, because the sites of chronic inflammation with IBD are associated with an increased risk of developing cancer. The prototype 5-ASA preparation is mesalamine (Asacol, Pentasa, Lialda)

Nursing Management of the Patient Receiving P Mesalamine

Core Drug Knowledge

Pharmacotherapeutics

Mesalamine is approved for use for patients with ulcerative colitis and proctosigmoiditis. It is used off-label for the management of Crohn disease.

Pharmacokinetics

Mesalamine is available in tablet, capsule, extended release capsule, suppository, and rectal suspension formulations. Oral bioavailability is 20% to 30%; rectal bioavailability is 10% to 35%. Both formulas are metabolized in the liver. Oral drugs are also metabolized in the intestinal mucosal wall and rectal formulas in the colonic epithelium. Mesalamine is excreted in feces.

Pharmacodynamics

The action of mesalamine is unknown. Mucosal production of arachidonic acid metabolites is increased in patients with IBD through both the cyclooxygenase and lipoxygenase pathways. Mesalamine is thought to inhibit these pathways, thereby decreasing the production of prostaglandins, leukotrienes, and hydroxyeicosatetraenoic acids.

Contraindications and Precautions

Mesalamine is contraindicated for patients with a hypersensitivity to salicylates or with active peptic ulcer disease. It is

TABLE 37.7 Summary of Selected Drugs to Treat Inflammatory Bowel Disease

Drug (Trade) Name	Selected Indication	Route and Dosage Range	Pharmacokinetics
P mesalamine (Asacol, Pentasa, Rowasa, Lialda)	Ulcerative colitis	*Oral tablet:* 800 mg tid for 6 wk *Oral capsule:* 1 g qid up to 8 wk *Extended release capsule (Apriso):* 1.5 g daily *Oral tablet (Lialda):* 2.4 g once daily *Suppository:* 500 mg bid for 3–6 wk *Enema:* 4 g rectally at bedtime for 3–6 wk	*Onset:* Oral, unknown; rectal, 3–21 d *Duration:* Unknown $t_{1/2}$: Oral, 2–15 h; rectal: 5–10 h
balsalazide (Colazal)	Ulcerative colitis	*Adult:* PO, 2.25 g tid for 8–12 wk	*Onset:* Within 1 h *Duration:* Unknown $t_{1/2}$: Unknown
sulfasalazine (Azulfidine, Azulfidine Entabs)	Ulcerative colitis Rheumatoid arthritis	*Ulcerative colitis:* PO, 1 g tid–qid *Rheumatoid arthritis:* 500 mg to 2 g/d in 2–4 divided doses	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 5.7–10 h
Certolizumab (Cimzia)	Crohn's Disease	*Crohn's disease:* SQ, 400 mg initially and then at wk 2, 4 and then every 4 wk as maintenance	*Onset* *Duration*
	Rheumatoid arthritis	*Rheumatoid Arthritis:* 400 mg initially and then at wk 2, 4 and then 200 mg every other weeks.	

TABLE 37.8 Agents That Interact with P Mesalamine

Interactants	Effect and Significance	Nursing Management
thiopurines	Mesalamine may inhibit thiopurine-metabolizing enzyme, thiopurine methyltransferase.	Monitor for leukopenia.
Warfarin	Anticoagulant effect of warfarin may be decreased; mechanism is unknown.	Monitor PT/INR.

used cautiously in patients with renal and hepatic impairment and in women who are pregnant or breast-feeding. Mesalamine is a pregnancy category B drug.

Adverse Effects

Common adverse effects of mesalamine include diarrhea, abdominal pain, cramps, flatulence, nausea, and headache. Serious, but rare, adverse effects include blood dyscrasias, exacerbation of colitis, pericarditis, renal impairment, and hepatotoxicity.

Drug Interactions

Mesalamine interacts with thiopurines such as azathioprine and mercaptopurine. It also interferes with salicylates (Table 37.8).

Assessment of Relevant Core Patient Variables

Health Status

Assess for hypersensitivity to salicylates or sulfites prior to administration. Mesalamine contains potassium metabisulfite, so a hypersensitivity reaction may occur in patients with sulfite hypersensitivity. Evaluate reflexes, affect, urinary output, and thyroid and renal function tests. Evaluate hair pattern; hair loss may occur but is generally mild and transient. Communicate positive findings to the health care provider.

Life Span and Gender

Mesalamine is a pregnancy category B drug. It is contraindicated for women who are pregnant or breast-feeding. It is not approved for use in children.

Nursing Diagnoses and Outcomes

- Risk for Altered Elimination, Constipation, related to potential adverse effect of mesalamine
  Desired outcome: *The patient will not develop serious constipation while on mesalamine.*
- Acute pain related to drug induced adverse GI effects.
  Desired outcome: *The patient will take acetaminophen for pain as needed.*

Planning and Intervention

Maximizing Therapeutic Effects

To administer mesalamine as an enema or suppository, assist the patient into a side-lying position on his or her left side (to facilitate migration of the drug into the sigmoid colon) or a knee–chest position, whichever is most comfortable. Prior to administering the enema, shake the bottle thoroughly. Handle the suppository as little as possible, because it melts at body temperature. Explain the importance of retaining the enema for 8 hours and the suppository for 3 hours.

Minimizing Adverse Effects

Administer the oral medication at even intervals throughout the day. Be sure the patient does not crush or chew the capsules or tablets.

Providing Patient and Family Education

- Educate patients about the potential adverse effects of mesalamine.
- Instruct patients to stop taking the drug if fever or rash occurs.
- Instruct patients how to administer an enema if ordered. Be sure they understand that the goal is to retain the enema for 8 hours.
- Instruct patients to limit handling of the suppository to avoid melting.
- Instruct patients to swallow capsules and tablets whole; emphasize the patient should not to crush or chew oral forms of mesalamine.
- To help prevent or minimize constipation, encourage patients to drink sufficient fluids daily.

Ongoing Evaluation and Assessment

Assess the patient throughout mesalamine therapy for relief of pain. Drug therapy is considered effective if the symptoms of IBD are decreased and the patient does not develop serious complications.

Drugs Closely Related to P Mesalamine

Balsalazide

Balsalazide (Colazal), the newest IBD drug, is delivered intact into the colon, where it is cleaved to release mesalamine. More free and active mesalamine is delivered by balsalazide than by the other preparations. Balsalazide is used in the treatment of mildly to moderately active ulcerative colitis. It should not be used in patients with sensitivity to aspirin. The most common adverse effect is headache, followed by abdominal pain, nausea, and diarrhea. Balsalazide is a safe and effective first-line drug for treating ulcerative colitis.

MEMORY CHIP

P Mesalamine

- Used to treat IBD
- Works by decreasing the production of prostaglandins, leukotrienes, and hydroxyeicosatetraenoic acids.
- Major contraindication: hypersensitivity to salicylates and sulfites
- Most common adverse effects: GI effects and headache
- Most serious adverse effects: blood dyscrasias, exacerbation of colitis, pericarditis, renal impairment, and hepatotoxicity
- Minimizing adverse effects: Ensure the oral formulation is swallowed whole.
- Most important patient education: Contact the health care provider if fever or rash occurs.

Olsalazine

Olsalazine (Dipentum) is used to maintain remission of ulcerative colitis when the patient is intolerant to sulfasalazine. It is a sodium salt of a salicylate compound that is bioconverted to mesalamine in the colon by bacteria. The very slow absorption rate from the colon results in very high local concentrations in the colon. Olsalazine produces diarrhea in approximately 17% of patients taking the drug, a finding that may be difficult to distinguish from the diarrhea caused by IBD.

Sulfasalazine

Sulfasalazine (Azulfidine) is used to treat ulcerative colitis; it also is used to treat rheumatoid arthritis. It is a combination of mesalamine (5-ASA) and sulfapyridine, a sulfa antibiotic that prevents mesalamine from being absorbed until it reaches the colon. In the colon, the intestinal bacteria break sulfasalazine into the two main components. The sulfapyridine plays no active role in the treatment of IBD, and all of the therapeutic effects come from the mesalamine. Because of its sulfa component, sulfasalazine should not be used in people allergic to sulfa. The sulfa component accounts for most of the adverse and allergic reactions in up to 33% of the people who take the drug. These common adverse effects are heartburn, headache, loss of appetite, nausea, vomiting, and temporarily lower sperm count in men. Sulfasalazine also may turn the urine bright orange-yellow. Rare but serious adverse effects include a lupus-like disorder, pancreatitis, liver damage, and potentially life-threatening blood disorders (including aplastic anemia, leukopenia, and neutropenia).

Drug Significantly Different From P Mesalamine

Infliximab

Infliximab (Remicade) is an immune response modulator used to treat moderate to severe Crohn disease or ulcerative colitis, as well as ankylosing spondylitis. In combination with methotrexate, it is used for severe active rheumatoid arthritis and psoriatic arthritis. It reduces the signs and symptoms of IBD, induces and maintains clinical remission in patients with moderate to severe IBD, and reduces the number of draining enterocutaneous fistulas associated with Crohn disease. Infliximab is a monoclonal antibody produced using recombinant technology. It neutralizes the biological activity of tumor necrosis factor-alpha by inhibiting its binding to receptor sites. This effect reduces the infiltration of inflammatory cells and tumor necrosis factor-alpha production in inflamed areas of the intestine. Infliximab is administered as an infusion. Its most common adverse effect, which requires discontinuing the therapy, is an infusion-related reaction (characterized by dyspnea, flushing, headache, and rash). Potentially serious infections are possible with infliximab, and GI complaints (nausea, diarrhea, abdominal pain, vomiting, painful digestion) are fairly common. Monoclonal antibodies are discussed further in Chapter 55.

Certolizumab

Certolizumab (Cimzia) is a TNF (tumor necrosis factor) blocker that is used in the treatment of Crohn disease. It is also used in the treatment of rheumatoid arthritis. Administered as a subcutaneous injection, the usual dose is is 400 mg (initially administered as two separate injections), at weeks 2 and 4. If the patient responds to the medication, the recommended maintenance dose is 400 mg every 4 weeks. Patients taking Cimzia are at increased risk of developing significant infections that may require hospitalizations. The risk of serious infection is exacerbated if the patient is also taking immunosuppressants or corticosteroids.

CHAPTER SUMMARY

- Drugs used to treat digestive disorders of the lower GI tract include antiflatulents, antidiarrheals, laxatives, and drugs used to treat IBS and IBD.
- Antiflatulents are drugs that decrease gas production and cause gas bubbles to coalesce, facilitating the passage of gas through belching and expelling flatus. These drugs are used to provide relief from postoperative gastric distention, dyspepsia, peptic ulcer, spastic colon, and diverticulosis. Simethicone is the prototype antiflatulent.
- Charcoal is another antiflatulent. Unlike simethicone, it interferes with the absorption of many drugs and is therefore useful in the treatment of poisoning and drug overdose.
- Diarrhea occurs when GI motility is too rapid, which prevents water from being reabsorbed from the stool. Infections of the GI tract may cause some diarrhea. Changes in diet and emotional stress also may contribute to diarrhea.
- Antidiarrheals are used to slow motility of the GI tract. OTC antidiarrheals are used widely, although specific data on their efficacy are lacking. The prototype antidiarrheal is diphenoxylate HCl with atropine sulfate. This drug is structurally similar to meperidine. A small amount of

atropine sulfate is combined with diphenoxylate to discourage deliberate abuse. It acts systemically to reduce intestinal motility and slow peristalsis.

- Constipation occurs when excessive water is reabsorbed from the stool while it is in the colon, drying and preventing passage of the stool. Lacking or deficient peristalsis, dietary factors, and changes in activity also may contribute to constipation. Laxatives are used to treat constipation. Types of laxatives include saline laxatives, hyperosmotics, stimulants and irritants, stool softeners, and lubricants.
- Laxatives are contraindicated in patients who have undiagnosed severe abdominal pain, who are nauseated and vomiting, or who have a bowel obstruction.
- Magnesium hydroxide, the prototype saline laxative, works by attracting water into the colon, increasing intracolonic pressure, and increasing peristalsis. It should not be used if the patient has renal failure because the additional magnesium is not excreted renally and may cause hypermagnesemia.
- Lactulose, a hyperosmotic laxative, also attracts water into the colon. A unique feature of this laxative is that it additionally produces acid in the colon, which attracts ammonia from the blood. Lactulose is therefore also used therapeutically to decrease serum ammonia levels in patients with hepatic coma.
- Peripherally selective Mu (μ) opioid receptor antagonists are not used for routine constipation. They are reserved for prophylaxis of postoperative ileus or opioid-induced constipation.
- Serotonin stimulates receptors in the bowel, producing bowel motility, bowel secretions, and visceral sensations. Drug therapy to treat IBS is directed at these serotonin (5-HT) receptors. Alosetron is a 5-HT_3 blocker that is used to treat severe IBS-D.
- Other medications that treat any one of the symptoms of IBS may not be as effective as the drugs that affect 5-HT.
- The inflammation seen in IBD is treated with 5-ASA preparations (e.g., mesalamine), corticosteroids, and immunosuppressant agents (e.g., infliximab).

QUESTIONS FOR STUDY AND REVIEW

1. What instructions should be given to the patient taking simethicone tablets?
2. Why is atropine sulfate added to diphenoxylate HCl?
3. What class of laxative would be used prophylactically for a patient recovering from a cataract extraction? Why?
4. Should a patient with severe constipation and renal failure receive magnesium hydroxide?
5. What nonlaxative effect of lactulose is desired for patients with severe hepatic disease?
6. Why is the sale of alosetron limited to women with severe IBS-D?
7. Why are drugs that affect serotonin receptors used to treat IBD?

UNIT 10
Antimicrobial Drugs

38

Principles of Antimicrobial Therapy

Learning Objectives

At the completion of this chapter the student will:

1. Describe the classifications of antimicrobial drugs.
2. Describe the principle of selective toxicity and how it applies to antimicrobial therapy.
3. Explain the emergence of drug-resistant microbes.
4. Identify and discuss the four most common drug-resistant pathogens.
5. Distinguish between drug of choice and alternative drugs used to manage infections.
6. Discuss the procedures used to identify pathogens.
7. Relate the principle of drug susceptibility to antimicrobial therapy.
8. Identify patient care variables that influence the choice of antimicrobial agents.
9. Describe appropriate laboratory tests to monitor antimicrobial therapy.

Key Terms

anthelminthic
antibacterial
antifungal
anti-infectives
antimicrobials
antiprotozoal
antiviral
bacteriocidal
bacteriostatic
culture
empiric therapy
Gram stain
microbe
nosocomial
pathogen
postantibiotic effect
selective toxicity
sensitivity
spectrum
superinfection

Drugs used to manage infections are called **antimicrobials, anti-infectives,** or **antibiotics.** The first effective antimicrobial drug was penicillin. Since its introduction, morbidity and mortality from infections have steadily declined. However, as we grow in our knowledge of how specific types of microbes work and how to eradicate them, microbes also continue to develop ways to mutate or to secrete enzymes that make current antimicrobials ineffective. This chapter focuses on the basics of antimicrobial therapy, including classification of antimicrobial drugs, selective toxicity, antimicrobial resistance, general considerations of antimicrobial therapy, and monitoring of antimicrobial therapy.

CLASSIFICATION OF ANTIMICROBIAL DRUGS

Two popular ways to classify antimicrobial drugs are by susceptible organism and by mechanism of action.

Classification by Susceptible Organism

A **microbe** is a unicellular or small multicellular organism. Microbes that are capable of producing disease are called **pathogens.** Types of microbes include bacteria, viruses, protozoa, some algae and fungi, and some worms (helminths). Drugs used to treat infection can be classified according to the type of microbe they affect. The major classifications include **antibacterial** drugs, **antiviral** drugs, **antiretroviral** drugs, **antifungal** drugs, **antiparasitic** drugs, **antiprotozoal** drugs, and **anthelminthic** drugs. Antibacterial drugs are subdivided into narrow-spectrum, broad-spectrum, or antimycobacterial drugs. As the name implies, a narrow-spectrum drug is effective against a few types of bacteria, whereas a broad-spectrum drug is effective against many types of bacteria. The antiviral classification also has a subdivision: antiretroviral agents. Table 38.1 outlines these classifications.

TABLE 38.1 Classification of Antimicrobial Drugs by Susceptible Organism

Susceptible Organisms	Antimicrobial Classification
Bacteria	Antibacterial drugs
• Mycobacterium	
Viruses	Antiviral drugs
Retroviruses	Antiretroviral drugs
Fungi	Antifungal drugs
Parasites	Antiparasitic drugs
Protozoa	Antiprotozoal drugs
Helminths (worms)	Anthelminthic drugs

Classification by Mechanism of Action

Antimicrobial drugs work in a variety of ways:

- Inhibition of bacterial cell wall synthesis
- Inhibition of protein synthesis
- Inhibition of nucleic acid synthesis
- Inhibition of metabolic pathways (antimetabolites)
- Disruption of cell wall permeability
- Inhibition of viral enzymes

These classifications, with examples of antibiotics for each group, are outlined in Table 38.2. In addition to being classified by their mechanisms of action as already listed, antibiotic drugs are either bacteriostatic or bacteriocidal. **Bacteriostatic** drugs inhibit bacteria, but their effect is reversible if the drug is removed, unless the host defense mechanisms have eradicated the organism. Sulfonamides, erythromycin, and tetracyclines are examples of bacteriostatic drugs. Antibiotics that actually kill bacteria are **bacteriocidal.** They depend less on the body's defense mechanisms than bacteriostatic drugs do. Examples include beta-lactam antibiotics such as the penicillins and cephalosporins or aminoglycosides. Additionally, some antibiotics exhibit a **postantibiotic effect:** organisms may not resume growing for several hours after exposure to the drug, despite undetectable drug levels.

Inhibition of Bacterial Cell Wall Synthesis

Unlike human cells, bacteria have rigid cell walls containing complex macromolecules, which are formed through

TABLE 38.2 Classification of Antimicrobial Drugs by Mechanism of Action

Mechanism of Action	Antimicrobials
Inhibit cell wall synthesis	Cephalosporins
	Daptomycin
	Penicillins
	Vancomycin
Inhibit protein synthesis	Aminoglycosides
	Chloramphenicol
	Clindamycin
	Erythromycin
	Tetracyclines
Inhibit nucleic acid synthesis	Fluoroquinolones
	Rifampin
Disrupt cell membrane permeability	Polymyxins
	Polyene antimicrobials
	Imidazole antifungal agents
Work as an antimetabolite	Sulfonamides
	Trimethoprim
Inhibit viral enzymes	Acyclovir
	Saquinavir

biosynthetic pathways. The osmotic pressure within the cell is very high and relies on the integrity of the cell wall to resist the absorption of water. Without the rigid cell wall, the bacteria would absorb water, swell, and then lyse. Several antimicrobial drugs weaken the cell wall, allowing the cell to absorb water, a process that causes bacterial death. Penicillins and cephalosporins bind to specific proteins located within the bacterial cytoplasmic membrane, the portion of the cell wall that borders the cytoplasm. Binding to these proteins causes inhibition of transpeptidase, an enzyme needed for the final step of cell wall synthesis. The result is decreased cell wall synthesis. These antibiotics also activate autolytic enzymes that are destructive to the cell wall. Another antibiotic, vancomycin, interferes with bacterial cell wall synthesis by inhibiting the synthesis of precursors of murein or by preventing the formation of linear peptidoglycan chains. These chains are polysaccharides and polypeptides that are cross-linked to form the bacterial cell wall.

Inhibition of Protein Synthesis

Both human and bacterial cells require ribosomes to synthesize protein for use by the cell (see Chapter 40). However, human cell ribosomes are structurally different than bacterial cell ribosomes. Because of this difference, many of the commonly used antimicrobial drugs are able to disrupt bacterial protein synthesis without affecting protein synthesis in human cells.

Tetracyclines, aminoglycosides, erythromycin, clindamycin, and chloramphenicol all inhibit protein synthesis; however, they do so by binding or inhibiting different subunits of the process of protein binding.

Inhibition of Nucleic Acid Synthesis

Many bacteria use enzymes for replication that do not exist in human cells. For instance, fluoroquinolones inhibit deoxyribonucleic acid (DNA) gyrase, an enzyme needed for bacterial DNA replication. Although human cells contain an enzyme that functions in the same manner, the human enzyme is not affected by fluoroquinolones.

Inhibition of Metabolic Pathways (Antimetabolites)

Nucleic acid synthesis is dependent on folic acid (folate), which acts as a coenzyme in many biosynthetic reactions. Humans obtain folate in the diet, but many microorganisms must synthesize folate. Sulfonamides inhibit bacterial folate synthesis by acting as an antimetabolite of the precursor to folate, para-aminobenzoic acid (PABA). Similarly, trimethoprim is an antimetabolite of folic acid that selectively inhibits dihydrofolate reductases of bacteria and protozoa.

Disruption of Cell Wall Permeability

Drugs that disrupt the integrity of the bacterial cell wall cause the cell to leak components that are vital to its survival. The polymyxins disrupt the membranes of the bacterial cell wall by inserting themselves into the lipid bilayer and forming artificial pores. The polyene antimicrobials bind to membrane components that are present only in microbial cells. The imidazole antifungal agents act as selective inhibitors of enzymes involved in the synthesis of sterols that are essential components of fungal membranes.

Inhibition of Viral Enzymes

The replication of viruses requires multiple enzymatic activities. Nucleoside analogues, such as acyclovir, and protease inhibitors, such as saquinavir, interrupt important enzymes required for viral replication.

SELECTIVE TOXICITY

An important principle of antimicrobial therapy is **selective toxicity,** which is the ability to suppress or kill an infecting microbe without injury to the host. Selective toxicity is achievable because the drug accumulates in a microbe at a higher level than in human cells; the drug has a specific action on cellular structures or biochemical processes that are unique to the microbe; or an action of a drug on biochemical processes is more harmful to the microbe than to host cells. For example, differences in the chemical compositions of the cell walls of microbes and human cells permit the selective toxicity of polymyxins, polyene antimicrobials, and imidazole antifungal agents. Tetracycline and chloramphenicol do not have absolute selective toxicity: they are able to inhibit protein synthesis in some human cells as well. Understanding selective toxicity has made antimicrobial drugs safe and effective for managing infection in humans.

ANTIMICROBIAL RESISTANCE

Antimicrobial resistance refers to the resistance of the microbe, not the patient, to the drug. Because of antimicrobial resistance, pharmaceutical companies are constantly looking for new ways to eradicate microbes despite the large number of antimicrobial agents available. Antimicrobial resistance is a major problem, especially in developed countries where antimicrobial agents are used daily. In the United States, the Centers for Disease Control and Prevention (CDC) issued a "Campaign to Prevent Antimicrobial Resistance in Healthcare Settings" in 2002 (Box 38.1). The campaign focuses on hospitals because they are most likely to harbor resistant bacteria, and it is most useful to prescribers such as physicians, nurse practitioners, and physician assistants. However, certain sections are clearly within the domain of the nurse. For instance, use of aseptic technique for all procedures, obtaining culture specimens appropriately, timely communication of culture and sensitivity results, adherence to isolation procedures, clear documentation of improvement or worsening of symptoms of infection, and most important, washing hands between contact with patients, are all among the CDC's campaign objectives.

Box 38.1 TWELVE STEPS FOR PREVENTION OF ANTIMICROBIAL RESISTANCE IN HOSPITALIZED ADULTS

Prevent Infection

Step 1. Vaccinate
- Give influenza/pneumococcal vaccine to at-risk patients before discharge
- Get influenza vaccine annually

Step 2. Get the Catheters Out
- Use catheters only when essential
- Use the correct catheter
- Use proper insertion and catheter-care protocols
- Remove catheters when they are no longer essential

Diagnose and Treat Infection Effectively

Step 3. Target the Pathogen
- Culture the patient
- Target empiric therapy to likely pathogens and local antibiogram
- Target definitive therapy to known pathogens and antimicrobial susceptibility test results

Step 4. Access the Experts
- Consult infectious diseases experts for patients with serious infections

Use Antimicrobials Wisely

Step 5. Practice Antimicrobial Control
- Engage in local antimicrobial control efforts.

Step 6. Use Local Data
- Know your antibiogram.
- Know your patient population.

Step 7. Treat Infection, Not Contamination
- Use proper antisepsis for blood and other cultures.
- Culture the blood, not the skin or catheter hub.
- Use proper methods to obtain and process all culture specimens.

Step 8. Treat Infection, Not Colonization
- Treat pneumonia, not the tracheal aspirate.
- Treat bacteremia, not the catheter tip or hub.
- Treat urinary tract infection, not the indwelling catheter.

Step 9. Know When to Say "No" to Vanco
- Treat infection, not contaminants or colonization.
- Fever in a patient with an intravenous catheter is not a routine indication for vancomycin.

Step 10. Stop Antimicrobial Treatment:
- When infection is cured
- When cultures are negative and infection is unlikely
- When infection is not diagnosed

Prevent Transmission

Step 11. Isolate the Pathogen
- Use standard infection control precautions.
- Contain infectious body fluids. (Follow airborne, droplet, and contact precautions.)
- When in doubt, consult infection control experts.

Step 12. Break the Chain of Contagion
- Stay home when you are sick.
- Keep your hands clean.
- Set an example.

Fact sheet from the CDC's Campaign to Prevent Antimicrobial Resistance in Healthcare Settings. Retrieved from http://www.cdc.gov/drugresistance/healthcare/tools.htm#factsheets.

Contributing Factors

Antimicrobial resistance may occur for several reasons: production of drug-inactivating enzymes, changes in receptor structure, changes in drug permeation and transport, development of alternative metabolic pathways, emergence of drug-resistant microbes, or factors that facilitate the development of resistance.

Production of Drug-Inactivating Enzymes

This common mechanism causes resistance to many beta-lactam antibiotics. The microbe synthesizes hydrolytic beta-lactamases, enzymes that are specific for certain penicillin and cephalosporin structures called beta-lactams. The beta-lactam structure must remain intact for the antibiotic to be effective; thus, when these enzymes affect the beta-lactam structure, the antibiotic becomes ineffective. To date, more than 100 beta-lactamases have been identified. Pathogens such as *Staphylococcus aureus, Haemophilus* species, and *Escherichia coli* have specificity to affect penicillins but not cephalosporins. *Pseudomonas aeruginosa* and *Enterobacter* species have a broader spectrum and may affect cephalosporins as well as penicillins.

Changes in Receptor Structure

Bacteria contain molecules that act as targets, or receptors, for antimicrobial drugs. These molecules may undergo changes in their structures. These structural changes make the microbe less susceptible to the toxic action of antibiotics. For example, alteration in penicillin-binding proteins (PBPs) decreases the affinity for binding beta-lactam antibiotics.

Changes in Drug Permeation and Transport

The antimicrobial action of many drugs depends on their ability to penetrate the cell membranes of an organism and reach effective intracellular concentrations. The organism's defense starts in the efficiency of its cell wall. If an antibiotic reaches the interior structures of the cell rapidly, the cell is unable to overcome the activity of the drug. However, if the antibiotic has difficulty passing through the cell wall, the bacteria are able to hydrolyze the antibiotic as it slowly enters the cell. Another bacterial defense mechanism is the production of an efflux pump, which effectively extrudes certain drugs, such as tetracycline, from the cell.

Development of Alternative Metabolic Pathways

Some bacteria are affected by antibiotics, such as sulfonamides, that act as antimetabolites by interrupting their metabolic pathway for replication. In the case of sulfonamides, the antibiotic inhibits dihydropteroate synthase, the enzyme

necessary to metabolize folic acid. Resistant bacteria may produce levels of PABA, the precursor to folic acid, that are high enough to overcome the inhibition of dihydropteroate synthase. Additionally, certain bacteria are able to use preformed folic acid from their environment, thus bypassing the inhibitory actions of the sulfonamides.

Emergence of Drug-Resistant Microbes

All antimicrobials have the ability to promote the emergence of drug-resistant microbes. However, resistance is more likely to occur in organisms exposed to broad-spectrum drugs. Although the use of antimicrobials promotes the potential for drug resistance to occur, they do not directly cause the resistance. Drug-resistant microbes develop in two ways: by spontaneous mutation and by conjugation. Spontaneous mutation is exactly what the name infers: a change in the genetic composition of the microbe that may just be a random occurrence, or the microbe may have mutated by acquiring DNA from an external source. The resistance developed is drug specific. Conjugation is a form of sexual reproduction in which two individual microbes join in temporary union to transfer genetic material. Conjugation may occur between two microbes of the same species or between different species.

Factors That Facilitate the Development of Resistance

Several factors facilitate the development of resistance. Drug concentrations in tissues that are too low to kill resistant organisms contribute to the development of resistance. The minimum inhibitory concentration (MIC) of a drug must be present to stop or slow the replication of the microbe. When a tissue does not reach MIC, the microbe can become resistant to the antimicrobial. Inadequate tissue concentrations may occur because of an improper dose of drug or improper length of time between doses. Insufficient duration of therapy may allow resistant organisms to repopulate and re-establish an infection. Patients frequently stop taking antibiotics when they feel better "to save some in case the infection comes again." Treatment must be continued beyond clinical improvement, especially if there is any problem with host defenses.

Prophylactic use of antibiotics may also contribute to the development of resistant organisms. Prophylactic use of antimicrobial drugs means that the drug is given to prevent an infection rather than to treat an infection. This practice increases the risk of the development of resistant microbes; therefore, antimicrobial prophylaxis should be reserved for appropriate indications. Such indications include:

- Exposure to sexually transmitted diseases
- Recurrent urinary tract infections
- Neutropenia
- Surgery, especially within the gastrointestinal tract
- Bacterial endocarditis

COMMON ANTIBIOTIC-RESISTANT MICROBIAL INFECTIONS

Although any microbe may become drug resistant, four important microbes are most prevalent: methicillin-resistant *Staphylococcus aureus* (MRSA), penicillin-resistant *Streptococcus pneumoniae,* vancomycin-resistant *Enterococcus* (VRE), and multiple drug–resistant *Mycobacterium tuberculosis* (MDR-TB). Microbes that cause antimicrobial-resistant nosocomial infections may also develop.

Methicillin-Resistant *Staphylococcus Aureus* (MRSA)

The abbreviation MRSA is commonly used for this infection; however, the abbreviation is somewhat misleading. In actuality, the pathogen is widely resistant to all of the antistaphylococcic penicillins, not just methicillin. In MRSA, PBPs are altered, reducing the ability of penicillins to inhibit cell wall synthesis, except at very high drug concentrations that may not be achievable because of poor tissue penetration and toxicity concerns. Many strains of MRSA are also resistant to aminoglycosides, tetracyclines, erythromycin, and clindamycin.

Closely related to MRSA is methicillin-resistant *Staphylococcus epidermidis* (MRSE). MRSE frequently colonizes the nasal passages of health care workers, resulting in the spread of nosocomial infections, especially in critical care units.

Vancomycin is the drug of choice to manage infections caused by MRSA and MRSE. Because vancomycin is also used for many other drug-resistant microbes, vancomycin resistance is emerging. New drugs with different mechanisms of action, such as linezolid (Zyvox), dalfopristin-quinupristin (Synercid), and daptomycin (Cubicin), have been developed to treat vancomycin-resistant microbes. Older drugs such as sulfamethoxazole/trimethoprim (Septra/Bactrim) and rifampin also have been found to be effective in the treatment of MRSA.

Penicillin-Resistant *Streptococcus Pneumoniae*

In the past, penicillins have successfully treated pneumococcal infections such as otitis media in children, community-acquired pneumonia, and meningitis. Because they are used so frequently, particularly in children and the elderly, strains of penicillin-resistant streptococci are emerging. To decrease penicillin resistance among *Streptococcus pneumoniae,* the CDC suggested that clinicians stop using penicillins and cephalosporins as prophylaxis for otitis media and that patients over the age of 65 years or those under the age of 2 years, who have an increased risk for pneumococcal infections, be immunized.

Vancomycin-Resistant *Enterococcus* (VRE)

Infection due to *Enterococcus* is generally treated with a combination of antibiotics: an aminoglycoside with a penicillin or

an aminoglycoside with a cephalosporin. The penicillin or cephalosporin damages the bacterial cell wall and allows the aminoglycoside to penetrate the cell. Strains of *Enterococcus* have developed resistance to penicillin, gentamicin, and vancomycin, however. Potential alternative drugs for VRE include teicoplanin (Targocid), minocycline (Minocin), ciprofloxacin (Cipro), quinupristin-dalfopristin (Synercid), and daptomycin (Cubicin).

Multiple Drug–Resistant *Mycobacterium Tuberculosis* (MDR-TB)

Multiple drug–resistant TB is increasingly common. Although some of the bacilli are inherently resistant, others develop resistance over the long course of TB treatment, which can last up to 2 years. The cause of MDR-TB is inadequate drug therapy, a category that includes a duration of therapy that is too short; a dose that is too low; or, more commonly, patient adherence that is only intermittent. To decrease the incidence of MDR-TB, multiple-drug therapy is implemented at the onset of treatment, followed by a decrease in the number of drugs, but no less than four drugs are given at any time.

Nosocomial Infections

A **nosocomial** infection is an infection that originates or occurs in a hospital or hospital-like setting. Such infections occur because the hospital setting has a high prevalence of pathogens, a high prevalence of compromised hosts, and an efficient mechanism of transmission from patient to patient. According to the World Health Organization, an estimated 2 million patients per year in the United States acquire a nosocomial infection, resulting in 247 deaths per day. Nosocomial infections with antibiotic-resistant bacteria such as MRSA, which are difficult to treat, are transmitted primarily by the contaminated hands of health care providers. Handwashing with soap and water or with waterless, alcohol-based hand antiseptics after leaving the bedside of each patient and before touching the next patient results in an immediate and profound reduction in the spread of resistant bacteria.

GENERAL CONSIDERATIONS FOR SELECTING ANTIMICROBIAL THERAPY

The most important factor in managing infections is to "match the drug with the bug." Each pathogen has a "drug of choice" and "alternative drugs." Several factors must be considered when choosing the drug of choice or an alternative:

1. Identification of the pathogen
2. Drug susceptibility
3. Drug spectrum
4. Drug dose
5. Time to affect the pathogen
6. Site of infection
7. Patient assessment

Identification of the Pathogen

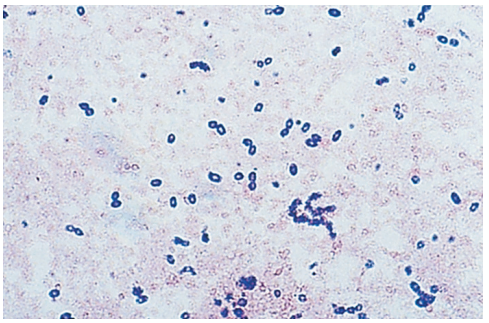
To eradicate an infection, drugs must be specific to the type of pathogen involved. An antiviral agent will not eradicate bacteria, nor will an antibacterial agent eradicate fungi. In fact, an antibiotic may not affect the bacteria causing a particular infection. Thus, effective treatment requires identification of the specific pathogen.

The first step in the identification of the pathogen is viewing a Gram-stained preparation under a microscope. A **Gram stain** is a simple test done with a dye and a glass slide. A sample of the pathogen is obtained from body fluids, sputum, blood, or exudates. Visualization under the microscope shows the shape of the pathogen, which aids in identifying it (Figure 38.1). The Gram stain indicates whether the pathogen is gram-positive or gram-negative type. Gram-positive bacteria absorb Gram stain and are often aerobic. Aerobic bacteria need a fresh and continuous supply of oxygen to reproduce. Gram-negative bacteria do not absorb Gram stain and tend to be anaerobic. Anaerobic bacteria are much more difficult to eradicate than aerobic bacteria because anaerobes can reproduce in an environment that is oxygen-free. Some drugs affect only gram-positive microbes; some affect only gram-negative microbes; and some affect both, but not to the same extent. In some cases, the pathogen must be grown in a culture medium for identification.

Drug Susceptibility

To choose the right drug for the infection, a drug susceptibility test is optimal. However, it is not always required. The site of infection is frequently a clue to the causative agent. For instance, *E. coli* causes most urinary tract infections. The health care practitioner therefore initially chooses a drug that can eradicate *E. coli*. Prescribing antibiotic treatment before the pathogen has been definitively identified is called **empiric therapy.** When multiple microbes may be the causative agent, empiric therapy may be started, but a culture specimen of the infected area should be taken before treatment with antimicrobial agents is started because antimicrobial use may make identification of the microbe difficult. The culture is then used to determine drug susceptibility.

The most common test to identify drug susceptibility is called a culture and sensitivity. A sample of the exudate,



• FIGURE 38.1 Gram-stained slide. This slide contains a type of gram-positive bacilli.

CRITICAL THINKING SCENARIO

WORKING WITH CULTURE AND SENSITIVITY REPORTS

Your patient has been receiving IV ciprofloxacin (Cipro) for a pulmonary infection, and you are about to hang a new infusion. The culture and sensitivity report has just arrived and shows an "R" next to ciprofloxacin. What should you do?

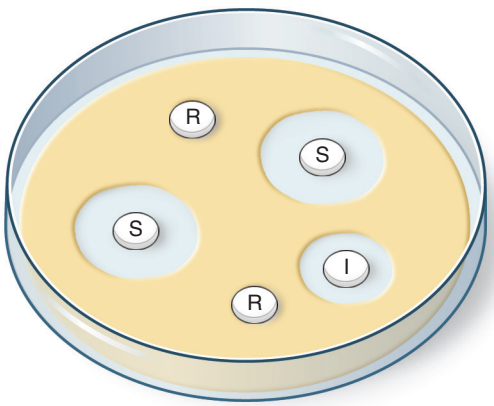
body fluids, or serum is sent to the laboratory. The **culture** determines the identity of the microbe, and the **sensitivity** determines which antimicrobial agent will be therapeutic. Check the sensitivity test result of a patient receiving empiric therapy and notify the prescriber immediately if the current antibiotic is rated as "resistant." Sensitivity testing can be done by a disk diffusion test or broth dilution procedure.

Disk Diffusion Test

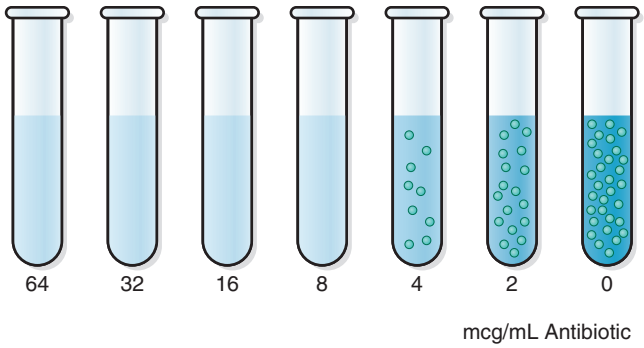
This is the most commonly performed test to determine drug susceptibility. In the disk diffusion method, disks containing a standardized amount of an antimicrobial agent are placed on an agar plate inoculated with the infecting organism. The plate is placed in an incubator, and the bacterial lawn is allowed to grow. A growth inhibition zone will appear around each antibiotic that affects the microbe (Figure 38.2). The diameter of the visible growth inhibition zone correlates with the MIC, which is the lowest concentration of an antibiotic that prevents visible growth of a microbe. Organisms are rated as sensitive (S) to a particular antibiotic if they are affected by it and resistant (R) if they are not.

Broth Dilution Procedure

In the broth dilution procedure, the bacteria are inoculated into a liquid medium containing graduated concentrations of the test antimicrobial. This method directly determines the MIC (Figure 38.3). The broth dilution procedure also determines the minimum bactericidal concentration (MBC), that is, the lowest concentration that will kill more than 99.9% of the original inoculum of the microbe. The broth dilution procedure is particularly helpful in managing difficult infections because it demonstrates both MIC and MBC.



• FIGURE 38.2 Disk diffusion test. In the disk diffusion test, samples of antibiotics are placed on a plate of the infecting organism. The organism is "sensitive" (S) to the antibiotic if there is a bacteria-free zone around the antibiotic, "resistant" (R) if the bacteria remain around the antibiotic, and "intermediate" (I) if there is a zone of inhibition but not sufficient to eradicate the organism.



• FIGURE 38.3 Broth dilution procedure. Bacteria are inoculated into a liquid medium containing graduated concentrations of the test antimicrobial. A clear test tube indicates that the concentration of the antimicrobial is sufficient to eradicate the microbe.

Drug Spectrum

Choosing a drug with the narrowest possible **spectrum** is important. The range of microbes against which a drug is active is its spectrum. Narrow-spectrum drugs affect only a few microorganisms, whereas broad-spectrum drugs affect many microorganisms. The benefit of a narrow-spectrum antimicrobial agent is that it limits the potential for adverse effects, such as superinfection. A **superinfection** is one that occurs during the course of treatment for a primary infection. For example, an antibiotic suppresses all susceptible microbes, including the body's natural flora, which may keep other microbes in check. In the absence of these bacteria, nonsusceptible microbes can proliferate because they no longer have other microbes secreting toxins in their proximity and because they no longer need to compete for available nutrients. Two consequences may occur: secondary infections and the development of drug-resistant microbes.

An alternative to the use of broad-spectrum antimicrobials is combination therapy. Combination therapy is used frequently for an initial severe infection in which the pathogen is unknown. Once the pathogen is known, the appropriate drug can be administered. Another use for combination therapy is to treat an infection that is caused by more than one pathogen. This kind of infection is known as a mixed infection. Combination therapy is also used to prevent resistant microbes from developing. For instance, drug resistance occurs frequently during TB treatment as a result of its duration. When multiple drugs are given at the same time, the pathogen is less likely to be able to become resistant to all of the drugs employed. Another benefit of combination therapy is enhanced antibacterial action. For instance, some bacteria are capable of secreting enzymes that inhibit the action of the antibacterial

agent. Combining beta-lactam inhibitors such as tazobactam with a penicillin allows the destruction of the enzyme by tazobactam, thus allowing penicillin to penetrate the cell wall and destroy the microbe.

Although combination therapy has many benefits, it also has many disadvantages compared with monotherapy. These disadvantages include an increased risk for toxic or allergic reactions, an increased risk for the development of resistant bacteria, and an increased risk for superinfection.

Drug Dose

Choosing the antimicrobial agent with the lowest effective dose is important. The dose of the antimicrobial agent is adjusted to affect the MIC at the site of infection. Pediatric doses are calculated as mg/kg/d.

Duration

Choosing the antimicrobial agent that takes the shortest time to affect the pathogen is equally important. The drug must remain at the site of infection at drug concentrations equal to or greater than MIC. The duration of treatment depends on the type of pathogen, the site of infection, and the presence or absence of host defenses. The duration of antimicrobial treatment is generally 7 to 10 days, but it may be extended to 30 days or more for infections such as prostatitis.

It is important to instruct the patient to take antimicrobial medication until all the medication is gone. Stopping therapy early may result in reinfection with the same pathogen, which will have become more drug resistant as a result of inadequate treatment.

Site of Infection

To be effective, a drug must be able to reach the site of infection at a concentration equal to or greater than the MIC. Achieving this concentration is a particular problem when the infection is in the meninges, because many drugs do not cross the blood–brain barrier. Another difficult site is within an abscess because abscesses are poorly vascularized, and the presence of pus impedes drug concentrations. Specific types of infections, such as endocarditis, are difficult to treat because the vegetative growths are hard to penetrate.

Infections that occur in foreign objects such as pacemakers or prosthetic joints are also difficult to treat. When a foreign object enters the body, the immune system attempts to destroy the object by phagocytosis. While the phagocytes are busy attacking the foreign object, they are less able to attack bacteria that are multiplying at the site. Frequently, the infected foreign object must be removed to eradicate the bacterial infection.

Patient Assessment

Nurses need to evaluate the individual patient before starting antimicrobial drugs. Important core patient variables include health status, life span, gender, environment, and culture.

Health Status

The type of antimicrobial agent chosen must reflect the immune status of the patient. Remember that most antimicrobial agents cannot eradicate infection without the assistance of the immune response. Immunocompetent patients may receive either bacteriocidal or bacteriostatic drugs because their immune systems can function with adequate response from phagocytic cells such as macrophages and neutrophils. Immunocompromised patients should receive drugs that are quickly bacteriocidal because such patients' immune responses are limited.

The patient must also be assessed for previous allergic responses to a particular drug class. When the patient states she or he has an allergy to a certain drug, find out what symptoms occurred when they took the drug. Many patients think that nausea, diarrhea, or headaches reflect an "allergy" to a certain drug. True allergic symptoms reflect an antigen–antibody reaction and are characterized by symptoms such as rash, itching, hives, periorbital swelling, and shortness of breath.

Life Span and Gender

Infants and the elderly are the populations most vulnerable to drug toxicity. In the infant, the liver and kidneys are still immature and may have difficulty metabolizing or excreting the drug, which results in accumulation. The same process in the elderly is related to the age of their liver and kidneys, which may no longer be functioning at an optimal level.

Prescribers may request lower doses of antimicrobial agents for these two populations to minimize the risk for toxicity.

During pregnancy, antimicrobial drugs may cross the placenta and cause damage to the developing fetus. For instance, tetracycline binds to developing teeth, producing a gray mottled discoloration.

Most antimicrobial agents enter breast milk, resulting in injury to the nursing child. For example, sulfonamide drugs may cause kernicterus, a type of brain damage caused by hyperbilirubinemia in the neonate.

Environment

The severity of the infection may influence the environment in which the antimicrobial is administered. The highest serum drug concentration is achieved when the antimicrobial is administered intravenously.

Another aspect to consider for intravenous (IV) therapy is the potential for severe adverse effects. For instance, amphotericin B, a powerful antifungal agent, causes an infusion reaction when administered. For that reason, most patients receiving amphotericin B are admitted to a facility that employs licensed nurses to administer the drug.

Culture and Inherited Traits

Certain genetic factors may influence antimicrobial therapy. For example, some groups, especially African Americans, have

a predisposition to glucose-6-phosphate deficiency (G6PD). This deficiency causes red blood cells to be destroyed, resulting in hemolytic anemia, which is potentially lethal. Patients with this deficiency should not receive antimicrobials such as sulfonamides, which may induce red blood cell lysis.

MONITORING ANTIMICROBIAL THERAPY

Successful antimicrobial therapy eradicates the infection. Some antimicrobial agents have the ability to induce toxic adverse effects. Serum drug levels should be monitored for drugs that have a high potential for severe adverse effects. In addition, serum peak and trough levels may be measured, although in some hospitals, only trough levels are taken. Blood for a peak level is generally drawn 1 hour after IV or intramuscular (IM) administration. Trough levels are drawn just prior to the next dose of medication, once steady state has been reached. Individual drugs may need to have the peak level drawn at a different time, so it is prudent to verify the appropriate timing of the peak level with the laboratory performing the test. The goal is to keep the serum drug level within the therapeutic margin.

For patients receiving long-term or high-dose antimicrobial therapy, other laboratory testing may be indicated. For instance, if an antimicrobial is known to cause anemia, the patient should be monitored using serial complete blood counts (CBCs).

The very young and the very old should also be monitored closely. Immaturity or advanced maturity may affect liver and kidney functioning. Appropriate testing includes hepatic and renal function tests.

The bottom line for patient monitoring is that it must be individualized according to the type of pathogen, site of infection, potential for adverse effects during therapy, and the patient care variables associated with each patient.

CHAPTER SUMMARY

- Bacteriocidal drugs kill bacteria, whereas bacteriostatic drugs inhibit bacterial growth but rely on the immune system to eradicate the pathogen.
- Antimicrobial therapy is effective because of the principle of selective toxicity: the ability of the drug to harm the pathogen without injuring the host.
- Drug resistance is an ever-present danger to effectively managing infection.
- Prophylactic use of antimicrobial drugs must be limited to appropriate indications to decrease the potential development of drug-resistant microbes.
- There are four major drug-resistant pathogens in the United States: methicillin-resistant *Staphylococcus aureus* (MRSA), penicillin-resistant *Streptococcus pneumoniae,* vancomycin-resistant *Enterococcus* (VRE), and multiple drug–resistant *Mycobacterium tuberculosis* (MDR-TB).
- Nosocomial infections are difficult to treat because hospital settings have a high prevalence of pathogens, a high prevalence of compromised hosts, and an efficient mechanism of transmission from patient to patient.
- Handwashing before contact with each patient is the most effective way of limiting the patient's risk of a nosocomial infection.
- The most important principle in managing infection is to use the right drug for the right bug.
- A culture determines which pathogen is present, whereas a sensitivity test determines the susceptibility of the pathogen to a particular antibiotic.
- The antimicrobial agent used should be the one with the narrowest spectrum, at the lowest dose, that needs to be taken for the shortest time to affect the pathogen.
- Narrow-spectrum drugs affect only a few microorganisms, whereas broad-spectrum drugs affect many microorganisms.
- The minimum inhibitory concentration (MIC) is the minimum concentration of an antibiotic that completely suppresses bacterial growth.
- The minimum bactericidal concentration (MBC) is the concentration of an antibiotic that kills 99.9% of the initial inoculum in a broth dilution.
- Treatment with the drug of choice to eradicate a particular pathogen may have to be changed to an alternative drug because of specific core patient variables such as health status, life span, gender, environment, and culture and inherited traits.
- The most important element of patient education is to advise the patient to complete the entire course of therapy, taking the prescribed dose at the prescribed intervals.

QUESTIONS FOR STUDY AND REVIEW

1. What is the most important principle of antimicrobial therapy?
2. How are antimicrobials classified?
3. How do most antimicrobials work?
4. What is the principle of selective toxicity?
5. How does a superinfection occur?
6. In the United States, what microbes have developed substantial resistance to antimicrobials?
7. How can nurses assist in the CDC's "Campaign to Prevent Antimicrobial Resistance in Healthcare Settings"?
8. What is the best method to limit the patient's risk for acquiring a nosocomial infection?

Antibiotics Affecting the Bacterial Cell Wall

Learning Objectives

At the completion of this chapter the student will:

1. Identify the antibiotic drug classes that affect the bacterial cell wall and name at least one drug in each class.
2. Describe the primary therapeutic uses for each antibiotic drug class that affects the bacterial cell wall.
3. Identify core drug knowledge pertaining to antibiotics that affect the bacterial cell wall.
4. Identify core patient variables pertaining to antibiotics that affect the bacterial cell wall.
5. Relate the interaction of core drug knowledge to core patient variables for antibiotics that affect the bacterial cell wall.
6. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for antibiotics that affect the bacterial cell wall.
7. Describe nursing interventions to maximize therapeutic and minimize adverse effects for antibiotics that affect the bacterial cell wall.
8. Determine key points for patient and family education for antibiotics that affect the bacterial cell wall.

Key Terms

bacterial cell envelope
beta-lactam
beta-lactamases
cephalosporinases
penicillinases
penicillin-binding proteins (PBPs)

Antibiotic Affecting the Bacterial Cell Wall

Penicillins

Narrow-spectrum penicillins
- **penicillin G** (P)
- penicillin G benzathine
- penicillin G procaine
- penicillin V

Broad-spectrum penicillins (aminopenicillins)
- ampicillin
- amoxicillin

Extended-spectrum penicillins (antipseudomonal penicillins)
- piperacillin
- ticarcillin

Penicillinase-resistant penicillins (antistaphylococcal penicillins)
- dicloxacillin
- nafcillin
- oxacillin

Beta-lactamase inhibitors
- clavulanic acid
- sulbactam
- tazobactam

Cephalosporins

- **cefazolin** (P)

First generation
(cefadroxil, cephalexin)

Second generation
(cefaclor, cefprozil, cefotetan, cefuroxime, cefoxitin)

Third generation
(cefdinir, cefditoren, cefixime, cefpodoxime, ceftibuten, cefotaxime, ceftriaxone, ceftazidime)

Fourth generation
(cefepime)

Vancomycin

- **vancomycin** (P)

Monobactum Antibiotics

aztreonam

Carbapenems

cilastatin-imipenem
doripenem
ertapenem
meropenem

The symbol (C) indicates the drug class.
Drugs in **bold type** marked with the symbol (P) are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Drugs affecting the bacterial cell wall include the antibiotics known as the penicillins, monobactams, carbapenems, cephalosporins, and vancomycin. Penicillin G is the prototype drug for the penicillin drug class; drugs significantly different from penicillin are the beta-lactamase inhibitors and bacitracin. Other prototype drugs discussed in this chapter include aztreonam for the monobactam drug class; imipenem for the carbapenem drug class; cefazolin for the cephalosporin drug class; and vancomycin, which is the only drug in its class.

In addition to explaining how these drugs work, this chapter discusses nursing management related to evaluating the patient's condition, monitoring the patient's response, and teaching the patient and family about antibiotic therapy.

PHYSIOLOGY

Bacteria are surrounded by a rigid cell wall that is responsible for maintaining the integrity of the internal cellular environment. The interior of the cell has a high osmotic pressure. If the bacterial cell wall is not intact, the internal osmotic pressure draws fluid into the cell until it bursts.

Even when the cell wall is breached by an antibiotic, bacterial death may not occur because of bacterial resistance. Bacterial resistance occurs for one of two reasons: the drug is unable to reach binding sites within the cell, or the bacteria produce an enzyme that inactivates the drug.

Bacterial Cell Envelope

Drugs that affect the bacterial cell wall must be able to penetrate the cell wall to bind to molecular targets on the cytoplasmic membrane within the cell. Gram-positive bacteria have a **cell envelope** with only two layers: a thick cell wall and cytoplasmic membrane. Despite the thickness of the cell wall, many drugs are capable of penetrating this wall and attaching to the targets on the cytoplasmic membrane. Gram-negative bacteria have a cell envelope with an additional outer membrane, and the cell wall is much thinner. Although the cell wall can be penetrated easily, the outer membrane cannot. Only drugs that can pass through the very small pores of the outer membrane can reach the target sites on the cytoplasmic membrane (Figure 39.1).

Bacterial Enzymes

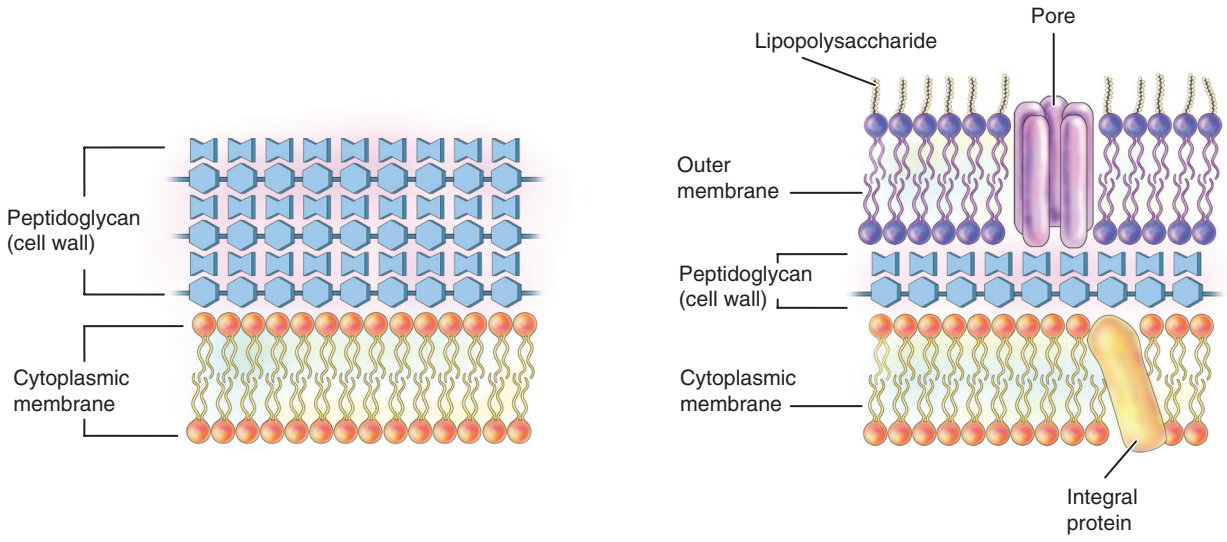
Beta-lactamases are enzymes that disrupt the beta-lactam ring. This mechanism inactivates **beta-lactam** drugs, such as penicillins and cephalosporins, because their antibiotic activity is derived from characteristics of the beta-lactam ring. Enzymes that affect penicillins are called **penicillinases,** whereas enzymes that affect cephalosporins are called **cephalosporinases.**

PATHOPHYSIOLOGY

Bacteria may cause infections in any body organ, structure, or fluid. In addition to the original bacterial infection, the loss of certain "good" bacteria may result in a superinfection, such as that caused by *Candida* species.

PENICILLINS

Penicillins were the first antibiotics introduced for clinical use. They are also called beta-lactam antibiotics because their chemical structure contains a beta-lactam ring that is essential for antibacterial activity. All penicillins contain this essential beta-lactam ring; however, adding a side chain to



Gram-positive cell envelope **Gram-negative cell envelope**

• FIGURE 39.1 Although the gram-positive cell wall is much thicker than the gram- negative cell wall, antibiotics can attach to targets on the cytoplasmic membrane. In the gram-negative cell, the wall is thinner, but the cell also contains an outer membrane that makes it difficult for antibiotics to permeate the cell.

specific types of penicillins influences their pharmacokinetic properties, binding capabilities, penicillinase resistance, and resistance to stomach acids. Penicillins are most effective against cells undergoing active growth and division. Penicillins are classified as narrow-spectrum penicillins, aminopenicillins (broad-spectrum penicillins), extended-spectrum penicillins, and penicillinase-resistant penicillins. Table 39.1 presents a summary of selected penicillins. Penicillin G aqueous, a narrow-spectrum penicillin, is the prototype for the penicillin class.

Nursing Management of the Patient Receiving P Penicillin G

Core Drug Knowledge

Pharmacotherapeutics

Penicillin G is indicated for use in infections caused by susceptible gram-positive bacteria, anaerobes, and spirochetes, including streptococci, non–penicillinase-producing staphylococci, and *Treponema pallidum*. Clinically, these bacteria cause infections such as pneumonia, pharyngitis, tonsillitis, endocarditis, and scarlet fever. Other clinical uses include therapy for tetanus, anthrax, meningitis, syphilis, diphtheria, rat-bite fever, and fusospirochetal infections.

Penicillin G may also be used as prophylaxis in special patient populations to prevent bacterial endocarditis prior to procedures likely to produce temporary bacteremia. These patients include those with prosthetic heart valves, mitral valve prolapse, most congenital heart diseases, and acquired valvular heart disease. It may also be used as prophylaxis in patients with recurrent rheumatic fever or rheumatic heart disease.

Pharmacokinetics

Penicillin G is absorbed rapidly from the gastrointestinal (GI) tract but is unstable in gastric acid. This instability means that the amount of penicillin G that is actually absorbed with any given dose varies with the acidity of stomach contents. Because of this instability, penicillin G is not given orally. The oral form of penicillin with the same indications as penicillin G is penicillin V.

Three forms of parenteral penicillin G are commercially available: penicillin G aqueous (which may be sodium based or potassium based), penicillin G benzathine, and penicillin G procaine. Penicillin G aqueous may be administered intravenously or intramuscularly. Benzathine and procaine penicillin are referred to as repository forms of penicillin because they provide tissue depots from which the drug is absorbed over several hours (penicillin procaine) or days (penicillin benzathine). As such, benzathine and procaine penicillins are administered only intramuscularly.

Penicillin G binds to plasma proteins and circulates in the blood to be released at various tissue sites. The average peak drug effect is 4 hours after administration. Penicillin G crosses the placenta and is secreted in breast milk. It does not penetrate the blood–brain barrier very well except in the presence of meningeal inflammation, a fact that makes it somewhat useful in treating meningitis.

Penicillin G is rapidly cleared unchanged from the plasma by the kidneys (by glomerular filtration and renal tubular secretion). Because this rapid clearance of the drug makes it somewhat difficult to maintain therapeutic levels, around-the-clock administration is needed for therapy to be truly effective.

Pharmacodynamics

Penicillin G inhibits the third and final stage of bacterial cell wall synthesis by binding to specific **penicillin-binding proteins** (PBPs) located inside the bacterial cell wall. After binding with specific PBPs, penicillin inhibits transpeptidase, an enzyme that is responsible for developing cross-bridges within the cell wall. These cross-bridges give the cell wall its strength. Additionally, penicillin affects autolytic enzymes (autolysins) that promote active cell wall destruction. The relationship between PBPs and autolysins is unclear; possibly, penicillin interferes with an autolysin inhibitor. As the cell wall weakens, the internal osmotic pressure of the bacteria changes, allowing the cell to swell, then burst. The body's immune system completes the process of fighting the infection and cleans up debris from ruptured bacteria.

Penicillin has selective toxicity to bacteria because human cells do not use the biochemical process that the bacteria use to form a cell wall and are thus protected from destruction.

Contraindications and Precautions

Penicillin G is contraindicated in the presence of known allergies to penicillin, cephalosporins, or imipenem. Penicillin sensitivity tests are available if the patient's history of allergy is unclear and penicillin is the drug of choice. Caution should be exercised in the presence of renal disease, pregnancy, and lactation.

Adverse Effects

The most serious adverse effect of penicillin G is allergic reaction: rash, fever, and wheezing, and possibly anaphylaxis and death. More common adverse effects of penicillin therapy involve the GI tract: nausea, vomiting, diarrhea, abdominal pain, glossitis, stomatitis, gastritis, sore mouth, and furry tongue. These effects are primarily related to the loss of normal flora (naturally occurring bacteria in the body) and subsequent opportunistic infections. Other adverse effects include superinfections (e.g., yeast infections) and local pain or inflammation at the injection site. Other, less common effects include lethargy, hallucinations, anemia, thrombocytopenia, nephritis, and sodium overload (especially with the sodium salt of penicillin G).

Drug Interactions

The effectiveness of penicillin G is decreased when it is taken concurrently with tetracyclines. Parenteral aminoglycosides (amikacin, gentamicin, kanamycin, neomycin,

TABLE 39.1 Summary of Selected Penicillins and Other Beta-Lactam Antibiotics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Penicillins			
penicillin G (Pfizerpen)	Pneumococcal infections Streptococcal infections (Group A) Bacterial endocarditis Diphtheria Neurosyphilis Congenital syphilis	Penicillin G is administered IV as penicillin G aqueous and IM as penicillin G procaine or benzathine. Dosages highly individualized. *Adult:* IM, 300,000–8 million units daily in divided doses; IV, 6–20 million units daily by continuous or intermittent infusion (q2–4 h) *Child:* IM/IV, 25,000–250,000 U/kg/d in divided doses	*Onset:* IM, rapid; IV, rapid *Duration:* Varies $t_{1/2}$: 30–60 min
penicillin G benzathine (Bicillin-CR, Bicillin LA Permapen)	Streptococcal infections Early syphilis Syphilis of >1-y duration	*Adult:* IM, 1.2 million U q4wk *Adult:* IV, 2.4 million U in one single dose *Adult:* Parenteral, 2.4 million U once weekly for 3 wk *Child:* >27 kg, parenteral, 900,000–1.2 million U in one dose; < 27 kg, 300–600,000 U in one dose	*Onset:* IM, slow *Duration:* 1–4 wk $t_{1/2}$: 30–60 min
penicillin G procaine	Pneumococcal infections Staphylococcal infections	*Adult and child:* IM, 600,000–1.2 million U/d in one or two doses for 10 d–2 wk	*Onset:* IM, slow *Duration:* 15–20 h $t_{1/2}$: 30–60 min
penicillin V (Pen-Vee K, Veetids)	Fusospirochetal infections Streptococcal infections	*Adult:* PO, 250–500 mg q6–8 h *Adult:* PO, 125–250 mg q6–8 h for 10 d *Child:* PO, 25–50 mg/kg/d q6–8h	*Onset:* Rapid *Duration:* Varies $t_{1/2}$: 30–60 min
Aminopenicillins			
ampicillin (Omnipen)	Septicemia Bacterial meningitis Respiratory/soft-tissue infections	*Adult:* IV, 150–200 mg/kg/d for 3 d, then IM q3–4 h *Child:* Same as adult *Adult:* IV, 150–200 mg/kg/d by continuous infusion and then IM injections q3–4 h *Child:* Same as adult *Adult:* PO, ≥40 kg; IV or IM, 250–500 mg q6 h; <40 kg, IV or IM, 25–50 mg/kg at 6–8 h intervals; <20 kg, PO, 50 mg/kg/d in equal doses q6–8 h	*Onset:* PO, 30 min; IM, 15 min; IV, immediate *Duration:* 6–8 h $t_{1/2}$: 1–2 h
amoxicillin (Amoxil)	URI, GU infections Lower respiratory tract infections	*Adult:* PO, 250–500 mg q8h *Child:* Same as adult *Adult:* PO, 500 mg q8h *Child:* Same as adult	*Onset:* Varies *Duration:* 6–8 h $t_{1/2}$: 1–1.4 h
Extended-Spectrum Penicillins			
piperacillin (Pipracil)	Lower respiratory tract infections Skin and skin structure infections Bone and joint infections Intra-abdominal infections Gynecologic infections Bacteremia Septicemia	*Adult:* IV, 3–4 g infusion over 20–30 min q4h *Child:* Although safety and efficacy in children have not been fully established, pediatric patients have received 76–100 mg/kg/d IV or IM in divided doses q4h	*Onset:* IV, rapid *Duration:* 4–6 h $t_{1/2}$: 0.7–1.3 h
Penicillinase-Resistant Penicillins			
dicloxacillin (Dynapen)	Infections due to penicillinase-producing staphylococci	*Adult and child >40 kg:* PO, 125 mg q6h; up to 250 mg q6h in severe infections *Child <40 kg:* PO, 12.5–25 mg/kg/d in equally divided doses q6h; up to 25 mg/kg/d in equally divided doses q6h in severe infections	*Onset:* Varies *Duration:* 6–8 h $t_{1/2}$: 30–90 min

(*Continued*)

TABLE 39.1 Summary of Selected Penicillins and Other Beta-Lactam Antibiotics *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
nafcillin (Nallpen)	Infections due to penicillinase-producing staphylococci Infections caused by group A beta-hemolytic streptococci, *Streptococcus viridans*	*Adult:* IV, 0.5–2 g q4 h *Child:* IV, 50–100 mg/kg/d in equally divided doses q6 h; for severe infections, 100–200 mg/kg/d *Adult:* IM, 500 mg q4–6 h *Child:* IM, 50–100 mg/kg/d in equally divided doses q6 h; for severe infections, 100–200 mg/kg/d *Adult:* PO, 0.25–1 g q4–6 h *Child:* PO, 50–100 mg/kg/d in divided doses q6 h	*Onset:* PO, varies; IM, rapid; IV, immediate *Duration:* PO and IV, 4 h; IM, 4–6 h $t_{1/2}$: 1 h
oxacillin (Bactocill)	Infections due to penicillinase-producing staphylococci Infections caused by streptococci	*Adult and child >40 kg:* IM/IV, 0.25–2 g q4–6 h; maximum daily dose, 23 g *Child <40 kg:* IM/IV, 50–100 mg/kg/d in equally divided doses q4–6 h *Adult and child ≥40 kg:* PO, 0.5–1 g q4–6 h *Child <40 kg:* PO, 50–100 mg/kg/d in equally divided doses q4–6 h	*Onset:* PO, varies; IM/IV, rapid *Duration:* PO/IM, 4–6 h; IV, length of infusion $t_{1/2}$: 0.5–1 h
Monobactams			
aztreonam (Azactam)	Moderately severe systemic infection with *Pseudomonas aeruginosa* Urethritis Endocervicitis Proctitis Gonococcal infections	*Adult:* IV, 0.5–2 g q6–12 h *Infant and child ≥1 mo:* IV, 30 mg/kg q6–8 h; for patients with cystic fibrosis, 50 mg/kg q6–8 h *Infant and child ≥1 mo:* IV, 50 mg/kg q4–6 h *Adult:* IM, 1 g as a single dose	*Onset:* IM, varies; IV, rapid *Duration:* 6–8 h $t_{1/2}$: 1.5–2 h
Carbapenems			
cilastatin-imipenem (Primaxin)	Intra-abdominal infections Gynecologic infections Lower respiratory tract infections Skin and skin structure infections Bone and joint infections Bacteremia or septicemia Endocarditis Febrile neutropenia	*Adult:* IV, 250–500 mg q 6 h to a maximum of 4 g/d *Adult:* IM, 500–750 mg q 12 h, depending on severity of infection *Child >3 mo:* IV, 15–25 mg/kg q6 h to a maximum dose of 2 g/d	*Onset:* IM, rapid; IV, immediate *Duration:* 6–12 h $t_{1/2}$: 90–120 min
doripenem (Doribax)	Complicated abdominal or urinary tract infections Pyelonephritis	*Adult IV: 500 mg every 8 h*	*Onset: rapid* *Duration: length of infusion* *T1/2: 1 hour*
ertapenem (Invanz)	Community-acquired pneumonia Skin and skin structure infections Complicated GI infections Complicated intra-abdominal infections Acute pelvic infections	*Adult:* IM/IV, 1 g/d *Child:* Safety in children not established	*Onset:* IM, 10 min; IV, rapid *Duration:* Unknown $t_{1/2}$: 4 h
meropenem (Merrem)	Intra-abdominal infections Bacterial meningitis	*Adult and child >50 kg:* IV, 1–2 g q8 h *Child <50 kg:* IV, 20–40 mg/kg q8 h	*Onset:* Immediate *Duration:* 10–12 h $t_{1/2}$: 1 h

paromomycin, streptomycin, tobramycin) are inactivated when these drugs are administered with penicillin G. Table 39.2 lists agents that interact with penicillin G.

Oral probenecid, a drug used in the treatment of gout, is sometimes given with intravenous (IV) penicillin G because it slows the excretion of the drug by competing with the penicillin molecule for excretion sites in the renal tubule. The result is that penicillin levels stay high for a longer time, achieving a greater effect.

Assessment of Relevant Core Patient Variables

Health Status

Take a careful health history to assess for any known reactions to antibiotics. Examine the skin for any rash or lesions to provide a baseline to avoid misdiagnosis of an allergic reaction. Assess the respiratory status of the patient as a baseline for possible wheezing associated with an allergic reaction.

For patients with a questionable history of allergic reaction to penicillin, perform a skin test to determine current allergic status. Because the skin test itself may cause an anaphylactic response in susceptible patients, it should be performed only in a setting staffed and equipped to respond to a potential emergency. In rare situations, it may be necessary to give penicillin to a penicillin-allergic patient. In these rare cases, penicillin is administered according to a desensitization schedule. Desensitization does not always stop an allergic response; therefore, it must be performed in an acute care setting. Epinephrine and respiratory support must be immediately available for either skin testing or desensitization.

For elderly patients or patients with kidney disease, evaluate kidney function (including blood urea nitrogen [BUN] and creatinine clearance) to determine baseline functioning. Patients with severe decreased kidney function may need a reduced dose of penicillin G. For long-term therapy, also

TABLE 39.2 Agents That Interact with P Penicillin G

Interactants	Effect and Significance	Nursing Management
aminoglycosides	GI absorption of penicillins may be impaired by aminoglycosides. Penicillins may inactivate certain aminoglycosides.	Avoid combination therapy if possible. Administer at least 2 h apart. Tailor dose of penicillin as needed. Monitor peak and trough levels of aminoglycoside.
anticoagulants	Large IV doses of penicillin may prolong bleeding time.	Monitor for signs of bleeding. Monitor PT/INR
food	GI absorption of penicillins are impaired by the presence of food.	Administer at least 1 h before or 2 h after meals.
oral contraceptives	Penicillins may suppress intestinal flora, which provide an enzyme essential for enterohepatic recirculation for certain oral contraceptives. This may result in a decreased contraceptive plasma level.	Advise patients taking oral contraceptives to use an additional method of birth control while taking penicillins.
methotrexate	Coadministration may increase serum methotrexate levels, resulting in toxicity.	Avoid if possible. Monitor signs and symptoms of methotrexate toxicity.
tetracyclines	The bacteriostatic action of tetracyclines may impair the bactericidal activity of penicillins.	Avoid combination therapy.

perform baseline liver function tests (LFTs). In addition, assess for previously prescribed drugs that may interact with penicillin to cause undesired effects.

When penicillin G is used for gram-negative infections, always perform culture and sensitivity tests to be sure that the causative bacteria are sensitive to penicillin G.

Life Span and Gender

Document the method of birth control used by a woman of childbearing age because antibiotics, such as penicillin G, can counteract the effects of an oral contraceptive. Assess women of childbearing age for pregnancy and lactation. Give pregnant and lactating women penicillin G with caution because superinfections may occur in the fetus or infant, or the infant may develop diarrhea. If the patient is elderly, he or she may need a reduced dose because of decreased kidney function.

Lifestyle, Diet, and Habits

Instruct patients self-administering penicillin G to administer the drug around the clock to ensure that drug levels stay within a therapeutic range. Assess the patient's daily schedule to ensure that the patient who is self-administering penicillin G can complete the therapy as prescribed.

Environment

Be aware of the environment in which the drug will be administered. Whether administered at home or in an acute care setting, penicillin G solution should be mixed and stored in a refrigerator between 2° and 8°C (36° and 46°F) for up to 7 days. It should never be frozen. Commercially prepared infusion solutions may be kept at room temperature for 24 hours. Oral penicillin does not have specific environmental requirements.

Nursing Diagnoses and Outcomes

- Risk for Injury related to drug-related allergic reactions
  Desired outcome: *The patient will recognize symptoms of allergy and contact the prescriber immediately to minimize ill effects.*
- Imbalanced Nutrition: Less than Body Requirements related to drug-induced GI effects, such as diarrhea, GI upset, altered taste sensation, or superinfection
  Desired outcome: *The patient will maintain consistent body weight and consult prescriber about persistent adverse effects that affect nutritional status.*
- Diarrhea related to drug therapy
  Desired outcome: *The patient will avoid dehydration, maintain fluid intake, and contact prescriber about persistent diarrhea.*
- Risk for Infection related to overgrowth of nonsusceptible organisms.
  Desired outcome: *The patient will report signs of superinfection to the prescriber.*

Planning and Intervention

Maximizing Therapeutic Effects

Review culture and sensitivity reports to make sure that penicillin G is appropriate for the patient, especially for gram-negative infections. Administer penicillin G as prescribed, spaced evenly around the clock to increase effectiveness. For oral preparations, administer the dose on an empty stomach. Optimally, drug therapy should continue for at least 7 to 10 days, but it may continue for 2 weeks.

In acute care settings, retrieve the antibiotic from the refrigerator approximately 15 minutes before administration, and evaluate the IV site for signs of phlebitis before and after administration.

Administer intramuscular (IM) penicillin deep into the muscle mass. Aspirate the syringe to avoid accidental injection into the vasculature. Assess landmarks for IM administration to avoid injection into a nerve.

Minimizing Adverse Effects

Provide small, frequent meals; mouth care; and ice chips for the patient to suck on if stomatitis and sore mouth are problems. Monitor the patient to ensure that adequate fluids are given to replace fluid lost with an adverse effect such as diarrhea. Monitoring fluid intake and output is especially important. Notify the prescriber if a substantial change develops in the intake-to-output ratio, because such a change may be the first indication of kidney dysfunction.

When administering penicillin parenterally (IM or IV), monitor the patient for a minimum of 30 minutes. Epinephrine and respiratory support should be immediately available whenever parenteral penicillin is administered.

Read the penicillin label carefully prior to administration. Penicillin G benzathine and penicillin G procaine must be given intramuscularly. Inadvertent administration into the vasculature has been associated with cardiopulmonary arrest and death.

Providing Patient and Family Education

- Teach patients that penicillin is one drug within a class of drugs. Advise patients who have ever had any type of allergic reaction to penicillin never to take any other drug with a name that ends with "cillin."
- Explain to patients with penicillin allergy the importance of wearing some form of identification (e.g., MedicAlert necklace or bracelet) to alert health care personnel of the allergy in an emergency.
- Stress the importance of completing the full course of antibiotics, explaining the purpose of the drug and stating that it may not work for other types of infection.
- Emphasize the need to take penicillin G exactly as prescribed at evenly spaced intervals around the clock. Instruct the patient that oral drugs should be taken on an empty stomach 1 hour before or 2 hours after a meal.
- Instruct patients to take missed doses as soon as remembered but not at the time that the next dose is scheduled.
- If patients must mix the solution, instruct them to do so just before administration. When premixed solutions are used, they should be kept in the refrigerator and retrieved approximately 15 minutes before administration.
- Advise patients to contact the prescriber if no improvement occurs within 3 days.
- Because any patient may develop sensitivity to penicillin G at any time, discuss the signs and symptoms of allergic reaction and instruct patients to stop the drug and call the prescriber if a rash, welts, itching, or shortness of breath develops.
- Review common adverse effects and home interventions that may relieve discomfort. Patients who experience abdominal cramps or GI distress may try eating small, frequent meals. To relieve a sore mouth or throat, sucking on ice chips may help. If diarrhea occurs, teach patients to increase fluid intake and to contact the prescriber if symptoms do not resolve in 24 hours.
- Teach patients about other adverse effects, such as a change in tongue color, fatigue, easy bruising, and vaginal discharge. Instruct patients to report these signs and symptoms of superinfection to the prescriber immediately.
- Advise women of childbearing age to use a backup method of birth control for the duration of therapy.
- Explain the importance of sterile technique if family members administer IV therapy at home (Box 39.1).

BOX 39.1 COMMUNITY BASED CONCERNS

Taking Antibiotics Safely

Every year, families in the community face colds, sore throats, flu, and other types of infections. Should all of these conditions be treated with antibiotics? Even as a new member of the health care team, you can answer questions concerning antibiotic safety with ease. Be sure to emphasize these key points:

- Illnesses with very similar symptoms may be caused by entirely different types of microbes.
- Illnesses caused by microbes other than bacteria are generally not affected by antibiotics.
- Overuse, including inappropriate use of antibiotics, leads to bacterial resistance (super-strains of microbes that are very difficult to kill).
- Antibiotics take time to work, so it will take a couple of days to feel better.
- Take the medication exactly as prescribed—don't take fewer pills per day to make the prescription last longer.
- Never take medication from a previous illness—if its expiration date has passed, it might not work.
- Never take medication prescribed for another person, even if your symptoms are similar to theirs.
- All medications can cause adverse effects, especially nausea or diarrhea, but these effects are not signs of allergy.
- Signs of allergy include reddened skin, rash, itching, hives, swelling of one or more body parts, shortness of breath, wheezing, or chest palpitations. If you have these symptoms, do not take any more of the drug! Call the person who prescribed the medication immediately.

Ongoing Assessment and Evaluation

Monitor for signs of allergic reaction and for resolution of the presenting symptoms of infection (e.g., fever, lethargy, or hot and reddened or inflamed skin). Failure of these symptoms to resolve may indicate a treatment failure. Monitor for signs of superinfection and notify the prescriber immediately to arrange for treatment. For patient comfort, provide warm compresses and gentle massage to painful or swollen injection sites and observe for signs of phlebitis or abscess formation.

Monitor patients receiving parenteral sodium penicillin G for potential fluid overload. Monitoring is especially important in patients with cardiac disease or hypertension. Monitor patients receiving potassium penicillin G for signs

MEMORY CHIP

P Penicillin G

- Used for infections caused by gram-positive bacteria, anaerobes, and spirochetes. Also used as prophylaxis to prevent bacterial endocarditis.
- Major contraindications: hypersensitivity to penicillin, cephalosporins, or imipenem
- Most common adverse effects: nausea, vomiting, diarrhea
- Most serious adverse effect: hypersensitivity
- **Life span alert: Elderly patients may need reduced dosage because of decreased kidney function.**
- Maximizing therapeutic effects: Oral preparations should be given on an empty stomach. When using for gram-negative infections, be sure culture and sensitivity tests are done before administration.
- Minimizing adverse effects: Monitor intake and output because it may be the first sign of kidney dysfunction. Blood levels may become toxic if the kidneys cannot excrete penicillin.
- Most important patient education: Take the medication exactly as prescribed until the entire prescription is completed, despite the absence of symptoms. Monitor for signs and symptoms of allergic response and stop the medication if any occur.
- **Black box warning: Penicillin G has three formulations— penicillin G aqueous, penicillin G procaine, and penicillin G benzathine. Only penicillin G aqueous may be given intravenously.**

of hyperkalemia that may result in cardiac arrhythmias. Arrange for periodic electrolyte studies for patients receiving either preparation.

When treatment ends, the initial infection should be resolved. The patient should be adequately nourished and hydrated, and any adverse drug effects should be resolved.

Drugs Closely Related to P Penicillin G

Other Narrow-Spectrum Penicillins

Penicillin G benzathine is the benzathine salt of penicillin G. It has low solubility and provides an IM reservoir for low levels of penicillin over a long time. It can be detected in serum for up to 12 weeks after injection. It is used primarily for treating syphilis and preventing rheumatic fever.

Penicillin G procaine is the procaine salt of penicillin G. Because it is given by IM injection only, its use has been limited by the advent of IV antibiotics and newer broad-spectrum IM antibiotics. This drug must be stored in the refrigerator. Because it is viscous, it must warm at room temperature for approximately 15 minutes before being injected. Patients may react to procaine with confusion or agitation. This response is sometimes mistaken for a penicillin allergy.

Both penicillin G procaine and penicillin G benzathine have a Black Box warning that these two forms of penicillin G must be administered by the IM route. IV administration is associated with cardiorespiratory arrest and death.

Penicillin V (Pen-Vee-K, V-cillin-K) is the acid-stable oral form of penicillin G. It is indicated for the same infections as penicillin G and for prophylaxis during dental and upper respiratory procedures for patients who are immunocompromised or who are prone to bacterial endocarditis.

CRITICAL THINKING SCENARIO

IMPLEMENTING PENICILLIN V THERAPY

You have a patient who has been taking penicillin V for 2 days to "cure" an infection. You find out that this antibiotic was left over from an upper respiratory infection for which it had been prescribed 2 years earlier. The patient states that he stopped the drug when he felt better and kept it around just in case he got sick again. Describe how you would explain the dangers of taking antibiotics in this manner in a way that makes sense to the patient and leads to his adherence to antibiotic therapy in the future.

The contraindications, precautions, drug interactions, and adverse effects associated with penicillin V are the same as those associated with penicillin G. Penicillin V should be given only on an empty stomach, 1 hour before or 2 to 3 hours after meals, with a full glass of water. Advise the patient to continue the drug for the full course of the drug therapy, usually 7 to 10 days. Advise the patient neither to save the drug for self-medication at a later date nor to share the drug with any other person.

Broad-Spectrum Penicillins (Aminopenicillins)

Ampicillin and amoxicillin are aminopenicillins. The aminopenicillins have a slightly altered side chain that makes them effective against many gram-negative microorganisms, including *Haemophilus influenzae, Escherichia coli, Salmonella* and *Shigella* species, and indole-positive *Proteus mirabilis*. Aminopenicillins are ineffective against most infections caused by *Staphylococcus aureus* because they are easily inactivated by penicillinase produced by this species.

The benefits of these drugs include their higher oral absorption, higher serum levels, and longer half-lives. Ampicillin is the only drug that may be is available for both oral and intravenous administration.

Because these drugs are available for oral use and are effective against some of the most serious pediatric infections, they are frequently used to treat otitis media, upper respiratory infections, tonsillitis, skin infections, and pneumonia in children. Aminopenicillins should be used only for infections that are not sensitive to penicillin G or penicillin V because they have a broader spectrum of activity and therefore pose a greater opportunity for resistant strains to develop and adverse effects to occur.

Teach parents or other caregivers to follow storage and administration instructions exactly, to discard leftover drug and not save it for later use, to report frequently occurring rash or diarrhea, and to watch for signs of superinfections.

Extended-Spectrum Penicillins (Antipseudomonal Penicillins)

Piperacillin and ticarcillin are the extended-spectrum penicillins. They have an even broader spectrum than the aminopenicillins. The extended-spectrum penicillins are effective against

all of the organisms susceptible to the aminopenicillins, plus *Pseudomonas aeruginosa, Enterobacter* species, *Bacteroides fragilis,* many *Klebsiella* species, *Proteus vulgaris, Proteus morganii,* and *Proteus rettgeri*. Like the aminopenicillins, extended-spectrum penicillins are easily inactivated by penicillinase produced by *S. aureus*. They are available for oral or parenteral administration.

When given to combat *Pseudomonas,* extended-spectrum penicillins are frequently given concurrently with aminoglycoside antibiotics. When administered appropriately, this combination is highly effective. Remember to administer these two antibiotics at least 2 hours apart to avoid an antagonist drug–drug interaction.

The extended-spectrum penicillins should be reserved for use in serious infections by susceptible organisms. Again, caution patients to take oral preparations on an empty stomach, to complete the full course, and to monitor for side effects.

Penicillinase-Resistant Penicillins (Antistaphylococcal Penicillins)

With the use of penicillins over the years, increasing numbers of bacterial species are developing the enzyme penicillinase to counteract the effects of penicillin. The penicillinase-resistant drugs (dicloxacillin, nafcillin, and oxacillin) were developed to remain effective against bacteria that produce penicillinase and thus are resistant to penicillin. Although the penicillinase-resistant antibiotics are highly effective against strains of staphylococci, they are inactive against many other bacteria that secrete penicillinase, especially gram-negative bacteria. Culture and sensitivity tests are mandatory when using a penicillinase-resistant drug. The drugs in this group include dicloxacillin, which is an oral preparation, and nafcillin and oxacillin, which are IV preparations.

Certain strains of staphylococci are resistant to the drugs in this class. A patient infected with these strains of staphylococci may have an infection known as methicillin-resistant *Staphylococcus aureus* (MRSA). Resistance to methicillin implies resistance to any drug in this class. Methicillin (which is no longer available in the United States) is used infrequently because it can cause interstitial nephritis, whereas nafcillin and oxacillin are equally effective and do not have this adverse effect. The oral use of these drugs is now recommended for treating all gram-positive infections, because staphylococci are almost entirely penicillin resistant. Again, urge the patient to complete the full course of drug therapy, to take oral drugs on an empty stomach, and not to self-medicate with this drug at another time.

Drugs Significantly Different From P Penicillin G

Beta-Lactamase Inhibitors

Resistance to beta-lactams, such as penicillin, may occur because of the bacteria's ability to produce beta-lactamase. Clavulanic acid, sulbactam, and tazobactam are beta-lactamase inhibitors. On their own, they exhibit only weak antibacterial effects, and they are combined with other penicillin antibiotics to act as competitive "suicide" inhibitors of bacterial beta-lactamases. They accomplish this feat by binding to the enzyme's active site, thus allowing the penicillin to reach its target site. Clavulanic acid, sulbactam, and tazobactam do not alter the actions of the beta-lactam antibiotics. They simply prevent penicillins from being destroyed. Box 39.2 identifies the most common combination drugs that contain beta-lactamase inhibitors.

Box39.2 COMBINATION DRUGS WITH BETA-LACTAMASE INHIBITORS

Ampicillin + Sulbactam = Unasyn
Amoxicillin + Clavulanic Acid = Augmentin
Ticaracillin + Clavulanic Acid = Timentin
Piperacillin + Tazobactam = Zosyn

Bacitracin

Bacitracin is an oral, parenteral, and topical polypeptide antibiotic. It acts principally against gram-positive bacteria. Thus, it is combined frequently with drugs such as neomycin and polymyxins, which are active against gram-negative bacteria. The most common use of bacitracin is as a topical agent to prevent superficial skin and eye infections following minor injuries. It is available as a cream or ointment as well as ophthalmic drops or ointment.

Oral bacitracin is designated as an orphan drug to treat pseudomembranous colitis caused by *Clostridium difficile*. IM bacitracin is used rarely because of the risk for serious nephrotoxicity. However, IM bacitracin may be used to treat infants with pneumonia or empyema. Oral or parenteral bacitracin is used only in clinical situations in which less toxic drugs have not been effective.

To avoid systemic absorption of topical bacitracin, do not apply it to serious burns, deep wounds, or animal bites, over large areas of the body, or into a perforated tympanic membrane. Although topical bacitracin has few adverse effects, rare cases of anaphylaxis have been reported. Ophthalmic bacitracin may cause blurred vision that resolves spontaneously.

C MONOBACTAM ANTIBIOTICS

Aztreonam (Azactam) is a monobactam with a mechanism of activity similar to that of penicillin: it inhibits bacterial cell wall synthesis. It is used to manage infections caused by gram-negative aerobic bacteria. It has no activity against gram-positive bacteria or anaerobes. The structure of aztreonam differs substantially from the structures of other beta-lactam antibiotics; this drug may be given safely to penicillin-allergic patients because there is little cross-sensitivity.

Aztreonam is administered intravenously or intramuscularly and is eliminated by renal tubular secretion. It is also available as an inhaled drug (Cayston) for cystic fibrosis patients with *Pseudomonas aeruginosa*. Half-life is prolonged in patients with renal failure. It is widely distributed throughout the body, including the central nervous system (CNS).

Hypersensitivity is the only contraindication to aztreonam therapy. Common adverse effects include vertigo and

headache. Serious, but rare, adverse effects include GI distress with possible superinfection, hepatotoxicity, seizures, and blood dyscrasias, including neutropenia.

Important drug–drug interactions include synergistic effects when aztreonam is given with aminoglycosides and other beta-lactam antibiotics. Antagonistic effects may occur when it is given with cefoxitin or imipenem. Toxic aztreonam levels may occur when probenecid is given at the same time.

When giving aztreonam intravenously, check frequently for signs of thrombophlebitis at the IV insertion site. For long-term therapy, monitor laboratory studies, such as complete blood count (CBC), LFTs, prothrombin time (PT), partial thromboplastin time (PTT), and platelet count.

CARBAPENEMS

Like monobactams, carbapenems are chemically different from penicillins but retain the beta-lactam ring structure. They are very broad-spectrum antibiotics with activity against gram-positive cocci, gram-negative cocci, and bacilli, and they are the most effective beta-lactam antibiotics for use against anaerobes. Imipenem, meropenem, and ertapenem, and doripenem are the carbapenems approved for use in the United States.

Cilastatin-Imipenem

Imipenem is rapidly inactivated by renal dehydropeptidase 1. Therefore, imipenem is always administered with cilastatin, a drug that inhibits this enzyme. Cilastatin-imipenem (Primaxin) given IV or IM has a high affinity for bacterial PBPs and thus penetrates the cell wall efficiently. It also has a high resistance to bacterial enzymes, making it a very effective antibiotic.

Cilastatin-imipenem is structurally similar to penicillin and cephalosporins. For that reason, patients with a severe hypersensitivity to either of these agents should not be given cilastatin-imipenem. Cilastatin-imipenem is given cautiously to patients with head trauma, brain lesions, and pre-existing seizure disorders because these patients have a high risk for cilastatin-imipenem–induced seizures. Because cilastatin-imipenem is substantially excreted by the kidneys, patients with renal insufficiency, including the elderly, need a reduced dose. Cilastatin-imipenem is a Food and Drug Administration (FDA) pregnancy category C drug; however, whether it is excreted in human milk is unknown. Drug–drug interactions include cyclosporine, ganciclovir, or theophylline; the CNS effects of these drugs may be additive. Serious adverse effects include seizures, pseudomembranous colitis, and blood dyscrasias. More common adverse effects include GI distress, superinfections such as candidiasis, injection-site reactions, phlebitis, and elevations of LFT, BUN, and creatinine.

Doripenem

Doripenem (Doribax) is the newest carbapenem drug to be approved in the United States. It is FDA approved for the management of complicated abdominal or urinary tract infections and pyelonephritis. Like the other carbapenems, hypersensitivity is the only contraindication. Doripenem should not be given cautiously with probenecid or valproic acid. When administered with probenecid, doripenem levels are increased resulting in an increased risk for adverse effects. Like meropenem, doripenem may decrease serum valproic acid levels. Doripenem is a pregnancy category B; whether it is excreted into breast milk is unknown. Like ertapenem, it is not approved for use in children. Common adverse effects include phlebitis, rash, GI distress, and headache. Serious adverse effects are similar to those of cilastatin-imipenem.

Ertapenem

Ertapenem (Invanz) is administered either intramuscularly or intravenously. Its spectrum of activity is less than that of cilastatin-imipenem or meropenem. Most important, ertapenem has little or no activity against *P. aeruginosa* or *Acinetobacter* species. Ertapenem is indicated to manage moderate to severe complicated intra-abdominal infections, skin and skin structure infections, pyelonephritis, acute pelvic infections, and community-acquired pneumonia. Like meropenem, ertapenem is administered as a single agent. It is also excreted primarily by the kidneys, and reduced doses are required for patients with renal compromise. It belongs to FDA pregnancy category B and is secreted in breast milk. Ertapenem is not indicated for use in children. Contraindications and precautions are similar to those for cilastatin-imipenem and meropenem. Probenecid decreases the renal clearance of ertapenem. Adverse effects are similar to those of other carbapenems, and although seizures may occur, they are less likely to occur with ertapenem.

Meropenem

Meropenem (Merrem) is an IV antibiotic that is similar to cilastatin-imipenem. It is used to manage abdominal infections, such as appendicitis and peritonitis, and bacterial meningitis. It is also useful in managing nosocomial infections that are resistant to other antibiotics. Meropenem is not degraded by renal dipeptidases and can therefore be given as a single agent. As with cilastatin-imipenem, hypersensitivity is the only contraindication. Precautions to meropenem use are the same as for cilastatin-imipenem. Meropenem is excreted substantially unchanged; thus, a reduced dose is necessary for patients with renal insufficiency. It belongs to FDA pregnancy category B; whether it is excreted into breast milk is unknown. Meropenem may interact with valproic acid; thus, patients receiving valproic acid should be monitored to ensure that their treatment is effective. Adverse effects are similar to those of cilastatin-imipenem; however, seizures are less likely to occur.

CEPHALOSPORINS

The cephalosporins were first introduced in the 1960s. They are similar to the penicillins in structure and in activity and are also considered beta-lactam antibiotics. Four generations of cephalosporins have been introduced, each group with its

own spectrum of activity. Selecting an antibiotic from this class depends on the sensitivity of the involved organism, the preferred route of administration, and sometimes the cost of therapy. The major differences between the generations include their activity against gram-negative bacteria, their resistance to beta-lactamases, and their ability to distribute into cerebrospinal fluid. The first-generation cephalosporins have the least activity against gram-negative bacteria, and the fourth-generation cephalosporins have the most. The first-generation cephalosporins have little resistance to beta-lactamases; resistance increases in second and third generations, with the fourth generation having the most resistance. First- and second-generation cephalosporins have poor distribution into cerebrospinal fluid, and third- and fourth-generation cephalosporins have good distribution. Cefazolin (Ancef, Kefzol), a first-generation agent, is the prototypical cephalosporin. See Table 39.3 for a summary of selected cephalosporins.

Nursing Management of the Patient Receiving P Cefazolin

Core Drug Knowledge

Pharmacotherapeutics

Cefazolin can be used to treat many kinds of infections: skin, bone, heart, blood, respiratory tract, GI tract, sinus, ear, and urinary tract. Cefazolin is also used for perioperative prophylaxis in surgeries involving the GI or genitourinary tracts, bone, and skin.

Pharmacokinetics

Cefazolin is rapidly absorbed after IM injection. Peak effect occurs within 1.5 to 2 hours. It is also administered by the IV route, with immediate onset and peak effect in 5 minutes. Only two of the first-generation cephalosporins are available exclusively for oral use: cefadroxil and cephalexin.

Cefazolin is widely distributed to body fluids and tissues, including bone. It does not cross the blood–brain barrier, but it does cross the placenta and enters breast milk. It is excreted unchanged in the urine.

Pharmacodynamics

Cefazolin, like penicillin G, has no direct effect on the body. Cefazolin produces its bactericidal effects by binding with PBPs, which disrupts bacterial cell wall synthesis. Like penicillin, it also activates autolysins, which results in additional damage to the cell wall, allowing the cell to swell and then burst from the osmotic pressure within the cell. Like penicillins, it is most effective against cells undergoing active growth and division.

Contraindications and Precautions

Cefazolin is contraindicated in anyone with a known allergy to cephalosporins. Caution must be used in patients with renal failure and in pregnant or lactating patients. Because of the structural similarities between cephalosporins and penicillins, patients who are allergic to one type of drug may experience cross-sensitivity to the other. Cephalosporin hypersensitivity occurs in 5% to 10% of patients with penicillin allergy. Patients with a history of severe allergic reactions to penicillins should not receive cephalosporins because of the increased risk for cross-sensitivity reactions in these patients.

Adverse Effects

Hypersensitivity reactions occur frequently with cephalosporin drugs. Severe immediate reactions are rare. Hypersensitivity presents most frequently as a maculopapular rash that develops several days after the onset of therapy.

Other common adverse effects of cefazolin involve the GI tract. Nausea, vomiting, diarrhea, anorexia, abdominal pain, and flatulence are common side effects. Pseudomembranous colitis, a potentially dangerous disorder, has also been reported with cefazolin. The drug should be discontinued immediately at any sign of violent, bloody diarrhea and abdominal pain.

CNS symptoms include headache, dizziness, lethargy, and paresthesias. Nephrotoxicity is also associated with the use of cefazolin, most particularly with patients who have predisposing renal insufficiency. Superinfections are also common with cephalosporin use. As with the penicillins, this adverse effect is related to the normal flora having been destroyed. Thrombophlebitis and an abscess at the injection site are potential adverse effects of administering cephalosporins intravenously.

Serum sickness–like reactions, such as erythema multiforme or skin rashes accompanied by polyarthritis, arthralgia, and fever, may occur following a second course of therapy. Symptoms resolve after the patient stops taking the drug.

Drug Interactions

Risk for nephrotoxicity is greater when cefazolin is given concurrently with aminoglycoside antibiotics. Patients receiving oral anticoagulants may experience increased bleeding when also given cefazolin. Like penicillin, cefazolin may have prolonged effects when given concurrently with probenecid. Table 39.4 presents agents that interact with cefazolin. A disulfiram-like reaction may occur in patients taking cephalosporins with a chemical structure similar to that of disulfiram (see Chapter 9). Symptoms of a disulfiram-like reaction include flushing, shortness of breath, nausea and vomiting, chest pains, palpitations, dizziness and faintness, confusion, sweating, blurred vision, and possibly respiratory depression, seizures, and unconsciousness.

Effects on Test Results

False-positive results may occur in tests of urine glucose using Benedict solution, Fehling solution, and Clinitest tablets. Blood glucose monitoring is therefore recommended in patients with diabetes who are receiving cefazolin. False-positive results have also been noted in direct Coombs tests and measurements of urinary 17-ketosteroids. These tests should be avoided in patients receiving any cephalosporins.

TABLE 39.3 Summary of Selected Cephalosporins

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
First-Generation Cephalosporins			
P cefazolin (Kefzol, Ancef)	Respiratory tract infections Skin, joint, biliary, genital infections Endocarditis Surgical prophylaxis Septicemia	*Adult:* IM/IV Life-threatening infections, 1–2 g q6 h Moderate infections, 250 mg–1 g q8 h *Child:* IM/IV Life-threatening infections, 100 mg/kg in 3–4 divided doses Moderate infections, 25–50 mg/kg in 3–4 equal doses	*Onset:* IM, 30 min; IV, 10 min *Duration:* 6–12 h $t_{1/2}$: 90–120 min
cefadroxil (Duricef)	Respiratory tract infections Skin infections Otitis media Tonsillitis/pharyngitis UTI Endocarditis prophylaxis	*Adult:* PO, 1–2 g every day or q12 h in divided doses Loading dose of 1 g initially *Adult:* 2 g 1 h before procedure *Child:* PO, 30 mg/d divided, twice daily, up to a maximum of 2 g/d; 50 mg/kg 1 h before procedure	*Onset:* Rapid *Duration:* 12–24 h $t_{1/2}$: 1 1/2–2 h
cephalexin (Keflex, Biocef)	Respiratory tract infections Skin, bone infections Otitis media UTI	*Adult:* PO Severe infections, 500 mg–1 g q6 h Moderate infections, 250–500 mg q6 h *Child:* PO Severe infections, 50–100 mg/kg in 4 equal doses Moderate infections, 25–50 mg/kg day in 4 equal doses	*Onset:* 15–30 min *Duration:* 6–12 h $t_{1/2}$: 50–80 min
Second-Generation Cephalosporins			
cefaclor (Raniclor)	Respiratory tract infections UTI Skin, bone, joint infections Gynecologic infections Septicemia Otitis media	*Adult:* PO, 250–500 mg q8 h *Child:* PO, 20–40 mg/kg/d in divided doses q8 h	*Onset:* 15 min *Duration:* 6–12 h $t_{1/2}$: 30–60 min
cefprozil (Cefzil)	Respiratory tract infections UTI Skin infections Otitis media	*Adult:* PO, 250–500 mg 1–2 ×/d *Child:* PO, 7.5–15 mg/kg q12 h	*Onset:* Varies *Duration:* 12–24 h $t_{1/2}$: 1–1 $_{1/2}$ h
cefotetan	Respiratory tract infections Skin and bone infections Gynecological infections Intra-abdominal infections Urinary Tract Infections Surgical prophylaxis	*Adults IM/IV: 1–2 g every 12 h* *500 mg every 12 h* *1–2 g 30–60 min before surgery*	*Onset: rapid* *Duration: unknown* $t_{1/2}$: *3–4.5 h*
cefuroxime (Ceftin, Zinacef)	Severe respiratory tract infections Skin infections Otitis media Surgical prophylaxis	*Adult:* PO, 250–500 mg PO q12 h *Adult:* IM/IV, 750 mg q8 h *Child:* PO, 125 mg PO q12 h *Child and infant ≥3 mo:* IM/IV, 50–100 mg/ kg/d in equally divided doses q6–8 h *Neonate:* IM/IV, 20–100 mg/kg/d in equally divided doses q12 h	*Onset:* PO, varies; IM, 20 min; IV, rapid *Duration:* 18–24 h $t_{1/2}$: 1–2 h
cefoxitin	Lower respiratory tract infections Skin and bone infections Gynecologic infections Gonococcal infections Septicemia Peritonitis	*Adult:* IM/IV, 1–2 g q6–8 h *Child >3 mo:* IM/IV, 80–160 mg/kg/d in divided doses q4–6 h	*Onset:* IM, 5–10 min; IV, immediate *Duration:* 6–8 h $t_{1/2}$: 40–60 min
Third-Generation Cephalosporins			
cefdinir (Omnicef)	Pneumonia CAL exacerbations Otitis media Maxillary sinusitis Pharyngitis/tonsillitis Skin infections	*Adult:* PO, 600 mg/d *Child:* PO, 14 mg/kg/d *Infants ≥6 mo:* PO, 14 mg/kg/d Note: All may be divided into 2 doses given q12 h	*Onset:* 2 h *Duration:* 8–10 h $t_{1/2}$: 1.7 h

TABLE 39.3 Summary of Selected Cephalosporins *(continued)*

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
cefditoren (Spectracef)	Bronchitis, chronic Acute bacterial infection Community-acquired pneumonia Infection of skin and/or subcutaneous tissue Pharyngitis Tonsillitis	*Adult:* PO, 400 mg 2×/d for 10 d 400 mg 2×/d for 14 d 200 mg 2×/d for 10 d	*Onset:* Rapid *Duration:* 8–10 h $t_{1/2}$: 1.6–2 h
cefixime (Suprax)	Acute exacerbation of COPD Acute bronchitis Acute otitis media Pharyngitis Tonsillitis Uncomplicated UTI Gonococcal infections	*Oral Suspension Only* *Adult:* PO, 400 mg daily (may be divided) *Adult:* 400 mg one time only *Child 60 mo–12 y:* PO, 8 mg/kg/d (may be divided) *Child >12 y or 50 kg:* same as for an adult	*Onset:* Unknown *Duration:* Unknown $t_{1/2}$: 3–4 h
cefpodoxime (Vantin)	Respiratory tract infections UTI Skin infections Otitis media STDs	*Adult:* PO, 200–400 mg q12 h *Child:* PO, 5 mg/kg q12 h	*Onset:* Varies *Duration:* 12 h $t_{1/2}$: 2–3 h
ceftibuten (Cedax)	Respiratory tract infections Otitis media	*Adult:* PO, 400 mg every day *Child >6 mo:* 9 mg/kg to a maximum of 400 mg/d	*Onset:* Rapid *Duration:* 24 h $t_{1/2}$: 1–1.5 h
cefotaxime (Claforan)	Serious lower respiratory tract infections UTI Skin and bone infections Gonococcal infections Bacteremia Septicemia Meningitis	*Patient ≥50 kg:* IM/IV, 1 g q12 h Moderate to severe infections: 1–2 g q8 h Severe infections: 2 g q6–8 h Life-threatening infections: 2 g q4 h; maximum dosage is 12 g/d *Child and infant 1 mo–12 y, <50 kg:* 75–100 mg/ kg/d given in 3–4 divided doses Severe infections: 150–225 mg/kg/d given in 3–4 equally divided doses *Neonate 1–4 wk:* IM/IV, 50 mg/kg every 6 or 8 h *Neonate >7 d, ≤ 2 kg:* 50 mg/kg IV or IM every 8 h (or every 12 h in neonates weighing >2 kg)	*Onset:* IM, 30 min; IV, 5–10 min *Duration:* 4–12 h $t_{1/2}$: 1 h
ceftriaxone (Rocephin)	Serious lower respiratory tract infections UTI Skin, bone, joint infections Gonococcal infections Intra-abdominal infections	*Adult:* IM/IV, 1–2 g q12–24 h; maximum dosage is 4 g/d *Child and infant ≥1 mo:* IM/IV, 50–75 mg/kg/d divided, every 12–24 h; maximum dose is 2 g/d *Neonate ≤ 7 d, <2000 g:* IM/IV, 50 mg/kg/d q24 h *Neonate ≤7 d:* IM/IV, 50 mg/kg/d q24 h *Neonate >7 d, >2000 g:* IM/IV, 50–75 mg/kg/d q24 h	*Onset:* IM, 30 min; IV, immediate *Duration:* 12–24 h $t_{1/2}$: 5–8 h
ceftazidime (Fortaz, Tazicef)	Serious respiratory tract infections UTI Skin, bone, joint infections Gynecologic infections Intra-abdominal infections Septicemia Meningitis	*Adult:* IM/IV, 1–2 g q8 h; maximum dose is 6 g/d *Child and infant ≥1 mo:* IV, 30–50 mg/kg q8h; maximum dose is 6 g/d *Neonate 0–4 wk:* IV, 30 mg/kg q12 h	*Onset:* IM, 30 min; IV, immediate *Duration:* 6–12 h $t_{1/2}$: 1/2–1 h
Fourth-Generation Cephalosporins			
cefepime (Maxipime)	Lower respiratory tract infections UTI Skin and bone infections Gonococcal infections Septicemia Peritonitis	*Adult and adolescent >16 y:* IV, 2 g IV q8 h *Infant and child ≤40 kg:* IV, 50 mg/kg/dose q8 h	*Onset:* IM, 30 min; IV, immediate *Duration:* 10–12 h $t_{1/2}$: 2–2.3 h

TABLE 39.4 Agents That Interact with P Cefazolin

Interactants	Effect and Significance	Nursing Management
alcohol	Combination may cause disulfiram-like reaction.	Advise patient to refrain from alcohol for 72 h.
aminoglycosides	Increased risk of nephrotoxicity, although the mechanism of action is unknown.	Monitor peak and trough levels of aminoglycoside. Monitor BUN and creatinine levels closely. Contact provider to discuss decreasing dose or discontinuing drug if signs of kidney dysfunction occur.
oral anticoagulants	Some cephalosporins may have a warfarin-like activity and antiplatelet effects. This results in an augmentation of the action of oral anticoagulants and an increased risk of bleeding.	Advise patients of the signs and symptoms of overanticoagulation. Monitor oral anticoagulant levels. Discuss reducing oral anticoagulant dose with the provider.

Assessment of Relevant Core Patient Variables

Health Status

Follow the same guidelines used for evaluating the health status of a patient receiving penicillin.

Life Span and Gender

Document the age of the patient and, if appropriate, assess for pregnancy and lactation. In elderly patients who have any degree of renal insufficiency, cefazolin should be used cautiously, and the dosage should be adjusted. Adjusted dosage recommendations are based on creatinine clearance levels. Cefazolin is not recommended for infants younger than 1 month because of their immature renal and hepatic functioning.

Lifestyle, Diet, and Habits

Assess the patient's lifestyle and dietary practices to ensure that the drug can be taken consistently, completely, and on an empty stomach, if possible. Assess for the patient's use of alcoholic beverages. Although not all cephalosporins cause a disulfiram-like reaction, it is preferable to refrain from drinking alcohol while on cephalosporin therapy.

Environment

Be aware of the environment in which the drug will be administered. After dilution, cefazolin can be kept at room temperature for 24 hours or in a refrigerator between 2°C and 8°C (36°C and 46°F) for 96 hours (4 days). In acute care settings, retrieve the antibiotic from the refrigerator and let it warm at room temperature for about 15 minutes before administering it. The IV site should be evaluated for signs of phlebitis before and after drug administration. Premixed solutions should be kept in the refrigerator and retrieved approximately 15 minutes before administration as well.

Nursing Diagnoses and Outcomes

- Diarrhea related to drug effects
  Desired outcome: *The patient will avoid dehydration, maintain fluid intake, and contact the prescriber if diarrhea persists.*
- Imbalanced Nutrition: More or Less than Body Requirements, related to GI effects, alteration in taste, superinfections
  Desired outcome: *The patient will maintain body weight and contact the prescriber if persistent adverse effects alter nutritional status.*
- Risk for Infection related to overgrowth of nonsusceptible organisms
  Desired outcome: *The patient will report signs of superinfection to the prescriber.*

Planning and Intervention

Maximizing Therapeutic Effects

Review culture and sensitivity tests to evaluate the efficacy of treatment. Oral suspensions of cephalosporins should be kept in the refrigerator. Be sure that the patient receives injections of cefazolin as prescribed around the clock for increased effectiveness. Monitor the site of infection and presenting signs and symptoms throughout the course of drug therapy. Failure of the signs and symptoms of infection to resolve may indicate the need to repeat culture and sensitivity testing. For optimal effect, drug therapy should continue for at least 2 days after all signs and symptoms resolve.

Minimizing Adverse Effects

Cefazolin may be taken with food or fluids to decrease GI distress. Provide small, frequent meals; mouth care; and ice chips to suck on if stomatitis and sore mouth are problems. Monitor the patient's hydration status and ensure that adequate fluids are given to replace fluid lost with diarrhea. Evaluate the patient for CNS effects and use safety precautions, such as elevating side rails.

Administer IM cefazolin deep into a large muscle. Forewarn the patient that the injection may be uncomfortable. The patient receiving IM cefazolin should be monitored for an abscess at the injection site. IV administration may be as an IV push or IV piggyback. Administer IV cefazolin exactly as prescribed by the prescriber. In addition, monitor the patient receiving IV cefazolin for the possibility of thrombophlebitis.

Monitor the patient receiving combination therapy with aminoglycoside antibiotics (serum BUN and creatinine

MEMORY CHIP

P Cefazolin

- Used for infections caused by gram-positive bacteria, anaerobes, and spirochetes. Also used as prophylaxis in patients having GI or GU surgery.
- Major contraindication: hypersensitivity to cephalosporins or penicillin
- Most common adverse effects: nausea, vomiting, diarrhea
- Most serious adverse effect: hypersensitivity
- **Life span alert: Cefazolin should be used cautiously and the dosage adjusted in elderly patients who have any degree of renal insufficiency.**
- Maximizing therapeutic effects: When using for gram-negative infections, be sure culture and sensitivity tests are done before administration.
- Minimizing adverse effects: Inject IM preparations into a large muscle mass. Be sure IV preparations are administered according to the health care prescriber's orders, either IV push or IV piggyback.
- Most important patient education: Take the medication exactly as prescribed until the entire prescription is completed, despite the absence of symptoms. Monitor for signs and symptoms of allergic response and stop the medication if any occur.
- **Patient safety alert: The generic names of the cephalosporins are very similar. Triple-check the order before administering the medication.**

levels) frequently for nephrotoxicity. Give the patient receiving oral anticoagulants in addition to cefazolin instructions about monitoring for signs of blood loss, for example, bleeding gums and easily bruised skin. Dosage of the oral anticoagulant may have to be reduced.

Providing Patient and Family Education

- Because cefazolin and the other cephalosporins are similar to penicillins, follow the same guidelines for providing patient and family education to a patient receiving penicillin.
- In addition, inform patients about possible interactions between cephalosporins and alcohol, urging the patient to refrain from drinking alcohol for 72 hours after drug therapy stops.
- Educate patients on hidden sources of alcohol, such as over-the-counter cough and cold preparations.

Ongoing Assessment and Evaluation

Monitor the patient for any signs of superinfection and notify the prescriber immediately to arrange for treatment if superinfection does occur. Monitor also for signs of allergic or serum sickness-like reactions (fever, hives, swollen glands, neutropenia, arthralgia, and edema). Implement comfort measures as needed and monitor for signs of phlebitis, abscess formation, and other complications. When treatment ends, the initial infection should be resolved. The patient should be adequately nourished and hydrated, and any adverse drug effects should be resolved.

Drugs Closely Related to P Cefazolin

First-Generation Cephalosporins

Cefadroxil and cephalexin are oral first- generation cephalosporins. Both of these drugs cover basically the same spectrum of pathogens. They are most active against gram-positive bacteria, especially staphylococci and nonenterococcal streptococci. They have minor activity against gram-negative bacteria. Most first-generation cephalosporins are destroyed by beta-lactamases and have minimal ability to concentrate in the cerebrospinal fluid (CSF). Oral forms are not affected by food and are best taken with food to decrease the GI upset that accompanies their use.

Second-Generation Cephalosporins

Second-generation cephalosporins include cefaclor and cefprozil which are available for oral administration; cefuroxime, which is available in oral, IM, or IV preparations; and cefotetan, cefoxitin, and cefuroxime, which are available for IM or IV administration. These drugs are less sensitive to destruction by beta-lactamases than first-generation drugs but still cannot achieve effective concentrations in the CSF.

The second-generation cephalosporins have broader coverage against gram-negative bacteria than first-generation cephalosporins because they are better able to penetrate the gram-negative cell envelope and have an increased affinity for the PBPs of gram-negative bacteria. They are used in the same way as first-generation cephalosporins as well as uncomplicated gonorrhea.

Third-Generation Cephalosporins

Third-generation cephalosporins include the oral drugs cefdinir, cefditoren, cefixime, cefpodoxime, and ceftibuten and the IM and/or IV drugs cefotaxime, ceftriaxone, and ceftazidime. These drugs are highly resistant to destruction by beta-lactamases and are highly effective against gram-negative aerobes. Ceftazidime is especially effective for bacterial strains resistant to aminoglycosides and is also effective against *P. aeruginosa*. This generation of cephalosporins is used for severe infections or in immunocompromised patients. The exception is ceftriaxone, which is the drug of choice for gonorrhea. With the exception of cefixime, third-generation cephalosporins can penetrate the blood–brain barrier to treat CNS infections.

Cefditoren contains a milk protein. Thus, it is contraindicated for patients with a milk-protein allergy, although it may be given to patients who are lactose intolerant. Cefditoren is excreted with carnitine, an amino acid responsible for transport of fatty acids into mitochondria, and should be given cautiously to patients with carnitine deficiency. This may occur during periods of growth or pregnancy, when the body needs more carnitine than it naturally produces. Carnitine deficiency may also occur in patients with vitamin C deficiency because vitamin C is necessary for synthesis of carnitine.

Fourth-Generation Cephalosporins

Cefepime is the first fourth-generation cephalosporin. It is active against both gram-positive and gram-negative organisms. It has a greater spectrum than third-generation drugs, is more active against organisms such as *P. aeruginosa* or Enterobacteriaceae that have developed resistance to third-generation drugs, and has good penetration into the CSF. Like third-generation cephalosporins, cefepime is highly resistant to destruction by beta-lactamases.

VANCOMYCIN

Vancomycin (Vancocin) is a complex and unusual tricyclic glycopeptide antibiotic. It is the only drug in its class. The use of vancomycin is limited by its ability to produce toxic effects. Because of its toxicity, vancomycin is used only when other antibiotics fail to resolve an infection. It has been touted as able to eradicate most gram-positive pathogens; however, the emergence of vancomycin-resistant enterococci (VRE) has become problematic. Table 39.5 presents an overview of vancomycin.

Nursing Management of the Patient Receiving Vancomycin

Core Drug Knowledge

Pharmacotherapeutics

Vancomycin is used in treating bacterial septicemia, endocarditis, bone and joint infections, and pseudomembranous colitis caused by *C. difficile*. Vancomycin is exceptionally effective for treating gram-positive infections in penicillin-allergic patients. It is also used for penicillin- and methicillin-resistant staphylococcal infections.

Vancomycin is used with aminoglycosides to combat *Streptococcus faecalis* and methicillin-resistant organisms. However, this synergism also increases possible toxicity.

Gram-negative bacteria and mycobacteria are resistant to vancomycin. Vancomycin is not used in treating meningitis because of poor penetration into CSF.

Pharmacokinetics

Oral bioavailability of vancomycin is extremely low; therefore, it is generally administered intravenously. Oral administration is used in treating some GI infections, such as pseudomembranous colitis, but only after a trial of another antimicrobial—metronidazole. Some patients, especially those with renal impairment, have developed detectable vancomycin serum levels following oral administration.

After IV administration, plasma concentrations reach a peak approximately 1 hour after infusion. In patients with normal renal function, vancomycin has a serum half-life of 4 to 6 hours, but in elderly patients or those with renal impairment, half-life can be as long as 146 hours.

Vancomycin is distributed widely into most body tissues and fluids, including pericardial, pleural, ascitic, and synovial fluids, and the meninges if they are inflamed. It is not known whether any metabolism takes place. Excretion is mainly by glomerular filtration; only small amounts are excreted in the feces. With oral administration, excretion is mainly fecal.

Pharmacodynamics

Vancomycin is bactericidal because it inhibits cell wall synthesis by altering the cell's permeability. Vancomycin also inhibits the synthesis of ribonucleic acid (RNA). Because of this dual mechanism of action, resistance to vancomycin has been limited to strains of group D streptococci. The body is not directly affected.

Contraindications and Precautions

Vancomycin is contraindicated for patients with hypersensitivity to it and for pregnant patients. Although it is excreted into breast milk, vancomycin is not contraindicated for breast-feeding women. However, breast-feeding neonates

TABLE 39.5 Overview of Vancomycin

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
Vancomycin (Vancocin)	MRSA	*Adult IV:* 2 g/d IV divided every 6–12 h *Child IV*: 10 mg/kg IV every 6 h *Neonate IV*: 15 mg/kg IV, followed by 10 mg/kg IV every 12 h for neonates in the first week of life, and every 8 h thereafter up to the age of 1 mo	*Onset Oral:* varies *Onset IV:* rapid *Duration:* unknown $t_{1/2}$: 6–6 h
	Bacterial meningitis	*Adult IV*: 30–45 mg/kg/d divided every 8–12 h 2 g/d IV divided every 6–12 h administered over at least 60 min *Child IV > 28 d*: 60 mg/kg/d divided every 6 h *Neonate IV 8–28 d*: 8–28 d, 30–45 *Neonate 0–7* d: 20–30 mg/kg/d divided every 8–12 h;	
	Infective endocarditis	*Adult IV:* 2 g/d IV divided every 6–12 h *Child IV:* 10–15 mg/kg IV every 6 h	
	Antibiotic induced pseudomembranous enterocolitis	*Adult Oral:* 500 mg to 2 g daily divided every 6–8 h *Child Oral:* 40 mg/kg/d divided every 6–8 h	

and infants should be monitored for vancomycin serum concentration to avoid potential toxicities. Use it with caution in patients with renal disease, such as renal failure or renal impairment, and in patients receiving other drugs with the potential for nephrotoxicity, such as aminoglycosides.

Oral vancomycin should be used with caution in patients with inflammatory bowel disease because this disorder increases absorption of oral vancomycin, thereby increasing the risk for toxicity.

Adverse Effects

The most serious toxicities caused by vancomycin are ototoxicity and nephrotoxicity. Ototoxicity can take the form of cochlear toxicity (tinnitus, hearing loss) or vestibular toxicity (ataxia, vertigo, nausea and vomiting, nystagmus).

Nephrotoxicity can also occur with vancomycin, although its incidence has decreased since the newer formulations have less impurities. Nephrotoxicity and elevated serum concentrations are more likely to occur in patients receiving other nephrotoxic drugs, such as aminoglycosides. Cases of interstitial nephritis, a hypersensitivity reaction, have been reported.

Vancomycin can cause histamine release, resulting in anaphylactoid reactions. Symptoms include fever, chills, sinus tachycardia, and pruritus. Paresthesias, flushing, rash, or redness in the face, neck, upper body, arms, or back are also symptoms of histamine release. In some cases, hypotension occurs. Because of the presenting symptoms, this histamine-release reaction is often called the "red man" or "red neck" syndrome. Other adverse reactions include phlebitis or other injection-site reactions, leukopenia, and thrombocytopenia.

Drug Interactions

Orally administered vancomycin should be avoided in patients receiving antihyperlipidemic drugs (HMG-CoA reductase inhibitors, statins). Vancomycin should be used with caution in combination with other drugs that have potential nephrotoxic or ototoxic effects and in patients receiving nondepolarizing muscle relaxants. Table 39.6 presents drugs that interact with vancomycin.

Assessment of Relevant Core Patient Variables

Health Status

Assess the patient for contraindications or precautions to the use of vancomycin, including other drugs with potential nephrotoxicity and ototoxicity. Lower doses of vancomycin are recommended for patients with renal dysfunction or for patients receiving other ototoxic or nephrotoxic drugs. Assess gross hearing in patients with pre-existing hearing impairment. Periodic audiograms may be necessary during therapy. For patients with expected long-term therapy, perform a baseline CBC and hepatic and renal function tests. Consult with the prescriber about any laboratory abnormalities before vancomycin therapy begins.

Life Span and Gender

Ask women of childbearing age about their contraceptive methods and assess for pregnancy and lactation. Vancomycin should not be given to pregnant women and should be given cautiously to breast-feeding women. Note whether patients are elderly, because such patients are at higher risk for toxicity and drug accumulation because of their age-related decreases in renal function.

Environment

Be aware of the environment in which the drug will be administered. Generally, vancomycin is administered in an inpatient setting because of its potentially serious toxicities and the need to closely monitor vancomycin serum concentrations.

Nursing Diagnoses and Outcomes

- Risk for Injury related to drug-induced histamine-release reactions
  Desired outcome: *The patient will experience no preventable reaction related to vancomycin.*
- Disturbed Sensory Perception (auditory) related to drug-induced ototoxicity
  Desired outcome: *The patient will report any unusual auditory sensations and have periodic audiograms to detect early ototoxicity.*
- Excess Fluid Volume related to nephrotoxicity from drug therapy
  Desired outcome: *The patient will remain normovolemic throughout therapy.*
- Risk for Infection related to overgrowth of nonsusceptible organisms.
  Desired outcome: *The patient will report signs of superinfection to the prescriber.*

Planning and Intervention

Maximizing Therapeutic Effects

Ensure that the patient receives the full course of vancomycin as prescribed, divided around the clock to increase effectiveness. Coordinate administering drugs to decrease potential drug–drug interactions. In addition, culture and sensitivity results should be monitored to be sure that vancomycin is the drug of choice for this patient.

Minimizing Adverse Effects

Administer vancomycin over at least 60 minutes. This rate diminishes effects such as flushing, tachycardia, hypotension, or rashes that occur when administration is too fast. Slowing the IV rate also decreases the potential for phlebitis. Assess the IV site frequently for signs of phlebitis.

Ototoxicity after IV administration is believed to be associated with serum concentration ranges above 60 to 80 mcg/mL, which may occur when doses are too large or infused too rapidly. Administering IV vancomycin too rapidly may also lead to red man syndrome. In addition, take care to avoid extravasation because vancomycin is extremely irritating to tissues.

TABLE 39.6 Agents That Interact with P Vancomycin

Interactants	Effect and Significance	Nursing Management
methotrexate	Coadministration may increase methotrexate serum concentration.	Monitor CBC. Monitor for myelosuppression.
Nephrotoxic drugs aminoglycosides amphotericin B bacitracin cisplatin cyclosporine polymyxin B	Parenteral vancomycin with other nephrotoxic drugs can lead to additive risks for nephrotoxicity.	Monitor renal function closely. Consider lower doses of vancomycin.
Nondepolarizing muscle relaxants	Vancomycin may affect presynaptic and postsynaptic myoneural function and act synergistically with nondepolarizing muscle relaxants.	Avoid this combination when possible. When given, monitor neuromuscular function closely, and be prepared to initiate mechanical ventilation.
Ototoxic drugs aminoglycosides salicylates ethacrynic acid furosemide paromomycin	Parenteral vancomycin with other ototoxic drugs can lead to additive risks for ototoxicity.	Monitor sensory/hearing functions closely. Consider lower doses of vancomycin. Monitor for neuromuscular paralysis and respiratory collapse.
succinylcholine	Vancomycin may potentiate the neuromuscular blocking effects of succinylcholine.	

Peak and trough levels are terms associated with serum concentration measurements. Obtain the peak serum level 1 hour after completion of the infusion and the trough serum level 30 minutes before beginning the next infusion. Some hospitals obtain only a trough level unless the patient is at high risk for nephrotoxicity.

MEMORY CHIP

P Vancomycin

- Used for serious gram-positive infections, especially *Clostridium difficile* and methicillin-resistant *Staphylococcus aureus*.
- Major contraindications: hypersensitivity and pregnancy
- Most common adverse effects: histamine release resulting in "red-man" syndrome
- Most serious adverse effects: ototoxicity and nephrotoxicity
- **Life span alert: Elderly patients may need vancomycin concentration monitoring because of a higher risk of toxicity and drug accumulation secondary to age-related decreases in renal function.**
- Maximizing therapeutic effects: Obtain culture and sensitivity report before administration.
- Minimizing adverse effects: Administer over 60 minutes.
- Most important patient education: Need for periodic CBC when taking for prolonged period or high doses. Need to advise the health care team for changes in hearing.

Providing Patient and Family Education

- Advise the patient of the importance of completing therapy.
- Explain the potential adverse effects and need for periodic blood monitoring.
- Advise the patient to report symptoms such as tinnitus, hearing loss, vertigo, or nausea and vomiting.
- Teach the patient the importance of accurate fluid intake and output measurements.

Ongoing Assessment and Evaluation

Elderly patients may need vancomycin concentration monitoring because age-related decreases in renal function put them at risk for toxicity and drug accumulation.

Monitor for signs of ototoxicity. Factors that may increase the risk for developing ototoxicity include excessive dose, serum concentrations above 60 mcg/mL, prolonged exposure to the drug, multiple ototoxic drugs, dehydration, excessive noise, and bacteremia. Assess for symptoms, such as ataxia and nystagmus, which may indicate ototoxicity. Monitor fluid intake and output to assess for potential nephrotoxicity.

For patients receiving long-term or high-dose therapy, coordinate periodic audiometric testing and serial CBCs, LFTs, and kidney function tests. As with other potent antibiotics, monitor for signs of superinfection. When treatment ends, the initial infection should be resolved. The patient should be adequately nourished and hydrated, and any adverse drug effects should be resolved.

CHAPTER SUMMARY

- Penicillins are classified as narrow-spectrum, penicillinase-resistant, aminopenicillins (broad-spectrum), and extended-spectrum (antipseudomonal) penicillins. They are also known as beta-lactam antibiotics.
- Penicillins may be inactivated by beta-lactamase, an enzyme produced by the bacteria. Penicillinase-resistant penicillins or penicillin–beta-lactamase combination drugs decrease the effects of penicillinase.
- Penicillins are most effective against gram-positive bacteria because they have difficulty penetrating the gram-negative cell envelope.
- Penicillins are the safest antibiotics available, except in patients with a hypersensitivity to penicillin.
- Penicillins can be administered orally, intramuscularly, or intravenously.
- Patients with a possible history of penicillin allergy should receive skin testing before administration.
- Patients with hypersensitivity to any penicillin should be considered allergic to all penicillins.
- Monobactam and carbapenem antibiotics are also beta-lactam antibiotics. Imipenem has the broadest spectrum of activity of all antibiotics.
- Cephalosporins are the antibiotics most widely used today.
- Cephalosporin antibiotics are structurally similar to penicillins. Between 5% and 10% of patients with hypersensitivity to penicillin will also react to cephalosporins.
- Cephalosporin antibiotics are grouped according to "generations."
- As cephalosporin generations progress, the drugs have increased activity against gram-negative bacteria and anaerobes, increased resistance to destruction by beta lactamases, and increased ability to reach the CSF.
- Most of the cephalosporins are administered parenterally.
- Vancomycin is very effective against most gram-positive infections; however, its use is limited by its potential to cause severe adverse effects.
- Vancomycin is the drug of choice for pseudomembranous colitis caused by *Clostridium difficile,* infections caused by methicillin- resistant *Staphylococcus aureus,* and serious infections in patients who are allergic to penicillin.
- Patients with an antibiotic allergy should wear a MedicAlert necklace or bracelet.

QUESTIONS FOR STUDY AND REVIEW

1. How do penicillins work?
2. Why are most penicillins ineffective against gram-negative bacteria?
3. On what basis are the penicillins classified into four groups?
4. Why are clavulanic acid, tazobactam, and sulbactam added to some penicillin preparations?
5. Compare and contrast the carbapenem antibiotics.
6. What is the difference between the generations of cephalosporins?
7. What classes of antibiotics are called beta-lactam antibiotics? Why?
8. Why is vancomycin reserved for serious infections?

Antibiotics Affecting Protein Synthesis

Learning Objectives

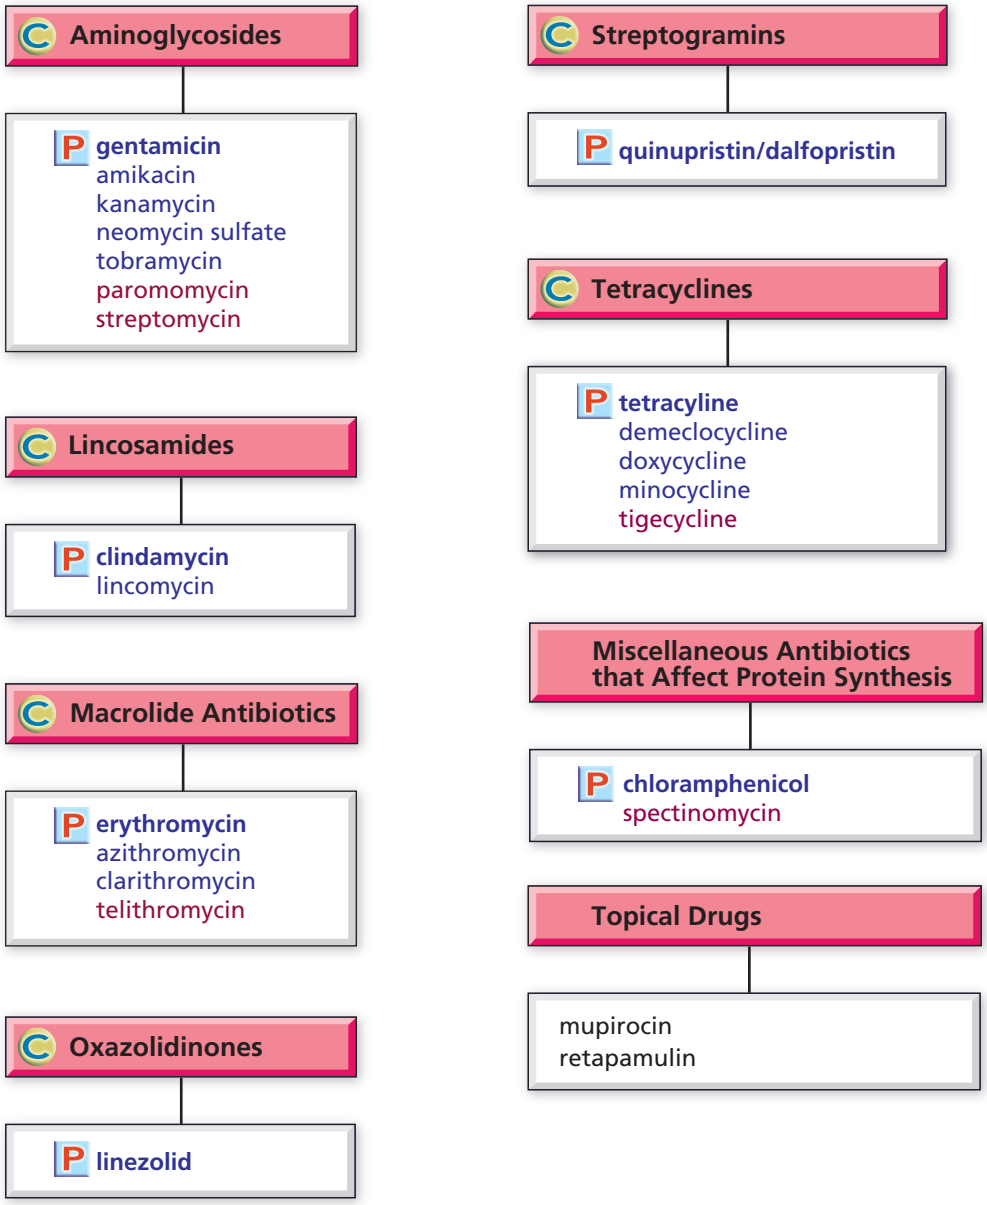
At the completion of this chapter the student will:

1. Identify core drug knowledge pertaining to drugs affecting protein synthesis.
2. Identify core patient variables pertaining to drugs affecting protein synthesis.
3. Relate the interaction of core drug knowledge to core patient variables for drugs affecting protein synthesis.
4. Generate a nursing plan of care from the interactions between core drug knowledge and core patient variables for drugs affecting protein synthesis.
5. Describe nursing interventions to maximize therapeutic and minimize adverse effects for drugs affecting protein synthesis.
6. Determine key points for patient and family education for drugs affecting protein synthesis.

Key Terms

azotemia
cylindruria
hyposthenuria
nephrotoxicity
ototoxicity
peak and trough
proteinuria
pyuria
xeroderma
xerophthalmia

Antibiotics Affecting Protein Synthesis



The symbol C indicates the drug class.
Drugs in **bold type** marked with the symbol P are prototypes.
Drugs in blue type are closely related to the prototype.
Drugs in red type are significantly different from the prototype.
Drugs in black type with no symbol are also used in drug therapy; no prototype.

Drugs affecting protein synthesis include aminoglycoside agents, ketolide agents, lincosamide agents, macrolide agents, oxazolidinones, streptogramins, tetracyclines, and miscellaneous antibiotics. The prototype drugs discussed in this chapter are gentamicin (aminoglycosides), clindamycin (lincosamides), erythromycin (macrolides), linezolid (oxazolidinones), quinupristin/dalfopristin (streptogramins), tetracycline (tetracyclines) and the miscellaneous agent chloramphenicol. In addition, telithromycin, a ketolide, and tigecycline, a glycylcycline antibiotic, are described.

In addition to explaining how these drugs work, this chapter discusses nursing management related to evaluating the patient's condition, monitoring the patient's response, and teaching the patient and family about antibiotic therapy.

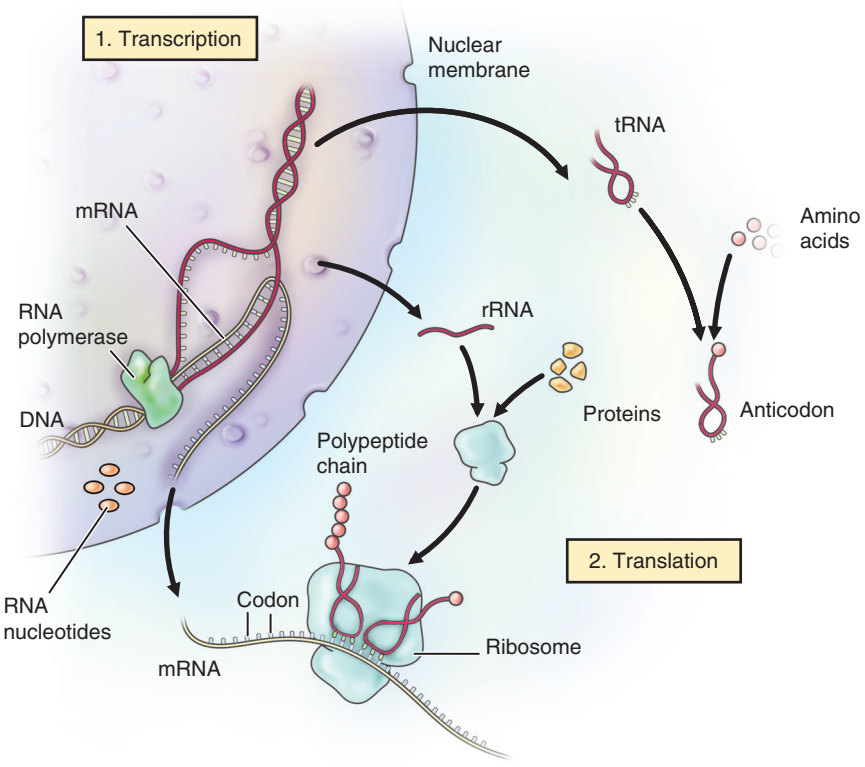
PHYSIOLOGY

In all cells, the process of protein synthesis is divided into two sections: transcription and translation. Initially, transcription occurs within the nucleus, producing messenger ribonucleic acid (mRNA). This mRNA migrates from the nucleus to the cytoplasm. During this step, mRNA goes through different types of maturation, including one called splicing, during which the noncoding sequences are eliminated. The coding mRNA sequence is a unit of three nucleotides, called a codon.

Translation occurs in the cytoplasm. The ribosome binds to the mRNA at the start codon (AUG) that is recognized only by initiator tRNA (transfer ribonucleic acid). The ribosome proceeds to the elongation phase of protein synthesis. During this stage, complexes composed of an amino acid linked to tRNA bind sequentially to the appropriate codon in mRNA by forming complementary base pairs with the tRNA anticodon. The ribosome moves from codon to codon along the mRNA. Amino acids are added one by one, translated into polypeptide sequences dictated by DNA and represented by mRNA. At the end, a release factor binds to the stop codon, terminating translation and releasing the completed polypeptide from the ribosome. Figure 40.1 illustrates the process of protein synthesis.

AMINOGLYCOSIDES

The aminoglycosides have been in use since 1944. They are extremely effective antibiotics for treating severe infections. However, their general use is limited because of the potential for serious adverse effects, especially ototoxicity and nephrotoxicity. Gentamicin is the most widely used, possibly because of its availability as a generic formulation, and is the prototype drug for the aminoglycoside family. Table 40.1 presents a summary of selected aminoglycoside agents.



• FIGURE 40.1 Protein synthesis.

TABLE 40.1 Summary of Selected C Aminoglycoside Antibiotics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P gentamicin (Garamycin;	Gram-negative infections Staphylococcal infections Localized eye infections	*Adult:* IM/IV, 3–5 mg/kg/d in divided doses *Child:* 6–7.5 mg/kg in divided doses *Infants and neonates:* 7.5 mg/kg in divided doses q8 h *Adult and Child*: 1 drop every 1–4 h	*Onset:* Rapid *Duration:* 6–8 h $t_{1/2}$: 2–3 h
amikacin (Amikin)	Gram-negative infections Staphylococcal infections	*Adult*: IM/IV, 15 mg/kg/d *Child*: Same as adults *Neonate*: IM/IV, 10 mg/kg initially then 7.5 mg/kg q12 h	*Onset*: IM, varies; IV, immediate *Duration*: 6–8 h $t_{1/2}$: 2–3 h
kanamycin (Kantrex)	*Escherichia coli* and other infectious agents Suppression of intestinal flora	*Adult*: IM, 15 mg/kg/d; IV, dilute 500 mg vial with 100–200 mL sterile diluent per day PO, 1 g every hour for 4 h then 1 g q6h for 36–72 h	*Onset*: IM/IV, rapid *Duration*: 8–12 h $t_{1/2}$: 2–3 h
neomycin (Mycifradin Sulfate)	Preoperative suppression of intestinal bacteria Hepatic coma	*Adult*: 1 g at 19, 18 and 9 h before surgery *Adult*: 4–12 g/d	*Onset*: PO, varies *Duration*: 6–8 h $t_{1/2}$: 3 h
paromomycin (Humatin)	Intestinal amebiasis Hepatic coma	*Adult and child*: 25–35 mg/kg/d in three divided doses *Adult*: 4 g/d in divided doses	*Onset*: Poorly absorbed *Duration*: Excreted $t_{1/2}$: Unchanged in feces
streptomycin	Non-tubercular Infections TB in conjunction with other drug therapy, prophylaxis of TB	*Adult*: IM, 1–2 g/d in divided doses *Child*: IM, 20–40 mg/kg/d q12 h *Adult*: IM, 15 mg/kg with a maximum of 1 g/d; reduce to 25–30 mg/kg or maximum of 1.5 g two to three times a week *Child*: IM, 20–40 mg/kg/d in divided doses q6–12 h to a maximum of 1 g/d; reduce to 25–30 mg/kg two to three times a week	*Onset*: Rapid *Duration*: 8–12 h $t_{1/2}$: 2.5 h
tobramycin (Nebcin)	Gram-negative infections especially Pseudomonas staphylococcal infections, burns Soft tissue wounds	*Adult and child*: 3–5 mg/kg every 12 h *Neonate <1 w*: IM/IV: up to 4 mg/kg every 12 h	*Onset*: Rapid *Duration*: 8–12 h $t_{1/2}$: 2–3 h

Nursing Management of the Patient Receiving P Gentamicin

Core Drug Knowledge

Pharmacotherapeutics

Clinically, gentamicin is useful in serious infections that include urinary tract infections (UTIs), such as pyelonephritis; gynecologic infections; peritonitis; endocarditis; pneumonia; bacteremia and sepsis; respiratory infections, including those associated with cystic fibrosis; osteomyelitis; and foot and other soft-tissue infections associated with diabetes.

Gentamicin is effective in managing infections caused by gram-negative bacilli. Susceptible organisms include *Pseudomonas aeruginosa, Proteus mirabilis, Escherichia coli; Klebsiella, Enterobacter, Serratia,* and *Citrobacter* species; and staphylococci. Gentamicin must be transported across the cell membrane in order to enter the cell and disrupt protein synthesis. This process requires oxygen; therefore, gentamicin and other aminoglycosides are ineffective against anaerobes. Gentamicin is not considered useful in treating meningitis unless it is administered intrathecally.

Gentamicin is also indicated for topical treatment of eye or skin infections caused by susceptible organisms. It is used as a liposome injection for treating disseminated *Mycobacterium avium-intracellulare* (MAC) infection, and it has an orphan drug indication as drug-impregnated polymethylmethacrylate (PMAA) beads on surgical wire for treating chronic osteomyelitis. Gentamicin liquid has been used successfully in bone cement for the management of musculoskeletal infections.

Pharmacokinetics

Parenteral gentamicin is widely distributed through the body in extracellular fluids; however, it does not penetrate appreciably into the central nervous system (CNS). It crosses the placenta and is secreted in breast milk. Gentamicin concentrates in the kidney, reaching levels 50 times higher than those in serum. It also concentrates in the endolymph and perilymph of the inner ear. High

concentrations of gentamicin in these fluids are associated with its major adverse effects—**nephrotoxicity** and **ototoxicity.** Parenteral gentamicin is excreted unchanged in urine, whereas oral gentamicin is excreted unchanged in feces.

Because it is poorly absorbed when taken orally, gentamicin is usually reserved for parenteral use. It may be given orally to effect a decrease in gastrointestinal (GI) tract flora before colorectal surgical or other invasive procedures. It may also be used topically for infections of the skin, eyes, and ears.

Pharmacodynamics

Gentamicin, like all antibiotics, has no direct effect on the cells of the body. It exerts its effect by entering the bacterial cell and binding to the 30S ribosomal subunit (see Chapter 38). This event leads to a misreading of the information used within the cell to form proteins. The cell then produces amino acids that do not link correctly. The result is a change in metabolic function that in turn prevents bacterial reproduction and weakens the cell wall, leading to cell wall rupture and death. Many strains of bacteria are resistant to the aminoglycosides and do not allow them to enter the cell. Because of this, aminoglycosides are often given with synergistic antibiotics to increase their effectiveness or to alter the cell wall so that the aminoglycoside can enter.

Contraindications and Precautions

Gentamicin is contraindicated during pregnancy and lactation. It is also contraindicated in patients with known allergy to any aminoglycoside. It is used cautiously in patients with renal or hepatic disease, dehydration, pre-existing hearing loss, and myasthenia gravis, as well as in patients receiving other nephrotoxic or ototoxic drugs.

Adverse Effects

Many serious side effects are associated with gentamicin, limiting its usefulness. The most well-known adverse effects are neurotoxicity, nephrotoxicity, ototoxicity, and neuromuscular blockade, which are all Black Box warnings. Ototoxicity occurs most frequently when serum trough levels are elevated, in infants or elderly patients, or with prolonged or high-dose therapy. Gentamicin may induce both cochlear and vestibular damage to the inner ear. Cochlear damage, a high-frequency hearing loss, may be preceded by high-pitched tinnitus. Nephrotoxicity occurs most frequently in infants or the elderly or with prolonged or high-dose therapy. Acute tubular necrosis is the most common gentamicin-induced nephrotoxicity. Neuromuscular blockade may result in profound respiratory depression. It occurs most frequently in patients with myasthenia gravis and in patients receiving general anesthetics or nondepolarizing skeletal muscle relaxants.

In the CNS, gentamicin therapy may induce confusion, depression, disorientation, numbness, tingling, and weakness. Leukemoid reactions and depressed bone marrow function are potential adverse effects in the hematologic system. GI symptoms include nausea, vomiting, diarrhea, weight loss, stomatitis, and hepatic toxicity. Gentamicin may induce palpitations, hypotension, and hypertension in the cardiovascular system. Hypersensitivity reactions include purpura, rash, urticaria, and exfoliative dermatitis. Other adverse effects such as superinfections, fever, apnea, and joint pain may also occur.

Drug Interactions

Gentamicin may interact with other drugs that are known to be ototoxic, nephrotoxic, or neurotoxic such as acyclovir, amphotericin B, cephalothin, cisplatin, cyclosporine, loop diuretics (especially ethacrynic acid), nonsteroidal anti-inflammatory drugs (NSAIDs), and vancomycin. Additionally, gentamicin may interact with general anesthetics, indomethacin, nondepolarizing skeletal muscle relaxants, extended penicillins, and cephalosporins. Table 40.2 lists drugs that interact with gentamicin.

Assessment of Relevant Core Patient Variables

Health Status

In assessing the health status of the patient taking gentamicin, elicit a thorough health history, particularly the renal history. Because gentamicin is excreted unchanged by glomerular filtration, patients with renal dysfunction or dehydration are at risk for nephrotoxicity. Evaluate patients for a history of hearing impairment and eighth cranial nerve impairment because these patients have an elevated risk for ototoxicity.

Investigate any patient with a history of myasthenia gravis or one who may have received neuromuscular blocking agents during surgical procedures. Gentamicin may cause severe neuromuscular weakness, lasting hours to days, because of its potential curare-like effect, and it may aggravate muscle weakness in these patients.

Perform a baseline gross hearing test before administering gentamicin. Evaluate laboratory test results that indicate the renal and hepatic function of the patient.

Life Span and Gender

Evaluate women for potential pregnancy. Although gentamicin is not absolutely contraindicated during pregnancy, it has been found to be ototoxic to the fetus. Evaluate neonates (younger than 1 month) and patients older than 65 years frequently because these patients have immature or decreased renal function, which increases their risk of ototoxicity and nephrotoxicity.

Lifestyle, Diet, and Habits

Assess the nutritional status of the patient. Patients whose oral intake is restricted and patients who eat poorly are at increased risk for hypomagnesemia during gentamicin therapy. Dehydrated patients have an increased risk of nephrotoxicity.

TABLE 40.2 Agents That Interact with P Gentamicin

Interactant	Effect and Significance	Nursing Management
Cephalosporins	Synergistic bacterial activity, however it may also increase risk for nephrotoxicity.	Synergistic bacterial interaction is beneficial Assess peak and trough level of aminoglycoside drug Monitor BUN and creatinine levels Monitor input and output
Extended penicillins	Extended penicillins may inactivate gentamicin.	Avoid combination when possible. Administer these drugs at least 2 h apart.
Loop diuretics, especially ethacrynic acid	Synergistic ototoxicity may cause hearing loss of varying degrees, with possibly permanent hearing loss. Patients with renal insufficiency have highest risk for ototoxicity.	Perform baseline and daily hearing function test Inform patient to immediately report ringing or roaring in the ears, or muffled sounds Advise family members to be alert for evidence of hearing loss.
General anesthetics	Gentamicin may induce a synergistic interaction resulting in an increased risk for prolonged respiratory depression and gentamicin toxicity.	Monitor for respiratory depression Have ventilatory support available Monitor BUN and creatinine levels
NSAIDS	NSAIDS may reduce glomerular filtration rate (GFR) allowing gentamicin to accumulate thus increasing the risk for toxicity	Assess peak and trough level of aminoglycoside drug Monitor BUN and creatinine levels Monitor input and output Inform patient to immediately report ringing or roaring in the ears, or muffled sounds Advise family members to be alert for evidence of hearing loss.
Nondepolarizing muscle relaxants	The actions of nondepolarizing muscle relaxants may be enhanced resulting in protracted respiratory depression.	Mark patient's chart and arrange for extended monitoring and support following anesthesia. Monitor respirations and other vital signs following anesthesia.
Ototoxic, nephrotoxic, and neurotoxic drugs	Risk for ototoxicity, nephrotoxicity, or neurotoxic effects are increased when these drugs are coadministered with gentamicin.	Avoid these combinations if possible. Assess peak and trough level of aminoglycoside drug Monitor BUN and creatinine levels Monitor input and output Inform patient to immediately report ringing or roaring in the ears, or muffled sounds Advise family members to be alert for evidence of hearing loss. Reduce dose of one or both drugs as ordered.
succinylcholine	Gentamicin may increase neuromuscular effects of succinylcholine.	Monitor for respiratory depression. Have bag-mask-valve apparatus and ventilation equipment available.

Environment

Be aware of the environment in which gentamicin will be administered and, if appropriate, assess the home or living environment for potential risk factors. Parenteral gentamicin is usually administered in the acute hospital setting; however, it may also be given in the home environment by a home health care nurse. Oral or topical gentamicin may be given in any environment.

In the hospital setting, store gentamicin in the refrigerator and be sure that it does not freeze. Before administration, gentamicin solution should be inspected for discoloration or particulates. After administration, any unused solution should be discarded.

Nursing Diagnoses and Outcomes

- Risk for Injury related to potential drug-related allergic reactions or neuromuscular blockade or suppression of bone marrow function
  Desired outcome: *The patient will remain free of injury and will contact the prescriber if unusual adverse effects occur.*
- Diarrhea related to drug effects
  Desired outcome: *The patient will avoid dehydration, maintain fluid intake, and contact the prescriber if diarrhea persists.*
- Imbalanced Nutrition: Less than Body Requirements, related to drug-induced GI effects or superinfection

Desired outcome: *The patient will maintain body weight and report to the health care provider any persistent adverse effects that affect nutritional status.*

- Risk for Injury related to CNS effects
  Desired outcome: *The patient will remain free of injury and contact the provider if confusion, disorientation, or depression occurs.*
- Disturbed Sensory Perception related to potential ototoxicity
  Desired outcome: *The patient will report sensory or perceptual changes to the prescriber.*
- Excess Fluid Volume related to potential nephrotoxicity
  Desired outcome: *The patient will report any weight gain exceeding 3 lb to the health care prescriber.*

Planning and Intervention

Maximizing Therapeutic Effects

Make sure that patients receive the full course of gentamicin as prescribed at around-the-clock intervals; coordinate the administration of drugs to decrease potential drug interactions; and evaluate culture and sensitivity reports to make sure that gentamicin is the appropriate drug.

Because gentamicin may be inactivated by extended penicillins, such as carbenicillin or ticarcillin, administer these drugs at least 2 hours apart to ensure the efficacy of gentamicin.

Minimizing Adverse Effects

To reduce the occurrence of adverse effects, it is imperative to maintain blood levels of gentamicin within a therapeutic margin that is very narrow. To do this, **peak and trough** drug levels are monitored throughout therapy. Blood for peak levels is drawn 30 minutes after the completion of a 30-minute intravenous (IV) administration or immediately after a 60-minute IV administration and 45 to 60 minutes after intramuscular (IM) administration. Blood for trough levels is drawn just before the next dose. Some hospitals obtain only a trough level unless the patient has an increased risk for nephrotoxicity.

Monitor for signs of ototoxicity. Before administering each dose, assess the patient's balance and gross hearing.

Monitor for signs of nephrotoxicity. Assess the hydration status of the patient and be alert for dilute urine or proteinuria. Monitor the patient for gentamicin-induced diarrhea because diarrhea may also cause dehydration.

If CNS effects occur, safety measures should be instituted to protect the patient. Small, frequent meals can be arranged for patients with GI effects, and frequent mouth care and ice chips can be offered to relieve stomatitis and sore mouth.

If a patient receiving gentamicin requires surgery, the chart should indicate prominently that gentamicin has been given. Remember that gentamicin may interact with neuromuscular blocking agents commonly used during surgery, resulting in prolonged neuromuscular blockade. The patient requires extended monitoring and support after surgery to detect problems and intervene if they occur.

Monitor laboratory tests such as renal and hepatic function tests, peak and trough levels of gentamicin, and the fluid intake and output status of the patient.

Providing Patient and Family Education

- Teach patients that gentamicin is one drug within a class of drugs. Ask if they have ever had a drug reaction to any drug with "micin" in its name.
- Advise female patients that they should not take this drug if they are pregnant or breast-feeding.
- Advise patients to take oral gentamicin on an empty stomach, 1 hour before or 2 hours after any meal or other drugs. Instruct patients to take forgotten doses as soon as they remember, but not to double the dose, and to contact the prescriber if symptoms do not improve in 3 days.
- Teach patients how to identify, report, and manage signs and symptoms of allergic reaction and adverse effects.
- Teach patients signs of ototoxicity such as persistent headache, nausea, balance difficulties, dizziness, vertigo, tinnitus, or high-frequency hearing loss. Instruct patients to contact their prescriber immediately if any of these symptoms occur.
- Instruct patients to take aspirin for headache or muscle pain because aspirin decreases the potential for gentamicin-induced hearing loss.
- Teach patients signs of nephrotoxicity, such as frequent or diminished urinary excretion. Instruct the patient to contact the prescriber immediately if such signs occur.
- Teach patients how to recognize superinfection and to watch for CNS effects such as confusion, depression, numbness, tingling, or weakness. Explain the importance of contacting the prescriber if any of these symptoms occur.
- Help patients develop strategies for minimizing GI upset and oral soreness.
- Show patients how to use gentamicin eye or ear drops correctly, making sure to stress the importance of keeping the dropper portion of the bottle from touching the eye or ear to avoid contamination.

Ongoing Assessment and Evaluation

Coordinate the care of the patient to ensure that other potentially nephrotoxic or ototoxic drugs are not added to the treatment plan. Notify the primary prescriber if any such drugs are added. Monitor peak and trough levels of gentamicin. Although maintaining gentamicin serum concentrations within traditional ranges is believed to minimize the risk for nephrotoxicity, some patients may still develop ototoxicity or nephrotoxicity. Monitor for **azotemia** (excessive urea levels in the blood), decreased creatinine clearance, **hyposthenuria** (loss of the ability to concentrate urine), **pyuria** (increased white blood cell count), **proteinuria,** and **cylindruria** (cells or casts in the urine).

Evaluate for signs of ototoxicity. Cochlear damage may be subtle; therefore, coordinate referrals for audiologic testing for patients who receive repeated or prolonged courses of gentamicin therapy. Vestibular damage is characterized by a headache followed by vertigo, dizziness, or nausea. To avoid permanent ototoxic damage, the drug should be withdrawn at the first sign of tinnitus or persistent headache.

CRITICAL THINKING SCENARIO

EXPLAINING THE DRUG SELECTION PROCESS

Georgia James, age 64 years, is admitted to your unit with a diagnosis of pneumonia. She has just completed her first dose of IV gentamicin when her granddaughter arrives. The granddaughter comes to the nurses' station and is very upset. She states in a very loud voice, "Why is my grandmother getting gentamicin? I saw on the Internet that there is a new type of drug for pneumonia called syner-something. Why isn't she getting the strongest kind of medication?" How would you handle this situation?

Evaluate patients for signs of neuromuscular blockade, such as muscle weakness, especially of the respiratory muscles. Observe the injection site regularly because IM injection of gentamicin can cause irritation.

When therapy ends, the presenting infection should be resolved. The patient should be adequately nourished and hydrated and free from adverse drug effects.

MEMORY CHIP

P Gentamicin

- Used for serious gram-negative infections
- Major contraindications: hypersensitivity, pregnancy, and breast-feeding
- Most common adverse effects: nausea, vomiting, diarrhea, and weight loss
- Most serious adverse effects: see black box warnings
- Maximizing therapeutic effects: Administer at least 2 hours before or after extended infusions of penicillins.
- Minimizing adverse effects: Monitor peak and trough levels throughout therapy.
- Most important patient education: Teach the patient the signs and symptoms of both nephrotoxicity and ototoxicity and also the importance of contacting the health care provider immediately if any symptoms should occur.
- **Black box warning: neurotoxicity, nephrotoxicity, ototoxicity, and neuromuscular blockade**

Drugs Closely Related to P Gentamicin

Drugs closely related to gentamicin include amikacin, kanamycin, neomycin sulfate, and tobramycin. Contraindications, adverse effects (including Black Box warnings), drug interactions, and patient management for all these drugs are the same as those of gentamicin.

Amikacin

Amikacin (Amikin) is a parenteral aminoglycoside with a broader spectrum of activity than gentamicin for gram-negative bacilli. It is also less likely to induce bacterial resistance.

Kanamycin

Kanamycin (Kantrex) is used orally to reduce ammonia-forming bacteria in hepatic coma and as an adjunctive therapy to decrease GI flora. Its use for systemic infections is limited by the number of bacteria that are resistant to it and the availability of gentamicin in its less expensive generic formulation.

Neomycin Sulfate

Neomycin sulfate (Neo-Fradin) has the highest risk of toxicity of all the aminoglycosides. Because it is so toxic, it is not administered parenterally. It is available orally to decrease GI flora as a preparation for bowel surgery and to treat hepatic encephalopathy. Because it is not absorbed from the GI tract, it frequently causes superinfection within the bowel. Neomycin is an ingredient combined with other topical prescription medications and alone as an over-the-counter (OTC) drug as a topical antibiotic.

Tobramycin

Tobramycin (Nebcin) is similar to gentamicin in its antibacterial spectrum; however, it is more active than gentamicin against *Pseudomonas* species. It is given parenterally for systemic infections or topically to treat superficial ophthalmic infections. Tobramycin solution for inhalation (TSI) is currently the only approved inhaled antibiotic in the United States. Peak and trough levels should be closely monitored in patients with serious infections or in disease states known to substantially alter aminoglycoside pharmacokinetics, such as cystic fibrosis, burns, or major surgery.

Drugs Significantly Different From P Gentamicin

Paromomycin

Paromomycin (Humatin) is an aminoglycoside antibiotic that differs from gentamicin because of its amebicidal and anthelminthic activity. Paromomycin has poor oral bioavailability; thus, it is used to treat intestinal amebiasis and various intestinal parasites by its local activity. It is also useful in managing hepatic encephalopathy or coma because it inhibits bacteria in the gut that produce urease, an enzyme that breaks down urea into carbon dioxide and ammonia.

Paromomycin is contraindicated in patients with renal failure or intestinal obstruction. Adverse GI effects of paromomycin include anorexia, nausea, vomiting, gastric burning and pain, abdominal cramps, and diarrhea.

The only important drug–drug interaction with paromomycin occurs with succinylcholine. When they are given in combination, paromomycin may potentiate the neuromuscular effects of succinylcholine.

Coordinate follow-up appointments for the patient. Stool cultures should be done weekly for 6 weeks after therapy, then monthly for 2 years.

Streptomycin

Streptomycin is a parenteral aminoglycoside. It is used as part of combination therapy both for active tuberculosis and

TABLE 40.3 Summary of Selected C Lincosamide Antibiotics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P clindamycin (Cleocin)	Skin and skin structure infection Respiratory tract infections Septicemia Intra-abdominal infections Osteomyelitis Gynecologic infection Endocarditis prophylaxis	*Adult:* PO, 150–450 mg q6 h; IM/IV, 600 mg–2.7 g q6–12 h up to 4.8 g/d for life-threatening infections *Child:* PO, 10–30 mg/kg/d in three divided doses every 6–8 h; IM/IV, 20–40 mg/kg q6–8 h up to 40 mg/kg/d for severe infection *Adult PO/IM/IV;* 600 mg *Child:* 20 mg/kg	*Onset:* PO, varies; IM, 20–30 min; IV, immediate *Duration:* 8–12 h $t_{1/2}$: 2–3 h
lincomycin (Lincocin)	Serious infections from streptococci, pneumococci, and staphylococci	*Adult*: PO, 500 mg q8 h; IM, 600–200 mg/d; IV, 600–1,000 mg q8–12 h	*Onset*: IM, 20–30 min; IV, immediate *Duration*: IM, 0.5 h; IV, 14 h $t_{1/2}$: 5 h

for treating streptococcal or enterococcal endocarditis. As a single agent, it is used for mycobacterial infections, plague, tularemia, and brucellosis. Streptomycin may induce the same Black Box adverse effects as gentamicin.

LINCOSAMIDES

The lincosamides include clindamycin (Cleocin) and lincomycin (Lincocin). They are very toxic drugs; thus, their use must be monitored and limited to situations with infections by bacteria with known sensitivity. Although lincomycin was the first drug developed in this class, it is rarely used. Clindamycin is discussed as the prototype lincosamide. Table 40.3 presents a summary of lincosamide antibiotics.

Nursing Management of the Patient Receiving P Clindamycin

Core Drug Knowledge

Pharmacotherapeutics

Clindamycin is active against a wide range of aerobic gram-positive cocci and several anaerobic gram-negative and gram-positive organisms. Clindamycin is used in the treatment of skin and skin structure infections, respiratory tract infections, septicemia, intra-abdominal infections, osteomyelitis, and as prophylaxis for endocarditis. Topical forms are used to treat acne vulgaris. A vaginal preparation is available for treating bacterial vaginosis.

Pharmacokinetics

The oral absorption of clindamycin varies greatly, depending on the presence of food in the stomach. Peak levels are achieved in about 1 to 2 hours. Given intramuscularly, clindamycin is rapidly absorbed within 20 to 30 minutes, with peak levels occurring at 1 to 3 hours. IV administration produces a peak effect within minutes. Topical clindamycin is only minimally absorbed.

Clindamycin crosses the placenta and enters breast milk and cerebrospinal fluid (CSF). It is readily carried to most body tissues. Metabolized in the liver, it is excreted through the bile and urine.

Pharmacodynamics

Clindamycin is either bacteriostatic or bactericidal, depending on its concentration at the site of action and on the specific susceptibility of the organism being treated. It enters the bacterial cell and binds to bacterial ribosomes, suppressing protein synthesis and leading to cell death in susceptible bacteria. It has no direct effect on the body.

Contraindications and Precautions

Clindamycin is contraindicated in pregnancy and lactation and in patients with a known allergy to lincosamides, history of asthma or other allergies, allergy to tartrazine (a component of several oral preparations of clindamycin), or hepatic or renal dysfunction. Caution should be exercised in patients with a history of antibiotic-associated colitis, regional enteritis, or ulcerative colitis.

Adverse Effects

The most serious adverse effect is pseudomembranous colitis (a Black Box warning), also known as *Clostridium difficile* colitis. Diarrhea, abdominal cramps, and abdominal tenderness may suggest antibiotic-associated colitis. Nausea and vomiting and abdominal pain following oral administration are the most common adverse effects of clindamycin.

Thrombocytopenia, neutropenia, and eosinophilia have been reported during clindamycin therapy. Sore throat or fever may indicate neutropenia.

Maculopapular rash, erythema, and pruritus can develop from systemic or topical use of clindamycin. Pathologic dryness of the skin (**xeroderma**), conjunctiva (**xerophthalmia**), or mucous membranes is the most common effect of topical application. Alcohol in some topical formulations may irritate the eyes, mucous membranes, or abraded skin if allowed to come into contact with them.

Hypersensitivity reactions range from skin rashes and urticaria to anaphylactoid reactions. After injection, pain, abscess, and phlebitis are relatively common.

Drug Interactions

Neuromuscular blockers, aluminum salts, and cyclosporine interact with clindamycin. Topical preparations containing

TABLE 40.4 Agents that Interact with P Clindamycin

Interactants	Effect and Significance	Nursing Management
aluminum salts or kaolin	Marked decreased GI absorption of oral clindamycin	Administer absorbent antidiarrheal product 2 h before or 3–4 h after administering oral clindamycin.
cyclosporine	Cyclosporine concentrations may be reduced, decreasing its pharmacologic effects	Monitor cyclosporine concentrations when clindamycin is started, stopped, or changed.
non-depolarizing muscle relaxants	Clindamycin potentiates the action of non- depolarizing muscle relaxants, resulting in increased neuromuscular blockade, respiratory depression, and extended paralysis.	Mark patient's chart with warning of the drug combination. Arrange for extended monitoring and support of patient after surgery or procedure. Monitor respiration and other vital signs. Be prepared for ventilatory support as needed

benzoyl peroxide, tretinoin, salicylic acid, or other topical preparations for acne, when used with clindamycin preparations, can cause a cumulative irritant effect, leading to excessive drying and peeling of the skin. Table 40.4 lists agents that interact with clindamycin.

Assessment of Relevant Core Patient Variables

Health Status

Assess patients for allergy to lincosamides or predisposition to such allergy as shown by a previous reaction to tartrazine. Some clindamycin preparations contain tartrazine dye, which can precipitate bronchial asthma or other allergic reactions in sensitive patients.

Next, investigate any history of GI disease because clindamycin predisposes patients to the overgrowth of nonsusceptible organisms and hence may induce pseudomembranous colitis.

Any previous renal or hepatic disease must be explored because the half-life of clindamycin is prolonged in patients with hepatic dysfunction, and toxicity can occur. Hepatic and renal function should be tested at baseline, and the results should be evaluated before beginning therapy. For patients with severe renal or hepatic impairment, dose reduction should be considered.

Patients on long-term therapy should have a baseline complete blood count (CBC) because of clindamycin's potential to induce blood dyscrasias.

Life Span and Gender

Explore the benefits of treatment versus potential risks with the pregnant or lactating woman. In general, clindamycin is prescribed for pregnant or lactating women only if the benefits outweigh the potential risks.

Assess the growth and developmental level of the child or infant. Clindamycin should be used cautiously in children. Neonates younger than 1 month (and premature infants) have a prolonged plasma half-life for clindamycin, probably because of an immature hepatic system.

Lifestyle, Diet, and Habits

Assess the patient's lifestyle to determine the likelihood that the patient will take the drug around the clock.

Environment

Be aware of the environment in which clindamycin will be administered and, if appropriate, assess the home or living environment for potential risk factors. Parenteral solutions of clindamycin must be used within 24 hours of reconstitution. Oral or topical clindamycin may be administered in any environment.

Nursing Diagnoses and Outcomes

- Risk for Injury related to allergic reactions
  Desired outcome: *The patient will stop drug therapy and immediately report symptoms of allergic reaction to the prescriber.*
- Diarrhea related to drug effects
  Desired outcome: *The patient will avoid dehydration and report persistent diarrhea to the provider.*
- Imbalanced Nutrition: Less than Body Requirements, related to drug-related GI effects, alteration in taste, superinfections
  Desired outcome: *The patient will maintain body weight and report persistent symptoms affecting nutritional status.*
- Risk for Injury related to possible blood dyscrasias
  Desired outcome: *The patient will remain injury free throughout drug therapy.*

Planning and Intervention

Maximizing Therapeutic Effects

Make sure that the patient receives the full course of clindamycin as prescribed, at around-the-clock intervals for maximal effectiveness. Coordinate the administration of drugs to decrease potential undesired interactions. Culture and sensitivity reports may be reviewed periodically to confirm that clindamycin is the appropriate drug for the patient.

Minimizing Adverse Effects

Clindamycin should be administered on an empty stomach with a full glass of water. For patients with GI effects,

provide a small meal with administration. Provide frequent mouth care and ice chips to suck on if stomatitis and sore mouth are problems. It is also important to keep this drug out of the reach of children to avoid accidental overdose. Report diarrhea to the provider immediately.

Providing Patient and Family Education

- Ensure that patients understand that they should not take clindamycin or any other lincosamide antibiotic if they have ever had a reaction to a drug with a generic name that ends with "mycin" or "micin."
- Advise patients to contact the prescriber immediately if they experience diarrhea.
- Advise pregnant or breast-feeding patients to avoid clindamycin.
- Discuss general dosage and safe storage recommendations.
- Advise patients to take clindamycin on an empty stomach with a full glass of water. If GI distress occurs, take with food.
- Urge patients to contact their prescriber if clindamycin therapy does not improve symptoms in 3 days.
- Teach patients to recognize and report symptoms of allergic reaction and superinfection (sore throat, easy bruising or bleeding, and fatigue).
- Advise women of childbearing age who are taking birth control pills to use a backup method of contraception while taking clindamycin.
- Advise patients using clindamycin lotion that dry skin may occur. Instruct patients to drink plenty of fluids and to keep the skin moisturized.

Ongoing Assessment and Evaluation

Monitor the patient for the onset of diarrhea. If it occurs, the prescriber should be notified immediately because diarrhea may be the presenting sign of pseudomembranous colitis. Obtain an order for the stool to be evaluated for white blood cells (WBCs), blood, and mucus. Arrange for a proctoscopy to be performed.

During therapy, monitor for potential procedures that would require the use of neuromuscular blocking agents. If a procedure is scheduled, note prominently on the patient's chart the current use of clindamycin. After the procedure, the patient should be monitored and supported for an extended period once the neuromuscular blocker is discontinued.

Monitor for sore throat and fever, which may be signs of thrombocytopenia, neutropenia, or eosinophilia.

When treatment ends, the initial infection should be resolved. The patient should be adequately nourished and hydrated, and any adverse drug effects should be resolved.

Drug Closely Related to P Clindamycin

Lincomycin (Lincocin) is a parenteral lincosamide antibiotic. It is used for serious staphylococcal and streptococcal infections. Lincomycin is usually reserved for patients who cannot take penicillins or clindamycin. It is not a drug of choice because it has been associated with severe or fatal colitis. Like clindamycin, lincomycin is used with caution in patients with asthma, liver disease, GI disease, colitis, and tartrazine sensitivity. Adverse effects, drug interactions, and patient management are similar to those of clindamycin.

MEMORY CHIP

P Clindamycin

- Used for serious infections caused by gram-positive cocci and both gram-positive and gram-negative anaerobes.
- Major contraindications: hypersensitivity, pregnancy, breast-feeding, and renal or hepatic dysfunction
- Most common adverse effects: nausea, vomiting, abdominal pain, rash, and pruritus
- Most serious adverse effect: pseudomembranous colitis
- Maximizing therapeutic effects: Administer at evenly spaced intervals.
- Minimizing adverse effects: Give with food to minimize GI distress.
- Most important patient education: Teach the patient the signs and symptoms of superinfection, especially pseudomembranous colitis, and explain the importance of contacting the health care provider immediately if any symptoms occur.
- **Black box warning: Pseudomembranous colitis: May range from severe to mild to life threatening.**

C MACROLIDE ANTIBIOTICS

The macrolide antibiotics have been in use since 1952. They are characterized by molecules made up of large-ring lactones. Macrolides are bacteriostatic or bactericidal in susceptible bacteria. They include erythromycin and troleandomycin. Synthetic derivatives of erythromycin, also classified as macrolide antibiotics, include azithromycin and clarithromycin. Erythromycin was the first macrolide discovered and is the prototype for this class. Table 40.5 presents a summary of macrolide antibiotics.

Nursing Management of the Patient Receiving P Erythromycin

Core Drug Knowledge

Pharmacotherapeutics

Erythromycin is commonly used in treating Legionnaire disease, *Mycoplasma pneumoniae* pneumonia, diphtheria, chlamydial infections, and chancroid, and as an alternative to beta-lactam antibiotics in patients who are allergic to penicillin. Erythromycin may have benefits in hypomotility conditions, such as diabetic gastroparesis, because it increases gastric motility and emptying.

Erythromycin is generally more effective against gram-positive organisms than against gram-negative organisms because of its ability to penetrate into gram-positive organisms.

TABLE 40.5 Summary of Selected Macrolide Antibiotics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P erythromycin (E-Mycin, Ilosone, EES, Erythrocin stearate)	Urethral, endocervical, or rectal infections Syphilis Legionnaire disease Rheumatic fever Bacterial endocarditis *Mycoplasma* infections Bronchitis Pharyngitis Skin infections	*Adult:* PO, 250–500 mg q6 h (maximum 4g) *Child:* PO, 30–50 mg q6–12 h (maximum 100 mg/kg in divided doses) (*Note:* EES dosage is slightly higher)	*Onset:* 1–2 h *Duration:* 6–8 h $t_{1/2}$: 3–5 h
azithromycin (Zithromax)	Lower respiratory tract infection Nongonococcal urethritis and cervicitis Skin infections Acute otitis media Pharyngitis/tonsillitis *Helicobacter pylori* infection *Mycobacterium avium* (prevention or treatment)	*Adult*: PO, 500 mg/d on first day, then 250 mg for days 2 through 5 *Child 6 mo–2 y*: PO, 10 mg/kg on d 1, then 5 mg/kg on days 2–5; >2 y, PO, 10 mg/kg as single dose (not to exceed 500 mg) first day; then 5 mg/kg (not to exceed 250 mg) once daily for 4 d *Adult*: PO, 500 mg q12 h *Adult*: PO, 250–500 mg q12 h for 7–14 d	*Onset*: Rapid *Duration*: 24 h $t_{1/2}$: 11–48 h
clarithromycin (Biaxin)	Respiratory infections Skin infections	*Adult*: PO 250–500 mg every 12 h for 7–14 d *Child*: PO 7.5 mg/kg 2×/d, to a maximum of 500 mg 2×/d	*Onset*: Rapid *Duration*: 8–12 h $t_{1/2}$: 3–7 h
telithromycin (Ketek)	Acute exacerbation of chronic bronchitis Acute bacterial sinusitis Community-acquired pneumonia Not approved for children	*Adult and Child >18 y*: PO 800 mg × 5 d *Adult and Child >18 y*: PO 800 mg qd 7–10 d	*Onset*: 1 h *Duration*: Unknown $t_{1/2}$: 10 h

Pharmacokinetics

Erythromycin base (E-Mycin, Ery-Tab) is easily inactivated by gastric acid; therefore, several formulations have been developed to overcome this problem. Erythromycin stearate (Erythrocin) is the most likely to yield to gastric acid destruction. Erythromycin estolate (Ilosone) is more acid stable, dissociates in the upper intestine, and releases an inactive ester that is absorbed and hydrolyzed in the blood to produce free erythromycin. Erythromycin ethylsuccinate (EES, EryPed) is first absorbed and then hydrolyzed in the blood to free erythromycin. The newest formulation of oral erythromycin is encapsulated pellets that are small enough to pass through the pyloric sphincter independent of gastric emptying and are absorbed as the base. None of the oral forms, however, allows complete absorption. The drug reaches peak levels 1 to 4 hours after administration. Erythromycin is also available for IV use as erythromycin lactobionate or erythromycin gluceptate. Administration of IV erythromycin is painful and is used only when high serum levels of erythromycin are required. When given intravenously, erythromycin peak effect occurs within 1 hour. Erythromycin is also available in an ophthalmic preparation.

Erythromycin crosses the placenta and is secreted in breast milk. It does not cross the blood–brain barrier. It is metabolized in the liver and excreted in the bile and urine. Table 40.5 has additional information.

Pharmacodynamics

Erythromycin has no direct effect on the body. The macrolides are bactericidal or bacteriostatic. They exert their effect by inhibiting RNA-dependent protein synthesis at the chain elongation step. This action can prevent the cell from dividing, or it can cause cell death, depending on the sensitivity of the bacteria and the concentration of the drug.

Contraindications and Precautions

Erythromycin is contraindicated in patients who are allergic to it. Caution should be used in any patient with hepatic insufficiency because the ability to break down erythromycin for excretion may be compromised. Caution should be exercised during pregnancy or lactation and in patients with impaired hearing, biliary function, GI disease, and cardiac arrhythmias. Ocular preparations are contraindicated in patients with viral, fungal, or mycobacterial infections of the eye.

Adverse Effects

Adverse effects suggesting allergic reaction to erythromycin include urticaria, maculopapular rash, erythema, and interstitial nephritis. Pruritus is a possible reaction to topical application of erythromycin.

The most common adverse effects related to erythromycin occur in the GI tract. They include nausea or vomiting,

abdominal pain, and diarrhea. These effects are often dose related and may occur regardless of the route of administration.

Rare potential adverse effects include hepatotoxicity, pseudomembranous colitis, QT interval prolongation and ventricular tachycardia of the torsades de pointes type, tinnitus, and reversible hearing loss.

Drug Interactions

Erythromycin inhibits the metabolism of many drugs, resulting in an increased risk of adverse effects and toxicity. A potentially fatal interaction may occur with astemizole and terfenadine. Although these two drugs are not available in the United States, it is still prudent to ask the patient if he or she is taking these drugs, because they can be acquired from other sources. Table 40.6 presents the most important potential drug interactions.

Assessment of Relevant Core Patient Variables

Health Status

In assessing a patient's health status before administering erythromycin, explore any history of hypersensitivity to erythromycin or other macrolide antibiotics because of the risk for cross-sensitivity.

Assess for hepatic or biliary dysfunction. Moreover, monitor hepatic function in patients receiving prolonged treatment. Ilosone, the estolate salt of erythromycin, should not be used in patients with hepatic disease because of the potential for hepatotoxicity.

Review the patients' GI history, particularly because the normal flora of the colon may allow an overgrowth of *Clostridium* organisms. A toxin produced by *C. difficile* is a primary cause of antibiotic-associated colitis. Patients who develop diarrhea while taking or soon after taking erythromycin should be evaluated for potential antibiotic-associated pseudomembranous colitis.

Monitor the patient's hearing because high-dose therapy with erythromycin may cause a reversible loss of hearing, and patients with preexisting hearing impairment may be at especially great risk.

In addition, explore any possibility of cardiovascular disorder, specifically a history of torsades de pointes, because IV administration of erythromycin at a rate above 15 mg/min may place patients with such a history at risk for this arrhythmia.

Life Span and Gender

Evaluate women for pregnancy and lactation. Erythromycin should be used with caution in breast-feeding women because it is excreted in breast milk at about 50% of maternal plasma concentrations, which may induce diarrhea and superinfection in the infant. Consider the developmental level of the patient. Erythromycin lactobionate injection may contain benzyl alcohol as a preservative, which can cause toxicity in neonates. Infants less than 2 weeks of age are at risk for developing hypertrophic pyloric stenosis with erythromycin therapy.

Lifestyle, Diet, and Habits

Assess the patient's dietary habits for drug sensitivity when taking drugs on an empty stomach and the frequency of eating grapefruit or drinking grapefruit juice. Instruct the patient to avoid grapefruit or grapefruit juice because it increases the serum concentration of erythromycin and may cause adverse effects or toxicity. Food decreases the absorption of nonenteric-coated erythromycin. Advise the patient to take erythromycin at least 1 hour before or 2 hours after meals.

Environment

Be aware of the environment in which the drug will be administered. Oral or ophthalmic erythromycin may be given in any environment, whereas IV infusion should be given in a monitored setting.

Nursing Diagnoses and Outcomes

- Risk for Injury related to possible allergic reactions
  Desired outcome: *The patient will stop drug therapy and report any signs of allergic reaction immediately to the prescriber.*
- Diarrhea related to drug-induced GI upset
  Desired outcome: *The patient will avoid dehydration, maintain fluid intake, and contact the prescriber if diarrhea persists.*
- Risk for Infection related to potential for superinfection following drug therapy
  Desired outcome: *The patient will contact the provider if any signs of superinfection occur, such as sore throat or fever.*

Planning and Intervention

Maximizing Therapeutic Effects

Reconstitute erythromycin with sterile water only. Diluents containing preservatives or organic salts should not be used. Prepared infusion solutions that are stored at room temperature must be used within 8 hours. Prepared solutions that are refrigerated must be used within 24 hours.

Evaluate culture and sensitivity reports to verify that erythromycin is the drug of choice. Moreover, administer erythromycin as prescribed, at around-the-clock intervals to increase effectiveness. Because food interferes with drug absorption, administer erythromycin stearate at least 1 hour before or 2 hours after meals. Other formulations of erythromycin may be given without regard to meals. If GI irritation occurs, however, erythromycin stearate may be administered with food. Each dose should be administered with a full glass of water, not with fruit juice.

Minimizing Adverse Effects

Provide small, frequent meals; mouth care; and ice chips to suck on if stomatitis and sore mouth are problems. Additionally, monitor regularly to ensure adequate

TABLE 40.6 Agents That Interact with P Erythromycin

Interactants	Effect and Significance	Nursing Management
Antidysrhythmic Agents	Erythromycin increases drug effect, especially dysrhythmias	Monitor heart rate and rhythm.
Benzodiazepines	Decreases the metabolism of many benzodiazepines, resulting in an increased CNS depression and prolonged effect	Monitor for sedation. Ensure safety precautions for patients. Discuss reduction of dosage of benzodiazepine with the prescriber.
bromocriptine	Increased pharmacologic effect of bromocriptine resulting in an increased risk for toxicity.	Monitor for bromocriptine toxicity. Discuss bromocriptine dose adjustment with the prescriber.
Calcium channel blockers (CCBs)	Decrease the metabolism of certain CCBs, resulting in hypotension	Monitor vital signs. Ensure safety precautions for patients. Discuss changing to azithromycin with the prescriber.
carbamazepine	Decreases the metabolism of carbamazepine, resulting in an increased risk for carbamazepine toxicity	Monitor carbamazepine levels closely. Discuss reduction of dosage of carbamazepine with the prescriber.
colchicine	Decreases the metabolism of colchicine, resulting in an increased risk for colchicine toxicity	Monitor for adverse effects, especially diarrhea.
cyclosporine	Decreases the metabolism of cyclosporine, resulting in an increased risk for adverse effects and toxicity	Avoid combination if possible. Monitor cyclosporine levels carefully. Monitor for cyclosporine toxicity. Adjust cyclosporine as ordered.
digoxin	Increases the serum concentration of digoxin, resulting in toxicity	Monitor digoxin levels carefully. Monitor for signs of toxicity. Discuss adjustment of digoxin dose with the prescriber.
Ergot Alkaloids	Acute ergotism such as peripheral ischemia may occur	Monitor peripheral circulation and sensation. Contact prescriber immediately if symptoms occur.
felodipine	Erythromycin may inhibit the metabolism of felodipine resulting in adverse effects	Monitor for tachycardia, palpitations, flushing, and ankle edema. Contact the prescriber if any occur.
Fluoroquinolone antibiotics	Sparfloxacin and moxifloxacin may induce life- threatening cardiac arrhythmias	Contact prescriber prior to administering this combination.
HMG-CoA Reductase Inhibitors (Statins)	Increases serum concentration of statins increasing risk for severe myopathy or rhabdomyolysis.	Monitor for muscle pain, weakness, or tenderness Avoid combination if possible. Discuss with the prescriber.
methylprednisolone	Decreases the metabolism of methylprednisolone, resulting in an increased risk for adverse effects and toxicity	Monitor therapeutic effects of methylprednisolone. Monitor for adverse effects and toxicity. May be beneficial effect for patients with asthma.
pimozide	Decreases the metabolism of pimozide, resulting in QT interval prolongation	Avoid combination. Discuss with the prescriber.
Rifamycins	The antimicrobial effects of erythromycin may be decreased and the GI adverse effects of rifamycins may be increased.	Monitor for efficacy of erythromycin therapy Monitor for GI distress.
repaglinide	Erythromycin may inhibit the metabolism of repaglinide resulting in an increased risk for adverse effects	Monitor blood glucose frequently Monitor for signs of hypoglycemia such as hunger dizziness, shakiness, sweating, or confusion
sildenafil	Decreases the metabolism of sildenafil, resulting in an increased risk for adverse effects and toxicity	Advise patient to seek medical attention for prolonged erection.
tacrolimus	Erythromycin inhibits tacrolimus metabolism resulting in an increased risk for toxicity.	Monitor renal status carefully. Discuss alternate antibiotic therapy with the prescriber.

(*Continued*)

TABLE 40.6 Agents That Interact with P Erythromycin *(continued)*

Interactants	Effect and Significance	Nursing Management
theophylline	Macrolides inhibit the metabolism of theophylline. Theophylline reduces the bioavailability and increases the renal clearance of erythromycin. These actions result in increased efficacy of theophylline and decreased efficacy of erythromycin.	Monitor theophylline levels closely. Monitor for theophylline toxic effects. Monitor for treatment failure of erythromycin.
vinblastine	Increased risk for severe vinblastine toxicity	Monitor for neutropenia, constipation, and myalgias. Contact the prescriber immediately if any occur.
warfarin	Decreases the metabolism of warfarin, resulting in an increased risk for warfarin toxicity	Monitor warfarin levels carefully. Monitor INR or PT frequently. Discuss adjustment of warfarin dose with the prescriber.

hydration, and provide fluids to replace those lost with diarrhea. Because erythromycin can be very irritating to veins, it is important to administer IV infusions over 30 to 60 minutes. If pain persists, reduce the rate of infusion. If pain persists, apply ice and notify the prescriber.

Providing Patient and Family Education

- Encourage patients to take the complete course of antibiotics.
- Explain safe drug handling and storage.
- Explain the importance of taking erythromycin around the clock to maintain a therapeutic drug level.
- Teach patients the potential adverse effects and the measures to alleviate discomfort if such events occur.
- Advise patients to take erythromycin on an empty stomach, unless GI distress is unbearable.
- Advise patients to contact the prescriber if there is no improvement in 3 days.

Ongoing Assessment and Evaluation

Monitor for signs of allergic reactions, resolution of presenting signs and symptoms of infection, signs of superinfection, and for patients receiving IV erythromycin, signs of phlebitis or abscess formation. When therapy ends, the patient should be free of the initial infection. The patient will be adequately nourished and hydrated, and adverse effects will be resolved.

Drugs Closely Related to P Erythromycin

Azithromycin and clarithromycin are similar to erythromycin. All of these drugs are comparable to erythromycin in terms of their adverse effects, drug interactions, and patient management.

Azithromycin

Azithromycin (Zithromax) is available in oral, ophthalmic and IV formulations. Generally active against organisms that are also usually susceptible to erythromycin, it produces less GI intolerance than erythromycin. Azithromycin is the drug of choice in the management of chlamydial infection.

Azithromycin is unique in that it can reach exceptionally high levels in tissues, thus increasing its efficacy and duration of action. For this reason, it is administered only once a day. Absorption of azithromycin *capsules* is decreased in the presence of food, and capsules should be given on an empty stomach. The absorption of azithromycin *suspension* is increased in the presence of foods, so much so that the serum concentration may be too high. For that reason, the suspension should be taken on an empty stomach. Conversely, azithromycin *tablets* have an increased absorption when given with a meal with high-fat content and may be given with or without food.

Clarithromycin

Clarithromycin (Biaxin, ZMAX) is an oral macrolide antibiotic similar to erythromycin and azithromycin. Like azithromycin, clarithromycin penetrates tissues to a greater degree than erythromycin. Clarithromycin is generally active against organisms that are usually susceptible to erythromycin. Combined with omeprazole, clarithromycin is useful for *Helicobacter pylori*–associated peptic ulcer disease. Clarithromycin is contraindicated during pregnancy. It is unknown whether clarithromycin is excreted in breast milk. It is used cautiously in patients with either hepatic or renal insufficiency because it is partially renally excreted.

MEMORY CHIP

P Erythromycin

- Used for infections caused by gram-positive organisms. Less effective for gram-negative organisms.
- Major contraindication: hypersensitivity
- Most common adverse effect: GI distress
- Most serious adverse effects: hepatotoxicity, QT prolongation, pseudomembranous colitis, and ventricular tachycardia
- Maximizing therapeutic effects: Administer on an empty stomach, unless GI distress is pronounced.
- Minimizing adverse effects: Provide small, frequent meals.
- Most important patient education: Complete the entire course of medication, even when feeling better.

Drug Significantly Different From P Erythromycin

Telithromycin (Ketek) is the first drug in a new class of antibiotics called ketolides. A semisynthetic drug structurally similar to macrolides, telithromycin is approved to treat community-acquired pneumonia caused by *S. pneumoniae* (including multidrug-resistant isolates [MDRSP]), *H. influenzae, M. catarrhalis, Chlamydophila* (formerly *Chlamydia*) *pneumoniae,* and *Mycoplasma pneumoniae*. Its advantages include once-daily dosing and a short duration of administration (5 to 10 days).

Contraindications to telithromycin include patients with a history of myasthenia gravis, hepatitis or jaundice that occurred when taking other macrolide antibiotics, and patients with concomitant use of cisapride or pimozide. Telithromycin is given cautiously in cases of congenital prolongation of the QT interval, uncorrected hypokalemia and hypomagnesia, and clinically important bradycardia because these are considered prodysrhythmic conditions.

Telithromycin may induce several serious adverse effects. There is a black box warning regarding the use of telithromycin in patients with myasthenia gravis because of the potential to induce an exacerbation that may include life-threatening acute respiratory failure. Telithromycin may also cause liver dysfunction such as acute hepatic failure, severe liver injury, fulminant hepatitis, and hepatic necrosis. In addition, it may cause fainting spells and visual disturbances, both of which place the patient at risk for injury. Lastly, telithromycin may cause a prolonged QT interval or Torsades de pointes.

The common adverse effects for telithromycin are similar to that for erythromycin—mainly nausea, diarrhea, headache, and dizziness. In addition, telithromycin may cause. A potent CYP3A4 inhibitor, telithromycin has a long list of potential drug–drug interactions. Telithromycin is a pregnancy category C drug and is not recommended for patients under the age of 18 years.

C OXAZOLIDINONES

Oxazolidinones are the first new class of antibiotics developed specifically for treating methicillin-resistant *Staphylococcus aureus* (MRSA) infections. Linezolid (Zyvox) is the prototype for this new class of drugs (Table 40.7).

Nursing Management of the Patient Receiving P Linezolid

Core Drug Knowledge

Pharmacotherapeutics

Linezolid is approved for use in treating bacteremia associated with vancomycin-resistant *Enterococcus faecium* or *E. faecalis* (VRE); complicated skin infections; nosocomial or community-acquired pneumonia; bacteremia associated with nosocomial or community-acquired pneumonia; and infective endocarditis. It is also being used in the management of peritonitis in patients receiving peritoneal dialysis in certain circumstances.

Pharmacokinetics

Linezolid is available in both oral and parenteral formulations. Oral linezolid is 100% bioavailable, which means that the IV and oral forms are interchangeable without making dosage adjustments. Oral linezolid is rapidly absorbed from the GI tract and is widely distributed. Food delays absorption but does not decrease peak plasma concentrations. Linezolid is partly metabolized in the liver and is excreted in urine.

Pharmacodynamics

Linezolid attacks bacteria by blocking the early stages of the process bacteria use to make proteins, whereas other antibiotics act at later stages of protein synthesis. This unique mechanism of action suggests that bacteria may not be able to develop resistance as quickly and that cross-resistance between linezolid and other antibiotics is less likely to occur.

Contraindications and Precautions

The only contraindication for linezolid is hypersensitivity. Linezolid oral suspension should be used with caution in patients with phenylketonuria because the linezolid oral suspension is formulated with aspartame, which supplies roughly 20 mg of phenylalanine in each 5-mL suspension. Other linezolid products do not contain phenylalanine. Linezolid is given cautiously to patients with pre-existing blood dyscrasias because it may suppress bone marrow function. For the same reason, it should be given cautiously to patients receiving other drugs known to suppress bone marrow function. Because linezolid is a nonselective inhibitor of

TABLE 40.7 Overview of C Linezolid

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P linezolid (Zyvox)	Vancomycin-resistant *Enterococcus faecium* infection Community-acquired pneumonia, complicated skin and skin-structure infections, diabetic foot ulcers Infective endocarditis Uncomplicated skin and skin-structure infections	*Adult IV/PO:* 600 mg every 12 h for 14–28 d Child < 11 y IV/PO: 10 mg/kg every 8 h *Adult IV/PO: 600 mg every 12 h for a minimum of 8 wk* *Adult PO:* 400–600 mg every 112 h for 10–14 d *Child 5–11 y PO:* 10 mg/kg every 12 h *Child <5 y PO:* 10 mg/kg every 8 h	*Onset IV/PO:* rapid *Duration:* unknown $t_{1/2}$: 5 hours

monoamine oxidase (MAO), it should be used with caution in patients with hypertension, untreated hyperthyroid disease, severe cardiac disease, cerebrovascular disease, or pheochromocytoma. These patients have an increased risk of poor sequelae because linezolid-induced MAO inhibition reduces the metabolism of pressor amines, which may increase blood pressure in these individuals. Linezolid is classified as an FDA pregnancy category C drug.

Adverse Effects

Linezolid is generally well tolerated. The most common adverse effects associated with linezolid therapy are rash, fever, diarrhea, headache, nausea, and vomiting, usually mild to moderate in intensity and limited in duration. Serious adverse effects include seizures, blood dyscrasias, myelosuppression, lactic acidosis, serotonin syndrome, elevated hepatic enzyme levels, and pseudomembranous colitis. Hypertension is another potentially serious adverse effect in people with existing hypertension, untreated hyperthyroid disease, severe cardiac disease, cerebrovascular disease, or pheochromocytoma. As with other antibiotics, superinfections may occur during linezolid treatment.

Drug Interactions

Because linezolid is a reversible, nonselective MAO inhibitor, most potential drug interactions are related to this action of the drug. Linezolid interactions include adrenergic and serotonergic agents. Table 40.8 presents potential drug interactions.

Dietary interactions with linezolid can be serious. Foods containing tyramine should be avoided.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a complete history from the patient focusing on preexisting medical conditions that require cautious use of linezolid. Evaluate the patient's current medications for drugs that may interact with linezolid. Communicate positive findings to the prescriber before administering linezolid.

Review the culture and sensitivity report to establish that linezolid is an appropriate therapy. For patients requiring therapy longer than 14 days, obtain a baseline CBC and liver function test values.

Life Span and Gender

Assess the patient for potential pregnancy or breast-feeding because linezolid is a pregnancy category C drug. Linezolid is not approved for use in children.

Lifestyle, Diet, and Habits

Ask the patient about dietary intake, focusing on foods that are rich in tyramine. Evaluate for potential alcohol abuse because alcohol consumption during therapy increases the risk for a hypertensive crisis.

Because linezolid may interact with many OTC medications, assess for self-medicating of coughs, colds, or allergies or to achieve weight loss.

Environment

Be aware of the environment in which linezolid will be administered. Parenteral linezolid should be administered in an acute hospital setting. Oral linezolid may be administered in any setting.

Nursing Diagnoses and Outcomes

- Deficient Fluid Volume related to nausea, vomiting, and diarrhea from linezolid therapy
  Desired outcome: *The patient will remain well hydrated throughout therapy.*
- Risk for Injury related to thrombocytopenia and pseudomembranous colitis
  Desired outcome: *The patient will remain free from injury and contact the health care provider immediately if any signs of bleeding or abdominal pain occur.*
- Risk for Injury related to hypertensive crisis
  Desired outcome: *The patient will remain normotensive by adhering to antihypertensive therapy and limiting foods or beverages with tyramine, caffeine, or alcohol.*

TABLE 40.8 Agents That Interact with P Linezolid

Interactants	Effect and Significance	Nursing Management
Rifamycins	Rifamycins may decrease the serum concentration of linezolid	Monitor for linezolid efficacy
SSRI	Linezolid is a reversible, non-selective MAOI and can potentially interact with serotonergic agents, precipitating the serotonin syndrome.	Monitor for symptoms of "serotonin syndrome" such as irritability, increased muscle tone, shivering, myoclonus, and altered consciousness. Contact the prescriber if any occur.
tyramine	Linezolid may inhibit tyramine metabolism resulting in a severe pressor response	Avoid administration of large quantities of foods or beverages with high tyramine content (greater than 100 mg tyramine per meal)

Planning and Intervention

Maximizing Therapeutic Effects

Administer linezolid at evenly spaced intervals throughout the day (Box 40.1).

Minimizing Adverse Effects

To avoid hypertensive crisis, monitor the patient's intake of food or beverages containing tyramine, caffeine, or alcohol. Serial blood pressure readings should be obtained throughout therapy.

Providing Patient and Family Education

- Explain the importance of taking linezolid exactly as prescribed for the entire course of treatment, even if the patient feels better.
- Explain the need for periodic laboratory tests if therapy is anticipated to last longer than 14 days.
- Explain dietary restrictions, focusing on food or beverages containing tyramine, caffeine, or alcohol.
- Explain the importance of not using OTC drugs that may interact with linezolid.

BOX 40.1 FOCUS ON RESEARCH

Nosocomial MRSA

Henderson, D. K. (2006). Managing methicillin-resistant staphylococci: A paradigm for preventing nosocomial transmission of resistant organisms. *American Journal of Infection Control, 34*(5 Suppl. 1), S46–S54; discussion S64–S73.

The Study

Multidrug-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA), are endemic in health care settings in the United States and many other countries of the world. MRSA causes serious infections commonly seen in clinical settings. Nosocomial transmission of MRSA serves as a source of hospital outbreaks, and recent reports of vancomycin-resistant *S aureus* strains in the United States emphasize the need for better control of MRSA and other resistant bacteria within health care settings. Colonization with *S aureus* or MRSA is relatively common in both healthy and hospitalized people; it most often involves the anterior nares and is frequently asymptomatic. Colonization increases risk of infection. Patient-to-patient transmission of MRSA within health care settings primarily occurs via carriage on the hands of health care workers. The Society for Healthcare Epidemiology of America (SHEA) has developed guidelines for the prevention of transmission of MRSA and vancomycin-resistant enterococci within health care settings, and chief among the recommendations is an emphasis on adherence to hand hygiene guidelines.

Nursing Implications

Health care providers have been identified as a primary route of MRSA transmission. The SHEA guidelines mimic the Centers for Disease Control and Prevention (CDC) guidelines developed in 2003 to control the spread of MRSA. The CDC and SHEA guidelines include those listed below. In addition, the SHEA guidelines emphasize improved antibiotic stewardship, staff cohorting, maintenance of appropriate staffing ratios, reductions in length of hospital stays, contact isolation, active microbiologic surveillance, and better staff education.

Patient Considerations

- Place the patient with MRSA in a private room. When a private room is not available, the patient may be placed in a room with patients who have active infection with MRSA but no other infections (a practice called cohorting).
- Limit the movement and transport of the patient from the room for essential purposes only.
- Ensure that patient-care items, bedside equipment, and frequently touched surfaces receive daily cleaning.
- Dedicate the use of noncritical patient-care equipment and items, such as stethoscope, sphygmomanometer, bedside commode, or electronic rectal thermometer, to a single patient (or cohort) infected or colonized with MRSA and avoid sharing such items between patients.

Handwashing

- Wash hands after touching blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn.
- Wash hands immediately after gloves are removed, between patient contacts, and when otherwise indicated, to avoid transferring microorganisms to other patients or environments.
- Wash hands between tasks and procedures on the same patient to prevent cross-contamination of different body sites.

Gloving

- Wear gloves (clean nonsterile gloves are adequate) when touching blood, body fluids, secretions, excretions, and contaminated items.
- Put on clean gloves just before touching mucous membranes and nonintact skin.
- Remove gloves promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient.
- Wash hands immediately after glove removal to avoid transferring microorganisms to other patients or environments.

Masking

- Wear a mask and eye protection or a face shield to protect mucous membranes of the eyes, nose, and mouth during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions.

Gowning

- Wear a gown (a clean nonsterile gown is adequate) to protect skin and prevent soiling your clothes during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions or otherwise soil clothing.

Appropriate Device Handling

- Handle used patient-care equipment soiled with blood, body fluids, secretions, and excretions in a manner that prevents exposure to skin and mucous membranes, contamination of clothing, and transfer of microorganisms to other patients and environments.
- Ensure that reusable equipment is not used to care for another patient until it has been appropriately cleaned and reprocessed and that single-use items are properly discarded.

Appropriate Handling of Laundry

- Handle, transport, and process used linen soiled with blood, body fluids, secretions, and excretions in a manner that prevents exposure to skin and mucous membranes, contamination of clothing, and transfer of microorganisms to other patients and environments.

TABLE 40.9 Overview of C Quinupristin/Dalfopristi

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P quinupristin/dalfopristin (Synercid)	Life-threatening vancomycin-resistant *Enterococcus.faecium* bacteremia Infective endocarditis Complicated skin Infections	Adult IV; 7.5 mg/kg every 8 h 7.5 mg/kg every 8 h for a minimum of 8 wk 7.5 mg/kg every 12 h	*Onset:* immediate *Duration:* unknown $t_{1/2}$: 3 h quinupristin 1 h dalfopristin

- Explain that linezolid may interact with many types of prescription medications. Patients should contact their prescriber before taking any other medications, even those prescribed by another health care professional.
- Teach patients the signs and symptoms of thrombocytopenia and pseudomembranous colitis. Advise patients to contact their prescriber immediately if any symptoms occur.

Ongoing Assessment and Evaluation

Monitor for efficacy of treatment and the resolution of the presenting infection. Monitor for signs and symptoms of thrombocytopenia and pseudomembranous colitis and advise the prescriber if any occur. Monitor the patient's blood pressure and intake of foods or beverages containing tyramine, caffeine, or alcohol. Coordinate serial CBC and liver enzyme tests if therapy lasts more than 14 days.

When treatment ends, the initial infection should be resolved. The patient should be adequately nourished and hydrated, and any adverse drug effects should be resolved.

C STREPTOGRAMINS

Streptogramins are the newest class of antibiotics, specifically designed to eradicate "superbugs" resistant to other antibiotics. Quinupristin and dalfopristin are the only streptogramins approved for use in the United States by the FDA; they are marketed as the combination drug quinupristin/ dalfopristin (Synercid) (Table 40.9).

MEMORY CHIP

P Linezolid

- Used for infections caused by vancomycin-resistant Enterococcus faecium or E. faecalis (VRE), methicillin-resistant Staphylococcus aureus (MRSA), and penicillin-susceptible Streptococcus pneumoniae.
- Major contraindication: hypersensitivity
- Most common adverse effects: nausea, vomiting, headache, and diarrhea.
- Most serious adverse effects: thrombocytopenia and pseudo-membranous colitis.
- Maximizing therapeutic effects: Administer at evenly spaced intervals.
- Minimizing adverse effects: Monitor the patient's intake of foods and beverages containing tyramine, caffeine, or alcohol.
- Most important patient education: Teach the patient dietary restrictions and the importance of not taking any medications, including OTC medications, without the health care provider's approval.

Nursing Management of the Patient Receiving P Quinupristin/Dalfopristin

Core Drug Knowledge

Pharmacotherapeutics

Quinupristin/dalfopristin is indicated for the treatment of serious or life-threatening infections associated with VRE bacteremia, infective endocarditis, and for complicated skin and skin-structure infections. It is also used off label to treat MRSA and in the management of peritonitis in patients receiving peritoneal dialysis in certain circumstances.

Pharmacokinetics

Quinupristin/dalfopristin is administered by the IV route only. Both drugs are converted to several active major metabolites and are excreted primarily through bile.

Pharmacodynamics

Quinupristin/dalfopristin inhibits bacterial protein synthesis by irreversibly blocking ribosome functioning. When used as single agents, these drugs are bacteriostatic. When used in combination, quinupristin/dalfopristin has up to 16 times the activity of each agent alone and is bacteriocidal against most organisms.

Contraindications and Precautions

The only contraindication to use of quinupristin/dalfopristin is hypersensitivity. Because quinupristin/dalfopristin received accelerated FDA approval based on the drug's ability to clear VRE from the bloodstream, there is a black box warning that there are no clinical studies to confirm efficacy of the drug.

Adverse Effects

Serious adverse effects include pseudomembranous colitis, superinfection, and angioedema. Common adverse effects include injection site reaction, injection site pain, nausea, vomiting, diarrhea, thrombophlebitis, arthralgias and myalgias, rash, pruritus, and hyperbilirubinemia.

Drug Interactions

Quinupristin/dalfopristin is a potent inhibitor of CYP3A4, a cytochrome of P-450. Serum concentrations of drugs metabolized through this pathway may be increased. Table 40.10

TABLE 40.10 Agents That Interact with P Quinupristin/Dalfopristin

Interactants	Effect and Significance	Nursing Management
P-450 3A4 drugs	Quinupristin/dalfopristin inhibits cytochrome P-450 3A4 and will decrease the elimination of drugs metabolized by this pathway. This results in an increased risk for toxicity and adverse effects.	Avoid these drugs if possible. Monitor for toxicity if coadministration is unavoidable.
Calcium Channel Blockers (CCBs)	Quinupristin/dalfopristin may decrease the metabolism of CCBs	Monitor BP—may increase if quinupristin/dalfopristin is initiated/dose increased, or decreased if quinupristin/dalfopristin is discontinued/dose decreased.
Cyclosporine	Quinupristin/dalfopristin may decrease the metabolism of cyclosporine	Monitor for signs of toxicity if quinupristin/dalfopristin is started; monitor for decreased efficacy of cyclosporine if quinupristin/dalfopristin is discontinued.

presents drugs metabolized through this pathway, which may therefore interact with quinupristin/dalfopristin.

Assessment of Relevant Core Patient Variables

Health Status

Elicit a complete medical history to evaluate for potential contraindications or precautions to the administration of quinupristin/dalfopristin. Be especially alert for a history of liver dysfunction. Evaluate the patient's current medications for drugs that are metabolized through the CYP3A4 enzyme system. Be sure to communicate any positive findings to the prescriber before administering this drug.

Coordinate baseline liver function and bilirubin tests on blood drawn before administration of quinupristin/ dalfopristin. Coordinate liver function and bilirubin tests twice weekly for the first week of therapy and once weekly thereafter.

Life Span and Gender

Evaluate the patient for pregnancy and lactation. Quinupristin/dalfopristin is an FDA pregnancy category B drug. It is unknown whether quinupristin/dalfopristin is secreted in breast milk. Consider the ratio of benefits to potential risks for the pediatric patient. Quinupristin/dalfopristin has not been approved for use in children; however, it has been administered to children in emergency situations.

Environment

Be aware of the environment in which the drug will be administered. Quinupristin/dalfopristin should be administered in an acute hospital setting. Review the policy of the parent institution and be sure that approval by the Infectious Disease Committee is documented if needed.

Nursing Diagnoses and Outcomes

- Pain related to IV administration
  Desired outcome: *The patient will inform you immediately should pain at the injection site occur.*
- Diarrhea related to potential pseudomembranous colitis
  Desired outcome: *The patient will remain well hydrated throughout therapy and report any diarrhea immediately.*
- Risk for Injury related to potential superinfection or hepatotoxicity
  Desired outcome: *The patient will remain free of injury throughout therapy.*
- Risk for Impaired Skin Integrity related to rash or pruritus.
  Desired outcome: *The patient will report itching or rash immediately to minimize potential for infection.*

Planning and Intervention

Maximizing Therapeutic Effects

Quinupristin/dalfopristin should not be administered with any other medications through a Y-site infusion unless compatibility with both the drug and diluent is established. Flush the line before and after administration with 5% dextrose and water (D_5W) to minimize venous irritation. *DO NOT FLUSH* the IV line with saline or heparin after administering quinupristin/dalfopristin because this procedure is not compatible with these solutions.

Minimizing Adverse Effects

Because injection site problems are very common with the administration of quinupristin/dalfopristin, administer these drugs in a peripherally inserted central catheter (PICC) or central line whenever possible. If administering them peripherally, dilute them in 250 mL of D_5W and infuse over 1 hour.

Providing Patient and Family Education

Because quinupristin/dalfopristin is used for serious life-threatening infections, the patient may not be able to comprehend patient teaching at the onset of therapy. When appropriate, teaching should include the following:

- Encourage patients to report any pain during infusion.
- Teach patients the potential adverse effects associated with quinupristin/dalfopristin such as arthralgias and myalgias, rash, and pruritus.

- Advise patients to report cough, congestion, rash, or feeling warm because these may indicate a superinfection.
- Advise patients to report any diarrhea immediately to avert pseudomembranous colitis, if possible.

Ongoing Assessment and Evaluation

During infusion, monitor the IV site for signs of infiltration, edema, or phlebitis. Question the patient regarding pain at the injection site. During therapy, monitor for signs and symptoms of hyperbilirubinemia. Monitor for diarrhea. Pseudomembranous colitis may develop from a toxin produced by *C. difficile*. Therefore, this diagnosis should be considered in any patient who complains of diarrhea after administration of quinupristin/dalfopristin.

At the end of therapy, the initial infection should be resolved. The patient will be adequately nourished and hydrated and will have normal liver function and bilirubin test results, and any adverse effects will be resolved.

C TETRACYCLINES

The tetracyclines were developed as semisynthetic antibiotics based on the structure of a common soil mold. They are broad-spectrum antibiotics that affect both gram-positive and gram-negative bacteria. The first syllables of their name derive from the four-ring structure common to all of these drugs. Over the years, major resistance has developed to tetracyclines, and less toxic, more effective drugs have been discovered. Still, tetracyclines are effective against certain organisms for which they remain the drug of choice. Tetracyclines include tetracycline, demeclocycline, doxycycline, and minocycline. Table 40.11 provides a summary of tetracycline antibiotics. The prototype for the tetracycline class is tetracycline

MEMORY CHIP

P Quinupristin/Dalfopristin

- Used for vancomycin-resistant Enterococcus faecium bacteremia and for complicated skin and skin-structure infections due to *Staphylococcus aureus*
- Major contraindication: hypersensitivity
- Most common adverse effects: injection site pain, swelling, or phlebitis
- Most serious adverse effect: hepatotoxicity
- Maximizing therapeutic effects: Do not use saline or heparin to flush the solution because they are not compatible with this drug.
- Minimizing adverse effects: Administer through PICC or central line whenever possible.
- Most important patient education: Teach the patient about the potential for injection-site adverse effects and about the importance of notifying the nurse if injection site pain occurs.
- **Black box warning: FDA accelerated approval, no clinical studies to ensure efficacy**

Nursing Management of the Patient Receiving P Tetracycline

Core Drug Knowledge

Pharmacotherapeutics

Oral tetracycline (Sumycin) is FDA approved for many types of infection, however, it has acquired substantial resistance patterns so it not used for all of its indications. It is used for infections caused by *Borrellia burgdorferi*, *Rickettsia* species, *Mycoplasma pneumoniae,* and *Chlamydia trachomatis*. It is also used to treat brucellosis, cholera, anthrax, Lyme disease, and *H. pylori* infection.

Pharmacokinetics

Tetracycline is administered orally because it is no longer available for parenteral administration. In the fasting state, tetracycline is about 75% to 77% absorbed. Absorption takes place mainly in the stomach and upper intestine. As the dosage is increased, the percentage absorbed decreases. Absorption is decreased in the presence of food, iron preparations, and antacids containing calcium, magnesium, and aluminum salts.

Tetracycline is widely distributed into body fluids, including CSF. Tetracycline tends to concentrate in bone, liver, tumors, spleen, and teeth. It crosses the placenta and is distributed in breast milk. Tetracycline is about 65% bound to plasma protein and does not appear to undergo hepatic metabolism; however, it undergoes enterohepatic circulation and is excreted in the feces by way of the bile. The primary excretion route is the kidney. About 60% of a dose is excreted unchanged from both routes. The serum half-life of tetracycline is between 6 and 12 hours in adults with normal renal function but is greatly increased in patients with severely impaired renal function.

Pharmacodynamics

The tetracyclines are bacteriostatic; they inhibit or retard the growth of bacteria but do not kill them. They retard bacterial growth by inhibiting protein synthesis in sensitive bacteria and by preventing cell division and replication. Like other antibiotics, their effect on the body is indirect.

Contraindications and Precautions

Tetracycline is contraindicated in patients with a known allergy to tetracyclines or to tartrazine (specific oral preparations contain tartrazine) and during pregnancy and lactation. Tetracycline should be used with caution in children younger than 8 years and in patients with hepatic and renal dysfunction.

Adverse Effects

The common adverse effects of tetracycline therapy involve the GI tract and the CNS; they include nausea, vomiting, diarrhea, abdominal or epigastric discomfort, headache, dizziness, and photosensitivity. Rare but serious adverse effects include anaphylaxis, angioedema, blood dyscrasias, damage to the teeth (in children < 8 years), and hepatotoxicity or nephrotoxicity. Like other broad-spectrum antibiotics,

TABLE 40.11 Summary of Selected Tetracycline Antibiotics

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P tetracycline (Sumycin; Bristacycline)	Brucellosis Syphilis Uncomplicated gonorrhea Gonococcal urethritis Uncomplicated chlamydial infections Severe acne	Adult PO: 500 mg 4x d 30–40 g in divided doses over 10–15 d 1.5 g initially followed by 500 mg every 6 h to a total of 9 g 1.5 g initially followed by 500 mg every 4–6 h for 4–6 d 500 mg 4x d for at least 7 d 125–500 mg/d	*Onset:* PO, varies *Duration:* Varies $t_{1/2}$: 6–12 h
demeclocycline (Declomycin)	Same as tetracycline	*Adult*: PO, 600 mg in four doses of 150 mg each *Child >8 y*: PO, 6–12 mg/kg in two to four doses	*Onset*: Varies *Duration*: 18–20 h $t_{1/2}$: 12–16 h
doxycycline (Vibramycin)	Same as above and for anti-diuretic hormone-secreting tumors, bacterial enteritis and Lyme disease	*Adult*: PO, 200 mg initially; maintenance, 100 mg/d; IV, 200 mg/d initially, then 100–200 mg depending on infection *Child 8 y*: PO, 4.4 mg/kg divided in two doses initially; maintenance, 2.2 mg/kg in one or two doses per day; IV, 4.4 mg/kg on first day in one or two infusions depending on infection	*Onset*: PO, varies; IV rapid *Duration*: 24–36 h $t_{1/2}$: 15–25 h
doxycycline (Oracea)	Rosacea	*Adult PO*: 40 mg daily	
minocycline (Minocin)	Same as tetracycline and Neisseria meningitidis	*Adult*: PO, 200 mg initially followed by 100 mg q12h; IV, 200 mg followed by 100 mg q12 h not to exceed 400 mg/d *Child >8 y*: PO, 4 mg/kg initially, followed with 2 mg/kg q12h; IV, 4 mg/kg followed by 2 mg/kg q12 h	*Onset*: PO, varies; IV, rapid *Duration*: 24–36 h $t_{1/2}$: 11–18 h
tigecycline (Tygacil)	Complicated skin and skin structure infections Complicated intra-abdominal nfections	*Adult and Child >18 y*: IV, 100 mg initially followed by 50 mg every 12 h	*Onset*: Immediate *Duration*: Unknown $t_{1/2}$: 42.4 h

tetracycline has a high potential to cause superinfections, such as candidiasis.

Drug Interactions

The effectiveness of penicillin G decreases if it is taken concurrently with tetracyclines. If this combination is used, the dosage of the penicillin will have to be increased. Oral contraceptives may be less effective if taken with tetracycline. Patients taking oral contraceptives should be advised to use an additional form of birth control while receiving tetracycline. Tetracycline forms an insoluble chelate with aluminum, bismuth, calcium, iron, magnesium, and zinc salts, which are frequently an ingredient in antacids. This chelate decreases absorption of either tetracycline or the salt. For more information on drug interactions, see Table 40.12.

Assessment of Relevant Core Patient Variables

Health Status

Follow the same guidelines for evaluating health status as those for a patient receiving penicillin. Assess for known allergies to any drug with a name ending in the suffix "cycline." Additionally, closely evaluate the renal and hepatic status of patients prescribed tetracycline. Anuric patients should not receive tetracycline, and the dosage should be decreased in patients with renal insufficiency. If renal impairment exists, even usual doses may lead to excessive systemic accumulation of tetracycline, resulting in liver or kidney toxicity.

Life Span and Gender

Evaluate women for potential pregnancy because tetracycline is an FDA pregnancy category D drug. Because the tetracyclines bind to calcium in developing teeth and bones, women in the second and third trimesters of pregnancy should not take this drug. In infants born to mothers who take tetracyclines during pregnancy, mottled and discolored deciduous teeth may develop. To prevent damage to the developing permanent teeth, tetracycline should not be given to children younger than 8 years.

Lifestyle, Diet, and Habits

Because many OTC drugs contain mineral salts that may decrease the absorption of tetracycline, obtain an OTC drug history from the patient or an appropriate caregiver. Explore the dietary habits of the patient, because tetracycline is not absorbed effectively when taken with food or dairy products.

TABLE 40.12 Agents That Interact with P Tetracycline

Interactants	Effect and Significance	Nursing Management
Antacids aluminum salts bismuth salts calcium salts iron salts magnesium salts zinc salts	Tetracycline forms an insoluble chelate with antacids, decreasing absorption and serum levels of either or both.	Avoid simultaneous administration. Separate administration by 3–4 h.
digoxin	In some patients, digoxin is metabolized by bacteria in the GI tract. Tetracycline may reverse the process by altering GI flora, allowing more digoxin to be absorbed and increasing digoxin levels.	Monitor digoxin levels. Monitor pulse rate. Monitor patient for signs of digoxin toxicity.
Food	Foods such as milk and dairy products contain calcium, which forms poorly absorbed chelates with tetracyclines.	Administer tetracycline at least 1 h before or 2 h after meals.
insulin	Tetracycline may increase extrapancreatic response to insulin, resulting in hypoglycemia.	Monitor blood glucose frequently. Monitor for signs of hypoglycemia such as hunger, dizziness, shakiness, sweating, or confusion.
lithium	Increased serum concentration of lithium resulting in increased risk for lithium toxicity.	Monitor for drowsiness, slurred speech, tremor, and thirst. Contact the prescriber immediately should symptoms occur.
methotrexate	Increased serum concentration of methotrexate resulting in increased risk for adverse effects and toxicity	Monitor CBC. Monitor for signs and symptoms of bone marrow suppression. Contact the prescriber immediately should symptoms occur.
methoxyflurane	Tetracycline may induce biotransformation and impairment of renal excretion of toxic metabolites of methoxyflurane, resulting in an increased risk of nephrotoxicity.	Avoid this combination.
Oral contraceptives	Tetracyclines may suppress intestinal flora, which provides an enzyme essential for enterohepatic recirculation for certain oral contraceptives. This may result in a decreased contraceptive plasma level.	Advise patients taking oral contraceptives to use an additional method of birth control while taking tetracyclines.
Penicillins	The bacteriostatic action of tetracyclines may impair the bactericidal activity of penicillins.	Avoid combination therapy.
Retinoids	Increased risk of pseudotumor cerebri (benign intracranial hypertension) due to additive or synergistic effect	Monitor for headache, nausea, vomiting, and visual disturbances. Notify the prescriber immediately should symptoms occur.
theophylline	There is an increased risk for adverse effects to theophyllines.	Monitor theophylline level. Monitor for theophylline toxicity.
Urinary alkalinizers	This combination may alter tubular reabsorption of tetracycline, resulting in a decreased absorption of tetracycline.	Separate administration of these drugs by 3–4 h. Monitor for efficacy of tetracycline therapy. Tetracycline dosage may need to be increased.
warfarin	Elimination of vitamin K–producing gut bacteria by tetracycline may increase the activity of warfarin.	Monitor PT and INR frequently. Monitor for bruising or bleeding.

Environment

Assess for the patient's potential to be outdoors while taking tetracycline. Because this drug causes photosensitivity, teach the patient to avoid direct sunlight, and if going outdoors is unavoidable, encourage the patient to wear appropriate cover-up clothing, hat, and sunglasses, plus a sunscreen that has a sun protection factor (SPF) of at least 30.

Nursing Diagnoses and Outcomes

- Risk for Injury related to potential superinfection or allergic drug reaction
  Desired outcome: *The patient will experience no new infection and no preventable allergic reaction related to tetracycline.*
- Diarrhea related to drug-induced GI effects

Desired outcome: *The patient will report any incidence of diarrhea and follow the prescriber's recommendation.*

- Imbalanced Nutrition: Less than Body Requirements, related to adverse GI effects of nausea, vomiting, diarrhea, and altered taste
  Desired outcome: *The patient will maintain dietary intake to provide adequate nutrition.*
- Risk for Impaired Skin Integrity related to drug-induced photosensitivity
  Desired outcome: *The patient will dress appropriately and take adequate precautionary measures while outdoors to avoid sunburn.*

Planning and Intervention

Maximizing Therapeutic Effects

To judge the efficacy of ongoing treatment, evaluate results of initial culture and sensitivity tests performed on samples from the infection site. Make sure that the patient receives tetracycline as prescribed, divided around the clock to increase effectiveness. To maximize absorption, oral preparations should be administered on an empty stomach either 1 hour before or 2 hours after any meals or other drugs. In addition, remind the patient to avoid antacids within 3 hours of tetracycline administration. It is optimal to continue drug therapy for at least 7 to 10 days.

Minimizing Adverse Effects

Provide small, frequent meals; mouth care; and ice chips or sugarless candy to suck on if stomatitis and sore mouth are problems. Monitor the patient to ensure that adequate fluids are given to replace fluid lost with diarrhea. In addition, remind patients of the potential for photosensitivity and the need to wear protective clothing and a sunscreen with a minimum 15 SPF.

Caution patients about taking outdated tetracycline. The shelf life of tetracycline is limited, and ingestion of outdated tetracycline has been associated with the development of nausea, vomiting, and renal failure. These reactions are thought to be a result of the effects of degradation products.

Providing Patient and Family Education

- Explain that tetracycline is one drug in a class of drugs. It is important that patients understand that they should not take this drug if they have ever had a reaction to a drug with a name that ends with "cycline."
- Advise women of childbearing age that tetracycline should not be taken during pregnancy or breast-feeding.
- Explain that tetracycline is prescribed for a particular infection and should not be used to self-medicate or treat any other infection.
- Emphasize that tetracycline should not be given to any other person, especially a child, and that it must be kept out of the reach of children.
- Advise patients to complete the full course of drug therapy, even if they feel better, and to avoid taking any outdated tetracycline because it may cause liver damage.
- Advise patients to take tetracycline on an empty stomach, with water and not dairy products.
- Advise patients to take OTC medications, such as antacids, that contain mineral salts at least 3 hours after administration of tetracycline.
- Teach patients to take forgotten doses as soon as they remember, but not if it is almost time for the next dose.
- Instruct patients to call the prescriber if the symptoms do not improve in 3 days.
- Explain the potential adverse effects of tetracycline and the potential remedies for these discomforts. Measures to relieve GI upset include taking small, frequent meals if patients experience GI distress and increasing fluid intake for diarrhea. Patients with a sore mouth or throat should be advised to suck on ice chips or hard candy.
- Teach patients signs and symptoms of superinfection, such as discoloration of the tongue, fatigue, easy bruising, or vaginal discharge. Caution patients about the potential for photosensitivity and the importance of staying out of direct sunlight and wearing sunscreen.
- Advise women who use oral contraceptives to use a backup method of contraception while taking tetracycline.

Ongoing Assessment and Evaluation

Monitor the site of infection and compare it with presenting signs and symptoms throughout the course of drug therapy. Failure to resolve these signs and symptoms may indicate a treatment failure. Also, monitor the patient to ensure that the full course of therapy is completed.

Monitor renal status to detect and prevent hepatotoxicity and to observe for any signs of superinfection. Notify the provider immediately if they occur.

At the end of therapy, the patient should be free of the initial infection. The patient will have maintained adequate nutrition and hydration, and any adverse effects will be resolved.

MEMORY CHIP

P Tetracycline

- Used for Rickettsia, Mycoplasma pneumoniae, chlamydia, and acne
- Major contraindications: pregnancy, breast-feeding, and in children younger than 8 years of age
- Most common adverse effects: discoloration of teeth, nausea, vomiting, and photosensitivity
- Most serious adverse effect: azotemia
- Maximizing therapeutic effects: Administer at evenly spaced intervals on an empty stomach.
- Minimizing adverse effects: Give frequent small meals and increase mouth care when GI distress is present.
- Most important patient education: Teach the patient to complete the entire course of medication, despite feeling better. Teach the patient to keep medication out of the reach of children.

Drugs Closely Related to P Tetracycline

Demeclocycline, doxycycline, and minocycline are similar to tetracycline. Contraindications, other adverse effects, drug interactions, and patient management are comparable to those for tetracycline.

Demeclocycline

Demeclocycline (Declomycin) has the same FDA indications as tetracycline. In addition, it is used for treating Syndrome of Inappropriate Antidiuretic Hormone secretion (SIADH) and fluid imbalances. Demeclocycline inhibits ADH-induced water reabsorption in the kidneys, resulting in diuresis.

Demeclocycline has similar contraindications, precautions, drug interactions, and adverse effects as tetracycline. There is an increased risk of photosensitivity with demeclocycline. It is a pregnancy category D drug.

Doxycycline

Doxycycline (Vibramycin) is a new type of tetracycline. It has the same pharmacotherapeutics as tetracycline and is used frequently for nongonococcal urethritis or cervicitis, as well as prophylaxis against STDs after sexual aggression. Taken orally, it is better absorbed than tetracycline, even in the presence of food and dairy products. It is excreted mainly through feces, unlike the other tetracyclines. Because of its excretion pattern, doxycycline is useful in patients with compromised renal function. Its half-life is longer than that of tetracycline, allowing for twice-daily dosing.

A new formulation of doxycycline (Oracea) is specifically used to manage inflammatory lesions of rosacea, not infections generally treated with doxycycline. Oracea contains 30 mg of immediate-release doxycycline and 10 mg of delayed-release doxycycline that targets the underlying inflammatory pathophysiology of rosacea, without exerting antimicrobial effects.

Minocycline

Minocycline (Minocin, Dynacin, Solodyn) is another fairly new tetracycline. Like doxycycline, minocycline has a long half-life. In addition to sharing the utility of other tetracyclines, minocycline is also used to treat meningococcal carrier states of *Neisseria meningitidis*. Minocycline is also useful in decreasing the symptoms of rheumatoid arthritis. Solodyn is an extended-release formulation of minocycline specifically used for acne.

Minocycline may cause vestibular toxicity with symptoms of dizziness, light-headedness, or vertigo. Patients should be cautioned to assess for these symptoms before driving a motor vehicle or performing hazardous tasks.

Drugs Significantly Different From P Tetracycline

Tigecycline (Tygacil) is the first drug in a new class of drugs called glycylcycline antibiotics. They are structurally similar to tetracyclines but are designed to circumvent key bacterial resistance mechanisms. Tigecycline is indicated for the management of complicated skin and skin structure infections, complicated intra-abdominal infections, and community-acquired pneumonia. Its spectrum of activity is broad and includes resistant organisms such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococcus (VRE), extended-spectrum beta-lactamase (ESBL) producing bacteria, like *E. coli* and *Klebsiella pneumoniae*, and *Acinetobacter* species.

Because tigecycline is structurally similar to tetracycline, it may induce many of the same adverse effects. The most common adverse effects are nausea and vomiting. Tigecycline is contraindicated during pregnancy because it may cause fetal harm. It is given cautiously to patients with a known sensitivity to tetracyclines, patients less than 8 years of age, those with intestinal perforation, and in patients taking warfarin. The PT and international normalized ratio (INR) of patients taking warfarin should be monitored. To maintain the effectiveness of tigecycline, it should be used only to treat infections caused by susceptible bacteria.

C MISCELLANEOUS ANTIBIOTICS THAT AFFECT PROTEIN SYNTHESIS

Miscellaneous antibiotics include chloramphenicol and spectinomycin. Chloramphenicol is the prototypical miscellaneous antibiotic (Table 40.13). In 1947, chloramphenicol was isolated from *Streptomyces venezuelae* and used to treat large outbreaks of typhus. It is now available synthetically as chloramphenicolor chloramphenicol succinate.

TABLE 40.13 Overview of C Chloramphenicol

Drug (Trade) Name	Selected Indications	Route and Dosage Range	Pharmacokinetics
P chloramphenicol	Serious infections caused by *Salmonella, Haemophilus influenzae,* rickettsiae, lymphogranuloma	*Adult IV:* 50–100 mg/kg/d in divided doses every 6 h *Child IV:* 50–75 mg/kg/d in divided doses every 6 h *Ophthalmic Adult and Child:* As prescribed	*Onset:* 20–30 min *Duration:* 48–72 h $t_{1/2}$: 1.5–4 h

Nursing Management of the Patient Receiving P Chloramphenicol

Core Drug Knowledge

Pharmacotherapeutics

Chloramphenicol is a true broad-spectrum antibiotic. It is active against a wide range of gram-positive and gram-negative bacteria, many anaerobic bacteria, *Bacteroides* species, and *Salmonella* species. However, it is inactive against fungi.

Chloramphenicol is relatively toxic and thus has a Black Box warning for use only in serious infections against which other antibiotics have been ineffective or in patients who cannot take safer drugs because of resistance or allergies. It is the drug of choice for treating meningitis caused by *Streptococcus pneumoniae, Neisseria meningitidis,* or *Haemophilus influenzae*. It is also used in treating brain abscesses, rickettsial infections, and acute typhoid fever.

Pharmacokinetics

Chloramphenicol base is administered orally; chloramphenicol succinate is administered intravenously. For chloramphenicol succinate to be active, it must be hydrolyzed to free chloramphenicol. Free chloramphenicol is rapidly absorbed from the GI tract. Peak action occurs within 1 to 3 hours. Peak concentrations rise with repeated administration. The goal is to keep plasma concentrations below 25 mcg/mL to decrease the risk for adverse hematologic effects. Plasma concentration levels of chloramphenicol are increased in patients with hepatic and renal dysfunction and in premature or newborn infants with immature systems.

Chloramphenicol is widely distributed throughout most body tissues and fluids, with highest concentrations in the liver and kidneys. Chloramphenicol can reach substantial CSF concentrations, especially in patients with inflamed meninges.

Following oral administration, between 5% and 15% of chloramphenicol is excreted unchanged in the urine by glomerular filtration, and the remainder is excreted by tubular secretion, mostly as inactive metabolites. Small amounts are excreted unchanged in the bile and feces.

Pharmacodynamics

Chloramphenicol is usually bacteriostatic but may be bactericidal in high concentrations or against more susceptible organisms, such as *H. influenzae* and *S. pneumoniae*. It works by inhibiting the protein synthesis of bacterial cells. Chloramphenicol also inhibits mitochondrial protein synthesis in both bacterial and human cells. In humans, the protein synthesis of rapidly proliferating cells, such as erythrocytes, may be affected. This effect may explain the mechanism of reversible depression of bone marrow function associated with chloramphenicol therapy.

Contraindications and Precautions

Chloramphenicol should not be given to patients who have had known toxic reactions to the drug because some fatal reactions have occurred. It should not be used systemically for minor infections because of the potential for serious toxicity. Chloramphenicol is also contraindicated in breast-feeding women because it can suppress bone marrow function in breast-feeding infants. The drug should be used with caution in patients with depressed bone marrow function and in those who have received cytotoxic drug therapy or radiation therapy. It can cause dose-related depression of bone marrow function and an idiosyncratic aplastic anemia.

Chloramphenicol should be given with extreme caution to pregnant women, infants, and children. Other patients at high risk during chloramphenicol therapy include patients with hepatic disease, renal impairment, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and acute intermittent porphyria.

Adverse Effects

A serious and potentially life-threatening adverse effect of chloramphenicol is "gray baby" syndrome. It is most common in premature infants or newborns receiving chloramphenicol, whose hepatic systems have difficulty conjugating or excreting chloramphenicol. This syndrome is characterized by failure to feed, abdominal distention, possible vomiting, progressive blue-gray skin, and vasomotor collapse. The infant may also have irregular breathing.

Other serious and potentially life-threatening adverse effects of chloramphenicol are blood dyscrasias, which are a Black Box warning. These include aplastic anemia, hypoplastic anemia, thrombocytopenia, pancytopenia, and granulocytopenia. These adverse effects have all occurred following short-term or long-term therapy as a result of depressed bone marrow function.

Bone marrow toxicity may or may not be dose related. Irreversible depression of bone marrow function, a type of toxicity unrelated to dose, can result in aplastic anemia, which has a high mortality rate. This type of aplasia or hypoplasia can develop months after the drug has been discontinued or from a single dose. Reversible depression of bone marrow function usually is dose related and is characterized by anemia, reticulocytopenia, leukopenia, or thrombocytopenia.

Other adverse effects, which may be dose related, are optic neuritis, which can cause blindness, and peripheral neuritis. Patients with either of these effects should discontinue the drug immediately.

Other neurotoxic effects include headache, mild depression, confusion, and delirium, but these reactions are usually mild. Patients should be monitored for other signs of peripheral neuropathy.

GI effects are usually minimal during therapy with chloramphenicol but can include nausea, vomiting, diarrhea, dysgeusia, glossitis, stomatitis, pruritus ani, or enterocolitis. Adverse GI symptoms should be reported immediately because they can indicate more severe reactions, such as superinfection.

Maculopapular rash and urticaria can occur from either systemic administration or topical application of

TABLE 40.14 Agents That Interact with P Chloramphenicol

Interactants	Effect and Significance	Nursing Management
Barbiturates	Coadministration may decrease chloramphenicol serum levels and may decrease barbiturate clearance resulting in increased adverse effects or toxicity.	Monitor for chloramphenicol efficacy. Monitor for signs of barbiturate poisoning. Contact the prescriber if symptoms occur.
cyclosporine	Coadministration may increase cyclosporine serum concentration resulting in increased risk for adverse effects and toxicity	Monitor BUN and creatinine levels. Monitor intake and output.
Hydantoins	Chloramphenicol alters metabolism of hydantoins, resulting in an increased risk for hydantoin toxicity.	Monitor serum concentration of hydantoins. Adjust hydantoin dosage as needed.
Iron salts	Chloramphenicol decreases iron clearance and erythropoiesis due to bone marrow toxicity. This may result in iron overload and anemia.	Monitor CBC. Monitor serum iron levels. Discuss iron dosage adjustment with prescriber as needed.
Oral anticoagulants	Chloramphenicol may interfere with hepatic metabolism of the anticoagulant and possibly the hypoprothrombinemic effect. This results in an increased risk of bleeding.	Monitor PT and INR closely. Monitor for signs of bleeding. Contact prescriber immediately if symptoms occur. Discuss adjustment of oral anticoagulant dose with the prescriber.
Oral hypoglycemic agents	Chloramphenicol may reduce hepatic clearance of oral hypoglycemics, resulting in clinical hypoglycemia.	Monitor blood glucose concentrations. Monitor for signs of hypoglycemia such as hunger dizziness, shakiness, sweating, or confusion.
penicillin	Synergistic effects may develop in the treatment of certain microorganisms, but antagonism may also occur.	Monitor for penicillin efficacy.
rifampin	Coadministration may decrease chloramphenicol serum concentration resulting in subtherapeutic effects	Monitor for chloramphenicol efficacy. Discuss chloramphenicol dose adjustment with the prescriber.
tacrolimus	Chloramphenicol inhibits the metabolism of tacrolimus resulting in an increased risk for adverse effects and toxicity	Monitor BUN and creatinine levels in renal transplant patients carefully. Monitor for fatigue, lethargy, headache, and tremors. Contact the prescriber immediately if symptoms occur.

chloramphenicol. Topical use can also cause pruritus and burning, vesicular dermatitis, or maculopapular rash. Adverse reactions require discontinuing the drug. Transient burning or itching of the eye can occur following ophthalmic application. Repeated or prolonged use of eye or topical preparations should be discouraged.

Drug Interactions

Chloramphenicol interacts with many different types of drugs. Table 40.14 describes potential interactions.

Assessment of Relevant Core Patient Variables

Health Status

Because therapeutic benefits generally do not outweigh the risks for chloramphenicol therapy, assess the culture and sensitivity findings to evaluate the efficacy of chloramphenicol.

Evaluate the patient for risk factors that would increase the potential for severe toxicities. Such factors include recent cytotoxic or radiation therapy, anemia, depressed bone marrow function, hepatic disease, renal impairment, acute intermittent porphyria, or G6PD deficiency. Patients with recent cytotoxic or radiation therapy are at risk for blood dyscrasias. Administering chloramphenicol increases the risk of these dyscrasias. Chloramphenicol therapy may also exacerbate acute intermittent porphyria or G6PD deficiency.

Evaluate the patient for the use of other drugs, such as oral hypoglycemics, oral anticoagulants, or antiepileptic agents, which may interact with chloramphenicol. Other drugs to consider are those with a high risk of hematologic toxicity, hepatic toxicity, or nephrotoxicity because blood, liver, or kidney problems increase the risk of adverse effects with chloramphenicol therapy.

Before initiating therapy, evaluate baseline laboratory test results, including CBC and hepatic and renal function. Communicate abnormal test findings to the prescriber immediately. Perform a baseline neurologic examination because chloramphenicol may induce adverse CNS effects.

Life Span and Gender

Evaluate women for pregnancy. Chloramphenicol is contraindicated for pregnant women who are near term because

it may depress bone marrow function or cause gray baby syndrome in the neonate. Determine whether the patient is breast-feeding. Chloramphenicol is contraindicated for use in nursing mothers. Because it is excreted into breast milk, chloramphenicol may depress bone marrow function in infants.

Assess the developmental status of infants. Premature infants and neonates may develop gray baby syndrome. This syndrome can affect children up to 2 years of age, but infants receiving chloramphenicol within the first 48 hours of life are at highest risk. Chloramphenicol should be discontinued at the first signs of gray baby syndrome because it can be fatal in a matter of a few hours.

Environment

Be aware of the environment in which the drug will be administered. Administration of chloramphenicol must occur in a setting where appropriate serum level and patient monitoring can be undertaken. Evaluate the patient frequently and contact the provider immediately for discontinuation of therapy at the first sign of adverse reactions.

Nursing Diagnoses and Outcomes

- Risk for Injury related to drug-induced adverse effects, such as blood dyscrasias, gray baby syndrome, and CNS effects, including optic or peripheral neuritis, headache, depression, confusion, or delirium
  Desired outcome: *Regular and careful monitoring will protect the patient from permanent drug-related adverse effects.*
- Risk for Impaired Skin Integrity, rash and pruritus, related to topical drug use
  Desired outcome: *The nurse and patient will observe for and report signs of unusual skin reaction and contact the prescriber.*

Planning and Intervention

Maximizing Therapeutic Effects

Oral chloramphenicol should be administered on an empty stomach 1 hour before or 2 hours after meals. However, for patients with GI distress, chloramphenicol may be administered with meals.

Minimizing Adverse Effects

Although adverse effects may occur when therapeutic concentrations are within normal limits, they are more likely to occur if they are high. Monitor plasma concentrations at least weekly or more often in patients with hepatic or renal impairment. Peak levels should be in the range of 10 to 20 mcg/mL, whereas trough levels should be 5 to 10 mcg/mL.

Avoid IM injections because they may cause bleeding, bruising, or hematomas as a result of thrombocytopenia resulting from chloramphenicol-induced depression of bone marrow function.

Providing Patient and Family Education

- Explain the importance of completing therapy.
- Point out the potential adverse effects and the need for periodic blood monitoring and daily assessment.
- Teach patients the importance of measuring fluid intake and output accurately.
- Advise patients to report any symptoms to the health care team immediately.

Ongoing Assessment and Evaluation

Serum concentrations and patients' responses to systemic chloramphenicol therapy are unpredictable. For patients receiving systemic therapy, coordinate serial monitoring of chloramphenicol plasma concentrations.

Assess patients receiving chloramphenicol therapy for signs of anemia and depressed bone marrow function; these signs include bleeding, easy bruising, and fatigue. Bone marrow function should be monitored with serial CBCs throughout therapy.

Monitor for signs of hepatic or renal insufficiency. For long-term or high-dose therapy or for patients with a history of hepatic or renal insufficiency, serial hepatic and renal function tests are important. In addition to increasing the risk for toxicities, impaired hepatic function has resulted in adult reactions similar to gray baby syndrome.

Other important assessments are GI and CNS effects. Although GI effects occur infrequently, they may indicate a more serious problem, such as superinfection. In the CNS, monitor for optic or peripheral neuritis, headache, depression, confusion, or delirium.

Because most adverse effects require that therapy be discontinued, assessing the patient frequently and communicating findings to the prescriber are the most important aspects of chloramphenicol therapy.

When treatment ends, the initial infection should be resolved. The patient should be adequately nourished and hydrated, and any adverse drug effects should be resolved.

Drug Significantly Different From P Chloramphenicol

Spectinomycin is related to the aminoglycosides but is somewhat different structurally. Spectinomycin is usually given as a one-time injection, followed by other antibiotic therapy, and is used to treat acute gonorrheal urethritis and prostatitis in men and acute gonorrheal cervicitis and proctitis in women. It is also a prophylactic treatment after known recent exposure to gonorrhea.

Spectinomycin is active against a number of other gram-negative bacteria, although it is inferior to other antibiotics commonly used to treat these organisms. It is contraindicated in patients with a known hypersensitivity to the drug. Soreness at the injection site is the most common adverse effect. Other serious adverse effects are limited because the drug is given only once.

MEMORY CHIP

Chloramphenicol

- Used for serious gram-positive or gram-negative infections, especially brain abscesses or meningitis
- Major contraindications: hypersensitivity and breast-feeding
- Most common adverse effects: headache, nausea, vomiting, and diarrhea
- Most serious adverse effects: blood dyscrasias, "gray-baby" syndrome
- Maximizing therapeutic effects: Administer oral preparations on an empty stomach.
- Minimizing adverse effects: Monitor peak and trough levels throughout therapy.
- Most important patient education: Teach the patient the signs and symptoms of bone marrow suppression and the importance of contacting the health care provider immediately if any symptoms occur.
- **Black box warning: Serious and fatal blood dyscrasias including aplastic anemia, hypoplastic anemia, thrombocytopenia, and granulocytopenia.**
