1. An antidote may either react with the poison to prevent its absorption or counteract the effects of the poison after its absorption.
2. Not all poisons have specific antidotes.
3. Information about appropriate antidotes for specific poisons is available through all poison control centers. Antidotes for the most common poisons should be listed in the emergency department of the hospital.
4. Effectiveness of the antidote usually depends on the amount of time that elapses between ingestion of the poison and administration of the antidote.

Eliminating the Absorbed Poison

1. Force dieresis.
    a. Administer large quantities of fluid either orally or via IV line.
    b. Carefully monitor intake and output.
2. Assist with kidney dialysis, which may be necessary if the child's kidneys are not functioning effectively.
3. Assist with exchange transfusion if this method is indicated for removing the poison.

Providing Emotional Support

1. Remain calm and efficient while working rapidly.
2. Reassure the child and his or her family that therapeutic measures are being taken immediately.
3. Discourage anxious parents from holding, caressing, and overstimulating the child.

Subsequent Nursing Assessment and Interventions

Observing the Child for Progression of Symptoms

1. CNS involvement.
    a. Observe for restlessness, confusion, delirium, seizures, lethargy, stupor, or coma.
    b. Administer sedation with caution—to avoid CNS depression and masking of symptoms.
    c. Avoid excessive manipulation of the child.
    d. See nursing care of the child with seizures, page 1252.
    e. See nursing care of the unconscious patient, Chapter 15.
2. Respiratory involvement.
    a. Observe for respiratory depression, obstruction, pulmonary edema, pneumonia, or tachypnea.
    b. Have artificial airway and tracheostomy set available.
    c. Be prepared to administer oxygen and provide artificial respiration.
    d. Other nursing concerns:
        i. Nursing care for mechanical ventilation, see page 1166.
        ii. Procedures for administration of oxygen, see page 181.

iii. Procedure for cardiopulmonary resuscitation, see page 1162.

3. Cardiovascular involvement.
   a. Observe for peripheral circulatory collapse, disturbances of heart rate and rhythm, or heart failure.
   b. Maintain IV therapy, as directed, to prevent shock. Assess for complications of overhydration.
   c. Be prepared for cardiac arrest.
4. GI involvement.
   a. Observe for nausea, pain, abdominal distention, and difficulty swallowing.
   b. Maintain IV therapy to replace water and electrolyte losses.
   c. Offer a diet that is easily swallowed and digested.
      i. Begin with clear liquids.
      ii. Progress to full liquids, soft foods, and then a regular diet as the child's condition improves.
5. Kidney involvement.
   a. Observe the child for decreased urine output. Record oral and IV intake and urine output exactly.
   b. Observe for hypertension.
   c. Insert indwelling catheter, if necessary, for urinary retention.
   d. Administer appropriate amounts of fluids and electrolytes.
   e. See nursing care of child with renal failure, page 1329.
   f. Correct and monitor acid–base balance.

Providing Supportive Care

1. Maintain adequate caloric, fluid, and vitamin intake. Oral fluids are preferable if they can be retained.
2. Avoid hypothermia or hyperthermia. (Control of body temperature is impaired in many types of poisoning.) Monitor the child's temperature frequently.
3. Observe closely for inflammation and tissue irritation.
   a. This is especially important in ingestion of kerosene or other hydrocarbons, which cause chemical pneumonitis.
   b. Isolate the patient from other children, especially those with respiratory infections.
   c. Administer antibiotics, as prescribed by the physician.
4. Counsel parents who typically feel guilty about the accident.
   a. Encourage parents to talk about the poisoning.
   b. Emphasize how their quick action in getting treatment for the child has helped.
   c. Discuss ways that they can be supportive to their child during the hospitalization.
   d. Do not allow prolonged periods of self-incrimination to continue. Refer parents to a psychologist for assistance in resolving these feelings, if necessary.
5. Involve the young child in therapeutic play to determine how he or she views the situation.
   a. The child commonly sees nursing measures as punishments for misdeed involving the poisoning.

b. Explain treatment and correct misinterpretations in a manner appropriate for child's age.

6. Initiate a community health nursing referral for any childhood poisoning incident. A home assessment should be made to identify any potential or actual problems and provide proper poisoning prevention interventions and education.

Family Education and Health Maintenance

Stressing Prevention

1. Information concerning poison prevention should be available on every hospital pediatric unit and during every child health care visit.
   a. Many free booklets and home safety checklists are available from such sources as insurance companies and drug companies.
   b. Teaching may be done with any parent regardless of the reason for the child's hospitalization or office visit.
2. Teach the following precautions:
   a. Keep medicines and poisons out of the reach of children.
   b. Provide locked storage for highly toxic substances; select cabinet that is higher than child can reach or climb.
   c. Do not store poisons in the same areas as foods.
   d. Make sure all containers are properly marked and labeled. Keep medicines, drugs, and household chemicals in their original containers.
   e. Do not discard poisonous substances in receptacles where children can reach them; however, do discard used containers of poisonous substances.
   f. Teach children not to taste or eat unfamiliar substances.
   g. Clean out medicine cabinets periodically.
   h. Keep medications in childproof containers that are securely closed.
   i. Read all labels carefully before each use.
   j. Do not give medicines prescribed for one child to another.
   k. Never refer to drugs as candy or bribe children with such inducements.
   l. Never give or take medications in the dark.
   m. Encourage parents not to take medication in front of young children because children role-play adult behavior.
   n. Suggest that mothers avoid keeping medications in their purses or on the kitchen table.
   o. Keep baby creams and ointments away from young children.
   p. Never puncture or heat aerosol containers.
   q. Store lawn and garden pesticides in a separate place under lock and key outside of the house; do not store large quantities of cleaning products or pesticides.
3. Advise parents to dispose of syrup of ipecac if they keep it in the household. According to the American

Academy of Pediatrics, there is no evidence supporting improved outcomes of poisonings with the use of ipecac. In addition, there is potential for abuse of ipecac with bulimic or anorexic teenagers; therefore, the recommendation for keeping ipecac on hand to induce vomiting has been rescinded.

4. Tell family to keep a list of emergency telephone numbers including the poison control center, health care provider's number, nearest hospital, and ambulance service.
5. Reinforce the need for vigilance and consistent supervision of infants and young children because of their increased mobility, increased curiosity, and increased dexterity.

Teaching Emergency Actions

1. Suspect poisoning with the occurrence of sudden, bizarre symptoms or peculiar behavior in toddlers and preschoolers.
2. Read label on the ingested product or call the health care provider, hospital, or poison control center for instructions about treatment for the poisoning. Give all relevant information about the child, condition, and substance ingested.
3. Maintain an adequate airway in a child who is convulsing or who is not fully conscious.
4. Dilute the poison with 100 to 200 mL of water, if advised by Poison Control or other medical provider.
5. Transport the child promptly to the nearest medical facility.
    a. Wrap the child in a blanket to prevent chilling.
    b. Bring the container and any vomitus or urine to the hospital with the child.
6. Avoid excessive manipulation of the child.
7. Act promptly but calmly.
8. Do not assume the child is safe simply because the emesis shows no trace of the poison or because the child appears well. The poison may have produced a delayed reaction or may have reached the small intestine where it is still being absorbed.

Lead Poisoning

There are approximately half a million children with elevated blood lead levels (greater than 5 mcg/dL) in the United States. Lead poisoning, referred to as *plumbism*, results from some form of lead consumption. Blood lead levels even lower than the prior accepted level of 10 mcg/dL can affect intellectual functioning in children. This has resulted in the acceptable lead level being lowered to 5 from 10 mcg/dL as of 2017.

Millions of children live in housing built before 1950, which contains the highest surface soil level and internal household dust contaminated with lead. Normal hand-to-mouth activities of children may introduce leaded household dust, soil, and nonfood items into their GI tract. Pica (eating nonfood substances, particularly leaded paint chips) is generally associated with more severe degrees of lead poisoning.

Pathophysiology and Etiology

Etiologic Factors

1. Multiple episodes of chewing on, sucking, or ingestion of nonfood substances.
    a. Toys, furniture, windowsills, household fixtures, and plaster painted with lead-containing paint.
    b. Cigarette butts and ashes.
    c. Acidic juices or foods served in lead-based earthenware pottery made with lead glazes.
    d. Colored paints used in newspapers, magazines, children's books, matches, playing cards, and food wrappers.
    e. Water from lead pipes.
    f. Fruit treated with insecticides.
    g. Dirt containing lead fallout from automobile exhaust.
    h. Antique pewter, especially when used to serve acidic juices or foods.
    i. Lead weights (curtain weights, fishing sinkers).
    j. Continuous proximity to lead-processing center.
    k. Occupations or hobbies that use lead.
    l. Imported folk remedies, cosmetics, food, or cookware that contains lead.
2. Inhalation of fumes containing lead (less common cause in children).
    a. Leaded gasoline.
    b. Burning storage batteries.
    c. Dust containing lead salts.
    d. Dust in the air at shooting galleries and in enclosed firing ranges with poor ventilation.
    e. Cigarette smoke.
3. Highest incidence in children between ages 1 and 6 years, especially those between ages 1 and 3 years.
    a. High incidence in individuals living in old homes or deteriorated housing conditions.
    b. No significant difference in incidence by sex.
    c. High incidence among siblings.

4. Symptomatic lead poisoning occurs most frequently in summer months.

NURSING ALERT Legislation stipulates that toys, children's furniture, and the interior of homes be painted with lead-free paint; however, the problem arises when deeper layers of paint and plaster on older products are contaminated with lead. One paint chip contains much more lead than is considered safe.

Systemic Effects

1. Lead absorption from GI tract is affected by age, diet, and nutritional deficiency. Young children absorb 40% to 50% and retain 20% to 25% of dietary lead.
2. It takes the body twice as long to excrete lead as it does to absorb lead.
3. Lead is stored in two places in the body:
   a. Bone.
   b. Soft tissue.
4. Principal toxic effects occur in nervous system, bone marrow, and kidneys.
5. Nervous system.
   a. Brain—increased capillary permeability results in edema, increased intracranial pressure, and vascular damage; destruction of brain cells causes seizures, mental retardation, paralysis, blindness, and learning disabilities.
   b. Neurologic damage cannot be reversed.
   c. CNS of young children and fetuses is most sensitive to lead.
6. Bone marrow.
   a. Lead attaches to red blood cells (RBCs).
   b. Inhibition of a number of steps in the biosynthesis of heme, thus reducing the number of RBCs, increasing fragility, and reducing half-life.
   c. The decreased production of hemoglobin results in anemia and respiratory distress.
7. Kidneys—injury to the cells of the proximal tubules, causing increased excretion of amino acids, protein, glucose, and phosphate.
8. Recurrence rate is high, especially if the lead is not removed from the home environment.

Clinical Manifestations

Symptoms in young children may develop insidiously and may abate spontaneously.

1. GI—anorexia, sporadic vomiting, intermittent abdominal pain (colic), constipation.
2. CNS—hyperirritability; decreased activity; personality changes; loss of recently acquired developmental skills; falling, clumsiness, loss of coordination (ataxia); local paralysis; peripheral nerve palsies.
3. Hematologic—anemia, pallor.

4. Cardiovascular—hypertension, bradycardia.

Diagnostic Evaluation

1. Detailed history with emphasis on the presence or absence of clinical symptoms; evidence of pica; family history of lead poisoning; possible source of exposure to lead; recent change in behavior, developmental delay, or behavior problems; recent change of address; or recent renovations in the home.
2. Assess serum lead level and repeat confirmatory, preferably by way of venipuncture. Recent changes in screening recommendations have been made to include targeted screening of all Medicaid-enrolled and Medicaid-eligible children. Additionally, all children born outside the United States should be screened.
   a. For levels greater than 5 μg/dL, a more extensive environmental history should be reviewed.
   b. For levels between 10 and 14 μg/dL, level should be confirmed and repeated in 3 months. Education on decreasing exposure and limiting absorption of lead should be done on all levels greater than 10 μg/dL.
   c. Levels between 15 and 19 μg/dL should be repeated within 2 months, while an environmental history additionally is reviewed.
   d. Levels between 20 and 44 μg/dL should be repeated within 2 days and referred to local health department plus a thorough medical history and physical examination added to education as noted above.
   e. Levels between 45 and 69 μg/dL should be confirmed immediately, referred to the local health department, and should be considered for chelation therapy in consultation with an expert.
   f. Immediate hospitalization is required for levels greater than 70 μg/dL.
3. Hematologic evaluation for iron deficiency anemia.
4. Flat plate of abdomen—may reveal radiopaque material if lead has been ingested during the preceding 24 to 36 hours.
5. Erythrocyte protoporphyrin level—not sensitive enough for identifying lead levels below 25 mg/dL. Can be used to follow levels after medical and environmental interventions for poisoned children have occurred. A progressive decline in erythrocyte protoporphyrin levels indicates that management is successful.
6. 24-Hour urine—more accurate than a single voided specimen in determining elevated urinary components that correspond with elevated blood lead levels.
7. Radiologic examination of long bones—unreliable for diagnosis of acute lead poisoning; may provide some indication of past lead poisoning or length of time poisoning has occurred.
8. Edetate calcium disodium provocation chelation test—used only in selected medical centers treating large numbers of lead-poisoned children; demonstrates increased lead levels in urine over an 8-hour period after injection of edetate disodium.

NURSING ALERT Venous sampling is the best method for assessing the level of lead in the blood

as it limits cutaneous contamination. If a fingerstick sample is being used, careful collection should include a free flowing specimen.

EVIDENCE BASE American Academy of Pediatrics. (2016). Prevention of childhood lead toxicity. *Pediatrics, 138*(1). Available: *www.pediatrics.aappublications.org/content/pediatrics/early/2016/06/16/peds.-1493*.

Management

Removal of Lead from the Environment

1. Remove leaded paint and paint chips or objects containing lead from the child's environment.
2. Remove child from environment during lead abatement process.

Nutritional Considerations

1. Consume adequate amounts of iron. Iron supplementation may be indicated to correct anemia.
2. Reduced-fat diet and small, frequent meals will reduce the GI absorption of lead.
3. Encourage foods high in vitamin C (such as fruits and juices) and calcium (such as milk, yogurt, and ice cream).

Chelation Therapy

According to the CDC, although chelation therapy is considered a mainstay in the medical management of children with blood lead levels greater than 45 mg/dL, it should be used with caution. An expert in the management of lead chemotherapy should be consulted prior to using chelation agents. State lead poisoning programs, local poison control centers, or the Lead Poisoning Prevention Branch at the CDC can be used as resources to identify accessible experts.

EVIDENCE BASE Barber, C., Huebner, J., Marquez, E., et al. (2018). Effective Recruitment Strategies for Lead Hazard Control and Healthy Homes Programs. *Journal of Environmental Health*, 80(7), 20–26.

Complications

1. Severe and usually permanent mental, emotional, and physical impairment.
2. Neurologic deficits.
   a. Learning disabilities.
   b. Mental retardation.

c. Seizures.

d. Encephalopathy.

Nursing Assessment

1. Partake in primary prevention through screening for lead poisoning—should target high-risk groups. This includes children:
   a. Who live in homes built before 1950.
   b. With iron deficiency anemia.
   c. Who are exposed to contaminated dust or soil.
   d. Who have developmental delays.
   e. Who are victims of abuse or neglect.
   f. Whose parents are exposed to lead through occupational hazards or hobbies.
   g. Who live in low-income families.
2. Screening should also be targeted at children who live in communities with more than 27% of houses built before 1950 or in populations where 12% or more of the children have elevated lead levels.
3. Assess all children for signs of lead toxicity, including hyperactivity, developmental delay, constipation, anorexia, colicky abdominal pain, clumsiness, and pallor.
4. Inquire about presence of pica behavior in children younger than age 6 years.
5. Assess the child's level of development. The Denver Developmental Screening Test II or other standardized developmental assessment tools may be useful for this purpose and will help detect delays possibly caused by lead poisoning.

Nursing Diagnoses

- Risk for Injury related to seizures and encephalopathy.
- Acute Pain related to chelation therapy injections.
- Delayed Growth and Development related to the effects of chronic lead exposure.
- Compromised Family Coping related to guilt and concern for child.

Nursing Interventions

Protecting the Child with Seizures and Encephalopathy

1. Maintain seizure precautions.
   a. Crib or bed rails elevated and padded.
   b. Tongue blade (if indicated per institutional guidelines) and suction equipment at bedside.
2. Be aware that encephalopathy may occur 4 to 6 weeks after first symptoms:
   a. Sudden onset of persistent vomiting.
   b. Severe ataxia.
   c. Altered state of consciousness.

d. Coma.
e. Seizures.
f. Massive cerebral edema in younger children.

3. Observe for signs of increased intracranial pressure (ICP) in the child with encephalopathy:
   a. Rising blood pressure.
   b. Papilledema.
   c. Slow pulse.
   d. Seizures.
   e. Unconsciousness.
4. Provide supportive care to maintain vital functions.

Reducing Pain Associated with Chelation Therapy

1. Plan appropriate play activities to prepare the child for the injections and as an outlet for the pain and anger the child feels.
2. Implement measures to decrease pain at injection site.
   a. Rotate injection sites.
   b. Apply warm packs to the site to decrease pain.
   c. Move painful areas slowly.
3. Provide diversion activities, fluids, and meals between injections.
4. Monitor intake and output and blood studies, such as electrolytes and liver and renal function tests, as directed.

Promoting Growth and Development

1. Provide and encourage activities that will help the child to learn and progress from his or her present developmental state to meet the next appropriate milestone.
2. Initiate appropriate referrals in cases of obvious developmental delays or learning difficulties. The referrals may be to such professionals as psychologists, psychiatrists, and specialists in early child education.
3. Share the results of developmental testing with the parents and discuss ways to provide stimulation for the child at home.

Strengthening Family Coping

1. Use sensitivity in interviewing and teaching to avoid causing or increasing guilt feelings about the poisoning and to establish a positive, trusting relationship between the family and the health care facility.
2. Explain the treatment and its purpose because parents are commonly faced with putting an asymptomatic child through painful treatments.
3. Encourage frequent visits by parents and siblings and facilitate family involvement.

Community and Home Care Considerations

1. Carry out lead screening in the community. It is recommended that all high-risk children be screened for high lead levels between ages 9 and 12 months and, if feasible, again at 24 months. Screening policies, universal or targeted, are determined by local departments of health, based on the prevalence of risk factors in the community.
2. Coordinate community care efforts to return the child to a safe home. Communicate with community outreach workers so that environmental case management is conducted. Lead abatement must be conducted by experts, not untrained parents, property owners, or contractors.
3. Suggest periodic, focused household cleaning to remove the lead dust; use a wet mop.
4. Encourage hand washing before meals and at bedtime to eliminate lead consumption from normal hand-to-mouth activity.
5. Observe the child and other children in the home for pica.
   a. Observe and record the child's eating habits and food preferences.
   b. Report any attempted eating of nonfood substances.
   c. Encourage caregivers to provide regular meals and make mealtime a pleasurable time for the child.
   d. Teach caregivers to discourage oral activity and to substitute activity that contributes to play, social skills, and ego development.
   e. Refer the family for additional social or psychiatric casework, if indicated, to reduce economic and other factors that result in pica in the child.
6. Screen siblings and playmates of known cases immediately.
7. Make sure that the family is able to provide close supervision of the child or assist them to make arrangements to ensure that the child is adequately supervised at home.

Family Education and Health Maintenance

Ensuring Long-Term Follow-Up

1. Teach the parents why long-term follow-up is important. Tell them that residual lead is liberated gradually after treatment and:
   a. May result in the renewal of symptoms.
   b. May increase serum lead to a dangerous level.
   c. May cause additional damage to the CNS, which may not become apparent for several months.
2. Stress that acute infections must be recognized and treated promptly because these may reactivate the disease.
3. Teach that iron supplementation may be continued to treat anemia. Advise the parents about medication administration and adverse effects and periodic complete blood count monitoring.

Preventing Re-Exposure of the Child to Lead

1. Advise the parents that the single most important factor in managing childhood lead poisoning is

reducing the child's re-exposure to lead.

2. Instruct the parents about the seriousness of repeated lead exposure.
3. Initiate referrals to home health nursing and community agencies, as indicated.

NURSING ALERT Children should not return home until their home environment is lead free.

Providing Community Education

1. Initiate and support educational campaigns through schools, day care centers, and news media to alert parents and children to hazards and symptoms of lead poisoning.
2. Provide literature in clinics, waiting rooms, and other appropriate settings that stresses the hazards of lead, sources of lead, and signs of lead intoxication.
3. Support legislation to study the nature and extent of the lead poisoning problem and to eliminate the causes of lead poisoning.
4. Include the topic of pica and lead poisoning in nutritional teaching.
5. For additional information, contact the state or local health department or CDC (*www.cdc.gov*).

Evaluation: Expected Outcomes

- Seizure precautions maintained; no signs of increased ICP.
- Tolerates chelation therapy injections; expresses anger through doll play.
- Parents provide appropriate play and stimulation for development.
- Family involved in care; provides support to the child.

Communicable Diseases

With the dramatic success of immunizations, many childhood diseases have decreased in frequency. However, a number of communicable diseases still cause significant morbidity in children (see Table 42-2). Many other infections that occur in childhood are covered elsewhere in the book such as Chapter 31, Infectious diseases, or the chapters of each body system.

Table 42-2 Communicable Diseases

DISEASE, AGENT, MODE OF TRANSMISSION, AGE WHEN MOST COMMON	INCUBATION AND COMMUNICABILITY PERIODS	SYMPTOMS	TREATMENT	COMPLICATIONS	NURSING CONSIDERATIONS
Chickenpox					
Varicella-zoster virus • Highly communicable; acquired in direct contact, droplet spread, and airborne transmission • 2–9 years; January to May *Diagnostic tests:* Tzanck smear shows multinucleated giant cells; a culture may be done for confirmation.	*Incubation (I):* 11–21 days after exposure. *Communicability (C):* onset of fever (1–2 days before first lesion) until last vesicle is dried (5–7 days)	• General malaise, low-grade fever, and anorexia for 24 hours • Rash—macules to papules and vesicles to crusts within several hours • Pruritus of lesions may be severe and scratching may cause scarring. • *Rash characteristics:* rash appears first on the head and mucous membranes and then becomes concentrated on body and sparse on extremities; papulovesicular eruption.	• Symptomatic: shorten fingernails to prevent scratching • Daily antiseptic baths • Oral antihistamines to decrease pruritus • Treatment of itching: baking soda (sodium bicarbonate) or oatmeal baths, calamine lotion to lesions • Isolation until all lesions have crusted • Acyclovir by mouth (PO) within first 24 hours • Avoid salicylates.	• Complications are rare in otherwise healthy children • Secondary bacterial infection of lesions • Hemorrhagic varicella, pneumonia, encephalitis, and thrombocytopenia are not common but they can occur. • Reye syndrome	• Severe in neonate and pregnant women • Varicella-zoster immune globulin is available for high-risk susceptible children who have been exposed to varicella zoster. • Prevention through immunization is the best practice.
Rubella (German 3-Day Measles)					
Rubella virus; RNA toga virus • Oral droplet or transplacentally • School age, young adults; spring, winter *Diagnostic tests:* tissue culture of throat, blood, or urine; latex agglutination, enzyme immunoassay, passive hemagglutination, fluorescent immunoassay tests *Passive immunity:* birth to age 6 months from maternal antibodies	*I:* 14–21 days after exposure. *C:* virus can be passed from 7 days before to 5 days after rash appears.	• Enlarged lymph nodes in postauricular, auricular, suboccipital, and cervical areas 24 hours before rash develops • Enanthem: discrete rose spots on soft palate • Exanthem: variable; begins on face, spreads quickly over entire body; usually maculopapular; clears by third day	• Symptomatic—isolation	• In adolescent females: arthritis; arthralgias • Encephalitis • Thrombocytopenia	• Exposure of nonimmune pregnant women in the first trimester results in a high percentage of affected fetuses and infants born with various birth defects: cataracts, deafness, growth retardation, congenital heart disease, mental retardation • Prevention is the best practice.
Roseola Infantum (Exanthem subitum)					
Human herpesvirus 6 • Direct contact or droplet • 6–24 months; late fall to early spring	*I:* 5–15 days. *C:* not known—believed not to be highly contagious	• Fever of 103°F–106°F (39.4°C–41.1°C), either intermittent or sustained 3–4 days with no clinical findings • Fever suddenly drops and macular or maculopapular rash develops on trunk, spreading to arms and neck; mild involvement of face and legs; rash fades quickly.	• Symptomatic—antipyretic	• Seizures due to high fever • Encephalitis (rare)	• Reassure family that this is a self-limiting illness.
Rubeola (Hard, Red, 7-Day Measles)					

Measles virus, RNA-containing paramyxovirus
• Direct contact with droplets from infected persons, respiratory route
• *Diagnostic tests:* serologic procedures not routinely done
• *Passive immunity:* birth to between ages 4 and 6 months if mother is immune before pregnancy
• 5–10 years, adolescents; spring
	I: 10–12 days. *C:* fifth day of incubation to fourth day of rash	• Fever, lethargy, cough, coryza, and conjunctivitis
		• 2–3 days later; Koplik spots on buccal pharyngeal mucosa (grayish white spots with reddish areolae), which disappear within 12–18 hours
		• 2 days later; maculopapular rash appears at hairline and spreads to feet in 1 day; rash begins to clear after 3–4 days
			• Symptomatic:
			  • Sedatives
			  • Antipyretic
			  • Bed rest in humid, comfortably warm room
			  • Dark room for photophobia
			  • Adequate fluids
				• Otitis media
				• Pneumonia, laryngitis
				• Mastoiditis, encephalitis
				• Appendicitis
					• Provide symptomatic care and respiratory isolation.
					• Prevention through immunization is the best practice.

Mumps					

Mumps virus, paramyxovirus
• Direct contact, through families, airborne droplets, saliva, and possibly urine
• School age; all seasons but slightly more frequent in late winter and early spring
Diagnostic tests: serologic testing and viral culture from throat swab
Passive immunity: birth to age 6 months if mother is immune before pregnancy
	I: 16–18 days. *C:* 3 days before to 9 days after swelling appears; virus in saliva greatest just before and after parotitis onset	• Headache, anorexia, generalized malaise; fever 1 day before glandular swelling; fever lasts 1–6 days
		• Glandular swelling usually of parotid—one side or bilaterally
		• Enlargement and reddening of Wharton duct and Stensen duct
		• Subclinical infection may occur
			• Isolation until swelling has subsided
			• Symptomatic:
			  • Analgesics
			  • Hydration
			  • Alimentation
			  • Antipyretics
			  • Rest
				• Meningoencephalitis
				• Orchitis, epididymitis
				• Auditory nerve involvement, resulting in unilateral deafness
					• Provide symptomatic care.
					• Prevention through immunization is the best practice.

Diphtheria					

Corynebacterium diphtheriae
• Acquired through secretions of carrier or infected individual by direct contact with contaminated articles and environment
• Unimmunized children under 15 years old; incidence increased in autumn and winter
Diagnostic tests: cultures of nose and throat
	I: 2–4 days. *C:* 2–4 weeks untreated; 1–2 days with antibiotic treatment	**Nasal diphtheria**
		• Coryza with increasing viscosity, possibly epistaxis, low-grade fever
		• Whitish gray membrane may appear over nasal septum
		Pharyngeal and tonsillar diphtheria
		• General malaise, low-grade fever, anorexia
		• 1–2 days later, whitish gray membranous patch on tonsils, soft palate, and uvula
		• Lymph node swelling, fever, rapid pulse, "bull neck"
		Laryngeal diphtheria
		• Usually spread from pharynx to larynx
		• Fever, harsh voice, stridor, barking cough; respiratory difficulty with inspiratory retraction
		Nonrespiratory diphtheria
		• Affects eye, ear, genitals, or, rarely, skin
			• Diphtheria antitoxin via IV line or IM
			• Antibiotic therapy (penicillin, erythromycin)
			• Supportive treatment:
			  • Respiratory support and cardiac monitoring
			  • Isolation until three cultures are negative after antibiotic therapy is completed
			  • Bed rest for 2–3 weeks
			  • Hydration
			  • Immunization with diphtheria toxoid after recovery
				• Myocarditis
				• Neuritis
				• Paralysis
				• Toxic neurosis and hyaline degeneration of heart, liver, adrenal glands, and kidneys
				• Gastritis, hepatitis
				• Nephritis
					• Identify close contacts and monitor for illness; culture nose, throat, and cutaneous lesions and administer prophylactic antimicrobial therapy.
					• Prevention through immunization is the best practice.

Pertussis (Whooping Cough)					

Bordetella pertussis
• Direct contact or respiratory droplet spread
• Infants and young children; females more than males
Diagnostic tests: culture of nasopharyngeal mucus
	I: 3–12 days; mean of 7 days. *C:* 7 days after exposure (greatest just before catarrhal stage) to 3 weeks after onset of paroxysms or until cough has ceased	**Stage I (catarrhal stage)**
		• Lasts 1–2 weeks
		• Rhinorrhea, conjunctival injection, lacrimation, mild cough, and low-grade fever
		Stage II (paroxysmal stage)
		• Lasts 2–4 weeks or longer
		• Frequent severe, violent coughing attacks occurring in clusters, leading to vomiting, cyanosis, and exhaustion
		Stage III (convalescent stage)
		• Lasts 2 weeks to several months
		• Coughing attacks decrease, but may return with each respiratory infection
		• Duration: 9 months to 2 years
			• Specific:
			  • Erythromycin estolate
			  • Azithromycin
			  • Clarithromycin
			• Supportive:
			  • Antipyretics
			  • Bed rest
			  • Quiet environment to reduce coughing
			  • Gentle suctioning
			  • Increase fluid intake
			  • Oxygen
				• Respiratory: pneumonia, atelectasis, emphysema, aspiration pneumonia, pneumothorax
				• CNS: convulsions, encephalopathy, coma
				• Death may occur among the unvaccinated
					• Erythromycin should be given to all close and household contacts for 14 days.
					• Neither immunization nor natural disease confers complete or lifelong immunity.

Staphylococcal Scalded Skin Syndrome (Ritter Disease)					

Group II phage-type *Staphylococcus aureus*
• Disseminated from a primary infection site (usually nose or around eyes)
• Infants and children under 10 years old
Diagnostic tests: cultures of skin, conjunctiva, nasopharynx, stools, and blood. Biopsy of exfoliated epidermis
	I: few days. *C:* onset of rash until after antibiotics initiated	• Malaise, fever, irritability, or asymptomatic
		• Rash develops in three phases:
		  • Erythematous—macular involving face, neck, axilla, and groin
		  • Exfoliative—upper layer of epidermis becomes wrinkled and can be removed by light stroking (Nikolsky sign); crusting around eyes, mouth, and nose produces characteristic "sunburst," radial pattern; irritable because of extreme tenderness of skin
		  • Desquamative—epidermis peels away, leaving moist areas that dry quickly and heal in 10–14 days
			• Specific:
			  • Therapy with penicillinase-resistant penicillin PO, IM, or via IV line
			• Symptomatic:
			  • Gentle cleaning of skin with compresses
				• Excessive fluid loss, electrolyte imbalance, pneumonia, septicemia, cellulitis	• Provide symptomatic care.

Erythema Infectiosum (Fifth Disease or Slapped Cheek)					

Parvovirus B19
• Respiratory route
• School-age children
Diagnostic tests: not widely available; IgM antibody test, polymerase chain reaction detection test
	I: 6–14 days. *C:* until rash develops	• Mild fever, chills, fatigue, or nonpruritic rash develops in three stages:
		  • Sudden appearance of bright erythema on cheeks
		  • Erythematous, maculopapular rash on trunk and extremities
		  • Rash on body fades with central clearing, giving a lacy or reticulated appearance
		• Rash lasts 2–39 days; frequently pruritic without desquamation
		• Occasional joint arthropathy
			• Symptomatic treatment
			• Immunoglobulin for immunocompromised patients
				• Complications are rare among otherwise healthy children.
				• Children with abnormal RBCs (sickle cell disease, hereditary spherocytosis, and thalassemia) can develop transient aplastic anemia and may require multiple transfusions.
				• Immunocompromised patients may develop severe, chronic anemia.
					• Avoid contact of child with pregnant female (<5% of exposed unborn children will have severe anemia; rare chance of miscarriage).

Rotavirus					
Reoviridae group A • Most common agent responsible for infantile diarrhea • Fecal–oral route • Ages 6 months to 2 years; most common in winter in temperate climates *Diagnostic tests:* enzyme-linked immunosorbent assay	*I:* 1–3 days. *C:* until 2–5 days after diarrhea	• Fever • Vomiting • Profuse, watery, non–foul-smelling diarrhea	• Oral fluid and electrohydrate solution	• Isotonic dehydration with acidosis • Malnourished infants may develop malabsorption dehydration and die.	• Excellent hygiene (hand washing) is necessary to avoid spreading disease. • Current vaccine will prevent 74% of all cases and 98% of severe cases.
Hand, Foot, Mouth Disease					
Coxsackie virus A16 or other enteroviruses • Moderately contagious by direct contact with nose and throat secretions, fluid from blisters, and stool • Most common in children under age 10 during summer and fall *Diagnostic tests:* throat swab or stool culture for virus; rarely indicated	*I:* 3–7 days. *C:* first week of illness	• Mild fever, poor appetite, malaise, and sore throat • Painful sores develop in the mouth 1–2 days after fever begins (usually on the tongue, gums, and buccal mucosa). A nonpruritic rash follows on the palms and soles, occasionally on the buttocks.	• Symptomatic for fever, aches, and mouth lesions	• Rare, asymptomatic meningitis	• Provide pain relief and monitor fluid intake to prevent dehydration from not eating.

Child Abuse and Neglect

EVIDENCE BASE Thomas, R. (2018). School Nurses and Child Sexual Exploitation: Keep on looking and listening. *British Journal of School Nursing*, 13(3), 150–151.

Child abuse is any type of maltreatment of children or adolescents by their parents, guardians, or caretakers. It is considered a major problem worldwide, with most countries tracking the problem and allocating some resources toward services to prevent and treat child abuse. Child abuse includes physical or emotional abuse, injury, trauma, neglect, or sexual abuse of a child that is intentional and nonaccidental. Abuse includes the following:

- Battering—physical injury.
- Drug abuse—intentional administration of harmful drugs, especially during pregnancy.
- Sexual abuse.
- Sexual assault or molestation (non–family member).
- Incest (family offender).
- Emotional abuse—scapegoating, belittling, humiliating, lack of mothering.

Neglect is the omission of certain appropriate behaviors, with such omission having detrimental physical or psychological effects on development. Neglect includes:

- Child abandonment.
- Lack of provision of the basic needs of survival, including shelter, clothing, stimulation, medical care, food, love, supervision, education, attention, emotional nurturing, and safety.

Etiology and Incidence

EVIDENCE BASE U.S. Department of Health and Human Services, Administration for Children and Families. (2017). *Child maltreatment 2015*. Washington, DC: Author.

The cause of child abuse and maltreatment is multidimensional. The abuse may be related to the combined presence of three factors: special kind of child, special kind of parent or caretaker, special circumstances of crisis. Abuse occurs in all ethnic, geographic, religious, educational, occupational, and socioeconomic groups.

1. In 2015, there were 683,000 reported victims of child abuse and neglect in the United States. Furthermore, 1,670 reported fatalities occurred. Maltreatment occurred approximately 91.6% of the time at the hands of one or both parents.

2. The most common type of abuse is neglect (75.3% of cases), followed by physical abuse (17.2%), sexual abuse (8.4%), and the remainder of reported cases (6.9%) suffered from other types of abuse, which include emotional maltreatment and medical neglect.

Contributing Factors

1. Incidents of child abuse may develop as a result of disciplinary action taken by the abuser who responds in uncontrolled anger to real or perceived misconduct of the child. The parents may confuse punishment with discipline. "Good parenting" may be equated with physical contact to eradicate child behavior. The abuser may be a stern, authoritarian disciplinarian.
2. Incidents of child abuse may develop out of a disagreement between caretakers. The child may come to the aid of one parent and may be entered into the midst of the quarrel; marital discord is common.
3. The abuser may be under a great deal of stress because of life circumstances (debt, poverty, illness) and may thus resort to child abuse. Crisis and stress may be ongoing. The abuser may have a low frustration tolerance level and may not have a well-developed means of coping with stress in general.
4. The abuser may be intoxicated with alcohol or drugs at the time of the abuse; only 10% of abusers have a history of mental illness.
5. Child abuse may occur by a surrogate caregiver, such as a babysitter or boyfriend.
6. Lack of effective parenting, inappropriate parent–child bonding, and punitive treatment as a child may contribute to the parent becoming an abuser.
7. Specific characteristics evident in many abusing parents include:
    a. Low self-esteem—a sense of incompetence in role, unworthiness, unimportance, or have difficulty controlling aggressive impulses; commonly live in social isolation.
    b. Unrealistic attitudes and expectations of the child, little regard for the child's own needs and age-appropriate abilities, lack of knowledge related to parenting skills.
    c. Fear of rejection—a deep need to feel wanted and loved, but a feeling of rejection when love is not obvious; a crying infant may elicit a feeling of rejection.
    d. Inability to accept help—isolation from the community, loneliness.
    e. Unhappiness due to unsatisfactory relationships; may look to child for satisfaction of own emotional needs.
    f. Child abusers are commonly the children of abuse or victims of spousal abuse.
8. Incidents of child abuse may develop from a general attitude or resentment or rejection on the part of the abuser toward the child.
9. Atypical child behavior (eg, hyperactivity or a technology-dependent child who needs additional care) may unintentionally provoke the abuser.
10. The degree of the family crisis is not usually in proportion to the degree of abuse.

Clinical Manifestations

Characteristics of the Child that Should Raise Suspicion

1. The child is usually younger than age 3 years. School-age children and adolescents are also subject to abuse. The average age of a sexually abused child is 9 years.
2. General health of the child indicates neglect (diaper rash, poor hygiene, malnutrition, unattended physical problem).
3. Characteristic distribution of fractures (scattered over many parts of body).
4. Disproportionate amount of soft tissue injury.
5. Evidence that injuries occurred at different times (healed and new fractures, resolving and fresh bruises).
6. Cause of recent trauma in question.
7. History of similar episodes in the past.
8. No new lesions during the child's stay in the hospital.
9. May show a wide range of reactions—may be either very withdrawn or overactive. The child may be anxious, tense, or nervous or show regressive behavior.
10. The child may show unusual affection for strangers or may be overly fearful of adults and avoid any physical contact with them.
11. For sexual abuse: the child may fear no one will believe him or her; may experience self-blame; most know their abusers.
12. Children may not "tell" about abuse from parents, fearing a loss of security; "a bad parent is better than no parent at all."
13. Behavior problems, depression, acting-out behaviors, and aggression toward younger children may result.
14. For abuse that occurs in school or daycare, the child may exhibit fear of the teacher, have nightmares, decrease school attendance, or develop psychosomatic illnesses.

Injuries or Types of Abuse that May Occur

1. Bruises, welts (linear or looplike).
2. Abrasions, contusions, lacerations (most common).
3. Wounds, cuts, punctures.
4. Burns (cigarette, radiator), scalding—stocking or glove distribution.
5. Bone fractures.
6. Sprains, dislocations.
7. Subdural hemorrhage or hematoma; "shaken baby syndrome."
8. Brain damage.
9. Internal injuries.
10. Drug intoxication.
11. Malnutrition (deliberately inflicted).
12. Freezing, exposure.
13. Whiplash-type injury.
14. Eye injuries, periorbital injuries, ear bruises.

15. Dirty, infected wounds or rashes.
16. Unexplained coma in infant.
17. Failure to thrive—developmental delay, malnutrition with decreased muscle mass, decreased interaction with environment and with others, dental caries, listlessness, behavior problems.
18. Sexually transmitted diseases—genital trauma, recurrent urinary tract infection, pregnancy.

NURSING ALERT Munchausen syndrome by proxy is a condition in which symptoms are induced in a child by the actions of a parent or caregiver. A wide range of methods have been noted as the basis for the fabricated illness, with most falling into one of four general categories: poisoning, bleeding, infections, and injuries. Many of the conditions cannot be observed by a health care provider nor can diagnosis be confirmed by further evaluation. Munchausen syndrome by proxy is a serious form of child abuse and is associated with a high rate of morbidity and mortality. It is important for nurses to obtain thorough histories of any illness or injury and be observant in any unusual cases.

Management

1. The goal of treatment is to ensure the physical and emotional safety of the child. Therefore, treatment is inclusive of other family members and caretakers and is often focused on the parents. A team approach is employed to determine the most effective use of community resources to protect the child and help the parents.
2. It is estimated that 80% to 90% of abusing parents can be rehabilitated. The ideal approach is to return the child to the biological parents after treatment concludes.
3. Counseling is offered to help parents do the following:
    a. Understand and redirect their anger.
    b. Develop an adequate parent–child relationship.
    c. See their child as an individual with his or her own needs and differences.
    d. Understand child development and normal behaviors of developing children.
    e. Learn about effective discipline techniques.
    f. Enjoy the child.
    g. Develop realistic expectations of their child.
    h. Decrease their use of criticism.
    i. Increase parents' self-esteem and confidence.
    j. Establish supportive relationships with others.
    k. Improve their economic situation (if appropriate).
    l. Show progress toward the physical, emotional, and intellectual development of their child.

Nursing Assessment

1. Identify family or child at risk.
    a. Alcohol or drug abuser.
    b. Adolescent parent.
    c. Low-income, single-parent family.
    d. Multiple births.
    e. Unwanted child.
    f. Sickly and more demanding child.
    g. Premature child with long separation from mother at birth.
2. Inspect for evidence of possible abuse.
    a. Describe completely on the medical record all bruises, lacerations, and similar lesions as to location and state of healing. Look carefully at areas generally covered with clothing (ie, buttocks, underarms, behind knees, bottom of feet).
    b. Ask how injuries occurred and record descriptions of the injury, including the date, time, and place of the event.
3. Collect necessary specimens for identification of organisms, sperm, or semen.
4. Take color photographs, as indicated.
5. Assess developmental level of the child.
6. Observe for behaviors common in abusing or neglecting parents. Be aware that not all abusing parents exhibit these behaviors but be alert for the parent who:
    a. Anxiously volunteers information or withholds information related to an injury.
    b. Gives explanation of the injury that does not fit the condition or gets story confused concerning the injury.
    c. Shows inappropriate reaction or concern to severity of injury.
    d. Becomes irritable about questions being asked.
    e. Seldom touches or speaks to the child; does not respond to child. May be critical or indicate unreal expectations of child (or may be over solicitous to the child).
    f. Delays seeking medical help; refuses to sign permit for diagnostic studies; frequently changes hospitals or health care providers.
    g. Shows no involvement in the care of the hospitalized child; does not inquire about the child.
    h. Obtains little or no prenatal care and shows inappropriate response to the neonate; acts disinterested or unhappy with the child.
7. Assess the parent–child relationship in the areas of appropriate involvement in care, show of affection, reaction to arrival and leaving, expectations, role portrayal.
8. Assess for signs of sexual abuse. Sexual abuse should be suspected when the young, prepubertal child presents with:
    a. Genital trauma not readily explained.
    b. Gonorrhea, syphilis, or other sexually transmitted organisms.

c. Blood in urine or stool.
d. Painful urination or defecation.
e. Penile or vaginal infection or itch.
f. Penile or vaginal discharge.
g. Report of increased, excessive masturbation.
h. Report of increased, unusual fears.
i. Trauma to genitalia, inner thigh, breast.

9. Establish a relationship with the child based on mutual respect, empathy, and sensitivity to facilitate further investigation.
   a. Consideration of the child's emotions in conjunction with a good relationship may encourage the child to express feelings either verbally or through drawings or play.
   b. Prepare the child physically and psychologically for the necessary physical and pelvic examination.
   c. Talk with the child without the presence of the parents, especially when incest is possible.
10. Report suspicion of child abuse based on your assessment. All states (as well as the District of Columbia) have mandatory reporting laws. All states provide statutory immunity for those who report real or suspected child abuse. There is no immunity from civil or criminal liability for failure to report such. Notify the appropriate officials.

NURSING ALERT If the alleged sexual abuse occurred within 72 hours of the health care visit, or if trauma or bleeding is present, an immediate physical examination should be done. Assessment and evidence collection is very important and every attempt should be made to enlist the assistance of a health care provider experienced in this task. Many emergency departments have SANE-Ps (Sexual Abuse Nurse Examiners–Pediatric) who have had extensive training in the acute management of sexual abuse and also in managing the long-term needs of the abused child. If more than 72 hours have passed since the alleged sexual abuse, the physical examination might be delayed. After child abuse has been reported, additional children in the family may be examined as well.

NURSING ALERT Every nurse is morally and legally responsible to report and provide protective services for the abused child. Become familiar with laws, procedures, and protective services in your community and state.

Nursing Diagnoses

- Fear related to experiences with abuse.
- Impaired Parenting related to abusive treatment of a child.

Nursing Interventions

Relieving Fear and Fostering Trust

1. Be aware that some of these children have never learned how to trust an adult; they are fearful of giving affection for fear of rejection.
2. Assign one nurse to care for the child over a period of time so that a therapeutic relationship can be established.
3. Make no threatening moves toward the child. The child will indicate readiness and awareness of the environment by verbal or facial expressions.
4. Touch the child gently.
5. Provide nonthreatening physical contact (hold and frequently cuddle the child). Pick up and carry child around; encourage any exploration of your face and hair.
6. Provide appropriate opportunities for play.
7. Set limits for the child.
8. Provide therapeutic play to allow the child to express fears and anger in a nonverbal manner; be nonjudgmental and supportive with expression of feelings; correct misconceptions.
9. Provide additional help in these areas:
    a. Having ambivalent feelings toward the parents or any adult caretaker.
    b. Overcoming low self-image and the fear that something is wrong with him or her.
    c. Fearing future abuse upon his or her return home or for misbehavior in the hospital.

Providing Support in Parenting

1. Assume a nonjudgmental attitude that is neither punitive nor threatening. Convey a desire to help the parents through the healing process.
2. Refrain from questioning them about the incident of abuse. The health care provider, social worker, and investigative authority will interview the suspected abuser.
3. Include the parents in the hospital experience (ie, orient them to the unit and to any procedure to be done to the child). Serve as a role model in the management of the child's behavior as well as their own. Try to give the parents as much information as possible about the care of their child. Listen to what they are saying.
4. Refrain from challenging all the information they may give.
5. Express appropriate concern and kindness. Remain objective, yet empathic. This will help foster the parents' self-respect and improve their self-image and dignity.
6. Discuss the reporting to the authorities with them because of the widespread nature of the problem and the need for education and assistance.
7. Support the parents who may have feelings of guilt, anger, and helplessness. Explain to them the extent of trauma and educate them. Allow them to express their feelings. Support their parental role in handling the child (eg, allow the child to talk about or play out the incident, but do not force it).

8. Build a relationship by working with the parents' strengths rather than their weaknesses. Use compliments as positive reinforcement.
9. Assist the parents to learn safe and appropriate parenting skills.
    a. Remember that many of these parents were abused as children and have no role models or personal experience with nurturing behaviors.
    b. Foster attachment between child and parents, not between child and nurse, when the parents are present; the latter would increase their feelings of incompetence in the parenting role.
    c. Correct erroneous expectations as to what is appropriate behavior for a particular age group.
    d. Encourage the parents to take time out from caring for their children to meet their own needs; assist them in identifying safe and appropriate resources for their child's care.
10. Provide the parents with psychological support and reinforcement for appropriate parenting behaviors.
11. Work with the parents in planning for the child's future care.
12. Determine the areas in which the parents need help. Does the infant cry often? How does this make the parents feel? How do the parents comfort the child? Is there someone the parents can call for help?

NURSING ALERT A critical part of working in this area is learning to recognize, examine, and work with your own feelings of anger, disgust, and contempt toward the parents. It may help to do the following:

---

1. Realize that most abusive parents do love their children and want the best for them despite their ambivalent feelings toward their children.
2. Understand the dynamics of child abuse and neglect. This crisis is due to stress, with which the parents are unable to cope, and to deprivations they have themselves suffered in the past.

Community and Home Care Considerations

Nurses typically provide home care visits as part of a multidisciplinary team engaging in extensive community follow-up. Education and continued assessment are the focus.

1. Teach the parents about normal growth and development (see Chapter 40).
    a. Give specific information about and examples of the types of behavior to expect at the various stages of development. Point out in a nonthreatening way normal behavior exhibited by their child.
    b. Provide specific strategies for dealing with whatever behavior the child exhibits.
    c. Serve as a role model and teacher; minimize intensity when the parents become threatened.
2. Teach the parents how to use discipline without resorting to physical force.
    a. Discipline must be consistent. Offer suggestions for alternative ways of handling undesirable behavior (eg, time-out).
    b. Suggest using a reward system for acceptable behavior (eg, a trip to the zoo, staying up later than

usual for a special television show, a special treat).

c. Instruct the parents to withhold rewards for unacceptable behavior.

3. Teach children how to avoid being the victims of abuse.
   a. Teach them about "good touch" and "bad touch."
   b. Emphasize that they can say no to anyone who wants to touch their body.
   c. Provide names or places where they can go if they feel they are being abused.
   d. Assist them in dealing with their fears that their parents will be sent to jail or that they will be removed from the home.
4. Be alert for signs of abuse in the school. If a teacher is suspected of being the abuser, the child may:
   a. Display increased fear of the teacher.
   b. Decrease school attendance.
   c. Develop psychosomatic symptoms during school days.
   d. Develop nightmares.
   e. Worry excessively over school performance

Bullying

Bullying is a form of abuse, frequently initiated among children. It is defined by the CDC as unwanted aggressive behaviors against a youth, initiated by another youth or groups of youths. Bullying can take many forms and can include physical, verbal, or social aggression. These behaviors can be direct with actual violence with verbal and/or physical results or indirect involving social media (spreading rumors). Bullying can cause physical and/or psychological symptoms in the victims of this abuse. Nurses should be aware of the possibility of bullying and refer to a primary health care provider, mental health counselor, or social worker for further care.

Family Education and Health Maintenance

1. Teach the parents and child (if age is appropriate) any specific instructions relative to injury and follow-up care.
2. Ensure that the family knows where and when to follow-up.
3. Review schedule for well-child visits and immunizations so the family can keep up with routine care.
4. Make known to the parents your continued concern and your availability as a source of help. Help them to use resources in the community, including the home health nurse, social worker, and therapists.
5. Refer those interested in learning more about abuse to the following agencies: Prevent Child Abuse America (*www.preventchildabuse.org*, 1-800-CHILDREN) and Child Welfare Information Gateway (*www.childwelfare.gov*).

Evaluation: Expected Outcomes

- Exhibits appropriate developmental behavior.
- Both parents participate in feeding and playing with child.

Care of the Sick or Hospitalized Child

General Principles

Pain Management

The Child Undergoing Surgery

The Dying Child

Pediatric Procedures

Restraints

Specimen Collection

Feeding and Nutrition

Fluid and Electrolyte Balance

Cardiac and Respiratory Monitoring

Cardiopulmonary Resuscitation

GENERAL PRINCIPLES

Hospitalization of a child brings about a range of emotions in the child and his or her family. To care for the hospitalized child, one must take into consideration the child's development and family coping skills. Being hospitalized versus receiving care at home affects the child's response to his or her illness. In addition, family presence is often an integral part of pediatric patient care. Facilitating family-centered care allows the family to fully support the child during his or her hospitalization. Knowledge of these aspects will assist the registered nurse in providing appropriate pediatric patient care.

Pain Management

EVIDENCE BASE Sng,Q., He, H., Wang, W. (2017). A Meta-Synthesis of Children's Experiences of Postoperative Pain Management. *Worldviews on Evidence-Based Nursing, 14*(1), 46–54.

Accurate assessment and timely management of pain in children is an important and challenging nursing responsibility because infants and young children cannot express their pain, as adults can.

General Considerations

1. Pain experienced by infants and children often is not effectively identified or managed by health care providers.
2. There are still misunderstandings about the ways pain is experienced and expressed by infants and children. Studies have shown that long-term effects can occur from inadequately treated pain.
3. Behavioral and physiologic cues are used to assess pain in infants. Special rating tools are available to involve children in assessing the intensity of their pain, including the Pain Experience Inventory, CRIES Neonatal Postoperative Pain Measurement Scale, Oucher Pain Rating Scale, numerical or visual analog scale, FLACC Behavioral Pain Assessment Scale, and the Wong-Baker FACES Pain Rating Scale (see Figure 43-1).
4. Pain caused by a condition is not always proportional to the seriousness of the illness or injury. For example, a relatively minor illness, such as an earache, is a very painful experience, whereas an enlarging tumor may not cause pain in early stages.
5. It is important to consider pain when a child is noncommunicative, has decreased consciousness, is intubated, or whose chosen language is not understood by the health caregivers. Changes in vital signs (such as heart rate, respiratory rate, and blood pressure) may indicate pain.
6. It is equally important to consider pain when a child requires an injection, blood test, or noninvasive or invasive diagnostic test.
7. Consider parents when assessing and managing the pain of their child. It is well documented that parents are important influences on their children.
    a. Consider the way in which the parents view the situation experienced by the child and work with them to intervene effectively.
    b. Presence of the parents during a procedure can be very positive, especially when the family has been prepared.
    c. At other times, it is recommended that the parents mutually agree to wait in a nearby area.
    d. Arbitrary rules against parental presence are often designed to meet the needs of staff, not the needs of the child and his or her parents.

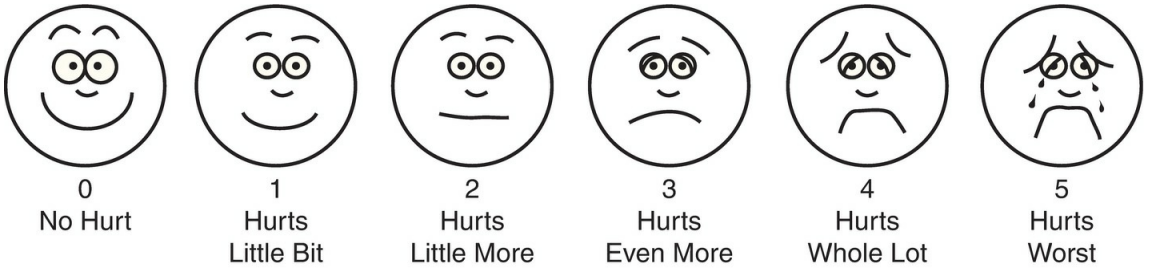

Figure 43-1. Wong-Baker FACES Pain Rating Scale. (© 1983 Wong-Baker FACES Foundation. *www.WongBakerFACES.org*. Used with permission. Originally published in Whaley & Wong's Nursing Care of Infants and Children. © Elsevier Inc.)

Nursing Interventions

1. Anticipate pain and intervene early.
2. Use a rating scale that the child can understand and use it consistently with that child for initial pain assessment and to determine the effectiveness of interventions. Attempt to introduce the pain rating scale to the child prior to the surgery or procedure.
3. Use self as therapeutic presence to help ease pain.
4. Teach self-regulation and self-control techniques.
5. Utilize distraction by sounds, music, audio images, and movies.
6. Allow self-soothing maneuvers (thumb-sucking, clinging to blanket, rocking).
7. Reposition patient, as needed.
8. Decrease environmental light and noise when possible.
9. Consider referral for self-hypnosis and conscious relaxation techniques.
10. Utilize medication delivered by way of noninvasive routes where possible.
11. Administer premedication—anesthetizing, antianxiety, and antiemetic medications—as indicated.
12. Assist with conscious sedation when indicated, following standards of practice related to assessment, staffing, care, and documentation.
13. Reassess the patient's response to the intervention and document appropriately. This is important to evaluate effectiveness and identify possible new pain issues.

The Child Undergoing Surgery

EVIDENCE BASE Al-Sagarat, A. Y., Al-Oran, H. M., Obeidat, H., et al. (2017). Preparing the family and children for surgery. *Critical Care Nursing Quarterly, 40*(2), 99–107.

Physical and emotional preparation for surgery will minimize stress and will help the child and family cope effectively with surgery. Also, see Chapter 7, Perioperative Nursing.

Psychological Preparation and Support

1. Potential threats for the hospitalized child anticipating surgery are as follows:
   a. Physical harm—bodily injury, pain, mutilation, death.
   b. Separation from parents; peers for the older child or adolescent.
   c. The strange and unknown—possibility of surprise.
   d. Confusion and uncertainty about limits and expected behavior.
   e. Relative loss of control of their world, loss of autonomy.
   f. Fear of anesthesia.
   g. Fear of the surgical procedure itself.
   h. Misinterpretation of medical jargon (eg, *dye/die*).
2. The attitudes of the parents toward hospitalization and surgery largely determine the attitudes of their child.
   a. The experience may be emotionally distressing.
   b. Parents may have feelings of fear or guilt.
   c. The preparation and support should be integrated for parent, child, and family unit.
   d. Give individual attention to parents; explore and clarify their feelings and thoughts; provide accurate information and appropriate reassurance.
   e. Stress parents' importance to the child. Help parents understand how they can care for their child.

Preoperative Teaching

1. All preparation and support must be based on the child's age, developmental stage, and level, personality, past history and experience with health professionals and hospitals, and background including religion, socioeconomic circumstances, culture, and family attitudes and dynamics. Anxiety level and coping skills should be taken into consideration.
2. Inquire as to what information the child has already received.
3. Determine what the child knows or expects; identify family myths and possible misunderstandings.
4. Additional guidelines in preparation include the following:

a. Use illustration or model of a child's body, concrete examples, and simple terms (not medical jargon).
b. Identify changes that may occur as a result of the procedure, in both body and daily routine.
c. Give explanations slowly and clearly, saving anxiety-producing aspects until the end. Repeat as needed.
d. Make use of the child's creative ability and logical thinking powers to aid in preparation for procedures.
e. Involve parents, as indicated, depending on the situation.
f. Allow and encourage the child to participate as able.
g. Suggest ways for the child to cope—crying is okay.
h. Offer constant reassurance; speak in a calm manner.
i. Evaluate the child's understanding of your teaching. Repeat and correct information, as necessary.

5. Orient the patient and family to the unit, room, location of playroom, operating room, and recovery room (if applicable) and introduce them to appropriate personnel. Make arrangements for the child to meet the anesthesiologist as well as the operating room nurse and recovery room nurse.
6. Allow and encourage questions. Give honest answers.
   a. Such questions will give the nurse a better understanding of the child's fears and perceptions of what is happening.
   b. Infants and young children need to form a trusting relationship with those who care for them.
   c. The older the child, the more reassuring information can be.
7. Provide opportunity for the child and parents to work out concerns and feelings (play, talk). Such supportive care should result in less upset behavior and more cooperation.
8. Prepare the child for what to expect postoperatively (ie, equipment to be used or attached to child, where the child will wake up, how the child will feel, what the child will be expected to do, diet, any physical restrictions). Be honest about what pain they may experience.
9. Educate parents regarding the option to be with their child, if available at the facility, during induction of anesthesia to reduce separation anxiety and fear.

Physical Preparation

1. Assist with necessary laboratory studies. Explain to the child what is going to happen before the procedure and how he or she may respond. Give continual support during the procedure.
2. See that the patient has nothing by mouth (NPO). Explain to the child and his or her parents what NPO means and the importance of it. Place signs on the patient's hospital door indicating the NPO status to ensure that nonfamily members and nonstaff members do not give the patient food.
3. Assist with fever reduction.
   a. Fever can result from some surgical problems (eg, intestinal obstruction).
   b. Fever increases risk of anesthesia and need for fluids and calories.
4. Administer appropriate medications, as prescribed. Sedatives and drugs to dry the secretions are often

given on the unit preoperatively.

5. Establish good hydration. Parental therapy may be necessary to hydrate the child, especially if the child is NPO, vomiting, or febrile.
6. With the parents in attendance, assist the surgeon with marking the patient's intended surgical site, as recommended by the Joint Commission as part of the National Safety Goals.
7. Allow the child to carry a toy or other comfort item to the preoperative area.

Immediate Postoperative Care

1. Maintain a patent airway and prevent aspiration.
    a. Position the child as ordered depending on his or her surgical procedure; position as needed to allow secretions to drain and to prevent the tongue from obstructing the pharynx.
    b. Suction any secretions present. Avoid causing a gag reflex or spasm during suctioning.
2. Make frequent observations of general condition and vital signs. Postoperative protocols may vary per procedure and facility.
    a. Take vital signs every 15 minutes until the child is awake and his or her condition is stable.
    b. Note temperature, respiratory rate and quality, pulse rate and quality, blood pressure, and skin color.
    c. Watch for signs of shock.
        i. Children in shock may have signs of pallor, coldness, increased pulse, and irregular respiration.
        ii. Older children have decreased blood pressure and respiration.
    d. Change in vital signs may indicate airway obstruction or compromise, hemorrhage, atelectasis, and altered hemodynamics.
    e. Restlessness may indicate pain or hypoxia. Medication for pain is not usually given until anesthesia has worn off. Give analgesics and sedatives per the pain management team orders.
    f. Check dressings for drainage, constriction, and pressure. Perform dressing changes per protocol.
3. See that all drainage tubes are connected and functioning properly. Gastric decompression relieves abdominal distention and decreases the possibility of respiratory compromise. Chest tubes evacuate pleural air and fluid. Ensure all tubes are secure to prevent accidental removal.
4. Monitor parenteral fluids, as prescribed.
5. Be physically near as the child awakens to offer soothing words and a gentle touch. Reunite the parents and child as soon as possible after the child recovers from anesthesia. If a language barrier exists, the parents should be with the child during recovery from anesthesia and an interpreter should be present when medical explanations are being given to the parents or child.

After Recovery from Anesthesia

After undergoing simple surgery and receiving a small amount of anesthesia, the child may be ready to play and eat in a few hours. More complicated and extensive surgery debilitates the child for a longer period of time.

1. Continue to make frequent and astute observations in regard to behavior, comfort level and pain control,

vital signs, dressings or operative site, and special apparatus (intravenous [IV] lines, chest tubes, oxygen, nasogastric tubes).

   a. Note signs of dehydration—dry skin and membranes, sunken eyes, poor skin turgor, sunken fontanelle in an infant, poor urine output.
   b. Record any passage of flatus or stool and bowel sounds. Observe for intestinal ileus. Gastric distention may be caused by swallowed air in the crying child.
   c. Record vomiting including time, amount, and characteristics.

2. Assess behavior for signs of pain and medicate appropriately.
3. Record intake and output accurately.
   a. Parenteral fluids and oral intake.
   b. Drainage from gastric tubes or chest tubes, colostomy, wound, and urinary output.
   c. Parenteral fluid is evaluated and prescribed by considering output and intake. It is usually maintained until the child is taking adequate oral fluids.
4. Advance diet as tolerated, according to the child's age and the health care provider's directions.
   a. First feedings are usually clear fluids; if tolerated, advance slowly to full diet for age. Note any vomiting or abdominal distention.
   b. Because anorexia may occur, offer what the child likes in small amounts and in an attractive manner.
5. Prevent infection.
   a. Keep the child away from other children or personnel with respiratory or other infections.
   b. Change the child's position every 2 to 4 hours; support infant with a blanket roll.
   c. Encourage the child to cough and breathe deeply; let the infant cry for short periods of time, unless contraindicated. Offer older children incentive spirometry every hour while awake.
   d. Keep operative site clean—change dressing, as ordered; in infant, keep the diaper away from the wound.
   e. Enforce diligent handwashing by family members and staff before any contact with the patient.
   f. Do not cohort surgical patients with patients with a proven or presumptive infection.
   g. Administer prophylactic antibiotics, as ordered.
6. Provide good general hygiene and opportunities for exercise and diversional activity; encourage sleep and rest.
7. Provide emotional support and psychological security. Reassure the child that things are going well; if there are complications, offer honest information based on the patient's health and developmental level and the parents' willingness to share this information with their child. Talk about going home, if appropriate.

TRANSITIONAL CARE ALERT Hospitalization can be anxiety provoking for both the child

and caregivers. Identify caregivers early, and try to coordinate nursing care and education with their visits. This includes teaching special procedures, providing written instructions, and arranging for home nursing and/or supplies.

The Dying Child

The nursing role is to assist the child and family to cope with the experience in such a way that it will promote growth rather than destroy family integrity and emotional well-being.

EVIDENCE BASE Kubler-Ross, E. (1997). *On death and dying*. New York: Scribner.

Schonfield, D. J., Demaria, T., & AAP Committee on Psychosocial Aspects of Child and Family Health, Disaster Preparedness Advisory Council. (2016). Supporting the grieving child and family. *Pediatrics, 138*(3), e20162147.

Recognize the Stages of Dying

See Table 43-1.

Table 43-1 Stages of Dying as Identified by Dr. Elizabeth Kübler-Ross

STAGE	NURSING CONSIDERATIONS
I. Denial, shock, disbelief	• Accept denial, but function within a reality sphere. Do not tear down the child's (or family's) defenses. • Be aware that denial usually breaks down in the early morning when it may be dark and lonely. • Be certain that it is the child or family who is using denial, not the staff.
II. Anger, rage, hostility	• Accept anger and help the child express it through positive channels. • Be aware that anger may be expressed toward other family members, nursing staff, physicians, and other persons involved. • Help families recognize that it is normal for children to express anger for what they are losing.
III. Bargaining (from "No, not me," to "Yes, me, but …")	• Recognize this period as a time for the child and family to regain strength. • Encourage the family to finish any unfinished business with the child. This is the time to do things such as take a promised trip or buy a promised toy.
IV. Depression (the child and/or family experiences silent grief and mourns past and future losses)	• Recognize this as a normal reaction and expression of strength. • Help families to accept the child who does not want to talk and excludes help. This is the usual pattern of behavior. • Reassure the child that you can understand his or her feelings.
V. Acceptance	• Assist families to provide significant loving human contact with their child and one another.

1. Be aware that the patient, his or her family, and the health care providers all progress through these stages; however, not necessarily at the same time.
2. Children experience the stages with much variation. They tend to pass more quickly through the stages and may merge some of these stages.
3. The nursing goal is to accept the child and his or her family at whatever stage they are experiencing, not to push them through the stages.
4. Understand the meaning of illness and death at various stages of growth and development (see Table 43-2).
5. Be aware of other factors that influence a child's personal concept of death. Of particular importance are the following:
   a. The amount and type of direct exposure a child has had to death.
   b. Cultural values, beliefs, and patterns of bereavement.
   c. Religious beliefs about death and an afterlife.

6. Meet with the parents separately from the child and discuss their wishes regarding dissemination of information to their child.

Table 43-2 Stages in the Development of a Child's Concept of Death

AGE OF CHILD	STAGE OF DEVELOPMENT
Child up to age 3	• At this stage, the child cannot comprehend the relationship of life to death because the child has not developed the concept of infinite time. • The child fears separation from protecting and comforting adults. • The child perceives death as a reversible act.
Preschool child	• At this age, the child has no real understanding of the meaning of death; the child feels safe and secure with parents. • The child may view death as something that happens to others. • The child may interpret the separation that occurs with hospitalization as punishment; the painful tests and procedures that the child is subjected to support this idea. • The child may become depressed because of not being able to correct these wrongdoings and regain the grace of adults. • The concept may be connected with magical thoughts of mystery.
School-age child	• The child at this age sees death as the cessation of life; child understands that he or she is alive and can become "not alive"; child fears dying. • The child differentiates death from sleep. Unlike sleep, the horror of death is in pain, progressive mutilation, and mystery. • The child is vulnerable to guilt feelings related to death because of difficulty in differentiating death wishes and the actual event. • The child believes death may be caused by angry feelings or bad thoughts. • The child learns the meaning of death from own personal experiences, such as the death of pets, family members, and public figures. • Television and movies have contributed to the concept of death and understanding of the meaning of illness. There may be more knowledge in the meaning of the diagnosis and an awareness that death may occur violently.
Adolescent	• The adolescent comprehends the permanence of death as the adult does, although the adolescent may not comprehend death as an event occurring to persons close to self. • The adolescent wants to live—sees death as thwarting pursuit of goals: independence, success, achievement, physical improvement, and self-image. • The adolescent fears death before fulfillment. • The adolescent may become depressed and resentful because of bodily changes that may occur, dependency, and the loss of social environment. • The adolescent may feel isolated and rejected because adolescent friends may withdraw when faced with impending death of a friend. • The adolescent may express rage, bitterness, and resentment; especially resents the fact that fate is to die.

Communicate with the Child about Death

Research indicates that children generally can cope with more than adults will allow and that children appreciate the opportunity to know and understand what is happening to them. It is important that the child's questions be answered simply but truthfully. The answers should be based on the child's particular level of understanding. The following responses have been suggested by Easson in *The Dying Child: The Management of the Child or Adolescent Who Is Dying* and may be useful as a guide:

Preschool-Age Child

1. When the child at this age is comfortable enough to ask questions about illness, questions should be answered. When death is anticipated at some future time and the child asks, "Am I going to die?," a response might be, "We will all die someday, but you are not going to die today or tomorrow."
2. When death is imminent and the child asks, "Am I going to die?," the response might be, "Yes, you are going to die, but we will take care of you and stay with you."
3. When the child asks, "Will it hurt?," the response should be truthful and factual.
4. Death should never be described as a form of sleep. Some children may fear sleep as the result of this type of explanation. Anesthesia is sometimes called a "special sleep" so it is not currently recommended

to refer to death as "sleep."

5. Parents can express to the child the fact that they do not want the child to go and that they will miss the child very much; they feel sad, too, that they are going to be separated.

School-Age Child

1. Responses to the school-age child's questions about death should be answered truthfully. The child looks for support from those he or she trusts.
2. The school-age child should be given a simple explanation of his or her diagnosis and its meaning; the child should also receive an explanation of all treatments and procedures.
3. The child should be given no specific time in terms of days or months because each individual and each illness is different.
4. When the school-age child asks, "Am I going to die?" and death is inevitable, the child should be told the truth. The school-age child has the emotional ability to look to parents and those he or she trusts for comfort and support.
5. The school-age child believes in his or her parents. The child should be allowed to die in the comfort and security of his or her family.
6. The school-age child knows death means final separation and knows what will be missed. The child must be allowed to mourn this loss. The dying child may be sad and bitter and demonstrate aggressive behavior. The child must be allowed the opportunity to verbalize this if able to do so.

Adolescent

1. The adolescent should be given an explanation of his or her illness and all necessary treatments and procedures.
2. The adolescent feels deprived and reasonably resentful regarding his or her illness because he or she wants to live and reach fulfillment.
3. As death approaches, the adolescent becomes emotionally closer to his family.
4. The adolescent should be allowed to maintain emotional defenses—including absolute denial. The adolescent will indicate by questions what types of answers are desired.
5. If the adolescent states, "I am not going to die," he or she is pleading for support. Be truthful and state, "No, you are not going to die right now."
6. The adolescent may ask, "How long do I have to live?" Adolescents are able to face reality more directly and can tolerate more direct answers. No absolute time should be given because that blocks all hope. If an adolescent has what is felt to be a prognosis of approximately 3 months, the response might be, "People with an illness like yours may die in 3 to 6 months, but some may live much longer."

Support Parents' Adaptation to Child's Death

1. Develop a care plan that includes this approach:
   a. The primary responsibility for communicating with the parents should be designated to one nurse.
   b. Information regarding the parents' concerns should be communicated to all staff members and should

be included in the patient's care plan.

2. Accept parental feelings about the child's anticipated death and help parents deal with these feelings.
   a. It is not unusual for parents to reach the point of wishing the child dead and to experience guilt and self-blame because of this thought.
   b. The parents may withdraw emotional attachments to the child if the process of dying is lengthy. This occurs because the parents complete most of the mourning process before the child reaches biologic death. They may relate to the child as if he or she were already dead.
3. Provide anticipatory guidance regarding the child's actual death and immediate decisions and responsibilities afterward.
   a. Describe what the death will probably be like and how to know when it is imminent. This is necessary to dispel the horrifying fantasies that many parents have. Reassure the parents that all measures will be taken to keep the child comfortable at the time of death. (*Note:* Certain diseases, despite appropriate medical interventions, may cause an uncomfortable or painful death. Parents should be promised complete comfort for their child only if this expectation is realistic.)
   b. Clarify the parents' wishes about being present at the child's death and respect their desires. See if they want to hold the child—before, during, or after the death.
   c. If appropriate, allow the parents to discuss their feelings about issues such as autopsy and organ donation in order that they may make appropriate decisions. Do not make them feel guilty if they do not consent.
   d. If necessary, assist the parents to think about funeral arrangements.
4. Be aware of factors that affect the family's capacity to cope with fatal illness, especially social and cultural features of the family system, previous experiences with death, present stage of family development, and resources available to them.
5. Contact the appropriate clergy if the family desires. Contact other extended family members for support if they wish.
6. During final hours, do not leave the family alone, unless they request it.
7. Encourage parents and siblings to share their thoughts with the dying child.
8. Provide information on bereavement support groups, usually available through hospital or church.

PEDIATRIC PROCEDURES

See additional online content: Procedure Guidelines 43-1–43-7

PROCEDURE GUIDELINES 43-1

Assisting with Blood Collection

EQUIPMENT

- 23- to 19-gauge short needle or scalp vein needle.
- Smaller volume or micro blood-collecting tubes.
- Antiseptic wipes (alcohol).
- Warm compresses.
- Smaller tourniquet (rubber band may be used with infant).
- Gloves per standard precautions.
- Band-aid or pressure dressing.

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. Perform hand hygiene.	1. Standard precautions.
2. Immobilize the child by placing in a mummy restraint, if necessary, or use distraction techniques.	2. Allows easier access to the venipuncture site and protects the child from injury.
3. Position the patient.	3. These positions allow for optimal visualization and stabilization of the patient.
a. *Femoral venipuncture*: Place the child back with legs in froglike position. Place your hands on the child's knees.	a. Cover the perineum to protect site in case the child voids.
Assisting with jugular venipuncture. From Pillitteri, A. (1999). *Maternal and child health nursing: Care of the childbearing and childrearing family* (3rd ed.). Philadelphia, PA: Lippincott-Raven. Photograph by Barbara Proud.	Assisting with antecubital fossa venipuncture. From Pillitteri, A. (1999). *Maternal and child health nursing: Care of the childbearing and childrearing family* (3rd ed.). Philadelphia, PA: Lippincott-Raven. Photograph by Barbara Proud.
b. *External jugular venipuncture*: Place the child in mummy restraint and lower head over the side of the bed or table. Turn head to side and stabilize. (See accompanying figure.)	b. Crying will make external jugular vein visible and causes blood to flow more readily.
c. *Antecubital fossa venipuncture*: Place the child in a supine position. The nurse stands on the side opposite the site to be used (across from the person drawing the specimen). The nurse positions her right arm across the upper part of the child's chest and grasps the shoulder at the axilla position. The nurse's left arm is placed across the lower part of the child's chest and is used to extend the child's arm at the wrist (see accompanying figure). If possible, allow the child to sit upright while being held by parent to decrease stress of the child and parent.	c. The nurse's hands are used to straighten and hold the child's arm still; arms are used to maintain the stability of the child's upper body.
d. *Infant—heel, toe, or digital puncture*: Warm area with warm compress for 5 to 10 minutes.	d. This dilates vessels, allowing blood to flow more freely, and reduces bruising.

Nursing Action	Rationale
Performance phase	
1. *Capillary*: Clean the area with antiseptic and dry with sterile 2 inches × 2 inches gauze. Hold heel firmly and with free hand quickly puncture with microlancet or sterile 21-gauge needle on most medial or lateral part of plantar surface. Puncture deeply enough to get free-flowing blood—never deeper than 2 mm. Discard first drop of blood; rapidly collect specimen in proper capillary tube.	1. Standard precautions. Both persons holding the infant and drawing the blood should wear gloves. Gowns, masks, and goggles may be used if splattering is anticipated.
2. After the specimen is collected and the needle is removed, apply pressure to the site with dry gauze for 3 to 5 minutes.	2. The femoral and jugular veins are large vessels. Because intravascular pressure is great, bleeding, oozing, and hematoma formation may result. External pressure prevents this from happening.
a. *Jugular venipuncture*: While applying pressure to the site, place the patient in an upright sitting position. Do not apply excessive pressure that may compromise circulation or respiration.	a. Upright position will reduce pressure in jugular vein.
3. When the bleeding has stopped, apply a pressure dressing or adhesive bandage to the site. Soothe and comfort the child before leaving.	3. Crying and thrashing about may initiate bleeding.
Follow-up phase	
1. Check the patient frequently for 1 hour after the procedure for oozing, bleeding, or evidence of a hematoma.	
2. Record carefully and accurately:	2. For continuity of care.
a. Site of venipuncture.	
b. How the patient tolerated procedure?	
c. Bleeding stopped or continued and for how long?	
d. Test for which the specimen was collected as well as the place to which it was sent for analysis and the time at which it was sent.	
e. Amount of blood loss.	

PROCEDURE GUIDELINES 43-2

Collecting a Urine Specimen from the Infant or Young Child

EQUIPMENT

- Collecting device—plastic, disposable urine bag, or collector (Hollister, U-Bag, double chamber).
- Cleansing agent.
- Wiping material—4 inches Ã— 4 inches gauze pads or cotton balls.
- Sterile water.
- Containers for solutions.
- Specimen container.
- Gloves.
- Chemical adhesive (tincture of benzoin).

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. Prior to obtaining urine sample, consult facility policy or laboratory manual for type of specimen container and amount of urine to be collected.	1. Amount of urine and type of container may vary by test ordered.
2. Offer the young child a choice of fluids to drink 30 to 60 minutes before the procedure, if no contraindications.	2. Increases urine production.
3. Position the patient, so genitalia are exposed by placing the child back with legs in a froglike position. Assistance may be needed to hold the legs of the young child in proper position.	3. Proper positioning will facilitate cleansing and allow for proper placement of collection device.
4. When small samples of urine are needed for tests to be done by the nurse, such as dipstick tests, urine can be extracted from the diaper using a syringe or dropper.	4. Several mL of urine may be collected by dropper.
Performance phase	
1. Perform hand hygiene; wear gloves.	1. Standard precautions.
2. Cleanse the genital area. a. *Female*: Using cotton balls, dip into cleansing agent, wipe labia majora from top to bottom (clitoris to anus) only once with each cotton ball. Repeat this once more. Wipe again with sterile water. Then spread labia apart with one hand while wiping the labia minora in the same manner with the other hand. Wipe the area dry. b. *Male*: Wipe tip of the penis in circular motion down toward the scrotum. Be certain to retract foreskin, if present. Wipe first with cleansing agent two to three times, then sterile water. Dry the area.	2. This method of cleansing the female will prevent contamination of the genitalia from the anus and will prevent contamination of the urine specimen obtained. During the cleansing, be gentle to avoid any injury or possible stimulation of urination.
3. Apply a chemical adhesive.	3. Helps to provide a better seal between the bag and child's skin.
4. Apply a collecting bag firmly so the opening is exposed to receive urine. a. *Female*: Stretch the perineum taut during application. Attach the bag to the perineum first, then proceed up to symphysis. b. *Male (small boys)*: Place the penis inside the bag.	4. If collecting bag is properly and securely placed, it is less likely that the procedure will have to be repeated. a. This should ensure leakproof contact.
5. Apply diaper and comfort the patient; possibly give additional clear fluids.	
6. Elevate head of bed or place the child in an infant seat, if appropriate.	6. Aids flow of urine by gravity.
7. Check the patient every 5 to 10 minutes to see whether he or she has voided. When the patient has voided, and after gloves are on, gently remove the bag. Cleanse the area and reapply diaper to the child. If the child has not voided within 45 minutes, procedure must be repeated.	7. The adhesive on the collecting bag may tend to be sticky. Careful removal of the bag will prevent skin injury on and around the genitalia. Also avoid spilling urine out of the bag during removal. Reapplication of the bag will decrease the possibility of unreliable test results.

Nursing Action	Rationale

Urine collector for male infants. From Pillitteri, A. (1999). *Maternal and child health nursing: Care of the childbearing and childrearing family* (3rd ed.). Philadelphia, PA: Lippincott-Raven. Photograph by Barbara Proud.

Follow-up phase

1. Pour specimen into proper collecting container. Send the specimen to the laboratory within 30 minutes or refrigerate.
   1. Prompt delivery of the specimen to the laboratory will prevent growth of organisms in an uncontrolled environment and distortion of the test results.
2. Accurately chart and describe the following in the nurse's notes:
   a. Time specimen collection was started and ended.
   b. Amount of urine voided.
   c. Color of urine (cloudy, clear, any sediment).
   d. Type of test to be done.
   e. Condition of the skin in the perianal area.
   2. For continuity of care.

Note: If 24-hour urine collection is needed, use a collection bag that has a long tube attachment to facilitate frequent emptying of urine every 1 to 2 hours. Place urine in a labeled receptacle in the refrigerator. Adherence of the bag to skin can be improved by applying a thin coating of tincture of benzoin to the skin and allowing this to dry before attaching the collection bag.

PROCEDURE GUIDELINES 43-3

Collecting a Stool Specimen

EQUIPMENT

- Diaper.
- Cellophane or plastic liner (used when stool is loose or watery).
- Specimen container.
- Tongue blade.
- Gloves.

Note: Collecting a stool specimen from an older child who is toilet-trained is the same as collecting a specimen from an adult.

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. If a specimen is needed from a patient whose stools are loose or watery enough to be absorbed in the diaper, line the diaper with a piece of cellophane or plastic, or use a urine bag to collect stool. Place liner between the diaper and the skin. Then apply the diaper to the child and position so head is slightly elevated. If stools are soft or formed, apply only the diaper.	1. The liner and position will allow the loose stool specimen to collect in the liner and not be absorbed by the diaper.
Performance phase	
1. Wear gloves.	1. Standard precautions.
2. Check the child frequently to see if a bowel movement has occurred.	2. A fresh specimen should be obtained so test results will not be distorted by time lapse. This will also decrease the chance of contamination of the stool with urine and will prevent skin irritation from the stool.
3. Remove soiled diaper from the child. Clean the perineal area, apply clean diaper, and leave the child comfortable.	
4. Remove small amount of stool from diaper with the tongue blade and place it in the clean specimen container.	
5. Send the labeled specimen to the laboratory promptly.	5. Prompt delivery to the laboratory will prevent changes from occurring in the specimen that could alter the test results.
Follow-up phase	
1. Accurately describe and record the following: a. Time specimen was collected. b. Color, amount, and consistency of stool (note any foul smell or blood-tinged stool). c. Type of specimen collected. d. Nature of test for which the specimen was collected. e. Nature of test for which the specimen was collected. f. Condition of the perineal and anal areas.	1. For continuity of care.

PROCEDURE GUIDELINES 43-4

Infant Gavage Feeding

EQUIPMENT

- Sterile rubber or plastic catheter, rounded-tip, size 5 to 12 French (Argyle feeding tubes).
- Clear, calibrated reservoir for feeding fluid.
- 5 to 10 mL syringe.
- Stethoscope.
- Sterile water or normal saline.
- Tape—hypoallergenic.
- Feeding fluid, room temperature.
- Pacifier.

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. Perform hand hygiene.	1. Standard precautions.
2. Position the child on side or back with a rolled diaper placed under shoulders. A mummy restraint may be necessary to help maintain this position (see page 1155).	2. Allows for easy passage of the catheter, facilitates observation, and helps avoid obstruction of the airway.
3. Measure the distance from the tip of the patient's nose to earlobe to xiphoid process of the sternum and mark the length on the feeding tube with tape.	3. Premeasuring the catheter provides a guideline as to how far to insert the catheter.
4. Have suction apparatus readily available.	4. Suctioning clears the airway and prevents aspiration if regurgitation occurs.
Performance phase	
1. Lubricate the catheter with sterile water, normal saline solution, or water-soluble lubricant.	1. Do not use oil because of danger of aspiration.
2. Stabilize the patient's head with one hand; use the other hand to insert the catheter.	
a. *Insertion through nares*: Slip the catheter into the patient's nostril and direct it toward the occiput in a horizontal plane along the floor of the nasal cavity. Do not direct the catheter upward. Observe for respiratory distress.	a. This direction will follow the nares' passageway into the pharynx. Positioning in the nares may cause partial airway obstruction. Avoid this route if there is critical airway compromise.
b. *Insertion through the mouth*: Pass the catheter through the patient's mouth toward the back of the throat, with his or her head tilted slightly forward.	b. Facilitates passage into the esophagus.
3. If the patient swallows, passage of the catheter may be synchronized with the swallowing. Do not push against resistance. Gently try rotating the tube if resistance is met.	3. Swallowing motions will cause esophageal peristalsis, which opens the cardiac sphincter and facilitates passage of the catheter. Perforation can occur with very little pressure. Prevents trauma to tissue.
4. If there is no swallowing, insert the catheter smoothly and quickly. Avoid inserting the catheter into the infant's trachea.	4. Because of cardiac sphincter spasm, resistance may be met at this point. Pause a few seconds, then proceed. An infant's anatomy makes it relatively difficult to enter the trachea because the esophagus is behind the trachea, but it may occur.
5. In the infant especially, observe for vagal stimulation (i.e., bradycardia and apnea).	5. Stimulation of vagal nerve branches with the catheter will slow the heart rate.
6. When the catheter has been inserted to the premeasured length, tape the catheter to the patient's face (see accompanying figure).	6. Prevents movement of the catheter from the premeasured, pre-established correct position. Alternative method: Loop narrow cloth tape around the tube just below the nostril, then secure it above lip or nose with tape. Some movement of the tube may be seen with swallowing. Avoid upward pressure of the nares in order to prevent ulceration.

Nursing Action	Rationale
 Gavage tube in the jejunum.	 Steps in preparing adhesive tape to retain gavage tube.
7. Test for correct position of the catheter in the stomach, according to institution policy. Radiographic assessment is most reliable but may subject the patient to multiple x-rays and increased exposure to radiation. Injection of air into the catheter while auscultating over the stomach is a procedure used by some; however, the preferred method is to aspirate a small amount of stomach content and test for acidity. If unsure of placement at any time, obtain an abdominal x-ray.	7. X-ray is the most reliable method to verify placement, but another method may be used. Injection of air may cause abdominal distension. Failure to obtain aspirate does not indicate improper placement; there may not be any stomach content, or the catheter may not be in contact with the fluid.
8. Further secure the tube to the patient's cheek by using tape or Opsite©. Avoid using paper tape, which loosens if exposed to secretions or formula.	8. Adhesive should not loosen easily and should be washable because it may be exposed to secretions.
9. The feeding position should be right side–lying or supine, with head and chest elevated 30 degrees. Attach the reservoir to catheter, and fill with feeding fluid. Encourage the infant to suck on a pacifier during feeding. Hold the infant when possible.	9. This position allows the flow of fluid to be aided by gravity. The use of the pacifier will relax the infant, allowing for easier flow of fluid as well as provide for normal sucking needs. Sucking will help develop muscles and provide a positive association between sucking and relief of hunger.
10. Aspirate the tube before feeding begins to assess for residual contents and to remove any air.	10. This is done to monitor for appropriate fluid intake, digestion time, and overfeeding that can cause distension. Notify the health care provider of a large residual. Document any residual amount after each aspiration.
a. If over one half of the previous feeding is obtained by aspiration, withhold the next feeding. Do not return aspirate to the stomach. Notify the health care provider of the large residual volume.	a. Indicates slow gastric emptying. Overfeeding will result in distension.
b. If a small residual of formula is obtained, return it to the stomach and subtract that amount from the total amount of formula to be given. Document any residual contents.	b. Residual of <25% of the feeding is considered small and should be tolerated if refed. Recheck residual in 30 to 60 minutes and notify health care provider if it is over half.

Nursing Action	Rationale
11. The flow of the feeding should be slow. Do not apply pressure. Elevate the reservoir 6 to 8 inches (15 to 20 cm) above the patient's head.	11. The rate of flow is controlled by the size of the feeding catheter; the smaller the size, the slower the flow. If the reservoir is too high, the pressure of the fluid itself increases the rate of flow.
a. Feedings given too rapidly may interfere with peristalsis, causing abdominal distension, regurgitation, and, possibly, emesis.	a. The presence of food in the stomach stimulates peristalsis and causes the digestive process to begin. Also, when the tube is in place, incompetence of the esophageal–cardiac sphincter may result in regurgitation.
b. Feeding time should last approximately as long as when a corresponding amount is given by nipple, 5 mL/5 to 10 minutes or 15 to 20 minutes of total time.	
12. When the feeding is completed, the catheter may be irrigated with clear water. Before the fluid reaches the end of the catheter, clamp it off and withdraw it quickly or keep in place for the next feeding.	12. Clamp the catheter before air enters the stomach and causes abdominal distension. Clamping also prevents fluid from dripping from the catheter into the pharynx, causing the patient to gag and aspirate.
13. Discard the feeding tube and any leftover solution.	
NURSING ALERT Intermittent gavage feeding is commonly preferred to indwelling gavage feeding. An indwelling catheter may coil and knot, perforate the stomach, and cause nasal airway obstruction, ulceration, irritation of the mucous membranes, incompetence of esophageal–cardiac sphincter, and epistaxis. However, if intermittent placement is not well tolerated and the indwelling method is used, the catheter should be clamped to prevent loss of feeding or entry of air. Some new catheters can remain in place for up to 30 days. (Use alternate sides of the nares with each tube change.) Constant alertness to the above problems should be stressed. Indwelling method may be preferred with an older infant or child.	
Follow-up phase	
1. Burp the patient. (The patient may not burp if air was aspirated from the tube following the feeding.)	1. Adequate expulsion of air swallowed or ingested during feeding will decrease abdominal distension and allow for better tolerance of the feeding.
2. Place the patient on right side for at least 1 hour.	2. Facilitates gastric emptying and minimize regurgitation and aspiration.
3. Observe the patient's condition after feeding; bradycardia and apnea may still occur.	3. Because of vagal stimulation, as mentioned above.
4. Note vomiting or abdominal distension.	4. Because of overfeeding or too rapid feeding. Regurgitation of 1 to 2 mL may occur in the premature infant as the musculature of the sphincter of the GI tract is relaxed and allows for easy reflex.
5. Note the infant's activity.	5. Fatigue or peaceful sleep offers insight as to tolerance of the feeding.
6. Accurately describe and record procedure, including type and size of tube used, verification of placement, time of feeding, type of gavage tube feeding, type and amount of feeding fluid given, amount retained or vomited, how the patient tolerated feeding, and activity before, during, and after feeding.	6. Continuity of care. Observe for readiness of the infant to feed by nipple—note sucking activity and sleep–wake cycle in relation to feeding.

PROCEDURE GUIDELINES 43-5

Gastrostomy Feeding

EQUIPMENT

- Appropriately prepared feeding fluid.
- Pacifier.
- Reservoir syringe or feeding bag.
- Syringe for aspirating.

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. Gastrostomy tube may be in one of three positions between feedings:	
a. Lowered and open for drainage.	a. Constant decompression.
b. Open, connected to reservoir (funnel, syringe) that is elevated 4 to 6 inches (10 to 15 cm).	b. Serves as safety valve outlet to prevent esophageal reflux and increased stomach pressure.
c. Clamped.	c. Most "normal" physiologic setup.
2. Perform hand hygiene.	2. Universal precautions.
3. The nurse may be directed to check residual stomach contents before any feeding.	3. This is done to monitor for appropriate fluid intake, digestion time, and overfeeding, which can cause distension.
a. Attach syringe and aspirate stomach contents.	
b. Measure volume.	
c. Residual fluid may be returned to stomach or discarded, depending on the amount, as per order.	c. Residual may be returned to the stomach or discarded, depending on the amount as per order. Large-volume residual may indicate reduced gastric emptying and cause abdominal distension.
d. Assess the skin around the tube for excoriation, redness, drainage.	d. May indicate infection.
4. A Y-tube that is connected at the point where reservoir and gastrostomy tube join may be used during feeding.	4. Provides simultaneous decompression (venting) during feeding.
5. When feeding is about to begin, the patient should be placed in a comfortable position in bed—with head slightly elevated. If condition permits, the nurse or family member should hold the patient. A pacifier can be given.	5. When the patient is comfortable and relaxed, feeding fluid will flow more easily into the stomach. Pacifier will satisfy normal sucking activity, provide exercise for jaw muscles, and relax musculature as well as provide pleasure normally associated with feeding.
Note: The child may have a gastrostomy button in place. In this case, insert the appropriate extension set into the button and follow the feeding procedure in the performance phase.	
Performance phase	
1. Attach reservoir syringe or primed feeding bag to the tube or extension set (if not already open to continuous venting) and fill reservoir syringe with feeding fluid. Unclamp the tube.	1. Prevents air from entering tube (and then stomach), which may cause distension.
2. If providing bolus feed via syringe, elevate the tube and reservoir to 4 to 4¾ inches (10 to 12 cm) above the abdominal wall. Do not apply pressure to start flow. If providing continuous feedings or bolus feed via pump, program pump as prescribed and start feed via pump.	2. This elevation level will allow for slow, gravity-induced flow. Pressure may cause a backflow of fluid into the esophagus.
3. Feed slowly, taking 20 to 45 minutes. Fill the reservoir with remaining fluid before it is emptied to avoid instillation of air.	3. Too rapid feeding will interfere with normal peristalsis and will cause abdominal distension and backflow into the reservoir or esophagus.
4. Continue to provide the infant with pleasant feelings associated with feeding (i.e., pacifier).	

Nursing Action	Rationale
5. When feeding is completed either:	
a. In still, clear water (0.3 to 1 ounce [10 to 30 mL]) if the tube is to be clamped. Apply a clamp before water level reaches the end of the reservoir.	a. This rinses tubing and will prevent clogging.
or	
b. Leave the tube unclamped and open to continuous elevation.	b. Feeding fluid is allowed to return to the reservoir if the infant cries or changes position, and thus decreases pressure in the stomach.
6. Commonly, when oral feedings are started, they are given simultaneously with gastrostomy feedings.	6. Allows the infant to learn or re-establish the sucking–swallowing process as well as to build up tolerance to eating without compromising nutritional intake.
Follow-up phase	
1. Check dressing and skin around the point of tube entry for wetness. Clean the skin and apply skin barrier, if ordered. Ensure that there is no pull on the tube.	1. Skin breakdown is caused by continued exposure to stomach contents that may be leaking out around the tube, causing excoriation and infection. Constant pulling on the tube can cause widening of skin opening and subsequent leakage.
2. Leave the patient dry and comfortable. If unable to hold the patient during feeding, this may be a good time to hold and provide warmth and love. Place on right side or in Fowler position.	2. Promotes relaxation and improved digestion of feeding.
3. Accurately describe and record procedure, including time of feeding, type and amount of feeding fluid given, amount and characteristics of residual (if any) and what was done with it, how the patient tolerated the feeding, any abdominal distension, and activity after feeding.	3. Continuity of care.

PROCEDURE GUIDELINES 43-6

Nasojejunal and Nasoduodenal Feedings

EQUIPMENT

- Sterile radiopaque silicone or polyvinyl nasojejunal (NJ) or nasoduodenal (ND) tube, 36 inches (91 cm) (appropriate size for the child); may have weighted tip.
- Tape.
- pH paper or pH probe.
- Reservoir (syringe or bag) for feeding.
- Appropriate feeding pump.
- Three-way stopcock.
- Syringe—0.5 mL normal saline solution or sterile water.
- Equipment for nasogastric (NG) tube insertion; introducer catheter.
- Cardiac monitoring equipment.

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. Perform hand hygiene.	1. Standard precautions.
2. Apply cardiac monitoring leads.	2. Allows for continuous monitoring of heart rate and rhythm in the event that the vagus nerve is stimulated as the catheter is passed, causing bradycardia.
3. Flush the tube with 5 mL of water.	3. Confirms tube's patency and functionality.
4. Tube is generally inserted by a health care provider (with or without fluoroscopy).	
a. Measure from the tip of the patient's nose to the ear lobe then down to between the xiphoid process and the umbilicus. Add 8 to 10 inches and mark the tube at this measurement.	a. Equals distance to the stomach.
b. Measure and mark the remaining length of tubing and record.	b. Serves as a double check to ensure that the tube has not advanced farther than intended.
5. Place the patient on right side with his or her hips slightly elevated. Gentle restraint or soft mittens may have to be applied.	5. Facilitates passage of the tube. Restraints prevent the patient from pulling out the tube before the tip passes the pylorus. Do not place on left side.
6. The tube is inserted by threading the NJ or ND through the nostril into the stomach and through the pylorus.	6. Oral insertion may cause increased salivation, air swallowing, and regurgitation.
7. Check intestinal aspirate for pH every 1 to 2 hours. The infant may be positioned on right side, back, or abdomen. When the tube is past the pylorus, abdominal posteroanterior and lateral x-rays are taken to confirm that the tip of the catheter is at the ligament of Treitz. Remove the guidewire. If the pH results are inconclusive or the NJ is difficult to place, it may be placed under fluoroscopy.	7. When aspiration fluid reaches a pH of 6 to 8 or bile-colored fluid is obtained, the tip of the tube may have passed the pylorus and duodenum into the jejunum.
8. A small NG feeding tube may be passed through the other nostril at this time and left indwelling. This is used to check the stomach for residual fluid and regurgitation through the pylorus.	8. If gastric residual is significant, it will interfere with prescribed feeding. Notify the health care provider (4 mL/kg reflux in the stomach is usually tolerated). Do not remove NG tube because it will adhere to NJ tube during withdrawal and also pull out the NJ tube.
Performance phase	
1. NJ feedings are generally given by continuous slow drip.	1. Commonly preferred method to minimize the satiety–hunger cycle and large-volume instillation to prevent dumping syndrome.
a. Fill reservoir as needed, with no more than 4 hours' worth of feeding fluid.	a. Ensures a constant flow and minimizes overinfusion directly into the jejunum or duodenum.
b. Feeding is given at room temperature. Avoid cold fluid.	b. Cold fluid may cause infant discomfort.
c. If breast milk is used, gently knead the reservoir periodically to mix settled-out fat content.	c. Breast milk may separate, providing uneven infusion of nutrients.
2. Reservoir chamber and tubing should be changed every 4 hours in the hospital and daily at home.	2. Prevents growth of bacteria.

Nursing Action	Rationale
3. Many medications may be given by way of ND and NJ tubes, if prescribed	
a. A three-way stopcock will have to be placed at the connection of the NJ tube and the line from the feeding fluid.	a. Provides access port for medications without disconnecting the line each time a medication is to be administered.
b. Flush tubing with small amounts of sterile water after medication is administered. Pills should be crushed finely.	b. Ensures that the infant receives entire dosage prescribed, prevents any sediment from remaining in the tubing, and prevents tube clogging.
c. Alternative method for administering oral medications is by-passing an oral–gastric or NG feeding tube.	c. The stomach and process of digestion and absorption are not bypassed.
Follow-up phase	
1. Be constantly alert for mechanical problems:	
a. Tube clogging—check external tube measurement.	a. Because of inadequate flushing or tube advancing too far into the jejunum.
b. Check for abdominal distension by palpating abdomen, measuring abdominal girth every 3 to 8 hours, and checking residual formula in the stomach every 3 to 8 hours.	b. Resulting from the patient's inability to handle ingested amount of fluid.
c. Check external tube measurement.	c. May indicate dislodgement of tube.
2. Discard or refeed residual formula, as prescribed.	2. Increasing residual may cause aspiration.
3. Check stools for occult blood and blood glucose as ordered.	3. Determines tolerance of feeding fluid.
4. Stop feeding and flush tube with warm water every 4 to 6 hours.	4. Maintains patency of tube.
5. Hold and give positive stimulation to the patient, if conditions permit.	5. This procedure limits the normal pleasures associated with feeding. The patient needs attention to oromotor needs.
6. Accurately document condition of the patient and the procedure, including type and amount of feeding given, amount of residual and characteristics, and any signs of impending patient distress or problems.	6. Continuity of care.

PROCEDURE GUIDELINES 43-7

Intravenous Fluid Therapy

EQUIPMENT

Needle method

- IV solution
- The kind of solution is specified by the health care provider.
- For small children, 250-mL bottles should be used for purposes of safety.
- IV pole, pump device.
- IV administration set, pump tubing.
- Micropore filter.
- Syringe, 3 mL—with normal saline solution.
- Butterfly needle or catheter of appropriate gauge.
- The size of the needle depends on the age and size of the child, the size and location of the vascular access, and the type of fluid to be administered.
- Alcohol pads, dry pads.
- Betadine or other antibacterial cleansing solution.
- Normal saline solution.

- Small tourniquet or rubber band.
- 5-0 black silk suture with a straight-eye needle.
- 1% to 2% procaine.
- Normal saline solution.
- Tourniquet.
- Sterile gloves.
- Restraining devices.
- Hypoallergenic (silk or cloth) tape, ½ inch, 1 inch, 2 inches.
- Padded armboard.
- Gauze bandage for securing the extremity to the armboard.
- Restraining devices—bath blanket, extremity restraint, covered sandbags (the type of restraint depends on the child's age, level of cooperation, and the location of the IV line to be started).
- Safety razor (if scalp vein is to be used).

Cutdown Method

- IV solution, IV pole, IV administration set.
- Alcohol wipes.
- Hypoallergenic (silk or cloth) tape, ½ inch, 1 inch, 2 inches.
- Padded armboard.
- Dry wipes.
- Gauze bandage.
- Sterile cutdown tray
- The tray should include the following equipment: medicine cups, sterile treatment towels, wound towel, syringes, 25-gauge 5/8-inch needle and catheter, 20-gauge 1-inch needle, knife handle and #15 blade, forceps, scissors, gauze sponges, 4-0 black silk suture, needle holder.
- Assorted sizes of sterile polyethylene tubing and Luer adapters.
- 5-0 black silk suture with a straight-eye needle.
- 1% to 2% procaine.
- Normal saline solution.
- Tourniquet.
- Sterile gloves.
- Restraining devices.

PROCEDURE

Nursing Action	Rationale
Inserting an IV line	
Preparatory phase	
1. Perform hand hygiene.	1. Standard precautions.
2. Obtain the IV solution.	2. Although the type of solution and the rate of flow are prescribed, the nurse should be aware of the composition of common parenteral solutions and should know how to calculate maintenance therapy.
3. Check the IV fluid for sediment or contaminant by holding the container up to the light. Ensure light-sensitive IV fluids are properly contained and covered.	3. Contaminant is most easily identified with the container in this position. If sediment is observed, the solution should be discarded.
4. Check the container for cracks.	4. If a flash of light can be seen through the bottle, it has a razor-thin crack and should be discarded.
5. Attach a micropore filter to the end of the infusion tubing that attaches to the catheter hub. Use aseptic technique.	5. A 0.45-μm filter prevents entry into the vein of larger particles, air emboli, and most bacterial and fungal organisms except some *Pseudomonas* organisms. A 0.22-μm filter prevents entry of any organisms but requires the use of an IV pump.
6. Remove the seal from the IV container without touching the rubber top.	6. Do not use the solution if the seal has been broken. It is not necessary to cleanse the sterile, rubber top with alcohol unless it has been accidentally contaminated.

Nursing Action	Rationale
7. Following product information, insert the end of the administration set into the container's opening. Fill the tubing with solution.	
8. Label the IV fluid and tubing with the date, time, and initials.	8. Serves as a reminder of when tubing and fluid should be changed.
9. Perform the procedure in the treatment room unless another location is requested by the patient or his or her family.	9. Although it is usually best to move the child to a different room for the procedure, some children will be less fearful if the procedure is performed in the familiar surroundings of their own rooms.
10. Promote the cooperation of the child. The family may be present, if desired.	10. The procedure will be less traumatic if the child is cooperative and does not resist.
a. *Infant*: Provide with a pacifier.	
b. *Young child*: Avoid placing IV into the dominant extremity (i.e., the hand used to suck the thumb).	
c. *Older child*: Explain the procedure and its purpose.	
d. *Adolescent*: Give choice as to the location of the IV, if possible.	
11. Position the child for comfort.	
12. Restrain the child, as necessary.	12. Protective devices may be necessary to prevent the child from dislodging the IV needle or catheter. The type and size of such devices should be appropriate for the child's age and the position of the IV.
a. *Infant or young child*: Restraints may include mummy wrappings, jacket or elbow restraints, or small sandbags.	
b. *Older child*: The extremity to be used should be comfortably restrained on the armboard. Free extremities may also require light restraints to remind the child not to move.	b. Toes and fingers should be visible to avoid compromising blood flow. The restraint board must be padded and the main pressure points (heel, palm) padded with gauze. Before strapping an extremity to the armboard, back the adhesive with tape or gauze wherever it touches the skin.
Performance phase	
1. The persons starting the IV and holding the infant should wear gloves and other protective equipment (gown, mask, and goggles) if blood splattering is anticipated.	1. Standard precautions.
2. Assist, as necessary.	2. The nurse may insert the IV, based on facility policy.
3. Check the restraints at intervals and adjust them, as necessary.	3. The restraints may become loose after a period of time and must be secured to ensure the child's safety. They may also become too tight and require loosening to maintain adequate circulation.
4. Connect and start IV fluids, as prescribed.	
Follow-up phase	
1. Comfort and reassure the child.	1. The procedure is usually disturbing for the child. This should be acknowledged. If crying and upset, the child should be reassured that this behavior is acceptable.
2. Regulate the IV rate by way of a pump	2. Pump infusion devices should always be used in IV rate regulation of infants and children.

Nursing Action	Rationale
3. Record: • Type of solution being used. • Reading on the container or reservoir. • Rate of flow. • Time that the infusion began. • Name of the physician or nurse who started the IV. • Site of administration. • Reaction of the child to the procedure.	3. Continuity of care.
Irrigating an IV line	
1. Perform hand hygiene. Then, irrigate the IV, as necessary, if an occlusion or infiltration is suspected. Irrigate intermittent infusion devices every 8 hours.	1. Irrigation may be required to dislodge small clots in the catheter or to maintain the infusion rate of a sluggish IV.
2. Gather equipment: • Syringe with 1 to 3 mL normal saline solution or heparinized saline. • Several alcohol wipes.	
3. Clamp off the IV solution.	
4. Disconnect the IV tubing at the catheter insertion site. Keep it sterile by covering the tip with a cap.	4. Tubing can be reinserted and infusion restarted if sterility is maintained.
5. Remove the needle from the syringe.	5. Just the syringe is needed for irrigation.
6. Connect the syringe to the tubing at the catheter insertion site or stopcock.	
7. Slowly inject the normal saline solution or heparinized saline. If the catheter cannot be flushed, it may be occluded or infiltrated and removal may be necessary.	7. Great force of injector should be avoided because this may cause the vein to rupture or the catheter to become dislodged from the vein.
8. Disconnect the syringe and reconnect the IV tubing to the needle insertion site.	
9. Unclamp the IV and regulate the flow of the solution.	
10. Check frequently to make certain that the IV is functioning properly and there is no apparent infiltration.	10. Manipulation of the catheter increases risk of infiltration.
Removing an IV line	
1. Perform hand hygiene. Gather equipment: • Scissors, gloves. • 2 inches × 2 inches gauze square. • Adhesive bandage.	
2. Stop the IV infusion when prescribed or if it has obviously infiltrated.	
3. Explain the procedure to the child (depending on the child's age).	3. Enlists cooperation.
4. Apply gloves.	4. Standard precautions.
5. Remove the tape and armboard from the extremity.	5. Provides open access to IV site.
6. Loosen the tape around the catheter, holding it firmly in position so it does not slip out.	6. Careless dislodgment of the catheter may cause bleeding and bruising.
7. Hold the 2 inches × 2 inches gauze lightly over the insertion site and remove the needle quickly and carefully.	7. Alcohol wipes should not be used for removing IV catheters because the stinging of alcohol on the puncture site causes unnecessary discomfort. If the intracath or plastic needle is not intact, notify the health care provider.
8. Apply pressure to the site immediately and hold until bleeding stops.	8. Aids clotting.

Nursing Action	Rationale
9. Apply adhesive bandage.	9. The bandage should not be applied until all bleeding has stopped to minimize the possibility of prolonged or unnoticed bleeding.
10. Comfort the child as required.	
11. Note the fluid level on the container or reservoir and complete recordings.	11. Documentation for continuity of care.
12. Record that the IV was discontinued.	

For additional information relating to IV therapy, including criteria for selecting a suitable vein for venipuncture, guidelines for administering an infusion using the antecubital fossa, and complications of IV therapy, refer to Chapter 6, Intravenous therapy.

Restraints

EVIDENCE BASE Longo, M. A., & Miller-Hoover, S. (2016). Effective decision making in the use of pediatric restraints. *Journal of Pediatric Nursing, 31*, 217–221.

Protective measures to limit movement may be necessary for restraining children in the health care setting (see Figure 43-2). They can be a short-term restraint to facilitate examination and minimize the child's discomfort during special tests, procedures, and specimen collections. Restraints can also be used for a longer period of time to maintain the child's safety, protection from injury, and/or protection of medically necessary devices.

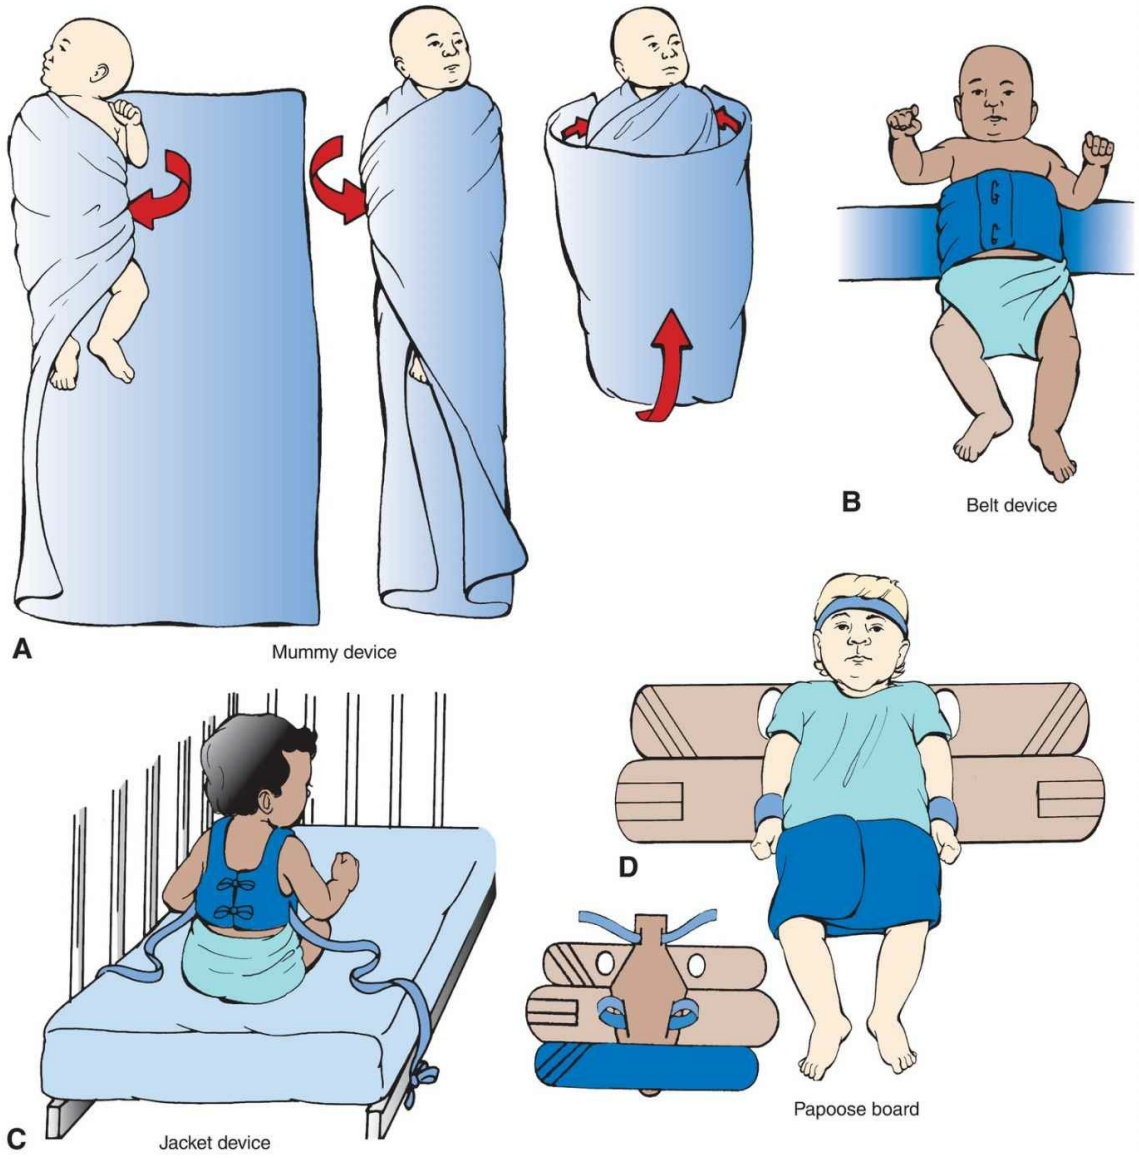

Figure 43-2. Types of restraints.

General Considerations

1. Protective devices should be used only when necessary and after all other considerations are exhausted, never as a substitute for careful observation of the child.
2. Protective devices cannot be used on a continuous basis without an order. Continuous use requires justification and full documentation of the type of restraint used, reason for use, and the effectiveness of the restraint used. Ongoing monitoring, documentation, and renewal of the order, with the length of time the restraint will be in place, are required.
3. The reason for using the protective device should be explained to the child and parents to prevent misinterpretation and to ensure their cooperation with the procedure. Children often interpret restraints as punishment.
4. Teach the child and family about specific devices they may be using in the hospital (ie, side rails) and after discharge (ie, mitts, elbow restraints).

5. Any protective device should be checked frequently to make sure it is effective and is not causing any ill side effects. It should be removed periodically to prevent skin irritation or circulation impairment. Provide range of motion and skin care routinely.
6. Do not cover an IV site with a restraint when possible.
7. Protective devices should always be applied in a manner that maintains proper body alignment and ensures the child's comfort.
8. Any protective device that requires attachment to the child's bed should be secured to the bed springs or frame, never the mattress or side rails. This allows the side rails to be adjusted without removing the restraint or injuring the child's extremity.
9. Any required knots should be tied in a manner that permits their quick release. This is a safety precaution.
10. When a child must be immobilized, an attempt should be made to replace the lost activity with another form of motion. For example, although restrained, a child can be moved in a stroller, in a wheelchair, or in bed. When arms are restrained, the child may be allowed to play kicking games. Water play, mirrors, body games, and blowing bubbles are helpful replacements.
11. Restraints should be removed as soon as the child is no longer considered a danger to self or others or when medical devices are no longer in place.

NURSING ALERT An order from a health care provider is needed to initiate continuous restraints. Proper documentation is required when restraints are in use. Do not secure restraints to bed rails or mattresses. Hourly assessment of the restrained extremity is needed to ensure there has been no impairment of circulation and constriction or respiratory compromise with chest restraints.

Mummy Device

The *mummy device* involves securing a sheet or blanket around the child's body in such a way that the arms are held to the sides and leg movements are restricted (see Figure 43-2). This short-term type of restraint is used on infants and small children during treatments and examinations involving the head and neck.

Equipment

Small sheet or blanket.

Nursing Action

1. Place the blanket or sheet flat on the bed.
2. Fold over one corner of the blanket.
3. Place the child on the blanket with shoulder at the edge of the fold.
4. Pull the right side of the blanket firmly over the child's right shoulder.
5. Tuck the remainder of the right side of the blanket under the left side of the child's body.

6. Repeat the procedure with the left side of the blanket.
7. Separate the corners of the bottom portion of the sheet and fold it up toward the child's neck.
8. Tuck both sides of the sheet under the child's body.
9. Secure by crossing one side over the other in the back and tucking in the excess or by pinning or taping the blanket in place.

Special Precautions

Make certain the child's extremities are in a comfortable position during this procedure. Make sure that the restraint is not obstructing the child's airway.

Jacket Device

The *jacket device* is a piece of material that fits the child like a jacket or halter. Long tapes are attached to the sides of the jacket (see Figure 43-2). Jacket device restraints are used to keep the child in a wheelchair, high chair, or crib.

Nursing Action

1. Put the jacket on the child so the opening is in the back.
2. Tie the strings securely with a knot that can be easily released, if necessary.
3. Position the child in a wheelchair, high chair, or crib.
4. Secure the long tapes appropriately:
   a. Under the arm supports of a chair.
   b. Around the back of the wheelchair or high chair.
   c. To the springs or frame of a crib.

Special Precautions

Children in cribs must be observed frequently to make certain they do not become entangled in the long tapes of the jacket device. Release, reposition, and perform range-of-motion exercises as per hospital policy.

Belt Device

The *belt device* is exactly like the jacket method of restraining, except that the material fits the child like a wide belt and buckles in the back (see Figure 43-2).

Elbow Device

The *elbow device* is a plastic device that fits around the arm at the elbow bend and is secured with a Velcro strap. This type of restraint prevents flexion of the elbow. It is especially useful for pediatric patients receiving IV therapy, those with eczema or other skin rashes, and those following a cleft lip repair, eye surgery, or any other type of procedure or surgery in which touching the upper extremities, head, or neck should be prevented.

Equipment

1. Elbow device.
2. Skin protective material for under the device (long-sleeved shirt or gauze).

Nursing Action

1. Cover the elbow with a long-sleeved shirt or gauze if irritation or sweating is expected.
2. Place the child's arm in the center of the appropriately sized elbow restraint.
3. Wrap the restraint around the child's arm.
4. Secure with Velcro.

Special Precautions

1. The child's fingers should be observed frequently for coldness or discoloration and the skin under the device should be checked for signs of irritation.
2. The device should be removed periodically according to facility policy or standards of care to provide skin care and range of motion.

Devices to Limit Movement of the Extremities

Many different kinds of devices are available to limit motion of one or more extremities. One commercial variety consists of a piece of material with tapes on both ends to be secured to the frame of the bed. The material also has two small flaps sewn to it for securing the child's ankles or wrists. Similar devices are available that use sheepskin flaps. These should be used when the device will be necessary over a prolonged period or for children with sensitive skin. This restraining device may be used to restrain infants and young children for procedures, such as IV therapies and urine collection.

Equipment

1. Extremity restraint of appropriate size for the child (small, medium, or large).

Nursing Action

1. Secure the device to the crib or bed frame.
2. Velcro the small flaps securely around the child's ankles or wrists.

Special Precautions

1. The child's fingers or toes should be observed frequently for coldness or discoloration and the skin under the device should be checked for signs of irritation.
2. The device should be removed periodically according to policy or standards of care to provide skin care and range-of-motion exercises and documentation should be completed.

Abdominal Device

The *abdominal device* is used for restraining a small child in a crib. It operates exactly like the method described for limiting the movements of extremities. However, the strip of material is wider and has only one wide flap sewn in the center for fastening around the child's abdomen.

Mitts

Mitts are used to prevent a child from injuring self with his or her hands and from removing tubes or IV lines. They are especially useful for children with dermatologic conditions such as eczema or burns and for those with nasogastric or nasojejunal feeding tubes. Mitts can be purchased commercially or made by wrapping the child's hands in Kling gauze or by covering the child's hands with a pair of clean socks and securing them to the wrist with tape.

NURSING ALERT Mitts should be removed at least every 4 hours to permit skin care and to allow the child to exercise fingers.

Crib Top Device

A *crib top device* is used to prevent an infant or small child from climbing over the crib sides. Several types of commercial devices are available, including nets, plastic tops, and domes. A crib top device should be applied to the crib of a child capable of climbing over the crib sides (usually between ages 1 and 4).

NURSING ALERT In all instances, it is essential to be certain that the crib sides are kept all of the way up and latched securely.

Papoose Board

A papoose board is a restraint device to be used for procedures of the head, chest, and abdomen. Straps restrain the child or infant at the forehead, lower arms, and thighs (see Figure 43-2, page 1155).

Specimen Collection

Evaluation of specimens such as blood, urine, and stool is important in determining the status of the child. The nurse should be adept in the techniques for obtaining specimens, as well as meticulous in labeling and recording them.

KEY DECISION POINT

Anticipate bleeding if venipuncture was difficult. Hold pressure over the area until oozing has stopped (longer if the child is being treated with aspirin or an anticoagulant). Assess frequently and reapply pressure, if needed; report continued oozing or hematoma formation.

EVIDENCE BASE Bowden, V. R., & Greenberg, C. S. (2015). *Pediatric nursing procedures* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

For catheterization of the urinary bladder, refer to Chapter 21. For infants and children, the catheter size is 6 to 10 F, depending on the size of the child.

EVIDENCE BASE Patel, V., Romano, M., Corkins, M., et al. American Society for Parenteral and Enteral Nutrition. (2014). Nutrition screening and assessment in hospitalized patients: A survey of current practice in the United States. *Nutrition in Clinical Practice, 29*(4), 483–490.

Feeding and Nutrition

Nutritional requirements may increase while infant or child is ill, but the ability to feed naturally may be impaired by illness or the child's response to illness. If existing feeding patterns cannot be maintained, alternate methods may be necessary. The ability to feed enterally is preferred over parenteral nutrition because of decreased risk of complications as well as improved physiological response.

Gavage Feeding

KEY DECISION POINT

If improper placement occurs and the catheter enters the trachea, the patient may cough, fight, and become cyanotic. Remove the catheter immediately and allow the patient to rest before attempting to insert the tube again.

KEY DECISION POINT

If bradycardia occurs, remove tube and allow the patient to relax. If the child appears to be in distress, follow basic life support protocols and contact the health care provider. When the patient's vital signs normalize, attempt tube replacement.

EVIDENCE BASE Clifford, P., Heimall, L., Brittingham, L., et al. (2015). Following the evidence: Enteral tube placement and verification in neonates and young children. *The Journal of Perinatal & Neonatal Nursing, 29*(2), 149–161.

---

1. *Gavage feeding* is a means of providing food by way of a catheter passed through the nares or mouth, past the pharynx, down the esophagus, and into the stomach, slightly beyond the cardiac sphincter. Feedings may be continuous or intermittent.
2. Gavage feedings can provide a method of feeding or administering medications that require minimal patient effort when the child is unable to suck or swallow adequately.
3. Gavage feedings can be used to administer supplemental calories to a patient who is unable to meet their caloric needs by mouth. They also can be used to provide full calories to those unable to tolerate oral intake.
4. Gavage feedings can prevent fatigue or cyanosis that can occur from bottle-feeding in susceptible infants. They can provide supplements for an infant who is a poor bottle-feeder.
5. Gavage feedings can provide a safe method of feeding patients with hypotonia, patients experiencing

respiratory distress, patients with uncoordinated suck and swallow, patients that are intubated, patients with a debilitation, and patients with anomalies of the digestive tract.

Gastrostomy Feeding

KEY DECISION POINT

If the gastrostomy tube becomes dislodged and if it is newly placed (less than 6 weeks), replace tube (if allowed in scope of practice) with gastrostomy tube or Foley catheter and secure tube. Frequently, a smaller size must be used if the stoma is closing. Notify health care provider before using the tube, as oftentimes imaging will be needed to confirm correct tube placement, and accurately record events.

If gastrostomy tube is established (more than 6 weeks) and dislodged, replace with a Foley catheter or comparable-sized gastrostomy tube and aspirate the tube for gastric contents. If gastric contents are obtained, feeds may be resumed. If there is difficulty verifying placement, notify the health care provider.

1. Gastrostomy feeding is a means of providing nourishment and fluids by way of a tube that is surgically inserted through an incision made through the abdominal wall into the stomach. A gastrostomy tube may also be placed surgically or by endoscopy using interventional radiology. Gastrostomy placement is the method of choice for those requiring tube feedings for an extended period of time (usually longer than 4 to 6 months).
2. Gastrostomy feedings provide a safe method of feeding a hypotonic or debilitated patient or one who cannot tolerate alternative methods. Prolonged feeding problems occur frequently in those with physical disabilities, prematurity, and chronic disease. Gastrostomy feedings may provide a route that allows adequate calorie or fluid intake in a child with chronic lung disease or in one who does not have continuity of the GI tract, such as in esophageal atresia, chronic reflux, or aspiration processes.
3. Gastrostomy tubes can also allow better decompression of the stomach because of larger tube size.

Community and Home Care Considerations

TRANSITIONAL CARE ALERT If gastrostomy feedings are likely to be ordered upon discharge, involve caregivers in early education. Ensure that home health team is ready to support patient and family immediately upon discharge.

---

1. Teach the child (if age appropriate) and caregivers about the gastrostomy tube and feeding regimen.
   a. Anatomy of tube placement.
   b. Type of gastrostomy tube (button or tube).
   c. Amount and timing of feedings.

d. Signs and symptoms of problems—tube obstruction or displacement, distended stomach, infection.
e. Appropriate actions to be taken if problems occur—call home care nurse or health care provider.

2. Teach use of equipment: syringes, feeding bag, feeding tubing.
3. Teach the use of feeding pump (for continuous feedings or slow boluses).
4. Teach care of the gastrostomy tube—how to clamp, observe for leakage, determine amount of water in the balloon, and how to change a gastrostomy tube at home, if the site is mature and family is willing to learn.
5. Teach stoma care—clean area with soap and water, observe for breakdown, and apply skin barrier cream or powder, as appropriate.
6. Instruct about formula—proper mixing if not reconstituted; need to refrigerate if opened; discard any unused and nonrefrigerated formula after 4 hours.
7. Teach measures to take in an emergency.
   a. Procedure to follow if the tube falls out—replace tube (gastrostomy or Foley catheter), secure and cover site with gauze dressing, and call health care provider or proceed to emergency room if the tube has been in place less than 6 weeks. If tube has been in place for longer than 6 weeks, the tube may be replaced by the family or home care nurse.
   b. Troubleshooting for nonfunctioning equipment—ensure that the pump is plugged in and turned on; tubing is unclamped, not kinked; and abdomen is not distended.
   c. Proper phone numbers available to have as a resource or to obtain assistance.
8. Perform regular home visits as prescribed to assess nutritional and hydration status of the child, check tube placement and stoma site, and modify the care plan, as needed.

Nasojejunal and Nasoduodenal Feedings

KEY DECISION POINT

If abdominal pain, distention, diarrhea, or vomiting occurs, stop feeds and check emesis and stools for gross blood and report to health care provider immediately—this may be a sign of necrotizing enterocolitis.

1. Nasojejunal (NJ) or nasoduodenal (ND) feedings are means of providing full enteral feedings by way of a catheter passed through the nares, past the pharynx, down the esophagus, through the stomach, through the pylorus into the duodenum or jejunum.
2. Duodenal or jejunal feedings may decrease the risk of aspiration and can minimize regurgitation and gastric distention because the feeding bypasses the stomach and pylorus.
3. ND and NJ feedings provide a route that allows for adequate calorie or fluid intake (a full enteral feeding) by way of continuous drip.
4. ND or NJ feedings may also provide a route for administration of enteral medications.

5. ND or NJ feedings can provide a method of feeding that requires minimal patient effort when the child or infant is unable to tolerate alternative feeding methods (low birth weight, increased respiratory effort, and intubated patient).
6. ND or NJ feeding tubes may be placed under fluoroscopy, endoscopically, or at the bedside.

Fluid and Electrolyte Balance

EVIDENCE BASE Parker, S., Benzies, K., Hayden, K., et al. (2017). A systematic review: effectiveness of pediatric peripheral intravenous catheterization strategies. *Journal of Advanced Nursing, 73*(7), 1570–1582.

Basic Principles

1. Infants and small children have different proportions of body water (see Table 43-3) and body fat than adults.
   a. The body water of a neonate is approximately 75% of body weight compared with that of an average adult man, which is approximately 60%.
   b. The normal neonate demonstrates a rapid physiologic decline in the ratio of body weight to body water during the immediate postpartum period.
   c. Proportion of body water declines more slowly throughout infancy and reaches the characteristic value for adults by about age 2 years.
2. Compared with adults, a greater percentage of the body water of infants and small children is contained in the extracellular compartment.
   a. Infants—approximately one half of the body water is extracellular.
   b. Adults—approximately one third of the body water is extracellular.
3. Compared with adults, the water turnover rate per unit of body weight is three or more times greater in infants and small children.
   a. The child has more body surface in relation to weight.
   b. The immaturity of kidney function in infants may impair their ability to conserve water.
4. Electrolyte balance depends on fluid balance and cardiovascular, renal, adrenal, pituitary, parathyroid, and pulmonary regulatory mechanisms (see Table 43-4).
5. Infants and children are more vulnerable to dehydration than adults.
   a. The basic principles relating to fluid balance in children make the magnitude of fluid losses considerably greater in children than in adults.
   b. Children are prone to severe disturbances of the GI tract that result in diarrhea and vomiting.
   c. Young children cannot independently respond to increased losses by increased intake. They depend on others to provide them with adequate fluid.

Table 43-3 Body Fluids Expressed as Percentage of Body Weight

FLUID	ADULT		
	MALE (%)	FEMALE (%)	INFANT (%)
Total body fluids	60	54	75
Intracellular	40	36	35
Extracellular	20	18	40

Table 43-4 Common Abnormalities of Fluid and Electrolyte Metabolism

SUBSTANCE AND MAJOR FUNCTION	ABNORMALITY	CAUSE	CLINICAL MANIFESTATION	LABORATORY DATA
Water				
Medium of body fluids, chemical changes, body temperature, lubricant	Volume deficit	• Primary—inadequate water intake • Secondary—loss following vomiting, diarrhea, and GI obstruction	Oliguria, weight loss, signs of dehydration including dry skin and mucous membranes, lassitude, sunken fontanelles, lack of tear formation, increased pulse rate, decreased blood pressure	Concentrated urine; azotemia; elevated hematocrit, hemoglobin level, erythrocyte count, and sodium level
	Volume excess	• Failure to excrete water in the presence of normal intake, such as in cardiac disease or failure or renal disease • Water intake in excess of output	Weight gain, peripheral edema, signs of pulmonary congestion	Variable urine volume, low specific gravity of urine, decreased hematocrit
Potassium				
Intracellular fluid balance, regular heart rhythm, muscle and nerve irritability	Potassium deficit	• Excessive loss of potassium because of vomiting, diarrhea, prolonged cortisone, corticotropin or diuretic therapy, diabetic acidosis • Shift of potassium into the cells, such as occurs with the healing phase of burns, recovery from diabetic acidosis	Signs and symptoms variable, including weakness, lethargy, irritability, abdominal distention, and, eventually, cardiac arrhythmias	Low plasma potassium level (<3.5 mEq/L) may be normal in some situations; hypochloremic alkalosis; ECG changes
	Potassium excess	• Excessive administration of potassium-containing solutions, excessive release of potassium because of burns, severe kidney disease, adrenal insufficiency • Beta-blocker therapy	Variable, including listlessness, confusion, heaviness of the legs, nausea, diarrhea, abdominal cramping, ECG changes, and, ultimately, paralysis and cardiac arrest	Elevated potassium plasma level; decreased arterial pH; ECG abnormalities
Sodium				
Osmotic pressure, muscle and nerve irritability	Sodium deficit	• Water intake in excess of excretory capacity, replacement of fluid loss without sufficient sodium; excessive sodium losses	Headache, nausea, abdominal cramps, confusion alternating with stupor, diarrhea, lacrimation, salivation, later hypotension; early polyuria, later oliguria	Sodium plasma level may be normal or low (<135 mEq/L).
	Sodium excess	• Inadequate water intake especially in the presence of fever or sweating; increased intake without increased output; decreased output	Thirst, oliguria, weakness, muscular pain, excitement, dry mucous membranes, hypotension, tachycardia, fever, agitation	Elevated sodium plasma level (>148 mEq/L), high plasma volume
Bicarbonate				
Acid–base balance	Primary bicarbonate deficit	• Diarrhea (especially in infants), diabetes mellitus, starvation, infectious disease, shock or cardiac failure producing tissue anoxia and renal failure	Progressively increasing rate and depth of respiration—ultimately becoming Kussmaul respiration; flushed, warm skin; weakness; disorientation progressive to coma	• Urine pH usually <6.0 • Plasma bicarbonate < 20 mEq/L • Plasma pH < 7.35
	Primary bicarbonate excess	• Loss of chloride through vomiting, gastric suction, or the use of excessive diuretics; excessive ingestion of alkali	Depressed respiration, muscle hypertonicity, hyperactive reflexes, tingling of fingers and toes, tetany, and, sometimes, convulsions	Urine pH usually >7, plasma bicarbonate > 26 mEq/L (30 mEq/L in adults), plasma pH > 7.45

Common Fluid and Electrolyte Therapy

1. Repair of preexisting deficits that may occur with prolonged or severe diarrhea or vomiting.
   a. Deficits are estimated and corrected as soon and as safely as possible.
   b. Initial therapy is aimed at restoring intravascular and intracellular fluid volume to relieve or prevent shock and restore renal function.
   c. Intracellular deficits are replaced slowly over an 8- to 12-hour period after the circulatory status is improved.
2. Provision of maintenance requirements.
   a. Maintenance requirements occur as a result of normal expenditures of water and electrolytes because of metabolism.
   b. Maintenance requirements bear a close relationship to metabolic rate and are ideally formulated in terms of caloric expenditure.
3. Correction of concurrent losses that may occur by way of the GI tract as a result of vomiting, diarrhea, or drainage of secretions.
4. Replacement should be similar in type and amount to the fluid being lost.
5. Replacement is usually formulated as milliliters of fluid and milliequivalents of electrolytes lost.

Intravenous Fluid Therapy

IV therapy refers to the infusion of fluids directly into the venous system. This may be accomplished through the use of a needle or by venous cut down and insertion of a small catheter directly into the vein (see Figure 43-3). IV therapy is used to restore and maintain the child's fluid and electrolyte balance and body homeostasis when oral intake is inadequate to serve this purpose

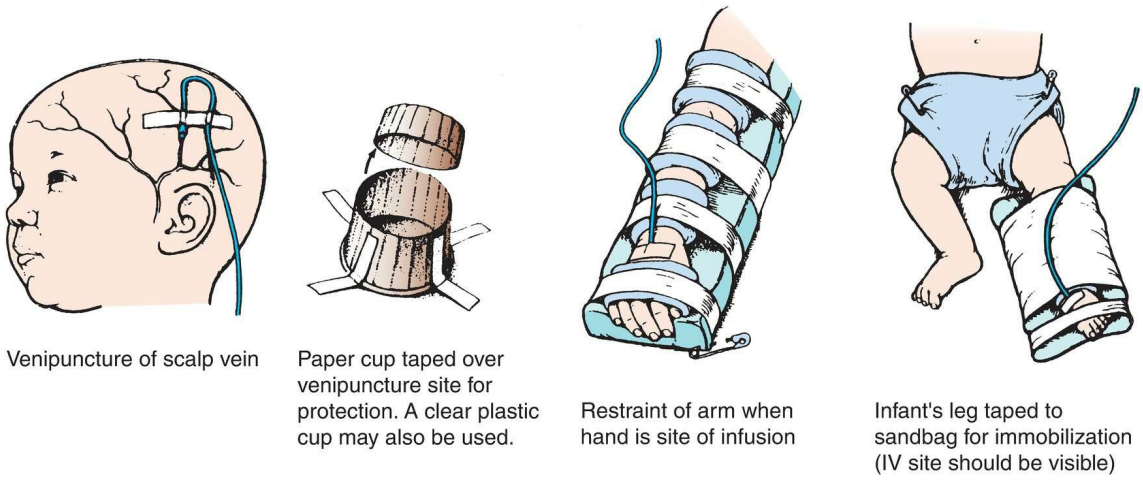

Figure 43-3. IV fluid therapy.

1. Infusion pumps are often used in pediatrics to provide a controlled, constant rate of infusion.

2. Because infants and children are vulnerable to fluid shifts, the rates need to be monitored carefully.
3. During an IV infusion, every hour, check the following:
    a. Rate of infusion.
    b. Volume delivered.
    c. IV site for infiltration, because many pumps will continue to infuse solution even if infiltration has occurred.

See Standards of Care Guidelines 43-1.

Standards of Care Guidelines 43-1

Pediatric IV Therapy

When caring for a child undergoing IV therapy:

- Check IV site hourly, noting skin color and evidence of swelling. Compare to the opposite extremity or look for asymmetry. Feel area for sponginess. Observe for leakage.
- Check the IV tubing and equipment hourly. Stop the infusion if any cracks are noted in the tubing or there is discoloration of the IV fluid.
- Record the reading on the container or reservoir, amount of fluid absorbed in the hour, flow rate.
- Check for blood return in the tube by stopping IV fluid flow. It may be normal not to see blood return due to small catheter size.
- Check function of pump rate set versus amount infused.
- Maintain accurate intake and output record and 24-hour totals.
- Describe consistency and approximate volume of all stools and vomitus.
- Weigh child at regular intervals, using the same scale each time. An increase or decrease of 5% body weight in a relatively brief time period is usually significant.
- Monitor electrolytes (see Table 43-4, page 1160).
- Report evidence of electrolyte imbalances: decreased skin turgor, marked increase or decrease in urination, fever, sunken or bulging fontanelles, sudden change in vital signs, diarrhea, weakness, lethargy, apathy, pyrogenic reactions, and arrhythmias.
- If the child is experiencing severe reactions, the IV should be discontinued and the solution saved for possible analysis.
- Change the IV container and tubing every 24 hours or as per facility policy.
- If infiltration occurs, remove the IV, raise the affected extremity, apply heat to the site, and restart the IV at an alternative site. Notify the health care provider if irritation develops or toxic medication has infiltrated.

This information should serve as a general guideline only. Each patient situation presents a unique set of clinical factors and requires nursing judgment to guide care, which may include additional or alternative measures and approaches.

Cardiac and Respiratory Monitoring

Cardiac and respiratory monitoring refers to electrical surveillance of heart and respiratory rates and patterns. It is indicated for patients whose conditions are unstable, patients with cardiac or respiratory disorders, and patients receiving anesthesia or conscious sedation.

Nursing Management

1. Select a monitor that is appropriate for the child's needs. This will depend on the child's age and ability to cooperate, purpose for monitoring, information desired, and equipment available.
2. Stabilize the device to reduce the amount of mechanical noise and for safety considerations. Ensure the equipment is functioning well and there are no frayed cords. Plug into an emergency power outlet.
3. Reduce the child's anxiety:
    a. Provide age-appropriate explanations of the equipment.
    b. When possible, involve the child in care, including change of electrodes.
4. Select lead placement sites according to equipment specifications:
    a. Cardiac monitors frequently use three leads located at:
        i. Right upper chest wall below the clavicle.
        ii. Left lower chest wall in the anterior axillary line.
        iii. Left upper chest wall below the clavicle.
    b. Respiratory monitors frequently use three electrodes located:
        i. On either side of the chest (anterior axillary line in fourth or fifth intercostal space).
        ii. A reference electrode placed on the manubrium or other suitable distal point.
5. Apply electrodes by:
    a. Cleaning the appropriate areas on the chest with soap and water.
    b. Placing pregelled, disposable electrodes to dry skin.
6. Plug the leads into the lead cable at appropriate insertion points.
7. Make sure that the monitor alarms are in the "on" position. High- and low-alarm limits should be set according to the child's age and condition so that apnea, tachypnea, bradycardia, and tachycardia can be readily detected.
8. Avoid skin breakdown by changing lead placement sites, as needed. Clean and dry old sites and expose them to air.
9. Check integrity of the entire system at least once per shift.
    a. Carefully inspect lead wires and cable for breaks and proper attachment.
    b. If malfunction is suspected, change equipment and notify the engineering department or manufacturer immediately.
10. Continue to count respiratory and apical rates at least once per shift.
    a. Compare with monitor rates to verify accuracy of equipment.

b. It must be remembered that monitors cannot substitute for close observation and nursing assessments of the child.

EVIDENCE BASE American Heart Association. (2015). *BLS for the healthcare provider: Student manual*. Dallas, TX: Author.

Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation (CPR) involves measures instituted to provide effective ventilation and circulation when the patient's heart and lungs have ceased to function. In children, the most common initial cause is respiratory distress.

Underlying Considerations

Cardiac Arrest

1. Signs—absence of heartbeat and absence of carotid and femoral pulses.
2. Causes—asystole, ventricular fibrillation, cardiovascular collapse, shock, or progression of respiratory failure.

Respiratory Arrest

1. Signs—apnea and cyanosis.
2. Causes—obstructed airway, depression of the central nervous system, neuromuscular paralysis.

Emergency Preparation

1. Every hospital should have a well-defined and organized plan to be carried out in the event of cardiac or respiratory arrest.
2. Emergency carts should be placed in strategic locations in the hospital and checked daily to ensure that all equipment is available.
3. Personnel should be trained in up-to-date CPR maneuvers and be certified in basic life support at least every 2 years.

Equipment

1. Emergency cart—assembled and ready for use.
2. Positive pressure breathing bag with nonrebreathing valve and universal 15-mm adapter.
3. Mask (premature neonate, child, adult sizes).
4. Oropharyngeal airway tubes, sizes 0 to 4.
5. Laryngoscope with blades of various sizes.
6. Extra batteries and light bulbs for laryngoscope.
7. Endotracheal tubes with connectors (complete sterile set, 2.5- to 8-mm inner diameter).
8. Portable suction equipment and sterile catheters of various sizes.
9. Bulb syringe, DeLee trap.
10. Oxygen source—portable supply, gauge, and tubing.
11. Cardiac board (30 × 50 cm).
12. Emergency drugs:
    a. Sodium bicarbonate.

b. Epinephrine.

c. Isoproterenol.

d. Normal saline solution (for dilution).

e. Diphenhydramine.

f. Diazepam.

g. Hydrocortisone sodium succinate.

h. Digoxin.

i. Naloxone.

j. Calcium gluconate.

k. Calcium chloride 10%.

l. Dextrose 50%.

m. Lidocaine.

n. Atropine.

o. Phenytoin.

p. Insulin.

q. Procainamide.

r. Propranolol.

s. Dopamine.

t. Bretylium tosylate.

u. Volume expanders (lactated Ringer solution, normal saline solution).

v. Vasopressin.

w. Amiodarone.

x. Magnesium sulfate.

y. Vecuronium.

13. Intracardiac needles, 20G and 22G, 2 to 3 inches long.

14. IV equipment, including infusion set, IV fluids.

15. Tourniquet, armboards, and tape.

16. Scalp vein needles of various sizes.

17. Gloves, mask, gown, other protective barriers.

18. Nasogastric tubes of various sizes.

19. Syringes and syringe needles of various sizes.

20. Intraosseous needles.

21. Long dwell catheters of various sizes.

22. Three-way stopcock.

23. Cutdown set.

24. Alcohol wipes.

25. Tongue blades.
26. Sterile 4″ × 4″ gauze pads.
27. Sterile hemostat.
28. Sterile scissors.
29. Blood specimen tubes.
30. Electrocardiograph (ECG) monitor, lead wires.
31. Defibrillator and paddles (pediatric and adult), lubricating jelly.
32. Arrest documentation record and patient-specific labels.

Artificial Ventilation

Mouth-to-Mouth Technique

1. Infants:
    a. Slightly extend neck by gently pulling chin up and forward and the head back by pressing forehead into a neutral position (known as head tilt–chin lift; use jaw thrust if cervical trauma is suspected). Place a rolled towel or diaper under the infant's shoulder or use one hand to support the neck in an extended position. Do not hyperextend the neck because this narrows the airway.
    b. Check the mouth and throat, and clear mucus or vomitus with finger or suction, if visible.
    c. Take a breath.
    d. Make a tight seal with your mouth over the infant's mouth and nose.
    e. Gently blow air from the cheeks and observe for chest rise. Give a total of two slow breaths.
    f. Remove your mouth from infant's mouth and nose and allow the infant to exhale.
    g. If spontaneous respiration does not return, continue breathing at a rate and volume appropriate for the size of the infant (usually 12 to 20 times/minute or 1 breath every 3 to 5 seconds).
2. Children older than age 1 year:
    a. Clear mouth of mucus or vomitus with fingers or suction.
    b. Extend neck with one hand or a rolled towel (head tilt, chin lift, or jaw thrust, if cervical trauma is suspected).
    c. Clamp the nostrils with the fingers of one hand, which also continues to exert pressure on the forehead to maintain the neck extension.
    d. Take a deep breath.
    e. Make a tight seal with your mouth over the child's mouth.
    f. Force air into the lungs until the chest expansion is observed.
    g. Release your mouth from the child's mouth and release nostrils to allow the child to exhale passively. Give a total of two slow breaths.
    h. Repeat approximately 10 to 12 times/minute or 1 breath every 5 to 6 seconds if spontaneous breathing does not occur.

Hand-Operated Ventilation Devices

1. Remove secretions from mouth and throat and move chin forward.
2. Appropriately extend the neck with one hand or place a diaper roll behind the neck.
3. Select an appropriate-sized mask to obtain an adequate seal and connect mask to bag.
4. Hold the mask snugly over the mouth and nose, holding the chin forward and the neck in extension.
5. Squeeze the bag, noting inflation of the lungs by chest expansion. If there is no chest expansion, realign the patient's head and adjust the mask; retry.
6. Release the bag, which will expand spontaneously. The child will exhale and the chest will fall.
7. Repeat 12 to 20 times/minute (depending on the size of the child).
8. Because this technique is commonly difficult to master, it should be practiced in advance, under supervision.

Indications of Effective Technique

1. Victim's chest rises and falls.
2. Rescuer can feel in his or her own airway the resistance and compliance of the victim's lungs as they expand.
3. Rescuer can hear and feel the air escape during exhalation.
4. Victim's color improves.

Management of Complications

1. Gastric distention (occurs frequently if excessive pressure is used for inflation).
    a. Turn victim's head and shoulders to one side.
    b. Exert moderate pressure over the epigastrium between the umbilicus and the rib cage.
    c. A nasogastric tube may be used to decompress the stomach.
2. Vomiting.
    a. Turn patient on side for drainage.
    b. Clear the airway with finger or suction.
    c. Resume ventilations after the airway is clear and patent.

Artificial Circulation

General Principles Related to Artificial Circulation

See Table 43-5, page 1164. See also Figure 43-4, page 1164.

Table 43-5 Technique of Artificial Circulation

SIZE OF CHILD	PREPARATORY PHASE	ACTION PHASE	COMPRESSION	RATE
Neonate, premature, or otherwise small infant	1. Place in supine position. 2. Encircle the chest with the hands, with thumbs over the midsternum. *or* Use method for a larger infant.	1. Compress midsternum with both thumbs, gently but firmly.	1/3 the depth of the chest (~1½ inches)	At least 100/min
Larger infant	1. Place on a firm, flat surface. 2. Support the back with one hand or use a small blanket under the shoulders. 3. Place the tips of the index and middle fingers of one hand over the midsternum, just below the nipple line.	1. Compress the midsternum with the tips of the index and middle fingers.	1/3 the depth of the chest (~1½ to 2 inches)	At least 100/min
Small child	1. Place on a firm, flat surface. 2. Support the back by slipping one hand beneath it, or use a small blanket. 3. Place the heel of one hand over the midsternum, parallel with the long axis of the body (at the nipple line).	1. Apply a rapid downward thrust to the midsternum, keeping the elbow straight. 2. Instantly and completely release the pressure so the chest wall can recoil. 3. Do not remove the heel of the hand from the chest.	1/3 the depth of the chest (~2 inches)	At least 100/min
Larger child, adolescent	1. Place on a flat, firm surface, or place a board under the thorax. 2. Place the heel of one hand on the lower half of the sternum, about 1 to 1½ inches (2.5 to 3.8 cm) from the tip of the xiphoid process and parallel with the long axis of the body. 3. Place the other hand on top of the first one (may interlock fingers). 4. Place shoulders directly over child's sternum, to use own weight in application of pressure.	1. Exert pressure vertically downward to depress lower sternum, keeping elbows straight. 2. Instantly and completely release the pressure so the chest wall can recoil. 3. Do not remove the hands from the chest.	2 inches (5 cm)	At least 100/min

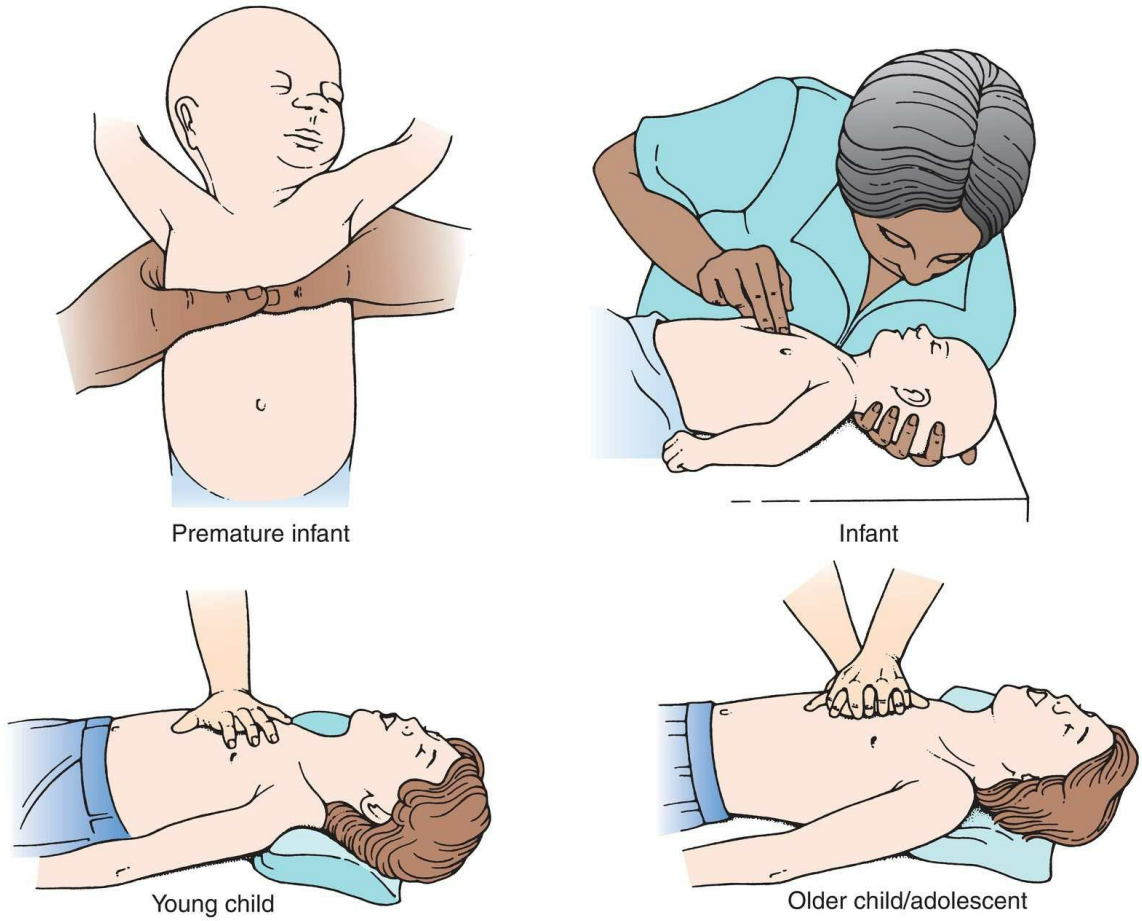

Figure 43-4. Cardiopulmonary resuscitation in children. In the young child, the heel of the hand is placed over the lower sternum at the nipple line. In older children and adolescents, both hands are used.

1. A backward tilt of the head lifts the back in infants and small children. A firm support beneath the back is therefore essential if external cardiac compression is to be effective.
2. A supine position on a firm surface is mandatory. Only in this position can chest compression squeeze the heart against the immobile spine enough to force blood into the systemic circulation.
   Because most infant/child cardiac arrests are the result of respiratory failure or shock, there is a decrease in the oxygen levels in the blood prior to the arrest. Thus, chest compressions alone are not an effective method for delivering oxygen to the heart and brain.
3. This is different from cardiac arrest in an adult, in which the blood usually has a high level of oxygen and compressions alone are an effective way to deliver oxygen to the heart and brain.
4. Compressions must be regular, smooth, and uninterrupted. Avoid sudden or jerking movements. Push hard and push fast. Compressions should be done at a rate of at least 100 compressions/minute.
5. The chest must recoil (return to normal position) fully after each compression.
6. Between compressions, the fingers or heel of the hand must completely release their pressure but should remain in constant contact with the chest. This allows for complete recoil of the chest while minimizing interruptions to the compressions.

7. Fingers should not rest on the patient's ribs during compression. Pressure with fingers on the ribs or lateral pressure increases the possibility of fractured ribs and costochondral separation.
8. Never compress the xiphoid process at the tip of the sternum. Pressure on it may cause laceration of the liver.
9. Indications of effective technique include the following:
    a. A palpable femoral or carotid pulse.
    b. Decrease in size of pupils.
    c. Improvement in the patient's color.

Nursing Management

1. Recognize cardiac and respiratory arrest.
2. Send for assistance and note time.
3. Initiate CPR:
    a. Check for responsiveness and breathing; if the patient is unresponsive and not breathing, palpate a pulse. Checking for a pulse should not take more than 10 seconds.
    b. If no pulse is felt, institute artificial circulation using appropriate technique.
    c. For an infant or child, each cycle contains a ratio of 30 compressions to two breaths, starting with compressions.
    d. Continue repeating this cycle until help arrives.
    e. If alone, perform CPR as previously described for five cycles or 2 minutes of CPR, then call for help. After call, resume CPR until help arrives.
4. When help arrives:
    a. One rescuer performs mouth-to-mouth resuscitation or institutes bag breathing.
    b. Another rescuer performs cardiac compressions.
    c. A ratio of 15 compressions to two breaths is maintained for both infants and children.
    d. Cardiac compression should not be stopped for respiration. Breaths should be interposed on the upstroke of each fifth cardiac compression.
5. Anticipate and assist with emergency procedures.
    a. Assist with intubation, monitoring, placement of intravascular access, administration of IV fluids, defibrillation, and other definitive measures.
    b. Prepare and administer emergency medications, as prescribed. Record dose and time.
    c. Notify family of current management and CPR.
6. After resuscitation:
    a. Care for the child, as required.
    b. Determine if family members have been notified and are being cared for.
    c. Record all events.
    d. Restock emergency cart.

TRANSITIONAL CARE ALERT After the stress of having a hospitalized child, families will need support in the transition to home or another aftercare location. It is crucial that they have complete and understandable care instructions on home care, medications, and follow-up appointments. If arrangements have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to assist understanding, pictorial) instructions on signs and symptoms to monitor that could suggest worsening of status.

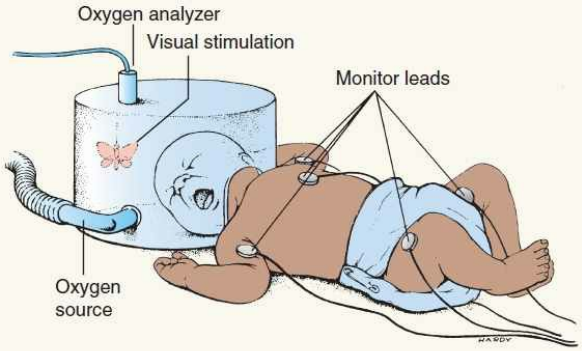
Oxygen Therapy for Children

PROCEDURE

Nursing Action	Rationale
1. Explain the procedure to the child and allow the child to feel the equipment and the oxygen flowing through the tube and mask.	1. The child will be reassured if he or she understands the procedure and knows what to expect.
2. Maintain a clear airway by suctioning, if necessary.	2. The delivery of oxygen requires a clear airway.
3. Provide a source of humidification.	3. Oxygen is a dry gas and requires the addition of moisture to prevent drying of the tracheobronchial tree and thickening and consolidating secretions.
4. Measure oxygen concentrations every 1–2 hours when a child is receiving oxygen through incubator hood. a. Measure when the oxygen environment is closed. b. Measure the concentration close to the child's airway. c. Record oxygen concentrations and simultaneous measurements of the pulse and respirations.	4. It is desirable to keep the oxygen concentration as low as possible while still providing for physiologic requirements. This minimizes the child's risk of developing retinopathy of prematurity. (Desired oxygen concentrations are determined by the arterial oxygen tension measurement.) The oxygen analyzer should be calibrated daily on both room air and 100% oxygen. The concentration of oxygen within the space is determined by litre flow, efficiency of the equipment, and frequency with which it is opened to the external environment.
5. Observe the child's response to oxygen.	5. Desired response includes the following: a. Decreased restlessness. b. Decreased respiratory distress. c. Improved color. d. Improved vital sign values.
6. Organize nursing care so interruption of therapy is minimal.	6. Interruption of therapy may result in the return of anoxia and defeats the goals of therapy.
7. Periodically check all equipment during each span of duty.	7. For optimal functioning, the equipment should be clean, undamaged, and in good working order.
8. Clean equipment daily and change it at least once per week. (Tubing and nebulizer jars should be changed daily.)	8. Unclean equipment may be a source of contamination.
9. Keep combustible materials and potential sources of fire away from oxygen equipment. a. Avoid using oil or grease around oxygen connections. b. Avoid the use of wool blankets and those made from some synthetic fibers. c. Prohibit smoking in areas where oxygen is being used. d. Have a fire extinguisher available. e. Avoid lengthy oxygen tubing in any young child that is not being constantly supervised.	9. Oxygen supports combustion. a. Are easily combustible. b. May cause injury due to static electricity. c. Limits the risk of fire. e. May be at risk for injury including strangulation in active children.
10. Terminate oxygen therapy gradually. a. Slowly reduce litre flow. b. Open air vents in incubators.	10. Allows the child to adjust to normal atmospheric oxygen concentrations.
11. Continually monitor the child's response during weaning. Observe for restlessness, increased pulse rate, respiratory distress, and cyanosis.	11. These are indications that the child is unable to tolerate reduced oxygen concentration
Oxygen by nasal cannula or catheter	
1. Refer to Procedure Guidelines 10-12, page 239.	
2. Nasal cannulas are available in a variety of sizes for neonates, infants, and children.	
3. Low-flow meters are available to titrate oxygen at levels under 1 L/minute	3. Lower flow rate may be necessary for infants.

Nursing Action	Rationale
Oxygen by mask	
1. Choose an appropriate-size mask that covers the mouth and nose of the child but not the eyes.	1. Extra space under mask and around face is added dead space and decreases effectiveness of the therapy.
2. Use a mask that is capable of delivering the desired oxygen concentration.	2. Venturi masks for pediatric use deliver low to moderate concentrations of oxygen: 24%, 28%, 31%, 35%, or 40%.
3. Place the mask over the child's mouth and nose so it fits securely. Secure the mask with an elastic head grip.	3. Make sure the mask is adjusted properly over the mouth and nose. Do not allow the oxygen to blow in the child's eyes.
4. Remove the oxygen mask at hourly intervals; wash and dry the face.	4. Makes the patient feel more comfortable.
5. Do not use masks for comatose infants or children.	5. Such children are more likely to vomit. The risk of aspiration may be increased with mask therapy because of obstruction of the flow of vomitus.
6. For additional information, refer to Procedure Guidelines 10-14, page 242, and Procedure Guidelines 10-13, page 240.	
Face tent	
1. Face tents are available in adult size only. They can be used effectively in pediatric patients if inverted to create a smaller reservoir and better fit.	1. Face tents combine the positive qualities of aerosol masks and mist tents. The child is accessible and may continue to play without feeling confined.
2. A flow of 8–10 L/minute should be used to flush the system and provide a stable oxygen concentration.	2. Larger children will require higher flows.
A child receiving humidity and oxygen by way of an aerosol face tent.	
T-Bars and tracheostomy masks	
1. These devices are used to deliver oxygen to intubated patients.	
2. The flow rate must be set to meet the minute volume requirements of the child and to provide a 100% source of gas.	2. T-bars require a short, flexible tube on the distal end to act as a reservoir and prevent room air entrapment.
Closed incubator and Isolettes	
1. The incubator is used to provide a controlled environment for the neonate.	1. The unit is able to provide precise environmental control of temperature, oxygen, humidity, and isolation.
2. Adjust the oxygen flow to achieve the desired oxygen concentration.	2. Follow manufacturer's instructions for each make of incubator.
a. An oxygen limiter prevents the oxygen concentration inside the incubator from exceeding 40%.	a. This is desirable because it reduces the hazard of the child's developing retinopathy of prematurity.
b. Higher concentrations (up to 85%) may be obtained by placing the red reminder flag in the vertical position.	b. This operates by reducing the air intake.

Nursing Action	Rationale
3. Secure a nebulizer to the inside wall of the incubator if mist therapy is desired.	3. This should be cleaned and autoclaved daily. Sterile solutions are used to keep the bacteria count at a minimum.
4. Keep sleeves of incubator closed to prevent loss of oxygen.	4. When the incubator or sleeves are opened, supply supplemental oxygen with oxygen mask to face and nose.
5. Periodically analyze the incubator atmosphere.	5. Be certain that the child is receiving the desired concentration of oxygen.
6. Drain and fill reservoirs with sterile water at least every 24 hours.	6. Decreases risk of *Pseudomonas* contamination.
Oxygen hood/box	
1. Warmed, humidified oxygen is supplied through a plastic container that fits over the child's head. This method is more suitable for a child under 1 year of age.	1. This is especially useful when high concentrations of oxygen are desired. The hood may be used in an incubator or with a warming unit. Oxygen should not be allowed to blow directly into the infant's face.



2. Continuously monitor the oxygen concentration, temperature, and humidity inside the hood.	2. Oxygen should be warmed to 87.8°–93.2° F (31°–34° C) to prevent a neonatal response to cold stress, including oxygen deprivation, metabolic acidosis, rapid depletion of glycogen stores, and reduction of blood glucose levels.
3. Open the hood or remove the baby from it as infrequently as possible.	3. Prevents fluctuations of heat and oxygen, which may further debilitate the young infant.
4. Several different designs are available for use. The manufacturer's directions should be carefully followed.	4. This is a safety consideration.

EVIDENCE BASE Ghuman, A. K., Newth, C. J. L., & Khemani, R. G. (2010). Respiratory support in children. *Paediatrics and Child Health*, 21, 4.

Oxygen Therapy

Children with respiratory problems may receive oxygen therapy via nasal cannula, mask, face tent, endotracheal (ET) tube, or tracheostomy device (see pages 179 to 181). An Isolette or oxygen hood may also be used for infants and young children.

Mechanical Ventilation

Infants and children requiring mechanical ventilation need specialized care. These patients are typically treated in facilities that focus on providing a safe environment for technology-dependent children, with care provided by highly skilled nurses, respiratory therapists, and pediatricians. Specific nursing procedures and interventions and management of technology-dependent infants and children are beyond the scope of this text. General considerations are as follows.

Maintenance of a Patent Airway

1. Artificial airway options include nasotracheal, orotracheal, and tracheostomy. ET and tracheostomy tubes are available in several sizes, cuffed and uncuffed, for the pediatric population.
    a. Several methods are available to determine the appropriate size, such as ET tube size = age in years + 16 divided by 4 (consult facility policy).
2. The patient should be closely monitored for hypoxia and bradycardia during intubation.
    a. Only experienced and highly trained and skilled practitioners should perform intubation.
    b. Resuscitation and reintubation equipment and access to oxygen and suction equipment must always be readily available.
    c. An appropriately sized self-inflating bag with reservoir for oxygenation and mask should remain with the patient.
3. Action should be taken to prevent dislodgement of the artificial airway (especially during movement of the child) and obstruction of the airway.
    a. Pediatric ET tubes have small diameters and are easily obstructed by thick secretions.
    b. Adequate humidification will loosen secretions, and suctioning will prevent airway obstruction.
    c. Frequent vital signs and respiratory assessments are necessary. Cardiorespiratory monitors, pulse oximeter, end-tidal carbon dioxide, or transcutaneous carbon dioxide monitors are also necessary.
4. Nursing care should address issues of hydration, nutrition, sedation, skin integrity, tissue perfusion, infection control, communication, safety, and parental support and education.
5. Available ventilators for pediatric use have a wide range of capabilities, versatility, and clinical application. Some are more suitable for use with infants; others with older children.
    a. Nurses must be well acquainted with the characteristics of the particular machine being used and the meaning of the settings and alarms on each of the various machines.

Nursing Management

See Chapter 10, page 183. In addition the nurse who is caring for a pediatric patient should remember the following.

Setting Controls

In setting controls, inspiratory flow rate will be less and the respiratory rate will be greater than in the adult patient. These parameters depend on the patient's size and condition and are determined by the health care

provider or respiratory therapist.

Humidification

During ventilation of an infant in an incubator, the amount of ventilator tubing outside the incubator should be kept to a minimum. The warm temperature inside the incubator helps decrease the amount of condensation in the tubing and thus provides higher water content in the inspired gas.

Oxygen Concentration

1. In infants, inspired concentrations of oxygen should always be kept as low as possible (while still providing for physiologic requirements) to prevent the development of retinopathy of prematurity or pulmonary oxygen toxicity.
2. The oxygen concentration should be checked periodically with an analyzer.

Blood Gases

1. Blood gas analysis, via arteriopuncture or umbilical or arterial lines, is necessary to monitor oxygenation.
2. The arterialized capillary sample method is inaccurate for infants in respiratory distress because the constricted peripheral circulation may not reflect the ABG (arterial blood gases) levels accurately.

Sterile Precautions

The neonate has only those antibodies transferred across the placenta from the mother. Therefore, sterile precautions are essential.

1. Ventilator tubing should be changed every 24 hours.
2. Routine cultures should be taken after intubation: may include frequent Gram staining of secretions.
3. Suctioning requires aseptic technique.

Tubing Support

1. Special frames are available to support ventilator tubing; this helps to prevent accidental decannulation in infants and small children.
2. Infants may require support or padding on either side and at the top of their heads to decrease mobility and take up space between the head and the frame.

Monitoring the Ventilator

1. Pressure gauges should be checked at frequent intervals as this gives an indication of changing compliance or increased airway resistance.
2. Volume measurements are difficult to obtain in infants because most spirometers incorporated into ventilators and meters do not read accurately at low volumes and flows. However, they are helpful with older children.
3. Measure respiratory rates of the machine and the patient at least every hour and record.

See additional online content: Procedure Guidelines 44-2

PROCEDURE GUIDELINES 44-2

Promoting Postural Drainage in the Pediatric Patient

Postural drainage is the positioning of the patient so gravity will assist in the movement of secretions from the smaller bronchial airways to the main bronchus and trachea, from which the secretions can be removed by coughing or suctioning.

NURSING ALERT Percussion, vibration, and squeezing of the chest are contraindicated in children with pulmonary hemorrhage, pulmonary embolism, end-stage renal disease, increased intracranial pressure, osteogenesis imperfecta, and minimum cardiac reserve.

PROCEDURE

Nursing Action	Rationale
Preparatory phase	
1. Assess the child's respiratory status. a. Obtain a baseline respiratory rate. b. Observe for respiratory distress, retractions, nasal flaring, hypoxemia, and bronchospasm.	1. This is necessary to evaluate the effectiveness of the therapy.
2. Identify the involved portions of the lung by auscultation, percussion, or review of the x-ray report.	2. The positions selected for drainage will depend on what portion of the lung is involved (see Figure 44-6, page 1511).
3. Explain the procedure to the child and the parent.	3. Allays anxiety and helps to secure the child's cooperation. a. Assists in relaxing and decreasing strain on the abdominal muscles during coughing. b. Collects mucus. c. Facilitates positioning.
4. Make the child comfortable. a. Remove constricting clothes. b. Flex the child's knees and hips. c. Have tissues and an emesis basin available. d. Have several pillows available.	4. Proper position will provide the infant with comfort and security and will make it easier to suck and swallow. Holding the infant will enhance trust building and provide sensory stimulation.
5. Provide bronchodilator or nebulization therapy before the procedure, if indicated.	5. It is easier to raise mucus mechanically after the bronchi are dilated and the secretions are thinned.
Performance phase	
1. Place the child in a series of appropriate positions.	1. The positions are selected and modified according to the lung area involved, the child's age and general condition, and equipment such as an IV tracheostomy, monitors, and ventilators.
a. Infants are positioned on the nurse's lap, in the Isolette, or in the crib; older children may be treated on a tilt board or in bed.	
b. The area to be drained should be elevated and its respective bronchus placed in a vertical position.	b. Facilitates drainage by gravity.
2. Unless contraindicated, cup the chest wall for 1–2 minutes.	2. More secretions can be raised in a shorter period of time when cupping and vibration are added to posturing.
3. Have the child inhale deeply; then, with exhalation, vibrate the chest wall during three to five exhalations.	3. Helps open airways and mobilize secretions.
4. Encourage the child to cough. Infants and young children may require suctioning.	4. Facilitates movement of secretions.

Nursing Action	Rationale
5. Allow the child to rest for a minute, then repeat cupping, vibration, and coughing until no more mucus is produced or the child's condition indicates that the procedure should be stopped. Total treatment time should generally not exceed 20–30 minutes. a. In acute conditions such as atelectasis, postural drainage may be done for 5 minutes of every hour. b. In chronic conditions such as cystic fibrosis, postural drainage may be done two to five times per day for 15–30 minutes.	5. Procedure may be tiring, so rest will be necessary.
 Cupping the chest.	 To assist with percussing an infant or small child, an alternative percussion device may be used, such as a mask from a manual resuscitation bag.
6. Stay with the child during the procedure, especially when in a head-down position.	6. Provides for patient safety.

NURSING ALERT Postural drainage should not be done immediately after meals because it may induce vomiting.

EVIDENCE BASE Flume, P. A., Robinson, K. A., O'Sullivan, B. P., et al. (2009). Cystic fibrosis guidelines: Airway clearance therapies. *Respiratory Care*, *54*(4), 522–537.

Common Pediatric Respiratory Infections

Respiratory tract infection is a frequent cause of acute illness in infants and children. Many pediatric respiratory infections are seasonal. The child's response to the infection will vary based on the age of the child, causative organism, general health of the child, and existence of chronic medical conditions. Information about specific respiratory infections, including bacterial pneumonia, viral pneumonia, *Pneumocystis* pneumonia, *Mycoplasma* pneumonia, bronchiolitis, croup, and epiglottitis, may be found in Figure 44-1 and Table 44-1, pages 1168 to 1177.

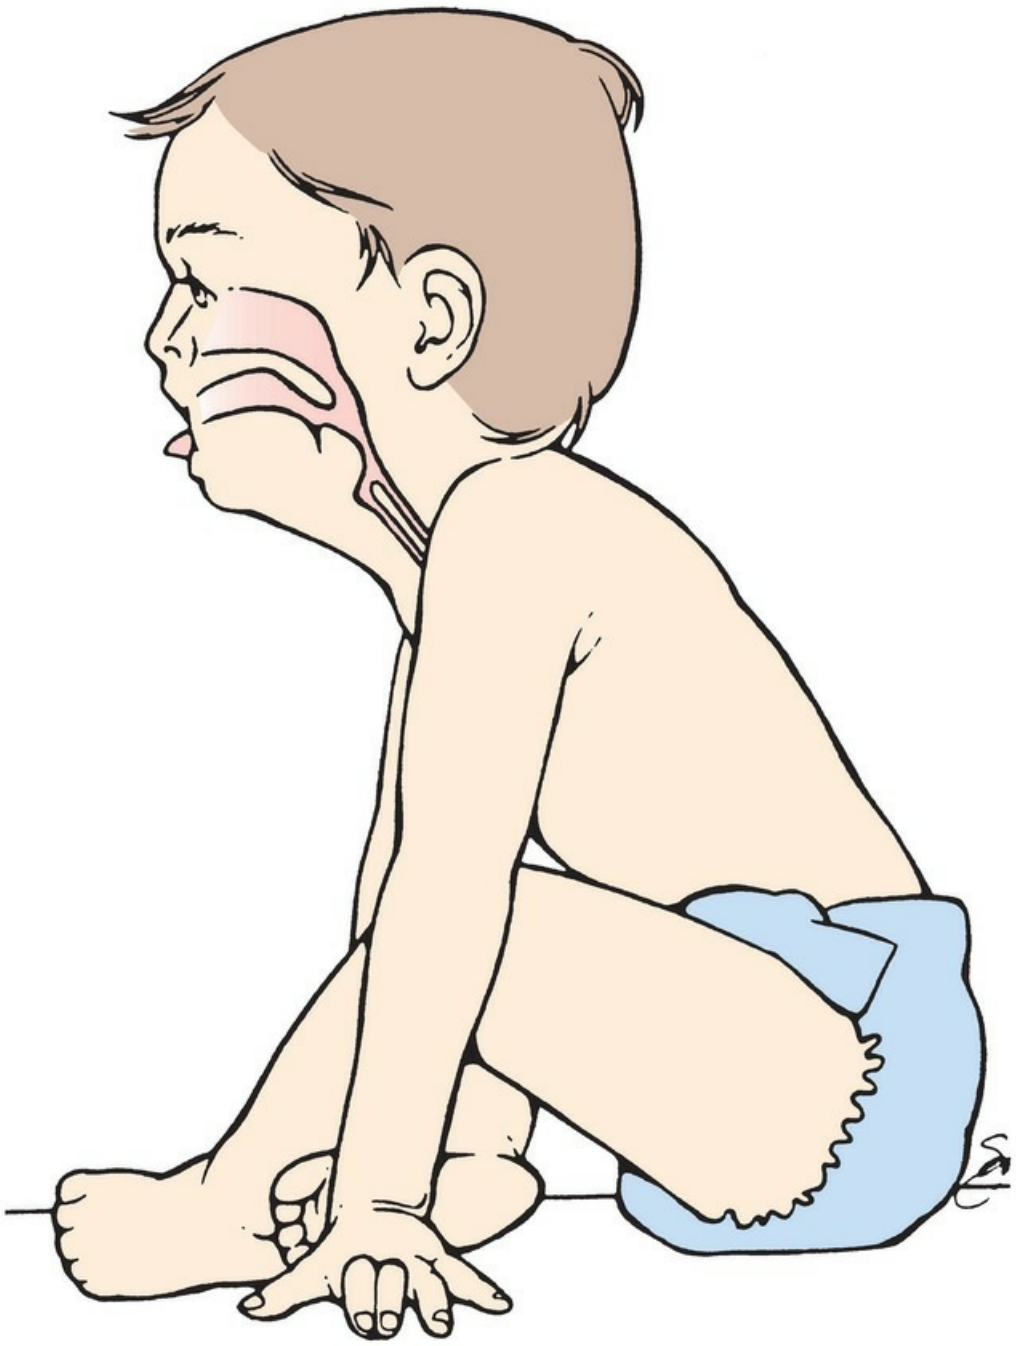


Figure 44-1. Characteristic posture of a child with acute epiglottitis: leaning forward on hands, in

the “tripod” position; mouth open, tongue out, head forward, and tilted up in a sniffing position in an effort to relieve the acute airway obstruction secondary to swollen epiglottis.

Table 44-1 Common Pediatric Respiratory Infections

CONDITION AND CAUSATIVE AGENT	AGE AND INCIDENCE	CLINICAL MANIFESTATIONS
Bacterial Pneumonia		
Bacterial infection of the lung parenchyma. General considerations: In the normal child, bacterial pneumonias are not common. A viral respiratory infection commonly occurs before bacterial pneumonia. The initial viral infection alters the lungs' defense mechanisms.		
Pneumococcal pneumonia The most common causative agent is Streptococcus pneumoniae.	• Responsible for the majority of bacterial pneumonias in ages 1 month through 6 years. However, it is seen in all age groups. • The incidence has declined because of the use of the vaccine. • Most common in winter and spring.	• *Infants:* Mild URI of several days' duration, poor feeding, decreased appetite. • Abrupt onset of fever 102.2°F (39°C) or higher; restlessness, respiratory distress, air hunger, pallor, cyanosis (common), nasal flaring, retractions, grunting, tachypnea, tachycardia, irritability; may see abdominal distention due to swallowed air or ileus. • Older child: Mild URI, followed by fever up to 104.9°F (40.5°C), shaking chills, headache, decreased appetite, abdominal pain, vomiting, drowsiness, restlessness, irritability, lethargy, rhonchi, fine crackles, dry hacking cough, increased respirations, anxiety, occasionally circumoral cyanosis, pleuritic pain, diminished breath sounds, may develop a pleural effusion, empyema.
NURSING ALERT Pneumococcal polysaccharide vaccine provides protection from 23 types of *S. pneumoniae*. It is recommended for children age 2 years and older with sickle cell disease, functional or anatomic asplenia, nephrotic syndrome, human immunodeficiency virus (HIV) infection, and Hodgkin disease before beginning cytoreduction therapy.		
Streptococcal pneumonia • Beta-hemolytic Streptococcus group A	• Ages 3–5 years. Uncommon, serious. • An endemic influenza predisposes to streptococcal pneumonia and tracheobronchitis.	• Sudden onset, high fever, chills, worsening cough, pleuritic pain, respiratory distress, grunting, retractions, altered mental status, signs of shock, decreased capillary refill, tachycardia. • May be insidious, mildly ill, low-grade fever. • Severe infections—*toxic shock syndrome* with erythematous rash, desquamation, hypotension, hepatic dysfunction, renal involvement, vomiting and diarrhea, hematologic abnormalities, acute respiratory distress syndrome.
Staphylococcal pneumonia • *Staphylococcus aureus*, Gram-positive	• Most common in children ages 6 months to 1 year. October–May (rare).	• Predisposing factors: cystic fibrosis, maternal infection, immunodeficiency. • Usually preceded by a viral URI. Changes abruptly to high fever, cough, respiratory distress, tachypnea, grunting, nasal flaring, cyanosis, retractions. • Anxiety, lethargic, occasionally vomiting, diarrhea, anorexia, abdominal distention, toxic appearance.
***Haemophilus influenzae*, type B**	• Majority of children younger than age 4 years. • Infants and children who are not immunized. • Winter and spring.	• Usually preceded by URI. Associated with otitis media, epiglottitis, and meningitis; appears toxic. • Insidious onset; cough, febrile, tachypneic, nasal flaring, retractions.
Viral Pneumonia		
• Respiratory syncytial virus (RSV); parainfluenza virus types 1, 2, 3; adenovirus types 1, 2, 5, 6 and types 3, 7, 11, 21; influenza A and B.	• Peak age for bronchiolitis is within the first year of life. Peak age for viral pneumonia is age 2.3 years. • Typically seen in the winter months.	• Usually preceded by URI with symptoms of cough, rhinitis, and mild fever. Progressing to tachypnea, poor feeding in infants and retractions (suprasternal, intercostal, subcostal, and substernal), leading to nasal flaring. Along with use of accessory muscles, wheezing, severe cough, cyanosis, and respiratory fatigue. • Viral pneumonia may present concurrently with bacterial pneumonia. Adenovirus types 3, 7, 11, and 21 may cause severe necrotizing pneumonia in infants.
• RSV subgroup A (more virulent, associated with more severe disease). RSV subgroup B.	• In infants, RSV is the most common cause of pneumonia, bronchiolitis, and hospitalizations. • Severity of RSV infection decreases with age and subsequent infections. • Peak age is 2–7 months, October–April.	• Typically begins with URI, rhinorrhea, fever usually <102°F (38.9°C), otitis media, and conjunctivitis. • Progressing to coughing, wheezing, tachypnea (>70 breaths/minute), intercostal and subcostal retractions, poor air exchange, hypoxia, decreased breath sounds, cyanosis, lethargy, listless apneic episodes, and irritability. Infants will present with poor feeding, inability to suck and breathe.
Respiratory syncytial virus (continued)		
Pneumocystis carinii Pneumonia		
• *P. carinii*, also known as *P. jiroveci*, is a fungus with similarities to protozoa. The organism exists in three forms in the tissues: trophozoite, spirozoite, and cyst.	• Most healthy humans are infected before age 4 years and are asymptomatic. • Life-threatening pneumonia is seen in the immunosuppressed host. PCP in severely immunocompromised children with acquired or congenital immunodeficiency disorders, malignancies, organ transplant recipients, and debilitated, malnourished, and premature infants. In HIV-infected children, it most commonly occurs between ages 3 and 6 months. PCP can occur during remission or relapse in patients with leukemia or lymphoma.	• Slow onset, tachypnea, retractions, and nasal flaring cyanosis. • Sporadic form in immunocompromised patients. Signs may vary; onset may be acute or fulminant. • Fever, tachypnea, dyspnea, cough, nasal flaring, cyanosis, subacute, diffuse pneumonitis with dyspnea at rest, tachypnea and decreasing oxygen saturation. Extrapulmonary sites rarely occur and usually produce no symptoms.
Mycoplasma Pneumonia		
• *Mycoplasma pneumoniae*, microorganisms with properties between bacteria and viruses.	• Fall and winter. • Crowded living conditions. Seen frequently in school age children and adolescents.	• Slow onset; 2- to 3-week incubation period. Coryza, malaise, headache, anorexia, normal temp or low-grade fever, sore throat, muscle pain, vomiting, subacute tracheobronchitis, shortness of breath, dry cough that progresses to mucopurulent cough, mild chest pain, wheezing. May present with maculopapular rash.
Bronchiolitis		
• Inflammation of the bronchioles. Causative agents: RSV, adenovirus, parainfluenza type 1 or 2, influenza virus, and *M. pneumoniae*.	• Winter and spring. • Most common in infants younger than 6 months old, may occur up to age 2 years. • Greater incidence in males than in females. • Increased in day care centers.	• Gradual onset after exposure to an individual with URI. Coryza, tachypnea, respiratory rate >50 bpm, retractions, wheezing, paroxysmal cough, fever, cyanosis, dehydration, poor feeding, vomiting, tachycardia, irritability, dyspnea. • Apnea may be first sign in infants with RSV. Decreased breath sounds with prolonged expiratory phase. Hypoxemia may persist for 4–6 weeks.
Croup Syndromes		
Croup syndromes refer to infections of the supraglottis, glottis, subglottis, and trachea.		
Acute laryngotracheobronchitis (subglottic croup) • Parainfluenza types 1, 2, 3; RSV; influenza A and B; adenovirus; measles.	• Ages 3 months to 5 years. Peak ages 1–2 years. • Greater incidence in males than in females. • Late autumn, early winter.	• Usually a preceding URI is seen. Initially, a mild brassy or barking cough, hoarse, intermittent stridor, progresses to continuous stridor. • Nasal flaring, suprasternal, infrasternal, intercostals, retractions. • Breathing labored, prolonged expiratory phase. Temperature slightly elevated. • Crying and agitation aggravate signs. • Child prefers to be held upright or sit up in bed. Symptoms are worse at night. • Severe croup: restlessness, air hunger, decreased breath sounds, hypoxemia, hypercapnia, anxiety, cyanosis, tachycardia, and cessation of breathing.
NURSING ALERT If ABG analysis is done, a normal partial pressure of arterial carbon dioxide may not indicate decreased severity. By the time hypercapnia is seen, intubation will be required. Children decompensate very quickly.		
Spasmodic croup and acute spasmodic laryngitis • No infectious agents seen. Thought to be related to spasm of laryngeal muscle. • Cause may be viral in a few cases, allergic or psychological.	• Ages 1–6 years. • Peak incidence 7–36 months.	• Similar to acute laryngotracheobronchitis. Symptoms are sudden, in the evening. • Afebrile, barking, brassy cough, hoarse, stridor. Child may be anxious and frightened. • Breathing is noisy on inspiration, slow, and labored; respiratory distresses. • Tachycardia. Skin cool, moist. Dyspnea is worse with excitement. • Cyanosis is rare; severity decreases over time. Patient appears well in the morning, may cough or sound hoarse. The symptoms may recur for subsequent nights; however, they will be less severe.
Bacterial tracheitis (pseudomembranous croup) • Tracheal inflammation in the subglottic region. • *S. aureus*, *H. influenzae*, streptococci groups A and B, *Escherichia coli*, *Klebsiella*, *Moraxella catarrhalis*, *Pseudomonas*, *Chlamydia trachomatis*, and *Corynebacterium diphtheriae* should be considered in the nonvaccinated patient.	• No season variation. • Age is variable, 1 month to 6 years; however, most are younger than age 3 years.	• Usually follows a viral illness. Slow or sudden deterioration, child appears toxic. • High fever, stridor, hoarse, respiratory distress. Thick, purulent, copious airway secretions. • Mucosal necrosis, brassy or barking cough. Epiglottitis may coexist. May cause life-threatening airway obstruction.
Acute epiglottitis • Supraglottitis, inflammation of the epiglottis and edema of the aryteneopiglottic folds. • *H. influenzae type B, most common. S. pneumoniae, S. aureus*, group A. Beta-hemolytic streptococcus, *Streptococcus pyogenes*, *Moraxella catarrhalis*, and *Candida albicans* (in the immunocompromised).	• Range ages 2–7 years; peak ages 3–5 years. • Autumn and winter. • Incidence significantly decreased because of the routine use of the *H. influenzae* vaccine.	• Sudden fulminating course, high fever, toxic appearance, sore throat, drooling, dysphagia, aphonia, retractions, air hunger, anxiety, tachycardia, hoarseness, irritability, restlessness, rapid progression to respiratory distress. • Sitting forward, neck hyperextended, mouth open, tongue protruding. Older child will sit in tripod position. Drooling, agitation, and absence of spontaneous cough are predictive of epiglottitis. • Absence of croupy cough.
Acute epiglottitis (Continued)		• Complete fatal airway obstruction and death may occur within hours if not treated. In group A beta-hemolytic streptococcus and *H. influenzae*, patient will present with acute respiratory distress. • Stridor and breath sounds decrease as child begins to tire. • A brief episode of air hunger with restlessness and agitation may rapidly progress into increasing cyanosis, coma, and death.

ABG, arterial blood gas; ASO, antistreptolysin; CBC, complete blood count; HIV, human immunodeficiency virus; ICU, intensive care unit; MRSA, methicillin-resistant S. aureus; PCP, Pneumocystis carinii pneumonia; RSV, respiratory syncytial virus; URI, upper respiratory infection.

Nursing Assessment

Determine the severity of the respiratory distress that the child is experiencing. Make an initial nursing assessment.

1. Observe the respiratory rate and pattern. Count the respirations for 1 full minute, document, and note level of activity, such as awake or asleep. Determine if the rate is appropriate for the child's age (see page 1098).
2. Observe respiratory rhythm and depth. Rhythm is described as regular, irregular, or periodic. Depth is normal, hypopnea or too shallow, and hyperpnea or too deep.
3. Auscultate breath sounds for a full cycle of inspiration and expiration over all lung fields. Note airflow and presence of adventitious sounds such as crackles, wheeze, or stridor.
4. Observe degree of respiratory effort—normal, difficult, or labored. Normal breathing is effortless and easy.
5. Document character of dyspnea or labored breathing; continuous, intermittent, worsening, or sudden onset. Note relation to activity, such as rest, exertion, crying, feeding, and association with pain, positioning, or orthopnea.
6. Note presence of additional signs of respiratory distress: nasal flaring, grunting, and retractions. Note location of retractions (see Figure 44-2) and character (mild, moderate, or severe).
7. Observe for head bobbing, usually noted in a sleeping or exhausted infant. The infant should be held by the caregiver with head supported on the caregiver's arm at the suboccipital area. The head bobs forward with each inspiration.
8. Observe the child's color. Note the presence and location of cyanosis—peripheral, perioral, facial, and trunk. Note degree of color changes, duration, and association with activity such as crying, feeding, and sleeping.
9. Observe the presence of cough, noting type and duration, such as dry, barking, paroxysmal, or productive. Note any pattern, such as time of day or night, association with activity, physical exertion, or feeding. Severity of croup may be determined by cough and signs of respiratory effort.
    a. Mild croup—occasional barking cough, no audible stridor at rest, and either mild or no suprasternal or intercostal retractions.
    b. Moderate croup—frequent barking cough, easily audible stridor at rest, and suprasternal and sternal retractions at rest, but little or no agitation.
    c. Severe croup—frequent barking cough, prominent inspiratory and occasional expiratory stridor, marked sternal retractions, and agitation and distress.
    d. Impending respiratory failure—barking cough (often not prominent), audible stridor at rest (may be hard to hear), sternal retractions (may be marked), lethargy or decreased level of consciousness, and often dusky appearance in the absence of supplemental oxygen.

10. Note the presence of sputum, including color, amount, consistency, and frequency.
11. Observe the child's fingernails and toenails for cyanosis and the presence and degree of clubbing, which indicate underlying chronic respiratory disease.
12. Evaluate the child's degree of restlessness, apprehension, level of responsiveness, and muscle tone.
13. Note the presence or complaint of chest pain and its location, whether it is local or generalized, dull or sharp, and associated with respiration or grunting.
14. Assess for signs of infection, such as elevated temperature; enlarged cervical lymph glands; purulent discharge from nose or ears; sputum; or inflamed mucous membranes.

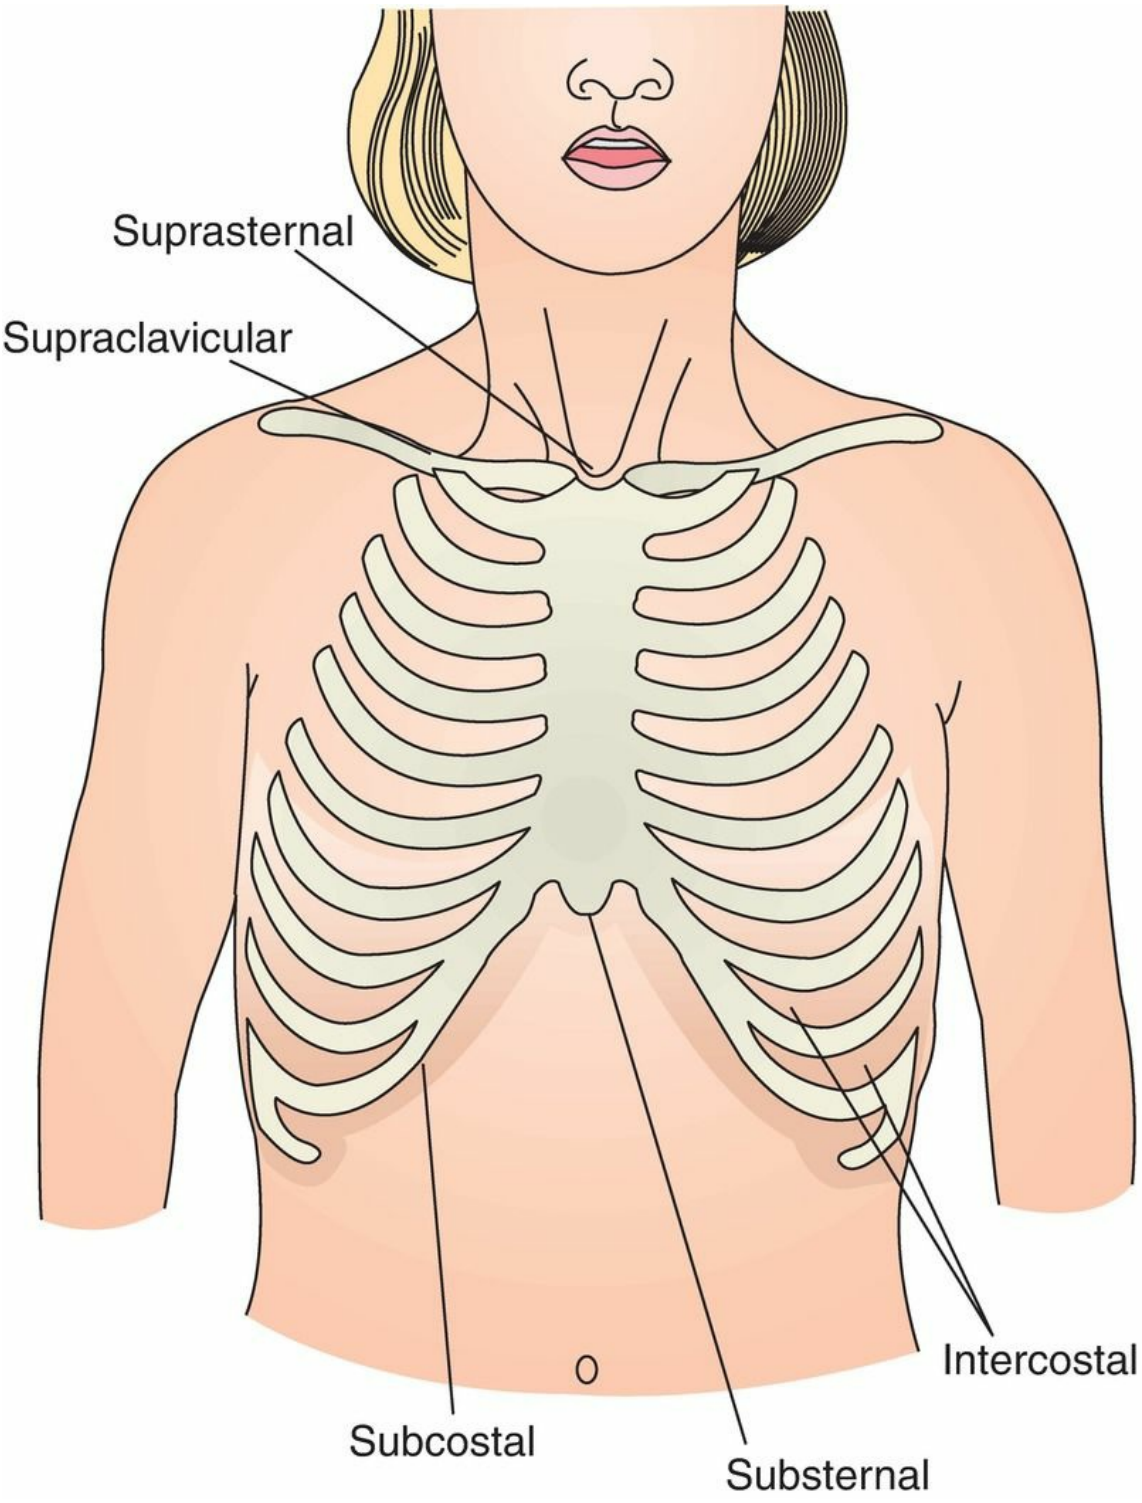

Figure 44-2. Sites of respiratory retractions. (Pillitteri A. [2013]. Maternal and child health nursing: Care of the childbearing and childrearing family [7th ed.]. Philadelphia: Lippincott Williams & Wilkins.)

EVIDENCE BASE Grundfast, K., Insalaco, L., & Levi, J. (2017). The 10 commandments of

management of acute upper airway obstruction in infants and children. *JAMA Otoloaryngology, Head and Neck Surgery, 143*(6), 539–540.

Nursing Diagnoses

- Ineffective Airway Clearance related to inflammation, obstruction, secretions, or pain.
- Ineffective Breathing Pattern related to inflammatory process or pain.
- Deficient Fluid Volume related to fever, decreased appetite, and vomiting.
- Fatigue related to increased work of breathing.
- Anxiety related to respiratory distress and hospitalization.
- Parental Role Conflict related to hospitalization of the child.

Nursing Interventions

Promoting Effective Airway Clearance

1. Provide a humidified environment enriched with oxygen to combat hypoxia and to liquefy secretions.
2. Advise the parents to use a jet or ultrasonic nebulizer at home if prescribed and to encourage fluids, as tolerated.
3. Keep nasal passages free of secretions. Infants are obligate nose breathers. Use a bulb syringe to clear nares and oropharynx.

Improving Breathing Pattern

1. Place the child in a comfortable position to promote easier ventilation.
    a. Maintain semi-Fowler position—use infant seat or elevate head of bed.
    b. Do not place the infant in prone position. Occasional side or abdominal position will aid drainage of liquefied secretions.
    c. Do not position the child in severe respiratory distress in a supine position. Allow the child to assume a position of comfort.
2. Provide measures to improve ventilation of the affected portion of the lung.
    a. Change position frequently.
    b. Provide postural drainage, if prescribed.
    c. Relieve nasal obstruction that contributes to breathing difficulty. Instill normal saline solution or prescribed nose drops and apply nasal suctioning.
    d. Quiet prolonged crying, which can irritate the airway, by soothing the child; however, crying may be an effective way to inflate the lungs.
    e. Realize that coughing is a normal tracheobronchial cleansing procedure, but temporarily relieve coughing by allowing the child to sip water; use extreme caution to prevent aspiration.
    f. Insert a nasogastric tube, as ordered, to relieve abdominal distention, which can limit diaphragmatic excursion.

3. Ensure that the child's oxygen input is not compromised.
    a. Monitor oxygen saturations, as indicated; pulse oximetry should be performed if hypoxia is suspected.
    b. If compressed air or oxygen is to be administered to a small infant, use a method that is best tolerated, monitoring excess carbon dioxide concentrations and increased respiratory rate.
4. Administer appropriate antibiotic or antiviral therapy.
    a. Observe for drug sensitivity.
    b. Observe the child's response to therapy.
5. Administer specific treatment for respiratory syncytial virus (RSV), if ordered.
    a. There is presently no evidence that supports the use of ribavirin or inhaled corticosteroids in acute bronchiolitis; however, some health care providers do consider these options in the management of RSV, especially in high-risk populations such as children who have undergone a stem cell transplant.
6. If the decision is made to initiate ribavirin therapy, appropriate precautions should be implemented to protect personnel and caregivers.
    a. Information about the potential but unknown risk of exposure to ribavirin.
    b. Pregnant women should not provide direct care to patients who are receiving ribavirin therapy. Pregnant women should not enter the patient's room while ribavirin is being administered.
    c. Methods to reduce environmental exposure to ribavirin should be employed:
        i. Stop aerosol administration before opening hood or tent.
        ii. Use room with adequate ventilation of at least six air exchanges per hour. Place the patient in a negative pressure room if indicated by organizational policy.
        iii. Consider the use of scavenger devices to help decrease the escape of ribavirin into the air.
        iv. Gowns and N95 face masks should be used for the duration of the time the nebulizer is in use.
7. For cases of severe respiratory distress, assist with intubation or tracheostomy and mechanical ventilation.
    a. Tracheostomy and ET tubes are generally not cuffed for infants and small children because the tube itself is big enough relative to the size of the trachea to act as its own sealer.
    b. Position the infant with a tracheostomy with the neck extended by placing a small roll under the shoulders to prevent occlusion of the tube by the chin. Support his or her head and neck carefully when moving the infant to prevent dislodgement of the tube.
    c. When feeding, cover the tracheostomy with a moist piece of gauze, or use a bib for older infants or young children.
    d. See page 1166 in this chapter as well as Chapter 10 for care of the patient on mechanical ventilation.

EVIDENCE BASE Pascoal, L., Lopes, M., da Silva, V., et al. (2016). Clinical differentiation of respiratory nursing diagnoses among children with acute respiratory infection. *Journal of Pediatric Nursing, 31*(1), 85–91.

Fisk, A.C. (2018). The effects of endotracheal suctioning in the pediatric population: An integrative review. *Dimens Crit Care Nurs, Jan/Feb, 37*(1), 44–56.

NURSING ALERT Infants with a history of very low birth weight and bronchopulmonary dysplasia have chronic, compensated carbon dioxide retention. Careful attention must be given to oxygen administration to avoid respiratory depression by suppressing their hypoxic drive.

Promoting Adequate Hydration

1. Administer fluids via intravenous (IV) route at the prescribed rate.
2. To prevent aspiration, withhold oral food and fluids if the child is in severe respiratory distress.
3. Offer the child small sips of clear fluid when respiratory status improves.
   a. Note any vomiting or abdominal distention after the oral fluid is given.
   b. As the child begins to take more fluid by mouth, notify the health care provider and modify the IV fluid rate to prevent fluid overload.
   c. Do not force the child to take fluids orally as this may cause increased distress and possibly vomiting. Anorexia will subside as the condition improves.
4. Assist in the control of fever to reduce respiratory rate and fluid loss.
   a. Give antipyretics, as prescribed.
5. Record the child's intake and output and monitor urine-specific gravity.
6. Provide mouth care or offer mouth rinse if child is able to perform this safely.

Promoting Adequate Rest

1. Disturb the child as little as possible by organizing nursing care, and protect the child from unnecessary interruptions.
2. Be aware of the age of the child and be familiar with the level of growth and development as it applies to hospitalization.
3. Encourage the parents to stay with the child as much as possible to provide comfort and security.
4. Provide opportunities for quiet play as the child's condition improves.

Reducing Anxiety

1. Explain procedures and hospital routine to the child as appropriate for age.
2. Provide a quiet, stress-free environment.
3. Observe the child's response to the oxygen therapy environment such as a mist tent or head box and provide reassurance.
   a. The child may experience fear of confinement or suffocation.
   b. Vision is distorted through the plastic.

c. The environment is noisy and damp.
d. Physical and diversional activities are restricted.
e. Parental contact is decreased.
f. The environment is often uncomfortable.

4. Avoid the use of sedatives and opiates, which may obscure restlessness. Restlessness may be a sign of increasing respiratory distress or obstruction.
5. Allow the child to assume a position of comfort.

Strengthening the Parents' Role

1. Help the parents understand the purpose of the oxygen therapy/humidifier and how to work with it.
2. Discuss their fears and concerns about the child's therapy.
3. Include the parents in planning for the child's care. Promote their participation in caring for the child.
4. Recognize that the parents will need rest periods. Encourage them to take breaks and eat on a regular basis.

Family Education and Health Maintenance

1. Teach the importance of good hygiene. Include information on hand washing and appropriate ways to handle respiratory secretions at home.
2. Teach the family when it is appropriate to keep the child home from school (any fever, coughing up secretions, and significant runny nose in toddler or younger child).
3. Teach methods to keep the ill child well hydrated.
   a. Provide small amounts of fluids frequently.
   b. Offer clear liquids and prepared electrolyte preparations.
   c. Offer frozen juice pops.
   d. Avoid juices with a high sugar content.
4. Teach ways to assess the child's hydration status at home.
   a. Decreased number of wet diapers or number of times the child urinates per day.
   b. Decreased activity level.
   c. Dry lips and mucous membranes.
   d. No tears when the child cries.
5. Teach the parents when to contact their health care provider—signs of respiratory distress, recurrent fever, decreased appetite and activity, and signs of dehydration.
6. Teach about medications and follow-up.
7. If a tracheostomy was required, teach care of the tracheostomy, use of equipment, safety, and referral for home nursing care before discharge.

Evaluation: Expected Outcomes

- Breath sounds clear and equal.
- Easy, regular, unlabored respirations on room air (or back to baseline if the child is on oxygen).
- Mucous membranes moist; urine output adequate.
- Bathing and feeding tolerated well.
- Child calm and interacts appropriately with family and staff.
- Parents participate in the child's care.

Disorders Requiring Surgery of the Tonsils and Adenoids

EVIDENCE BASE Kenney, K., & Gropman, R. (2013). What immediate post-operative nursing care contributes to a better patient outcome after a child has had a day surgery tonsillectomy and adenoidectomy (T and A)? *Journal of Perianesthesia Nursing, 28*(3), e44.

Tonsillectomy and *adenoidectomy* are the surgical removal of the adenoidal and tonsillar structures, part of the lymphoid tissue that encircles the pharynx. These are one of the most frequently performed surgical procedures in the child. The most common disease processes that require tonsillectomy and adenoidectomy are obstructive sleep apnea; chronic, persistent tonsillitis or adenoiditis; and chronic persistent otitis media.

Pathophysiology and Etiology

Function of Tonsils and Adenoids

1. They are a first line of defense against respiratory infections.
2. Because the growth of the tonsils and adenoids in the first 10 years of life exceeds general somatic growth, these structures are proportionally larger in the child.
3. The natural process of involution of tonsillar and adenoidal lymphoid tissue in the prepubertal years is associated with decreased frequency of throat and ear infections.

Obstructive Sleep Apnea

1. Adenotonsillar hypertrophy causes airway obstruction, leading to persistent hypoventilation during sleep.
2. Peak incidence in children is between ages 3 and 6 years.
3. Incidence is increased in children with Down syndrome.

Tonsillitis and Adenoiditis

1. In tonsillitis and adenoiditis, structures that are already large become inflamed because of an infectious agent and cause airway obstruction, decreased appetite, and pain.
2. Infection may be caused by bacterial or viral organisms, with viral organisms most commonly implicated.
3. Group A beta-hemolytic *Streptococcus* is the most common bacterial cause.
4. Enlarged adenoids may block nasal passages, resulting in persistent mouth breathing.
5. Chronic adenoiditis without tonsillitis is typically seen in children younger than in age 4 years.

Otitis Media

1. Bacterial infection caused most commonly by *Streptococcus pneumoniae* or *Haemophilus influenzae*.
2. Chronic infection may be associated with enlarged adenoids that block drainage from the eustachian tubes.

Clinical Manifestations

Obstructive Sleep Apnea

1. Loud snoring or noisy breathing in sleep.
2. Excessive daytime sleepiness.
3. Mouth breathing.

Chronic Infection of Tonsils and Adenoids

1. Mouth breathing or difficulty breathing.
2. Frequent sore throat.
3. Anorexia, decreased growth velocity.
4. Fever.
5. Obstruction to swallowing or breathing.
6. Nasal, muffled voice.
7. Night cough.
8. Offensive breath.

Chronic Otitis Media

1. Ear pain or general irritability in young children.
2. Alterations in hearing.
3. Fever.
4. Enlarged lymph nodes.
5. Anorexia.

Diagnostic Evaluation

1. Thorough ear, nose, and throat examination and appropriate cultures to determine presence and source of infection.
2. Preoperative blood studies to determine risk of bleeding—clotting time, smear for platelets, prothrombin time, and partial thromboplastin time.

Management

Appropriate antibiotics are given, and the decision is made to perform surgery. Tonsillectomy and adenoidectomy may be performed together or separately. Debate continues over indications for and benefits of surgery.

Indications for Tonsillectomy

1. Conservative.
    a. Recurrent or persistent tonsillitis. The widely accepted criteria for surgery are seven episodes of tonsillitis in the previous 12 months or five episodes in each of the preceding 2 years.

b. Marked hypertrophy of tonsils, which distorts speech, causes swallowing difficulties, and causes subsequent weight loss.
c. Tonsillar malignancy.
d. Diphtheria carrier.
e. Cor pulmonale due to obstruction.

2. Controversial.
a. Peritonsillar abscess or retrotonsillar abscess.
b. Suppurative cervical adenitis with tonsillar focus.
c. Persistent hyperemia of anterior pillars.
d. Enlarged cervical lymph nodes.

Indications for Adenoidectomy

1. Conservative.
a. Adenoid hypertrophy resulting in obstruction of airway, leading to hypoxia, pulmonary hypertension, and cor pulmonale.
b. Hypertrophy with nasal obstruction accompanied by breathing difficulty and severe speech distortion.
c. Hypertrophy associated with chronic suppurative or serous otitis media and sensorineural or conductive hearing loss, chronic mastoiditis, or cholesteatoma.
d. Mouth breathing due to hypertrophied adenoids.

2. Controversial.
a. Enlarged adenoids.
b. Chronic otitis media and no evidence of complications.
c. Child younger than age 4 years, unless life-threatening situation.

Contraindications to Surgery

1. Bleeding or coagulation disorders.
2. Uncontrolled systemic disorders (eg, diabetes, rheumatic fever, cardiac or renal disease).
3. Presence of upper respiratory infection in the child or immediate family.
4. Specific for adenoidectomy—certain palate abnormalities (ie, cleft palate or submucous cleft palate).

Complications

1. If untreated, obstructive sleep apnea in the child may result in pulmonary hypertension, cor pulmonale, failure to thrive, respiratory failure, attention-deficit disorders, and cardiac arrhythmias.
2. Untreated chronic tonsillitis may result in failure to thrive, peritonsillar or retropharyngeal abscess, difficulty swallowing, and poor eating.
3. Untreated chronic otitis media may result in hearing loss, scarring of the eardrum (tympanosclerosis), mastoiditis, and meningitis.
4. Complications of surgery include hemorrhage, reactions to anesthesia, otitis media, and bacteremia.

Nursing Assessment

Preoperative Assessment

1. Assess the child's developmental level.
2. Assess the parents' and child's understanding of the surgical procedure.
3. Assess psychological preparation of the child for hospitalization and surgery.
   a. Does the child understand what will happen?
   b. Do the parents know the importance of telling the child the truth, and do they have a good understanding of the procedure?
   c. Does the child have preconceived ideas that may pose a threat?
4. Obtain thorough nursing history from the child and parents to gather any pertinent information that would impact the child's care.
   a. Has the child had a recent infection? It is desirable for the child to be free of respiratory infection for at least 2 weeks.
   b. Has the child recently been exposed to any communicable diseases?
   c. Does the child have any loose teeth that may pose the threat of aspiration?
   d. Are there any bleeding tendencies in the child or family?
   e. Are there any family members with a history of adverse reactions to anesthesia?
5. Obtain the child's baseline vital signs along with his or her height and weight.
6. Assess the child's hydration status.

NURSING ALERT The preschool child is especially vulnerable to psychological trauma as a result of surgical procedures or hospitalization.

Postoperative Assessment

1. Assess respiratory status and pain often.
2. Assess frequently for signs of postoperative bleeding; monitor vital signs, as warranted.
3. Assess oral intake.
4. Assess for indications of negative psychological sequelae related to the surgery and hospitalization.

Nursing Diagnoses

- Fear related to painful procedure, unfamiliar environment.
- Anxiety of the parents related to concept of surgery.
- Risk for Deficient Fluid Volume related to reduced intake postoperatively and blood loss.
- Ineffective Airway Clearance related to pain and effects of anesthesia.
- Acute Pain related to surgical incision.

Nursing Interventions

Reducing Fear

1. Prepare the child and parents by encouraging participation in hospital tours and preadmission programs specifically for children.
2. Share information with the child, commensurate with their development stage and cognitive ability, as well as the family.
3. Prepare the child specifically for what to expect postoperatively, using techniques appropriate to the child's developmental level (books, dolls, drawings). Include the following:
   a. Where the child will wake up.
   b. Temporary sore throat, emesis of blood, position, and foul taste and smell in mouth.
   c. Medications.
   d. Fluid regimen and possible IV infusion.
4. Talk to the child about the new things to be seen in the operating room and clear up any misconceptions. Whenever possible, allow the child to see, touch, and examine equipment, such as thermometers, beds, tubings, and suction equipment.
5. Where available, involve the play specialist in the preparation.

Relieving Parental Anxiety

1. Help the parents prepare the child by talking at first in general terms about surgery and progressing to more specific information.
2. Reassure the parents that complication rates are low and that recovery is usually swift.
3. Encourage the parents to stay with the child and help provide care.

Maintaining Adequate Fluid Volume

1. Assess the child frequently for postoperative bleeding. Check all secretions and emesis for the presence of fresh blood. These are indications of hemorrhage:
   a. Increased pulse.
   b. Frequent swallowing while awake and asleep.
   c. Pallor.
   d. Restlessness.
   e. Clearing of throat and vomiting of blood.
   f. Continuous slight oozing of blood over a number of hours.
   g. Oozing of blood in back of throat.
2. Have suction equipment, oxygen, and packing material readily available in case of emergency.
3. Provide adequate fluid intake.
   a. Give ice cubes 1 to 2 hours after awakening from anesthesia.
   b. When vomiting has ceased, cautiously advance to clear liquids.

c. Offer cool fruit juices without pulp at first because they are best tolerated, avoid fluids that are red or purple in color; then offer ice pops and cool water for the first 12 to 24 hours. Avoid red and brown fluids.

d. There is some debate regarding the intake of milk and ice cream the evening of surgery. It can be soothing and can reduce swelling; however, it coats the mouth and throat, causing the child to clear the throat more often, which may initiate bleeding.

NURSING ALERT Notify the surgeon immediately if bleeding is suspected.

Promoting Effective Airway Clearance

1. Assist the child in maintaining a patent airway by draining secretions and preventing aspiration of vomitus.
2. Assess the child for signs and symptoms of airway obstruction and respiratory distress (stridor, drooling, restlessness, agitation, tachypnea, and cyanosis), which may result from edema or the accumulation of secretions.
   a. Place the child prone or semiprone with his or her head turned to side while still under the effects of anesthesia.
   b. Allow the child to assume a position of comfort when alert. (The parent may hold the child.)
   c. The child may vomit old blood initially. If suctioning is necessary, avoid trauma to the oropharynx.
   d. Remind the child not to cough, clear throat, or blow nose.

Improving Comfort

1. Give analgesics, as ordered, parenteral or rectally.
2. Rinse the child's mouth with cool water or alkaline solution.
3. Keep the child and environment free from blood-tinged drainage to help decrease anxiety.
4. Encourage the parents to be with the child when the child awakens.
5. When the parents must leave, reassure the child that they will return.

Family Education and Health Maintenance

1. Explain and write instructions concerning the care of the child at home after discharge.
   a. Diet should still consist of large amounts of fluids and soft, cool, nonirritating foods. (Supply a list of suggestions for the family.)
   b. Eating helps promote healing because it increases the blood supply to the tissues.
   c. Bed rest should be maintained for 1 to 2 days and then daily rest periods for about 1 week. Resume normal eating and activities within 2 weeks after surgery.
   d. Avoid contact with people with infections.

e. Discourage the child from blowing nose and frequent coughing and clearing of his or her throat.
f. Avoid gargling. Mouth odor may be present for a few days after surgery; only mouth rinsing is acceptable.
g. Discourage use of red dye–enhanced foods or analgesics if possible—can be difficult to differentiate from bleeding.

2. Advise the parents to call the health care provider if the following occur. (Ensure that the parents have the phone numbers of the health care provider and hospital emergency department.)
   a. Earache accompanied by fever.
   b. Any bleeding, often indicated only by frequent swallowing; most common between the 5th and 10th postoperative days when membrane sloughs from surgical site.
3. Teach about medications prescribed or suggested for pain relief.
4. Discuss with the parents what results they can expect from the surgery.
   a. Decreased number of sore throats.
   b. Lessened evidence of obstructive symptoms.
   c. Decreased incidence of cervical lymphadenitis.
   d. Improvement in nutritional status.
   e. No improvement in nasal allergies.
   f. No improvement in secretory otitis media.
5. Guide the parents in helping the child think of the experience as a positive one after the surgery is over, to make subsequent health care experiences easier.
   a. Talk about what happened and the positive outcomes.
   b. Let the child play out his or her feelings.

Evaluation: Expected Outcomes

- Acts out surgery with dolls, asks questions.
- Parents interact with the child, ask appropriate questions.
- Takes fluids well; no signs of bleeding.
- No vomiting; breathing without difficulty.
- Verbalizes reduced pain.

Asthma

Asthma is a chronic, inflammatory disease of the airways, characterized by airflow obstruction, bronchial hyperreactivity, and increased mucus production. The course of asthma is highly variable. Many cells and mediators play a role, including mast cells, eosinophils, neutrophils, and epithelial cells. Classic signs and symptoms include cough, wheezing, shortness of breath/dyspnea, and chest tightness. Children may also report stomach pain when they are experiencing an asthma exacerbation. The Global Initiative for Asthma (GINA) guidelines (2017), published by the World Health Organization, and the National Asthma Education and Prevention Program of the National Institutes of Health provide evidence-based categorization, treatment, and ongoing control information.

Assessment of Asthma Control

1. Although severity is best evaluated prior to the use of asthma medications, it can be established based on the medications necessary to gain control and direct initial therapy.
2. Two domains of asthma control are assessed at each encounter: risk and impairment.
    a. Risk is measured by exacerbations.
    b. Impairment is determined both on initial diagnosis and ongoing assessment.
3. Factors that affect impairment include the following:
    a. Day and nighttime asthma symptoms.
    b. Use of quick-relief medication.
    c. Pulmonary function tests/peak flow measurements if the child is capable.
    d. Limitations of daily activities.
    e. Adverse effects of medications.
    f. Progression of lung disease.
4. Several validated tools are available for patients aged 12 years and older to complete, including the Asthma Control Test, Asthma Control Questionnaire, and Asthma Therapy Assessment Questionnaire.
    a. These tools quantify symptoms, quick-relief medication usage, effect of asthma on quality of life, and patient/family perception of control.
    b. To assist in the diagnosis of asthma, particularly in very small children who cannot perform lung function tests, an asthma predictive index can help identify children likely to have asthma.

NURSING ALERT Level of control guides adjustment of medications, and nurses can use this assessment to identify patients/families who need more asthma education for better gain control of asthma.

EVIDENCE BASE Johnson, D. P., Arnold, D. H., Gay, J. C., et al. (2018). Implementation and

improvement of pediatric asthma guideline improves hospital-based care. *Pediatrics, 141*(2), 1–9.

Variations of Asthma

Cough Variant Asthma

Cough variant asthma is typically seen in children, where cough (especially at night) is the principal symptom. The child may never wheeze. Although the symptoms are chronic and commonly mild in many children, severe exacerbations (attacks) may arise, even resulting in respiratory failure and death.

Exercise-Induced Bronchospasm

Exercise-induced bronchospasm refers to symptoms of cough, shortness of breath, chest pain, tightness, wheezing, and endurance problems during or after vigorous activity. Typically, symptoms begin during exercise and peak 5 to 10 minutes after stopping; they may resolve spontaneously within 20 to 30 minutes. Diagnosis is confirmed by documenting a decrease in peak expiratory flow (PEF) or forced expiratory volume in 1 second (FEV_1), before and after exercise and at 5-minute intervals for 20 to 30 minutes. This condition may occur without chronic asthma and has a different pathophysiology from asthma that is triggered by exercise. The preferred treatment consists of short-acting beta-2 agonists, taken 15 minutes prior to exercise. Cromolyn sodium, available only for a nebulizer, is an alternative, although less effective.

Factors that Increase Risk of Asthma Death

EVIDENCE BASE Kim, C. K., Callawayc Z., & Gern, J. E. (2018). Viral infections and associated factors that promote acute exacerbations of asthma. *Allergy Asthma Immunol Res, 10*(1),12–17.

Global Initiative for Asthma. (2017). Pocket guide for asthma management and prevention. Available: *www.ginasthma.org.*

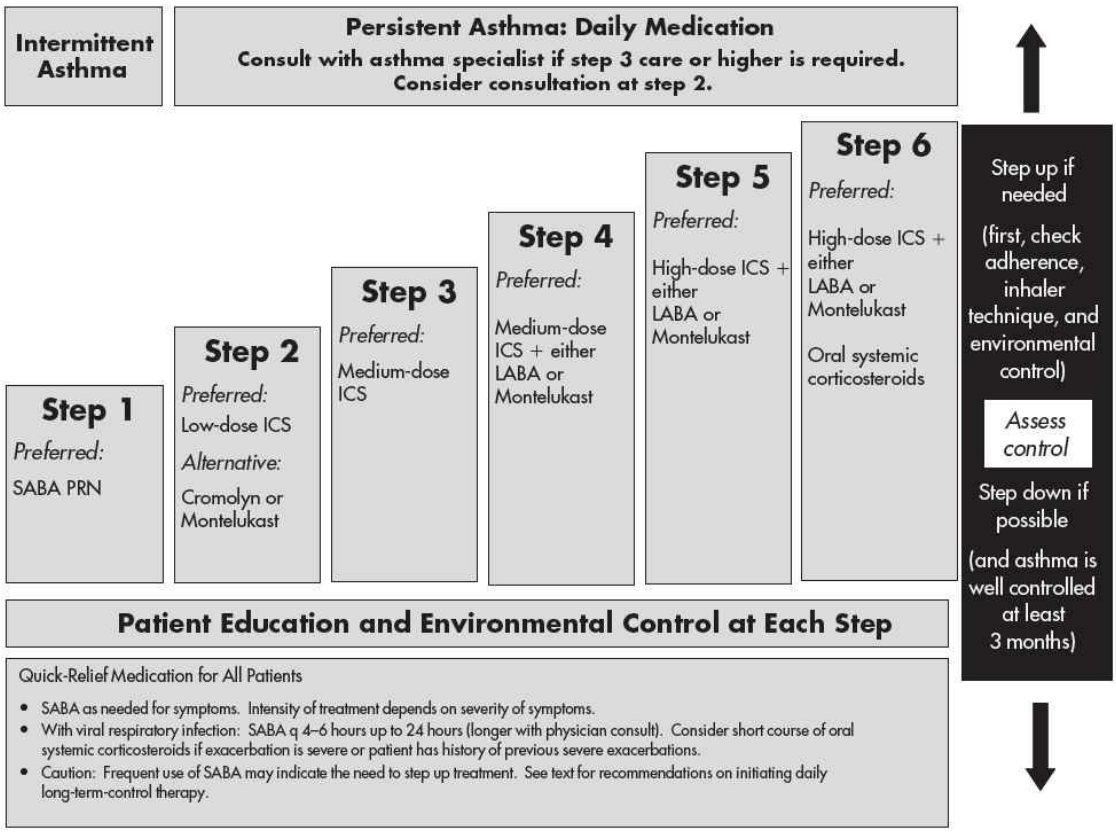
---

1. Previous severe exacerbation (intubation or intensive care admission).
2. Hospitalization two or more times within the year, three or more emergency department (ED) visits in the last year.
3. Use of more than two canisters per month of short-acting beta-adrenergic (SABA).
4. Difficulty perceiving airway obstruction or the severity of worsening asthma.
5. Low socioeconomic status or inner-city residence.
6. Illicit drug use.
7. Major psychological problems or psychiatric disease.
8. Comorbidity, such as cardiovascular disease or other chronic lung disease.
9. Other factors, lack of asthma action plan, sensitivity to *Alternaria*.

Management

The Stepwise Approach to Managing Asthma, developed by the EPR 3, identifies classifications of asthma according to symptoms and suggests pharmacologic options for the control of asthma. Medications may be "stepped up or down" depending on the patient's response to therapy. See Table 44-2 and Table 44-3, page 1184, for the recommended management of asthma for infants and children age 0 to 4 and 5 to 12 years. See page 801 for the management of older children with asthma.

Table 44-2 Stepwise Approach for Managing Asthma in Children 0–4 Years of Age



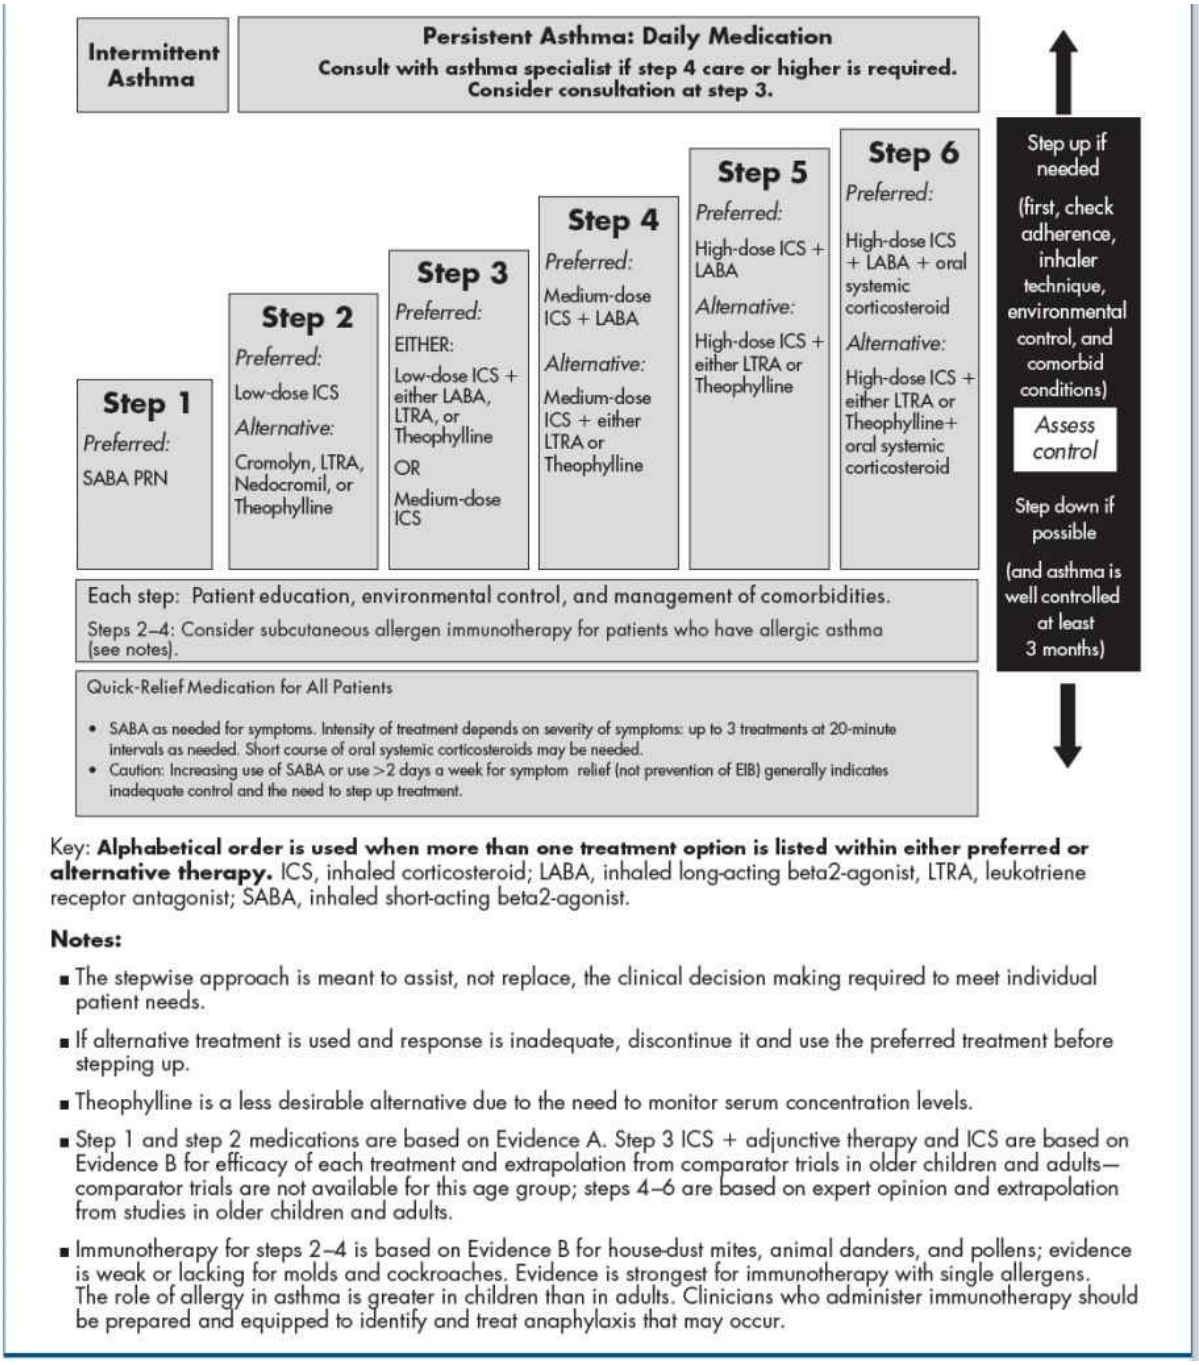
Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting beta2-agonist; SABA, inhaled short-acting beta2-agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4–6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children 0–4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.

From National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program. (2007). Expert panel report 3: Guidelines for the diagnosis and management of asthma (p. 305). Available: www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf.

Table 44-3 Stepwise Approach for Managing Asthma in Children 5–11 Years of Age



Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** ICS, inhaled corticosteroid; LABA, inhaled long-acting beta2-agonist, LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta2-agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Step 1 and step 2 medications are based on Evidence A. Step 3 ICS + adjunctive therapy and ICS are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

From National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program. (2007). Expert panel report 3: Guidelines for the diagnosis and management of asthma (p. 306). Available: www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf.

For additional information on treatment and specific dosages, see Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, National Heart, Lung and Blood Institute, National Asthma Education and Prevention Program, Full Report, NIH Publication No. 08-4051, 2007. Available: *www.nhlbi.nih.gov/guidelines/asthma/asthgdln.pdf*.

Acute Exacerbation

1. Be alert for severe asthma exacerbation. Exacerbations may be associated with viral respiratory infections.
2. In a severe exacerbation, the child is short of breath, may be audibly wheezing with a prolonged expiratory phase, restless, apprehensive, anxious, diaphoretic, and tachycardic; color may be pale or

flushed and lips may be dark red or cyanotic.

   a. There are signs of respiratory distress, such as nasal flaring, use of accessory muscles, retractions, one- to two-word dyspnea (speaking in short phrases), tachypnea, hypoxemia, and respiratory alkalosis progressing to respiratory acidosis.
   b. Breath sounds may be decreased and there may be decreased level of consciousness.
   c. A young child will assume tripod position; an older child will sit upright with shoulders hunched.

3. Signs of respiratory distress in infants include use of accessory muscles, inspiratory and expiratory wheezing, paradoxical breathing, cyanosis, respiratory rate greater than 60, and oxygen saturation less than 90%. These infants are at greater risk of respiratory failure.
4. The goals of emergency management are to quickly reverse airflow obstruction, to correct hypoxemia, and to reduce the likelihood of recurrence.
5. Assess PEF rate or FEV_1 upon arrival; assess degree of respiratory distress or fatigue.
6. Obtain an oxygen saturation level by pulse oximetry.
7. Obtain arterial or capillary blood gas levels in infants with an oxygen saturation of 90% or less and in a child with moderate to severe respiratory distress.
8. Deliver humidified oxygen via nasal cannula, hood, or face mask at lowest level necessary to maintain adequate oxygenation. Obtain a brief history and physical and focus on prior treatment and possible triggers of the episode, such as respiratory infection or lack of medication.
9. Administer emergency treatment, as indicated.
   a. SABA with ipratropium, either by nebulization or by MDI with spacer (with face mask in young child).
   b. Systemic corticosteroids should be administered early in treatment.
   c. Adjunctive treatments include IV leukotriene modifiers, heliox, and magnesium sulfate.
   d. Antibiotics are generally not used unless there is evidence of bacterial infection.
10. Hospitalized patients will need frequent assessment, repeat or continuous SABA treatments, corticosteroids, and treatment of any comorbid condition, such as sinusitis.
11. Discharge planning for patients with exacerbations should include an action plan for medications, recognition and treatment of acute asthma, and plans for follow-up.
12. Children in severe status asthmaticus unresponsive to the above therapy may require the following:
   a. Intubation and mechanical ventilation with 100% oxygen for impending or actual respiratory distress, decreased mental alertness, increased fatigue, or partial pressure of arterial carbon dioxide ($PaCO_2$) greater than or equal to 42 mm Hg.
   b. Nebulized beta-2 agonist, hourly or continuously.
   c. Anticholinergic such as ipratropium, although generally limited to the emergency department.
   d. IV corticosteroid therapy.
   e. Admission to ICU.
   f. Pharmacologic paralysis to ventilate effectively.

g. Cardiopulmonary monitoring of the child's response to treatment.

h. Placement of an arterial line for blood monitoring.

13. Therapies not recommended for treating an exacerbation, based on the 2007 National Heart, Lung, and Blood Institute Expert Panel Report:

a. Subcutaneous beta-2 agonist provides no advantage over inhaled medication.

b. Theophylline or aminophylline therapy is not recommended in the ED. It does not provide additional benefit to short-acting beta-2 agonists; it may produce adverse effects.

c. Chest physiotherapy (CPT) and mucolytics.

d. Antibiotics are not recommended for asthma treatment. However, antibiotics may be needed in patients with fever, purulent sputum, and evidence of bacterial pneumonia.

e. Anxiolytic and hypnotic drugs are contraindicated.

f. Aggressive hydration is not recommended in older children. Assess fluid status; make corrections, as needed, for infants and young children to decrease risk of dehydration.

NURSING ALERT Cyanosis of the lips and nail beds is an ominous sign.

NURSING ALERT Absence of wheezing with decreased breath sounds and inability to blow a PEF indicates minimal air exchange. This situation requires immediate, swift attention to prevent respiratory failure. Respiratory failure tends to progress quickly and is difficult to reverse.

TRANSITIONAL CARE ALERT To prevent readmission for acute asthma exacerbation in the transitional period from hospitalization to outpatient/community care, strategies prior to discharge should target medication adherence and parental knowledge of asthma. Compliance with treatment plan has been cited as the most important factor in preventing readmission.

EVIDENCE BASE Hewner, S., Sullivan. S. & Yu, G. (2018). Reducing Emergency Room Visits and Inpatient Hospitalizations by Implementing Best Practice for Transitional Care Using Innovative Technology and Big Data. *Worldviews Evidence Based Nursing*, 23, [epub ahead of print].

Long-Term Management

1. As the child becomes stabilized, begin to develop a home and school management plan. Components of the plan should include the following:
   a. The use of quick-relief medications (SABA); expected effect and side effects.
   b. The use of long-term controllers, which include corticosteroids, leukotriene modifiers, mast cell stabilizers, and long-acting beta agonists (LABA). See page 802 for mechanism and adverse reactions. Note: LABA should only be prescribed if poor control with other medications due to increased risk of asthma-related deaths.
   c. Inhalation technique with nebulizer or multidose inhaler with spacer (see Figure 44-3).
   d. Peak flow and symptom monitoring.
   e. Use of PEF zone system, if indicated (see below).
   f. Identification of triggers (eg, exercise, weather change, infection, allergen exposure [pollen, mold, dust mite, animal dander, cockroach or mouse exposure]).
   g. Environmental control by removal of suspected stimuli.
   h. Hydration, nutrition, rest, and exercise regimens.
   i. Emergency action plans.
2. Plan a team conference involving the child, parents, school nurse, and teacher, if possible. Ideally, the plan should be clear and easy for the child and family to follow, adapted to their lifestyle, and using the least amount of medications necessary to control and prevent the child's asthma symptoms. A written action plan should be submitted to the school, including information on medications (possible self-medication by the adolescent), identified triggers, steps in an emergency plan, and emergency contact information. Emergency action plans may need to include multiple family caregivers, and residences. An example of this form can be found at *https://www.nhlbi.nih.gov/files/docs/public/lung/asthma_actplan.pdf.* Stress that, without exception, no smoking should be permitted in the home or car of a child with asthma. Even if the child is out of the home, the residual odor will cause symptoms. Opening windows or using sprays and air cleaners are not acceptable alternatives.
3. Encourage the parents to pay particular attention to environmental control in the child's bedroom, including elimination of dust, not allowing any pets, and avoidance of any strong smells or sprays. If using wood stoves in the home, find out if there is an alternative source of heat.
4. Obtain more information from the National Asthma Education Program (*https://www.nhlbi.nih.gov/science/national-asthma-education-and-prevention-program-naepp*) the American Academy of Allergy, Asthma and Immunology (*www.aaaai.org*), or the American Lung Association (*http://lung.org/*).

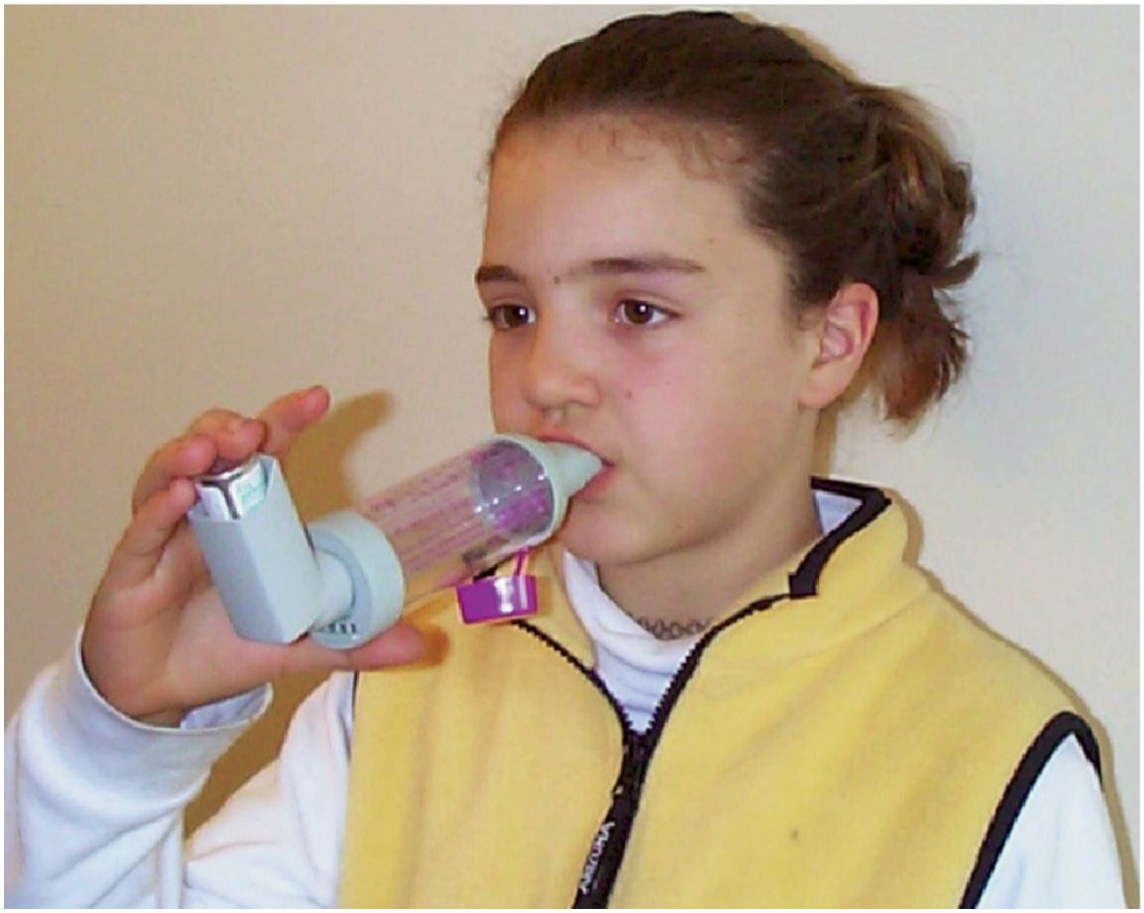


Figure 44-3. Multidose inhaler use with spacers.

Peak Expiratory Flow Monitoring and the Zone System

1. Teach the family and child about PEF monitoring at home as well as other important indicators, as directed (see Figure 44-4).
   a. PEF monitoring is not emphasized as much in current guidelines as in the past.
   b. Other indicators of severity include symptom assessment, need for medication, and measures of control such as the asthma control questionnaire.
2. A PEF meter measures the PEF rate that can be produced during a forced expiration. It measures airflow through the large airways; the result is effort dependent. PEF measurements can be initiated in children as young as age 5. Given time and practice, consistent readings will be produced. (See page 805 for directions on use of PEF meter.)
3. A table of predicted PEF values should be included in the packaging of the home PEF meter. These values are based on age and height. A few patients may find their readings above or below the published values. Therefore, each child should establish a personal best PEF value. Ideally, this should be implemented during a time when the child is symptom free. If PEF readings are consistently below predicted values, the health care provider should be contacted and additional medications may be necessary.
4. Use of the PEF zone system along with a home asthma management plan can assist families in the

proper use of medications, and assists in decision making regarding the degree of airflow obstruction. After the personal best PEF value is identified, teach the patient that subsequent PEF measurements can be classified into three zones that will dictate a home management plan.

a. Green Zone = 80% to 100% of personal best. No asthma symptoms are present. Continue usual medications.
b. Yellow Zone = 50% to less than 79% of personal best. Signals caution. May be experiencing an asthma episode or day-to-day control is suboptimal. Need to use short-acting inhaled beta-2 agonist, follow emergency plan, and contact health care provider for further instructions.
c. Red Zone = less than 50% of personal best value. This zone signals danger. Must take a short-acting inhaled beta-2 agonist immediately and, if PEF does not return to yellow or green zone, contact health care provider or proceed to the ED immediately.

Figure 44-4. Peak flow monitoring.

Respiratory Distress Syndrome (Hyaline Membrane Disease)

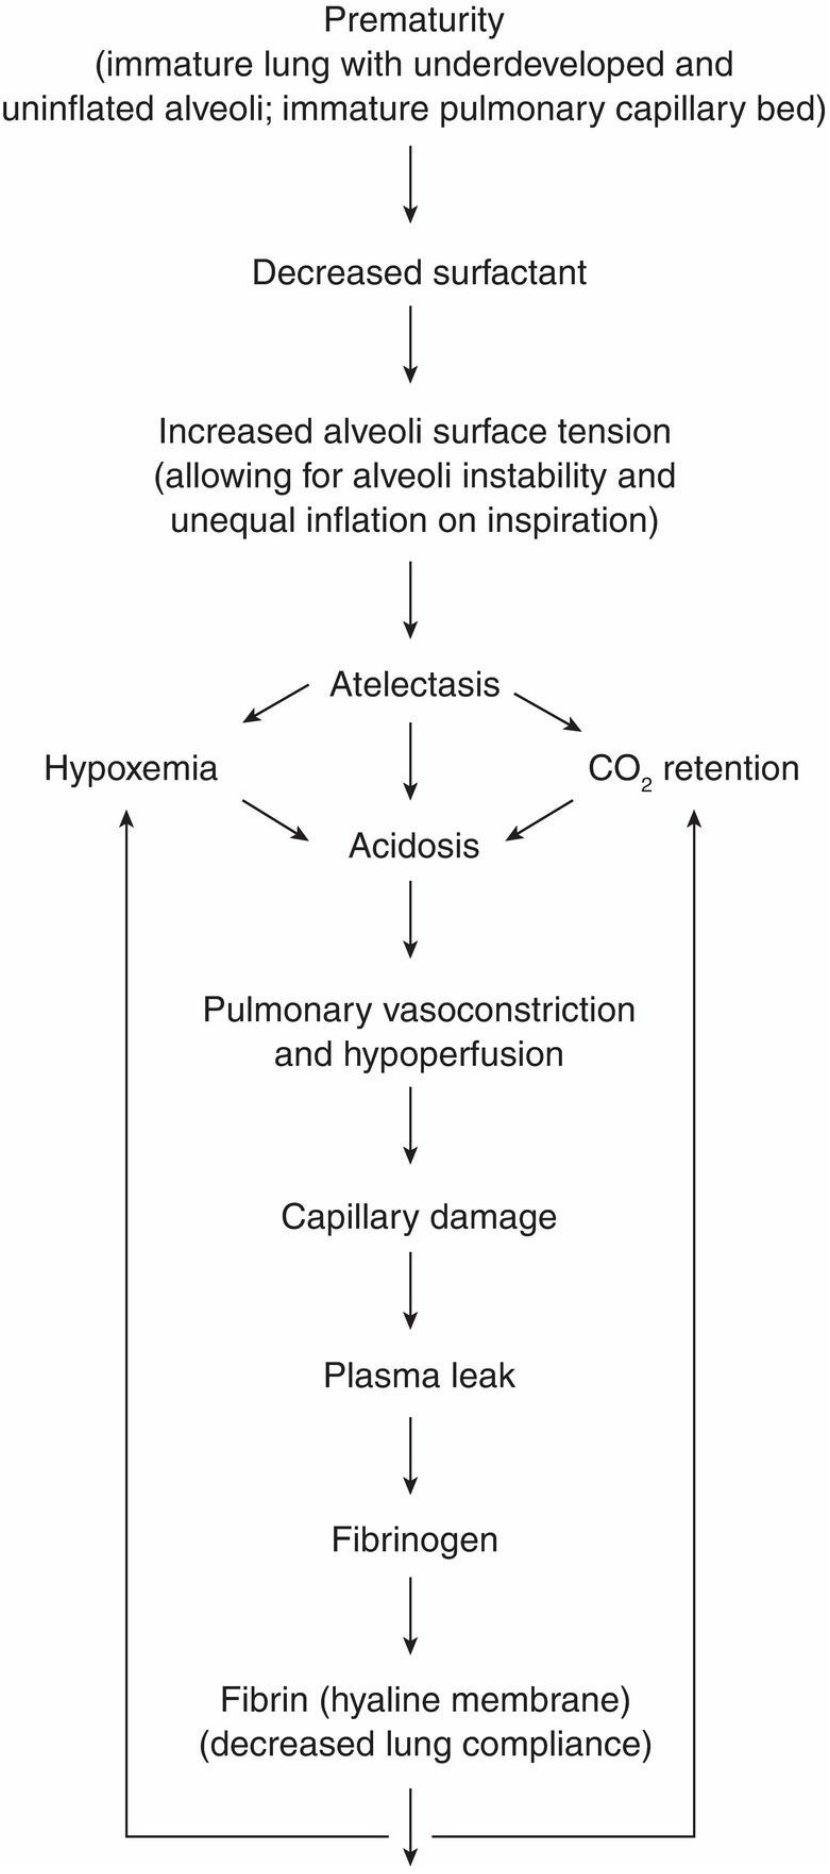
Respiratory distress syndrome (RDS), formerly known as hyaline membrane disease, is a syndrome of premature neonates that is characterized by progressive and usually fatal respiratory fail ure resulting from atelectasis and immaturity of the lungs. RDS occurs most commonly in premature neonates (primarily weighing between 1,000 and 1,500 g) and between 28 and 37 weeks' gestation. In neonates 26 to 28 weeks' gestation, the incidence is 50% to 70% and increases with degree of prematurity. RDS can be fatal; those who survive are at risk for chronic respiratory and neurologic complications.

Pathophysiology and Etiology

1. Adequate pulmonary function at birth depends on the following:
    a. An adequate amount of surfactant (a lipoprotein mixture) lining the alveolar cells, which allows for alveolar stability and prevents alveolar collapse at the end of expiration.
    b. An adequate surface area in air spaces to allow for gas exchange (ie, sufficient pulmonary capillary bed in contact with this alveolar surface area).
2. RDS is ultimately the result of decreased pulmonary surfactant, incomplete structural development of lung, and a highly compliant chest wall.
3. Contributing factors are any factor that decreases surfactant, such as the following:
    a. Prematurity and immature alveolar lining cells.
    b. Acidosis.
    c. Hypothermia.
    d. Hypoxia.
    e. Hypovolemia.
    f. Diabetes.
    g. Elective cesarean delivery.
    h. Fetal or intrapartum stress that compromises blood supply to fetal lungs: vaginal bleeding, maternal hypertension, difficult resuscitation associated with birth asphyxia. (Some situations, such as steroid therapy or a heroin-addicted mother, result in the acceleration of surfactant.)
    i. RDS due to nonpulmonary factors such as cardiac defects, sepsis, airway obstruction, intraventricular hemorrhage, hypoglycemia, and acute blood loss.
4. Surfactant production is deficient by type II alveolar cells. (Although some surfactant may be present at birth, it may not be regenerated at an adequate rate.) Surfactant production may be reduced because of the following:
    a. Extreme immaturity of alveolar lining cells.
    b. Diminished or impaired production rate resulting from fetal or early neonatal stress.
    c. Impairment of release mechanism for phospholipid from type II alveolar cells.
    d. Death of many of these cells responsible for decreased surfactant production.
5. Intra-alveolar surface tension is increased, and alveoli are unstable and collapse at the end of expiration.

Functional reserve capacity—the amount of air left in the lungs after expiration—is decreased; thus, the next breath requires almost as much effort as the first breath after birth.

6. More oxygen and energy are required to expand the alveoli with each breath, causing fatigue.
7. The number of alveoli that expand progressively decreases, leading to alveolar instability and atelectasis.
8. Pulmonary vascular resistance increases, causing hypoperfusion of lung.
9. Persistence of fetal circulation right-to-left shunt results, leading to hypoxemia and hypercapnia, which lead to respiratory and metabolic acidosis.
10. Hypoxemia and pulmonary vascular pressure cause ischemia in the alveoli, leading to transudate in the alveoli and formation of a membranous layer (see Figure 44-5).
11. Gas exchange becomes inhibited. Lungs become stiff (decreased compliance), requiring more pressure to expand them.
12. Airway obstruction leads to increased hypoxia and vasoconstriction, and the cycle continues.
13. RDS is usually a self-limiting disease and symptoms peak in about 3 to 4 days, at which time surfactant synthesis begins to accelerate and pulmonary function and clinical appearance begin to improve.
    a. Moderately ill infants or those who do not require assisted ventilation usually show slow improvement by about 48 hours and rapid recovery over 3 to 4 days with few complications.
    b. Severely ill and very immature infants who require some ventilatory assistance usually demonstrate rapid deterioration, such as decreased cardiac inflow, decreased arterial pressure, apneic episodes, cyanosis, pallor, and flaccid, unresponsive shocklike state. Ventilatory assistance may be required for several days, and chronic lung disease and other complications are common.



Prematurity
(immature lung with underdeveloped and
uninflated alveoli; immature pulmonary capillary bed)
Decreased surfactant
Increased alveoli surface tension
(allowing for alveoli instability and
unequal inflation on inspiration)
Atelectasis
Hypoxemia
CO_2 retention
Acidosis
Pulmonary vasoconstriction
and hypoperfusion
Capillary damage
Plasma leak
Fibrinogen
Fibrin (hyaline membrane)
(decreased lung compliance)

Figure 44-5. Schematic outline of respiratory distress syndrome.

Clinical Manifestations

Symptoms are usually observed soon after birth and may include those listed here and increase in severity over the first 2 days of life.

Primary Signs and Symptoms

1. Expiratory grunting.
2. Sternal, suprasternal, substernal, and intercostal retractions progressing to paradoxical seesaw respirations.
3. Inspiratory nasal flaring.
4. Tachypnea less than 60 breaths/minute.
5. Hypothermia.
6. Cyanosis when child is in room air (infants with severe disease may be cyanotic even when given oxygen), increasing need for oxygen.
7. Decreased breath sounds and dry "sandpaper" breath sounds.
8. Pulmonary edema.
9. As the disease progresses:
    a. Seesaw retractions become marked with marked abdominal protrusion on expiration.
    b. Peripheral edema increases.
    c. Muscle tone decreases.
    d. Cyanosis increases.
    e. Body temperature drops.
    f. Short periods of apnea occur.
    g. Bradycardia may occur.
    h. Changes in distribution of blood throughout the body result in pale gray skin color.
    i. Diminished breath sounds.

Secondary Signs and Symptoms

1. Hypotension.
2. Edema of the hands and feet.
3. Absent bowel sounds early in the illness.
4. Decreased urine output.

Diagnostic Evaluation

1. Prenatal diagnosis: evaluation of amniotic fluids to assess fetal lung maturity.
    a. Lecithin/sphingomyelin ratio—tests of surfactant phospholipids in amniotic fluid.

b. Phosphatidylcholine and phosphatidylglycerol (PG)—phospholipids that stabilize surfactant.
c. Fetal maturity assay—determines PG levels in amniotic fluid or neonatal tracheal aspirates.
d. Lamellar bodies test—measures a storage form of surfactant in amniotic fluids.

2. Laboratory tests:
   a. $PaCO_2$—elevated.
   b. Partial pressure of arterial oxygen (PaO_2)—low.
   c. Blood pH—low because of metabolic acidosis.
   d. Calcium—low.
   e. Serum glucose—low.
3. Chest x-ray—diffuse, fine granularity; "whiteout," very heavy, uniform granularity reflecting fluid-filled alveoli and atelectasis of some alveoli, surrounded by hyperdistended bronchioles; "ground glass" appearance with prominent air bronchogram extending into periphery of lung fields. Pulmonary interstitial emphysema is observed in premature neonates with RDS because of overdistension of distal airways.
4. Pulmonary function studies—stiff lung with a reduced effective pulmonary blood flow.

Management

EVIDENCE BASE Liu, J., Wang, W., Liu, F., & Li, Z. (2018). Pediatric acute respiratory distress syndrome - current views. *Exp Ther Med, 5*(2), 1775–1780.Pacheco, G.S., Mendelson, J., & Gaspers, M. (2018). Pediatric ventilator management in the emergency department. *Emerg Med Clin North Am., 36*(2), 401–413.

Early recognition is imperative so that treatment may be initiated to halt the progression of RDS. In fact, treatment should begin prior to birth if the mother is at risk for delivering the baby preterm. Transportation to a facility providing specialized care is desirable, when possible.

Supportive

1. Maintenance of oxygenation—PaO_2 at 60 to 80 mm Hg to prevent hypoxia; frequent arterial pH and blood gas measurements and use of a pulse oximeter.
2. Maintenance of respiration with ventilatory support, if necessary.
   a. Intermittent mandatory ventilations delivered via ET tube. Allows the infant to breathe spontaneously at his or her own rate while the ventilator provides a preset cycle of respirations and pressure.
   b. Positive end-expiratory pressure (PEEP) via ET tube. The ventilator is pressure or volume limited. Provides increased PEEP during expiration to prevent alveolar collapse; residual airway pressure is maintained.

c. Continuous positive airway pressure (CPAP) delivered via mask or nasal prongs. Used in spontaneous respiration to improve oxygenation by preventing collapse of the alveoli and increasing diffusion time.

d. Synchronized intermittent mandatory ventilation allows the infant to breathe spontaneously between mechanical breaths. In assist or control mode, mechanical breaths are delivered at a regular rate if spontaneous breaths are not detected.

3. Maintenance of normal body temperature.
4. Maintenance of fluid, electrolyte, and acid–base balance—metabolic acidosis buffered with sodium bicarbonate.
5. Maintenance of nutrition—IV fluids, as prescribed.
6. Antibiotics, as needed, to treat infection.
7. Constant observation for complications—pneumothorax, disseminated intravascular coagulation (DIC), patent ductus arteriosus (PDA) with heart failure, chronic lung disease.
8. Care appropriate for a small, premature neonate.
9. Prevent hypotension.
10. Maintain a hematocrit of 40% to 45%.

Aggressive (Offered in Tertiary Care Centers)

1. Administration of exogenous surfactant into lungs early in the disease.
   a. Especially beneficial in the very low birth weight (VLBW) infant.
   b. May be given preventively to VLBW infants at birth.
   c. Available preparations are natural (derived from animal lungs) and synthetic (protein free): bovine and synthetic surfactant.
   d. Administered into the ET tube.
2. Surfactant replacement therapy.
   a. Prophylactic surfactant therapy: infants at increased risk for RDS, infants of less than 27 weeks' gestational age, and infants with a birth weight of less than 1,250 g.
   b. Treatment initiated after infant is stabilized in the delivery room or within 15 minutes of life.
   c. Rescue surfactant therapy: infants with moderate to severe RDS, requiring ventilatory assistance, with an oxygen requirement greater than 40%.
   d. Benefits of surfactant: decreases oxygen requirement and mean airway pressure; decreases pulmonary leaks.
   e. Complications observed in surfactant administration: pulmonary hemorrhage, PDA, mucus plugging.
   f. Nursing assessment with surfactant administration: suctioning delayed for 1 hour or as indicated by protocol. Assist with delivery of surfactant, collection and monitoring of ABG studies, meticulous monitoring of oxygenation status with pulse oximeter or transcutaneous monitor ($TcpCO_2$).
   g. Assess the infant's tolerance of the procedure: increase in respiratory compliance, which will require

adjustments of the ventilator.

3. High-frequency ventilation—mechanical ventilation that uses rapid rates (can be greater than 900 breaths/minute) and tidal volumes near and, commonly, less than anatomical dead spaces.
   a. Jet ventilator delivers short burst of gases at high flow.
      i. Exhalation is passive.
      ii. Necrotizing tracheitis is a significant complication, along with hypotension and pneumopericardium.
   b. Oscillator ventilator delivers gases by vibrating columns of air.
      i. Exhalation is active.
      ii. The child appears to shake on the bed, which may be frightening for the parents.
4. Extracorporeal membrane oxygenation (ECMO)—indicated in infants with reversible cardiac or respiratory failure. ECMO is a modified heart–lung bypass machine used to allow gas exchange outside the body.
   a. Blood is removed from the venous system by a catheter placed in the internal jugular vein or right atrium.
   b. Oxygen is added and carbon dioxide is removed with a membrane oxygenator.
   c. Oxygenated blood is returned by way of the right common carotid (in venoarterial ECMO) or the femoral vein (in venovenous ECMO).
   d. The infant must be heparinized for the procedure, increasing the risk of intraventricular hemorrhage. For this reason, VLBW infants or infants of decreased gestational age are usually not candidates for the procedure.
   e. One nurse and one ECMO specialist must be present at the bedside at all times to monitor the patient and equipment. The patient will receive paralytic agents as well as analgesia and sedation; therefore, diligent continuous monitoring is required.
   f. Cannula dislodgement or tubing separation will result in immediate hemorrhage. Tubing and cannula must be secured and visible.
   g. Administration of vasoactive medications may be required to support alteration in cardiac output and blood pressure.
   h. Blood transfusions may be indicated because of blood loss from frequent sampling or anemia of prematurity.
5. Ventilatory support modalities for RDS currently under study: nitric oxide, liquid ventilation (tidal or partial), and perfluorocarbon-assisted gas exchange.

Complications

1. Complications related to respiratory therapy are as follows:
   a. Air leak: pneumothorax, pneumomediastinum, pneumopericardium, and pneumoperitoneum.
   b. Pneumonia, especially Gram-negative organisms.

   c. Pulmonary interstitial emphysema.
2. PDA or heart failure.
3. Hypotension.
4. Intraventricular hemorrhage—typically seen in infants weighing less than 1,500 g.
5. DIC.
6. Chronic problems associated with long-term use of oxygen:
   a. Bronchopulmonary dysplasia (BPD)—cystic-appearing lungs with hyperinfiltration, obstructive bronchiolitis, dysplastic changes, and pulmonary fibrosis.
   b. Chronic respiratory infections.
7. Necrotizing enterocolitis.
8. Tracheal stenosis.
9. Retinopathy of prematurity (retrolental fibroplasia).
10. Other complications related to prematurity.
11. Renal failure requiring use of dialysis.

Nursing Assessment

1. Review the birth history.
   a. Apgar scores 1 and 5 minutes after birth.
   b. Type of resuscitation required.
   c. Treatments or medications administered.
   d. Medications or anesthesia administered to the mother during labor.
   e. Estimated gestational age.
   f. Maternal history—contributing factors or complications.
2. Carefully assess the infant's respiratory status to determine the degree of respiratory distress.
   a. Determine the degree and severity of retractions.
   b. Count the respiratory rate for 1 full minute, note level of activity, and determine if they are regular or irregular.
   c. Identify periods of apnea, length, and type of stimulation necessary.
   d. Listen for expiratory grunting or whining sounds from the infant when quiet. This indicates an attempt to maintain PEEP and prevent alveoli from collapse.
   e. Note nasal flaring.
   f. Note cyanosis—location, improvement with oxygen.
   g. Auscultate chest for diminished breath sounds and presence of crackles.
3. Determine the infant's cardiac rate and rhythm.
   a. Count the apical pulse for 1 full minute.
   b. Note irregularities in the rate or bounding pulses.

4. Observe the infant's general activity.
    a. Lethargic or listless.
    b. Active and responds to stimuli.
    c. Infant's cry.
5. Assess the skin for cyanosis, jaundice, mottling, paleness or grayness, and edema.

Nursing Diagnoses

- Impaired Gas Exchange related to disease process.
- Imbalanced Nutrition: Less than Body Requirements related to prematurity and increased energy expenditure on breathing.
- Ineffective Thermoregulation related to immaturity.
- Impaired Parenting related to separation from the neonate due to hospitalization.

Nursing Interventions

Promoting Adequate Gas Exchange

1. Have emergency equipment readily available for use in the event of cardiac or respiratory arrest.
2. Institute cardiorespiratory monitoring to continuously monitor heart and respiratory rates.
3. Administer supplemental oxygen.
    a. Incubator with oxygen at prescribed concentration.
    b. Plastic hood with oxygen at prescribed concentration when using radiant warmer.
    c. CPAP, if indicated, using nasal prongs or ET tube.
4. Assist with ET intubation and maintain mechanical ventilation, as indicated.
5. Measure oxygen concentration every hour and record.
6. Monitor ABG levels, as appropriate. Obtain sample of blood through indwelling umbilical line, arterial puncture, or capillary puncture. (Capillary gas analysis for monitoring $PaCO_2$ and pH but not PaO_2.)
7. Institute pulse oximetry, if available, for continuous monitoring of the blood's arterial oxygen saturation (SaO_2).
    a. Avoid using adhesive to secure the sensor when the infant is active. Wrap it snugly enough to reduce sensitivity to movement but not tight enough to constrict blood flow.
    b. If transcutaneous PaO_2 monitor is used, reposition the probe every 3 to 4 hours to avoid burns caused by heating the probe to achieve sufficient arterialization.
8. Observe the infant's response to oxygen.
    a. Observe for improvement in color, respiratory rate and pattern, and nasal flaring.
    b. Note response by improvement in arterial or capillary blood gas levels.
    c. Observe closely for apnea.
9. Stimulate the infant if apnea occurs. If unable to produce spontaneous respiration with stimulation within 15 to 30 seconds, initiate resuscitation.

10. Position the infant to allow for maximal lung expansion.
    a. Prone position provides for a larger lung volume because of the position of the diaphragm, decreases energy expenditure, and increases the time spent in quiet sleep; however, it may be contraindicated because of placement of the umbilical catheter. The risk for sudden infant death syndrome (SIDS) is increased, but the infant is continuously monitored.
    b. Change position frequently.
11. Suction, as needed, because the gag reflex is weak and cough is ineffective.
12. Try to minimize time spent on procedures and interventions and monitor effects on respiratory status. (Infants undergoing multiple procedures lasting 45 minutes to 1 hour have shown a moderate decrease in PaO_2.)
13. The decision to suction should be based on assessment of the infant, such as auscultation of chest, decrease in oxygenation, excessive moisture in the ET tube, and irritability.
    a. Nasopharyngeal, tracheal, or ET tube suctioning should be done gently, quickly, 5 seconds or less, with intermittent suction applied as the catheter is withdrawn.
    b. To prevent hypoxemia, observe oximeter before, during, and after the procedure.
    c. Suctioning of the ET tube is done to maintain a patent airway. The practice of inducing a catheter into the tube until resistance is met and then withdrawn has been shown to cause trauma to the tracheal wall. Instead, the suction catheter should be premeasured according to the size of the infant's ET tube length and documented. When suctioning, do not insert the catheter beyond this predetermined length. This will prevent damage to the mucosa.
14. Observe for complications of suctioning: bronchospasm, vagal nerve stimulation, bradycardia, hypoxia, increased intracranial pressure, trauma to airway, infection, and pneumothoraces.
15. VLBW and extremely low birth weight neonates cannot tolerate percussion and vibration. Trendelenburg position is contraindicated in premature neonates and may result in increased intracranial pressure.
16. Record all nursing observations.

NURSING ALERT Prone position may present several problems: Turning head to side can compromise upper airway and increase airflow resistance; observation of chest is obstructed, making retractions difficult to detect; and abdominal distention is more difficult to recognize.

Promoting Adequate Nutrition and Hydration

1. Administer IV fluids or enteral feeding, as ordered, and observe infusion rate closely to prevent fluid overload.
2. Observe IV sites for infiltration or infection; use meticulous technique to prevent sepsis.
3. If umbilical artery catheter is in place, observe for bleeding.

4. Provide adequate caloric intake (80 to 120 kcal/kg/24 hours) through the following:
    a. Nasojejunal tube (best tolerated by VLBW neonates).
    b. Nasogastric tube.
    c. Parenteral nutrition—$D_{10}W$ or hyperalimentation fluid usually required, especially in the acute phase of illness.
5. Monitor for hypoglycemia, which is especially common during stress. Maintain serum glucose greater than 45 mg/dL.
6. Monitor intake and output closely.
    a. Include amount of blood drawn (small infants can become anemic because of frequent blood sampling).
    b. Apply urine collection bag to obtain sample of urine and measure specific gravity periodically.
7. Weigh the infant daily and record.

Maintaining Thermoregulation

1. Provide a neutral thermal environment to maintain the infant's abdominal skin temperature between 97°F and 98°F (36.1°C and 36.7°C) to prevent hypothermia, which may result in vasoconstriction and acidosis.
2. Adjust incubator or radiant warmer to obtain desired skin temperature. For the infant weighing less than 1,250 g, the radiant warmer should be used with caution because of increased water loss and potential for hypoglycemia.
3. Prevent frequent opening of incubator.
4. Ensure that oxygen is warmed to a temperature between 87.6°F and 93.2°F (30.9°C and 34°C) with 60% to 80% humidity.

Encouraging Parental Attachment

1. Identify factors that may prohibit the parents' visitation and communication: geographic distance, lack of transportation, care of siblings, employment restrictions, economic issues, lack of telephone in the home, and fear. Refer to social services for assistance and intervention, if required.
2. If the neonate was transported to a tertiary care center immediately after birth, send the mother a photograph of the neonate.
3. Call the parents daily to update them on the infant's condition until they are able to visit the child. Emphasize positive aspects of the infant's status.
4. Refer to the child by his or her first name when speaking with the parents.
5. Prepare the parents for the neonatal intensive care unit (NICU) environment and how their child will appear before their first visit.
6. Assist the parents to participate in the child's care, as appropriate.
7. Demonstrate for the parents how they can touch and speak to the child while the child is in an Isolette/incubator.

8. Allow the parents to hold the infant as soon as possible.
9. If the mother plans to breast-feed, assist her with expressing her milk and use the breast milk to feed the infant when enteral feedings are initiated.
10. If the infant has siblings, provide the parents with information on how to discuss the infant's illness with them.
11. If unit policies allow and the situation is appropriate, encourage sibling visitation with adequate preparation.
12. Provide the parents with information concerning the disease process, expected outcomes, and usual course of the NICU stay. Encourage the parents to ask questions and participate in the care plan.
13. Help parents work through their distress at the birth of a premature child.
14. Assess parents' support mechanisms (eg, grandparents, friends).

Family Education and Health Management

1. Prepare the family for long-term follow-up, as appropriate. Infants with BPD may eventually go home on oxygen therapy.
2. Stress the importance of regular health care, periodic eye examinations, and developmental follow-up with the parents.
3. Ensure that the family receives information on routine well-baby care.
4. Before discharge, parents should feel comfortable in their abilities to care for the infant. Referrals for home nursing visits should be completed and a physician identified for follow-up care.

Evaluation: Expected Outcomes

- Respiratory rate within normal range for age; pattern regular and unlabored.
- Tolerates enteral feedings well; weight gain noted.
- Maintains temperature within normal limits.
- Parents interact with infant, participate in care, and ask appropriate questions.

Cystic Fibrosis

EVIDENCE BASE Schmid-Mohler, G. (2018). Patient-reported outcome measures for symptom perception during a cystic fibrosis exacerbation. *Respiratory Care, 63*(3), 353–366.

Cystic fibrosis (CF) is an autosomal recessive disorder affecting the exocrine glands, causing abnormal viscosity of secretions. It primarily affects the pulmonary and GI systems. Approximately 4% to 5% of Caucasians are symptomless carriers of the CF gene. Slightly more males than females are affected. Incidence is estimated at approximately 1 in 3,500 live Caucasian births. CF is found in all racial groups. There are approximately 30,000 people living with CF in the United States, 45% of who are aged 18 or older. Presently, the predicted survival age extends to the late 40s, compared with a life expectancy of less than 1 year in the 1950s.

Pathophysiology and Etiology

1. CF is caused by a genetic defect in a single gene located on the long arm of chromosome 7 that encodes the cystic fibrosis transmembrane conductance regulator (CFTR).
2. The variations in the onset of the disease, symptomatology, and clinical presentation within the CF population are attributed to the over 1,000 mutations of the CF gene. CFTR is responsible for the fluid balance across epithelial cells.
3. The malfunction of CFTR results in the following:
    a. Decreased chloride secretion into the airway lumen.
    b. Increased sodium reabsorption, which leads to decreased airway surface liquid volume.
    c. Thickened mucus, impaired mucociliary clearance, chronic infection, plugged bronchi.
    d. Chronic inflammation, airway damage, atelectasis, and hyperinflation of lungs.
    e. Progressive bronchiectasis, irreversible fibrotic changes in lungs.
4. GI and pancreatic involvement includes the following:
    a. Acini and ducts of pancreas become filled with thick mucus and are obstructed.
    b. Trypsin, chymotrypsin, lipase, and amylase do not reach the small intestine.
    c. Digestion is impaired. Interruption of the enterohepatic circulation of bile acids probably results in interference with normal pancreatic lipolysis and fat absorption through the intestinal wall.
    d. Stools are abnormal and indicate malabsorption syndrome.
    e. Meconium ileus often occurs in infants, indicating that bowel is obstructed by thick intestinal secretions.
    f. Biliary cirrhosis occurs because the intrahepatic biliary tract is obstructed by thick secretions.
    g. In 30% of CF patients, the gallbladder is small, with suboptimal function. Gallstones develop in up to 10% of patients.

5. Sweat gland involvement includes the following:
    a. Secretions contain excessive amount of sodium and chloride, leading to excessive loss, especially with hot weather, fever, or exertion.
    b. Saliva also contains an excess of sodium and chloride.

Clinical Manifestations

Presentation usually occurs younger than age 6 months but may occur at any age. Signs and symptoms and severity of the disease vary and change over time as the disease progresses.

Respiratory Manifestations

1. Recurrent pulmonary infections—*H. influenza*, *S. aureus*, *P. aeruginosa*.
2. Cough, dry to productive. Chronic clearing of throat may indicate increased mucus production.
3. Wheezing, crackles on auscultation are indicative of respiratory exacerbation.
4. Dyspnea.
5. Barrel-shaped chest (increased anteroposterior chest diameter).
6. Cyanosis.
7. Clubbing of fingers and toes.
8. Nasal polyps and pansinusitis.
9. Progressive chronic obstructive pulmonary disease (COPD). A 10% drop in FEV_1 is a sign of an acute exacerbation or worsening lung disease.
    a. Mild form of CF—slightly decreased FEV_1 (70% to 90%).
    b. Moderate CF—FEV_1 of 40% to 69%.
    c. Severe forms of CF—life-threatening pulmonary disease with FEV_1 of less than 40%.

GI Manifestations

1. Meconium ileus found in neonates.
2. Failure to thrive and failure to gain weight in the presence of a good appetite.
3. Abdominal distention.
4. Vomiting, dehydration, and electrolyte imbalance.
5. Maldigestion, steatorrhea (fatty stools, loss of fat-soluble vitamins).
6. Rectal prolapse.
7. Distal intestinal obstructive syndrome.
8. Biliary cirrhosis, obstructive jaundice.
9. Pancreatitis.

Other Manifestations

1. Thin extremities, sallow skin, wasted buttocks.
2. Hyperglycemia, glucosuria, polyuria, weight loss.

3. Salty taste when parents kiss skin.
4. Sterility in males.
5. Hypoproteinemia and anemia.
6. Bleeding diathesis.
7. Hyponatremia and heat prostration.
8. Kyphosis.

Diagnostic Evaluation

1. Quantitative sweat chloride test; pilocarpine iontophoresis, performed at a CF Foundation accredited center by skilled personnel. Measures sodium and chloride content in sweat.
    a. Chloride level greater than 60 mEq/L is virtually diagnostic.
    b. Chloride of 40 to 60 mEq/L is borderline and should be repeated, followed by genotype for the most frequent CFTR mutations.
    c. Sodium level greater than 60 mEq/L is diagnostic.
2. Measurement of trypsin concentration in duodenal secretions; absence of normal concentration virtually diagnostic.
3. Analysis of digestive enzymes (trypsin and chymotrypsin) in stool—reduced, used for initial screening for CF.
4. Chest x-ray—may be normal initially; later shows areas of infection, overinflation, bronchial thickening and plugging, atelectasis, fibrosis, and emphysema.
5. Sinus radiograph or computed tomography shows mucus plugging.
6. Analysis of stool for steatorrhea.
7. Meconium strip test for stool includes lactose and protein content; used for screening.
8. Sputum or throat cultures to rule out infection.
9. Pulmonary function studies (after age 4 years).
    a. Decreased vital capacity and flow rates.
    b. Increased residual volume or increased total lung capacity.
10. Diagnosis made when a positive sweat test is seen in conjunction with one or more of the following:
    a. Positive family history for CF.
    b. Typical COPD.
    c. Documented exocrine pancreatic insufficiency.
    d. Failure to thrive.
    e. History of frequent respiratory infections.
11. Prenatal diagnostic tests—prenatal genetic screening for families affected with CF:
    a. Chorionic villus sampling at approximately 12 weeks' gestation.
    b. Deoxyribonucleic acid (DNA) probes.

c. Microvillar enzymes.

12. Neonatal screening: immunoreactive trypsinogen; if elevated, DNA assay for single and multiple CFTR mutations.

Management

Goals of treatment are to prevent and minimize pulmonary complications, ensure adequate nutrition for growth, and assist the family and child to adapt to chronic disease.

Pulmonary Interventions

1. Antimicrobial therapy, as indicated, for pulmonary infection.
   a. Oral antibiotics may be given prophylactically or when symptomatic.
   b. IV antibiotics are given when the child fails to respond to oral antibiotics; this may be inpatient or at-home therapy.
   c. Inhaled antibiotics such as tobramycin. Colistin may be used for severe lung disease or colonization of organisms. Recently, some practitioners advocate using nebulized antibiotics earlier in therapy.
   d. Patients with CF metabolize antibiotics rapidly; if drug dosage is higher than normal, monitor for signs of toxicity.
2. Bronchodilators to increase the airway size and assist with mucociliary clearance. Many CF patients also have airway hyperreactivity.
   a. Long-term clinical improvement with inhaled bronchodilators has not been well supported in the literature. Salmeterol, a long-acting bronchodilator, has demonstrated improvements in pulmonary function and is effective in decreasing nocturnal hypoxia.
   b. Inhaled steroids for treatment of airway hyperreactivity.
3. Aerosols, expectorants, and mucolytic agents to decrease viscosity of secretions.
   a. Recombinate human DNase administered via nebulizer improves pulmonary function and decreases sputum viscosity and pulmonary exacerbations.
   b. Hypertonic saline solution 3% to 7%.
   c. Improves airway clearance and lung function, although it is not as effective as recombinant human DNase.
   d. Acetylcysteine solution is not recommended because of irritant effect on airways.
4. CPT for bronchial drainage, especially during acute exacerbations.
   a. Postural drainage (see Figure 44-6, page 1193).
   b. Some patients use a vibrating vest that utilizes a shaking motion rather than manual postural drainage.
   c. Coughing and deep-breathing exercises; huffing helps move secretions from smaller airways.
   d. Increase physical activity—aerobic activity.
   e. Active cycle of breathing, a new technique, improves lung function without decreasing oxygenation. Consists of breathing control, thoracic expansion, forced expiratory technique, and huffing. An

assistant is not required.

f. Autogenic drainage—breathing at various lung volumes to move and evacuate mucus. Oxygenation should not be affected during procedure.

g. Positive expiratory pressure (PEP) and flutter. PEP airway technique is utilized by those with severe disease. It reduces airway collapse due to bronchiectasis. Available as low-pressure PEP, high-pressure PEP, and oscillating PEP with a flutter or acapella device.

h. High-frequency chest compressions—externally applied device provides oscillation to the chest, resulting in release of mucus from the airway wall.

5. Bronchopulmonary lavage—treatment of atelectasis and mucoid impaction using large volumes of saline (used in some institutions in the United States).
6. Lobectomy—resection of symptomatic lobar bronchiectasis to retard progression of lesion to total lung involvement.

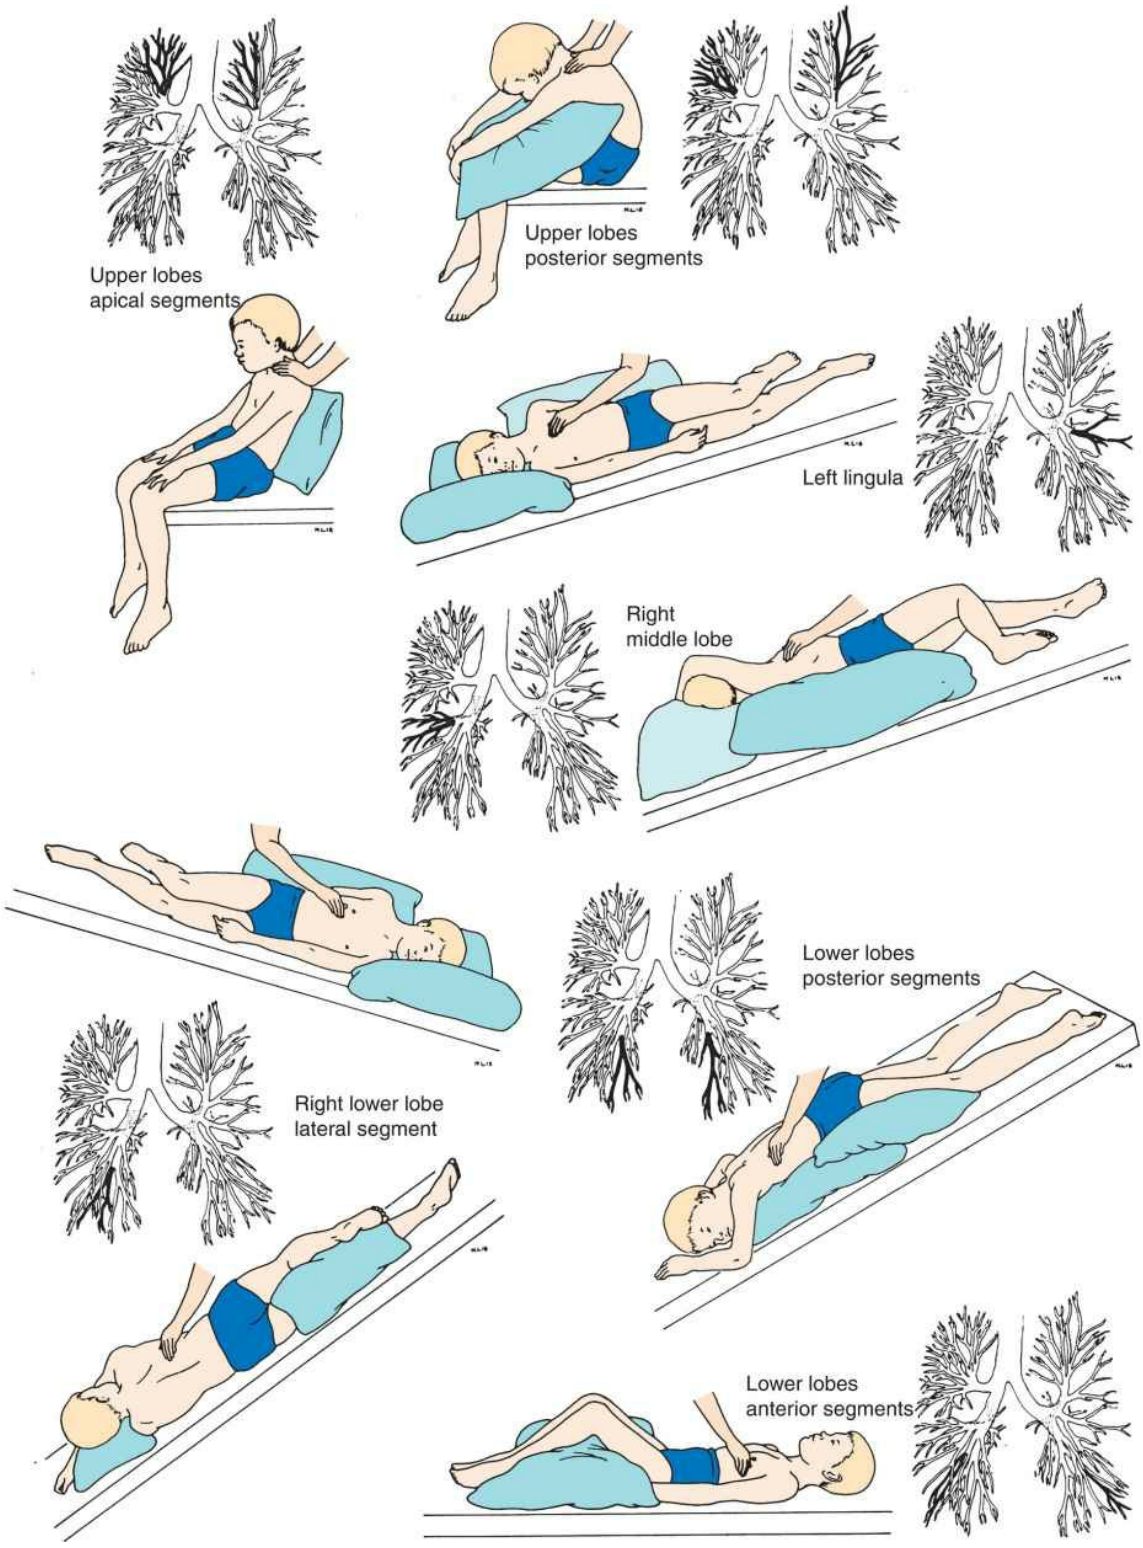


Figure 44-6. Positions for postural drainage.

EVIDENCE BASE Mikesell, C., Kempainen, B., Laguna, T., et al. (2017). Objective measurement of adherence to out-patient airway clearance therapy by high-frequency chest wall compression

in cystic fibrosis. *Respiratory Care, 62*(7), 920–927.

GI Interventions

1. Pancreatic enzyme supplementation is provided with each feeding.
   a. Favored preparation is pancrelipase.
   b. Antacids are occasionally helpful to improve tolerance of enzymes.
   c. Favorable response to enzymes is evidenced by tolerance of fatty foods, decreased stool frequency, absence of steatorrhea, improved appetite, and lack of abdominal pain.
2. Provide a high-energy diet by increasing carbohydrates, protein, and fat (possibly as high as 40%). Increases in dietary intake should consider growth and repair, infection, the work of breathing and energy expenditure for coughing, malabsorption, and physical activity.
3. Provide zinc and iron supplements and water-soluble and fat-soluble vitamins.
4. Ensure adequate fluid and salt intake.

Controversial and Experimental Treatments

1. Heart–lung, double-lung, or single-lung transplantation for end-stage lung disease.
   a. This treatment is limited by availability of donor organs.
   b. Long-term survival at 5 years is approximately 50%.
   c. Bilateral lobar transplantation using a new method, called bipartitioning of a single-donor lung, is under study. This method could result in increased availability of donor organs.
2. Liver transplant.
3. Gene therapy.
   a. This treatment is at present only being undertaken by a small number of centers because of its complexity.
   b. Therapy is based on somatic gene correction; an attempt to correct the defect in the cells of the individual is made by adding the correct gene sequence to the cells.
   c. One trial method will use a virus carrying DNA with the appropriate gene sequence, which will be introduced into the affected lung cells by nebulization.
   d. A second method being investigated is the introduction into the lungs of DNA by nebulization with the appropriate gene sequence suspended in liposomes.
   e. It is thought that the treatment will need to be repeated at regular intervals.
4. *Pseudomonas aeruginosa* genome is complete, which should lead to the development of new medications to combat this common lung infection in CF.

Complications

1. Pulmonary infections:
   a. Most frequently caused by *P. aeruginosa*, *S. aureus*, *H. influenzae*, and *Burkholderia cepacia*.

Pseudomonas is the most difficult organism to treat.

b. Bronchiectasis and bronchiolitis.

2. Other pulmonary complications—emphysema, atelectasis, pneumothorax, hemoptysis (primarily seen in adolescents), and pulmonary hypertension.
3. Biliary cirrhosis, leading to portal hypertension, esophageal varices, and splenomegaly.
4. Pancreatic fibrosis with islets of Langerhans involvement, resulting in glucose intolerance and CF-related diabetes.
5. Cor pulmonale.
6. Chronic sinusitis.
7. Rectal polyps (3 months to 3 years).
8. Rectal prolapse.
9. Intussusception (younger than 2 years).
10. Pancreatitis.
11. Hypertrophic pulmonary osteoarthropathy—arthritis, clubbing, periosteitis; the long tubular bones are most commonly involved.
12. Bone thinning and demineralization.
13. Depression.
14. Heat prostration.
15. Fibrosis of epididymis and vas deferens in male; aspermia.
16. Growth retardation.
17. Gastroesophageal reflux.
18. Allergic bronchopulmonary aspergillosis.
19. Respiratory failure and death.

NURSING ALERT *B. cepacia* affects approximately 5% of CF patients, is associated with a rapid decline in pulmonary function, and is multiple antibiotic-resistant. Twenty percent of colonized patients develop fulminant septicemia and necrotizing pneumonia, leading to death.

Nursing Assessment

1. Check for family history of CF, failure to thrive, and unexplained infant death; check the child's history and physical condition. Carefully listen for subtle information that may suggest CF.
2. Assess respiratory status—respiratory rate, presence of tachypnea, wheeze, cough, character of sputum, and oxygen saturation level.

a. Increased work of breathing.

b. Quality of breath sounds by auscultation.

c. Child's perception of respiratory status.
d. Ability to participate in activities of daily living, exercise tolerance, quality of sleep.
e. Assess for oxygen desaturation with sleep.

3. Assess nutritional status and characteristics of stool.

Nursing Diagnoses

- Ineffective Airway Clearance related to thick pulmonary secretions.
- Risk for Infection related to thick, tenacious secretions.
- Imbalanced Nutrition: Less than Body Requirements related to decreased appetite or inadequate absorption.
- Disturbed Body Image related to chronic disease process.
- Interrupted Family Processes related to the child with a chronic disease.

Nursing Interventions

Promoting Airway Clearance

1. Use intermittent nebulizer therapy three to four times per day when child is symptomatic.
   a. Use pretreatment postural drainage.
   b. Administer bronchodilators and other medications, diluted in normal saline, in aerosol form to penetrate respiratory tract. Proper technique is necessary to deliver the correct dose of medication. If using a face mask, it should fit snugly; movement of the mask by ¾ inch (2 cm) could decrease the delivery of medication by 85%.
2. Perform CPT three to four times per day after nebulizer therapy; perform more frequently if infection is present.
   a. Perform prior to meals or 1 hour after eating to prevent vomiting or discomfort.
   b. Place the child in a position that gives the greatest access to the affected lobes of the lung and facilitates gravity drainage of mucus from specific lung areas.
   c. Children with gastroesophageal reflux should not use the head-down position during CPT.
3. Help the child to relax to cough more easily after postural drainage.
4. Suction the infant or young child when necessary if he or she is unable to cough.
5. Teach child breathing exercises using pursed lips to increase duration of exhalation.
6. Monitor child's oxygen saturation levels during procedures.
7. Maintain cautious oxygen therapy because of chronic carbon dioxide retention.
8. Monitor for signs and symptoms of pneumothorax, such as tachypnea, tachycardia, pallor, dyspnea, and cyanosis.
9. Monitor for hemoptysis, which requires immediate treatment and may be life threatening.
10. Provide treatment of hemoptysis: bed rest, cough suppressants, and antibiotics.
    a. Bronchoscopy is used to locate the site, cauterize, or embolize.

b. Administer vitamin K, as directed.

NURSING ALERT Mist therapy is no longer recommended because water droplets may cause bronchospasm in some patients, and the equipment required to deliver the therapy is frequently contaminated with opportunistic organisms.

Preventing Infection

Adherence to infection control procedures must be enforced to prevent the spread of nosocomial infections.

1. Provide frequent mouth care to reduce the chance of infection because mucus is present.
2. Restrict contact with people with respiratory infections.
3. Administer antibiotics, as prescribed, to treat specific organisms when the child is symptomatic.
4. Most institutions change nebulizers after each use for CF patients.
5. Monitor closely for deteriorating respiratory status.
6. Provide good skin care and position changes to prevent skin breakdown of malnourished child.
7. Change diapers promptly to prevent diaper rash and superimposed infection.

NURSING ALERT To decrease the risk of transmission of *B. cepacia* within the hospital setting, children who test positive for the pathogen are placed on room isolation.

Promoting Adequate Nutrition

1. Refer to dietitian for dietary assessment.
2. Encourage diet composed of foods high in calories and protein and moderate to high in fat because absorption of food is incomplete. Provide 120% to 150% of recommended dietary allowances because only 80% to 85% of intake is absorbed.
3. Administer fat-soluble vitamins in water-miscible solution in two to three times the normal dose, as prescribed, to counteract malabsorption.
   a. Give vitamins A, D, and E on a daily basis.
   b. Give vitamin K when the child has an infection or is being treated with antibiotics.
4. Administer pancreatic enzymes with each meal and snack. Dose is based on the child's weight, weight gain, growth, food intake, and number and character of bowel movements.
   a. Mix capsule, granules, or powder with small portion of food for infant or small child; do not mix with formula, which may not be finished.
   b. Offer the older child capsules or tablets.
   c. Withhold enzymes, as ordered, if the child is taking only clear liquid diet or enteral feedings.

d. Beads should not be chewed or crushed.

e. The CF Foundation discourages the use of generic enzymes.

5. Increase salt intake during hot weather, fever, or excessive exercise to prevent sodium depletion and cardiovascular compromise.
6. To prevent vomiting, allow ample time for feeding, especially if irritable because of not feeling well and coughing.
7. Check weights at least weekly to assess nutritional interventions. Document and plot height and weight every 3 months.
8. Infants who are breast-fed will need enzyme supplementation. If supplementation with formula is necessary, choose a high-calorie preparation.
9. Administer supplemental parenteral or enteral feedings, as required.
10. Constipation, due to malabsorption, decreased gastric motility; viscous intestinal secretions may be treated with laxatives, stool softeners, or rectal administration of x-ray contrast material.

Enhancing Self-Esteem and Body Image

1. Explain each procedure, medication, and treatment to the child as appropriate for age.
2. Allow the child to show frustrations, fears, and feelings by talking, complaining, or crying.
3. Support and comfort the child by talking to and holding him or her.
4. Provide diversional activities related to the child's interests and praise the child for his or her accomplishments.
5. Encourage the older child to take an active role in his or her self-management and be involved in the care plan.
6. Help the child to identify strengths and limitations and to feel good about self.
7. Help to redirect feelings of anger, fear, or frustration, to increase compliance with CPT.
8. Encourage regular exercise and activity to foster a sense of accomplishment and independence and improve pulmonary function. Consent from health care provider is necessary prior to the initiation of an exercise program. Oxygenation status during exercise should be assessed.

Enhancing Family Processes

1. Provide opportunities for the parents to learn all aspects of care for the child.
2. Provide education and support during hospitalization to make home care easier.
3. Encourage maintenance of family activities and involvement with other children.
4. Initiate social work referral, as needed.
5. Encourage information sharing about CF with friends, teachers, and relatives. Explain that one of the most important things people can do to help a child with CF is to treat him or her just as they would any other child.
6. Help family share and interpret feelings about CF and its impact on all of their lives.
7. Encourage families to foster the older child's independence when the time comes.

Family Education and Health Maintenance

1. Teach parents to have a thorough understanding of the dietary regimen and special need for calories, fat, and vitamins. Consultation with a registered dietitian is recommended.
2. Discuss the child's need for salt replacement and free access to salt as well as the increased need for salt during hot weather or in the presence of fever, vomiting, or diarrhea.
3. Help the parents to become skilled at CPT and other pulmonary treatments. Demonstrate and explain procedures and evaluate their return demonstration.
4. Help the family to schedule care for the child within the framework of family life.
    a. CPT should be done at least 1 hour after meals.
    b. Nebulizer treatments should be done before CPT.
    c. Mild exercise and activity are beneficial to the child.
    d. Vacations and major family outings can be planned for remissions of the child's symptoms.
5. Help the parents to provide emotional support to their child. The child needs love, understanding, and security, not overprotection.
6. Stress the importance of regular medical care.
    a. Routine immunizations.
    b. Prompt attention to infection.
    c. Continued evaluation and supervision in home management.
    d. Attention to developments through research that may change therapy.
    e. Prevention or early detection of complications.
7. Stress the importance of following up with regular health care provider for routine follow-up according to Cystic Fibrosis Foundation.
    a. Outpatient visits, four per year.
    b. Pulmonary function tests, two or more per year.
    c. Respiratory cultures, at least one per year.
    d. Creatinine level, every year.
    e. Glucose level, every year if older than age 13.
    f. Liver enzymes, every year.
8. Discuss with parents the limitations and expectations for the child.
    a. With proper care, the child will most likely live to adulthood but may be smaller and shorter than peers.
    b. Play and school participation depends on severity of illness.
    c. Involve teachers and school nurses in planning of the child's day.
9. Suggest parents and child meet other CF families. Investigate location and participation in summer camps for children with CF.
10. Investigate home care options for families, especially respite services for caregivers.

11. After the diagnosis is confirmed, refer the parents to genetic counseling. It is important for the parents to realize that the affected child inherits the defective gene from both parents. Each pregnancy will result in a 25% chance that the infant will have CF, a 50% chance that it will be a carrier of the CF gene and *not* have CF, and a 25% chance that the infant will neither be a carrier of the CF gene nor have CF.
12. Refer families for additional information and support to agencies such as Cystic Fibrosis Foundation (*www.cff.org*). Most areas have local chapters of the organization.
13. The pediatric health care team should discuss with the patient and parents the concept of eventual transitioning of care from a pediatric CF center to an adult CF center as early as possible—an important issue that should not be left until adolescence. Facilitate a planned, efficient, and smooth transition by
    a. Encouraging the child to gradually assume responsibility for health care.
    b. Encouraging the parents to foster the adolescent's independence.
    c. Providing patient and family time to adjust and educate themselves about the transitioning process.
    d. Identifying and introducing the child and his or her family to members of the adult care team.
    e. Advocating for the patient in regard to any restrictions superimposed by the patient's health insurance plan.
14. Sadly, at some point, it will become apparent to the health care team that the time has arrived to discuss end-of-life issues. Use a family-centered approach to provide care for the child and family facing a life-threatening illness or death. Discuss hospice care and other available services with the family (see page 1153).

EVIDENCE BASE Butler, A., Hall, H., & Copnell, B. (2018). The changing nature of relationships between parents and healthcare providers when a child dies in the paediatric intensive care unit. *Journal of Advanced Nursing, 74*(1), 89–99.

Lynch, J., III, Savah, D., Belperio, J., & Weigt, S. S. (2015). Lung transplantation for cystic fibrosis: Results, indicators, complications, and controversies. *Seminars in Respiratory Critical Care Medicine, 36*(2), 299–320.

Evaluation: Expected Outcomes

- Tolerates CPT four times per day for 30 minutes with stable oxygen saturation.
- No signs of respiratory infection.
- Eats well with no vomiting; weight stable.
- Plays, interacts appropriately.
- Parents ask questions; meet, as necessary, with a social worker; and take part in care of their child.

Apnea of Infancy and Brief Resolved Unexplained Events in Infants

Apnea of infancy (AOI) is defined as an unexplained episode of cessation of breathing for 20 seconds or longer or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and marked hypotonia in an infant of 37 weeks' gestation or more at the onset of apnea.

Apnea of prematurity (AOP) is defined as sudden cessation of breathing that lasts for 20 seconds and may or may not be accompanied by bradycardia and cyanosis in an infant younger than 37 weeks' gestation.

Brief Resolved Unexplained Event in Infants are defined as an episode that is frightening to the observer and is characterized by some combination of apnea (central or obstructive), color change, cyanosis, pallor or plethora, marked change in muscle tone, extreme limpness, choking, or gagging.

Pathophysiology and Etiology

1. Cause is often unknown—may result from many different pathologic processes; may be idiopathic.
2. Apnea may be related to organic disorders, such as seizure disorders, sepsis, severe infection, hypoglycemia, and impaired regulation of breathing while sleeping or feeding, gastroesophageal reflux, upper airway abnormalities, metabolic disorders, or abuse.
3. Abnormal properties of surfactant have been reported in some children with recurrent ALTE.
4. A diagnosis of AOI is made when no identifiable cause of ALTE is found.
5. AOP is related to immature neurologic and respiratory control mechanisms.

Clinical Manifestations

1. The infant may be found by parents or caretaker to be limp, cyanotic, and pale with no respiration. Skin is cool to the touch.
2. Some form of resuscitation may be required.
3. The infant usually exhibits symptoms when asleep, although the syndrome may occur during waking hours.
4. Types of AOP are as follows:
    a. Central or diaphragmatic—chest movement ceases, absence of airflow.
    b. Obstructive—chest and diaphragm move, but there is no air exchange.
    c. Mixed—cessation of airflow and chest movement, followed by respiratory effort without airflow.

Diagnostic Evaluation

Complete history, physical examination, and diagnostic tests are aimed at ruling out other medical problems that could result in respiratory failure as a secondary cause.

1. Complete blood count with differential, serum glucose, electrolytes, calcium, phosphate, magnesium, and ABG levels, as indicated.
2. Chest x-ray.
3. Electrocardiogram.

4. Electroencephalogram (may not be routine) and neurologic examination.
5. Respiratory studies—a 12- to 24-hour pneumogram recording of small changes in electrical resistance with each breath or respiratory pattern; multichannel sleep test with continuous printout, monitoring heart rate, chest impedance, nasal airflow, and oxygen saturation.
6. Continuous cardiac and apnea monitoring for recurrence of event, prolonged apnea, or bradycardia.
7. Barium swallow for GER.
8. Because of hypoxemia that may have occurred, the child should be assessed for learning difficulties, discrete neurologic impairments, impaired hearing or vision, and personality disorders.
9. Polysomnograph—records brain waves, eye movements, esophageal manometry, and end-tidal carbon dioxide.

Management

1. BRUE may require hospitalization and cardiorespiratory monitoring.
2. Specific treatment of the underlying cause, if identified.
3. Theophylline may be used to decrease apneic episodes (therapeutic levels of 6 to 13 mcg/mL). Caffeine, which also acts as a central nervous system stimulant for breathing, may be given to maintain a trough level of 5 to 20 mcg/mL.
4. Long-term follow-up for physiologic and neurologic behavioral functions.
5. Prevention of SIDS: the most effective method of prevention is public education to avoid prone sleeping. More education is needed, with an emphasis on poor, underserved areas (see Box 44-1).

BOX 44-1 Sudden Infant Death Syndrome

EVIDENCE BASE Goldber, N., Rodriguez-Prado, Y., Tillery, R., et al. (2018). Sudden Infant Death Syndrome: A Review. *Pediatric Annals, 47*(3), e118–e123.Stiffler, D., Ayers, B., Fauvergue, C., et al. (2018). Sudden infant death and sleep practices in the Black community. *Journal of Specialists in Pediatric Nursing, 23*(2), e1.

Sudden infant death syndrome (SIDS) is sudden death of an infant under the age of 1 year, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of clinical history.

The peak incidence occurs between 2 and 3 months of age. In addition, it has been found that there is a higher rate of incidence, two to three times the national average, in children who are black or American Indian or of Alaskan origin. Additional infant risk factors include male gender, prematurity, preterm birth or low birth weight, low Apgar scores, prone sleeping position, overheating, sleeping on soft surfaces, and twin victim of SIDS. Maternal risk factors include young maternal age, late or no prenatal care, smoking or exposure to smoking during pregnancy, history of sexually transmitted disease or urinary tract infection,

anemia, and poverty.

There has generally been a reduction in death rate, with 1.2 deaths per 1,000 live births reported in 1992 and 0.5% deaths per 1,000 live births in 2002. However, since 2001, there has been a slightly higher proportion of deaths occurring in the neonatal period and after 6 months of age, possibly due to classification.

Current theories on the cause of SIDS focus on abnormalities of the brain stem and its network. Recent autopsy results from victims of SIDS have indicated deficits in serotonin receptors in this network, which are responsible for breathing, body temperature, blood pressure, and arousal.

The American Academy of Pediatric's Task Force on Sudden Infant Death Syndrome introduced a policy statement in November 2005 that put forth a number of recommendations that were developed to reduce the risk of SIDS.

The recommendations are as follows:

- Infants should be placed in the supine position for sleep.
- A firm sleep surface should be used. For example, soft items, such as quilts or pillows, should not be placed under the infant.
- Soft objects and loose bedding should not be part of the infant's sleeping environment.
- Smoking and exposure to passive smoke during pregnancy should be avoided.
- Infants should not share the same bed as adults.
- Overheating should be avoided.
- Using a pacifier, when placing the infant down to sleep, should be considered.
- Home monitors should not be used as a strategy to reduce the risk of SIDS as there is no evidence that proves their effectiveness for this purpose. This is only suggested for infants who have had an apparent life-threatening event.

NURSING ALERT Infants who have experienced apnea may be at risk for recurrent apnea, hypoxia, and sudden death and should be monitored closely. Research has shown that SIDS is more likely in infants sleeping prone. It is now recommended that all infants be put to sleep on their backs or sides.

Nursing Assessment

1. Obtain a nursing history, including the parents' description of the events that preceded the hospitalization, and their understanding of prolonged apnea.
   a. This information may provide clues for factors to observe during hospitalization and provides data for the development of a teaching plan.
   b. It allows for the correction of misinformation and misconceptions.
2. Have the parents describe sleep patterns, feeding habits, prior health problems, immunizations, and medications; this may provide data regarding possible influencing factors or causes of the condition.

3. Have the parents describe a typical day in the life of the infant and the family unit. This provides important data on how home monitoring may affect family life and contributes to the effective development of home management and family teaching plans; it also provides a basis for continuity of care for the infant.

Nursing Diagnoses

- Ineffective Breathing Pattern related to periods of apnea.
- Anxiety of the parents related to life-threatening event.
- Deficient Knowledge regarding home monitoring.

Nursing Interventions

Maintaining Breathing Pattern

1. Be prepared for the infant's admission and have all equipment, including apnea monitor, ready for use. Continuous cardiac monitoring is also recommended.
    a. Select a room that is clearly visible from the nursing station; the room should be quiet to reduce sensory stimulation, which may reduce the likelihood of a recurring episode.
    b. Be aware that the family has just experienced the extreme stress of feeling that their infant has almost died. Reassure them with empathy and efficiency at the time of admission.
2. Continuously monitor respirations. Document apnea along with state of consciousness; sleep state; color; position of infant; muscle tone; respiratory effort before, during, and after event; relationship to activity (eg, feeding); and intervention necessary (nothing, gentle stimulation, vigorous stimulation, resuscitation).
3. Administer theophylline, if prescribed. Observe for signs of toxicity: apical rate above 200, vomiting, and agitation. Concentration of theophylline for apnea is lower than the concentration for bronchospasm.
4. Continue the infant's normal activities whenever possible (eg, holding him or her for feedings, playing with him or her, disconnecting from monitor for bathing); allow for continuation of usual eating or sleeping patterns. Simulating the home environment as much as possible will encourage deep sleep patterns, which may stimulate apnea and provide valuable diagnostic information.

Minimizing Anxiety

1. Encourage the parents to continue involvement in infant care during hospitalization.
2. Clarify any misconceptions about apnea and SIDS.
3. Allow ventilation of feelings and concerns.
4. Assess family dynamics for any conflicts or maladapted responses; intervene or refer, as appropriate.
5. Use anticipatory guidance in preparing the parents for emotional responses to home monitoring.
    a. Increased anxiety or tension.
    b. Constant worry about the alarm even when it does not go off.
    c. Fatigue.

d. Financial and emotional burdens encountered by the family.

e. Perceived loss of "normal, healthy child"; parents may grieve when given the diagnosis.

Increasing Confidence in Home Monitoring

1. Demonstrate operation and maintenance of the monitor. Reinforce teaching by equipment supplier. Provide information on contacting a monitor technician. Teach parents proper electrode and belt placement and skin care.
   a. Do not adjust monitor to eliminate false alarms.
   b. Maintain an unobstructed view of the monitor. Plug power cord directly into outlet—do not use extension cords. Check battery and charger. Place monitor on firm surface.
   c. Monitored infant should not share his or her bed.
2. Identify the presence of a telephone in the home and, if not, devise an alternative plan in the event of an emergency situation.
3. Describe how to record apnea in relation to activity and position and when to report apnea to health care provider.
4. Teach methods of responding to alarms; what to observe and document in diary (eg, color, presence or absence of breathing) and how to respond (gentle vs. vigorous stimulation, cardiopulmonary resuscitation [CPR]). Never vigorously shake the child.
5. Discuss the necessary adjustments in daily living and anticipated changes.
   a. Emphasize that responsibility must be shared by family members.
   b. Discuss the possible impact on siblings.
   c. Advise the parents to eliminate noises that would interfere with their ability to hear the alarm (eg, showering, vacuuming). Someone must always be available to hear and respond to the alarm. Be aware of electrical interference from appliances or cellular phones and in public places such as airports.
   d. Avoid traveling long distances alone with the infant.
   e. Encourage the parents to enlist the assistance of a third person who is willing to learn CPR and to help care for the infant and provide the parents with an opportunity for respite time.
6. Emphasize the healthy aspects of the infant. Encourage the parents to continue as many usual routines as possible. Provide specific things parents can do to encourage normal development and a healthy parent–child relationship.
7. Encourage the parents to provide total care for their infant 24 hours before discharge so they regain confidence in caring for their child.

Family Education and Health Maintenance

1. Advise the family to keep emergency numbers near the telephone or set on speed dial.
2. Educate about feeding precautions: frequent burping, no bottle in bed, upright position after feeding, positioning the infant on his or her back or side, not abdomen. Avoid soft, moldable sleeping surfaces

and pillows; toys and stuffed animals should be removed from the crib.

3. Have parents contact local emergency service to inform them about their infant and to be certain that they have infant resuscitation equipment. Arrange for notification of the utility company to plan for the event of a power outage.
4. Instruct the parents in the administration of any new medications.
5. Teach CPR to all those involved in providing care for the infant.
6. Refer the family to a home care agency for home nursing visits, additional teaching, and support.

Evaluation: Expected Outcomes

- Monitoring maintained; respirations regular without apnea.
- Parents verbalize concern over infant's well-being.
- Parents demonstrate correct operation of respiratory monitor and response to alarms.

TRANSITIONAL CARE ALERT Respiratory disorders are among the most common conditions in the pediatric population due to their developing airways and their potential for rapid decompensation. Children being discharged with respiratory disorders may require oxygen therapy, suction procedures, and a multitude of medications delivered in many routes (oral, nebulizer, etc.). If arrangements have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to assist understanding, pictorial) instructions on signs and symptoms to monitor for worsening of status. Nurses responsible for discharging children should ensure that families understand (and can demonstrate if possible) proper use of necessary treatments.

CARDIAC PROCEDURES

Cardiac Catheterization

Cardiac catheterization is an invasive procedure used to identify cardiac anatomy; measure intracardiac pressures, shunts, and oxygen saturations; and calculate systemic and pulmonary vascular resistance.

Procedure

1. Catheter insertion sites include femoral vein or artery, umbilical vein or artery, brachial vein, or internal jugular vein.
2. Under fluoroscopy, catheters are guided through the heart, collecting pressure measurements and oxygen saturations.
3. Contrast dye is injected through the catheters to visualize blood flow patterns and structural abnormalities.
4. Cardiac catheterization is usually an outpatient procedure for children who undergo an elective procedure. After interventional procedures, some children are observed in the hospital for 12 to 24 hours.

Indications

1. To confirm or establish the diagnosis.
2. To measure cardiac output.
3. To measure pressures and oxygen saturations.
4. To calculate intracardiac shunting and pulmonary and systemic vascular resistance.
5. To visualize coronary arteries.
6. To assess for myocarditis or rejection following heart transplantation.
7. To intervene in congenital heart disease (see Box 45-1 for definitions of abbreviations):
   a. Balloon atrial septostomy (Rashkind) for restrictive atrial septum.
   b. Balloon valvuloplasty (arterial stenosis [AS], pulmonary stenosis [PS]) and angioplasty (recurrent coarctation of the aorta [CoA]).
   c. Endomyocardial biopsy.
   d. To occlude vessels (coil embolization) or defects (atrial septal defect [ASD], ventricular septal defect [VSD], or patent ductus arteriosus [PDA] closure devices).
   e. To stent vessels open (branch pulmonary artery [PA] stenosis, recurrent CoA).
   f. To dilate stenotic valves (mitral, pulmonary, tricuspid).
   g. To dilate conduits used to repair defect.

BOX 45-1 Abbreviations Used for Congenital Heart Disease

ASD	Atrial septal defect
AV	Atrioventricular
CoA	Coarctation of the aorta
HLHS	Hypoplastic left heart syndrome
IAA	Interrupted aortic arch
IVC	Inferior vena cava
LVOTO	Left ventricular outflow tract obstruction
PA	Pulmonary artery
PAPVR	Partial anomalous pulmonary venous return
PDA	Patent ductus arteriosus
PFO	Patent foramen ovale
PS	Pulmonary stenosis
PVR	Pulmonary vascular resistance
SVC	Superior vena cava
TA	Tricuspid atresia
TAPVR	Total anomalous pulmonary venous return
TGA	Transposition of great arteries
TOF	Tetralogy of Fallot
VSD	Ventricular septal defect

Complications

1. Arrhythmias (usually catheter induced).
2. Infection.
3. Bleeding at catheter insertion site; large hematoma.
4. Allergic reaction to contrast material.
5. Loss of pulse in the extremity used for cannulation.
6. Perforation of heart or vessels.
7. Stroke.
8. Dislodgment of coils, closure devices, or stents.
9. Death.

Nursing Diagnoses

Preoperative

- Fear related to surgical procedure.
- Deficient Knowledge regarding surgical procedure and associated nursing care.

Postoperative

- Risk for Injury related to complications of cardiac catheterization.

Nursing Interventions

Reducing Fear in Child and Parents

1. Provide specific instructions in nonthreatening manner:
    a. Day and time of the procedure.
    b. Nothing-by-mouth (NPO) guidelines.
    c. Sedation versus general anesthesia.
    d. Site of the planned arterial and venous puncture.
    e. Routine postprocedure care.
2. Provide appropriate teaching geared toward the child's age and level of cognitive development. Use diagrams and models, as appropriate.
3. Provide parents an opportunity, without the child present, to discuss the procedure, risks, benefits, and alternative choices.
4. Give the child an opportunity to express fears and ask questions.
5. Provide tour of the cardiac catheterization laboratory, if appropriate.
6. Use of child life specialist, if available, to prepare for procedure, aid in insertion of IV.

Explaining and Providing Nursing Care

1. Obtain baseline set of vital signs: heart rate, BP, respiratory rate, and oxygen saturation.
2. Measure and record the child's height and weight.
3. Note the time of last oral intake: solids and liquids.
4. Identify known allergies.
5. List current medications and note time last taken.
6. Help the child change into a hospital gown.
7. Start peripheral IV, as needed.
8. Administer sedation, as prescribed.
9. Assess and mark the location of pulses (dorsalis pedis, posterior tibial).

Observe for and Prevent Complications

1. Monitor and record routine vital signs (q 15 min × 4, q 30 min × 2, then q 1 hr); extremity temperature, color, and pulse check with vital signs.
2. Notify health care provider for:
    a. Heart rate, respiratory rate, or BP outside normal parameters for age.
    b. Bleeding or increasing hematoma at puncture site.
    c. Change in oxygen saturations.
    d. Fever.
    e. Cool, pulseless extremity.
3. Observe puncture site for redness, pain, swelling, or induration.
4. Maintain the child in a reclining position for 4 to 6 hours after the procedure, with no ambulation.

5. Offer fluids as soon as the child is ready.

Family Education and Health Maintenance

1. Provide discharge information:
   a. Care of incision or puncture site (keep dry for 48 hours).
   b. Activity restrictions (usually for 48 hours, but may be up to 2 weeks following placement of closure devices).
   c. Observe for and report late complications: redness, swelling, drainage from puncture site.
   d. Follow-up medical care.
   e. Reinforce infective endocarditis precautions.
2. If cardiac catheterization was a preoperative procedure, use the recovery time to teach the child and family about upcoming hospital stay.

Evaluation: Expected Outcomes

- Child describes procedure in own words; parents and child discuss procedure and ask appropriate questions.
- Child cooperative with preoperative nursing care.
- Insertion site intact without drainage, redness, or hematoma.

Cardiac Surgery

The ultimate goal of treatment of cardiovascular disease in children is to restore normal heart structure and function. Most types of CHDs can be palliated or definitively repaired.

Procedures

Closed-Heart Surgery

1. Surgical approach: lateral thoracotomy or mediastinal incision.
2. Indications:
    a. PDA ligation.
    b. PA banding.
    c. CoA repair.
    d. Vascular ring repair.
    e. Blalock-Taussig shunt (BT shunt) placement.
    f. Occasionally, Glenn and Fontan procedures.

Open-Heart Surgery

1. Surgery is done through a mediastinal incision.
2. With the use of cardiopulmonary bypass, the surgeon can stop the heart and operate inside to repair the defects.
3. Deep hypothermia with circulatory arrest, and/or aortic cross clamping, allows the surgeon to safely stop cardiopulmonary bypass and remove arterial or venous cannulas to better visualize and repair the defects.
4. Indications:
    a. Anomalous coronary arterial anatomy.
    b. ASD, VSD, atrioventricular (AV) canal defect.
    c. Aortic stenosis, pulmonary stenosis.
    d. Tetralogy of Fallot (TOF).
    e. Transposition of great arteries (TGA).
    f. Tricuspid atresia.
    g. Total anomalous pulmonary venous return (TAPVR) or partial APVR.
    h. Truncus arteriosus.
    i. Hypoplastic left heart syndrome (HLHS).
    j. Complex single ventricle.

Potential Complications of Specific Surgeries

1. PDA ligation: laryngeal nerve damage, phrenic nerve damage, diaphragm paralysis, thoracic duct injury.
2. CoA: rebound hypertension, mesenteric arteritis (abdominal pain), coarctation restenosis.

3. Aorta-pulmonary shunt (modified BT shunt): shunt occlusion, PA distortion, pulmonary overcirculation.
4. ASD: atrial arrhythmias, sinoatrial node dysfunction.
5. VSD: transient or permanent heart block, residual VSD, ventricular dysfunction.
6. TOF: low cardiac output, residual right ventricular outflow tract obstruction (RVOTO) or VSD, ectopic junctional tachycardia or arrhythmias, thoracic duct injury.
7. TGA: arterial switch operation—coronary artery injury, ventricular dysfunction, suprapulmonary stenosis.
8. TGA: atrial switch operation—baffle obstruction, RV failure, atrial arrhythmias.
9. Valvotomy (for valve stenosis): valve insufficiency.
10. Bidirectional Glenn shunt: superior vena cava (SVC) syndrome, low cardiac output, hypoxia, pleural effusions.
11. Fontan completion: low cardiac output, pleural effusions, ventricular dysfunction, thrombus formation, arrhythmias, hepatic dysfunction, lymphatic dysfunction.

Cardiac Transplant Surgery

Cardiac transplantation is a treatment option for children with progressive congestive heart failure (CHF) or certain cardiac diseases not amenable to conventional medical–surgical therapy. Children who cannot grow and meet developmental milestones or who have unacceptable quality-of-life issues may benefit from cardiac transplant surgery. However, approximately one in four children dies while waiting for an organ donor. Those children who receive a donor heart can develop significant complications and must take lifelong immunosuppression medications to prevent organ rejection.

Indications for Cardiac Transplantation

1. End-stage cardiomyopathy.
2. Untreatable complex CHD.
3. Malignant arrhythmia.
4. Retransplant for cardiac graft failure.

Immunosuppressive Medications

EVIDENCE BASE Rossano, J. W., Cherikh, W. S., Chambers, D., et al. (2017). The registry of the International Society for Heart and Lung Transplantation: Twentieth pediatric heart transplantation report - 2017; Focus theme: Allograft ischemic time. The Journal of Heart and Lung Transplantation, *36*(10), 1060–1069.

Immunosuppressive therapy is divided into two phases, induction and maintenance. Induction therapies reduce early rejection and may help to reduce the child's overall exposure to corticosteroids. Combination

therapy is usually used in the maintenance phase to ensure ongoing protection against rejection.

1. Phase I: Induction.
    a. Polyclonal antibodies.
        i. Antibodies harvested from equine (Atgam) or rabbit (thymoglobulin).
        ii. Interlukin-2 receptor antibodies.
            1) Daclizumab.
            2) Basiliximab.
2. Phase II: Maintenance therapies.
    a. Calcineurin inhibitors.
        i. Cyclosporine.
        ii. Tacrolimus.
    b. Antiproliferative agent.
        i. Azathioprine.
        ii. Mycophenolate mofetil.
    c. Mammalian target of rapamycin inhibitors.
        i. Sirolimus.
        ii. Everolimus.
        iii. Less nephrotoxic than calcineurin inhibitors.
    d. Corticosteroids.
    e. Oral prednisone and prednisolone most common.
        i. Used in higher doses early post-transplant, gradually tapering over time.
        ii. Short burst IV doses of methylprednisolone can be used in acute rejection.

Complications

1. Organ rejection: routine surveillance endomyocardial biopsies are performed to assess for rejection.
    a. With mild to moderate rejection, children may initially be asymptomatic.
    b. With severe rejection, children are usually symptomatic with hemodynamic instability.
2. Infection.
3. Adverse effects of immunosuppressive agents.
    a. Polyclonal antibodies—fever, chills, urticaria, headaches, severe hypotension, abdominal pain, leukopenia, and thrombocytopenia
    b. Reactions can be minimized by premedicating with corticosteroids, acetaminophen, diphenhydramine
    c. Calcineurin inhibitors.
        i. Ciclosporin—nephrotoxicity, hypertension, diabetes mellitus, hirsutism, gingival hyperplasia, tremor.

ii. Tacrolimus—nephrotoxicity, diabetes mellitus, hypertension, hyperkalemia, hypomagnesemia, tremor.

d. Antiproliferative agent.

i. Azathioprine—leukopenia, thrombocytopenia, nausea, hepatic dysfunction, pancreatitis.

ii. Mycophenolate mofetil—leukopenia, nausea, vomiting, diarrhea, anorexia.

e. Mammalian target of rapamycin inhibitors—hyperlipidemia, thrombocytopenia, anemia, leukopenia, interference with wound healing, oral lesions.

f. Prednisone—hypertension, Cushing syndrome, growth retardation.

4. Graft dysfunction/failure.

a. Leading cause of death posttransplant.

b. The most severe cases become apparent in the immediate post-operative period.

c. Treat with inotropic drugs, short-term mechanical circulatory support with extracorporeal membrane oxygenation (ECMO) or ventricular assist device (VAD), eventual retransplantation.

5. Cardiac allograft vasculopathy (CAV).

a. Occurs late after transplant.

b. Unique and progressive atherosclerosis affecting only transplanted hearts.

c. Treat with mechanical circulatory support, discontinuation of all immunosuppressive agents.

6. Posttransplant lymphoproliferative disease.

Routine Follow-Up

1. Routine well-child care visits to primary care provider.

a. Transplant children should not receive any live virus immunizations (oral polio, measles–mumps–rubella, varicella). Monitor for adverse effects of chronic steroids and immunosuppressive medications.

2. Routine cardiology clinic visits.

a. Laboratory studies: chemistry, hematology, therapeutic drug levels.

b. Vital signs.

c. Electrocardiogram (ECG).

d. Echocardiography.

3. Serial cardiac catheterizations and endomyocardial biopsies.

4. Yearly coronary angiography.

Nursing Assessment

Baseline Assessment on Day of Surgery

1. Measure and record height and weight.

2. Document vital signs: heart rate, respiratory rate, BP, and oxygen saturation.

3. Assess for preoperative infection: fever, signs of upper respiratory infection (cough, runny nose, crackles),

vomiting, or diarrhea might necessitate delaying surgery.

4. Document last oral intake.
5. Void on call to the operating room.

Nursing Diagnoses

Preoperative

- Fear related to surgical procedure.

Postoperative

- Delayed Surgical Recovery related to complications.
- Impaired Adjustment related to postsurgery care.

Nursing Interventions

Preparing the Child and Family and Reducing Fear

1. Be honest and use nonthreatening language the child can understand.
2. The following are frequently asked questions from parents. Address them with the parents:
   a. What to tell the child.
   b. When to tell the child.
   c. What to bring to the hospital.
   d. Anticipated hospital course: how long in the operating room; how many days in the intensive care unit (ICU); how many days on the general care unit; visiting policy, rooming-in accommodations.
3. Review preoperative instructions.
   a. NPO guidelines.
   b. Where to report on the day of the surgery.
   c. Time to arrive at the hospital; time of surgery.
   d. Preoperative medications (injection, liquid, inhalation).
   e. What the operating room looks like; what the people wear in the operating room (hats, gowns, and masks).
4. Explain the preoperative period.
   a. Change into a hospital gown.
   b. Parents stay with the child.
   c. Transportation to the operating room (walking, wheelchair, or stretcher).
5. Explain the operative period.
   a. Operating room waiting room.
   b. Updates during the surgery will come from the surgical scrub nurses.
   c. Surgeon will meet the family after surgery to review the surgical findings and to describe the

operation.

6. Explain the postoperative period. Use models and diagrams.
    a. Pediatric ICU routines and procedures.
    b. Monitoring lines and equipment.
    c. Ventilators, oxygen therapy.
    d. Protective restraints.
7. Offer medical equipment to handle and play with (ECG leads, face mask, BP cuff), age-appropriate books about surgery and hospital stays, and tour of ICU and surgical area, as available.
8. Prehospital tour of the pediatric ICU and general pediatric care unit.
9. Allow an opportunity for the child and family to ask questions, express their concern, or ask for more detail.

Observing for and Preventing Complications

1. Assess respiratory status and maintain respiratory support.
    a. Maintain ventilatory support, as needed.
    b. Maintain patent airway with routine endotracheal suctioning.
    c. Auscultate breath sounds frequently. Decreased breath sounds may indicate pleural effusions, atelectasis, pneumothorax, or hemothorax.
    d. Report results of routine chest x-ray.
    e. Perform frequent position changes: side-back-side.
    f. Monitor arterial blood gas levels and oxygen saturations.
    g. Assess chest or mediastinal tube drainage; examine characteristics and quantify hourly in the initial postoperative period.
    h. Identify those patients at risk for pulmonary hypertension in the postoperative period.
    i. Treatment includes oxygen, analgesia and sedation, prevention of acidosis, chemical paralysis, and inhaled nitric oxide.
    j. Extubate when hemodynamically stable and when patient meets extubation criteria.
    k. Administer oxygen therapy, as needed, after extubation.
2. Assess cardiac status.
    a. Monitor vital signs and oxygen saturations.
    b. Auscultate heart sounds immediately upon admission, noting quality and presence of any residual murmurs.
    c. If patient has had a BT shunt placed, frequently assess shunt murmur presence and volume. Sudden or progressive muting of this could indicate shunt occlusion and is an emergency.
    d. Maintain continuous ECG monitoring.
        i. Daily 12-lead ECG to assess rhythm.
        ii. Temporary epicardial pacemaker wires available for atrial and/or ventricular pacing, as needed.

iii. In presence of these, keep pacer located at the bedside.

e. Continuous BP monitoring (arterial line).

f. Monitor intracardiac pressures (central venous pressure [CVP], left atrial [LA], PA).

g. Monitor peripheral perfusion, capillary refill, toe temperature.

h. Titrate vasopressors (dopamine, dobutamine, epinephrine, milrinone), as prescribed.

3. Assess fluid status.

a. Record hourly intake (IV fluids, blood products, fluid boluses).

b. Record hourly output (urine, chest/mediastinal tube drainage, nasogastric drainage).

c. Concerning if chest/mediastinal tube output exceeds 5 to 10 cc/kg/hour.

d. Take note if chest/mediastinal tube drainage suddenly decreases, concern for obstruction in tube with resultant pericardial or pleural effusion.

e. Perform daily weights.

f. Administer diuretics, as prescribed, noting response.

4. Assess neurologic status.

a. Monitor level of responsiveness, response to verbal commands, and response to pain.

b. Check pupil size and reactivity to light.

c. Document movement of all extremities.

d. Monitor all invasive lines for air bubbles and potential air embolism.

e. Observe for signs of neurologic injury related to hypoperfusion or embolism.

5. Monitor for potential specific complications related to particular surgery for CHD.

6. Assess for postoperative pain.

a. Monitor level of responsiveness, agitation.

b. Implement pediatric pain scale rating to assist the child in identifying the severity of pain.

c. Administer pain and anxiolytic medication, as prescribed: continuous IV infusion and IV boluses, as necessary to control pain and hypertension related to pain and anxiety.

d. Utilize patient-controlled analgesia continuous pump, as appropriate.

7. Assess serum electrolyte balance. Obtain blood tests and report results. Treat deficits with supplements, paying particular attention to potassium, calcium, and magnesium levels.

8. Assess packed cell volume, platelet count, and coagulation studies.

a. Low hematocrit (less than 30): consider directed donor transfusion or blood bank transfusion.

b. Low platelet count: continue to monitor; if bleeding persists, transfuse platelets.

c. Prolonged coagulation studies: continue to monitor; if bleeding or oozing persists, give fresh frozen plasma, protamine.

Enhancing Adjustment Postoperatively

1. Provide continuity of care (primary nursing and consistent medical team).

2. Explain all procedures and routines to the child and parents to minimize fear.

3. Explain to the parents a child's typical reactions to stressful events.
    a. Regression—temporary loss of developmental milestones.
    b. Fear of any medical personnel (white coat anxiety).
    c. Sibling jealousy that one child is receiving a lot of attention.
    d. Withdrawal—related to stimulation overload and lack of undisturbed sleep.
    e. Nightmares.
    f. Increased dependency; clinging behavior.
4. Suggest parent and patient support groups, Child Life Therapy, community resources, and counseling, as needed.

Family Education and Health Maintenance

1. Provide the child and family with oral and written discharge instructions and recommendations.
    a. Medications.
    b. Activity restrictions.
    c. Sternal precautions
        i. No strenuous activity or contact sports for 6 to 8 weeks after surgery.
        ii. Most children are ready to return to school at least part time about 2 weeks after surgery.
        iii. If child needs prolonged recovery time at home, may need to consider home tutoring.
        iv. No gym class until full recovery.
    d. Care of the incision.
    e. Dietary recommendations.
    f. Bathing or showering guidelines.
2. Provide the child and family with a list of potential signs of complications and instructions to notify the health care provider.
    a. Fever greater than or equal to 101.5°F (38.6°C).
    b. Any redness, swelling, or drainage from chest incision.
    c. Partial opening of the chest incision.
    d. Poor appetite, nausea, vomiting.
    e. Breathing difficulties, shortness of breath.
    f. Lethargy, sustained.
    g. For neonates and infants, increased fussiness or sudden inconsolability.
3. Provide the family with the names and phone numbers of people to call for questions and emergencies.
4. Make follow-up appointments for the child to be seen by his or her primary care provider 2 to 3 days after discharge from the hospital and 10 to 14 days to be seen by their pediatric cardiologist.
5. Review American Heart Association's recommendations for infective endocarditis prophylaxis. In children with CHD, prophylaxis is indicated only for patients who:

a. Have cyanotic heart disease that has not been fully repaired.
b. Have prosthetic material or device for the first 6 months postoperatively.
c. Have residual cardiac lesions even after repair, such as abnormal flow or regurgitation at patches or valves.

Community and Home Care Considerations

1. Arrange skilled home nursing visits, as needed, to:
   a. Review medications.
   b. Assess wound healing.
   c. Monitor vital signs and oxygen saturations.
   d. Monitor growth for single ventricle infants post-operatively, during the interstage period, optimize nutrition.
   e. Assess oral intake; nutritional status.
   f. Resource for family.
2. Make referral to community agencies, as needed (infant and toddler program).
3. Arrange for home medical equipment (oxygen, feeding pump, and supplies), as needed.
4. Review safety precautions in the home:
   a. Childproof medication bottles.
   b. Poison control phone number for accidental medication overdose.
   c. Infant and child CPR techniques.
   d. Bleeding precautions for children on anticoagulation therapy. No aspirin or ibuprofen products. Be sure to read the labels on over-the-counter cold and cough syrups. Avoid activities with high risk of injury. All head injuries need to be evaluated by a physician. Signs of bleeding:
      i. Blood in the urine.
      ii. Black tarry stools.
      iii. Prolonged nosebleeds.
      iv. Bleeding gums.
      v. Bruising for no known trauma.
      vi. Spitting or coughing up blood.
      vii. Any unusual swelling or pain.
   e. MedicAlert bracelet or tags.
5. Discuss developmental issues with the family.
   a. A child on diuretics may have difficulty with toilet training.
   b. Disciplining, establishing behavioral expectations, and setting limits in a child with CHD should be similar to those for a child without CHD.
6. Discuss the need for home schooling or tutoring during recovery time. Return to the classroom as soon as the child is ready.

7. Discuss infants with CHD in daycare situations—address each case individually. Daycare programs usually have increased risk of URIs and other communicable diseases.
8. Encourage routine dental visits to prevent dental caries (dental caries predispose to bacteremia and endocarditis).
9. Encourage heart-healthy eating and exercise routines.
10. Encourage age-appropriate activities. A few children will need exercise restrictions. Children with CHD should be allowed to participate in activities with rest periods, as needed. Children with pacemakers and children on anticoagulation therapy should refrain from contact sports.
11. Maintain standard childhood immunization schedule. Delay vaccines around the perioperative time until fully recovered from surgery (no immunizations for 6 weeks postoperatively).
12. Encourage yearly influenza vaccine for children with unrepaired or complex CHD.
13. Encourage respiratory syncytial virus (RSV) immunization for children younger than age 2 with complex CHD and those at risk of CHF or pulmonary hypertension.

Evaluation: Expected Outcomes

- Child describes procedure without fear; parents and child discuss procedure and ask appropriate questions.
- Vital signs stable, no signs of infection.
- Parents offer support to child.

CONGENITAL HEART DISEASEOVERVIEW

EVIDENCE BASE Bouma, B. J., & Mulder, B. J. M. (2017). Changing landscape of congenital heart disease. *Circulation Research, 120*, 908–922.

Congenital heart disease (or *defects*) *(CHD)* is one of the most common forms of congenital anomalies. It involves the chambers, valves, and vessels arising from the heart (see Figure 45-1, page 1207). In most cases, the cause of CHD is not known. Some infants and children with CHD may appear perfectly healthy, whereas others may present as critically ill. Most infants and children with CHD can be successfully managed with medications and surgeries.

Patent Ductus Arteriosus
Patent ductus arteriosus (PDA) is a vascular connection that, during fetal life, shunts blood from the pulmonary artery to the aorta. Functional closure of the ductus normally occurs soon after birth. If the ductus remains patent after birth, the direction of blood flow in the ductus is reversed from aorta to pulmonary circuit by the higher pressure in the aorta.

Ventricular Septal Defect
Ventricular septal defect (VSD) is an abnormal opening between the right and left ventricle. VSDs vary in size and may occur in either the membranous or muscular portion of the ventricular septum. Due to the higher pressure in the left ventricle, a shunting of blood from the left to right ventricle occurs during systole. If pulmonary hypertension or obstruction to pulmonary flow exists, the shunt of blood is then reversed from the right to the left ventricle, with cyanosis resulting.

Pulmonary Stenosis
Pulmonary stenosis refers to any lesion that obstructs the blood flow from the right ventricle to the pulmonary artery. This obstruction may cause right ventricular hypertrophy and eventual right-sided heart failure.

Aortic Stenosis
Aortic stenosis may be at the subvalvular, valvular (with thickening or fusion of the cusps), or supravalvular level. Subaortic stenosis is caused by a fibrous ring below the aortic valve in the outflow tract of the left ventricle. At times, valvular and subaortic stenosis exist in combination. The obstruction presents an increased workload for the normal output of the left ventricular blood and results in left ventricular enlargement.

Coarctation of the Aorta
Coarctation of the aorta is characterized by a narrowed aortic lumen. It normally occurs in the juxtaductal position. Coarctations exist with great variation in anatomic features. The lesion produces an obstruction to the flow of blood through the aorta, causing increased left ventricular pressure and workload.

Tetralogy of Fallot
Tetralogy of Fallot is characterized by the combination of four defects: (1) pulmonary stenosis, (2) ventricular septal defects, (3) overriding aorta, (4) hypertrophy of right ventricle. It is the most common defect causing cyanosis in patients surviving past age 2. The severity of symptoms depends on the degree of pulmonary stenosis, the size of the VSD, and the degree to which the aorta overrides the ventricular septal defect.

Complete Transposition of Great Vessels
The aorta originates from the right ventricle and the pulmonary artery from the left ventricle. An abnormal communication between the two circulations (atrial septal defect [ASD] or VSD) must be present to sustain life.

Atrial Septal Defect
An atrial septal defect (ASD) is an abnormal opening between the right and left atria. Basically, three types of abnormalities result from incorrect development of the atrial septum: (1) sinus venosus at the top of the atrial septum, (2) ostium secundum at the middle of the atrial septum, (3) ostium primum at the bottom of the atrial septum. In general, left-to-right shunting of blood occurs in all ASDs.

Tricuspid Atresia
Tricuspid valvular atresia is characterized by absence of the tricuspid valve, a small right ventricle, and usually diminished pulmonary circulation. Cyanosis is present because blood from the right atrium passes through an ASD into the left atrium, mixes with oxygenated blood returning from the lungs, flows into the left ventricle, and is propelled into the systemic circulation. The lungs may receive blood through one of three routes: (1) VSD, (2) PDA, and (3) collateral aortopulmonary vessels.

Hypoplastic Left Heart Syndrome
A collection of complex congenital heat lesions results in the abnormal development of the left side of the heart. These lesions include: (1) mitral stenosis/atresia, (2) aortic stenosis or atresia, (3) aortic arch hypoplasia, and (4) hypoplastic left ventricle. The right ventricle pumps blood through the pulmonary and systemic circulations. A patent foramen ovale allows a left-to-right shunt and blood is shunted from left atrium back to right atrium. A PDA is often the sole supply of blood to the systemic circulation.

Figure 45-1. Congenital heart abnormalities.

Etiology and Incidence

1. CHD affects 8 of every 1,000 live births (range from 3 to 10).
2. Exact cause of CHD is unknown in approximately 85% of cases.
3. The heart begins as a single cell and develops into a four-chambered pumping system during the 3rd to 8th weeks of gestation.
4. Associated factors for CHD include:
    a. Fetal or maternal infection during the first trimester (rubella).
    b. Chromosomal abnormalities (trisomy 21, 18, 13).
    c. Maternal insulin-dependent diabetes.
    d. Phenylketonuria
    e. Systemic lupus erythematosus.
    f. Teratogenic effects of drugs and alcohol.
        i. Lithium—Ebstein anomaly.
        ii. Phenytoin—aortic and pulmonic stenosis.
        iii. Alcohol—ASD and VSD.
5. Syndromes that include CHD:
    a. Marfan syndrome—mitral valve prolapse (MVP), dilated aortic root.
    b. Turner syndrome—aortic valve stenosis (AVS), CoA.
    c. Noonan syndrome—dysplastic pulmonary valve.
    d. William syndrome—supravalvular PS.
    e. DiGeorge syndrome—interrupted aortic arch (IAA), truncus arteriosus, TGA, and TOF.
    f. Down syndrome (trisomy 21)—endocardial cushion can develop abnormally, commonly AV canal defect, VSD. About 50% of children with Down syndrome have a CHD.

DRUG ALERT Teratogenic drugs also include amphetamines, estrogen, progesterone, retinoic acid, selective serotonin reuptake inhibitors, trimethadione, and valproic acid.

Common Congenital Heart Malformations

Congenital heart defects can be classified into three categories: obstruction to blood flow, increased pulmonary blood flow (acyanotic lesions), and decreased pulmonary blood flow (cyanotic lesions).

1. Obstructive lesions:
    a. AS—valvular, subvalvular, or supravalvular.
    b. CoA.
    c. PS—valvular, subvalvular, or supravalvular.

   d. IAA.
2. Increased pulmonary blood flow (acyanotic):
   a. PDA.
   b. ASD.
   c. VSD.
   d. AV canal (balanced or unbalanced).
   e. PAPVR.
3. Decreased pulmonary blood flow (cyanotic):
   a. TOF.
   b. TA.
   c. TAPVR.
   d. TGA.
   e. Truncus arteriosus.
   f. HLHS.
   g. DORV.

Aortic Stenosis

EVIDENCE BASE Friedland-Little, J. M., Zampi, J. D., & Gajarski, R. J. (2016). Aortic stenosis. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 1085–1101). Philadelphia, PA: Lippincott Williams & Wilkins.

Congenital *aortic stenosis (AS)* is a left ventricular outflow tract obstructive lesion. It may be caused by a bicuspid aortic valve with fused commissures that does not open completely, by a hypoplastic aortic valve annulus, or by stenosis above or below the aortic valve (subvalvular or supravalvular stenosis). The result is turbulent blood flow across the aortic valve and into the ascending aorta. Patients with AS must be evaluated for additional left heart lesions that include coarctation of the aorta, mitral valve stenosis, hypertrophic cardiomyopathy, and hypoplastic left heart. AS is the most common form of left ventricular outflow tract obstruction (LVOTO). It accounts for 3% to 6% of CHDs. AS may occur at any age, and it occurs more commonly in boys than in girls.

Pathophysiology and Etiology

1. Blood flows at an increased velocity across the obstructive valve or stenotic area and into the aorta.
2. During systole, left ventricular pressure rises dramatically to overcome the increased resistance at the aortic valve.
3. Myocardial ischemia may occur because of an imbalance between the increased oxygen requirements related to the hypertrophied left ventricle (LV) and the amount of oxygen that can be supplied.
4. A consistent increased pressure load on the LV causes pathologic ventricular remodeling. Progression to left-sided heart failure and eventual cellular changes is reflected in clinical signs of failure.

Clinical Manifestations

Neonate

Onset of symptoms occurs quickly with critical AS, upon the closure of the ductus arteriosus.

1. Severe CHF.
2. Metabolic acidosis.
3. Tachypnea.
4. Faint peripheral pulses, poor perfusion, poor capillary refill, cool skin.
5. Poor feeding and feeding intolerance.

Child and Adolescent

Symptoms may be slower to progress and develop over time.

1. Chest pain on exertion, decreased exercise tolerance.

2. Dyspnea, fatigue, shortness of breath.
3. Syncope, light-headedness.
4. Palpitations.
5. Sudden death.

Diagnostic Evaluation

1. Auscultation.
   a. Systolic ejection murmur heard best at right upper sternal border, radiates to neck.
   b. Ejection click. May be absent with severe stenosis.
   c. S_2 splits normally or narrowly.
2. Four-limb blood pressure.
   a. Systolic blood pressure normally 5 to 10 mm higher in lower extremities.
   b. For patients with supravalvar aortic stenosis, right arm may have a 15 to 20 mm Hg increase in systolic pressure as compared to left arm.
3. Palpation.
   a. Thrill may be palpable over suprasternal notch with mild valvar aortic stenosis, right upper sternal border in moderate or worse stenosis.
4. Auscultation.
   a. May hear harsh crescendo–decrescendo systolic ejection murmur, at the right upper sternal border for valvar and supravalvar stenosis, at the left mid-sternal border for subvalvar stenosis.
5. ECG: left ventricular hypertrophy (LVH) with a strain pattern may be seen in severe cases.
6. Chest x-ray: increased cardiac silhouette, increased pulmonary vascular markings. A prominent aortic knob may be seen occasionally from poststenotic dilatation with valvular AS.
7. Echocardiogram: two-dimensional echocardiogram with Doppler study and color flow mapping to visualize the anatomy and to estimate the gradient across the valve and through the aorta.

Management

Neonate

1. Stabilize with prostaglandin E_1 (PGE_1) infusion to maintain cardiac output through the PDA.
2. Inotropic support, as needed.
3. Intubation and ventilation, as needed.
4. Cardiac catheterization after initial stabilization: aortic balloon valvuloplasty or aortic balloon angioplasty.
5. Surgical valvotomy, commissurotomy, or myectomy/myotomy.

Child and Adolescent

1. Medical management with close follow-up to monitor increasing gradient across the aortic valve or

through the aorta.

2. Continued hypertension can significantly dilate the aortic root over time.
3. Exercise testing to determine recommended level of activity. Those who have more abnormal results and/or EKG changes should stay away from sports with a high aerobic component.
4. Aortic balloon valvuloplasty or aortic balloon angioplasty.
5. Surgical intervention.
    a. Surgical valvotomy, commissurotomy, or myectomy/myotomy.
    b. In neonates with critical aortic stenosis, success of a biventricular repair has to be determined, gauging the strength of the LV and its associated structures. If damage is too great, then a single ventricle staged repair approach may be used.
    c. Aortic valve replacement.
        i. Mechanical prosthesis (St. Jude valve).
        ii. Ross procedure (pulmonary autograft, placement of right ventricle to pulmonary artery conduit).

Complications

1. CHF and pulmonary edema.
2. Dizziness, light-headedness, and syncope.
3. Palpitations, arrhythmias.
4. Infective endocarditis.
5. Sudden death.

Coarctation of the Aorta

EVIDENCE BASE Kaya, U., Colak, A., Becil, N., et al. (2018). Surgical management of aortic coarctation from infant to adult. Eurasian Journal of Medicine, 50(1), 14–18.

Coarctation of the aorta (CoA) is a discrete narrowing or a long segment hypoplasia of the aortic arch, usually in the juxtaductal position. It accounts for 6% to 8% of CHDs and is two to five times more common in males. Thirty percent of infants with Turner syndrome have CoA. Commonly associated defects include VSD, mitral valve stenosis, and bicuspid aortic valve.

Pathophysiology and Etiology

1. The discrete narrowing or hypoplastic segment of the aorta increases the workload of the left ventricle (increased LV systolic pressure).
2. In a neonate with critical CoA, lower body blood flow occurs through the PDA (right-to-left shunting).
3. In the older child, collateral vessels grow and bypass the coarctation to perfuse the lower body.

Clinical Manifestations

1. The neonate with critical CoA (ductal dependent lesion):
   a. Asymptomatic until the PDA begins to close, rapid decompensation at 8 to 10 days of life.
   b. After PDA closure: severe CHF, poor lower body perfusion, tachypnea, acidosis, progressive circulatory shock, absent femoral and pedal pulses.
2. The child or adolescent with CoA:
   a. Usually asymptomatic—normal growth and development.
   b. Hypertension in the upper extremities, with absent or weak femoral pulses.
   c. Murmur present.
   d. Nosebleeds, headaches, leg cramps with exercise.

Diagnostic Evaluation

1. Auscultation—varies; nonspecific systolic ejection murmur. Murmur may be heard over the base or posteriorly in the left scapular region. Single S_2 loud S_3 gallop is usually present.
2. Four-limb blood pressure.
   a. Systolic blood pressure elevated in upper extremities, proximal to coarctation, as compared to lower extremities. A significant gradient exists between the two.
3. Chest x-ray—cardiomegaly and pulmonary edema or pulmonary venous congestion.
4. ECG—varies; normal or right ventricular hypertrophy (RVH) in infants and LVH in older children.
5. Two-dimensional echocardiography with Doppler and color flow mapping identifies area of aortic arch

narrowing and associated lesions (bicuspid aortic valve, VSD, PDA).

6. Invasive studies (cardiac catheterization) usually not needed to make the initial diagnosis; may need aortic angiography to identify collateral vessels before surgery.
7. Cardiac magnetic resonance imaging may be done to noninvasively assess the location and degree of narrowing and identify collateral vessels.

Management

Critical Coarctation in the Neonate

1. Medical management:
   a. Resuscitation and stabilization with PGE_1 infusion: monitor for complications related to PGE_1 therapy (fever, apnea).
   b. Intubation and ventilation, as needed.
   c. Anticongestive therapy (digoxin and Lasix) and inotropic support, as needed.
   d. Assessment of renal, hepatic, and neurologic function.
2. Balloon angioplasty may be indicated for infants who are at high surgical risk.
3. Surgical intervention: usually performed as soon as the diagnosis is made.
   a. Subclavian flap repair (Waldhausen procedure).
   b. End-to-end anastomosis.
   c. Dacron patch repair.
   d. Stent implantation.

Coarctation in the Child or Adolescent

1. Surgical intervention.
   a. End-to-end anastomosis.
   b. Dacron patch.
   c. Stent implantation.
2. Medical management for hypertension (beta-adrenergic blockers).

Recurrent Coarctation in the Neonate or Child

More common in the patient who underwent repair in infancy.

1. Balloon angioplasty in the cardiac catheterization laboratory.
2. Redo surgical intervention.

Complications

1. Systemic hypertension.
2. CHF—occurs in 20% to 30% of all infants with CoA by age 3 months.
3. Intracranial hemorrhage.

4. Left ventricular failure.

5. Aortic aneurysm.

Pulmonary Stenosis

EVIDENCE BASE Nielsen, E., & Vibeke, E. (2016). Surgically treated pulmonary stenosis: over 50 years of follow up. Cardiology of the Young, 26(5), 860–866.

The pulmonary valve opens during systole to let blood flow from the right ventricle into the main PA. Obstruction to flow can occur at three levels: subvalvular, valvular, or supravalvular. The most common cause of RV outflow tract obstruction is pulmonary valve stenosis (PS). PS accounts for 8% to 10% of CHDs.

Pathophysiology and Etiology

1. Critical PS in the neonate: blood flows into the right atrium, across a patent foramen ovale (PFO) into the left side of heart; pulmonary blood flow comes from a left-to-right shunt through a PDA.
2. Right ventricular pressure increases to pump blood across the obstructive pulmonary valve.
3. Right ventricular hypertrophy develops in response to the increased pressure gradient across the pulmonary valve.
4. Signs of right-sided heart failure include hepatic congestion, neck vein distention, and elevated CVP.

Clinical Manifestations

Critical PS in the Neonate

1. Hypoxia.
2. Tachypnea.
3. RV failure.

Mild to Moderate PS in the Child and Adolescent

1. Asymptomatic.
2. Decreased exercise tolerance, fatigue, exertional dyspnea.
3. Chest pain.

Diagnostic Evaluation

1. Auscultation: systolic ejection murmur heard best at the left upper sternal border; ejection click.
2. ECG: varies; normal in mild cases and RVH in moderate to severe cases.
3. Chest x-ray: varies; may show right ventricular enlargement; poststenotic dilatation of PA.
4. Two-dimensional echocardiography with Doppler study and color flow mapping to visualize the sites of obstruction, observe the degree of RVH, and estimate the pressure gradient across the valve.
5. Cardiac catheterization is usually not needed for the initial diagnosis.

Management

Neonate with Critical PS

1. Medical management:
    a. Stabilize and improve oxygen saturations with PGE_1 infusion.
    b. Intubation and ventilation, as needed.
    c. Inotropic support, as needed.
2. Balloon pulmonary valvuloplasty.
3. Blalock-Taussig shunt (Gore-Tex graft between the subclavian artery and the PA to supply pulmonary blood flow), as initial intervention.

Child and Adolescent with PS

1. Medical management:
    a. Close follow-up to monitor and record RV to PA gradient and assess RV function.
    b. Restrict strenuous exercise.
    c. Refer for intervention when RV pressure is greater than two thirds of the systemic pressure.
2. Balloon pulmonary valvuloplasty in the cardiac catheterization laboratory.
3. Surgical intervention:
    a. Valvotomy or valvectomy for dysplastic pulmonary valve.
    b. Patch repair of the right ventricular outflow tract.
    c. Placement of an RV-to-PA conduit.

Complications

1. Cyanosis (critical PS in the neonate as a result of suprasystemic pulmonary pressures through anatomic shunt).
2. Arrhythmia; sudden death.
3. Infective endocarditis.
4. Right ventricular failure.

Patent Ductus Arteriosus

EVIDENCE BASE Taggart, N. W. & Qureshi, M. Y. (2016). In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 803–813). Philadelphia, PA: Lippincott Williams & Wilkins.

The *ductus arteriosus* is a normal fetal connection between the left PA and the descending aorta. During fetal life, blood flow is shunted away from the lungs through the ductus arteriosus and directly into the systemic circulation. PDAs occur in up to 60% of premature neonates who weigh less than 1,000 g. In term infants, PDAs account for 5% to 10% of CHDs; the male to female ratio is 1:2.

Pathophysiology and Etiology

1. During fetal life, the ductus arteriosus allows blood to bypass the pulmonary circulation (fetus receives oxygen from the placenta) and flow directly into the systemic circulation.
2. After birth, the ductus arteriosus is no longer needed. Functional closure usually occurs within 24 to 72 hours after birth. Anatomic closure is completed by age 2 to 3 weeks.
3. When the ductus arteriosus fails to close, blood from the aorta (high pressure) flows into the low-pressure PA, resulting in pulmonary overcirculation.
4. Increased pulmonary blood flow leads to a volume-loaded LV.

Clinical Presentation

Small- to Moderate-Sized PDA

Usually asymptomatic.

Large PDA

1. CHF, tachypnea, frequent respiratory tract infections.
2. Poor weight gain, failure to thrive.
3. Feeding difficulties.
4. Decreased exercise tolerance.
5. Infective endocarditis.

Diagnostic Evaluation

1. Auscultation: continuous murmur heard best at left upper sternal border. Hyperactive precordium with large PDAs.
2. Wide pulse pressure; bounding pulses.
3. Chest x-ray: varies; normal or cardiomegaly with increased pulmonary vascular markings.

4. ECG: varies; normal, LVH, or RVH.
5. Two-dimensional echocardiogram with Doppler study and color flow mapping to visualize the PDA with left-to-right blood flow.
6. Elevated levels of N-terminal pro-B-type natriuretic peptide and cardiac troponin T.
7. Cardiac catheterization is not needed for the initial diagnosis.

Management

1. In the symptomatic premature neonate—NSAIDs (indomethacin and ibuprofen) are given via IV line. These drugs are not effective in term infants.
2. Medical management:
   a. Monitor growth and development.
   b. Reassess for spontaneous PDA closure.
   c. Diuretics (furosemide, chlorothiazide) for pulmonary congestion.
   d. Increase caloric intake as needed for normal weight gain.
   e. Infective endocarditis prophylaxis for 6 months after surgery or coil occlusion.
3. Cardiac catheterization:
   a. For small PDAs, coil occlusion.
   b. For larger PDAs, a closure device may be used.
4. Surgical management through PDA ligation.

Complications

1. CHF, pulmonary edema.
2. Infective endocarditis.
3. Pulmonary hypertension/pulmonary vascular occlusive disease.
4. Recurrent pneumonia.

Atrial Septal Defect

EVIDENCE BASE Sachdeva, R. (2016). Atrial septal defect. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 743–753). Philadelphia, PA: Lippincott Williams & Wilkins.

Atrial septal defect (ASD) is an abnormal communication between the left and right atria. ASDs account for 8% to 10% of CHDs. There are four types:

1. Ostium secundum ASD: most common type of ASD (accounts for 50% to 70%); abnormal opening in the middle of the atrial septum.
2. Ostium primum ASD (accounts for 30%): abnormal opening at the bottom of the atrial septum; increased association with cleft mitral valve and atrioventricular defects.
3. Sinus venosus ASD (accounts for 10%): abnormal opening at the top of the atrial septum; increased association with partial anomalous pulmonary venous return.
4. Coronary sinus defect (rare): abnormal opening between coronary sinus and left atrium.

Pathophysiology and Etiology

1. Blood flows from the higher pressure left atrium across the ASD into the lower pressure right atrium (left-to-right shunt).
2. Increased blood return to the right side of the heart leads to right ventricular volume overload and right ventricular dilation.
3. Increased pulmonary blood flow leads to elevated pulmonary artery pressures.

Clinical Manifestations

1. Usually asymptomatic.
2. Clinical symptoms vary depending on type of associated defects and degree of shunting:
   a. CHF (usually not until the third or fourth decade of life).
   b. Frequent upper respiratory infections (URIs).
   c. Poor weight gain.
   d. Decreased exercise tolerance.
   e. Dyspnea and fatigue.

Diagnostic Evaluation

1. Auscultation: soft systolic ejection murmur heard best at the left upper sternal border; widely split, fixed second heart sound.
2. Prominent systolic impulse.

3. Chest x-ray: varies; normal to right atrial and ventricular dilation, increased pulmonary markings.
4. ECG: varies; right axis deviation and mild RVH or right bundle-branch block. Alterations are present only when the shunt is large and the pulmonary resistance to systemic resistance ratio is greater than 1.5:1 (Q_P:Q_S > 1.5:1).
5. Two-dimensional echocardiogram with Doppler study and color flow mapping to identify the site of the ASD and associated lesions and document left-to-right flow across the atrial septum.
6. Cardiac catheterization is usually not needed for initial diagnosis; performed if defect can be closed using an atrial occlusion device (device can be used only in ostium secundum defects).

Management

1. Medical management:
   a. Monitor and reassess (spontaneous closure rate is small but may occur up to age 2).
   b. Treatment with diuretics may be necessary if signs of CHF are present (usually not until third to fourth decade of life if ASD unrepaired).
   c. Infective endocarditis prophylaxis for 6 months after surgery or atrial occlusion device is used.
2. Cardiac catheterization for placement of an atrial occlusion device for ostium secundum defects.
3. Surgical intervention:
   a. Primary repair: suture closure of the ASD.
   b. Patch repair of the ASD.

Complications

1. CHF (rare).
2. Infective endocarditis.
3. Embolic stroke.
4. Pulmonary hypertension.
5. Atrial arrhythmias.

Ventricular Septal Defect

EVIDENCE BASE Cohen, M. S., & Lopez, L. (2016). Ventricular septal defects. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 783–800). Philadelphia, PA: Lippincott Williams & Wilkins.

A *ventricular septal defect (VSD)* is an abnormal communication between the right and left ventricles. It is the most common type of CHD, accounting for up to 40% of CHDs. VSD is slightly more common in females and is the most common lesion found in chromosomal syndromes (Trisomy 13, 18, 21). VSDs vary in size (small and restrictive to large and nonrestrictive), number (single vs. multiple), and type (perimembranous or muscular).

Pathophysiology and Etiology

1. Blood flows from the high-pressure left ventricle across the VSD into the low-pressure right ventricle and into the PA, resulting in pulmonary overcirculation. The size of the defect determines the physiologic effect on the infant.
2. A left-to-right shunt because of a VSD results in increased right ventricular pressure and increased PA pressure.
3. The increased pulmonary venous return to the left side of the heart results in left atrial dilation.
4. Long-standing pulmonary overcirculation causes a change in the pulmonary arterial bed, leading to increased pulmonary vascular resistance. High pulmonary vascular resistance (PVR) can reverse the blood flow pattern that leads to a right-to-left shunt across the VSD (Eisenmenger syndrome), resulting in cyanosis. Once this develops, the child is no longer a candidate for surgical repair.

Clinical Manifestations

1. Small VSDs—usually asymptomatic; high spontaneous closure rate during the first year of life. Ongoing risk of endocarditis.
2. Moderate VSDs—present with similar symptoms as the larger VSDs, but in milder form that is not quite as pronounced or significant.
3. Large VSDs—typical presentation at 4 to 8 weeks of age.
    a. CHF: tachypnea, tachycardia, excessive sweating associated with feeding, hepatomegaly.
    b. Frequent URIs.
    c. Poor weight gain, failure to thrive presenting at age 2 to 3 months.
    d. Feeding difficulties.
    e. Fatigue.

Diagnostic Evaluation

1. Auscultation: harsh systolic regurgitant murmur heard best at the lower left sternal border (LLSB); systolic thrill felt at LLSB, narrowly split S_2. The murmur may radiate toward the head along the left parasternal border or to the right of the sternum.
2. Chest x-ray: varies; normal or cardiomegaly and increased pulmonary vascular markings. Pulmonary vascular markings are directly proportionate to the amount of left-to-right shunting.
3. ECG: varies; normal to biventricular hypertrophy.
4. Two-dimensional echocardiogram with Doppler study and color flow mapping to identify the size, number, and sites of the defects; estimate pulmonary artery pressure; and identify associated lesions.
5. Cardiac catheterization usually not needed for initial diagnosis; may be needed to calculate the size of the shunt or to assess PVR. May be performed if defect can be closed using a ventricular occlusion device (device can be used only in muscular defects).

Management

Small VSD

1. Medical management:
   a. Usually no anticongestive therapy is needed.
   b. Infective endocarditis prophylaxis for 6 months after surgical implantation of a ventricular occlusion device.
2. Cardiac catheterization for placement of a ventricular occlusion device for muscular defects (for Qp:Qs > 1.5:1).
3. Surgical intervention is usually not necessary.

Moderate to Large VSD

1. Medical management:
   a. CHF management: digoxin, ACE inhibitors, and diuretics.
   b. Avoid oxygen; oxygen is a potent pulmonary vasodilator and will increase blood flow into the PA.
   c. Maximize nutrition: increase caloric intake by fortifying formula or breast milk to make 24 to 30 cal/ounce; supplemental nasogastric feeds, as needed.
   d. Infective endocarditis prophylaxis for 6 months after surgery/ventricular device occluder.
2. Cardiac catheterization for placement of a ventricular occlusion device for muscular defects (for Qp:Qs > 1.5:1).
3. Refer for surgical intervention.
   a. Usually repaired before age 2.
   b. Patch closure of VSD.

Long-Term Follow-Up

1. Monitor ventricular function.
2. Monitor for subaortic membrane and double-chamber RV.
3. Monitor for formation of residual VSD following patch closure.

Complications

1. CHF.
2. Frequent URIs.
3. Failure to thrive; poor weight gain.
4. Infective endocarditis.
5. Arrhythmias (right bundle branch block, transient complete heart block in postop period).
6. Eisenmenger syndrome.
7. Pulmonary hypertension.
8. Aortic insufficiency.

Tetralogy of Fallot

EVIDENCE BASE Roche, S. L., Greenway, S., & Redington, A. (2016). Tetralogy of Fallot with pulmonary stenosis, pulmonary atresia, and absent pulmonary valve. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 1029–1047). Philadelphia, PA: Lippincott Williams & Wilkins.

Tetralogy of Fallot (TOF) is the most common complex CHD. The four abnormalities of TOF include:

1. A large, nonrestrictive VSD.
2. Overriding aorta.
3. Pulmonary stenosis (right ventricular outflow tract obstruction).
4. Right ventricular hypertrophy.

Pathophysiology and Etiology

1. Degree of cyanosis depends on the size of the VSD and the degree of RVOTO.
2. Obstruction of blood flow from the right ventricle to the PA results in deoxygenated blood being shunted across the VSD and into the aorta (right-to-left shunt causes cyanosis).
3. RVOTO can occur at any or all of three levels: pulmonary valve stenosis, infundibular stenosis, or supravalvular stenosis.
4. The right ventricle becomes hypertrophied as a result of the increased gradient across the RVOT.
5. Minimal RVOTO results in a pink TOF variant, with the physiology behaving more like a large, nonrestrictive VSD. As pulmonary vascular resistance decreases, signs/symptoms may become more apparent as a result of increased shunting.

Clinical Manifestations

1. Clinical manifestations are variable and depend on the size of the VSD and the degree of RVOTO.
2. Cyanosis.
   a. Neonate may have normal oxygen saturations; as the infant grows, the RVOTO increases and the oxygen saturation falls.
   b. Neonate with unacceptably low oxygen saturation needs PGE_1 infusion to maintain ductal patency and adequate oxygen saturation (necessary for the TOF with pulmonary atresia).
   c. Cyanosis may initially be observed only with crying and with exertion (increasing PVR and right to left shunting).
3. Loud second heart sound with a harsh systolic ejection murmur.
4. Polycythemia.

5. Decreased exercise tolerance.
6. A common clinical manifestation years ago was squatting, a posture characteristically assumed by older children to increase systemic vascular resistance and to encourage increased pulmonary blood flow. Squatting is rarely seen currently, however, because TOF is now surgically repaired during the first year of life.
7. Hypercyanotic spells (formerly known as Tet spells): life-threatening hypoxic event with a dramatic decrease in oxygen saturations; mechanism is usually infundibular spasm, which further obstructs pulmonary blood flow and increases right-to-left flow across the VSD.
    a. Typical hypoxic spells occur in the morning soon after awakening; during or after a crying episode; during or after a feeding; during painful procedures such as blood draws.
    b. Typical scenario includes tachypnea, irritability, and increasing cyanosis, followed by flaccidity and loss of consciousness.
    c. Home treatment for the caregiver: soothe the infant and place him or her in a knee–chest position; notify the health care provider immediately.
    d. Hospital treatment includes knee–chest position, sedation (morphine), oxygen, beta-adrenergic blockers (propranolol) to relax the infundibulum, and administration of medications to increase systemic vascular resistance (phenylephrine, norepinephrine).
    e. Intubation and ventilation as needed to reduce work of breathing and oxygen consumption.
    f. Hypercyanotic spells usually prompt the cardiologist to refer for surgical intervention.

Diagnostic Evaluation

1. Auscultation: harsh systolic ejection murmur heard best at the upper left sternal border (RVOT murmur); single loud second heart sound; aortic ejection click. Murmur is caused by pulmonary stenosis—in mild stenosis, the murmur is louder and longer than when stenosis is more severe; during a hypercyanotic spell, the murmur disappears.
2. Palpation: systolic thrill palpable along left lower and left middle sternal border (50% of cases). RV tap at left sternal border.
3. Chest x-ray: varies; normal or decreased pulmonary vascular markings. The heart may appear "boot shaped" because of a concave main PA with an upturned apex resulting from RVH.
4. ECG: varies; normal or RVH.
5. Two-dimensional echocardiogram with Doppler study and color flow mapping to identify the structural abnormalities, estimate the degree of RVOTO, and assess the coronary artery pattern.
6. Cardiac catheterization is usually not needed for the initial diagnosis. May be performed before surgical intervention to identify the location and number of VSDs, the PVR, the degree of RVOTO, and the presence of any coronary abnormalities.

Management

1. Medical management:

a. Monitor oxygen saturation level.
b. Monitor growth and development.
c. Monitor for hypercyanotic spells (many spells go unnoticed by parents).
d. Infective endocarditis prophylaxis (lifelong).
e. Restrict strenuous activity and participation in competitive sports.

2. Balloon pulmonary angioplasty (rarely).
3. Infants with severe pulmonary stenosis may require PGE_1 to maintain ductal patency.
4. Surgical intervention: palliative versus definitive repair.
   a. Many centers prefer definitive, one-stage repair.
   b. Potential obstacles for one-stage repair: abnormal coronary artery distribution (left anterior descending arises from right coronary artery and crosses RVOT); multiple VSDs; hypoplastic branch pulmonary arteries; small infant weighing less than 5.5 pound (2.5 kg).
   c. Palliative surgery: modified BT shunt-tube Gore-Tex graft between the left subclavian artery and the PA; increased pulmonary blood flow results in higher oxygen saturations.
   d. Reparative surgery: patch closure of VSD, relief of right ventricular outflow tract obstruction; with or without transannular patch across the pulmonary valve.
   e. For patients with pulmonary atresia, a RV to PA conduit is placed, bypassing the atretic RVOT. As the patient grows, this conduit will need to be upsized, up to several times throughout childhood.

Long-Term Follow-Up

1. Assess RV outflow tract, monitor degree of pulmonary insufficiency.
2. Monitor RV function and exercise tolerance.
3. Monitor for arrhythmias.
4. Continue monitoring for incompletely understood sequelae of long-term effects of repaired physiology, extending to adulthood.

Complications

1. Hypoxia.
2. Hypercyanotic spells.
3. Polycythemia.
4. CHF: rare; associated with pink TOF.
5. Right ventricular dysfunction.
6. Ventricular arrhythmias.
7. Infective endocarditis.

Transposition of the Great Arteries

EVIDENCE BASE Qureshi, A. M., Justino, H., & Heinle, J. S. (2016). Transposition of the great arteries. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 1164–1183). Philadelphia, PA: Lippincott Williams & Wilkins.

Transposition of the great arteries (TGA) occurs when the PA arises off the left ventricle and the aorta arises off the right ventricle. It accounts for 5% of CHDs and is more common in males. The most commonly associated additional lesion is a ventricular septal defect. Ten percent of infants with TGA also have noncardiac malformations.

Pathophysiology and Etiology

1. This defect results in two parallel circulations:
   a. The right atrium receives deoxygenated blood from the inferior vena cava (IVC) and SVC; blood flow continues through the tricuspid valve into the right ventricle and is pumped back to the aorta.
   b. The left atrium receives richly oxygenated blood from the pulmonary veins; blood flow continues through the mitral valve into the left ventricle and is pumped back into the PA.
2. To sustain life, there must be an accompanying defect that allows mixing of deoxygenated blood and oxygenated blood between the two circuits, such as PDA, ASD, PFO, or VSD.
3. Neonates born with TGA with an intact ventricular system are usually more cyanotic and sicker than neonates born with TGA with a VSD.

Clinical Manifestations

Symptoms evident soon after birth; clinical scenario and varying degrees of clinical manifestations are influenced by the extent of intercirculatory mixing (presence or absence of intact ventricular septum).

1. Cyanosis.
2. Tachypnea.
3. Metabolic acidosis.
4. CHF.
5. Feeding difficulties.

Diagnostic Evaluation

1. Auscultation: varies; no murmur or a murmur related to an associated defect, single loud S_2.
2. Chest x-ray: varies; neonate chest x-ray usually normal; cardiomegaly with a narrow mediastinum (egg-shaped cardiac silhouette) and increased pulmonary markings; or decreased pulmonary markings with

pulmonary stenosis.

3. ECG: right atrial enlargement, RVH, or biventricular hypertrophy.
4. Two-dimensional echocardiogram with Doppler study and color flow mapping identifies the structural abnormalities: transposed vessels, coronary artery pattern, and degree of mixing across the atrial septum plus associated lesions.

Management

Medical Management

1. Stabilize with PGE_1 infusion.
2. Correct metabolic acidosis.
3. Supplemental oxygen to decrease PVR.
4. Treat pulmonary overcirculation with digoxin and diuretics, as needed.
5. Intubate and ventilate, as needed.
6. Inotropic support, as needed.
7. Infective endocarditis prophylaxis (lifelong).

Cardiac Catheterization

1. Balloon atrial septostomy (Rashkind) is indicated for severe hypoxia to create or improve atrial level mixing, for those patients who have an intact ventricular septum.

Surgical Management

1. Arterial switch operation (Jatene)—procedure of choice:
   a. Ideally performed during the first 1 to 2 weeks of life—center-specific timing.
   b. The aorta and PA are switched back to their anatomically correct ventricle above the level of the valve.
   c. Coronary arteries are transferred to the new aorta.
   d. Associated lesions are also repaired at this time.
2. Rastelli operation—performed for TGA, VSD, and PS.
   a. Repaired during the first year of life.
   b. VSD patch repaired to include LV to aortic outflow continuity with pulmonary blood flow provided via an RV to PA homograft.
3. Atrial switch operation—Mustard or Senning procedure:
   a. Rerouting of atrial blood flow: RA → mitral valve → LV → PA and LA → tricuspid valve → RV → Ao.
   b. Restores oxygenated blood into the systemic system and deoxygenated blood guided to the pulmonary system.
   c. Disadvantages:

i. RV is left as the systemic ventricle—will develop RV dysfunction.

ii. Increased incidence of atrial dysrhythmias and baffle obstruction.

Complications

1. Severe hypoxia.
2. Multiorgan ischemia.
3. Arrhythmias.
4. RV dysfunction.
5. Coronary artery obstruction leading to myocardial ischemia or death.
6. Long-term follow up is necessary for pediatric and adult patients, regardless of surgical repair technique.

Tricuspid Atresia

EVIDENCE BASE Cetta, F., Dearani, J. A., O'Leary, P. W., & Driscoll, D. J. (2016). Tricuspid valve disorders: Atresia, dysplasia, and Ebstein anomaly. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 950–958). Philadelphia, PA: Lippincott Williams & Wilkins.

Tricuspid atresia involves the absence of the tricuspid valve and hypoplasia of the right ventricle. Such associated defects as ASD, VSD, or PDA are necessary for survival. Tricuspid atresia accounts for about 3% of CHDs.

Pathophysiology and Etiology

1. With tricuspid atresia, systemic venous return enters the right atrium and cannot continue into the RV; blood flows across an atrial septal opening into the left atrium.
2. Pulmonary blood flow occurs through a PDA or VSD.

Clinical Manifestations

1. Cyanosis.
2. Tachypnea.
3. Feeding difficulties.
4. Additional signs of failure.

Diagnostic Evaluation

1. Auscultation: murmurs vary depending on the associated lesions; single S_2.
2. Palpation: if a restrictive VSD is present, a thrill may be palpated.
3. Chest x-ray: pulmonary vascular markings related to the amount of pulmonary blood flow (usually decreased); normal to slightly increased cardiac silhouette.
4. ECG: superior axis; right and left atrial hypertrophy; LVH. First-degree AV block can be common.
5. Two-dimensional echocardiogram identifies the atretic tricuspid valve and hypoplastic RV; Doppler study and color flow mapping documents the right-to-left atrial shunt and the size of the PDA or VSD.
6. Cardiac catheterization may be necessary to delineate anatomy.

Management

Medical Management

1. Stabilize with PGE_1 infusion.
2. Maintain oxygen saturation at greater than 75%.

3. Intubate and ventilate, as needed.
4. Inotropic support, as needed.

Surgical Management

1. First surgery—neonate:
   a. BT shunt—indicated if pulmonary blood flow is insufficient.
   b. Pulmonary artery band—indicated if pulmonary blood flow is excessive.
   c. No treatment is required if pulmonary blood flow is balanced.
   d. If the great arteries are transposed, Damus-Kaye-Stansel (DKS) may be performed—placement of a modified BT shunt as well as joining of the aorta and main pulmonary artery.
2. Second surgery—ages 6 to 9 months:
   a. Bidirectional Glenn shunt: end-to-side anastomosis of the SVC to the right PA.
3. Third surgery—ages approximately 3 to 4 years
   a. Fontan completion: IVC to PA connection (extracardiac conduit with or without fenestration or intracardiac baffle).

Complications

1. CHF.
2. Persistent pleural effusion (especially after stage II and stage III repairs).
3. Thrombus formation in the systemic venous system.
4. Infective endocarditis.
5. Rarely, heart block.
6. Eventual Fontan circulation can result in lifelong multisystem complications, to varying degrees, in childhood, as well as adulthood.

Hypoplastic Left Heart Syndrome

EVIDENCE BASE Spillane, N. T., Kashyap, S., Bateman, D., Weindler, M., & Krishnamurthy, G. (2016). Comparison of feeding strategies for infants with hypoplastic left heart syndrome. *World Journal for Pediatric and Congenital Heart Surgery, 7*(4), 446–453.

Tweddell, J. S., et al. (2016). Hypoplastic left heart syndrome. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 1085–1101). Philadelphia, PA: Lippincott Williams & Wilkins.

Hypoplasic left heart syndrome (HLHS) is a constellation of left-sided heart abnormalities that include:

1. Critical mitral stenosis or atresia.
2. Hypoplastic LV.
3. Critical aortic stenosis or atresia.
4. Hypoplastic ascending aorta with severe coarctation of the aorta.
5. Associated anomalies include CoA (75%), ASD (15%), and VSD (10%).

HLHS accounts for 1.4% to 3.8% of all CHDs. It is the most common cause of death from cardiac defects in the first month of life.

Pathophysiology and Etiology

1. The left side of the heart is underdeveloped and essentially nonfunctional.
2. The right ventricle supports the pulmonary and systemic circulations.
3. An ASD allows blood to flow from the left atrium into the right heart.
4. Blood flows right to left across the PDA and into the descending aorta to deliver oxygen and nutrients to the body.

Clinical Manifestations

1. Neonate may appear completely well initially but becomes critically ill when the PDA closes.
2. Once the PDA begins to close:
   a. Tachypnea due to CHF.
   b. Decreased urine output.
   c. Poor feeding and feeding intolerance.
   d. Lethargic; change in level of alertness.
   e. Pallor; gray.
   f. Weak peripheral pulses.
   g. Cyanosis.

h. Metabolic acidosis.

Diagnostic Evaluation

1. Auscultation: single S_2; usually no heart murmur is present, but occasionally, a soft systolic ejection murmur may be heard. As CHF develops, gallop rhythm may be heard.
2. Chest x-ray: cardiac silhouette varies (normal to increased size); increased pulmonary markings and pulmonary edema.
3. ECG: RV hypertrophy; decreased electrical forces in V_5 and V_6.
4. Two-dimensional echocardiogram with Doppler study and color flow mapping identifies the structural abnormalities and the altered blood flow patterns.
5. A cardiac catheterization is usually not needed for initial diagnosis. It may be performed if a balloon atrial septostomy is needed to improve oxygenation.

Management

Medical Management

1. Resuscitation and stabilization with PGE_1 infusion.
2. Inotropic support, as needed (dopamine, dobutamine).
3. Intubate and ventilate, as needed.
4. Correct metabolic acidosis.
5. Assess hepatic, renal, and neurologic function.
6. Infective endocarditis prophylaxis (lifelong).
7. Refer for surgical intervention.

Cardiac Catheterization

1. May need balloon atrial septostomy to allow unrestrictive LA to RA blood flow.
2. Hybrid approach to first stage palliation, combining both catheterization and surgery; often consists of stenting the PDA and placement of bilateral PA bands.

Surgical Management

1. Palliative, staged repair:
   a. Stage I Norwood (neonate): reconstruction of the hypoplastic aorta using the PA and an aortic or pulmonary allograft, an atrial septectomy, repair of the coarctation, and placement of a BT shunt or RV-PA conduit (Sano modification).
   b. Postoperatively, desire to have a balanced systemic and pulmonary circulation, maintaining oxygen saturations at approximately 75% to 85%.
   c. Stage II bidirectional Glenn shunt (ages 6 to 9 months): transect the SVC off the right atrium and directly suture end to side to right PA; ligate BT shunt.
   d. Expect goal oxygen saturations postoperatively to be approximately 75% to 85%.

e. Stage III Fontan (ages 18 months to 4 years): IVC to PA connection (extracardiac conduit with or without fenestration or intracardiac baffle).

f. Expect goal oxygen saturations postoperatively to be greater than 85%, increasing to near normal postdischarge.

2. Cardiac transplantation.

Complications

1. Cyanosis.
2. Metabolic acidosis.
3. Persistent pleural effusion (especially after stage II or III repair).
4. Thrombus formation in the systemic venous system.
5. Infective endocarditis.
6. Cardiovasclar collapse, multisystem failure, possible death.
7. Interstage period, between stage I and II of surgical repair, has been identified as a vulnerable period for neonates, the second highest risk for mortality. As a result, most programs have adopted interstage monitoring, consisting of oxygen saturation and weight checks, designed to be completed in the home. This may identify top risk factors that can be recognized early and treated during this time.

Nursing Care of the Child with Congenital Heart Disease

EVIDENCE BASE Cao, J. Y., Lee, S. Y., Phan, et al. (2018). Early outcomes of hypoplastic left heart syndrome infants: Meta-analysis of studies comparing the Hybrid and Norwood procedures. *World Journal for Pediatric and Congenital Heart Surgery, 9*(2), 224–233. Peterson, J. K., & Evangelista, L. S. (2017). Developmentally supportive care in congenital heart disease: A concept analysis. *Journal of Pediatric Nursing, 36*, 241–247.

Nursing Assessment

1. Obtain a thorough nursing history.
2. Discuss the care plan with the health care team (cardiologist, cardiac surgeon, nursing case manager, social worker, and nutritionist). Discuss the care plan with the patient, parents, and other caregivers.
3. Measure and record height and weight and plot on a growth chart.
4. Record vital signs and oxygen saturations.
    a. Measure vital signs at a time when the infant/child is quiet.
    b. Choose appropriate-size blood pressure (BP) cuff.
    c. Check four extremity BP × 1.
5. Assess and record:
    a. Skin color: pink, cyanotic, mottled.
    b. Mucous membranes: moist, dry, cyanotic.
    c. Extremities: check peripheral pulses for quality and symmetry; dependent edema; capillary refill; color and temperature.
6. Assess for clubbing (cyanotic heart disease).
7. Assess chest wall for deformities; prominent precordial activity.
8. Assess respiratory pattern.
    a. Before disturbing the child, stand back and count the respiratory rate.
    b. Loosen or remove clothing to directly observe chest movement.
    c. Assess for signs of respiratory distress: increased respiratory rate, grunting, retractions, and nasal flaring.
    d. Auscultate for crackles, wheezing, congestion, and stridor.
9. Assess heart sounds.
    a. Determine rate (bradycardia, tachycardia, or normal for age) and rhythm (regular or irregular).
    b. Identify murmur (type, location, and grade).
10. Assess fluid status.

a. Daily weights.
b. Strict intake and output (number of wet diapers; urine output).

11. Assess and record the child's level of activity.
    a. Observe the infant while feeding. Does the infant need frequent breaks or does he or she fall asleep during feeding? Assess for sweating, color change, or respiratory distress while feeding.
    b. Observe the child at play. Is play interrupted to rest? Ask the parent if the child keeps up with peers while at play.
    c. Assess and record findings relevant to the child's developmental level: age-appropriate behavior, cognitive skills, gross and fine motor skills.

Nursing Diagnoses

- Impaired Gas Exchange related to altered pulmonary blood flow or pulmonary congestion.
- Decreased Cardiac Output related to decreased myocardial function.
- Activity Intolerance related to hypoxia or decreased myocardial function.
- Imbalanced Nutrition: Less Than Body Requirements related to excessive energy demands required by increased cardiac workload.
- Risk for Infection related to chronic illness.
- Fear and Anxiety related to life-threatening illness.

Nursing Interventions

Relieving Respiratory Distress

1. Position the child in a reclining, semi-upright position.
2. Suction oral and nasal secretions, as needed.
3. Identify target oxygen saturations and administer oxygen, as prescribed.
4. Administer prescribed medications and document response to medications (improved, no change, or worsening respiratory status).
    a. Diuretics.
    b. Bronchodilators.
5. May need to change oral feedings to nasogastric feedings because of increased risk of aspiration with respiratory distress.

Improving Cardiac Output

See Table 45-1.

Table 45-1 Common Cardiac Drugs

DRUG CLASSIFICATION	MECHANISM OF ACTION	EXAMPLES
Beta-adrenergic blockers	Antagonize epinephrine receptors resulting in decreased cardiac contractility and decreased heart rate	Propranolol, esmolol, atenolol
Angiotensin-converting enzyme (ACE) inhibitor	Lowers blood pressure by decreasing blood vessel tone (reduces afterload)	Captopril, enalapril
Angiotensin II receptor blockers	Decrease blood pressure by causing dilation of blood vessels	Losartan, valsartan
Calcium-channel blockers	Decrease intracellular calcium leading to reduced cardiac and vascular smooth muscle contraction and lower blood pressure	Amlodipine, diltiazem, felodipine, isradipine, intravenous nicardipine, nifedipine, and verapamil
Vasopressors	Increase cardiac contractility and vascular muscle tone resulting in increased blood pressure	Dopamine, dobutamine, milrinone, epinephrine
Diuretics	Reduce blood volume by increasing urinary output Used to treat high blood pressure and congestive heart failure	Furosemide, spironolactone
Antiarrhythmics	Various classifications used to treat cardiac dysrhythmias	Lidocaine, amiodarone, disopyramide adenosine
Cardiac glycosides	Strengthens cardiac contractility and decreases heart rate Used to treat congestive heart failure	Digoxin

1. Organize nursing care and medication schedule to provide periods of uninterrupted rest.
2. Provide play or educational activities that can be done in bed with minimal exertion.
3. Maintain normothermia.
4. Administer diuretics (furosemide, spironolactone), as prescribed.
    a. Give the medication at the same time each day. For older children, do not give a dose right before bedtime.
    b. Monitor the effectiveness of the dose: measure and record urine output.
    c. Monitor serum electrolytes. Can experience hypokalemia, hypocalcemia with diuretic use.
5. Administer digoxin, as prescribed.
    a. Check heart rate for 1 minute. Withhold the dose and notify the physician for bradycardia (heart rate less than 90 beats/minute).
    b. Lead II rhythm strip may be ordered for PR interval monitoring. Prolonged PR interval indicates first-degree heart block (dose of digoxin may be withheld).
    c. Give medication at the same time each day. For infants and children, digoxin is usually divided and given twice per day.
    d. Monitor serum electrolytes. Increased incidence of digoxin toxicity associated with hypokalemia.
6. Administer afterload-reducing medications (captopril, enalapril), as prescribed.
    a. When initiating medication for the first time: check BP immediately before and 1 hour after dose.
    b. Monitor for signs of hypotension: syncope, light-headedness, and faint pulses.
    c. Withhold medication and notify the physician according to ordered parameters.

Improving Oxygenation and Activity Tolerance

1. Place pulse oximeter probe (continuous monitoring or measure with vital signs) on finger, earlobe, or toe. Preductal and postductal saturation monitoring provides the most comprehensive information about oxygenation.
2. Administer oxygen, as needed.

3. Titrate amount of oxygen to reach target oxygen saturations.
4. Assess response to oxygen therapy: increase in baseline oxygen saturations, improved work of breathing, and change in patient comfort.
5. Explain to the child how oxygen will help. If possible, give the child the choice for face mask oxygen or nasal cannula oxygen.

Providing Adequate Nutrition

1. For the infant:
    a. Small, frequent feedings.
    b. Fortified formula or breast milk (up to 30 cal/ounce).
    c. Limit oral feeding time to 15 to 20 minutes.
    d. Supplement oral feeds with nasogastric feedings, as needed, to provide weight gain (ie, continuous nasogastric feedings at night with ad-lib by-mouth feeds during the day).
2. For the child:
    a. Small, frequent meals.
    b. High-calorie, nutritional supplements.
    c. Determine child's likes and dislikes and plan meals accordingly.
    d. Allow the parents to bring the child's favorite foods to the hospital.
3. Report feeding intolerance: nausea, vomiting, and diarrhea.
4. Document daily weight (same time of day, same scale, same clothing).
5. Record accurate intake and output; assess for fluid retention.
6. Fluid restriction not usually needed for children; manage excess fluid with diuretics.

Preventing Infection

1. Maintain routine childhood immunization schedule. With the exception of RSV and influenza, immunizations should not be given for 6 weeks after cardiovascular surgery.
2. Administer yearly influenza vaccine.
3. Administer RSV immunization for children younger than age 2 with complex CHD and those at risk for CHF or pulmonary hypertension.
4. Prevent exposure to communicable diseases.
5. Good handwashing.
6. Report fevers.
7. Report signs of URI: runny nose, cough, and increase in nasal secretions.
8. Report signs of GI illness: diarrhea, abdominal pain, and irritability.

Reducing Fear and Anxiety

1. Educate the patient and family.
2. Provide the family with contact phone numbers: how to schedule a follow-up visit; how to reach a

cardiologist during the work week, evenings, weekends, and holidays.

Family Education and Health Maintenance

1. Instruct the family in necessary measures to maintain the child's health:
   a. Complete immunization.
   b. Adequate diet and rest.
   c. Prevention and control of infections.
   d. Regular medical and dental checkups. The child should be protected against infective endocarditis when undergoing certain dental procedures.
   e. Regular cardiac checkups.
2. Teach the family about the defect and its treatment.
   a. Provide patients and families with written and verbal information regarding the CHD. Offer appropriate Internet resources for information about CHD and medical and surgical treatment options.
   b. Provide individualized resources for parents and patient if applicable. Visual aid of current physiology as well as repair, medication list, emergency action cards, upon discharge.
   c. Signs and symptoms of CHF (see page 1219).
   d. Signs of hypercyanotic spells associated with cyanotic defects and need to place child in knee–chest position.
   e. Need to prevent dehydration, which increases risk of thrombotic complications.
   f. Emergency precautions related to hypercyanotic spells, pulmonary edema, cardiac arrest (if appropriate).
   g. Special home care equipment, monitors, oxygen.
3. Encourage the parents and other people (teachers, peers) to treat the child in as normal a manner as possible.
   a. Avoid overprotection and overindulgence.
   b. Avoid rejection.
   c. Promote growth and development with modifications. Facilitate performance of the usual developmental tasks within the limits of the child's physiologic state.
   d. Prevent adults from projecting their fears and anxieties onto the child.
   e. Help family deal with anger, guilt, and concerns related to the disabled child.
4. Initiate a community health nursing referral, if indicated.
5. Stress the need for follow-up care.
6. Encourage attendance in support groups for patients and families.

Evaluation: Expected Outcomes

- Improved oxygenation evidenced by easy, comfortable respirations.

- Improved cardiac output demonstrated by stable vital signs, adequate peripheral perfusion, and adequate urine output.
- Increased activity level.
- Maximal nutritional status demonstrated by weight gain and increase in growth curve percentile.
- No signs or symptoms of infection.
- Parents discuss diagnosis and treatment together and with child.

Congestive Heart Failure

EVIDENCE BASE Benhase, C. (2018). Nursing aspects of heart failure. In Benhase, C., Faulkner, T.J., Hendricks, K., Sublett, J. (Eds.), Heart Failure in the Child and Young Adult: From Bench to Bedside, (p. 481–492). Cambridge, MA: Academic Press.

Jayaprasad, N. (2016). Heart failure in children. *Heart Views, 17*(3), 92–99.

Kirk, R., Dipchand, A. I., & Rosenthal, D. N. (2014). *International Society for Heart and Lung Transplantation guidelines for the management of pediatric heart failure*. Volume 8. Birmingham, AL, UAB Printing.

Congestive heart failure (CHF) occurs when cardiac output cannot meet the metabolic demands of the body.

Pathophysiology and Etiology

1. May result from:
   a. CHDs with a volume or pressure overload (moderate to large left-to-right shunt [PDA, VSD], AV valve insufficiency, or outflow obstruction [HLHS, CoA]).
   b. Acquired heart disease: myocarditis, cardiomyopathy, acute rheumatic fever.
   c. Chronic pulmonary disease: cor pulmonale, bronchopulmonary dysplasia.
   d. Arrhythmias: prolonged SVT, complete heart block.
   e. Anemia.
   f. Iatrogenic fluid overload.
2. In an attempt to meet the metabolic needs of the body, the heart rate increases to increase cardiac output.
   a. Cardiac output = heart rate × stroke volume.
   b. Stroke volume is the amount of blood (mL) ejected from the heart with each heartbeat; it depends on preload and vascular resistance.
3. Preload (CVP) increases as the failing heart contracts poorly.
4. With decreased cardiac output, the systemic vascular resistance increases to maintain BP. This increase in afterload limits cardiac output.
5. With decreased blood flow to the kidneys, the glomerular filtration rate decreases as tubular reabsorption increases sodium and water retention, resulting in decreased urine output.
6. Long term, these compensatory mechanisms are detrimental to the failing myocardium. The chronic increase in preload and afterload contributes to chamber dilation and myocardial hypertrophy, leading to progressive CHF.

Clinical Manifestations

1. Impaired myocardial function.
    a. Tachycardia, S_3 gallop.
    b. Poor peripheral perfusion: weak peripheral pulses, cool extremities, delayed capillary refill.
    c. Pallor.
    d. Exercise or activity intolerance.
2. Pulmonary congestion.
    a. Tachypnea.
    b. Cyanosis.
    c. Retractions, nasal flaring, grunting.
    d. Cough.
3. Systemic venous congestion.
    a. Hepatomegaly.
    b. Peripheral edema: scrotal and orbital.
    c. Water weight gain.
    d. Decreased urine output.

Diagnostic Evaluation

1. Characteristic physical examination findings.
2. Chest x-ray shows cardiomegaly and pulmonary congestion.
3. B-type natriuretic peptide (BNP) as a biomarker for diagnostic, prognostic, and therapeutic monitoring use for pediatric patients with congenital heart disease, cardiomyopathy.

Management

1. Diuretics to reduce intravascular volume (furosemide, spironolactone).
2. Digoxin to increase myocardial contractility for symptomatic patients with low ejection fraction. Not necessary for those asymptomatic patients with left ventricular dysfunction.
3. Afterload reduction to decrease the workload of the ailing myocardium (angiotensin-converting enzyme inhibitors—captopril, enalapril, lisinopril).
4. Beta-adrenergic blockers to counteract increased sympathetic activity and reduce systemic vascular resistance (metoprolol, carvedilol).
5. Angiotensin II receptor blockers (ARBs) for patients who are intolerant of ACE inhibitors, but who can benefit from RAAS blockade.
6. Inotropic support, as needed.

Complications

1. Pulmonary edema.
2. Metabolic acidosis.

3. Failure to thrive.
4. URIs.
5. Arrhythmia.
6. Death.

Nursing Assessment

1. Assess response to medical treatment plan.
2. Document vital signs and oxygen saturations.
3. Observe infant or child during feeding or activity. Assess for diaphoresis, need for frequent rest periods, and inability to keep up with peers.
4. Follow growth curve.

Nursing Diagnoses

- Decreased Cardiac Output related to myocardial dysfunction.
- Excess Fluid Volume related to decreased cardiac contractility and decreased excretion from the kidney.
- Impaired Gas Exchange related to pulmonary venous congestion.
- Activity Intolerance related to myocardial dysfunction and pulmonary congestion.
- Risk for Infection related to pulmonary congestion.
- Imbalanced Nutrition: Less Than Body Requirements related to increased metabolic demands with decreased caloric intake.
- Anxiety related to diagnosis and prognosis.

Nursing Interventions

Improving Myocardial Efficiency

1. Administer digoxin, as prescribed.
    a. Measure heart rate. Hold medication and notify health care provider for heart rate less than 90 beats/minute.
    b. Check most recent potassium level. Hold medication and notify health care provider for potassium less than 3.5 mEg/L.
    c. Run lead II ECG, if ordered, to monitor PR interval. If first-degree AV block occurs, notify health care provider and hold medication, as directed.
    d. Report signs of possible digoxin toxicity: vomiting, nausea, visual changes, and bradycardia.
    e. Double-check dose of digoxin with another nurse before administering the dose. Make sure the digoxin order has two signatures.
2. Administer afterload reduction medications, as prescribed.
    a. Measure BP before and after giving the patient the medication. Hold the medication and notify the health care provider for low BP (greater than a 15-mm Hg drop from baseline).

b. Observe for other signs of hypotension: dizziness, light-headedness, and syncope.

Maintaining Fluid and Electrolyte Balance

1. Administer diuretics, as prescribed.
   a. Obtain daily weights.
   b. Keep strict intake and output record.
   c. Monitor serum electrolytes. Provide potassium supplements, as needed.
2. Sodium restriction: not usually needed in children; provide dietary assistance, as needed.
3. Fluid restriction: not usually needed in children.

Relieving Respiratory Distress

1. Administer oxygen therapy, as prescribed.
2. Elevate head of bed; infants may be more comfortable in an upright infant seat.

Promoting Activity Tolerance

1. Organize nursing care to provide periods of uninterrupted sleep/rest.
2. Avoid unnecessary activities.
3. Respond efficiently to a crying infant. Provide comfort and treat the source of distress: wet or dirty diaper, hunger.
4. Provide diversional activities that require limited expenditure of energy.
5. Provide small, frequent feedings.

Decreasing Risk of Infection

1. Ensure good handwashing by everyone.
2. Avoid exposure to ill children or caretakers.
3. Monitor signs of infection: fever, cough, runny nose, diarrhea, and vomiting.

Providing Adequate Nutrition

1. For the older child: provide nutritious foods that the child likes, along with supplemental high-calorie snacks (milkshake, pudding).
2. For the infant:
   a. High-calorie formula (24 to 30 cal/ounce).
   b. Supplement oral intake with nasogastric feedings. Allow ad-lib oral intake through the day with continuous nasogastric feedings at night.

Reducing Anxiety and Fear

1. Communicate the care plan to the child and family.
2. Educate the family about CHF and provide home care nursing referral to reinforce teaching after discharge.

3. Encourage questions; answer questions as able or refer to another member of the health care team.

Family Education and Health Maintenance

1. Teach the signs and symptoms of CHF.
2. Teach medications: brand name and generic name, expected effects, adverse effects, and dose.
3. Demonstrate medication administration.
4. With the family, design a medication administration time schedule.
5. Provide guidelines for when to seek medical help.
6. Teach infant and child cardiopulmonary resuscitation (CPR), as needed.
7. Reinforce dietary guidelines; provide a recipe to the parent on how to make high-calorie formula.
8. Reinforce ways to prevent infection.
9. Make sure that follow-up visit with health care providers is scheduled, prior to discharge.
10. Educate the patient and family on infective endocarditis guidelines and provide them with written materials. Standard general prophylaxis for children at risk: amoxicillin 50 mg/kg (maximum dose = 2 g) given orally 1 hour before the procedure.

Evaluation: Expected Outcomes

- Heart rate within normal range for age; adequate urine output.
- No unexpected weight gain.
- Clear lungs; normal respiratory rate and effort.
- Participates in quiet diversional activities.
- No signs or symptoms of infection.
- Adequate intake of small, frequent feedings.
- Parents express understanding of disease process and treatment.

ACQUIRED HEART DISEASE

Note: Kawasaki disease is discussed in Chapter 53.

Acute Rheumatic Fever

EVIDENCE BASE Tani, L. (2016). Rheumatic fever and rheumatic heart disease. In H. D. Allen, R. E. Shaddy, D. J. Penny, T. F. Feltes, & F. Cetta (Eds.), *Moss and Adams' heart disease in infants, children, and adolescents* (9th ed., pp. 1799–1801). Philadelphia, PA: Lippincott Williams & Wilkins.

Acute rheumatic fever (ARF) is an acute autoimmune disease that occurs as a sequela of group A beta-hemolytic streptococcal infection. It is characterized by inflammatory lesions of connective tissue and endothelial tissue, primarily affecting the joints and heart.

Pathophysiology and Etiology

1. Most initial attacks of ARF occur 1 to 5 weeks (average 3 weeks) after a streptococcal infection of the throat or of the upper respiratory tract.
2. Peak incidence occurs in children ages 5 to 15 years. Incidence after a mild streptococcal pharyngeal infection is 0.3%; after a severe streptococcal infection, 1% to 3%.
3. Family history of rheumatic fever is usually positive.
4. Streptococcal infection abates with or without treatment; however, autoantibodies attack the myocardium, pericardium, and cardiac valves.
   a. Aschoff bodies (fibrin deposits) develop on the valves, possibly leading to permanent valve dysfunction, especially of the mitral and aortic valves.
   b. Severe myocarditis may cause dilation of the heart and CHF.
5. Inflammation of the large joints causes painful arthritis that may last 6 to 8 weeks.
6. Involvement of the nervous system causes chorea (sudden involuntary movements).

Clinical Manifestations

Documented or undocumented group A beta-hemolytic streptococcal infection is usually followed (within several weeks) by fever, malaise, and anorexia. Major symptoms of ARF may appear several weeks to several months after initial infection.

Major Manifestations (Jones criteria)

1. Carditis—manifested by sinus tachycardia, a soft blowing pansystolic murmur, prolonged PR and QT intervals on ECG, and possibly by signs of CHF (see page 1219).
2. Polyarthritis—pain and limited movement of two or more joints; joints are swollen, red, warm, and tender.
3. Chorea—purposeless, involuntary, rapid movements commonly associated with muscle weakness, involuntary facial grimaces, speech disturbance, and emotional lability.
4. Erythema marginatum—nonpruritic pink, macular rash mostly of the trunk with pale central areas;

migratory.

5. Subcutaneous nodules—firm, painless nodules over the scalp, extensor surface of joints, such as wrists, elbows, knees, and vertebral column.

Minor Manifestations

1. History of previous rheumatic fever or evidence of preexisting rheumatic heart disease.
2. Arthralgia—pain in one or more joints without evidence of inflammation, tenderness, or limited movement.
3. Fever—temperature greater than 100.4°F (38°C).
4. Laboratory abnormalities—elevated erythrocyte sedimentation rate, positive C-reactive protein, elevated white blood cell count.
5. ECG changes—prolonged PR interval.

Diagnostic Evaluation

1. Diagnosed clinically through use of the Jones criteria from the American Heart Association—presence of two major manifestations or one major and two minor manifestations (as listed above), with supporting evidence of a recent streptococcal infection.
2. ECG to evaluate PR interval and other changes.
3. Laboratory tests listed above. In addition, group A streptococcal culture and/or antistreptolysin-O titer to detect streptococcal antibodies from recent infection.
4. Chest x-ray for cardiomegaly, pulmonary congestion, or edema.

Management

1. Course of antibiotic therapy to completely eradicate streptococcal infection (may be given despite previous treatment).
   a. Usually benzathine penicillin is given IM in a single dose or a 10-day course of oral penicillin V.
   b. Oral erythromycin may be used for children who are allergic to penicillin.
2. Nonsteroidal anti-inflammatory drugs (naproxen sodium) usually used to control pain and inflammation of arthritis. Aspirin for acute carditis.
3. Corticosteroids may be used in severe cases to try to control cardiac inflammation; however, there is limited evidence to support their use.
4. Phenobarbital, diazepam, or other neurologic agent to control chorea.
5. Bed rest during the acute phase to rest the heart. Gradual return to activities is recommended once acute symptoms resolve.
6. Mitral valve replacement may be necessary in some cases.
7. Secondary prevention of recurrent ARF:
   a. Risk of recurrence greatest within first 5 years, with multiple episodes of ARF, and with rheumatic heart disease. Prophylactic antibiotic treatment may be lifelong.

b. For those at low risk for recurrence, antibiotic prophylaxis may be continued for 5 years or longer.
c. Antibiotic regimens may include:
    i. Benzathine penicillin IM once.
    ii. Penicillin V 250 mg orally twice per day for children less than 27 kg, 500 mg orally twice per day for patients greater than 27 kg.
    iii. Patients with penicillin allergies may be prescribed cephalosporin, clindamycin, azithromycin, or clarithromycin.

Complications

1. CHF.
2. Pericarditis, pericardial effusion.
3. Permanent damage to the aortic or mitral valve, possibly requiring valve replacement.

Nursing Assessment

1. Assess for signs of cardiac involvement by auscultation of the heart for murmur and cardiac monitoring for prolonged PR interval.
2. Monitor pulse for 1 full minute to determine heart rate.
3. Assess temperature for elevation.
4. Observe for involuntary movements: stick out tongue or smile; garbled or hesitant speech when asked to recite numbers or the ABCs; hyperextension of the wrists and fingers when trying to extend arms.
5. Assess child's ability to feed self, dress, and do other activities if chorea or arthritis present.
6. Assess pain level using scale appropriate for child's age.
7. Assess parents' ability to cope with illness and care for child.
8. Assess need for home schooling while the patient is on bed rest.

Nursing Diagnoses

- Decreased Cardiac Output related to carditis.
- Acute and Chronic Pain related to arthritis.
- Risk for Injury related to chorea.

Nursing Interventions

Improving Cardiac Output

1. Explain to the child and family the need for bed rest during the acute phase and as long as CHF is present. In milder cases, light indoor activity is allowed.
2. In severe cases, organize care to minimize exertion and provide uninterrupted rest.
3. Maintain cardiac monitoring, if indicated.
4. Administer course of antibiotics, as directed. Be alert to adverse effects, such as nausea, vomiting, and GI

distress.

5. Administer medications for CHF, as directed. Monitor BP, intake and output, and heart rate.

Relieving Pain

1. Administer anti-inflammatory medication, analgesics, and antipyretics, as directed.
   a. Monitor for side effects of corticosteroid use—GI distress, acne, weight gain, and emotional disturbances—or long-term effects, such as rounded face, ulcer formation, and decreased resistance to infection.
   b. Administer all anti-inflammatory medications with food to reduce GI injury.
   c. Be aware that anti-inflammatories may not alter the course of myocardial injury.
2. Teach family the importance of maintaining dosage schedule, continuing medication until all signs and symptoms of the ARF have gone, and tapering the dose, as directed by health care provider.
3. Assist child with positioning for comfort and protecting inflamed joints.
4. Suggest diversional activities that do not require use of painful joints.

Protecting the Child with Chorea

1. Use padded side rails if chorea is severe.
2. Assist with feeding and other fine-motor activities, as needed.
3. Assist with ambulation if weak.
4. Avoid the use of straws and sharp utensils if chorea involves the face.
5. Make sure that child consumes nutritious diet with recommended vitamins, protein, and calories.
6. Be patient if speech is affected and offer emotional support.
7. Protect the child from stress.
8. Administer phenobarbital or other medication for chorea, as directed. Observe for drowsiness.

Family Education and Health Maintenance

1. Teach the appropriate administration of all medications, including prophylactic antibiotic.
2. Encourage all family and household members to be screened for streptococcus and receive the appropriate treatment.
3. Instruct on additional prophylaxis for endocarditis with dental procedures and surgery, as indicated.
4. Encourage following activity restrictions, resuming activity gradually, and resting whenever tired.
5. Encourage keeping appointments for follow-up evaluation by cardiologist and other health care providers.
6. Advise the parents that child cannot return to school until health care provider assesses that all disease activity is gone. Parents may need to discuss with teachers how the child can catch up with schoolwork.
7. Instruct on follow-up with usual health care provider for immunizations, well-child evaluations, hearing and vision screening, and other health maintenance needs.

Provide general health education about early identification and treatment seeking for any possible

streptococcal infection (fever, sore throat). Compliance with 10 to 14 days of antibiotics can greatly reduce the risk of ARF and other poststreptococcal sequelae.

Evaluation: Expected Outcomes

- Heart rate and PR interval within normal range for age; no signs of CHF.
- Compliant with anti-inflammatory therapy; reports pain as 1 to 2 on scale of 1 to 10.
- Feeds self, washes face and hands, and ambulates to bathroom without injury.

Cardiomyopathy

EVIDENCE BASE Yuan, S. M. (2018). Cardiomyopathy in the pediatric patients. *Pediatrics and Neonatology, 59*(2), 120–128.Glotzbach, K., May, L., & Wray, J. (2018). Health related quality of life and functional outcomes in pediatric cardiomyopathy. *Progress in Pediatric Cardiology, 48*, 26–35.

According to the type of myocardial changes, *cardiomyopathy* can be classified into three categories: dilated, hypertrophic, and restrictive. The most common type in children is dilated cardiomyopathy. Hypertrophic cardiomyopathy is a leading cause of death in young athletes.

Pathophysiology and Etiology

1. Familial (family history, genetic predisposition) tendency.
2. Idiopathic in most cases.
3. May be related to:
   a. Nutritional deficiency (carnitine or selenium).
   b. Viral infection (myocarditis), human immunodeficiency virus.
   c. Collagen vascular disease (systemic lupus erythematosus).
   d. Cardiotoxic drugs (doxorubicin).
   e. Cocaine abuse.
   f. Infants of diabetic mothers.
   g. Ion channelopathies.
   h. Catecholamine surge; hyperthyroidism.
4. Dilated cardiomyopathy involves dilatation of one or both ventricles associated with normal septal and LV free wall thickness.
5. Decreased systolic function (contractility) results in CHF.
6. Increasing end-systolic dimension results in AV valve insufficiency, further worsening CHF.

Clinical Manifestations

1. Signs of CHF—tachycardia, tachypnea, dyspnea, crackles, hepatosplenomegaly.
2. Decreased exercise tolerance, fatigue, sweating.
3. Poor weight gain, nausea, abdominal tenderness.
4. Ventricular arrhythmia.
5. Chest pain.
6. Syncope.

Diagnostic Evaluation

1. Auscultation: systolic regurgitant murmur (if mitral or tricuspid insufficiency is present), S_2 is normal or narrowly split, prominent S_3 gallop.
2. ECG: tachycardia, abnormal ST segments, arrhythmia, ectopic atrial tachycardia, deep Q waves, LVH.
3. Chest x-ray: cardiomegaly, pulmonary congestion.
4. Two-dimensional echocardiogram: increased wall thickness, poor ventricular systolic function, dilated heart chambers; AV valve insufficiency.
5. Cardiac MRI will provide useful information on cardiac function and may demonstrate ventricular hypertrophy or fibrosis.
6. Cardiac catheterization: not needed for initial diagnosis; endomyocardial biopsy (to rule out myocarditis); assess PVR.

Management

General Measures

1. Identify and treat the underlying cause.
2. Maximize caloric intake: fortify formula; supplemental nasogastric feedings.
3. Supplemental oxygen, as needed.
4. Activity restriction (usually self-imposed by the younger child and infant). Restrict participation in strenuous and competitive sports.

Treatment of Systolic Dysfunction with Dilated Cardiomyopathy

1. Diuretics: furosemide, spironolactone.
2. Inotropes for patients with poor perfusion: milrinone, dopamine, epinephrine.
3. Afterload reduction: captopril, enalapril, lisinopril.
4. Anticoagulation: warfarin, low-molecular-weight heparin (enoxaparin).
5. Antiarrhythmics.
6. Placement of an automatic implantable cardioverter defibrillator.
7. Biventricular pacing.
8. Cardiac transplant.

Treatment of Diastolic Dysfunction with Hypertrophic Cardiomyopathy

1. Beta-adrenergic blockers: propranolol.
2. Calcium channel blockers: verapamil.
3. AV sequential pacing.
4. Myomectomy or myotomy.

Treatment of Diastolic Dysfunction with Restrictive Cardiomyopathy

1. Diuretics.
2. Anticoagulation.
3. Permanent pacemaker for advanced heart block.

Complications

1. Severe CHF.
2. Increased pulmonary vascular resistance.
3. Intracardiac thrombus.
4. Embolus.
5. Malignant arrhythmias.
6. Sudden death.

Nursing Assessment

Perform a thorough nursing assessment as for CHD (see page 1216).

Nursing Diagnoses

- Decreased Cardiac Output related to impaired systolic or diastolic ventricular function.
- Imbalanced Nutrition: Less Than Body Requirements related to increased metabolic demands and poor feeding from dyspnea, fatigue, and poor appetite.
- Ineffective Family Coping related to chronic illness.

Nursing Interventions

Maximizing Cardiac Output

1. Monitor vital signs; notify physician for hypotension, tachycardia, arrhythmia; increasing tachypnea.
2. Administer oxygen therapy, as prescribed.
3. Administer medications, as prescribed.
   a. Maintain bleeding precautions for anticoagulated patients.
   b. Document response to diuretics; monitor intake and output.
4. Monitor electrolytes.
5. Restrict level of activity.

Providing Maximal Nutritional Support

1. Encourage frequent, small meals. Provide foods the child likes.
2. Provide high-calorie supplements (milkshakes, pudding).
3. Administer supplemental tube feedings if nutritional needs are not being met.
4. Administer parenteral hyperalimentation and intralipids, as directed (rarely needed).

Promoting Effective Coping and Control within the Family

1. Organize a family meeting with various members of the health care team to review the child's medical condition and to explain the treatment plan.
2. Allow the child and family to express their questions, fears, and concerns.
3. Identify support systems and services for the child and family: extended family members, clergy, support groups, community resources.

Family Education and Health Maintenance

1. Teach child and family medication administration: purpose of the drug, drug dosage, drug schedule, and adverse effects.
2. Help family design a realistic medication schedule.
   a. Identify usual wake-up time and bedtime. Schedule medications accordingly.
   b. Do not give a diuretic right before bedtime or nap time.
   c. If possible, avoid having to give medications at school.
3. Teach bleeding precautions if the child is on anticoagulation agents (coumadin).
   a. Monitor prothrombin International Normalized Ratio regularly.
   b. Observe for signs of bleeding.
   c. Counsel regarding menses and pregnancy.
   d. Instruct on foods and medications that interfere with coumadin.
4. Give guidelines for notifying the physician.
   a. Worsening shortness of breath.
   b. Irregular pulse; palpitations.
   c. Syncope, dizziness, or light-headedness.
   d. Increasing fatigue, exercise intolerance.
5. Teach infant and child CPR to family members and other caregivers.

Evaluation: Expected Outcomes

- Stable vital signs.
- Maximal nutritional status, as evidenced by weight gain and growth.
- Compliance with the treatment plan and follow-up visits.

TRANSITIONAL CARE ALERT Many children discharged from the hospital diagnosed with a complex cardiac condition will have extensive discharge needs. Families will need support in the transition to home or another aftercare location. It is crucial that they have complete and understandable care instructions on home care, medications, and follow-up appointments. If arrangements have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to

assist understanding, pictorial) instructions on signs and symptoms to monitor, for that could suggest worsening of status. Instructions should include clear understanding of acceptable discharge expectations as many children may be in different phases if a surgical repair is necessary. Parents should be aware of when and where they should seek further emergency care if the child's condition deteriorates.

NEUROLOGIC AND NEUROSURGICAL DISORDERS

It is essential to have strong knowledge of growth and development and use physical assessment skills while caring for a child with a neurological or neurosurgical condition. Children are not little adults. They have their own unique physiology, which is important to consider when assessing and understanding the manifestation of neurological conditions in children. Young children often cannot either speak or express how they feel; therefore, a complete ongoing physical assessment is essential. Parents and caregivers are an invaluable source of information and know their child the best and should always be included in all aspects of care delivery.

Cerebral Palsy

Cerebral palsy (CP) is a nonprogressive disorder of posture, muscle tone, and movement. There are a number of causes, but CP is a result of abnormalities of the developing brain. The prevalence of CP is 2 per 1,000 live births with a higher prevalence in preterm than term infants. Preterm infants account for less than half of all cases of CP.

Pathophysiology and Etiology

1. Prematurity.
2. Perinatal hypoxic–ischemic injury.
3. Congenital abnormalities.
4. Genetic susceptibility.
5. Multiple births.
6. Stroke.
7. Intracranial hemorrhage.
8. Intrauterine postnatal causes.

Classification of Cerebral Palsy

Spastic Subtypes

1. Spastic Diplegia
    a. 13% to 25% of CP cases.
    b. Most commonly associated with periventricular leukomalacia.
    c. Lower limbs more affected than upper limbs.
    d. Presence of flexion, adduction, and internal rotation of the hips with contractures of hip flexors and hamstring muscles.
    e. Variable degrees of flexion at elbows and knees.
    f. Reduced limb length and muscle bulk in lower extremities.
2. Spastic Hemiplegia
    a. 21% to 40%
    b. One side of the body affected.
    c. The arm typically more affected than the leg.
    d. The arm adducted at the shoulder and flexed at the elbow with forearm pronated with the wrist and fingers flexed with hand closed.
    e. The hip partially flexed and adducted, the knee and ankle are flexed, and the foot may be in equinovarus or calcaneovalgus position.
    f. Sensory deficits present in most children.
    g. Postural abnormalities more apparent during walking or running in mildly affected children; walking

occurs at appropriate developmental stage unless in the presence of intellectual disability.

3. Spastic Quadriplegia
    a. 20% to 43%.
    b. All limbs affected.
    c. Upper limbs may be equally or more involved than lower limbs.
    d. Children often severely affected.
    e. Feeding difficulties, chronic respiratory insufficiency, and seizure disorders are common.

Dyskinetic Subtypes

1. 12% to 14%.
2. Involuntary movements.
3. Contractures not common but may evolve later in life.
4. Variable degree of dysarthria and intellectual disability.
5. Choreoathetotic CP
    a. Rapid, irregular, unpredictable contractions of individual muscles or small muscle groups that involve the face, bulbar muscles, proximal extremities, fingers, and toes.
    b. Athetosis—slow, smooth, writhing movements involving the distal muscles.
        i. Movements may be induced or may be heightened by emotions or change in posture.
        ii. Very obvious during reaching.
        iii. Chorea may be aggravated by fever, stress, or excitement.
        iv. Persistent primitive reflexes.
        v. Commonly seen are oropharyngeal difficulties.
6. Dystonic CP
    a. Slow or rapid repetitive, patterned, twisting, and sustained movements of the trunk and limbs.
    b. May have pyramidal signs and anarthria.
    c. Sudden involuntary increase (tension) in tone may affect flexor and extensor muscles during attempted movement or with emotion.
    d. It may be difficult to elicit tendon reflexes or they may be normal.
    e. Absence of clonus and extensor plantar responses.
7. Ataxic CP
    a. 4% to 13%.
    b. Ataxic movements.
    c. Widespread disorder of motor function.
    d. Over time, ataxia will usually improve.
    e. Speech is slow, jerky, and explosive.

Clinical Manifestations

Common associated findings include:

1. Pain (50% to 75%).
2. Intellectual disability (50%).
3. Speech–language disorders (40%).
4. Epilepsy (25% to 40%).
5. Visual impairment (30%).
6. Hip displacement (30%).
7. Behavior disorder (25%).
8. Bladder control problems (30% to 60%).
9. Sleep disorder (20%).
10. Drooling (20%).
11. Hearing impairment (10% to 20%).
12. Gastrostomy tube dependence (7%).

Diagnostic Evaluation

Diagnosis is based on clinical examination and history. Various diagnostic tests also help determine the cause and evaluate for associated problems.

History and Physical Examination

1. Review of prenatal and birth history.
2. Review of newborn screening results.
3. Review of family history
    a. Intellectual disability/developmental disabilities.
    b. Seizures.
    c. CP.
    d. Neuromotor/movement disorders.
    e. Neurobehavioral disorders.
    f. Joint contractures/stiffness.
    g. Thromboses/vascular accidents.
    h. Congenital anomalies.
    i. Infertility.
    j. Recurrent miscarriages/stillborn.
    k. Adult-onset neurodegenerative conditions.

Diagnostic Tests

Although CP is diagnosed based on clinical findings, diagnostic evaluation should be completed to identify underlying causes of CP and to rule out other conditions.

1. Magnetic resonance imaging (MRI) of the brain
    a. Should be obtained in all children with CP of undetermined etiology.
    b. MRI is preferred to computed tomography (CT) because of its higher diagnostic yield and it can help determine etiology and timing of insult.
    c. Abnormalities on MRI seen in patients with CP include hypoxic–ischemic lesions (periventricular leukomalacia or PVL), cortical malformations, and lesions in the basal ganglia.
2. Electroencephalography (EEG) should be obtained in children who are suspected of having seizure activity.
    a. 45% of children with CP have seizures.
3. Lumbar puncture (LP) should be obtained in children with drug-resistant seizures or movement disorders such as ataxic–spastic gait or dyskinesias.
    a. Screening is done for pediatric neurotransmitter disorders, to evaluate low cerebrospinal fluid (CSF) glucose concentration, which may be caused by glucose transporter deficiency (GLUT1).
4. Metabolic and genetic testing should be done if:
    a. Testing should be done if the history reveals features that are atypical for CP but suggestive of a genetic or metabolic etiology (eg, history of progressive encephalopathy, metabolic decompensation, family history of childhood neurologic disorder associated with CP, and history of consanguinity).
    b. If there is a developmental brain malformation on brain imaging (eg, lissencephaly, schizencephaly, pachygyria) or frontal/temporal atrophy.
    c. When no etiology has been identified on history and physical examination and on neuroimaging.
    d. If there are atypical symptoms or a brain malformation on MRI.
5. Thrombophilia screening should be done in children with hemiplegic CP or MRI evidence of a cerebral infarction.
    a. 50% to 60% of patients with hemiplegic CP have at least one prothrombotic coagulation abnormality.
    b. Test for factor V Leiden mutation, prothrombin 202210 mutation, antithrombin deficiency, protein C deficiency, protein S deficiency, hyperhomocysteinemia, antiphospholipid antibodies, and elevated factor VIII.

Management

Management of CP requires a multidisciplinary team that will look at medical, psychological, educational, social, and therapeutic needs. Management of CP includes the following:

Functional Evaluation

1. Important in planning treatment as functional evaluation is based on the limitations of the patient with respect to body structure and function.
2. Treatment is guided by standardized measurement of functional status such as the Gross Motor Function Classification System (GMFCS), Modified Ashworth Scale, Manual Ability Classification System (MACS), and Communication Function Classification System (CFCS).

Management of Spasticity

1. Botulinum toxin injections of botulinum type A (BTXA) into affected muscles
    a. Most commonly used in calf muscles in patients with diplegia or hemiplegia.
    b. To maintain efficacy, injections are repeated every three to eight months.
    c. Used to treat children who have increased muscle tone that negatively affects function, which, over time with growth, will likely result in formation of contractures.
2. Antispastic Drugs
    a. Although less effective than Botox, oral antispastic drugs such as baclofen, benzodiazepines (eg, diazepam), and dantrolene are sometimes used to treat spasticity in CP.

Intrathecal Baclofen

1. Administered via the intrathecal route to achieve higher cerebrospinal fluid (CSF) drug levels as opposed to oral administration, which results in lower CSF drug levels.
2. Reduces spasticity in severely affected children.
3. Has significant complications and is therefore reserved for children with severe spasticity that is unresponsive to other treatment modalities.

Surgical Treatment

1. Selective dorsal rhizotomy (SDR) is the primary surgical intervention used in the treatment of spasticity.
2. Deep brain stimulation (DBS) is an emerging therapy that has been used in the treatment of severe primary dystonia in adults who have failed to respond to pharmacotherapy such as Botox; however, further studies are needed to establish efficacy in treating dyskinetic CP.

Orthopedic Interventions

1. Gait analysis is utilized in identifying muscles that may benefit from surgical lengthening and is used postoperatively to evaluate surgical outcomes on function.
    a. Gait analysis is typically used in children aged 6 to 10 years who have a mature gait.
    b. Ankle–foot orthoses are often used to try to stabilize or improve range of motion or gait.
2. Casting
    a. Serial casting is often used to stretch and shorten muscles in lower limbs as well as improve range of motion.
3. Muscle–Tendon Surgery
    a. To reduce restrictions in joint motion or malalignment, surgical intervention to release or recess limb muscles and tendons is performed when function is affected by fixed contractures.
4. Surgical Treatment of Hip Disorders
    a. Children with spastic CP commonly have hip disorders including subluxation, dislocation, and dislocation with degeneration and pain.
    b. Soft tissue lengthening is done to correct hip subluxation, whereas reconstructive hip surgery is done

in children younger than four years old who are more severely affected but who have not developed degenerative changes of the femoral head.

Physical Therapy

1. Physical therapy is a vital component of treatment programs for the management of CP and includes establishing methods to promote posture, mobility, and transfer and to allow for effective methods of promoting activities of daily living.
2. Bimanual training for hemiplegic CP.
   a. The child is trained to use two hands together through repetitive tasks.
   b. Constraint-induced movement therapy (CIMT)—used in children who have hemiplegic CP to promote limb function through the use of intermittent restraint of the unaffected limb during therapeutic tasks and often involves casting of the unaffected limb.
   c. Context-focused therapy—the task or environment is changed to promote successful task performance rather than changing the child's approach.
   d. Goal-directed/functional training—promotes the focus of activities that are based on goals set by the child using a motor learning approach.
3. Occupational therapy for the upper limbs—involves physical therapy approaches and can be done concurrently with botulinum toxin treatment.

Feeding and Nutrition

Children with CP often have oromotor difficulties and feeding problems. Infants should be assessed for their ability to suck and for swallowing difficulties. School-aged children should be assessed for their height and weight status, as well as for any difficulty feeding, need for assistance with feeding, duration of feeding time, choking, and/or frequent vomiting and their nutritional status to ensure they receive adequate intake. Gastrostomy feeding should be considered in children with failure to thrive or who have chronic aspiration.

Management of Drooling

1. Children with CP who have oromotor dysfunction often drool. Management of drooling includes medication, behavior therapy, and surgery. Noninvasive methods such as behavior therapy and medications are often tried before surgical intervention.
2. Medications to manage drooling include anticholinergic agents such as benzhexol hydrochloride, scopolamine, or glycopyrrolate.
3. Botox injections into the salivary glands to decrease the flow of saliva are often used.
4. Surgical treatment of drooling targets the reduction of salivary production.
5. Behavior management includes behavior management techniques and biofeedback techniques.

Management of Osteopenia

1. For children with CP who have severe reductions in bone mineral density and/or pathological extremity fractures or vertebral compression, treatment with bisphosphonates is employed.

Urinary Incontinence

1. Anticholinergic medication is often used to treat urinary incontinence.
2. Children with CP who have a neurogenic bladder are managed with anticholinergic medication, modification of the toileting schedule or environment, and/or intermittent catheterization, which is contingent upon features of a neurogenic bladder.

EVIDENCE BASE Linsell, L., Malouf, F., Morris, J., et al. (2016). Prognostic factors for cerebral palsy and motor impairment in children born very preterm or very low birthweight: A systematic review. *Developmental Medicine and Child Neurology, 58*(6), 554–569.

DRUG ALERT Intrathecal baclofen lowers the seizure threshold. Children may develop severe withdrawal syndrome characterized by fever, hypertension, tachycardia, agitation, and hallucinations, which may occur in situations of pump malfunction, catheter breakage, or improper filling of pump.

EVIDENCE BASE Ozel, S., Switzer, L., Macintosh, A., et al. (2016). Informing evidence-based clinical practice guidelines for children with cerebral palsy at risk of osteoporosis: An update. *Developmental Medicine and Child Neurology, 58*(9), 918–923.

Complications

1. Contractures.
2. Hip subluxation/dislocation.
3. Malnutrition.
4. Scoliosis.
5. Osteopenia/fractures.
6. Gastroesophageal reflux.
7. Constipation.
8. Seizures.
9. Spasticity.
10. Pain.

Nursing Assessment

1. Perform a functional assessment; determine ability to perform activities of daily living (ADL).

2. Perform a developmental assessment; use Denver II developmental or other screening tools.
3. Evaluate ability to protect airway—gag reflex and swallowing.
4. Assess nutritional status—growth (height, weight, head circumference, ideal body weight), signs of nutritional deficiency, risk of aspiration, length of time it takes to feed, food diary to determine quantify of food and fluid consumed, and hydration.
5. Assess neuromuscular function and mobility—range of motion (ROM), spasticity, coordination, and scoliosis.
6. Assess speech, hearing, and vision.
7. Evaluate parent–child interaction.
8. Determine parents' understanding of and compliance with treatment plan.
9. Assess the skin for pressure sores, especially in areas of friction (splints).
10. Assess for the presence of pain (chronic or acute because of hip subluxation, dislocation).

Nursing Diagnoses

- Impaired Physical Mobility related to altered neuromuscular functioning.
- Delayed Growth and Development related to the nature and extent of the disorder.
- Interrupted Family Processes related to nature of disorder, role disturbances, and uncertain future.
- Risk for Injury related to deficit in motor activity and coordination.

Nursing Interventions

Increasing Mobility and Minimizing Deformity

1. Teach the parents to carry out appropriate exercises under the direction of the physical therapist and occupational therapist, and encourage them to incorporate this into their child's daily routine. Ensure they understand the rationale/importance of completing the exercises.
2. Use splints and braces to facilitate muscle control and improve body functioning.
    a. Apply, as directed.
    b. Remove for recommended time.
    c. Inspect the underlying skin for redness, irritation, skin breakdown, and signs of improper application or fit of splints or orthoses.
    d. Regularly inspect orthoses for cracks, loose screws, or broken Velcro straps.
    e. Use splint as directed for constraint-induced therapy in children with unilateral CP.
3. Use assistive devices, such as adapted grooming tools, writing implements, and utensils, to enhance independence. Handles for toothbrushes, spoons, and forks can be built up with sponges or specially curved to make holding easier.
4. Encourage self-dressing with easy pull-on pants, large sweatshirts, Velcro closures, and other loose clothing.
5. Use play, such as board games, ball games, pegboards, puzzles, computers, and tablets, to improve

coordination.

6. Maintain good body alignment to prevent contractures.
7. Provide adequate rest periods.
    a. Employ good sleep hygiene practices.
    b. Administer or teach parents about side effects of medications and how to administer medications safely, as prescribed.

Maximizing Growth and Development

1. Evaluate the child's developmental level and then assist with age-appropriate tasks.
2. Provide for continuity of care at home, daycare, therapy centers, and the hospital.
    a. Obtain a thorough history from the parents regarding the child's usual home routines, weaknesses and strengths, and likes and dislikes.
    b. Communicate with representatives from all disciplines involved in the child's care to ensure that the specific needs of the child are identified.
    c. Formulate a consistent care plan that incorporates the goals of all related disciplines and aligns with the goals of the child and family. Include in the care plan guidelines for the following:
        i. Feeding.
        ii. Sleeping.
        iii. Physical therapy/occupational therapy.
        iv. Play.
        v. Other ways to foster growth and development.
        vi. Medications.
        vii. Psychosocial needs.
        viii. Family needs.
        ix. Pain assessment/management.
3. During feeding, maintain a pleasant, distraction-free environment.
    a. Provide a comfortable chair.
    b. Serve the child alone, initially. After the child begins to master the task of eating, encourage the child to eat with other children.
    c. Do not attempt feedings if the child is very fatigued.
    d. Find the eating position in which the child can be most self-sufficient.
    e. Allow the child to hold the spoon even if self-feeding is minimal.
    f. Stand behind and reach over the child's shoulder to guide the spoon from the plate to the child's mouth.
    g. Serve foods that stick to the spoon, such as thick applesauce or mashed potatoes.
    h. Encourage finger foods that the child can handle to self-feed.
    i. Provide appropriate assistive devices for independent feeding, such as a spoon and fork with special

handles, plate and glass holders, and special feeding chair.

j. Disregard "messy" eating; use a large plastic bib, smock, or towel to protect the child's clothes.

4. If the child requires assistance with feeding, do so slowly and carefully. Be aware of difficulty sucking and swallowing caused by poor muscle control. Cut large pieces of food into small pieces or serve pureed foods.
5. Be alert for associated sensory deficits that delay development and could be corrected.
   a. Hearing, speech, and vision.
   b. Squinting, failure to follow objects, or bringing objects very close to the face.

Strengthening Family Processes

1. Assess parental coping and provide anticipatory guidance, emotional support, access to peer support, and contact with social worker, as needed.
2. Help the parents to recognize immediate needs and identify short-term goals that can be integrated into the long-term plan.
3. Assess for caregiver burden because of the numerous challenges of daily care, and link with appropriate resources (eg, home care, respite, funding) and provide access to social work for assistance in obtaining such support.
4. Provide positive feedback for effective parenting skills and positive approaches to caring for the child.
5. Assist the parents to deal with siblings' responses to the disabled child.
   a. Encourage parents to find time to spend with each sibling separately.
   b. Encourage family to maintain contact with friends and community and engage in outside activities as much as possible.
   c. Suggest family counseling.
6. Assist parents to find local resources to help in the child's care.
   a. Contact hospital social worker or discharge planner for information about local CP organizations, chapters, funding sources, community supports, or charities.
   b. Help to navigate through the national and regional programs that may have local chapters.

Protecting the Child from Injury

1. Evaluate the child's need for specific safety equipment, such as a suction machine, helmet, and walker, and modify the environment as appropriate to ensure the child's safety.
2. Provide for frequent position changes and adequate fit on orthotics, wheelchairs, and walking or standing devices to prevent skin breakdown. Assess skin integrity regularly.

Community and Home Care Considerations

1. Assess the home environment for safety. Stairs should be gated and paths should be cleared for walking with assistive devices or for adequate passage of wheelchairs, walkers, etc.
2. Assist parents in arranging for equipment that may be required in the home (eg, wheelchair, pump for

intermittent G-tube feedings, walkers, home suction machine).

3. Check all adaptive equipment, braces, and walkers for correct fit. Arrange for replacement, as needed.

Family Education and Health Maintenance

1. Instruct the parents in all areas of the child's physical care.
2. Encourage regular medical and dental evaluations.
3. Advise parents that the child needs discipline to feel secure.
4. Refer parents to such agencies as the United Cerebral Palsy Association of America (*www.ucp.org*).
5. Connect families with other families who have a child with CP so that they may provide a supportive network.
6. Encourage maintenance of good nutritional status.
7. Help the child engage in regular exercise to maintain health.

Evaluation: Expected Outcomes

- Dresses and feeds self as independently as possible; minimal contractures noted.
- Consistent growth curve maintained; sequential developmental milestones consistent with condition achieved.
- Family participates in usual school and community activities; uses respite care when available.
- Safety equipment used; no injury reported.

Hydrocephalus

Hydrocephalus is characterized by an increased volume of cerebrospinal fluid (CSF) that accumulates in the ventricles and/or subarachnoid spaces and is associated with progressive ventricular dilatation. There are two main categories of hydrocephalus: communicating and noncommunicating. Hydrocephalus occurs with such conditions as tumors, infections, congenital malformations, and hemorrhage. The incidence of hydrocephalus is 0.5 to 4 per 1,000 live births.

Pathophysiology and Etiology

1. Noncommunicating hydrocephalus—obstruction of CSF flow within the ventricular system or blockage of CSF flow from the ventricular system to the subarachnoid space.
    a. May be partial, intermittent, or complete.
    b. More common than communicating type.
    c. Congenital causes.
        i. Aqueductal stenosis.
        ii. Congenital lesions (vein of Galen malformation, congenital tumors).
        iii. Arachnoid cyst.
        iv. Chiari malformations (with or without myelomeningocele).
        v. X-linked hydrocephalus.
        vi. Dandy-Walker malformation.
    d. Acquired causes.
        i. Aqueductal gliosis (posthemorrhagic or postinfectious).
        ii. Space-occupying lesions (tumors or cysts).
        iii. Head injuries.
2. Communicating hydrocephalus—CSF circulates through the ventricular system into the subarachnoid space with no obstruction.
    a. Congenital causes.
        i. Achondroplasia.
        ii. Arachnoid cyst.
        iii. Craniofacial syndromes.
    b. Acquired causes.
        i. Posthemorrhagic (intraventricular or subarachnoid).
        ii. Choroid plexus papilloma or choroid plexus carcinoma.
        iii. Venous obstruction (eg, superior vena cava syndrome).
        iv. Postinfectious.

Clinical Manifestations

May be rapid, slow and steadily advancing, or intermittent. Clinical signs depend on the age of the child, whether the anterior fontanelle has closed, whether the cranial sutures have fused, and the type and duration of hydrocephalus.

Infants

1. Excessive head growth (may be seen up to age 3 years).
2. Delayed closure of the anterior fontanelle.
3. Fontanelle tense and elevated above the surface of the skull.
4. Signs of increased intracranial pressure (ICP) (see Box 46-1).
5. Alteration of muscle tone of the extremities, including clonus or spasticity.
6. Later physical signs:
    a. Forehead becomes prominent ("bossing").
    b. Scalp appears shiny with prominent scalp veins.
    c. Eyebrows and eyelids may be drawn upward, exposing the sclera above the iris.
    d. Infant cannot gaze upward, causing "sunset eyes."
    e. Strabismus, nystagmus, and optic atrophy may occur.
    f. Infant has difficulty holding head up.
    g. Child may experience physical or mental developmental lag.
7. Pseudobulbar palsy (difficulty sucking, feeding, and phonation, which leads to regurgitation, drooling, and aspiration).

BOX 46-1 Signs and Symptoms of Increased Intracranial Pressure in Infants and Children

- Vomiting.
- Restlessness and irritability.
- High-pitched, shrill cry (infants).
- Rapid increase in head circumference (infants).
- Tense, bulging fontanelle (infants).
- Changes in vital signs:
    - Increased systolic blood pressure.
    - Decreased pulse.
    - Decreased and irregular respirations.
    - Increased temperature.
- Pupillary changes.
- Papilledema.
- Possible seizures.
- Lethargy, stupor, and coma.
- Older children may also experience:

- Headache, especially on awakening.
- Lethargy, fatigue, and apathy.
- Personality changes.
- Separation of cranial sutures (may be seen in children up to age 10).
- Visual changes such as double vision.

NURSING ALERT It is important to measure head circumference because the infant's skull is highly elastic and can accommodate an increase in ventricular size. Ventriculomegaly may progress without obvious signs of increased ICP.

Older Children

Older children have closed sutures and present with signs of increased ICP.

Diagnostic Evaluation

1. Percussion of the infant's skull may produce a typical "cracked pot" sound (Macewen sign).
2. Ophthalmoscopy may reveal papilledema.
3. MRI is the diagnostic tool of choice.
4. CT is also used for diagnosis in cases where sedation poses added risk because of need for general anesthetic or in situations in which MRI is not available.
5. Ultrasonography is also used.

Management

Hydrocephalus can be treated through a variety of surgical procedures, including direct operation on the lesion causing the obstruction, such as a tumor; intracranial shunts for selected cases of noncommunicating hydrocephalus to divert fluid from the obstructed segment of the ventricular system to the subarachnoid space; and extracranial shunts (most common) to divert fluid from the ventricular system to an extracranial compartment, frequently the peritoneum or right atrium. CSF production may also be reduced by medication or surgical intervention.

Extracranial Shunt Procedures

1. Ventriculoperitoneal (VP) shunt (see Figure 46-1):
   a. Diverts CSF from a lateral ventricle or the spinal subarachnoid space to the peritoneal cavity.
   b. A tube is passed from the lateral ventricle through an occipital burr hole subcutaneously through the posterior aspect of the neck and paraspinal region to the peritoneal cavity through a small incision in the right lower quadrant.
   c. A ventricular access device is an implanted reservoir and catheter used for premature neonates <2,000 g in lieu of a shunt. The catheter drains fluid from the ventricles into the reservoir, which can then be

emptied using aseptic technique. When infant weight exceeds 2,000 g, a shunt can be placed.

2. Ventriculoatrial (VA) shunt:
    a. A tube is passed from the dilated lateral ventricle through a burr hole in the parietal region of the skull.
    b. It then is passed under the skin behind the ear and into a vein down to a point where it discharges into the right atrium or superior vena cava.
    c. A one-way pressure-sensitive valve will close to prevent reflux of blood into the ventricle and open as ventricular pressure rises, allowing fluid to pass from the ventricle into the bloodstream.
3. Ventriculopleural shunt:
    a. Diverts CSF to the pleural cavity.
    b. Indicated when the VP or VA route cannot be used.
4. Ventricle–gall bladder shunt:
    a. Diverts CSF to the common bile duct.
    b. Used when all other routes are unavailable.
5. Most shunts have the following components:
    a. Ventricular tubing.
    b. A one-way or unidirectional pressure-sensitive flow valve.
    c. A pumping chamber.
    d. Distal tubing.
6. Programmable shunts are available. These can be programmed to a certain flow pressure and pressure settings can be readjusted based on patient response. A magnetic device is used to adjust the pressure setting of the shunt valve. The use of a programmable shunt eliminates the need for multiple surgeries or hospital visits to adjust shunt pressure.

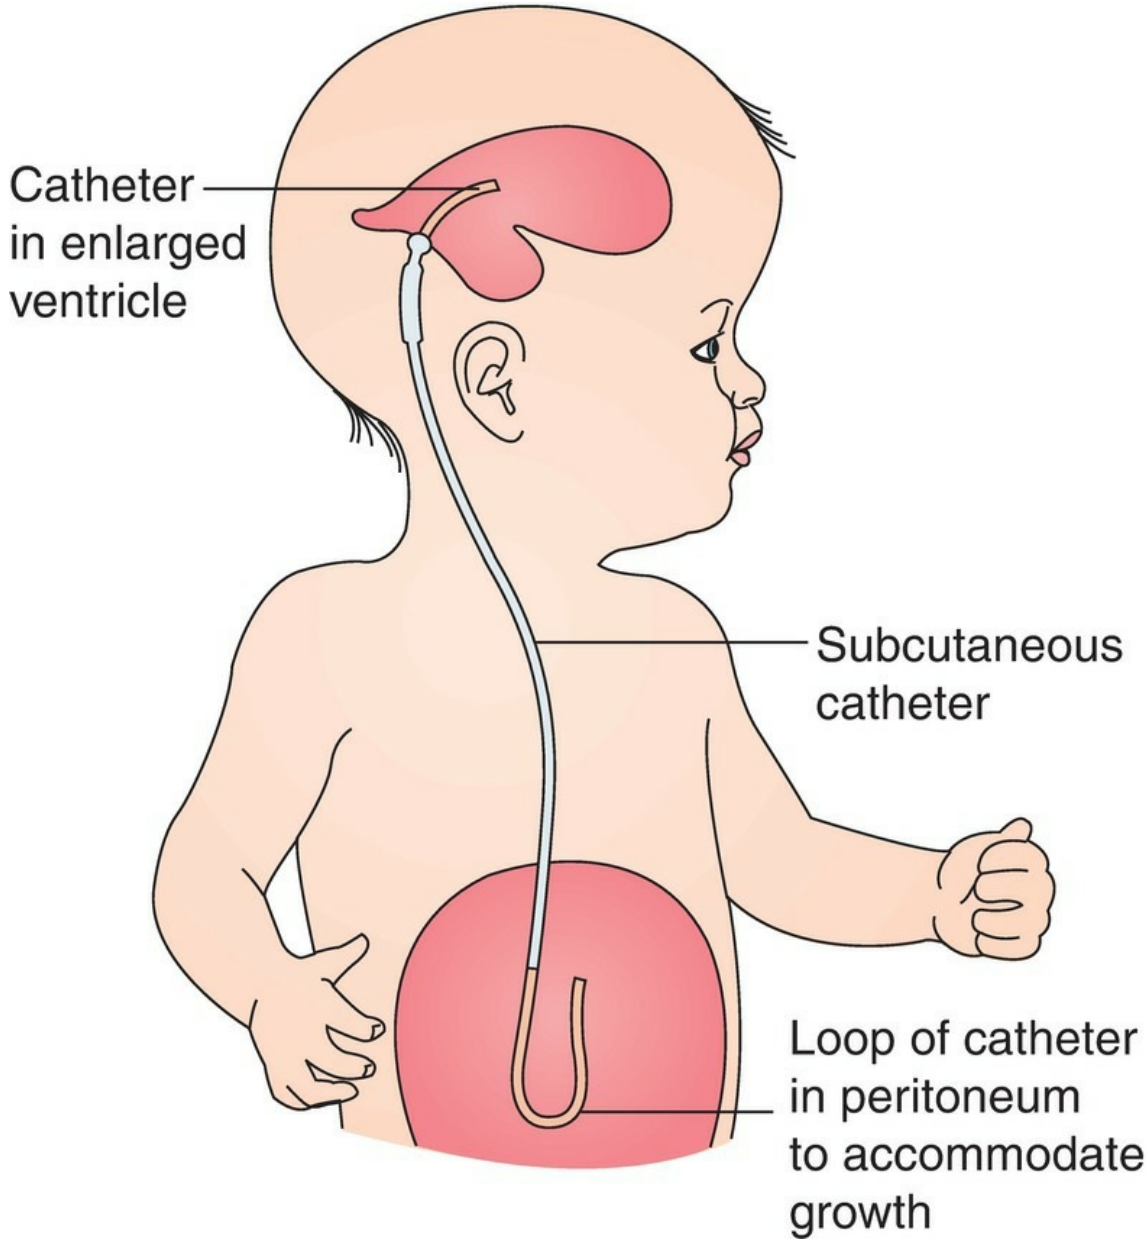

Figure 46-1. A ventriculoperitoneal shunt removes excessive cerebrospinal fluid from the ventricles and shunts it to the peritoneum. A one-way valve is present in the tubing behind the ear. (From Pillitteri, A. [2013]. *Maternal and child health nursing: Care of the childbearing and childrearing family* [7th ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Shunt Complications

1. Need for shunt revision frequently occurs because of occlusion, infection, or malfunction, especially in the first year of life.
2. Shunt revision may be necessary because of growth of the child. Newer models, however, include coiled tubing to allow the shunt to grow with the child.
3. Shunt dependency frequently occurs. The child rapidly manifests symptoms of increased ICP if the shunt does not function optimally. Onset may be sudden or insidious.

4. Children with VA shunts may experience endocardial contusions and clotting, leading to bacterial endocarditis, bacteremia, and ventriculitis or thromboembolism and cor pulmonale.
5. Children with VA shunts require biannual or annual chest x-ray to check length of tubing. Chest x-ray is also done during growth spurts, especially during puberty. When tubing is short or close to being out of the right atrium, shunt replacement needs to be scheduled.

Prognosis

1. Prognosis depends on early diagnosis and prompt therapy and the underlying etiology.
2. With improved diagnostic and management techniques, the prognosis is becoming considerably better.
    a. Many children experience normal motor and intellectual development.
    b. The severity of neurologic deficits is directly proportional to the interval between onset of hydrocephalus and the time of diagnosis.
3. Approximately two thirds of patients will die at an early age if they do not receive surgical treatment.
4. Surgery reduces mortality and decreases morbidity, with a survival rate of >90%.

Complications

1. Seizures and headaches.
2. Herniation of the brain.
3. Spontaneous arrest because of natural compensatory mechanisms, persistent increased ICP, and brain herniation.
4. Developmental delays.
5. Depression in adolescents is common.
6. Shunt malfunctions.

Nursing Assessment

Infants

1. Assess head circumference.
    a. Measure at the occipitofrontal circumference—point of largest measurement.
    b. Measure the head at approximately the same time each day.
    c. Use a centimeter measure for greatest accuracy.
2. Palpate fontanelle for firmness and bulging.
3. Assess pupillary response.
4. Assess level of consciousness (LOC).
5. Evaluate breathing patterns and effectiveness.
6. Assess feeding patterns and patterns of emesis.
7. Assess motor function.
8. Assess developmental milestones.

Older Children

1. Measure vital signs for signs of increased ICP.
2. Assess patterns of headache and emesis.
3. Determine pupillary response.
4. Evaluate LOC using the Glasgow Coma Scale.
5. Assess motor function.
6. Evaluate attainment of milestones and school performance.
7. Assess for behavioral changes.

Nursing Diagnoses

- Ineffective Cerebral Tissue Perfusion related to increased ICP before surgery.
- Imbalanced Nutrition: Less Than Body Requirements related to reduced oral intake and vomiting.
- Risk for Impaired Skin Integrity related to alterations in LOC and enlarged head.
- Anxiety of parents related to child undergoing surgery.
- Risk for Injury related to malfunctioning shunt.
- Risk for Deficient Fluid Volume related to CSF drainage and decreased intake postoperatively.
- Risk for Infection related to bacterial infiltration of the shunt.
- Ineffective Family Coping related to diagnosis and surgery.

Nursing Interventions

Maintaining Cerebral Perfusion

1. Observe for evidence of increased ICP and report immediately.
2. Assist with diagnostic procedures to determine cause of hydrocephalus and indication for surgical intervention.
    a. Explain the procedure to the child and parents at their levels of comprehension.
    b. Administer prescribed sedatives 30 minutes before the procedure to ensure their effectiveness.
    c. Organize activities so that the child is permitted to rest after administration of the sedative.
    d. Observe closely after ventriculography for the following:
        i. Leaking CSF from the sites of subdural or ventricular taps. These tap holes should be covered with a small piece of gauze or other dressing per institutional policy.
        ii. Reactions to the sedative, especially respiratory depression.
        iii. Changes in vital signs indicative of shock.
        iv. Signs of increased ICP, which may occur if air has been injected into the ventricles.

NURSING ALERT Brain stem herniation can occur with increased ICP and is manifested by

opisthotonic positioning (flexion of the head and feet backward). This is a grave sign and may be followed by respiratory arrest. Prepare for emergency resuscitation and corrective measures, as directed.

DRUG ALERT Sedatives are contraindicated in many cases because increased ICP predisposes the child to hypoventilation or respiratory arrest. If they are administered, the child should be observed very closely for evidence of respiratory depression.

Providing Adequate Nutrition

1. Be aware that feeding is frequently difficult because the child may be listless, have a diminished appetite, and be prone to vomiting.
2. Complete nursing care and treatments before feeding so that the child will not be disturbed during feeding.
3. Hold the infant in a semireclined position with head well supported during feeding. Allow ample time for bubbling.
4. Offer small, frequent feedings.
5. Place the child on side with head elevated after feeding to prevent aspiration.

Maintaining Skin Integrity

1. Prevent pressure sores (pressure sores of the head are a frequent problem) by placing the child on a sponge rubber or lamb's wool pad or an alternating-pressure or eggcrate mattress to keep weight evenly distributed. Be mindful of latex allergies and the type of padding used.
2. Keep the scalp clean and dry.
3. Turn the child's head frequently; change position at least every 2 hours.
   a. When turning the child, rotate head and body together to prevent strain on the neck.
   b. A firm pillow may be placed under the child's head and shoulders for further support when lifting the child.
   c. Keep weight off incision during immediate postoperative period.
4. Provide meticulous skin care to all parts of the body and observe the skin for signs of breakdown or pressure.
5. Give passive ROM exercises to the extremities, especially the legs.
6. Keep the eyes moistened with artificial tears if the child is unable to close the eyelids normally. This prevents corneal ulcerations and infections.

Reducing Anxiety

1. Prepare the parents for their child's surgery by answering questions, describing what nursing care will take place postoperatively, and explaining how the shunt will work.

2. Encourage the parents to discuss all the risks and benefits with the surgeon. Help them to understand the prognosis and what to expect of the child's neurologic and cognitive development.
3. Prepare the child for surgery by using dolls or other forms of play to describe what interventions will occur or solicit the help of a child life specialist to prepare the child for surgery through play.

Improving Cerebral Tissue Perfusion Postoperatively

1. Monitor the child's temperature, pulse, respiration, blood pressure (BP), and pupillary size and reaction every 15 minutes until stable; then, monitor every 1 to 2 hours or as indicated by child's condition and institutional policy.
2. Maintain normothermia.
    a. Provide appropriate blankets or covers, an Isolette or infant warmer, or hypothermia blanket.
    b. Administer a tepid sponge bath or antipyretic medication for temperature elevation.
3. Aspirate mucus from the nose and throat, as necessary, to prevent respiratory difficulty.
4. Turn the child frequently.
5. Promote optimal drainage of CSF through the shunt by pumping the shunt and positioning the child, as directed.
    a. If pumping is prescribed, carefully compress the valve at specified number of times at regularly scheduled intervals.
    b. Report any difficulties in pumping the shunt.
    c. Gradually elevate the head of child's bed to 30 to 45 degrees, as ordered. Initially, the child will be positioned flat to prevent excessive CSF drainage.
6. Assess for excessive drainage of CSF.
    a. Sunken fontanelle, agitation, and restlessness (infant).
    b. Decreased LOC (older child).
7. Assess closely for increased ICP, indicating shunt malfunction.
    a. Note especially change in LOC, change in vital signs (increased systolic BP, decreased pulse rate, decreased or irregular respirations), vomiting, and pupillary changes.
    b. Report these changes immediately to prevent cerebral hypoxia and possible brain herniation.
8. Prevent excessive pressure on the skin overlying shunt by placing cotton behind and over the ears under the head dressing and avoiding positioning the child on the area of the valve or the incision until the wound is healed.

Maintaining Fluid Balance

1. Accurately measure and record total fluid intake and output.
2. Administer intravenous (IV) fluids, as prescribed; carefully monitor infusion rate to prevent fluid overload.
3. Use a nasogastric tube, if necessary, for abdominal distention. This is most frequently used when a VP shunt has been performed.

a. Measure the drainage and record the amount and color.
b. Monitor for return of bowel sounds after nasogastric suction has been disconnected for at least 30 minutes.

4. Give frequent mouth care while the child is to have nothing by mouth.
5. Begin oral feedings when the child is fully recovered from the anesthetic and displays interest.
   a. Begin with small amounts of dextrose 5% in water.
   b. Gradually introduce formula.
   c. Introduce solid foods suitable to the child's age and tolerance.
   d. Encourage a high-protein diet.
   e. Observe for and report any decrease in urine output, increased urine specific gravity, diminished skin turgor, dryness of mucous membranes, or lethargy, indicating dehydration.

Preventing Infection

1. Assess for fever (temperature normally fluctuates during the first 24 hours after surgery), purulent drainage from the incision, or swelling, redness, and tenderness along the shunt tract.
2. Administer prescribed prophylactic antibiotics.

NURSING ALERT All children who have had surgery require assessments for pain. Although pain management is institution specific, acetaminophen is often the medication of choice. Also, use alternative modes of pain management, such as distraction and relaxation techniques, and ensure a quiet environment.

Strengthening Family Coping

1. Begin discharge planning early, including specific techniques for care of the shunt and suggested methods for providing daily care.
   a. Turning, holding, and positioning.
   b. Skin care over the shunt.
   c. Exercises to strengthen muscles—incorporated with play.
   d. Feeding techniques and schedule.
   e. Pumping the shunt.
2. Accompany all instructions with reassurance necessary to prevent the parents from becoming anxious or fearful about assuming the care of the child.
3. Offer opportunities for care by parent during hospitalization so that parents may become familiar and capable of care delivery in the home setting through practice.
4. Help the parents to assist siblings to understand hydrocephalus and the child's special needs. Encourage parents to spend individual time with siblings. Suggest family counseling and social work support, if needed.

5. Assist parents in locating additional resources.
    a. Social worker, discharge planner, or department of social services.
    b. Visiting or home health nurses or aides.
    c. Parent groups.
    d. Community agencies.
    e. Special programs at school.

Community and Home Care Considerations

1. Follow the community and home care considerations listed under "Cerebral Palsy" on page 1229. Check shunt functioning regularly, and reinforce parental performance of shunt checks and assessment for shunt malfunction and increased ICP.
2. Perform total physical assessment regularly, looking for signs of trauma or skin breakdown.
3. Patient should wear a medical alert bracelet when he or she starts to attend school or daycare.
4. Ensure parents or caregivers are certified in cardiopulmonary resuscitation (CPR).

Family Education and Health Maintenance

1. Stress the importance of recognizing symptoms of increased ICP and reporting them immediately.
2. Advise parents to report shunt malfunction or infection immediately to prevent increased ICP.
3. Teach parents that illnesses that cause vomiting and diarrhea or illnesses that prevent an adequate fluid intake are a great threat to the child who has had a shunt procedure. Advise parents to consult with the child's health care provider about immediate treatment of fever, control of vomiting and diarrhea, and replacement of fluids.
4. Tell the parents that few restrictions are required for children with shunts and to consult with the health care provider about specific concerns.
5. Alert parents that additional information and support are available from the Hydrocephalus Association (*www.hydroassoc.org*).

Evaluation: Expected Outcomes

- No changes in vital signs, LOC, or head size; no vomiting; pupils equal and responsive.
- Feeds every 4 hours without vomiting; no significant weight loss.
- No erythema, blanching, or skin breakdown; wound healing evident.
- Parents have an understanding of operative procedure, risks, and benefits.
- Shunt pumping without resistance; stable LOC and vital signs.
- Urine output equal to intake; skin turgor normal; electrolytes within normal limits.
- Afebrile; no drainage from shunt site.
- Parents actively seeking resources.

Spina Bifida

Spina bifida, also called *spinal dysraphia*, is a malformation of the spine in which the posterior portion of the laminae of the vertebrae fails to close. It occurs in approximately 1 per 1,000 live births in the United States and is the most common developmental defect of the central nervous system (CNS). It is more common in Caucasians than in other races. The incidence of spina bifida defects has been declining in the United States and United Kingdom because of antenatal screening and changes in environmental factors such as the consumption of folic acid in early pregnancy.

Several types of spina bifida are recognized, of which the following three are most common (see Figure 46-2, page 1234).

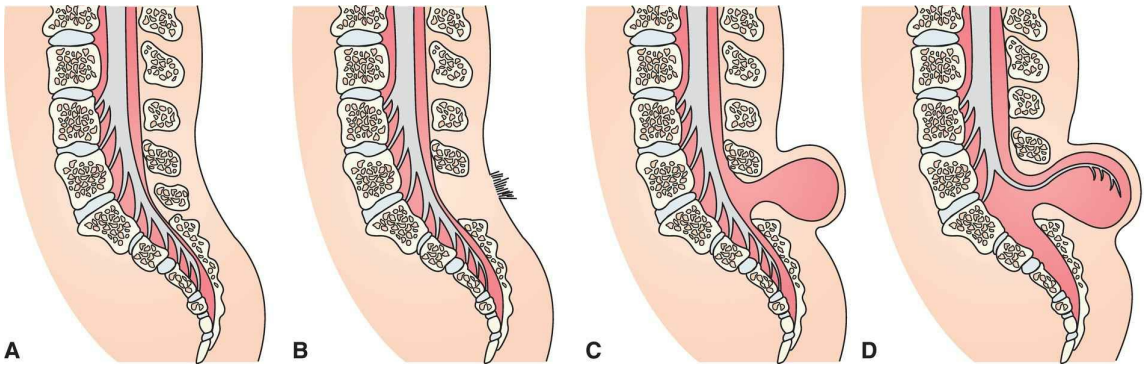

Figure 46-2. Spina bifida. **(A)** Normal spine. **(B)** Spina bifida occulta. **(C)** Spina bifida with meningocele. **(D)** Spina bifida with myelomeningocele. (From Pillitteri, A. [2013]. *Maternal and child health nursing: Care of the childbearing and childrearing family* [7th ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Spina Bifida Occulta

Spina bifida occulta is seen in 10% of the US population. It is a result of the posterior vertebral arches failing to fuse. A fat pad, dermal sinus, hairy tuft, or dimple in the lower back/lumbosacral region is often seen.

Meningocele

Meningocele is a herniation of the meninges through the defective posterior arches. The sac does not contain neural elements.

Myelomeningocele (or Meningomyelocele)

The spinal nerve roots and cord membranes protrude through the defect in the laminae of the vertebral column. Myelomeningoceles are covered by a thin membrane.

Pathophysiology and Etiology

1. Unknown etiology, but generally thought to result from genetic predisposition triggered by something in the environment.
    a. Certain drugs, including valproic acid, have been known to cause neural tube defects if administered

during pregnancy.

   b. Women who have spina bifida and parents who have one affected child have an increased risk of producing children with neural tube defects.

2. Involves an arrest in the orderly formation of the vertebral arches and spinal cord that occurs between the 4th and 6th weeks of embryogenesis.
3. Theories of causation include:
   a. Incomplete closure of the neural tube during the 4th week of embryonic life.
   b. The neural tube forms adequately and then ruptures.
4. In spina bifida occulta, the bony defect may range from a very thin slit separating one lamina from the spinous process to a complete absence of the spine and laminae.
   a. A thin, fibrous membrane sometimes covers the defect.
   b. The spinal cord and its meninges may be connected with a fistulous tract extending to and opening onto the surface of the skin.
5. In meningocele, the defect may occur anywhere on the cord. Higher defects (from the thorax and upward) are usually meningoceles.
   a. Surgical correction is necessary to prevent rupture of the sac and subsequent infection.
   b. Prognosis is good with surgical correction.
6. In myelomeningocele (meningomyelocele), the lesion contains both the spinal cord and cord membranes.
   a. A bluish area may be evident on the top because of exposed neural tissue.
   b. The sac may leak in utero or may rupture after birth, allowing free drainage of CSF. This renders the child highly susceptible to meningitis.
   c. Of all defects known as spina bifida cystica, 95% are myelomeningoceles and 5% are meningoceles.

DRUG ALERT Maternal periconceptional use of folic acid supplementation reduces by 50% or more the incidence of neural tube defects in pregnancies at risk.

Clinical Manifestations

Spina Bifida Occulta

1. Most patients have no symptoms.
   a. They may have a dimple in the skin or a growth of hair over the malformed vertebra.
   b. There is no externally visible sac.
2. With growth, the child may develop foot weakness or bowel and bladder sphincter disturbances.
3. This condition is occasionally associated with more significant developmental abnormalities of the spinal cord, including syringomyelia and tethered cord.

Meningocele

1. An external cystic defect can be seen in the spinal cord, usually in the midline.
    a. The sac is composed only of meninges and is filled with CSF.
    b. The cord and nerve roots are usually normal.
2. There is seldom evidence of weakness of the legs or lack of sphincter control.

Myelomeningocele

1. A round, raised, and poorly epithelialized area may be noted at any level of the spinal column. However, the highest incidence of the lesion occurs in the lumbosacral area.
2. Hydrocephalus occurs in approximately 90% of children with myelomeningocele because of associated Arnold-Chiari malformation, which causes a block in the flow of CSF through the ventricles.
3. Loss of motor control and sensation below the level of the lesion can occur. These conditions are highly variable and depend on the size of the lesion and its position on the cord.
    a. A low thoracic lesion may cause total flaccid paralysis below the waist.
    b. A small sacral lesion may cause only patchy spots of decreased sensation in the feet.
4. Contractures may occur in the ankles, knees, or hips. Hips may become dislocated.
    a. Nature and degree of involvement depend on size and location of the lesion.
    b. This occurs because some fibers of innervation get through. One side of a hip, knee, or ankle may be innervated, whereas the opposing side may not be. The unopposed side then becomes pulled out of position.
5. Clubfeet are a common accompanying anomaly; thought to be related to the position of paraplegic feet in the uterus.
6. Bladder dysfunction occurs because of how the sacral nerves that innervate the bladder are affected. The bladder fails to respond to normal messages that it is time to void and simply fills and overflows, causing incontinence and susceptibility to urinary tract infections (UTIs) because of incomplete emptying.
7. Fecal incontinence and constipation are caused by poor innervation of the anal sphincter and bowel musculature.
8. Most children have average intellectual ability despite hydrocephalus. Developmental disabilities include the following:
    a. Gross motor development—children will need assistance in gaining and maintaining mobility.
    b. Most children are able to learn in a "mainstream" school environment, provided they are able to overcome other barriers (architectural and attitudinal).

Diagnostic Evaluation

1. Prenatal detection is done through prenatal ultrasound and fetal MRI. This testing should be offered to all women at risk (women who are affected or who have had other affected children).
2. Diagnosis is primarily based on clinical manifestations.
3. CT scan and MRI may be performed to further evaluate the brain and spinal cord.

Management

Surgical Intervention

1. Procedure: laminectomy and closure of the open lesion or removal of the sac usually can be done soon after birth.
2. Purpose:
    a. To prevent further deterioration of neural function.
    b. To minimize the danger of rupture and infection, especially meningitis.
    c. To improve cosmetic effect.
    d. To facilitate handling of the infant.

Multidisciplinary Follow-Up for Associated Problems

1. A coordinated team approach will help maximize the physical and intellectual potential of each affected child.
2. The team may include a neurologist, neurosurgeon, orthopedic surgeon, urologist, primary care provider, social worker, physical therapist, occupational therapist, nurse practitioners, and a variety of community-based and hospital staff nurses, and the child and family.
3. Numerous neurosurgical, orthopedic, and urologic procedures may be necessary to help the child achieve maximum function.

Prognosis

1. Influenced by the site of the lesion and the presence and degree of associated hydrocephalus. Generally, the higher the defect, the greater the extent of neurologic deficit and the greater the likelihood of hydrocephalus.
2. In the absence of treatment, most infants with meningomyelocele die early in infancy.
3. Surgical intervention is most effective if it is done early in the neonatal period, preferably within the first few days of life.
4. Even with surgical intervention, infants can be expected to manifest associated neurosurgical, orthopedic, or urologic problems.
5. New techniques of treatment, intensive research, and improved services have increased life expectancy and have greatly enhanced the quality of life for most children who receive treatment.

Complications

1. Hydrocephalus associated with meningocele; may be aggravated by surgical repair.
2. Scoliosis, contractures, and joint dislocation.
3. Skin breakdown in sensory denervated areas and under braces.

Nursing Assessment

1. Assess sensory and motor response of lower extremities.

2. Assess ability to void spontaneously, retention of urine, and symptoms of UTI.
3. Assess usual stooling patterns and need for medications to facilitate elimination.
4. Assess mobility and use of orthoses, casts, and other special equipment.

Nursing Diagnoses

Neonates (Preoperative)

- Risk for Impaired Skin Integrity related to impaired motor and sensory function.
- Risk for Infection related to contamination of the myelomeningocele site.
- Impaired Urinary Elimination related to neurologic deficits.
- Ineffective Tissue Perfusion: Cerebral related to potential hydrocephalus.
- Fear (parents) related to neonate with neurologic disorder and to surgery.

Infants and Children (Postoperative)

- Ineffective Thermoregulation following surgery.
- Impaired Urinary Elimination related to sacral denervation.
- Bowel Incontinence or Constipation related to impaired innervation of anal sphincter and bowel musculature.
- Disturbed Body Image related to the child's appearance, difficulties with locomotion, and lack of control over excretory functions.

Nursing Interventions

Protecting Skin Integrity

1. Avoid positioning on the infant's back to prevent pressure on the sac. Check position at least once every hour.
2. Do not place a diaper or other covering directly over the sac.
3. Observe the sac frequently for evidence of irritation or leakage of CSF.
4. Use prone positioning and prevent hip flexion to decrease tension on the sac.
5. Place a foam rubber pad covered with a soft cloth between the infant's legs to maintain the hips in abduction and to prevent or counteract subluxation. A diaper roll or small pillow may be used in place of the foam rubber pad.
6. Allow the infant's feet to hang freely over the pads or mattress edge to prevent aggravation of foot deformities.
7. Provide meticulous skin care to all areas of the body, especially ankles, knees, tip of the nose, cheeks, and chin.
8. Provide passive ROM exercises for muscles and joints that the infant does not use spontaneously. Avoid hip exercises because of common hip dislocation, unless otherwise recommended.
9. Use a foam or fleece pad to reduce pressure of the mattress against the infant's skin.

10. Avoid pressure on the infant's back during feeding by holding the infant with your elbow rotated to avoid touching the sac or feeding while infant is lying on side or prone on your lap. Encourage the parents to use these positions to provide infant stimulation and bonding.

Preventing Infection

1. Be aware that infection of the sac is most commonly caused by contamination by urine and feces.
2. Keep the infant's buttocks and genitalia scrupulously clean.
   a. Do not diaper the infant if the defect is in the lower portion of the spine.
   b. Use a small plastic drape taped between the defect and the anus to help prevent contamination.
3. Apply a sterile gauze pad or towel or a sterile, moistened dressing over the sac, as directed.
   a. When the sterile covering is used, it should be changed frequently to keep the area free from exudate and to maintain sterility.
   b. Care must be taken to prevent the covering from adhering to and damaging the sac.
4. Monitor and report immediately any signs of infection.
   a. Oozing of fluid or pus from the sac.
   b. Fever.
   c. Irritability or listlessness.
   d. Seizure.

Promoting Urinary Elimination

1. Use Crede method for emptying the bladder (unless contraindicated by vesicoureteral reflux) and teach parents the technique.
   a. Apply firm, gentle pressure to the abdomen, beginning in the umbilical area and progressing toward the symphysis pubis.
   b. Continue the procedure as long as urine can be manually expressed.
2. Ensure fluid intake to dilute the urine.
3. Administer prescribed prophylactic antibiotics.
4. Monitor and report concentrated or foul-smelling urine.

Maintaining Cerebral Tissue Perfusion

1. Monitor for signs of hydrocephalus and report immediately.
   a. Irritability.
   b. Feeding difficulty, vomiting, and decreased appetite.
   c. Temperature fluctuation.
   d. Decreased alertness.
   e. Tense fontanelle.
   f. Increased head circumference.

Reducing Fear

1. Encourage parents to express feelings of guilt, fear, lack of control, or helplessness.
2. Provide accurate information about spina bifida and what to expect postoperatively.
3. Include the parents in all of infant's care and encourage private bonding time.

Maintaining Thermoregulation and Preventing Complications

1. Frequently monitor temperature, pulse, respirations, color, and level of responsiveness postoperatively, based on the infant's stability.
2. Use an Isolette or infant warmer to prevent temperature fluctuation.
3. Prevent respiratory complications.
   a. Periodically reposition the infant to promote lung expansion.
   b. Watch for abdominal distention, which could interfere with breathing.
   c. Have oxygen available.
4. Maintain hydration and nutritional intake.
   a. Administer IV fluids, as ordered; keep accurate intake and output log.
   b. Administer gavage feedings, as ordered.
   c. Begin bottle-feeding when infant is responsive and tolerating feedings. Give small, frequent feedings slowly so air can be expelled naturally without bubbling.
5. Keep the surgical dressing clean and dry and observe for drainage. Avoid pressure to the area and diapers that cover the incision until healed.
6. Monitor for and teach parents to recognize signs of hydrocephalus. Report immediately.
7. Limit or prevent direct contact of the child to products routinely used that contain latex, because of risk of latex allergy and severe reaction. Latex products include BP cuffs, tourniquets, tape, indwelling catheters, gloves, and IV tubing injection ports. Develop protocols specifying modification of care for children at risk for latex allergy.

NURSING ALERT Be aware that children with spina bifida have a far greater risk of latex allergy than the general population. It is estimated that up to 20% of spina bifida patients have a latex allergy. Symptoms include hives, itching, wheezing, and anaphylaxis. Incidence increases with time and may be related to repeated exposure to products containing latex.

Achieving Continence

1. Teach parents that continence can usually be achieved with clean, intermittent self-catheterization.
   a. Children can generally be taught to catheterize themselves by age 6 or 7.
   b. Parents can catheterize younger children.
2. Teach the following procedure:

a. Gather equipment: catheter, water-soluble lubricant, soap and water, and urine collection container.
b. Wash hands.
c. Position patient.
d. Clean the area around the urethral meatus.
e. Lubricate the catheter tip.
f. Insert the catheter until urine starts to flow. Have urine collection container or diaper available.
g. Remove catheter when urine is drained from the bladder.
h. Clean any lubricant off the child.
i. Dispose of urine.
j. Wash hands.

3. Teach about the action of medications, such as imipramine and ephedrine, if prescribed, which are used to help children retain urine rather than dribbling. When used with self-catheterization, many children can stay dry for 3 to 4 hours at a time.
4. Teach the signs of UTI (concentrated, foul-smelling urine; irritability; pain or burning; and fever) and the proper administration of antibiotics either prophylactically or when prescribed for infection.
5. For children who cannot achieve urinary continence through intermittent catheterization, provide information about options, such as surgically implanted mechanical urinary sphincters and bladder pacemakers, indwelling catheters, external collecting devices, and urinary diversion (may be necessary in some cases).

Achieving Regular Bowel Elimination

1. Assist with bowel training program to compensate for decreased sacral sensation.
   a. Children are placed on a toileting schedule and are taught to push.
   b. Medications, such as stool softeners, suppositories, or enemas, may be used initially to help determine scheduling.
2. To prevent constipation and enhance bowel control, encourage intake of high-fiber, high-fluid diet. Such medications as psyllium may be used to increase bulk or soften stool.

Fostering Positive Body Image

1. Emphasize rehabilitation that makes use of the child's strengths and minimizes disabilities.
2. Continually reassess functional abilities and offer suggestions to increase independence. Periodically consult with physical or occupational therapists to help maximize function.
3. Encourage the use of braces and specialized equipment to enhance ambulation while minimizing the appearance of the equipment. For example, wear pants instead of dresses or shorts to cover leg braces; choose a compact wheelchair that can be decorated or personalized for the child.
4. Encourage participation with peer group and in activities that build on strengths, such as cognitive abilities and interest in music or art.
5. Periodically reassess bowel and bladder programs. The ability to stay dry for reasonable time intervals is

one of the greatest factors in enhancing self-esteem and positive body image.

Community and Home Care Considerations

1. Follow the community and home care considerations listed under "Cerebral Palsy" on page 1229.
2. Survey the home environment for latex and substitute products obtained, if possible. Toys and equipment for children, such as nipples, pacifiers, and elastic on the legs of disposable diapers, also contain latex. Teach the parents how to recognize latex allergy and to notify the child's health care provider.
3. Teach the family how to clean and reuse urinary catheters. The catheter should be washed in warm, soapy water and rinsed well in warm water. The catheter should be air-dried and, when completely dried, placed in a clean jar or plastic bag. A catheter should be replaced when it becomes dry, cracked, and stiff or if the child develops a UTI.
4. Instruct the parents to notify the health care provider for signs of associated problems, such as hydrocephalus, meningitis, UTI, and latex sensitivity.

NURSING ALERT Ensure there is an emergency epinephrine injection available in case of inadvertent latex exposure.

Family Education and Health Maintenance

1. Prepare the parents to feed, hold, and stimulate their infant as naturally as possible.
2. Teach the parents the special techniques that may be required for holding and positioning, feeding, caring for the incision, emptying the bladder, and exercising muscles.
3. Alert the parents to safety needs of the child with decreased sensation, such as protection from prolonged pressure, the risk of burns because of bathwater that is too warm, and avoidance of trauma from contact with sharp objects.
4. Urge continued follow-up and health maintenance, including immunizations and evaluation of growth and development.
5. Advise parents that children with paralysis are at risk for becoming overweight because of inactivity, so they should provide a low-fat, balanced diet; control snacking; and encourage as much activity as possible.
6. For additional resources, refer families to agencies such as the Spina Bifida Association of America *www.spinabifidaassociation.org*.

Evaluation: Expected Outcomes

- No signs of meningeal sac or skin breakdown.
- Afebrile, alert, and active.

- Clear urine without odor; adequate elimination; no infection.
- Fontanelle soft; head circumference stable.
- Parents asking questions about surgery, showing affection for infant.
- Vital signs stable; incisional dressing dry and intact.
- Parents or child demonstrates proper catheterization technique.
- Passes stool once per day; adequate elimination; no constipation.
- Verbalizes participation in school and other social activities.

Muscular Dystrophy

Muscular dystrophy (MD) refers to a group of genetically determined, progressive, degenerative myopathies affecting a variety of muscle groups—most patients are children. The most common pediatric muscular dystrophies include Duchenne MD (DMD) and Becker MD (BMD). A 2015 US report estimated the prevalence of DMD and BMD at approximately 2 per 10,000. Most with Duchenne MD rarely survive beyond ages 20 to 25.

Pathophysiology and Etiology

1. Inherited; may be X-linked, autosomal dominant, or recessive.
2. Genetic coding defect causes abnormal muscle development and function—mutations of the dystrophin gene in DMD and BMD are termed dystrophinopathies.
3. Degeneration and loss of skeletal muscle fibers, but no associated structural abnormalities in peripheral nerves or spinal cord.
4. Marked reduction of dystrophin, a protein vital to muscle function. The amount of dystrophin levels varies with the type of MD.

Clinical Manifestations

1. Progressive muscular weakness, calf enlargement, and leg pain (see Table 46-1).
2. Gower sign is a hallmark feature of Duchenne MD, characterized by a child's difficulty rising from the floor. The child must take the following steps to assume a standing position:
   a. Roll onto hands and knees.
   b. Bear weight with legs by creating a wide base of support, while using hands on the floor to support some weight.
   c. Use arms to climb up legs.
   d. Push torso to an upright stance with legs remaining wide apart.
3. Heart muscle weakens and tachycardia develops.
4. Respiratory muscles weaken, causing ineffective cough and frequent infections.
5. May have mild cognitive impairment in Duchenne MD.

Table 46-1 Clinical Manifestations of Muscular Dystrophies

TYPE	ONSET	CLINICAL MANIFESTATIONS	OTHER INFORMATION
Duchenne	Age 2 to 6 years	Muscle atrophy and weakness over time affecting the pelvis, thighs, upper arms, and eventually all voluntary muscles; waddling gait, need for wheelchair by age 12; pulmonary and cardiac abnormalities; survival beyond age 20 is rare	Affects only males Most common type of MD in children
Becker	Age 2 to 16 years	Similar to Duchenne, but less severe, very mild in some cases; slower progression. Survival into middle age	Affects only males
Limb–girdle	Late teen to adult	Progressive weakness of the pelvic and shoulder girdles and then arms and legs. Walking becomes difficult over a 20-year period. Survival may be to late adulthood	Affects males and females Most common type overall
Facioscapulohumeral	Teen to early adult	Weakness of fascial muscles, wasting of shoulders and upper arms; slow progression with short periods of rapid deterioration. Causes problems with chewing, swallowing, speaking; characteristic "Popeye" arms and scapular winging. Survival well into adulthood	Affects males and females Severity varies widely
Congenital	At birth	General muscle weakness; possible joint deformities because of contractures; slow progression. Seizures and other brain abnormalities with Fukuyama type. Shortened life span	Affects males and females Several types have been identified
Emery-Dreifuss	Childhood to early teen	Slowly progressive weakness and atrophy of the shoulder, upper arm, and lower leg muscles; joint deformities; possible cardiac problems causing sudden death. Cardiac problems may affect carriers (including women)	Affects males only Rare form

Diagnostic Evaluation

1. Nerve conduction test and electromyography show abnormalities.
2. Serum creatinine kinase—elevated.
3. Deoxyribonucleic acid (DNA) analysis of blood.
4. Muscle biopsy may provide definitive diagnosis.
5. Electrocardiogram and echocardiogram to determine degree of cardiomyopathy.

Management

1. Goals of treatment are directed toward maintaining mobility, quality of life, and prevention of complications.
2. Medications to control symptoms, such as antiarrhythmics and bronchodilators.
3. Promotion of ambulation with appropriate aid after loss of ability to walk.
4. Provision of spinal orthotic supports.
5. Surgical tendon releasing to treat contractures.
6. Physical therapy, such as passive stretching, to preserve function.
7. Vigorous respiratory therapy, such as chest percussion, inspirometry, and assisted cough.
8. Pulmonary function monitoring.
9. Carrier detection and genetic counseling to explain implications of MD to parents and detect sibling carriers.
10. Glucocorticoids for DMD patients 4 years of age and older to delay the progression of muscle weakness.
11. May require early surgical intervention to correct scoliosis.

12. Nutritional management to prevent obesity is necessary as this may affect quality of life, life expectancy, and burden of care.
13. Frequent surveillance of cardiac function.

Complications

1. Infections (pulmonary, urinary, systemic).
2. Cardiac dysrhythmias.
3. Respiratory insufficiency and failure secondary to weakness of the diaphragm and chest muscles.
4. Aspiration pneumonia because of oropharyngeal dysfunction.
5. Depression.
6. Orthopedic deformities—contractures, lordosis, and scoliosis.
7. Learning and behavioral disorders.
8. Malignant hyperthermia—may develop in small number of children with mild or nonapparent muscle disease.
9. Osteopenia related to immobility.

Nursing Assessment

1. Assess muscle strength, atrophy, gait, age-related motor development, and progressive loss of function.
2. Evaluate respiratory and cardiac status—breath sounds, heart sounds, pulse rate and rhythm, BP, and peripheral perfusion.
3. Evaluate ADLs.
4. Assess degree of pain.
5. Identify psychosocial issues, such as altered self-concept, decreased socialization, and family discord.

Nursing Diagnoses

- Ineffective Breathing Pattern related to muscle weakness.
- Impaired Physical Mobility related to disease process.
- Acute pain related to neurologic effects from the disease process.
- Decreased Cardiac Output related to cardiac muscle involvement.
- Impaired Swallowing related to muscle weakness.
- Deficient Diversional Activity related to weakness.

Nursing Interventions

Maintaining Breathing Pattern

1. Encourage upright positioning to provide for maximum chest excursion.
2. Encourage energy conservation techniques and avoidance of exertion.
3. Teach deep breathing exercises to strengthen respiratory muscles.

4. Assess rate, depth, and pattern of respirations; listen to breath sounds; and report any change in condition.
5. Note results of arterial blood gas levels, sputum cultures, and chest x-rays.
6. Encourage coughing and deep breathing or perform chest physiotherapy, as indicated.

Preserving Optimal Motor Function

1. Refer to physical therapy for stretching and strengthening exercises to optimize remaining motor function.
2. Perform ROM exercises to preserve mobility and prevent atrophy.
3. Schedule activity with consideration to energy highs throughout the day.
4. Consult with occupational therapist for assistive devices to maintain independence.
5. Apply braces and splints to prevent contractures.
6. Ensure adequate pain management.

Improving Cardiac Output

1. Monitor vital signs, cardiac rhythm, and signs of heart failure, such as edema, adventitious breath sounds, and weight gain.
2. Monitor intake and output and maintain IV or oral fluid intake, as ordered.

Monitoring Swallowing Function

1. Assess cranial nerve function for swallowing (gag reflex) and chewing.
2. Provide a diet that the patient can handle; a pureed diet may be necessary.
3. Diet should be high protein and controlled calories to provide optimal nutritional value.
4. Encourage eating in upright position without talking and encourage consumption of smaller, frequent meals.
5. Administer alternative enteral feeding if gag reflex is diminished.

Encouraging Diversional Activities

1. Encourage diversional activities that prevent overexertion and frustration, but discourage long periods of bed rest and inactivity such as TV watching.
2. If upper extremities are mostly affected, suggest walking or riding a stationary bike; if lower extremities are mostly affected, encourage use of a wheelchair to promote mobility and performing simple crafts.
3. Discuss patient's interests and assist with preferred activities.
4. Investigate with the patient various methods of stress management to deal with frustration.
5. Administer analgesics and antidepressants, as ordered, to facilitate participation in activities.

Community and Home Care Considerations

1. Follow the community and home care considerations listed under "Cerebral Palsy" on page 1229.
2. Obtain services and devices that will promote maximal functioning, such as wheelchair ramp, wheelchair

van for transportation, and assistive devices.

3. Explore physical and recreational activities with family such as Special Olympics.
4. Assess child's educational progress and ability to attend school versus home schooling.
5. Collaborate with patient and family to establish daily plan of activities that incorporates patient's interests, ability, and need for rest periods.

Family Education and Health Maintenance

1. Offer genetic counseling, if indicated, to determine options of family planning.
2. Instruct the patient and family in ROM exercises, pulmonary care, and methods of transfer and locomotion.
3. Refer to community respite and counseling services.
4. Stress the importance of fluids to decrease risk of urinary/pulmonary infection and minimize constipation.
5. Advise patient or family to report signs of respiratory infection immediately to obtain treatment and prevent heart failure.
6. Refer patient and family to agencies such as the Muscular Dystrophy Association (*www.mdausa.org*).

Evaluation: Expected Outcomes

- Deep, unlabored respirations with clear breath sounds.
- Ambulates unassisted; no contractures noted.
- Vital signs stable; no edema.
- Tolerates small pureed feeds without aspiration.
- Out of bed most of day; engages in diversional and social activities.

Bacterial Meningitis

Bacterial meningitis is an inflammation of the meninges that follows the invasion of the spinal fluid by a bacterial agent. Inflammation occurs in the leptomeninges and tissues surrounding the brain and spinal cord. Since the introduction of the *Haemophilus influenzae* type B (1990) and pneumococcal conjugate (2000) vaccines to the pediatric immunization schedule, the incidence of bacterial meningitis has decreased in all age groups except in children under 2 months old. In 2006 to 2007, the US population–based surveillance found the peak incidence occurred under age 2 months (80.69 per 100,000) with the 2- to 23-month age group significantly less (6.91 per 100,000), dropping even further in the 2- to 10-year age group (0.56 per 100,000).

Pathophysiology and Etiology

1. The proportion of cases because of a specific organism varies from year to year; there is also considerable geographic difference. The organisms most commonly causing bacterial meningitis in different age groups include:
   a. ≥1 month and <3 months: *Escherichia coli*, *Streptococcus* group B, *Listeria monocytogenes*, *Pseudomonas aeruginosa*, *Staphylococcus* species, *Streptococcus pneumoniae*, *Neisseria meningitidis*, and gram-negative bacilli.
   b. ≥3 months to <3 years: *Streptococcus pneumoniae*, *Neisseria meningitidis* (meningococcal meningitis), and group B *Streptococcus*.
   c. ≥3 years to <10 years: *S. pneumoniae and N. meningitidis.*
   d. ≥10 years and <19 years: *N. Meningitidis*.
2. Bacterial meningitis is frequently preceded by an upper respiratory infection, which is complicated by bacteremia. Bacteria in the circulating blood then invade the CSF.
   a. Less commonly, bacterial meningitis may occur as an extension of a local bacterial infection, such as otitis media, mastoiditis, or sinusitis.
   b. Bacteria may also gain direct entry through a penetrating wound, spinal tap, surgery, or anatomic abnormality.
3. The infective process results in inflammation, exudation, and varying degrees of tissue damage in the brain.

Clinical Manifestations

1. Signs and symptoms are variable, depending on the patient's age, the etiologic agent, and the duration of the illness when diagnosed. Onset may be insidious or fulminant.
2. Infants younger than age 2 months usually display irritability, lethargy, vomiting, lack of appetite, temperature instability (fever or hypothermia), respiratory distress, poor tone, tremors, seizures, high-pitched cry, and full (possibly bulging) fontanelle.
3. Infants up to age 2 manifest symptoms similar to those of the young infant and may have a rash, altered sleep patterns, fever, tenseness of the fontanelle, nuchal rigidity, and positive Kernig or Brudzinski signs (see page 380).

4. Children older than age 2 initially have vomiting, headache, fever, mental confusion, lethargy, irritability, and photophobia. Later symptoms include nuchal rigidity within 12 to 24 hours after onset, positive Kernig or Brudzinski sign, seizures, and progressive decline in responsiveness.
5. Petechiae or purpura may develop.
    a. Characteristic skin lesions are most commonly observed in cases of meningococcal or *Pseudomonas* infection.
    b. Hemorrhagic rashes may occur in any child with overwhelming bacterial sepsis because of disseminated intravascular coagulation (DIC).
6. Septic arthritis suggests either meningococcal or *H. influenzae* infection.

Diagnostic Evaluation

1. Diagnosis is usually established through lumbar puncture and examination of CSF.
    a. Cloudy or turbid appearance.
    b. Elevated CSF pressure.
    c. High cell count with mostly polymorphonuclear cells.
    d. Low glucose level.
    e. Elevated protein level (also may be normal).
    f. Positive Gram stain and cultures (identifies the causative organism).
2. Additional laboratory studies include:
    a. Complete blood count (CBC)—total white blood cell count usually increased, with a preponderance of young neutrophils in the differential blood count (known as "shift to the left").
    b. Blood, urine, and nasopharyngeal cultures to look for source of infection.
    c. Platelet count, serum electrolytes, glucose, blood urea nitrogen and creatinine, and urinalysis usually done to monitor critically ill patient as well as clotting function if petechiae or purpuric lesions are noted.

Management

1. IV administration of the appropriate antimicrobial agents to promote rapid destruction of the bacteria and to suppress the emergence of resistant strains. The first dose of antibiotics should be administered as soon as possible (cultures should be taken before an antibiotic is given).
2. Recognition and treatment of hyponatremia caused by syndrome of inappropriate antidiuretic hormone (SIADH).
3. Supportive management of the comatose child or the child with seizures including neuroprotective measures.
4. Appropriate prophylactic treatment provided for contacts when indicated.

Complications

1. Acute—seizures, cerebral edema and increased ICP, shock, ischemia, infected subdural effusion,

disseminated illness (septic arthritis, pericarditis), and SIADH.

2. Long term—sensorineural hearing loss, hydrocephalus, blindness, learning disabilities, or developmental delays.
3. Disseminated intravascular coagulation (DIC).

Nursing Assessment

1. Obtain a history from the parents about recent upper respiratory or other infection.
2. Assess LOC and neurologic status.
   a. Evaluate for *Kernig sign*—with the child in the supine position and knees flexed, flex the leg at the hip so the thigh is brought to a position perpendicular to the trunk. Attempt to extend the knee. If meningeal irritation is present, this cannot be done, and attempts to extend the knee result in pain.
   b. Evaluate for *Brudzinski sign*—flex the patient's neck. Spontaneous flexion of the lower extremities indicates meningeal irritation.
3. Monitor breathing pattern and circulatory status.

Nursing Diagnoses

- Ineffective Tissue Perfusion: Cerebral related to endotoxin release into the CSF.
- Hyperthermia related to infectious process.
- Acute Pain related to neurologic effects from the disease process.
- Anxiety related to infection transmission precautions.
- Ineffective Tissue Perfusion: Cerebral related to complications of infectious process.
- Anxiety of parents related to severity of illness and hospitalization.

Nursing Interventions

See Standards of Care Guidelines 46-1, page 1241.

Standards of Care Guidelines 46-1

Caring for a Child with Neurologic Dysfunction

- Monitor vital signs, level of consciousness, pupillary reaction, and behavior, as indicated, and observe for signs of increased intracranial pressure; report significant changes immediately.
- Make sure that the patient receives all seizure medications and antibiotics, as directed, and that any deviation from dosage schedule or change in therapeutic serum drug levels is reported immediately.
- Assess for adequate elimination: ability for the child to urinate, or caregiver or child to do catheterization. Report deviation from normal pattern and take measures to prevent constipation and stool impaction.
- Assess for signs of secondary infection: postoperative incision infection; shunt malfunction and infection; pneumonia; skin breakdown. Report abnormality in timely fashion.
- Monitor for seizures and maintain safety. Document and report all seizures, including type, time of onset, duration, and behavior afterward. Administer medications, as needed, and as directed.

- Make sure that any assistive devices fit adequately to avoid tissue breakdown. Check more frequently if child is restless.
- Observe and assist with ambulation for safety.
- Train all caregivers in standards of home safety, including cardiopulmonary resuscitation, seizure control, and accident prevention.
- Make sure that the patient and family are aware of all community resources, including respite and support groups, educational assistance, and social services.
- Teach caregivers to do range of motion exercises to prevent contractures. Utilize physical and occupational therapy, as needed.
- Encourage regular health maintenance visits to monitor growth, development, and general health.

This information should serve as a general guideline only. Each patient situation presents a unique set of clinical factors and requires nursing judgment to guide care, which may include additional or alternative measures and approaches.

Maintaining Cerebral Tissue Perfusion

1. Administer antimicrobial agents at specified time intervals to obtain optimal serum levels. Obtain blood studies for peak and trough levels, as ordered.
2. Maintain patent IV line for medication administration; observe for signs of infiltration and phlebitis.
3. Monitor closely for signs of complications affecting cerebral perfusion.
    a. Monitor vital signs, LOC, and neurologic status at frequent intervals.
    b. Monitor intake and output, weight, and head circumference daily to assess for hydrocephalus.
    c. Be especially alert for lethargy or subtle changes in condition, which may indicate cerebral edema.
    d. Accurately chart child's behavior and clinical signs.

Reducing Fever

1. Administer antipyretics, tepid sponge baths, and hypothermia blanket, as ordered, to reduce fever. Fever increases metabolic rate and energy requirements by the brain; this may lead to hypoxemia and brain damage in the child with cerebral vascular compromise.
2. Monitor for seizures and use seizure precautions in the febrile child.
    a. There is an increased potential for seizures in the febrile child.
    b. Ensure safety by using padded bed or crib rails and having airway and suction equipment on hand.

Relieving Pain and Irritability

1. Reduce the general noise level around the child and prevent sudden loud noises.
2. Organize nursing care to provide for periods of uninterrupted rest.
3. Keep general handling of the child at a minimum. When necessary, approach the child slowly and gently.
4. Maintain subdued lighting as much as possible.
5. Speak in a low, well-modulated tone of voice.

6. Medicate for pain, as ordered, avoiding opioids that cause CNS and respiratory depression.

Preventing Transmission of Infection without Anxiety

1. Use infection control precautions at all times to prevent transmission of infection.
2. Practice careful hand-washing technique.
3. Explain the use of all protective equipment and procedures to child and family to allay anxiety.
4. Make sure that personnel with colds or other infections avoid contact with infants with meningitis and wear a mask when it is necessary to enter the nursery.
5. Teach parents and other visitors proper hand-washing and gown techniques.
6. Maintain sterile technique for procedures, when indicated.
7. Identify close contacts of the child with meningitis caused by *H. influenzae* or *N. meningitidis* who might benefit from prophylactic treatment.

Avoiding Complications

1. Monitor for and report any of the following:
    a. Decreased respirations, decreased pulse rate, increased systolic BP, pupillary changes, or decreased responsiveness, which may indicate increased ICP.
    b. Decreased urine volume and increased body weight, which may indicate SIADH.
    c. Sudden appearance of a skin rash and bleeding from other sites, which may indicate DIC.
    d. Persistent or recurring fever, bulging fontanelle, signs of increased ICP, focal neurologic signs, seizures, or increased head circumference, which may indicate subdural effusion.
    e. Hearing disturbances and apparent deafness, indicating cranial nerve involvement.
2. Observe for episodes of apnea and initiate measures to stimulate respiration.
    a. Institute respiratory monitoring.
    b. Stimulate the infant when apnea does occur.
        i. Pinch feet and provide more vigorous stimulation, if necessary.
        ii. When spontaneous respiration does not occur within 15 to 20 seconds, provide bag or mask ventilation.
    c. Report any periods of apnea.
    d. Record length of apneic episode and response to stimulation.

Allaying Parental Anxiety

1. Encourage the parents to engage in quiet activities with their child, such as reading or listening to soft music.
2. Provide the parents with an opportunity to express their concerns and answer questions they may have regarding the child's progress and care.
3. Engage the parents in the supportive care of the child so they may feel some control over the situation.

Family Education and Health Maintenance

1. Provide parents with appropriate information if they and other family members are to receive antibiotic prophylaxis.
2. Discuss symptoms for which the parents should watch as signs of possible latent complications, especially hydrocephalus.
3. Give specific instructions about medications to be administered at home.
4. Encourage regular health maintenance visits to chart growth and development and assess for any delays.
5. Parents can obtain more information about meningitis at *http://kidshealth.org/en/parents/meningitis.html*.

Evaluation: Expected Outcomes

- Alert without signs of increased ICP.
- Fever below 101°F (38.3°C); no subsequent infection.
- Resting comfortably; verbalizing reduced pain.
- Child expresses understanding of infection precautions.
- Vital signs stable; breathing pattern regular without apnea.
- Parents participate in child's care and ask questions.

Seizures and Epilepsy

Neonates, infants, and children with epilepsy differ from adults in many ways because of their immature brains: variances are noted in the etiology of seizures, clinical manifestations, responses to antiepileptic medications, and electroencephalogram (EEG) patterns. Although the immature brain is more prone to seizures, as the child grows and develops, some seizures may change and even disappear. In a nationally representative sample of US children, the estimated lifetime prevalence of epilepsy/seizure disorder was 10.2/1,000 (1%) and of current reported epilepsy/seizure disorder was 6.3/1,000. It is estimated that 1% of US children and teens will have at least one afebrile seizure by age 14 years.

Obtaining a thorough history and physical examination is crucial because the diagnosis of epilepsy is primarily based on clinical features.

The terms seizures and epilepsy are often used interchangably. A seizure is a physical minifestation of abnormal, excessive, synchronous neuronal discharges generated primarily from the cerebral cortex. The discharges are intermittent in nature and often self-limited and may last for several seconds to minutes.
Epilepsy is diagnosed when any one of the following exists:

- At least two unprovoked (or reflex) seizures that occur more than 24 hours apart.
- One unprovoked (or reflex) seizure with the likelihood of further seizures with a similar recurrence risk after two unprovoked seizures, occurring over the next 10 years (eg, in cases of remote structural lesions related to CNS infection, stroke, or certain types of traumatic brain injury).

Classification of Epilepsy Syndrome

1. A recent update to the International League Against Epilepsy (ILAE) Classification of the Epilepsies was published in March 2017 along with the revised ILAE 2017 Classification of Seizure Types.
2. This new classification of the epilepsies has three levels of diagnosis: seizure type, epilepsy type, and epilepsy syndrome.
3. The ILAE is aware neonatal seizures may have motor manifestations, and minimal or no behavioral manifestations. A Neonatal Seizure Task Force is currently developing a separate classification of neonatal seizures.

Seizure Type

1. The first step is to rule out another type of paroxysmal event and provide a definitive diagnosis of an epileptic seizure type based on the initial manifestation of the seizure.
2. There are three seizure types:
    a. Focal.
    b. Generalized.
    c. Unknown.

Epilepsy Based on Seizure Type

1. The second level of diagnosis for patients with epilepsy includes four categoires, two are new categories.

a. Focal.
b. Generalized.
c. Combined generalized and focal.
d. Unknown.

Epilepsy Syndromes

1. An epilepsy syndrome refers to a group of findings that occur together and define a clinically recognizable seizure disorder.
2. This cluster of findings includes certain seizure types, imaging and EEG features along with particular ages of onset, triggers, comorbidities, and prognoses, which may have specific treatment recommendations.
3. A new ILAE educational website EpilepsyDiagnosis.org provides diagnostic guidelines, videos of seizure types, and more relevant information on epilepsy syndromes.
4. Epilepsy syndromes recognized in the neonatal period include:
   a. Benign neonatal seizures.
   b. Benign familial neonatal epilepsy.
   c. Early myoclonic encephalopathy.
   d. Ohtahara syndrome.
5. Epilepsy syndromes of infancy (onset under 2 years) include:
   a. West syndrome.
   b. Dravet syndrome.
   c. Epilepsy of infancy with migrating focal seizures.
   d. Benign infantile epilepsy.
   e. Benign familial infantile epilepsy.
   f. Febrile seizures plus.
6. Epilepsy syndromes of childhood include:
   a. Lennox-Gastaut syndrome.
   b. Landau-Kleffner syndrome.
   c. Epileptic encephalopathy with continuous spike and wave during sleep (CSWS).
   d. Febrile seizures plus (may start in infancy).
   e. Childhood absence epilepsy.
   f. Epilepsy with myoclonic absences.
   g. Late-onset childhood occipital epilepsy (Gastaut type).
   h. Panayiotopoulos syndrome (early childhood onset occipital epilepsy).
   i. Epilepsy with myoclonic atonic (previously astatic) seizures.
   j. Benign epilepsy with centrotemporal spikes.
7. Epilepsy syndromes of adolescence to adulthood include:

a. Juvenile absence epilepsy (JAE).
b. Juvenile myoclonic epilepsy (JME).

Infantile Spasms

1. These seizures occur in infants; they are second in incidence only to generalized seizures in this age group.
2. Children with infantile spasms (IS) typically develop epileptic spasms with an associated EEG pattern known as hypsarrhythmia.
3. The triad of spasms, hypsarrhythmia, and developmental regression is known as West syndrome.
4. Peak incidence is in children between ages 3 and 7 months; onset after age 2 years is rare.
5. Clinical signs include the following:
   a. Sudden, forceful, myoclonic contractions involving the musculature of the trunk, neck, and extremities.
      i. Flexor type—infant adducts and flexes the extremities, drops the head, and doubles on him- or herself.
      ii. Extensor type—infant extends neck, spreads out arms, and bends body backward in a position described as "spread eagle."
      iii. Mixed—combination of the above two types, occurring in clusters or volleys of each.
   b. A cry or grunt may accompany severe attacks.
   c. The infant may grimace, laugh, or appear fearful during or after the attack.
6. Duration is momentary (usually <1 minute).
7. Frequency varies from a few attacks per day to hundreds per day.
8. Almost always associated with cerebral abnormalities. Mental retardation usually accompanies this disorder in 95% of cases.
9. Usually, this type of seizure disappears spontaneously by the time the child reaches age 4 years. Subsequent generalized or other types of seizures usually develop.

NURSING ALERT Occurrence of infantile spasms is a pediatric emergency. Delay in treatment could lead to permanent cognitive impairment and developmental delay.

Pathophysiology and Etiology

Etiologic Factors

1. *Structural etiology* refers to abnormalities seen on structural neuroimaging where the imaging along with the electroclinical findings indicates the abnormality is the probable cause of the seizures, such as hippocampal sclerosis. Structural abnormalities can be congenital such as tuberous sclerosis and cortical dysplasia or acquired by hypoxic–ischemic encephalopathy, infection, stroke, trauma, tumors,

neurosurgery, and genetic cortical malformations.

2. *Genetic etiology* refers to a pathogenic genetic variant (mutation) of significant effect that causes epilepsy. A large number of epilepsy gene mutations have been identified in both severe and mild epilepsies, many being de novo mutations. Examples of genetic etiologies in children include SCN1A mutations associated with Dravet syndrome and genetic/generalized epilepsy with febrile seizures plus (GEFS+) and mutations in the potassium channel genes KCNQ2 and KCNQ3 (benign familial neonatal epilepsy).
3. *Infectious etiology* refers to epilepsy resulting from a known infection including tuberculosis, cerebral malaria, HIV, neurocysticercosis, congenital infections (Zika virus, cytomegalovirus), cerebral toxoplasmosis, and subacute sclerosing panencephalitis (SSPE). Epilepsy, which develops after an acute infectious illness, may also fall in this category.
4. *Metabolic etiology* refers to epilepsy, which directly results from a presumed or known metabolic disorder, in which seizures are a main symptom. Often, metabolic disorders and epilepsies will be related to a genetic mutation, but some might be acquired. An example in children is pyridoxine deficiency.
5. *Immune etiology* refers to epilepsy, which directly results from a presumed or known immune disorder, in which seizures are a main symptom and where autoimmune-mediated central nervous system inflammation is noted. An example of this is anti-NMDA receptor encephalitis.
6. *Unknown etiology* refers to epilepsy in which the cause is not yet determined.

Altered Physiology

1. The basic mechanism for all seizures appears to be prolonged depolarization and other chemical changes, causing neurons to discharge in an uncontrolled manner.
2. This paroxysmal burst of electrical energy spreads to adjacent areas of the brain or may jump to distant areas of the CNS, resulting in a seizure.
3. Some seizures appear to occur under the influence of a triggering factor.
    a. Hormonal factors, such as those related to the menstrual period, menarche, and menopause.
    b. Nonsensory factors, such as hyperthermia; hyperventilation; metabolic disorders such as hypoglycemia, hyponatremia, and hypocalcemia; sleep deprivation; emotional disturbances; and physical stress.
    c. Sensory factors, such as those related to vision, hearing, touch, the startle reaction, and those that are self-induced.

Clinical Manifestation Based on the ILAE 2017 Classification of Seizure Types

Focal Onset Seizures

1. Focal onset seizures originate in networks limited to one hemisphere and include focal aware and focal impaired awareness seizures.
    a. Focal aware seizures were formerly known as simple partial seizures.
        i. No impairment of consciousness; retains awareness of self and environment even if immobile.
        ii. Caused by abnormal activation of a limited number of neurons that allow for localization of the

epileptic focus.

b. Focal impaired awareness seizures

   i. Includes all seizures with impaired consciousness during any portion of the event.

   ii. Formerly known as complex partial seizures.

2. Focal seizures are also subgrouped into those with motor or nonmotor signs and symptoms at the onset and can be further classified by the earliest prominent motor-onset or non–motor-onset characteristic:

   a Motor Onset seizures

      i. Automatisms—mouth movements (ie, chewing, lip smacking), hand movements (ie, picking at clothing, "pill rolling," grasping at objects), rubbing genitalia, eye blinking, head turning, and raising of arms.

      ii. Atonic—loss of tone (degree of awareness usually not specified).

      iii. Clonic—jerking of limbs, often asymmetric and irregular.

      iv. Epileptic spasms—spasms of muscles of the neck, trunk, and extremities (degree of awareness usually not specified).

      v. Hyperkinetic.

      vi. Myoclonic—brief synchronous jerks of one or more muscle groups.

      vii. Tonic—sustained muscle contraction with no clonic phase.

   a Nonmotor Onset

      i. Autonomic—changes in skin color, BP, heart rate, pupil size, piloerection, drooling, rising epigastric sensation, retching, and vomiting.

      ii. Behavioral arrest.

      iii. Emotional—fear, depression, anger, and irritability.

      iv. Sensory—tingling or numbness, simple visual phenomenon, hallucinations (visual, auditory, gustatory, olfactory), illusions of perception (size [macro- or micropsia], shape, weight, distance, sound), dysphasia, or aphasia.

3. Focal to Bilateral Tonic–Clonic Seizure:

   a. Formerly known as partial-onset seizure with secondary generalization.

   b. A special seizure type, which indicates a propagation pattern of a seizure.

Generalized Onset Seizures

1. Generalized onset seizures are characterized by global synchronized activation of neurons resulting in impaired consciousness, bilateral motor changes, and EEG abnormalities.

   a. Motor

      i. Tonic–clonic—consists of tonic phase (10 to 30 seconds), clonic phase (30 to 60 seconds), and postictal phase (2 to 30 minutes); postictal phase consists of confusion and fatigue.

      ii. Clonic—jerking that is often asymmetric and irregular; occurs more frequently in neonates, infants, and young children.

iii. Tonic—sustained muscle contractions with no clonic phase, can occur at any age, frequently seen in children with diffuse cerebral damage and Lennox-Gastaut syndrome.

iv. Myoclonic—brief involuntary muscle contractions of one or several muscle groups; may be triggered by action, noise, percussion, being startled, or photic stimulation; may occur alone or in clusters.

v. Myoclonic–tonic–clonic—combination of three seizure manifestations.

vi. Myoclonic–atonic—brief involuntary muscle contractions of one or several muscle groups and then sudden loss of tone.

vii. Atonic—sudden loss of tone.

viii. Epileptic spasms—involve spasms of muscles of the neck, trunk, and extremities.

b. Nonmotor (Absence)

i. Typical—abrupt onset of activity arrest, brief loss of consciousness, may have eye flickering, lasts 10 seconds, easily provoked by hyperventilation or photic stimulation, no postictal phase with resumption of normal activity, may occur in clusters.

ii. Atypical—frequently associated with symptomatic epilepsies and mixed seizure disorders, may have aura or automatisms; partial impairment of consciousness, may last several minutes; postictal headache, confusion, and emotional disturbances are common.

iii. Myoclonic—brief involuntary muscle contractions of one or several muscle groups; may be triggered by action, noise, percussion, being startled, or photic stimulation.

iv. Eyelid myoclonia.

Unknown Onset and Unclassified Seizures

1. Unknown onset seizures are those in which there is an absence of knowledge of the seizure's onset, but it can be provisionally classified based on key characteristics.
   a. Motor
      i. Tonic–clonic—consists of tonic phase (10 to 30 seconds), clonic phase (30 to 60 seconds), and postictal phase (2 to 30 minutes); postictal phase consists of confusion and fatigue.
      ii. Epileptic spasms—involve spasms of muscles of the neck, trunk, and extremities.
   b. Nonmotor
      i. Behavioral arrest—abrupt onset of activity arrest.
2. Unclassified—this category is for seizures for which there is a lack of or inadequate information or if the seizure cannot be placed in other categories because of its unusual presentation.

Status Epilepticus

1. A prolonged seizure or repeated seizures lasting longer than 30 minutes with no interictal recovery.
2. Most common pediatric neurologic emergency, possibly resulting in permanent neurologic sequelae.
3. May be overt seizure activity (convulsive) or subclinical (nonconvulsive).
4. Generalized tonic–clonic status epilepticus is life-threatening.

5. Causes include new acute illness, progressive neurologic disease, loss of seizure control in an epileptic, or a febrile seizure in a child who is otherwise in good health.
6. Recurrence occurs more often in children who have other neurologic abnormalities; recurrence is rare in children who experience febrile seizures.
7. Absence and complex partial status epilepticus are often difficult to identify, and children often appear to be in a mildly confused state.

Psychogenic Nonepileptic Seizures

1. Previously known as "hysterical" or "pseudoseizures" and are usually a method of seeking attention and secondary gain.
2. Occur most frequently in adolescents and more often in girls than boys (3:1).
3. History of sexual abuse is common in women with nonepileptic seizures.
4. May occur in people with true seizures that have come under control.
5. Difficult to distinguish by observation alone.
6. Most episodes of psychogenic nonepileptic seizures (PNES) occur in front of witnesses and tend not to occur during sleep.
7. Forced eye closure suggests PNES as eyes are usually open during the ictus of an epileptic seizure.
8. Often include three broad patterns:
    a. Unilateral or bilateral motor activity that may include tonic posturing or tremulousness—movements are thrashing or jerking, rather than tonic–clonic, and often different movements occur simultaneously.
    b. Behavioral or emotional changes—distress or discomfort, followed by semipurposeless—but not stereotyped—behaviors and may include walking or fumbling with objects.
    c. Periods of unresponsiveness with precipitation or cessation of the attack occurring after suggestion—no self-harm occurs, with no associated incontinence during these episodes.

Diagnostic Evaluation

Electroencephalogram

1. Used to confirm the clinical diagnosis, classify type of epilepsy, localize the area of epileptic focus, and determine when it is safe to discontinue treatment.
2. A normal EEG does not preclude the diagnosis of epilepsy. Indeed, about 10% to 20% of children who have epilepsy have a normal EEG.

Brain Imaging

1. CT scan and MRI—provide an anatomic picture of the brain; essential in ruling out the presence of a lesion. MRI is the gold standard in evaluation of epilepsy, although CT scan is used when MRI is not available.
2. Single-photon emission computed tomography (CT), positron emission tomography (PET), and

functional MRI (fMRI)—brain imaging techniques that measure local vascular or metabolic changes associated with neuronal activity; they can also map cortical function when resective surgery is being planned.

3. Magnetoencephalography (MEG)—noninvasive technology that helps map the sensory and language cortex when resective surgery is being planned.

Neuropsychological Evaluation

1. Used to evaluate the specific learning needs of children with epilepsy because many have learning difficulties.
2. Part of the presurgical workup is to determine cognitive deficits and predict long-term consequences of epilepsy, particularly when surgery is performed in an eloquent area.
3. WADA testing (named after its inventor, Juhn Wada) evaluates hemisphere dominance for language and memory when resective surgery is being planned.
   a. Involves the intracarotid administration of amobarbital to anesthetize each hemisphere of the brain separately.
   b. The patient is then shown objects to name and recall over a short period of time.
   c. Some facilities now use alternative anesthetic agents such as etomidate as amobarbital has not been readily available (ie, "eSAM"—etomidate speech and memory test).

Laboratory Studies

1. Serum electrolytes, magnesium, calcium, and fasting blood sugar to rule out metabolic causes.
2. Toxicology screen—drug overdoses may cause seizures.
3. Blood cultures—fever and CNS infections may cause seizures.
4. Lumbar puncture may be done if fever is present.
5. Serum levels of seizure medications should follow therapy.
6. Metabolic workup in infants or children with developmental delay.
7. Genetic testing to determine underlying epilepsy syndrome.

Management

Pharmacologic Management

1. Selection of the most effective drug depends on correct identification of the clinical seizure type (see Table 46-2).
2. A desirable drug level is one that will prevent seizures without producing undesirable adverse effects.
3. Dosages are adjusted according to blood level, clinical signs, and the child's weight.
4. Accurate timing is essential to prevent seizures. This is especially true when the child tends to have seizures at a certain time each day.
5. Enteric-coated tablets, which have a delayed effect, should be used for children who are prone to attacks during sleep.

6. Most anticonvulsants are available in liquid form and in capsules or tablets. Some drugs are less well absorbed in liquid form.
7. It may take several months to find the best combination of medications and the best dosages of each to control the child's seizures. Monotherapy is attempted initially. If this is not successful, a second drug may be tried or added on.
8. Symptoms may not be controlled 100% in every patient.
9. Dosage adjustments may be required from time to time because of the child's growth and clinical progress.
10. Blood counts, urinalysis, therapeutic drug levels, and liver function studies are done at regular intervals in children receiving certain anticonvulsants.
11. Medication is commonly not discontinued until 2 to 3 years after the last seizure and if the EEG is normal.
12. Weaning from medication should always be gradual, with stepwise reduction of dosage and withdrawal of one drug at a time.
13. There is some evidence to suggest that long-term use of some antiepileptic agents may cause intellectual impairment in children with epilepsy.
14. Monitor bone health and provide calcium supplementation if inadequate calcium intake.

Table 46-2 Drugs Used to Treat Seizures in Children

DRUGS AND DOSAGE	ADVANTAGES	ADVERSE EFFECTS	NURSING CONSIDERATIONS
Phenobarbital			
Maintenance dosage: 3 to 5 mg/kg given qid or bid *Status epilepticus:* 10 to 20 mg/kg, may repeat to maximum 40 mg/kg	Relatively safe and inexpensive	Excitement, hyperactivity, rash, GI distress, dizziness, ataxia, worsening of psychomotor seizures, drowsiness; toxicity causing respiratory depression, circulatory collapse, and renal impairment	• Contraindicated in hepatic or renal dysfunction, hypersensitivity • IM or IV loading dose can be given • IV rate should not exceed 1 mg/kg/min
Phenytoin			
Loading dose: 20 mg/kg *Maintenance:* 3 to 9 mg/kg given qid or bid	Safest drug for psychomotor seizures; does not cause drowsiness	Hypertrophy of gums, hirsutism, rickets, nystagmus, ataxia, rash; may accentuate absence seizures; toxicity may cause blood dyscrasias and liver damage	• May interact with a wide variety of drugs because of extensive protein binding • Daily gum massage may prevent gum disease • Avoid IM administration • If given IV, do not exceed rate of 0.5 mg/kg/min • Dilute with normal saline to prevent formation of precipitant
Ethosuximide			
Maintenance: 20 to 40 mg/kg given qid by oral route only	Used for absence seizures	Drowsiness, GI distress, lethargy, euphoria; may aggravate generalized seizures; toxicity causes blood dyscrasias and psychiatric symptoms	• This is contraindicated in hepatic or renal disease • Dosage should not be increased more frequently than every 4 to 7 days
Primidone			
Children younger than age 8 years: 10 to 25 mg/kg given tid *Children older than age 8 years:* 750 to 1,500 mg tid or qid by oral route only	May control generalized seizures not responsive to treatment by other drugs	Ataxia, vertigo, GI symptoms; megaloblastic anemia is a rare idiosyncratic reaction; drowsiness in breastfed infants of treated mothers; Stevens-Johnson syndrome, gum hypertrophy, night terrors	• Contraindicated in those hypersensitive to phenobarbital and those with porphyria • Commonly used with other drugs for mixed seizure • Dosage increases are usually done weekly until effect is seen
Diazepam			
IV dosage: 0.04 to 0.2 mg/kg to maximum of 10 mg if age 5 years or older; maximum of 5 mg if younger than age 5 years *Rectal dosage:* 0.5 mg/kg	Given IV, IM, or rectally for status epilepticus or as adjunct therapy	Ataxia, drowsiness, fatigue, venous thrombosis or phlebitis at injection site, confusion, depression, headache; tonic status epilepticus when given IV for absence seizures; toxicity may cause somnolence, confusion, diminished reflexes, hypotension, coma, apnea, cardiac arrest	• If administered IV, give no faster than 1 mg/min. Drug used cautiously in children with limited pulmonary reserve • Monitor respiratory status closely

Carbamazepine			
20 to 30 mg/kg tid or qid *Maximum dose:* 1,000 mg/day if older than age 12 years; 100 mg bid if ages 6 to 12 years; 20 mg/kg/day if younger than age 6 years	Especially useful for major motor and psychomotor seizures	Most likely to occur during initiation of therapy: dizziness, drowsiness, nausea, and vomiting; toxicity may cause bone marrow depression (fever, sore throat, oral ulcers, easy bruising)	• Administration with phenytoin reduces half-life of phenytoin; higher dose of phenytoin may be needed • Contraindicated in previous bone marrow depression and is used cautiously in patients with cardiac, hepatic, or renal problems • Erythromycin increases plasma levels • Give with food
Lorazepam			
0.05 to 0.1 mg/kg q 10 to 15 minutes *Maximum dose:* 4 mg	Given IV or rectally for status epilepticus; longer acting; may cause less respiratory depression	Sedation, dizziness, respiratory depression, hypotension, ataxia, weakness	• Use with caution in patients with hepatic or renal dysfunction • Monitor respiratory status closely
Valproic Acid			
Loading dose: 10 mg/kg/day *Maximum dose:* 30 to 60 mg/kg tid or qid	Adjunct for poor seizure control; some success with behavioral problems	Nausea, vomiting, anorexia, amenorrhea, sedation tremor, weight gain, alopecia, hepatotoxicity	• Use caution with hepatic dysfunction. Increases serum levels of phenytoin, phenobarbital, and primidone
Gabapentin			
Loading dose: 10 to 15 mg/kg/day in three divided doses *Maximum dose:* 25 to 40 mg/kg/day in three divided doses	Recommended for add-on therapy in children over age 3 with refractory partial seizures	May interfere with the action of other drugs, including cimetidine; nausea/dizziness	• Must exercise caution in patients with renal impairment
Topiramate			
Loading dose: 25 mg/day at bedtime for the first week *Maximum dose:* 200 to 400 mg/day in two divided doses	Recommended for patients aged 2 to 16 with partial-onset seizures and those seizures related to Lennox-Gastaut syndrome	Most commonly associated with fatigue, dizziness, sleepiness	• Must exercise caution in patients with renal impairment • Interacts with other anticonvulsants, altering drug concentrations; may interfere with effectiveness of hormonal contraceptives
Oxcarbazepine			
Loading dose: 8 to 10 mg/kg/day in two divided doses *Maximum dose:* children 2 to <4 years—60 mg/kg/day; children 4 to 16 years—900 to 1,800 mg/day based on weight	Adjunctive therapy in children aged 4 to 16 years for partial seizures	Fatigue, abnormal gait, sedation, difficulty in concentration, and memory impairment	• Need to monitor serum sodium • May interfere with other anticonvulsants by increasing serum concentration; decreases the effectiveness of hormonal contraceptives
Zonisamide			
Loading dose: 2 to 4 mg/kg/day *Maximum dose:* 12 mg/kg/day in two to three divided doses	Adjunctive therapy in children older than age 16; especially effective in refractive seizures, such as absence, Lennox-Gastaut syndrome, or infantile spasms	Drowsiness, ataxia, loss of appetite, GI upset, and slowing of mental activity, psychiatric symptoms (ie, depression, psychosis)	• Must exercise caution in patients with renal and/or hepatic impairment, and patients with sensitivity to sulfonamides • Pediatric patients may be at increased risk and may have more severe metabolic acidosis

Lacosamide			
Adolescents ≥17 years, monotherapy initial dose 100 mg bid, adjunctive therapy initial dose: 50 mg bid; maintenance dose: 200 to 400 mg/day *Children and adolescents under <17 years*: 1 to 2 mg/kg/day divided bid, may titrate to 1 mg/kg/day weekly to effect	Adjunctive therapy in the treatment of partial-onset seizures and severe refractory seizures in children <17 years	Dizziness, ataxia, light-headedness, excessive drowsiness, headaches, nausea, vomiting, tremors, change in vision or multiorgan sensitivity reactions Report signs of suicide ideation or depression	• Carbamazepine, fosphenytoin, phenobarbital, and phenytoin may decrease lacosamide serum concentration • May prolong PR interval (patients with conduction problems or severe cardiac disease should have ECG tracing prior to/during treatment)
Clobazam			
Lennox-Gastaut (adjunctive), US labeling: *Children ≥2 years:* refer to adult dosing Epilepsy (monotherapy or adjunctive), oral: *children <2 years, initial dose*: 0.5 to 1 mg/kg/day; *Children 2 to 16 years, initial dose*: 5 mg/day; *maximum*: 40 mg/day	Adjunctive treatment of seizures associated with Lennox-Gastaut syndrome (FDA-approved in ages ≥2 years and adults); has also been used as monotherapy and adjunctive treatment for other forms of epilepsy	Somnolence, fever, lethargy, upper respiratory tract infection, GI issues, muscle weakness, paradoxical reactions including hyperactive or aggressive behavior, anterograde amnesia, suicidal ideation **US Boxed Warning: Risks from concomitant use of benzodiazepines and opioids**	• May be administered with or without food • Tablets can be crushed and mixed in applesauce • Tolerance and loss of seizure control have been reported with chronic administration • Rebound or withdrawal symptoms may occur following abrupt discontinuation or large decreases in dose • Use caution, adjust dose in patients with hepatic impairment, respiratory disease, and pre-existing muscle weakness (Canadian labeling contraindicates use in myasthenia gravis)
Rufinamide, Oral			
Lennox-Gastaut syndrome: *Children ≥4 years, initial dose*: 10 mg/kg/day in two equally divided doses; *target dose*: 45 mg/kg/day; *maximum dose*: 3,200 mg/day)	Adjunctive therapy of seizures associated with Lennox-Gastaut syndrome (FDA-approved in ages ≥4 years and adults)	Cardiovascular: QT shortening (46% to 65%; may be dose-related), headache, somnolence, dizziness, fatigue, aggression, anxiety, ataxia/gait disturbance, vertigo, tremor, attention disturbance, back pain, hyperactivity, seizures, status epilepticus, suicidal thinking, pruritus, rash, frequent urination, anemia, leucopenia; visual, respiratory or GI disturbances	• Contraindicated in patients with familial short QT syndrome • Administer with food • Monitor for signs and symptoms of anxiety, depression, unusual mood or behavior changes, suicide ideation
Vigabatrin			
FDA approved in ages ≥ 10 years and adults: *Children, oral, initial dose*: 40 mg/kg/day in two divided doses, maintenance dosages based on patient weight Infantile spasms: *FDA approved in children 1 month to 2 years, initial dose*: 50 mg/kg/day in two divided doses; *maximum dose*: 150 mg/kg/day	Treatment of infantile spasms; adjunct therapy for refractory complex partial seizures in patients with inadequate response to several alternative treatments and for whom the potential benefits outweigh the potential risk of vision loss	Anemia, somnolence, headache, fatigue, irritability, sedation, nystagmus, tremor, insomnia, GI issues, weight gain, edema, peripheral neuropathy, neurotoxicity, suicidal ideation, vision loss, abnormal MRI changes have been reported in some infants **US Boxed Warning: Permanent Vision Loss** Only available in the United States under the Sabril REMS Program	• May be administered without regard to meals • Assess vision prior to initiating therapy or within 4 weeks from start, at least every 3 months during therapy and at 3 to 6 months after therapy has been discontinued • Assess for CNS depression, changes in behavior, and suicidal tendencies

Levetiracetam			
Partial-onset seizures: *Children 1 to <6 months, initial dose:* 7 mg/kg bid; *maximum dose:* 21 mg/kg bid *Children 6 months to <4 years, initial dose:* 10 mg/kg bid; *maximum dose:* 25 mg/kg bid *Children 4 to <16 years, initial dose:* 10 mg/kg/day bid; *maximum dose:* 30 mg/kg/day bid (*maximum daily dose:* 3,000 mg/day) Tonic–clonic seizures: *Children 6 to <16 years, initial dose:* 10 mg/kg bid; *recommended dose:* 30 mg/kg twice daily.	Adjunctive therapy in the treatment of partial-onset, myoclonic, and/or primary generalized tonic–clonic seizures	Behavioral/psychiatric symptoms, agitation, amnesia, anxiety, somnolence, fatigue, anorexia and other GI symptoms, ataxia and coordination problems, hypertension	• Be aware of neuropsychiatric adverse events as incidence of behavioral abnormalities and psychiatric symptoms may be increased in children • Use with caution and decrease dose in patients with renal dysfunction • May be administered without regard to meals
Stiripentol			
Children ≥3 years and adults, in conjunction with clobazam and valproic acid: increased over 3 days to a final dose of 50 mg/kg/day in 2 to 3 divided doses with food	Treatment of refractory generalized tonic–clonic seizures in conjunction with clobazam and valproic acid in patients with severe myoclonic epilepsy in infancy (Dravet syndrome) whose seizures are not adequately controlled with clobazam and valproic acid alone	Clobazam concentrations have increased 2- to 3-fold when given with stiripentol; a clobazam dosage reduction of 25% per week may be required in the presence of clobazam toxicity (drowsiness, hypotonia, and irritability)	• Product available in various countries; not currently available in the United States • Should be given with food, excluding fruit juice, dairy, or caffeinated or carbonated products
Perampanel			
Children ≥ 12 years and adolescents—with no enzyme inducing AED's: initial dose 2 mg HS, increase by 2 mg/week to recommended dose 8 to 12 mg; *with enzyme-inducing AEDs:* initial dose 4 mg HS, increase by 2 mg/week to 8 to 12 mg HS	Adjunctive therapy in treatment of partial-onset seizures with or without secondarily generalized seizures	Headache, nausea, vomiting, abdominal pain, fatigue, loss of strength and energy, back pain or weight gain, dizziness, passing out, change in balance or abnormal gait **US Boxed Warning: Serious psychiatric and behavioral reactions** such as depression, suicidal ideation, illogical thinking, aggression, anger, hostility, homicidal ideation	• Not recommended (not studied) in cases of severe renal and hepatic impairment; with mild to moderate renal and hepatic impairment, use caution and lower doses with slower titration • To be administered once daily at HS
Midazolam			
Infants 1 to 5 months: 0.2 mg/kg single dose; *infants ≥ 6 months, children and adolescents:* 0.2 to 0.3 mg/kg, maximum single dose 10 mg (intranasal dosing parameters)	For acute treatment of prolonged seizures	Antegrade amnesia, potential respiratory depression, and respiratory arrest if used with other CNS depressants; hypotension, CNS depression, paradoxical reactions such as agitation hyperactive or aggressive behavior **US Boxed Warning: Respiratory depression; IV dosing; neonates (injection); risk from concomitant use with opioids**	• Use a MAD nasal drug delivery device to administer intranasal • Maximum 1 mL per nostril (0.5 mL for infants < 1 year old) • Vial can be stored in cool, dry area at room temperature; an open vial can be stored up to 28 days and then must be discarded • Use with caution in children with cardiac, lung, hepatic, or renal impairment

bid, twice a day; CNS, central nervous system; ECG, electrocardiogram; FDA, Food and Drug Administration; GI, gastrointestinal; IM, intramuscular; IV, intravenous; qid, four times a day; tid, three times a day.

Surgical Management

1. If a cerebral lesion, such as a tumor, is found, surgical removal is the treatment of choice.
2. Surgical treatment, such as hemispherectomy, resection of localized seizure focus/epileptogenic zone, or corpus callosotomy, may be performed in children with severe, medically intractable seizure disorders.

Ketogenic Diet Therapy

1. The ketogenic diet is a high-fat, adequate protein, and low-carbohydrate diet is used for control of seizures refractory to medications. The diet consists of precisely calculated portions of protein, fat, and carbohydrates. The diet causes the child to become ketotic because fats are used for fuel rather than carbohydrates. It is thought that ketones may inhibit seizures, although the mechanism of action is not known.
2. There are several ketogenic diet types: classic, medium-chain triglyceride, modified Atkins, and the low glycemic index diet.
3. Children on this diet should not be given IV fluids with dextrose.
4. All medications should be in sugar-free and carbohydrate-free suspensions, tablets, or capsules.
5. The child will be on strict fluid restriction.
6. This diet must be carefully monitored by a dietitian. Ongoing surveillance monitors the child's growth and nutritional status as well as other parameters including kidney functions and lipid and micronutrient levels.
7. There is some evidence that this diet may put the child at increased risk for developing kidney stones. The risk may be increased when the child receives concomitant therapy with topiramate. Renal and abdominal ultrasounds are done periodically to monitor for stones.
8. Periodic electrocardiograms are performed to monitor for heart rhythm abnormalities.
9. Another form of the ketogenic diet is the medium-chain triglyceride (MCT) diet. The MCT diet allows for consumption of more carbohydrates than the classic ketogenic diet, reducing the side effects of vomiting and lack of energy.
10. Valproic acid must be weaned off prior to commencing treatment with the MCT ketogenic diet to prevent hepatic toxicity.

EVIDENCE BASE Cai, Q., Zhou, Z., Luo, R., et al. (2017). Safety and tolerability of the ketogenic diet used for the treatment of refractory childhood epilepsy: A systematic review of published prospective studies. *World Journal of Pediatrics, 13*(6), 528–536.

Modified Atkins Diet

1. Emerging as another form of diet therapy for seizure control.
2. Carbohydrates are restricted to 10 to 20 g per day, with no restriction of protein, fluid, or calories.
3. Hospital admission is not required to initiate the diet. The diet is often self-administered.

Vagal Nerve Stimulation

The vagal nerve stimulator is a pacemaker-like device that is surgically implanted into the chest and attached to coiled electrodes, which are tunneled to the left cervical vagus nerve. The generator emits a programmed stimulus to stop seizures of long duration (usually 1 minute or longer), and children/families may activate the

generator to allow for additional stimulus at times of seizure activity. Vagal nerve stimulation is an adjunctive treatment for intractable epilepsy—although the mechanism of action is unknown, studies have shown that VNS therapy reduces seizure frequency and is well tolerated.

EVIDENCE BASE Vaiman, M., Heyman, E., & Lotan, G. (2017). Neurological results of the modified treatment of epilepsy by stimulation of the vagus nerve. *Child's Nervous System, 33*(11), 2017–2022.

Behavioral Management

1. Psychiatric disorders, especially attention deficit hyperactivity disorder, depression, and anxiety, are common in children and adolescents who have epilepsy. They are more prevalent in this population than in children and adolescents in the general population or children who have other chronic conditions. Psychosis occurs infrequently.
2. It is important to monitor children with epilepsy for these disorders to ensure early recognition and treatment to minimize lifelong negative sequelae.
3. Further studies are needed to identify the most effective treatments.

General Prognosis

1. General prognosis depends on type and severity of seizure disorder, coexisting mental retardation, organic disorders, and the type of medical management.
2. Medically treated seizures—spontaneous cessation of seizures may occur. Drugs may be gradually discontinued when the child has been free from seizures for an extensive period and the EEG pattern has reverted to normal.
3. Untreated epilepsy—seizures tend to become more numerous.

Complications

1. Apnea/hypoventilation.
2. Hypoglycemia in status epilepticus.
3. Injuries sustained during a seizure.
4. Sudden unexpected death in epilepsy (SUDEP).
5. Osteopenia—because of restrictions in physical activity as a result of seizures or other conditions, such as CP, or treatment with antiepileptic medications, such as valproic acid and carbamazepine.

Nursing Assessment

1. During a seizure, assess the following:
   a. Indications of difficulties with airway or breathing.
   b. Significant preseizure events, such as noise, excitement, and lethargy.
   c. Behavior before the seizure, aura.

d. Types of movements observed.
e. Time seizure began and ended.
f. Site where twitching or contraction began.
g. Areas of the body involved.
h. Movements of the eyes and changes in pupil size.
i. Incontinence.
j. Color change—pallor, cyanosis, and flushing.
k. Mouth—teeth clenched, abnormal movements, and tongue bitten.
l. Degree of consciousness during the seizure.

2. After a seizure, assess the following:
   a. Degree of memory for recent events.
   b. Types of speech.
   c. Coordination, paralysis, or weakness.
   d. Length of time the child is postictal.
   e. Pupillary reaction.

NURSING ALERT devastating phenomenon of epilepsy is sudden unexpected death in epilepsy (SUDEP). The American Academy of Neurology and the American Epilepsy Society have created a practice guideline that directs clinicians to incorporate the following in their discussions:

- The incidence in children is 1 in 4,500 annually.
- For those children who have active generalized tonic–clonic seizures, they are strongly encouraged to pursue therapies to manage their epilepsy while incorporating individual treatment preferences in the context of a risk/benefit approach.
- Inform patients and families that freedom from generalized tonic–clonic seizures greatly decreases the risk of SUDEP.

Nursing Diagnoses

- Risk for Injury related to seizure activity.
- Ineffective Breathing Pattern related to spasms of respiratory musculature.
- Social Isolation related to the child's feelings about seizures or public fears and misconceptions.
- Chronic Low Self-Esteem related to lack of control over seizures.

Nursing Interventions

Ensuring Safety during a Seizure

1. Remove hard toys from the bed.
2. Pad the sides of the crib or side rails of the bed.
3. Assess level of consciousness.
4. Make sure the child can be readily observed.
5. During a seizure, monitor vital signs and assess neurologic status frequently.
6. After a seizure, check the child frequently and report the following:
    a. Behavior changes.
    b. Irritability.
    c. Restlessness.
    d. Listlessness.
    e. Neurologic signs.

Preventing Respiratory Arrest and Aspiration

1. During a seizure, take the following emergency actions:
    a. Clear the area around the child.
    b. Do not restrain the child.
    c. Loosen the clothing around the neck.
    d. Turn the child on side so saliva can flow out of the mouth.
    e. Place a small, folded blanket under the head to prevent trauma if the seizure occurs when the child is on the floor.
2. Do not give anything by mouth or attempt to place anything in the mouth.
3. After the seizure, place the child in a side-lying position.

Promoting Socialization

1. Advise the parents that the child should be in an environment that is as normal as possible.
2. Encourage regular attendance at school after the school nurse and teachers have been notified and emergency treatment of seizures is understood.
3. Encourage the child to participate in organizations and outside activities with limited restrictions.
    a. Each child must be treated individually; the kind of activity depends on the degree of seizure control.
    b. Generally, children with seizure disorders should not be allowed to climb in high places or to swim alone.
    c. Responsible adults should be made aware of the child's disorder.
    d. Children with seizures should wear a MedicAlert bracelet at all times.

Strengthening Self-Esteem

1. Offer reassurance and praise to the parents and child for coping effectively with seizures.
2. Observe parent–child interactions for evidence of rejection or overprotection.
    a. Tell the parents that the child should not be made to feel that he or she can never be left alone.

b. Advise the parents that the child needs to be disciplined as any other child and should not gain attention directly or indirectly by having seizures.

3. Help the child gain more control by providing education about seizure disorders.
   a. Include the child in treatment planning.
   b. Allow the opportunity to ask questions and answer them honestly.
   c. Make sure the child is aware of restrictions and can deal with them.
   d. Encourage parents gradually to give the child responsibility for taking medications.
4. Help the older child or adolescent to achieve independence.
   a. Encourage the parents to give the older child the opportunity for privacy to discuss concerns with the physician.
   b. Encourage parents to allow the older child to use his or her own judgment in making decisions.
   c. Help the older child to develop realistic educational and career goals.
5. Help parents deal with a noncompliant child. Refusal to take medications requires prompt intervention. Children need to be reassured that they are not abnormal, but that they do require medication to control seizures. Children need to be taught that they are normal and can have normal lives. This is most commonly seen during adolescence. Family counseling may be necessary.
6. Teach the parents and child seizure safety.

Community and Home Care Considerations

1. Follow community and home care considerations listed under “Cerebral Palsy” on page 1229.
2. Make sure that the home environment is safe, especially where the child sleeps and plays. Remove toys with sharp edges or parts or small pieces the child could choke on if they are put in the mouth, and cover very hard surfaces, such as the floor, against which the child could fall.
3. Reinforce parents’ knowledge and ability to dispense seizure medications.
4. Help the family acquire a medical alert tag that the child should wear at all times, especially when attending daycare or school.
5. Make sure that parents and caregivers know the seizure type, name of all medications, when to call the health care provider, and when to call 911.
   a. The health care provider should be notified of an increased frequency of seizures or new onset of symptoms.
   b. Emergency response should be activated when the child has been seizing for longer than 5 minutes or is unresponsive after a seizure.
6. Make sure that parents and caregivers are trained in CPR and seizure management.

Family Education and Health Maintenance

1. Describe completely any examinations, evaluations, and treatments that the child is receiving.
2. Provide information regarding the disorder itself.

a. Epilepsy is not contagious, is seldom dangerous, and does not indicate insanity or mental retardation.
b. Most children with epilepsy have infrequent seizures and with medications can completely control their convulsions.
c. The child may have normal intelligence and can live a useful and productive life.

3. Prepare the parents for the fact that it may take several months of regulating drug dosages before adequate control is obtained.
4. Encourage parents and older children to obtain genetic counseling.
   a. As genetic research progresses, an increasing number of mutations have been found in patients with both sporadic and inherited epilepsy syndromes. There is a genetic predisposition with certain types of seizures, such as absence, febrile, and juvenile myoclonic seizures.
   b. It is impossible to predict accurately the possibility of the seizure disorder appearing in siblings or offspring of the affected child.
5. Teach the parents and child factors that may precipitate a seizure.
   a. The child should be kept in optimal physical condition with routine immunizations, medical care, dental care, and eye care and should receive prompt evaluation and treatment of infections.
   b. Excessive fatigue, dehydration, and sleep deprivation should be avoided.
   c. Irregular, fluctuating schedules are detrimental. Advise the parents to maintain a daily routine.
   d. Fever or illness of any kind can trigger seizures in children diagnosed with epilepsy even though their seizures may otherwise be under control.
6. For additional resources, refer families to *www.aboutkidshealth.ca/En/ResourceCentres/Epilepsy/Pages/default.aspx*.

Evaluation: Expected Outcomes

- Padded bed rails in place.
- Breathing unlabored after seizure, with lungs clear.
- Parents and child verbalize understanding of child's ability to participate in activities.
- Child participates in treatment plan and takes medications as ordered without reminders; serum drug levels are therapeutic.

Febrile Seizures

Febrile seizures occur in childhood after 1 month of age and are associated with a febrile illness that is not caused by an infection of the central nervous system. There is no history of a previous neonatal seizure or a previous unprovoked seizure and the child does not have an acute symptomatic seizure. Most febrile seizures occur between 6 and 36 months of age, with the peak incidence at 12 to 18 months. In North America, 2% to 4% of all children will have at least one febrile seizure before age 5 years.

Febrile seizures may be simple or complex:

- Simple febrile seizures—brief, last <10 minutes; tonic–clonic convulsion occurs once in 24 hours; absence of focal features; resolve spontaneously; 70% to 75% of febrile seizures are simple.
- Complex febrile seizures—prolonged, last more than 10 to 15 minutes; focal in nature; may recur within the same febrile illness over 24 hours; approximately 20% of febrile seizures are complex in most series.

Pathophysiology and Etiology

1. Febrile seizures are associated with first- or second-degree relatives with a history of febrile seizure, daycare attendance, developmental delay, influenza A viral infection, herpes virus-6 infection, metapneumovirus, and iron-deficiency anemia.
2. Seizures often accompany intercurrent infections, especially viral illness, tonsillitis, pharyngitis, and otitis.
3. They appear to occur in a familial pattern, although exact pattern of inheritance is not completely understood. Children with a positive family history of febrile seizures have a greater risk of recurrent febrile seizures.
4. Clinical studies have now demonstrated that it is the actual maximum temperature attained rather than the rate of rise, which is the determinant of risk in febrile seizures. One key variable that alters fever effect is seizure threshold, which is lower in infants.
5. Most febrile seizures consist of generalized tonic–clonic seizures and the majority occur on the first day of illness (see above).

Clinical Manifestations

1. Fever is usually more than 101.8° F (38.8° C) rectally.
2. Seizures usually occur near the onset of fever rather than after prolonged fever.

Diagnostic Evaluation

Measures are directed toward delineating the cause of any seizure as precisely as possible so its implications and prognosis may be discussed with the parents. Diagnostic methods may include the following:

1. Careful history taking and physical examination.
2. CSF examination to detect CNS infection—strongly recommended in children experiencing their first febrile seizure, especially in children age < 12 months, those who have had a prolonged seizure including febrile status epilepticus, if there are any meningeal signs, if the child is on antibiotics (could mask

meningitis signs and symptoms) and for seizures that occur after the second day of febrile illness.

3. CBC and urinalysis to detect signs of infection.
4. Cultures of nasopharynx, blood, or urine, as appropriate, to determine cause of fever.
5. Blood glucose, calcium, and electrolyte levels to detect abnormalities that may cause seizures.
6. EEG (for atypical seizures or for a child at risk for epilepsy).
    a. Demonstrates mild, postictal slowing soon after the attack.
    b. Pattern is generally normal after a few days.

Management

The goals of treatment are to control seizures and decrease temperature.

1. Administration of antipyretics and other cooling measures.
2. Prevention of febrile seizures with anticonvulsants is not common practice. Prompt control of fevers is the desired course of action.
3. Rectal diazepam gel is the preferred method of acute seizure management for prolonged seizures >5 minutes or for someone who is at risk for status epilepticus. It is used only in extreme cases.
    a. Intermittent therapy with phenobarbital during febrile episodes is apparently of no value because of the length of time required to achieve therapeutic serum levels of the drug.
4. Airway management, as required.
5. Prognosis—likelihood of recurrence is about 33% in those who have had two febrile seizures. The younger the child is at the time of the first seizure, the greater the risk for additional febrile seizures.
6. The risk of development of nonfebrile seizures is relatively low (about 5%). At risk are children who demonstrate the following characteristics:
    a. Prolonged or complex febrile seizures.
    b. Abnormal or suspected abnormal development before the first seizure.
    c. Family history of nonfebrile seizures.
    d. Persistent EEG abnormalities.

Complications

Injury may occur during seizure.

Nursing Assessment and Interventions

Nursing assessment and interventions are the same as for seizure disorders, page 1250.

Family Education and Health Maintenance

1. Reinforce realistic, reassuring information, such as the following:
    a. A seizure does not necessarily imply that the underlying disease is serious.
    b. Febrile seizures are relatively common in children.
    c. The prognosis depends on the cause of the seizure.

i. A single febrile seizure does not indicate later chronic epilepsy.

ii. Children usually outgrow the tendency to develop febrile seizures by age 4 or 5.

iii. Occasional or brief seizures are thought to not have any effect on the child's overall development, although this is controversial.

2. Discuss and demonstrate emergency management of seizures.
   a. The child should be positioned on the side, on a flat surface from which he or she cannot fall.
   b. The surface should be padded, if possible, to prevent injury.
   c. An adult should stay with the child to monitor the airway and breathing until the seizure is complete.
   d. If the child vomits, immediately clear the mouth of all foreign material.
3. Stress that medical evaluation is indicated as soon as the child develops a fever.
   a. Review technique of temperature measurement.
   b. Prompt administration of antipyretic measures is necessary when the child is febrile but may not prevent a febrile seizure.
4. Review administration schedule, adverse reactions, and appropriate follow-up regarding anticonvulsant therapy.
5. Let the family know that when a child is diagnosed with febrile seizures, future events can be adequately managed at home and do not require emergency transport if <5 minutes in duration. However, parents should notify pediatrician of febrile illness and seizure occurrence.

Subdural Hematoma

Subdural hematoma refers to an accumulation of fluid, blood, and its degradation products within the potential space between the dura and arachnoid membranes (subdural space). Subdural hematomas are classified as acute or chronic, depending on the time between injury and the onset of symptoms.

Also, see for care of unconscious patient, ICP monitoring, and other neurologic care.

Pathophysiology and Etiology

Causes

1. Direct or indirect trauma to the head:
    a. Birth trauma.
    b. Accidental causes.
    c. Purposeful violence, as in cases of child abuse.
2. Meningitis.

Classification

1. Acute syndrome—presents as an acute problem, closely related to the time of presumed injury.
2. Chronic:
    a. Signs and symptoms are nonlocalizing and subacute.
    b. This is the most common type of subdural hematoma in children.
    c. It is usually difficult to delineate the exact time and type of injury because the precipitating episode may appear relatively insignificant.

Altered Physiology

1. Trauma to the head causes tearing of the delicate subdural veins, resulting in small hemorrhages into the subdural space. (Bleeding may be of arterial origin in cases of acute subdural hematoma.)
2. As the blood breaks down, there is an increased capillary permeability and effusion of blood cells and protein into the subdural space.
3. The breakdown products of blood stimulate the growth of connective tissue and capillaries largely from the dura.
4. A membrane is formed that usually extends frontally and laterally over the hemispheres, surrounding the clot.
5. Fluid accumulates within the membrane and increases the width of the subdural space.
6. Further hemorrhages occur.
7. The lesion enlarges, compressing the brain and expanding the skull, and, if unrelieved, ultimately causes cerebral atrophy or death from compression and herniation.
8. The lesion may arrest spontaneously at any point.
9. Further bleeding may occur into an already existing sac and may increase symptoms.

10. In long-standing subdural hematoma, the fluid may disappear, leaving a constricting membrane that prevents normal brain growth.

Clinical Manifestations

Acute

1. Typically present with continuous unconsciousness from the time of injury, but child may present with a lucid interval.
2. Ensuing manifestations include deterioration of LOC, progressive hemiplegia, focal seizures, and signs of brain stem involvement and herniation (pupillary enlargement, changes in vital signs, decerebrate posturing, and respiratory failure; see Figure 46-3).

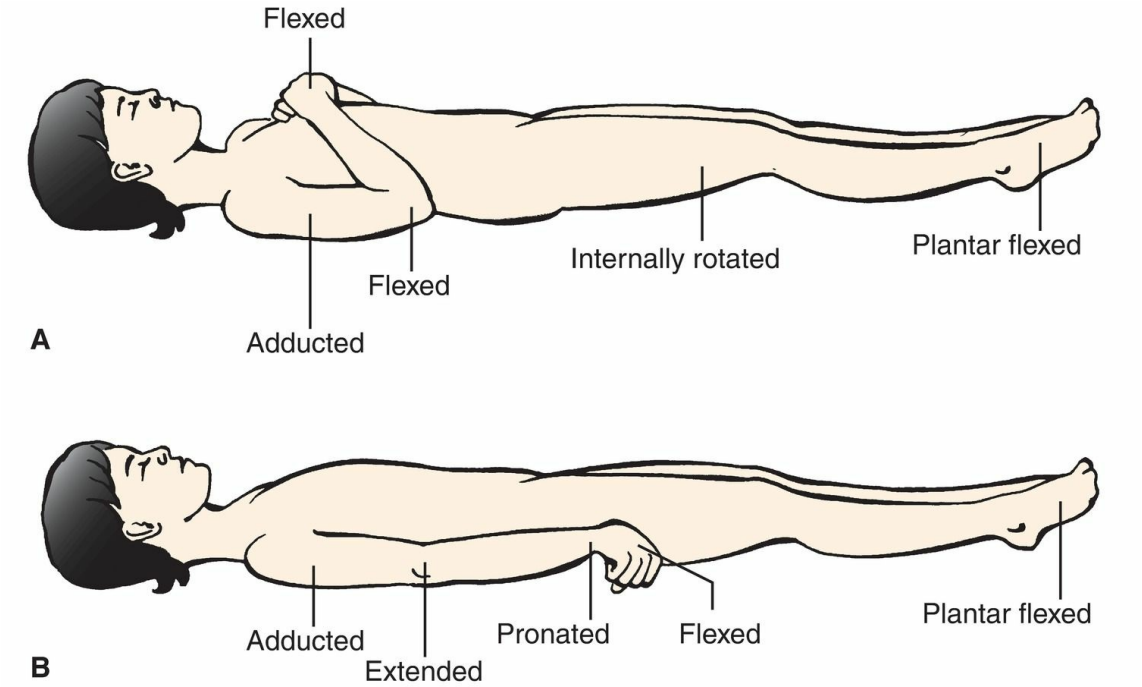

Figure 46-3. Primitive posturing in unconscious states because of loss of motor control. **(A)** Decorticate posturing occurs when cortical loss is present. **(B)** Decerebrate posturing occurs when the midbrain is involved. (From Pillitteri, A. [2013]. *Maternal and child health nursing: Care of the childbearing and childrearing family* [7th ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Chronic

This has a slow, gradual onset; symptoms are variable and are related to the age of the child.

1. Infants—early signs:
   a. Anorexia, difficulty feeding, and vomiting.
   b. Irritability.
   c. Low-grade fever.
   d. Retinal hemorrhages.

e. Failure to gain weight.

2. Infants—later signs:
   a. Enlargement of the head.
   b. Bulging and pulsation of the anterior fontanelle.
   c. Tight, glossy scalp with dilated scalp veins.
   d. Strabismus, pupillary inequality, and ocular palsies (rare).
   e. Hyperactive reflexes.
   f. Seizures.
   g. Retarded motor development.
3. Older children—early signs:
   a. Lethargy and anorexia.
   b. Symptoms of increased ICP (vomiting, irritability, headache).
4. Older children—later signs (may also occur immediately if bleeding takes place rapidly):
   a. Seizures.
   b. Coma.

Diagnostic Evaluation

1. Clinical features.
   a. In infants who are irritable, have failed to gain weight, and have developed an enlarged and tense fontanelle, chronic subdural hematoma should be suspected.
   b. Biparietal bulge of the head.
2. Imaging.
   a. Diagnosis and size of hematoma are confirmed by CT and, if necessary, by MRI.

Management

Acute Subdural Hematoma

This requires evacuation of the clot through a burr hole or craniotomy.

Chronic Subdural Hematoma

1. Repeated subdural taps are done to remove the collecting fluid.
   a. In infants, the needle can be inserted through the fontanelle or suture line.
   b. In older children, burr holes into the skull are necessary before the needle can be inserted.
   c. Subdural taps may be the only treatment required if the fluid disappears entirely and symptoms do not recur.
   d. Concurrently, treatment is instituted to correct anemia, electrolyte imbalance, and malnutrition.
2. Shunting procedure may be indicated if repeated taps fail to significantly reduce the volume or protein content of the subdural collections. Shunting is usually to the peritoneal cavity.

Prognosis

1. Treatment is usually successful when the diagnosis is made before cerebral atrophy and a fixed neurologic deficit have occurred. In such cases, subsequent development is normal.
2. Prognosis depends on the effect of the initial trauma on the brain and the effect of continued fluid collection.
3. Mortality in massive, acute subdural bleeding is very high, even if promptly diagnosed.

Complications

1. Mental retardation.
2. Ocular abnormalities.
3. Seizures.
4. Spasticity and paralysis.
5. Brain stem herniation and death.
6. Neurologic impairment (cognitive or physical).

Nursing Assessment

Assess the child's neurologic status to evaluate the effectiveness of treatment or to identify disease progress.

1. Observe general behavior, especially irritability, lethargy, and evidence of personality changes. It is important to obtain a thorough history from the parents regarding normal behavior and level of functioning so abnormalities can be more easily recognized.
2. Evaluate appetite and feeding difficulties, including vomiting.
3. Assess vital signs for signs of increased ICP—be alert for the following:
   a. Increased systolic BP.
   b. Widened pulse pressure.
   c. Decreased pulse or irregularities.
   d. Changes in respiratory rate or difficulty breathing.
4. Assess LOC; describe response explicitly, including what type of stimulus was required to elicit a response.
5. Assess pupillary and visual changes, especially dilated pupil, double vision, lack of response to light, alterations in visual acuity, and nonsymmetric or abnormal eye movements.
6. Monitor for seizures.
7. Evaluate motor function, including ability to move all extremities. The ability to grasp should be checked and compared bilaterally.
8. Inspect for drainage of CSF from the nose or ears, indicating fractured skull with CSF leak.

Nursing Diagnoses

- Ineffective Tissue Perfusion: Cerebral related to disease process.

- Impaired Physical Mobility related to decreased LOC.
- Imbalanced Nutrition: Less Than Body Requirements related to decreased LOC.
- Ineffective Family Coping: Compromised related to hospitalization of child.

Nursing Interventions

Maintaining Cerebral Tissue Perfusion

1. Avoid additional increase in ICP.
    a. Maintain a quiet environment.
    b. Avoid sudden changes in position.
    c. Organize nursing activities to allow for long periods of uninterrupted rest.
    d. Carefully regulate fluid administration to avoid danger of fluid overload.
    e. Measure urine output and record specific gravity.
    f. Administer laxatives or suppositories to prevent straining during a bowel movement.
2. Assist with subdural taps.
    a. Protect and restrain the child, as needed (see page 1222).
    b. Hold the child securely to avoid injury caused by sudden movement.
    c. Apply firm pressure over the puncture site for a few minutes after the tap has been completed to prevent fluid leakage along the needle tract.
    d. Observe the child frequently after the procedure for shock or drainage from the site of the tap.
    e. Note whether there is serous drainage or frank blood.
    f. Reinforce the dressing, as needed, to prevent contamination of the wound.
    g. Monitor temperature frequently and monitor for signs of developing infection.
    h. Report purulent drainage from the site of the subdural tap.
3. Avoid discussing the child's condition near the bed. Even though comatose, the child may be able to hear.
4. Have emergency equipment available for resuscitation.

Preventing Complications of Immobility

1. Change the child's position frequently and provide meticulous skin care to prevent hypostatic pneumonia and decubitus ulcers.
2. Prevent contractures.
    a. Apply passive ROM exercises to all extremities.
    b. Place pillows appropriately to support the child's body in good alignment.
    c. Use splints designed by physical therapy, as instructed.
3. Suction the child as necessary to remove secretions in the mouth and nasopharynx.
4. Observe for signs of respiratory or urinary infection related to stasis.
5. Keep the child's eyes well lubricated to prevent corneal damage.

Maintaining Nutritional Status

1. Provide nutrition and fluids through nasogastric feedings, as ordered. Observe for gastric distention.
2. Monitor urine output and specific gravity daily.
3. Monitor electrolyte and protein levels on laboratory work.
4. Do not neglect mouth care, even if child is not eating.

Strengthening Family Coping

1. Encourage the parents to hold and cuddle their child as much as possible.
2. Encourage the parents to bring diversional activities from home.
   a. Infants—mobiles or musical toys.
   b. Older children—quiet games, books, and dolls.
3. Provide emotional support to the parents.
   a. Encourage as much parental participation in the child's care as possible.
   b. Support parents and suggest pastoral counseling, as indicated.
4. Be nonjudgmental in cases caused by intentional or accidental trauma.
5. Make sure that cases of suspected child abuse have been reported to the appropriate agency and that parents have been referred for counseling.
6. Encourage visitation by siblings.

Community and Home Care Considerations

1. Follow community and home care considerations listed under "Cerebral Palsy" on page 1229.
2. Perform periodic developmental assessments and reinforce the need to report any signs of developmental delay to the health care provider.
3. Discuss return-to-activity/play as the child progresses, as directed by health care provider.

Family Education and Health

1. Reinforce explanations in the following areas:
   a. Condition.
   b. Causes of the child's specific symptoms.
   c. Need and rationale for treatment.
   d. Postoperative and recovery expectations.
2. Encourage parents to keep all follow-up appointments for medical evaluation and physical and occupational therapy.
3. Teach parents safety measures to prevent injuries in the future.
4. Assist parents in seeking additional support and resources through social work department, church groups, community agencies, or private counseling.

Evaluation: Expected Outcomes

- Drowsy but responsive to verbal stimuli; pupils equal and reactive to light; vital signs stable; ventricular tap site without drainage.
- Skin without signs of erythema or breakdown; full ROM of all joints; functional position maintained.
- Tolerates nasogastric feedings without distention; urine output sufficient.
- Parents participate in child's care, hold, and read to child; parents receive counseling.

TRANSITIONAL CARE ALERT The proper transition of pediatric patients to adult care has always been important to health care providers but has received more attention over the past several years as an increased number of children with serious and complex medical conditions are surviving into adulthood. Because of the need for proper transition of this population, many organizations have studied the myriad of transition issues and developed programs to ensure a smooth transition of children and their families to adult care.

The goal of transition is to help teens with chronic medical conditions (and their families) develop the knowledge and skills required to successfully manage their health care in the adult system while they are still within the pediatric system. With proper guidance, children and youth can acquire the skills to advocate for themselves (or through others), attain self-management of care when possible, and learn to successfully navigate and access adult health care services.

Many issues must be considered for a successful transition such as different levels of patient complexity, comorbid conditions, the need for multidisciplinary services, and the required links with appropriate community agencies. When these needs are all met, teens and their families will have a more positive experience with the transition process.

Functional Hearing Disorders

CONDITIONS OF THE EYE

Also see Chapter 16 for additional information on eye problems.

Infectious Processes

Infectious processes of the eye include conjunctivitis, periocular cellulitis, hordeolum (stye), or chalazion. They are characterized by inflammation, infectious exudate, and tissue damage caused by microbes, such as bacteria or viruses. Conjunctivitis is a common problem, affecting almost all children at some time or another.

Pathophysiology and Etiology

1. Microbes are usually introduced into the eye or surrounding tissues including eyelids, eyebrow, and cheeks by direct contact with infected objects. Orbital infections occur secondary to microbial spread from an adjacent sinus, direct inoculation from trauma, surrounding skin infection, or hematogenous spread from sepsis or dental infection.
2. An inflammatory response develops with engorgement and dilation of conjunctival blood vessels with or without discharge and chemosis or edema of the conjunctiva.
3. Common bacterial agents include nontypeable *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Pathogens in neonates and adolescents can include *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Viral infections are common and are usually caused by adenoviruses. Less commonly, coxsackievirus, enterovirus, Zika, and herpesvirus may occur.
4. The infecting agents are contagious and easily spread via hand to eye contact from infected objects (fomites). Outbreaks in which multiple children in the same family, classroom, or community are infected may occur.
5. Environmental allergens such as pollen are major contributors to conjunctivitis.

Clinical Manifestations

Redness of the eye is a common ophthalmic symptom comprising 1% of primary care office visits. The cause of this redness can arise from within or outside the globe. Causes range from minor eye dryness to life-threatening systemic illness. Such diverse causes of redness must be differentiated from the red eye of noninfectious processes (see Table 47-1).

Table 47-1 Common Causes of Eye Redness in Children

CAUSE	ASSOCIATED SYMPTOMS	MANAGEMENT
Conjunctivitis		
Viral	Commonly associated with other symptoms of generalized viral illnessCommonly known as "pink eye," itchy, burning eye	Hygiene (see page 1261), rest, cool compresses, artificial tears
Bacterial	Yellow, green, or white discharge, photophobia, tender eye	Antibiotic eyedrops or ointment, hygiene
Chlamydial	Cough, history of maternal infection	Systemic antibiotic
Herpetic	Pain, photophobia, skin lesions	Evaluation by specialist, antiviral agents
Allergic	Marked itching, bilateral, watery discharge, seasonal onset, other allergic symptoms (rhinorrhea, allergic shiners), cobblestoning of inner eyelids	Topical mast cell stabilizer/antihistamine eyedrops, oral antihistamines, avoidance of allergens
Chemical	Watery discharge, onset of symptoms when exposed to cigarettes or other irritants	Avoidance of irritating substances
Trauma	Pain, photophobia, increased tear production	May require eye protection, referral to specialist
Congenital glaucoma	Increased tear production, cloudiness of the cornea	Referral to specialist

Conjunctivitis

1. Acute onset of inflammation of palpebral and bulbar conjunctival layer leads to dilation of the blood vessels. Usually starts initially in one eye followed by the second a few days later.
2. Eyelid and conjunctiva edema.
3. Excessive tearing or exudate.
4. Gritty or burning feeling in the eye and itching.
5. Photophobia with fluctuating blurring and cloudy vision.
6. Accompanied by preauricular lymphadenopathy.

Preseptal Cellulitis

1. Unilateral swelling and redness of the eyelid and surrounding tissues that does not involve eyeball or internal structures.
2. No significant fever.
3. No pain with or limitation of eye movement.
4. No impaired vision.
5. Age less than 5 years.

Postseptal Cellulitis

1. Marked redness and swelling of eyelid and soft tissues surrounding the eye.
2. Pain and tenderness of the eye area.
3. Proptosis (forward displacement of the eye).
4. Purulent discharge from the eye.
5. Fever.
6. Limited mobility of the eye with reduced visual acuity.
7. Age over 5 years.

Hordeolum (Stye)

1. Acute inflammation of lubricating glands of eyelids and eyelashes.
2. Unilateral pustule of eyelash follicle accompanied by tenderness.
3. Does not respond to antibiotics.
4. Chalazion
5. Chronic, localized eyelid swelling and erythema.
6. “Lump under the eyelid.”
7. Does not respond to antibiotics.

Diagnostic Evaluation

1. Because of the cost of and the delay in results, laboratory testing is limited to cases that fail to respond to treatment. Appropriate laboratory media must be used to transport a swab of eye exudate for bacterial

culture, viral culture, and antigen testing. Swabs should be obtained immediately but treatment not delayed, especially in the cases of suspected *N. gonorrhea* or *C. trachomatis.*

2. Screening vision exam should be done.
3. A dendritic ulcer caused by herpesvirus can be visualized by instilling fluorescein dye and examining the cornea with a cobalt-filtered blue light, looking for the dendrite lesion.
4. Clinical evaluation and computed tomography scan are the best methods to distinguish preseptal from postseptal cellulitis.

NURSING ALERT A child who has a painful red eye should be referred immediately for medical evaluation because this could indicate an infectious process, exposure to a chemical or foreign body, or other traumatic etiology.

Management

1. Allergic conjunctivitis may respond to removal of the underlying allergen and avoidance of eye rubbing. Treatment includes systemic or topical agents such as antihistamines, mast cell stabilizers, and/or corticosteroids.
2. Antibiotic eyedrops or ointment—such as erythromycin, trimethoprim sulfate and polymyxin B, sulfacetamide, ciprofloxacin, tobramycin, azithromycin, or doxycycline—will shorten the course of bacterial conjunctivitis and make the child more comfortable.
3. Hordeolum and chalazion resolve without antibiotic treatment. Warm compresses applied four times daily are recommended. Lid washes of diluted baby shampoo in water aid with drainage. Incision and drainage may be necessary to promote healing of long-standing chalazion.
4. Systemic antibiotic treatment is indicated for postseptal cellulitis. These children require close follow-up as hospitalization and IV antibiotics may be necessary. A multidisciplinary approach, including an ophthalmologist, pediatrician, otolaryngologist, and, possibly, a neurosurgeon, may be indicated.

DRUG ALERT Topical corticosteroids should only be prescribed by an ophthalmologist because they may aggravate a herpetic infection.

Complications

1. Permanent scarring of the cornea and visual impairment with herpetic infection, *N. gonorrhoeae*, and *C. trachomatis*.
2. Spread of postseptal cellulitis to the central nervous system, with optic nerve damage, vision loss, ptosis, and strabismus.

3. Eyelid deformity.
4. Septicemia.

Nursing Assessment

1. Assess nature and extent of symptoms and their effect on child's activities.
2. Assess visual acuity.
3. Determine resources available to family for treatment and rehabilitation.

Nursing Diagnoses

- Risk for Infection (spread, secondary, transmission to others) related to hand-to-hand or hand-to-object contact.
- Acute Pain and Discomfort related to tissue swelling, inflammation, and light sensitivity.

Nursing Interventions

Preventing Spread of Infection

1. Perform or teach proper cleansing of drainage.
    a. Use warm water or saline and a disposable applicator, such as cotton balls or gauze.
    b. Use a separate applicator for each eye.
    c. Wipe from inner to outer canthus to avoid contamination of the other eye.
2. Teach self-care measures to prevent spread to others.
    a. Observe good handwashing practices.
    b. Wipe eyes and nose with tissues and dispose promptly. Do not wipe the nose and then eyes with same tissue.
    c. Avoid rubbing eyes to prevent spread.
3. Administer and teach proper instillation of eyedrops or ointment (see page 436).
4. Administer oral or IV antibiotics, as prescribed.
5. Advise parents to only use eyedrops prescribed or recommended by a health care provider and dispose of leftover medication at end of treatment period.

Minimizing Pain

1. Apply warm compresses to affected area.
2. Suggest darkened room and sunglasses for patients with photophobia.
3. Administer an analgesic, as prescribed.
4. Administer lubricating eyedrops and ointment, as needed.
5. Minimize environmental stimulation.

Family Education and Health Maintenance

1. Advise of ways to prevent transmission to others.

a. Handwashing is the most important factor in infection control.
b. Do not share washcloths or towels or handkerchiefs.
c. Change pillowcases frequently.
d. Avoid swimming until infection is resolved.
e. Return child to school only after having received antibiotic treatment for 24 hours.
f. Dispose of contaminated items in proper receptacles.
g. Discontinue use of contact lenses until infection is cleared.

2. Advise parents of indications for reevaluation by health care provider.
   a. Lack of response to antibiotic treatment.
   b. Increased swelling and tenderness; any eye pain.
   c. Worsening of visual acuity.
   d. Identification of dry eye.
   e. Development of additional symptoms such as fever.
3. Encourage routine follow-up visits and vision evaluation.
4. Advise about proper detection and early treatment of sinus, dental, and other infection.
5. Recommend updated immunization, including the *Haemophilus influenzae* type B vaccine in children.

Evaluation: Expected Outcomes

- Parents perform treatment correctly; hygiene procedures followed.
- Patient verbalizes less pain; tolerates bright light.

Congenital Problems

Congenital problems of the eye include structural defects present at birth or developing soon thereafter. These are usually genetically transmitted and include cataract, dacryostenosis, glaucoma, ptosis, and strabismus. See Table 47-2 for pathophysiology, clinical manifestations, and management of each.

Table 47-2 Congenital Eye Problems

CONDITION AND DESCRIPTION	CLINICAL MANIFESTATIONS	MANAGEMENT
Congenital Cataract Opacity of the lens. Possible causes include abnormal embryonic development, intrauterine infection, metabolic disorders, retinopathy of prematurity. Incidence is 1 in 250 neonates.	• Absence of red reflex • Visible clouding of lens • Varying impairment of vision, depending on size, location, and density of cataract • May result in amblyopia	• Surgical removal within first 3 months to promote visual stimulation. • Postoperative care: sedation for first 24 hours to prevent crying, vomiting, and increased IOP; dilating eyedrops; antibiotic and steroid ointments to prevent infection; eye patch and shield for several days. • Aggressive optical therapy and patching of nonoperative eye; monitoring for IOP.
Dacryostenosis Relatively common obstruction of the nasolacrimal duct caused by incomplete duct development and persistence of membrane at lower end of duct. Tears cannot exit via the duct into the nasal cavity and continuously spill over onto the cheek. May be unilateral or bilateral.	• Excessive tearing and spilling onto cheek • Crusted eyelashes and lids • Excoriated cheek • Normal-appearing eye structures and vision • Possible episodes of secondary conjunctivitis and lacrimal duct infection • Increased risk of dacryocystitis	• Resolves spontaneously in 90% of infants in first year of life. • Gentle massage of lacrimal duct four times daily. • Topical antibiotics for secondary infection. • Surgical probing of duct if persists beyond age 12 months; more complex surgery if probing unsuccessful.
Glaucoma Rare, congenital, or acquired abnormality in which the balance between aqueous fluid production and outflow is disrupted. Increased pressure of fluid in anterior chamber causes damage to the retina, cornea, and other structures.	• Corneal enlargement • Haziness of the cornea • Photophobia and intolerance to ordinary light • Excessive tearing • Decreased visual acuity (symptoms present in 35% at birth) • Amblyopia and permanent loss may result without treatment	• Early diagnosis is essential. • Monitoring of IOP by tonometry and central corneal thickness by pachymetry and fundoscopy. • Medical therapy. • Surgical intervention is first-line treatment. • Postoperatively, a patch and shield may be worn for several days to protect sutures. • Lifetime follow-up.
Ptosis Drooping of the upper eyelid caused by weakness of levator palpebrae or, less frequently, Möller muscle. May be congenital or acquired. Affects either the muscle or the nerve that innervates it. Particularly challenging to treat if amblyopia is also present.	• Drooping is visible on inspection • Vision may be impaired if eyelid covers the pupil • May be unilateral or bilateral • If unilateral, amblyopia may result without treatment	• Surgical correction to raise the eyelid and increase visual field. • Patching not necessary postoperatively. • Nonsurgical modalities, such as the use of "crutch" glasses to support the eyelid.
Strabismus Malalignment of the eyes caused by muscle imbalance or by paralysis, which prevents both eyes from focusing correctly on the same image. Affects 2% to 5% of the preschool population. Can cause visual and psychological disability.	• Asymmetric pupillary light reflexes • Asymmetric extraocular movements • Diplopia, impaired depth • Tendency to close one eye or tilt head during vision testing • Amblyopia may result without treatment	• Early and rigorous amblyopic occlusion therapy (patching of the stronger eye for a prescribed period each day may correct latent strabismus by exercising the muscles of the weaker eye). • Correction of refractive error. • Surgical repositioning of the extraocular muscles for severe or fixed cases. • Postoperatively: antibiotic ointment, no eye patch.

IOP, intraocular pressure.

Nursing Assessment

1. Assess for red light reflex, especially in neonates and infants. Absence or asymmetry of the red light reflex may indicate congenital cataract or an intraocular tumor or other eye disease.
2. Inspect the eyes for redness of conjunctiva, cloudiness of the cornea, excessive tearing, drooping eyelids that partially occlude the pupil, or obvious misalignment, which provide clues to congenital eye problems.
3. Assess visual acuity routinely in infants and children. Changes in acuity may be the first manifestation of a problem or indication of effectiveness of treatment. Prompt referral to a specialist is necessary.
4. Perform pupillary light reflex test using a penlight or "muscle light" or use a distant light source to help detect strabismus.
    a. Hirschberg test for symmetry of the pupillary light reflexes—normally, the light reflexes are in the same position in each pupil when a light is shone on the bridge of the nose, but asymmetrical reflection will occur with strabismus (positive Hirschberg test).
5. Perform the cover–uncover test to detect latent strabismus caused by weak eye muscles. When the patient is fixated on an object approximately 12 inches (30.5 cm) away, cover one eye. The eye with weak muscles will drift when covered and will snap back when uncovered. An eye with normal muscles will remain straight.

Nursing Diagnoses

- Disturbed Sensory Perception (Visual) related to reduction in visual acuity or no visual stimulation.
- Disturbed Body Image related to the need for patch or glasses.
- Risk for Injury related to reduced visual acuity and modified depth perception.
- Delayed Growth and Development related to altered visual stimulation and possible overprotective behavior of parents.

Nursing Interventions

Minimizing Effects of Vision Loss

1. Participate in visual acuity problem identification and encourage prompt treatment to minimize functional impairment. Accurate assessment of (corrected) monocular visual acuity is the single most important element in an examination.
    a. Effective newborn screening in the nursery helps to detect congenital eye problems.
    b. All children should be screened for visual acuity and strabismus. In young children, this is accomplished by physical examination and assessment of developmental milestones (ie, looks at parent's face, smiles responsively, reaches for objects). Instrument-based photoscreening can assess preverbal children. Special assessment tools are available to assess preverbal children. By age 3 to 5 years, most children can cooperate for performance of accurate visual acuity screening tests.
2. Encourage and assist parents in obtaining corrective lenses for the child.
3. Advise and encourage parents to adhere to the postoperative treatment plan, such as occlusion therapy following cataract surgery or proper use of eyedrops after glaucoma surgery.
4. Encourage and assist parents in providing normal experiences for child to achieve maximum potential:

a. Assist parents in locating and accessing resources, such as financial assistance, special education in Braille, or parent support groups.
b. Remind parents of their child's right to an education.

Minimizing Body Image Disturbance

1. Encourage parents to focus on normalization rather than on overprotection. Place expectations on the child's abilities rather than disabilities, provide opportunities for interaction with peers, and make the child's life as normal as possible.
2. Encourage acceptance of appearance and emphasize the positive aspects of treatment.

Preventing Injury

1. Encourage the family to be aware of safety in the home, school, and community.
   a. Suggest the use of impact-resistant polycarbonate eyeglasses and devices to keep eyeglasses in place.
   b. Advise the family to maintain a consistent and uncluttered furniture arrangement; notify child of planned changes.
   c. Instruct child in the use of a cane or other assistive device, if warranted.
   d. Teach traffic safety and personal security measures.
2. Orient visually impaired children to their immediate environment.
   a. Orient child to food placement on meal trays.
   b. Assist child with ambulation, and use side rails on bed or crib to prevent falls.

Promoting Normal Growth and Development

1. Encourage parents to provide many sensory opportunities, such as manipulating objects, hearing various sounds, noting the smells in the environment, and tasting an assortment of substances.
2. Allow child to perform activities of daily living (ADLs) as independently as possible.

Family Education and Health Maintenance

Postoperative Teaching

1. In the interest of hygiene and safety, the patient (if older) and parent should be taught correct handwashing technique before and after instilling eye medication, particularly eyedrops. This must be reinforced before discharge.
2. Teach about instillation of medications and use of eye shield to prevent injury to the operative eye after surgery.
3. Teach about activity restrictions after glaucoma surgery.
   a. Bed rest may be required immediately postoperatively.
   b. Older children should not engage in strenuous activity or contact sports for 2 weeks.
4. Advise that activity is not usually restricted after repair of ptosis.
5. Following strabismus repair, strenuous activity, contact sports, and swimming are restricted for 2 to 4

weeks.

6. After cataract surgery because of inflammatory reaction, encourage behaviors to reduce the risk of damage to sutures from increased intraocular pressure (IOP):
   a. Prevent vomiting.
   b. Minimize crying.
   c. Encourage intense occlusion therapy and use of optical correction with glasses or contact lenses as advised.
7. Encourage parents to remove eye discharge or crusts on lashes regularly by wiping the eyes with warm water. Separate washcloths should be used for each eye and each child. Moistened cotton balls may be used.
8. Advise and encourage about the importance of keeping postoperative follow-up appointments.
9. Advise of indications that would require reevaluation by health care provider:
   a. Worsening of visual acuity.
   b. Evidence of inflammation and infection, such as pain, redness, swelling, drainage, and increased temperature.
10. Refer family to Prevent Blindness America (*www.preventblindness.org*) for information on eye disease and safety measures. For cataract and glaucoma patients, refer to the Pediatric Glaucoma and Cataract Family Association (*www.pgcfa.org*). Lighthouse International (*www.lighthouse.org*) aids with rehabilitation of visual impairment.

Evaluation: Expected Outcomes

- Child wears glasses or contact lens, as prescribed; good visual outcome with adequate optical rehabilitation.
- Parents and child report involvement in activities, satisfactory school performance, and positive peer interactions.
- No injuries reported.
- Achieves age-appropriate developmental milestones.

Eye Trauma

EVIDENCE BASE Bagheri, N., Wajdi, B. N. (2017). *The Wills Eye manual: Office and emergency room diagnosis and treatment of eye disease* (7th ed.). Philadelphia, PA: Wolters Kluwer.

Eye trauma causes structural damage to the eye and is produced by mechanical force or contact with a corrosive chemical. Some common types of eye trauma are corneal abrasions, blunt trauma, perforating injuries, and chemical injuries. Eye injuries are common among children and are usually related to their involvement in vigorous play activities.

Pathophysiology and Etiology

Corneal Abrasion

1. Injury to corneal epithelium.
2. This may happen when a foreign object becomes lodged in the eye (eg, flying dust particle; contact lens rubbing against the eye because of inadequate tear production; injury from a fingernail, tree branch, or other sharp object entering the eye, and scraping the cornea).
3. May occur from the effects of general anesthetic, which cause decreased tear production, decreased eyelid reflexes, decreased perception of pain, and failure of the eye to close properly.
4. May result from corneal exposure with such conditions as ptosis or pressure on the globe, especially in the presence of dry eyes.
5. May result from contact with household or industrial chemicals.

Blunt Trauma

1. Occurs when the eye or surrounding tissues are struck by a blunt object such as a ball, a hockey puck, a bat, or a stick. May occur with airbag deployment in a motor vehicle accident.
2. The resulting injury depends on the size, hardness, and velocity of the blunt object and the force imparted. Injury may include tissue swelling and seepage of blood into the surrounding tissues.
3. The bony structures surrounding the eye may be fractured.
4. Subconjunctival hemorrhage, lens dislocation, hyphema (blood in the anterior chamber of the eye), and a retinal detachment may occur.

TRANSITIONAL CARE ALERT Care should be made to ensure that patients can safely transition from inpatient management (surgery, medical management, outpatient surgery, or emergency management) to home. Patients should be discharged with full instructions on medication administration including type and frequency of application as well as instructions for administration procedures. Patients

with hyphema should have a rigid shield placed over the involved eye. However, this should not be a patch as any change in vision noted by the patient may indicate rebleeding into the orbit.

Perforating Injury

1. When an object penetrates the eyeball, there may be loss of vitreous material and/or damage to the internal structures of the eye—vitreous hemorrhage, choroidal rupture, retinal tears, retinal detachment, and ruptured globe.
2. Bacteria may also be introduced into the interior of the eye causing infection.

Chemical Injury

1. Corrosive chemicals burn the delicate tissues of the cornea and may penetrate into deeper layers of the eye.
2. Healing may occur with scarring.

NURSING ALERT A chemical injury is a medical emergency.

Clinical Manifestations

1. Pain or sensation of a foreign body in the affected eye—because of the high concentration of nerve endings in the cornea from the ciliary body.
2. Increased tear production—one of the eye's defenses against injury or irritation.
3. Injection of the blood vessels of the cornea—increase of blood flow to the cornea is another protective mechanism; most likely seen with foreign bodies, abrasions, or chemical burns that affect the cornea.
4. Impaired visual acuity caused by:
   a. Swelling of the cornea, reducing its clarity.
   b. Swelling of the soft tissues surrounding the eye, causing the eye to partially or completely close.
   c. Excessive tear production, impairing vision.
   d. Damage to internal structures of the eye, altering or obstructing visual pathways.
5. Visible signs of injury—bruising, swelling, or a foreign object visible in the eye.

NURSING ALERT At times, pain may be useful in distinguishing a serious eye problem from a self-limiting condition.

Diagnostic Evaluation

1. Thorough inspection of the eye, including eversion of the upper lid to inspect for a foreign object.

2. A slit-lamp examination to determine the extent of the corneal abrasion.
3. Fundoscopic examination may detect abnormalities, such as a dislodged lens, retinal hemorrhage, retinal detachment, or papilledema with increased IOP.
4. Staining with fluorescein dye reveals lesions of the cornea such as abrasions.
5. Assessment of eye function, including near and far acuity, extraocular movements, and visual field testing.
6. CT scan of orbit(s) and brain if concern for fracture or brain hemorrhage.

Management

Most childhood injuries will resolve spontaneously with no adverse long-term consequences. Early detection and prompt intervention may help reduce the incidence of ocular morbidity.

Corneal Abrasion

1. Removal of the offending foreign body, such as contact lens.
2. Antibiotic drops or ointment for superficial abrasion.
3. For infected or inflamed abrasion, antibiotic eyedrops or ointment to prevent infection and anti-inflammatory drops to decrease inflammation.
4. Follow up for any recurrent symptoms because recurrent corneal erosion can occur months or years following injury because of spontaneous disruption of corneal epithelium that occurs near the site of the corneal abrasion.

NURSING ALERT Avoid topical anesthetic after the initial examination because this will slow down the healing process. Avoid the use of contact lens until the abrasion has healed. Patching is no longer recommended because it reduces the removal of pathogens by the tear film.

Blunt Trauma

1. The head should be elevated 45 degrees to facilitate settling of hyphema, if present.
2. Hospitalization may be necessary for noncompliant patients, patients with blood disorders such as sickle cell trait or disease, or if suspicion for child abuse.
3. Surgery may be required because of damage to underlying bones or eye structures.

Perforating Injury

1. Surgery is usually necessary to remove the object and reconstruct damaged tissues.
2. The head should be elevated 30 degrees. Avoid sneezing, nose blowing, and any activity.
3. The child should be kept on nothing-by-mouth status in preparation for surgery. Avoid topical medications. Tetanus toxoid should be given if greater than 7 years since last dose or unknown immunization status.

NURSING ALERT Never remove a penetrating object from the eye. It should be stabilized, and the eye should be shielded with a Fox shield, with no pressure applied. In an emergency, use a foam cup with part of the bottom cut off, if necessary, to support the object. Patch the unaffected eye during transport to the hospital.

Chemical Injury

1. Continuous, gentle flushing of the affected eye(s) with any available water until able to change to normal saline solution or Ringer lactate solution for at least 30 minutes (see page 436) to help remove the offending chemical. Evert the eyelids and flush from the inner aspect of the eye outward to prevent contaminated water from flowing into the other eye. Wash the patient's face and hands.
2. Further management depends on the nature and extent of the injury.

NURSING ALERT Acid chemicals coagulate the conjunctival protein, leaving the blood vessels undamaged. Alkaline chemicals rapidly permeate the eye's structure, thus causing more damage.

Complications

1. Infection.
2. Bleeding.
3. Refractive problems because of corneal scar, cataract, glaucoma, shrinkage of the affected eye, and inflammation of the unaffected eye may result in vision impairment or loss of vision.
4. Disfigurement may result from severe or extensive tissue damage.

Nursing Assessment

1. Obtain history of injury, including the child's account of how the injury occurred, and a description of symptoms experienced.
2. Inspect for location and extent of swelling and bruising, asymmetry, or abnormality in appearance of any part of the eye.
3. Obtain visual history preinjury. Assess visual acuity. This should include near and far acuity in each eye. If the patient cannot see well enough to read a Snellen chart, assess ability to count fingers or perceive light. Compare findings with preinjury visual history.

Nursing Diagnoses

- Acute Pain related to inflammation, photophobia, or trauma to eye tissue.
- Risk for Injury related to impaired vision and adverse effects of pain medications.

- Feeding, Dressing, and Grooming Self-Care Deficit related to impaired vision and adverse effects of pain medications.

Nursing Interventions

Minimizing Pain

1. Apply cold compresses to the affected area to help reduce swelling and discomfort.
2. Keep the child's room as dark as possible to help reduce pain for photophobic patients.
3. Administer analgesics, as prescribed.
4. Encourage quiet activities to act as a distraction to pain.

Preventing Injury

1. Enforce safety measures:
    a. Use of bed side rails.
    b. Assistance with ambulation.
    c. Close observation.

Maintaining ADLs

1. Provide assistance with eating, bathing, toileting, and other ADLs, as needed.
2. Teach child location of self-care items and positioning of food on tray to promote independence.
3. Encourage child to attempt self-care and offer praise even if unsuccessful.

Family Education and Health Maintenance

1. Teach indications for reevaluation by health care provider.
    a. Increase in swelling, tenderness, discoloration, or pain.
    b. Worsening of visual acuity.
    c. Development of additional symptoms, such as fever, alteration in sensorium, or other indications of neurologic injury.
2. Provide safety education to all families to prevent common causes of injury. Encourage families to use protective eyewear when participating in sports or other activities; proper use of infant car seat, booster seat, and seat belt; proper storage of household chemicals.
3. Provide families with information and support as they cope with having a visually impaired child in the home. The American Council of the Blind has multiple resources for families at its Web site (*https://acb.org*).

Evaluation: Expected Outcomes

- Demonstrates decreased pain.
- No injuries reported.
- Dressing and feeding self with minimal assistance.

Functional Problems

Functional problems of the eye involve vision impairment because of refractive errors or disuse of visual pathways. Such problems frequently result in amblyopia—impaired vision in one or both eyes because of poor visual stimulation rather than an structural problem. Abnormal vision screening with referral occurs in 1.2% of 5-year-old patients and increases to 9.1% by the time the child reaches age 13. Amblyopia affects 1% to 3% of the population and 2% to 4% of children in North America.

Pathophysiology and Etiology

1. Refractive errors are usually caused by a genetic predisposition to shortened or elongated eyeballs or by individual variations in growth.
    a. In an elongated or shortened eyeball, the visual image is focused either in front of or behind the retina, resulting in unclear images.
    b. The nearsighted (myopic) child can see near objects, such as print in schoolbooks, but cannot focus clearly on far objects, such as words on the blackboard.
    c. The farsighted (hyperopic) child can see far objects clearly but has difficulty seeing near objects.
    d. The problem may be unilateral or bilateral.
2. Amblyopia may result from any condition that causes the two retinas to receive different images. Etiology may include:
    a. Diplopia caused by strabismus.
    b. Significant difference in acuity of the two eyes.
    c. Cataract.
    d. Unilateral severe ptosis.
3. When a discrepancy exists between images received on the two retinas, the more unclear image is suppressed.
    a. Over time, a young child will become permanently unable to use the visual pathways of the suppressed eye.
    b. Although the visual pathways are structurally normal, the child is visually impaired in that eye because of poor visual stimulation.

Clinical Manifestations

Children usually do not complain that they cannot see well but may exhibit other signs of vision problems, including:

1. Poor academic performance or behavioral problems in school.
2. Dislike for reading.
3. Head tilting.
4. Squinting.
5. Sitting close to the television or holding reading materials close to the face.

6. Refusal or resistance to covering one eye during vision screening.

Diagnostic Evaluation

1. Standardized vision screening tests using optotype symbols such as HOTV or LEA may be used for acuity screening.
   a. Tests can be administered to children as young as age 3 years.
   b. Each eye should be tested separately making sure the nontested eye is occluded.
   c. A 2-line difference between eyes requires referral to an ophthalmologist.

Management

1. Most visual acuity problems can be treated by the use of corrective lenses or refractive surgery.
2. Amblyopia management focuses on prevention through early identification and treatment of conditions that caused it.
   a. Strabismus is treated with patching the stronger eye to strengthen the weaker eye. Glasses may also be prescribed to improve the vision. In some cases, however, surgery may be required.
   b. Topical miotic drops may be used if the child is not able to tolerate the daily patching required to correct amblyopia.
   c. Surgery may also be required to correct ptosis.
   d. Acuity problems because of refractive error are usually managed with the use of corrective lenses.
3. Optimal outcome is accomplished when treatment is begun early in life, whereas visual pathways are still developing. However, some visual function may be recovered even if the problem is treated in adolescence or adulthood. Ideally, the problem can be prevented by early identification and treatment of factors that may cause it.

EVIDENCE BASE DeSantis, D. (2014). Amblyopia. *Pediatric Clinics of North America, 61*(3), 505–518.

Donahue, S. P., Baker, C. N.; Committee on Practice and Ambulatory Medicine, Section on Ophthalmology, American Association of Certified Orthoptists, American Association for Pediatric Ophthalmology and Strabismus & American Academy of Ophthalmology. (2016). Procedures for the evaluation of the visual system by pediatricians. *Pediatrics, 137*(1), 1–9.

Complications

Injuries caused by visual impairment.

Nursing Assessment

1. Begin visual acuity screening early, in the preschool years and whenever a child displays behaviors

suggestive of acuity problems.

2. Assess Hirschberg test for symmetry of the pupillary light reflexes routinely, beginning at birth.
3. Perform the cover–uncover test as part of routine eye assessment.
4. Assess the effect of the functional deficit on the child's overall function, including academic progress, self-esteem, and safety.

Nursing Diagnoses

- Disturbed Sensory Perception (Visual) related to reduced acuity or inability to use one eye.
- Risk for Injury related to impaired visual acuity or lack of depth perception.
- Chronic Low Self-Esteem related to lowered performance caused by poor vision.

Nursing Interventions

Minimizing Effects of Sensory Deficits

1. Encourage the consistent use of corrective lenses, as prescribed.
2. Teach the parents ways to help develop the child's skills in interpreting information through the senses of hearing, smell, and touch.
   a. Familiarize the child with common sounds and smells in the environment. Also, orient the child to traffic sounds and sounds associated with danger, such as animals and speeding vehicles, and instruct the child how to respond.
   b. Use voice or touch, rather than facial expressions or gestures, to express emotion.
   c. Speak to the child before touching to reduce startling.
   d. Allow the child to touch and handle unfamiliar objects to learn about them.
   e. Have the child practice such things as retelling stories and giving the home telephone number and address.
   f. Explain unfamiliar sounds and smells to the hospitalized child.

Preventing Injury

1. Recommend the use of shatterproof eyeglasses with flexible frames.
2. Recommend the use of eye protection on a routine basis because eye trauma can occur unexpectedly. This is especially important for children who rely on only one eye.
3. Suggest extra protection, such as shatterproof goggles or shields, when participating in contact or ball sports and activities.
4. Maintain a stable arrangement of furniture in the home, adequate lighting, and an uncluttered environment to minimize falls.
5. Orient hospitalized children to the hospital room and offer assistance when walking.

Promoting a Positive Sense of Self-Esteem

1. Provide opportunities for mastery of developmentally appropriate activities such as tablet computer

applications.

2. Encourage interactions with sighted children to decrease feelings of isolation. Also, suggest interactions with children with similar alterations in vision.
3. Encourage the child to discuss feelings and strategies for coping with negative peer reactions such as teasing.
4. Encourage independence in self-care activities to promote autonomy, such as dressing, cooking, feeding, and use of bathroom.
5. Assist the patient and family with effective coping mechanisms to promote family stability.

Community and Home Care Considerations

1. Perform a safety inspection of the home environment and make changes as necessary to help prevent falls and other injuries.
2. Assist family access to financial and social resources, as needed.
3. Make sure that the child is receiving early intervention services and individualized educational resources.

Family Education and Health Maintenance

1. Teach the importance of patching for amblyopia and the wearing of corrective lenses, as prescribed, and their proper care.
2. Refer families of blind children to community resources that can help their child learn special skills, such as reading Braille, using a cane, or developing self-care skills. Information can be obtained from agencies such as the American Foundation for the Blind (*www.afb.org*).

Evaluation: Expected Outcomes

- Identifies common sounds.
- No injury reported; wears protective eyeglasses.
- Reports good school performance and participation in extracurricular activities; can eat and dress independently.

CONDITIONS OF THE EAR

Also see Chapter 17 for additional information on ear, nose, and throat problems.

Eustachian Tube Dysfunction

Eustachian tube dysfunction (ETD) is an umbrella term describing disorders that arise from closure of the eustachian tube, which ventilates the middle ear to equalize pressure on both sides of the tympanic membrane. ETD may be associated with otitis media with effusion (OME), also known as serous otitis; acute otitis media (AOM); and recurrent otitis media. Approximately 90% of children experience one or more episodes of middle ear effusion by age 2.

Pathophysiology and Etiology

1. Inflammation of the eustachian tube lining is caused by an acute upper respiratory infection, an allergic response, trauma, or inflammation of middle ear mucosa.
    a. Infected secretions may pass through the tube from the nasal area into the middle ear.
    b. When inflammation and swelling causes the eustachian tube to close, the passage of air into and out of the middle ear is prevented.
    c. The air in the middle ear is absorbed into the middle ear lining and a vacuum is created.
    d. The vacuum is filled by serous fluid that seeps out of the middle ear lining.
    e. The warm, moist environment of the middle ear and nutrients in the serous fluid are conducive to the growth of viruses or bacteria that may be present in the middle ear cavity.
2. Children between ages 6 and 24 months are predisposed to the development of AOM because their short, floppy, relatively straight eustachian tubes more easily allow the passage of infected nasal secretions into the middle ear cavity. See Box 47-1 for additional risk factors.
3. Viruses account for 15% to 20% of AOM cases. In 30% of AOM cases, there is no identifiable bacterial pathogen. The most common bacterial agents include:
    a. *S. pneumoniae*.
    b. Nontypeable *H. influenzae*.
    c. *Moraxella catarrhalis*.
4. Barotrauma, caused by rapid changes in atmospheric pressure, may also lead to closure of the eustachian tube and to the development of serous otitis. This is less likely to involve introduction of microorganisms through infected nasal secretions; development of AOM is less common.

BOX 47-1 Risk Factors for Eustachian Tube Dysfunction

- Frequent episodes of upper respiratory infections in younger children.
- Nasal allergies.
- Genetic predisposition to floppy eustachian tube.
- Native American or Eskimo heritage.
- Craniofacial abnormalities such as cleft lip and palate and Down syndrome.
- Enlarged adenoids.
- Lower socioeconomic status.

- Exposure to tobacco smoke.
- Bottle-feeding.
- Male gender.
- Day care attendance with greater than six attendees.
- Parental or sibling history of OM.
- Immune deficiencies such as cystic fibrosis.

EVIDENCE BASE Chonmaitree, T., Trujillo, R., Jennings, K., et al. (2016). Acute otitis media and other complications or viral respiratory infection. *Pediatrics, 137*(4), 1–10.

Clinical Manifestations

1. OME—decreased hearing, sensation of fullness in the affected ear(s) without pain or fever.
2. AOM—ear pain (otalgia) and signs of infection fever, fussiness, or decreased appetite.
3. ETD—popping sensations in the affected ear(s).

Diagnostic Evaluation

1. Otoscopic examination.
   a. OME—nonpurulent mucoid or serous effusion, prominent bony landmarks, a diffuse light reflex, and decreased mobility of tympanic membrane.
   b. AOM—inflamed tympanic membrane with purulent effusion and decreased or absent mobility; bulging of the tympanic membrane may obscure the bony landmarks and light reflex.
2. Tympanometry—quick and simple way to assess tympanic membrane mobility in children over 7 months of age
   a. A probe occludes the ear canal while pressure is varied and a test sound is emitted. The test produces a graphic display that shows the mobility of the tympanic membrane at various air pressures. A normal reading has a distinct peak in the middle of the graph.
   b. A flat tympanogram (no peak) indicates lack of mobility of the tympanic membrane, usually caused by serous otitis or AOM.
   c. A peak to the left of the center indicates negative pressure in the middle ear.

Management

EVIDENCE BASE Rosenfeld, R. M., Shin, J. J., Schwartz, S. R., et al. (2016). Clinical practice guideline: Otitis media with effusion (update). *Otolaryngology-Head and Neck, 154*(1 suppl), S1–S41.

American Academy of Family Physicians, American Academy of Otolaryngology- Head and Neck Surgery, American Academy of Pediatrics Subcommittee on Otitis Media With Effusion. (2004). Otitis media with effusion. *Pediatrics, 113*(5), 1412–1429.

Otitis Media with Effusion

1. Usually resolves spontaneously, but 30% to 40% of patients have repeated episodes, and approximately 25% have persistent effusion after 3 months.
2. OME is the leading cause of hearing loss, so interval visits for reexamination and hearing testing should be done. Hearing levels (HLs) of ≥40 dB requires an immediate, complete audi ologic evaluation and may indicate pressure equalization tubes (PETs). Persistent effusions of greater than 3 months and any concern for speech and language delay indicate need for referral to an otolaryngologist.
3. Patients less than 4 years of age with persistent OME should have PETs placed, and patients 4 years of age and older should have PETs placed with or without adenoidectomy.
4. Pharmacology treatment such as antihistamines, decongestants, antimicrobials, and corticosteroids is not indicated.
5. Tonsillectomy is not recommended.

EVIDENCE BASE Lieberthal, A. S., Carroll, A. E., Chonmaitree, T., et al. (2013). The diagnosis and management of acute otitis media. *Pediatrics, 131*(3), e964–e999.

Acute Otitis Media

1. All infants and children should be assessed for pain and inflammation of the inner ear.
2. All infants under age 6 months with presumed or certain AOM should be treated with antibiotics and analgesics.
3. Children ages 6 to 24 months with certain AOM accompanied by acute onset, moderate or severe otalgia, or temperature 39°C (102.2°F) or higher should be treated. Infants with unilateral AOM but no severe symptoms may be monitored. Those with bilateral AOM or severe symptoms should receive antibiotic therapy.
4. For children over age 2 years, observation may be considered for those with certain AOM but who do not have severe illness.
5. If not treating, the clinician should ensure that an adult caregiver is able to observe the child, recognize signs of serious illness, and be able to provide prompt access to medical care if improvement does not occur. If there is worsening of illness or no improvement in 48 to 72 hours, antibacterial therapy should be considered.
6. First-line treatment includes amoxicillin (80 to 90 mg/kg divided in 2 divided doses) or, for the penicillin allergic, cefdinir (14 mg/kg in 1 or 2 doses), cefuroxime (30 mg/kg in 2 divided doses), or cefpodoxime

(10 mg/kg in 2 divided doses) for 10 days.

7. Children who have received amoxicillin in the past 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent AOM unresponsive to amoxicillin should receive high-dose amoxicillin–clavulanate (90 mg/kg/day of amoxicillin with 6.4 mg/kg/day of clavulanate in 2 divided doses).
8. Alternative antibiotics for treatment failures include ceftriaxone (50 mg/kg/day IM or IV for 3 days) or clindamycin (30 to 40 mg/kg/day in 3 divided doses), with or without a second- or third-generation cephalosporin.

Recurrent Otitis Media

1. Placement of ventilating tubes by myringotomy (incision into the tympanic membrane) may be considered for children who experience three or more episodes in 6 months or four or more episodes per year (see Figure 47-1).
2. Antibiotic prophylaxis is no longer recommended because it may contribute to the problem of antibiotic-resistant bacteria.

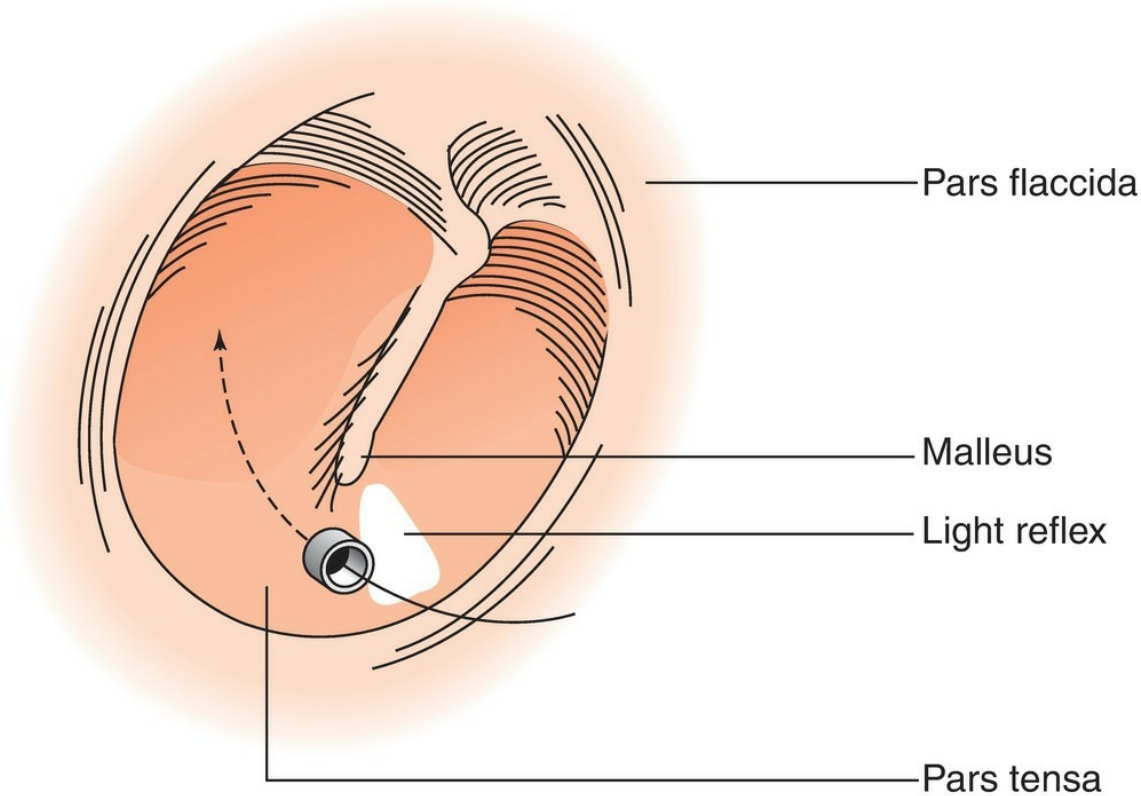

Figure 47-1. A ventilating (myringotomy) tube provides air to the middle ear to prevent otitis media. (From Pillitteri, A. [2013]. *Maternal and child health nursing: Care of the childbearing and childrearing family* [7th ed.]. Philadelphia, PA: Lippincott Williams & Wilkins.)

Complications

1. Perforations of the tympanic membrane, scarring because of healed perforations, or damage to the

ossicles of the middle ear may occur; permanent hearing loss is a rare complication.

2. Delayed speech and language development.
3. Mastoiditis, meningitis, lateral sinus thrombosis, or intracranial abscess; spread of bacterial infection may occur, although all are uncommon.

Nursing Assessment

1. Assess for etiologic factors that contribute to ETD.
2. Assess for symptoms of serous otitis and AOM to identify and to document the nature and severity of the illness.
3. Assess hearing after the middle ear effusion is resolved. Promptly identify any hearing loss that may have social and educational consequences.
4. Assess speech and language development in children who experience recurrent or prolonged infections to determine deficits.
5. Assess for effects of illness on family, such as sleep deprivation of parents caused by staying up with child at night or decreased attendance at work caused by keeping child out of school.

NURSING ALERT Prompt identification of speech and language delays is important in young children because speech and language development is quite rapid at this time. Young children may demonstrate either rapid regression or failure of progression of speech and language skills.

Nursing Diagnoses

- Acute Pain related to increased pressure in the middle ear.
- Impaired Verbal Communication caused by conductive hearing loss.

Nursing Interventions

Minimizing Discomfort

1. Administer and teach parents to administer antibiotics. Provide instruction in:
   a. Measurement of correct dosage.
   b. Time of doses.
   c. Importance of administering all doses.
   d. Proper storage and disposal of unused medication.
   e. Adverse effects.
2. Administer acetaminophen or ibuprofen, as directed, for pain or fever.
3. Apply warm compresses to the external ear.
4. Advise elevation of head to facilitate drainage of fluid from the middle ear into the pharynx.

5. Teach older children to stimulate opening of their eustachian tubes by yawning or performing Valsalva maneuver.

Facilitating Verbal Communication

1. Assess hearing, speech, and language development regularly.
2. Alert parents to report signs of hearing difficulty or delayed speech immediately to ensure early intervention.
3. Refer to a specialist for evaluation and treatment, if necessary.

Family Education and Health Maintenance

1. Teach parents that episodes of otitis may be minimized by:
   a. Breast-feeding.
   b. Placing older, bottle-fed infants in a sitting position during feeding.
   c. Identifying and eliminating allergens, such as particular foods, molds, and dust.
   d. Not exposing the child to cigarette smoke.
   e. Immunization with pneumococcal and influenza vaccines.
2. Teach the importance of taking antibiotics at prescribed times for the indicated length of therapy to prevent partial treatment and the development of resistance.
3. Teach all parents the difference between viral and bacterial infections, emphasizing that overuse of antibiotics for viral infections contributes to the development of resistant bacteria.
4. If ventilating tubes are placed, instruct parents to do the following.
   a. Prevent water or other fluids from entering the ear canal. Encourage use of earplugs when the child is bathing or swimming.
   b. Discourage instillation of eardrops or other medications in the external ear unless they have been prescribed by the health care provider.
   c. Tubes will fall out of the ear spontaneously, usually in 6 to 12 months.

EVIDENCE BASE Pettigrew, M. M., Alderson, M. R., Bakaletz, L. O., et al. (2017). Research conference report from the 18th international conference on recent advances in otitis media—Panel 6: Vaccines. *Otolaryngology–Head and Neck Surgery, 156*(4 suppl), S76–S87.

Evaluation: Expected Outcomes

- Demonstrates improved comfort; family states proper treatment regimen.
- Speech and language development appropriate for age; reports regular assessment; receives therapy from specialist, if indicated.

External Otitis

Acute *otitis externa* is inflammation in the external ear canal. It is frequently unilateral but may be bilateral. Commonly known as "swimmer's ear."

Pathophysiology and Etiology

1. Caused by bacteria or fungi. Common pathogens include:
    a. *Pseudomonas aeruginosa.*
    b. *Staphylococcus aureus.*
    c. *Proteus mirabilis.*
    d. *Streptococcus pyogenes.*
    e. Fungi *(Candida*, *Aspergillus)*.
2. Risk factors include:
    a. Frequent swimming.
    b. Insertion of objects, such as cotton swabs, into the ear canals.
    c. AOM with perforation of the tympanic membrane.
    d. Ventilation tubes with drainage.
    e. Poorly fitting ear plugs.
3. When water remains in the external ear canal, a warm, moist environment is created.
4. Skin lining the canal is irritated, causing breakdown of its protective barrier.
5. Bacteria or fungi overgrow in the conducive environment and cause symptoms of inflammation and infection in 1 to 2 days.
6. Breakdown of protective barrier and introduction and proliferation of infectious organisms can also occur through trauma to the ear canal, such as cleaning the ear with an inappropriate object or using an improper technique.

Clinical Manifestations

1. Intense ear pain, itching, and white, yellow, or greenish drainage.
2. Inflammation of the external ear canal and structures.
3. Pain when the ear pinna is manipulated.

Diagnostic Evaluation

1. Otoscopic examination may be difficult because of severe pain and swelling; redness, swelling, and drainage in external canal are noted while tympanic membrane appears normal.
2. Ear pain may be severe.
3. Cellulitis of the surrounding structures can result in displacement of the external ear out and away from the head.
4. Cultures are usually not necessary.

Management

1. Ear pain may be severe, and appropriate analgesia should be provided.
2. Effective topical treatments include acetic and boric acid solutions, which dry and modify the pH of the ear canal.
3. Topical antibiotic solution, possibly combined with a steroid to reduce significant discomfort and swelling.
4. Ear canal may be gently cleansed with curette, cotton swab, mild suctioning, or irrigation to remove drainage.
5. An ear wick may be used to aid in medication getting to the lining of the deeper ear canal.
6. Oral antibiotics may be used in addition to topical medications in severe cases or if cellulitis extends beyond the external canal.

Nursing Assessment

1. Assess severity of symptoms and need for pain relief.
2. Assess ear hygiene and the need for earplugs.

Nursing Diagnosis

- Acute Pain related to inflammation and irritation of drainage.

Nursing Interventions

Relieving Pain

1. Administer eardrops or teach parents administration, as prescribed.
    a. Have child lie on side with affected ear upward.
    b. Instill drops, using caution not to contaminate dropper, and press gently on tragus.
    c. Have child maintain position for 5 minutes to facilitate penetration of medication into ear canal.
    d. Repeat on other side, if ordered.
2. Administer analgesics, such as acetaminophen or ibuprofen, as directed.
3. Suggest application of warm or cold compresses to outer ear to relieve discomfort.
4. Frequently clean drainage from area surrounding opening of ear canal to relieve irritation.

Family Education and Health Maintenance

1. Teach proper ear hygiene.
    a. Insert nothing into ear canal for cleaning or scratching.
    b. Clean the outer area with a washcloth only.
    c. Drain water promptly from ear by leaning the child over and pulling auricle slightly downward and outward.
2. Instruct in the use of well-fitting earplugs, if necessary.

3. Instruct in the use of routine acetic acid solution instillation after water activity, if prescribed.

Evaluation: Expected Outcomes

- Reports pain relieved; uses compresses and analgesics, if necessary.

Functional Hearing Disorders

Functional hearing disorders arise from problems in the function of the ear. In a quiet environment, the healthy child can hear tones between 0 and 25 dB. Categories of hearing impairment include slight, 15 to 25 dB; mild, 25 to 40 dB; moderate, 40 to 65 dB; severe, 65 to 95 dB; and profound, 95 or more dB. In the United States, moderate to profound bilateral sensorineural hearing loss occurs in 0.5 to 1.0 per 1,000 live births each year. Factors that place an infant at high risk for hearing loss include low birth weight, craniofacial anomalies, family history of hereditary childhood hearing loss, and certain infections, such as rubella or bacterial meningitis.

Pathophysiology and Etiology

1. Hearing loss may be conductive, sensorineural, or mixed.
2. Conductive loss may uncommonly result from a congenital ear deformity. More commonly, conductive loss is acquired and occurs when sound transmission through the outer and/or middle ear is impaired, caused by impaction of cerumen in the external ear canal, fluid in the middle ear cavity, or scarring of the tympanic membrane.
    a. A mechanical obstruction, such as cerumen or a foreign object blocking the external ear canal, may block the passage of sound waves to the tympanic membrane.
    b. With otitis media or OME, fluid in the middle ear cavity does not transmit sound as well as air.
    c. A scarred or perforated tympanic membrane has lost its normal mobility and does not transmit sound as well as a normal one.
    d. Most cases of conductive hearing loss in children are reversible and produce no permanent effect.
3. Sensorineural hearing loss results from damage to the cochlea or auditory nerve and congenital defects of the cochlea. Examples include damage caused by ototoxic drugs, damage resulting from prenatal infections, and damage caused by prolonged exposure to loud noise.
    a. Damage to the auditory nerve prevents transmission of sound impulses to the brain for interpretation.
    b. Damage to hair cells of the cochlea may be caused by prolonged exposure to loud noise, resulting in hearing loss, especially pronounced for high-pitched sounds.
    c. Sensorineural problems are usually irreversible.

Clinical Manifestations

1. Infants may be noted to be unresponsive to sound. Response to sound, however, is not sufficiently reliable as a screening method, especially for high-risk infants.
2. Children usually do not complain that they cannot hear well. They may exhibit other signs of hearing problems, including:
    a. Poor academic performance or behavior problems in school.
    b. Lack of response to sounds.
    c. Delayed language development.

d. Listening to the television or radio at a loud volume.

e. Speaking loudly.

Diagnostic Evaluation

EVIDENCE BASE Harlor, A. D, Jr., Bower, C.; Committee on Practice and Ambulatory Medicine. (2009). Hearing assessment in infants and children: Recommendation beyond neonatal screening. *Pediatrics, 124,* 1252–1263.

Bass, P. F. (2016). *Hearing loss & the pediatrician*. Available: *www.ContemporaryPediatrics.com*, 14–17.

---

1. Universal newborn hearing screening using a two-stage process is advocated by the American Academy of Pediatrics and the Agency for Healthcare Research and Quality and is widely accepted as the standard of care for infants in the United States. This is accomplished by an initial automated transient evoked otoacoustic emission (OAE) before discharge from the hospital newborn nursery. If indicated, an automated auditory brain response test is used to confirm a positive OAE screen.
2. Infants who fail their initial screening need a follow-up evaluation at 1 month of age. Any infants with a second abnormal result should be evaluated by an audiologist as soon as possible. Infants with risk factors such as sepsis at birth requiring antibiotics require a repeat hearing evaluation at 3 months of age.
3. Infants with documented hearing loss need referral to specialists (otolaryngology and ophthalmology) by 3 months of age. Referral to other subspecialists (genetics, nephrology, neurology, etc.) may be necessary. The infant should be enrolled in Early Intervention Services (Part C) through the local school system in the United States no later than 6 months of age, which will supply physical therapy, occupational therapy, speech therapy, and visual intervention, as indicated.
4. Infants whose initial hearing screen is normal should be routinely assessed for their response to sound and achievement of developmental speech language milestones.
5. Routine audiometric screening should be done beginning as soon as the child can cooperate and follow instructions (between ages 3 and 5 years). It is important that the child be screened and hearing deficits addressed before entry into school.

Management

1. Treatment of the underlying problem, such as impacted cerumen or otitis media.
2. Hearing aids may be helpful for both conductive and sensorineural hearing loss.
3. Cochlear implants help some children with sensorineural hearing loss.
   a. Consists of an external microphone and speech processor, which sends radio signals to an internal electrode array implanted in the cochlea.
   b. Most effective in the young child who has had shorter hearing deprivation but requires a long period of rehabilitation.

4. If the problem cannot be corrected, the focus of treatment is on development of adaptive skills through special education, sign language or other communication alternatives, and/or technical devices for the hearing impaired.

Complications

1. Speech and language delays.
2. Inadequate social development.
3. Academic failure.

Nursing Assessment

1. Periodically assess hearing in the child with an identified hearing impairment to follow up promptly on changes in ability to hear.
2. Assess speech and language development frequently so that children may obtain special assistance, as indicated.
3. Assess social development and academic progress periodically so that counseling and intervention can be instituted.

Nursing Diagnoses

- Disturbed Sensory Perception (Auditory) related to limited ability to hear.
- Impaired Verbal Communication related to inability to hear and imitate speech sounds.
- Risk for Injury related to inability to hear warning sounds of impending danger.
- Chronic Low Self-Esteem related to social and academic difficulties.

Nursing Interventions

Minimizing Effects of Hearing Loss

1. Face the child, use appropriate facial expressions, and make sure the child can see your face clearly when communicating.
2. Approach the child so that you can be seen; touch the deaf child on the shoulder to get attention.
3. Assist the child in utilizing hearing aid, as prescribed, or assistive technology.

Promoting Effective Communication

1. Determine usual method of communication: ability to write, using verbal cues, or reading lips. Do not depend on gestures to communicate with child or with a third party who does not know sign language.
2. Obtain an interpreter, when necessary, for children who communicate using sign language. Adequate communication is especially important when providing health education or when treating children who may have been abused.
3. Help the parents of a young child to stimulate and communicate with him or her using visual language.
    a. Teach them to use gestures, mime, and nonverbal communication.

b. Teach them to help the infant to develop watching behavior by giving rewards of pleasure and praise.
c. Teach them to talk to the child while looking directly into his or her eyes and using appropriate facial expressions.

Preventing Injury

1. Advise parents that home safety devices, such as smoke detectors, may require visual or tactile alarms (flashing lights or vibration) rather than auditory alarms.
2. Encourage the use of other senses to compensate for inability to hear. For example, the child should be especially careful to look in all directions when crossing the street.
3. Do not leave the child alone in an unfamiliar environment without means of communication.
4. Provide close surveillance and frequent visual contact for the hospitalized child.

Increasing Self-Esteem

1. Inform families of the child's right to a public education in the least restrictive setting and promote use of augmented communication devices.
2. Encourage interaction with hearing and nonhearing children to promote integration.
3. Encourage mastery of developmental milestones and skills through self-care activities and play.
4. Help parents understand that the child may not be able to express anxiety or frustration and may act out instead.
5. Teach them to be consistent in their use of discipline and to provide alternative ways for the child to gain attention or to relieve stress.
6. Praise the child for accomplishments and attempts at social interaction.

Family Education and Health Maintenance

1. Encourage families to learn sign language and alternative methods of communication with the child.
2. Advise on proper hearing aid cleaning and maintenance.
3. Encourage attention to health maintenance needs, such as immunizations and well-child visits.
4. For additional support and information, refer to groups such as the American Society for Deaf Children (*deafchildren.org*).

Evaluation: Expected Outcomes

- Responds appropriately to environmental stimuli.
- Communicates effectively through sign language, interpreter, and visual cues.
- Reports no injuries.
- Reports adequate progress in school and participation in extracurricular activities.

TRANSITIONAL CARE ALERT Patients discharged with ear conditions and disorders may

require complex care at home. Family caregivers may not be experienced in administering otic medications and will require detailed instructions. Education may also be required if a child is discharged without an intact tympanic membrane (conditions that resulted in a perforation or surgical intervention for tympanostomy tubes) for injury and infection prevention. Children discharged to home with acute or chronic ear conditions may not have full hearing ability, and safety measures should be reviewed.

Failure to Thrive/Malnutrition

Hypertrophic Pyloric Stenosis

Celiac Disease

Diarrhea

Hirschsprung Disease

Intussusception

Anorectal Malformations

COMMON PEDIATRIC GASTROINTESTINAL DISORDERS

Cleft Lip and Palate

Cleft lip and palate are congenital anomalies, known as *orofacial clefts*, resulting in structural facial malformation. These defects are usually present in early fetal development, are one of the most common birth defects in the United States, and are associated with any of more than 400 syndromes. The lip, or the lip and palate, fails to close in approximately 1 in every 1,000 neonates. This equals approximately 7,000 infants born each year in the United States. Infants born with cleft lip with or without cleft palate number 4,440 per year.

Cleft lip and palate are most prevalent among Native Americans. Cleft lip (with or without cleft palate) occurs more frequently in males, and isolated cleft palate is more frequent in females. The chance of having a child with an orofacial cleft increases if one or both parents have a defect and if there is a sibling born with a defect.

---

1. A failure of fusion of lip/palate tissue between 5 and 7 weeks of gestation, resulting in defect in morphogenesis. It involves patterns of DNA signaling, gene and biochemical organizers, nuclear and cellular differentiation, proliferation, and migration. A major impact is at the level of the neural crest cell.
2. Although the syndrome is not well understood, genetic/hereditary factors may play a role; a fetus with an affected parent or sibling has a 3% to 5% risk of being affected.
3. In 2004, a gene variant was identified as being a major contributor to orofacial clefts. This gene variant may triple the risk of developing the defect in signaling and transcription proteins that are involved in development and differentiation. There is a 50% risk in monozygotic twins.
4. Environmental factors may include the following:
    a. Vitamin B and folic acid deficiency. Some studies have shown that consumption of multivitamins with folic acid prior to conception and during the first trimester may lower the incidence of cleft lip and palate. A study by the National Institute of Environmental Health Sciences in 2007 suggests taking a multivitamin containing 400 mcg of folic acid. New data suggests a correlation between

Vitamins A and D and cleft palate phenotypes.

b. Medications taken during pregnancy, including antiseizure drugs and corticosteroids.

c. Maternal alcohol and smoking.

d. Infections.

e. Diabetes.

EVIDENCE BASE Sarwer, D., Kazak, A., Clarke, A., et al. (2017). Body Image and Quality of Life in Adolescents with Craniofacial Conditions. *Cleft Palate- Craniofacial Journal, 54*(1), 2–12.

Types of Defects

1. Cleft lip—prealveolar cleft (see Figure 48-1):
   a. Varies from a notch in the lip to complete separation of the lip into the nose.
   b. May be unilateral or bilateral.
   c. Failure of maxillary process to fuse with nasal elevations on frontal prominence; normally occurs during 5th and 6th weeks of gestation.
   d. Merging of upper lip at midline complete between 7th and 8th weeks of gestation.
2. Isolated cleft palate—postalveolar cleft:
   a. Cleft of uvula.
   b. Cleft of soft palate.
   c. Cleft of both soft and hard palate through roof of mouth.
   d. Unilateral or bilateral.
   e. Failure of mesodermal masses of lateral palatine process to meet and fuse; normally occurs between 7th and 12th weeks of gestation.
3. Submucous cleft:
   a. Muscles of soft palate not joined.
   b. Not recognized until child talks; cannot be seen at birth.
4. Pierre Robin syndrome—cleft palate, glossoptosis (tongue lays back on pharynx), and micrognathia (underdeveloped mandible):
   a. This causes feeding difficulties, potential airway obstruction by tongue, slow weight gain, and ear infections.
   b. By age 3 to 4 months, the mandible has grown enough to accommodate the tongue, and respiratory difficulty is greatly diminished.

Figure 48-1. Cleft lip. (Nath, J. [2016]. *Stedman's Medical Terminology* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins.)

Clinical Manifestations

1. Physical appearance of cleft lip or palate:
   a. Incompletely formed lip—varies from slight notch in vermilion to complete separation of lip.
   b. Opening in roof of mouth felt with examiner's finger on palate.
2. Eating difficulty:
   a. Suction cannot be created for effective sucking.
   b. Food returns through the nose.
3. Nasal speech.
4. Increased incidence of otitis media, which may lead to mild to moderate hearing loss.
5. Speech delay secondary to lip defect as well as related to chronic otitis media.
6. Dental problems.

Diagnostic Evaluation

EVIDENCE BASE Woo, A. (2017). Evidence-based medicine: Cleft palate. *Plastic & Reconstructive Surgery, 139*(1), 191e–203e.

1. Prenatal ultrasonography to detect cleft lips and some cleft palates *in utero*.
2. Magnetic resonance imaging (MRI) and three-dimensional computed tomography to evaluate extent of abnormality before treatment.
3. Photography to document the abnormality.
4. Serial x-rays before and after treatment.
5. Dental impressions for expansion prosthesis.
6. Genetic evaluation to determine recurrence risk.

Management

EVIDENCE BASE Burg, M., Chait, Y., Yao, C., et al. (2016). Epidemiology, Etiology, and Treatment of Isolated Cleft Palate. *Frontiers in Physiology, 7*(67), epages.

Interdisciplinary approach begins early and continues into late adolescence. Craniofacial team consists of a plastic surgeon, otolaryngologist, pediatric dentist, prosthodontist, orthodontist, feeding specialist, speech pathologist, audiologist, geneticist, psychologist, and community health nurse. Each team member has a role at some point in the child's care.

1. General management is focused on proper growth and nutrition, closure of the clefts, prevention of complications, oral–motor rehabilitation, and facilitation of normal growth and development of the child.
2. Patients with isolated cleft lips have a greater chance of overcoming feeding difficulties than do those with combined defects.
3. The cleft lip is repaired before the palate defect, generally around age 3 months.
    a. Techniques performed include the Millard repair, which results in a zigzag scar on the lip, or placement of sutures where the line of the columella would have been.
    b. The surgical goals are adherence and the most cosmetically pleasing and naturally appearing lip.
4. Cleft palate repair may be done any time between ages 6 and 18 months. Surgery and timing are based on degree of deformity, width of oropharynx, neuromuscular function of palate and pharynx, and surgeon's preference. Some children may require more than one reconstructive surgery.
    a. Palatoplasty is the reconstruction of the palatal musculature.
    b. The surgical goal is adherence, development of normal speech pattern, and safe/appropriate eating

skills. Additionally, it should decrease the incidence of otitis media.

c. Surgery may be performed by craniofacial or plastic surgeon in conjunction with other specialists, including oral surgeon and dentist.

Complications

1. Respiratory distress.
2. Infection.
3. Palatal fistulas.
4. Dehydration and electrolyte imbalance.
5. Bleeding.

Nursing Assessment

1. If the newborn has a cleft lip, assess for cleft palate by direct visualization and palpation with finger.
2. Obtain family history of cleft lip or palate.
3. Evaluate feeding abilities.
   a. Effectiveness of suck and swallow.
   b. Amount taken.
   c. Vomiting, regurgitation, or formula coming from nose.
4. Observe for other syndromic features, such as small jaw, abnormal facies, micro/macrocephaly, heart murmur, anal–rectal defects.

Nursing Diagnoses

- Ineffective Infant Feeding Pattern related to defect.
- Risk for Infection related to open wound created by malformation, ear infections.
- Risk for Impaired Attachment related to malformation and special care needs of the infant.
- Risk for Aspiration related to tongue and palate deformities in Pierre Robin syndrome.
- Deficient Knowledge related to home management of infant with cleft malformation.
- Fear related to surgery.
- Deficient Knowledge related to postoperative care.

Nursing Interventions

EVIDENCE BASE Baylis, A. L., Pearson, G. D., Hall, C., et al. (2018). A quality improvement initiative to improve feeding and growth of infants with cleft lip and/or palate. *The Cleft Palate Craniofacial Journal*, Jan 01, 1545–1569.

Maintaining Adequate Nutrition

1. Facilitate nutrition and speech therapy for all infants.
2. Encourage the mother to begin feeding the infant as soon as possible to enhance bonding and to strengthen the oral structures needed for mastication and speech production.
3. If sucking is permitted:
   a. Encourage breast-feeding.
   b. Encourage and demonstrate breast pump.
   c. Use a soft nipple with crosscut to facilitate feeding.
4. If sucking is ineffective because of inability to create a vacuum, try alternate oral feeding methods.
   a. Feeding devices include preemie nipple, crosscut nipple, NUK nipple, Ross Cleft Palate Nurser, Mead Johnson Cleft Palate Nurser, Pidgeon nipple bottle system, Haberman Feeder, or palatal obturator.
   b. Avoid enlarging nipple holes because of infant's inability to control flow of milk, which will result in choking. Crosscut nipples allow milk to flow only when infant squeezes the crosscut open.
   c. Using a squeezable bottle (eg, Mead Johnson Cleft Palate Nurser) or plastic liner can be helpful by applying rhythmic pressure along with the infant's normal sucking and swallowing.
   d. Rubber-tipped Asepto syringe or dropper; the rubber extension should be long enough to extend back into the mouth to prevent regurgitation through the nose. Direct tip to side of mouth and feed slowly.
5. Feed infant in an upright, sitting position or the upright side-lying position if airway support is needed. This decreases possibility of fluid being aspirated or returned through the nose or back to the auditory canal.
   a. Feeding is usually easier if the nipple is angled to the side of the mouth away from the cleft so that the infant's tongue can press the nipple against the upper gum or dental arch.
   b. Feed slowly over approximately 18 to 30 minutes. Feedings longer than 45 minutes expend too many calories and tire the infant.
   c. Smaller but more frequent feedings may be necessary if the infant tires or requires extended time to eat.
   d. Burp frequently during feeding to decrease amount of air swallowed.
   e. If micrognathia exists, use of the pinky finger under the chin for support aids in improved sucking ability.
   f. Feed the infant before he or she becomes too hungry. If the infant is too agitated, feeding becomes a problem.
6. Administer enteral tube feedings if nipple feeding is to be delayed.
7. Advance diet as appropriate for age and needs of infant. Eating usually improves when solids are introduced because they are easier for the infant to manipulate.
8. Assess and calculate adequate nutritional intake.

Preventing Infection

1. Protect the child from infection so that surgery will not be delayed.
    a. Use and teach good hand-washing practice.
    b. Avoid patient contact with anyone who has an infection.
    c. Provide frequent assessment for otitis media.
2. Clean the cleft after each feeding with water and a cotton-tipped applicator.
3. Observe for fever, irritability, redness, or drainage around cleft and report promptly.
4. Monitor vital signs; report temperature greater than 101˚F (38.3˚C).

Promoting Acceptance and Adjustment

1. Show acceptance of the infant; maintain composure and do not show negative emotion when handling the infant. The manner in which the nurse handles the infant can make a lasting impression on the parents.
2. Support parents when showing a neonate for the first time. Demonstrate acceptance of the infant's and the parents' feelings. Parents may be grieving about the infant's cosmetic imperfections and may harbor ambivalent feelings.
3. Offer information and answer any questions in a simple, matter-of-fact manner. The better informed the family, the easier it will be for them to see the infant as a normal child with a physical difference that will require surgery, dental work, and possibly speech therapy.
4. Be aware that the normal sequence of parental responses may include shock, disbelief, worry, grief, and anger and then proceed to a state of equilibrium and reorganization.
5. Encourage parental involvement in infant's care: frequent holding, cuddling, and playing.

Preventing Aspiration and Airway Obstruction

1. Prevent respiratory obstruction by the tongue, especially on inspiration and when the infant is quiet.
    a. Positioning: elevated and side-lying.
    b. Tilt head back as tolerated by the infant, and elevate upper trunk slightly.
    c. Tongue/lip suture may be placed by otolaryngologist to prevent the tongue from interfering with airway. Assess for slippage, infection, pain, interference with eating.
    d. Suction nasopharynx, as needed.
2. Infants with Pierre Robin syndrome are at greater risk for airway compromise, especially when feeding.
    a. Feeding can be done with a nursing bottle (feeding techniques similar to those used for cleft palate).
    b. Generally use orthopneic position—vertical and slightly forward; this allows the infant to push the jaw forward to suck and allows the feeder a clear view of the infant.
    c. Use gentle finger pressure at mandibular attachment to bring the jaw forward.

Preparing for Home Management

1. Prepare family for home feedings by providing several days to practice feeding and to become familiar with the infant's feeding pattern.

2. Alert the caregiver to difficulties with feeding and how to manage them.
    a. Nasal regurgitation: feed in more upright position or stop feeding and allow the infant to cough and clear the airway; then continue with smaller feedings.
    b. Respiratory distress: feed slowly, give smaller feedings. Observe for signs of aspiration, such as coughing, color changes, increased respiration, fever, and/or formula coming from nose.
    c. Prolonged feeding: if oral feedings take longer than 20 to 30 minutes, energy expenditure increases. Smaller, more frequent feedings are indicated, or enteral tube feeding supplements may be warranted.
3. Suggest that about 1 week before scheduled admission for surgery, the mother begin using feeding techniques preferred by multidisciplinary team. Infants who feed well prior to surgery may do better postoperatively than poor feeders.
4. Encourage the parents to prepare siblings at home for the arrival of the infant. Suggest they show a picture of the new infant.
5. Offer parents available resources regarding children with cleft lip and palate.
6. Encourage parental involvement with local self-help groups that provide information and parent-to-parent contact.
7. Initiate referrals, as indicated, for additional support and financial assistance and early intervention programs.
8. Describe and reinforce surgical treatment plans to the parents to promote communication and hope.
9. Stress compliance with follow-up care with the pediatrician, plastic surgeon, dentist, orthodontist, psychologist, and speech therapist to prevent chronic otitis media, hearing loss, speech impairment, and emotional problems.
10. Initiate a community nurse referral to continue emotional support and teaching progress at home.

Providing Preoperative Care and Allaying Fear in the Child Undergoing Surgery

1. Prepare the infant or toddler for the postoperative experience to decrease fear and increase cooperation.
    a. Practice the feeding measure that will be used postoperatively—cup, side of spoon, or syringe.
    b. Use elbow immobilizers for short periods; allow the child to play with them and the caregiver to use them. Check your facility's policy regarding the use of immobilizers because this is considered a form of restraint but may be deemed medically necessary.
    c. Demonstrate and practice mouth irrigation because it will be done postoperatively for cleft palate repair; allow the child to assist if age appropriate.
2. Prepare the parents emotionally for the postoperative appearance of the child.
    a. Explain the use of the Logan bow (a curved metal wire that prevents stress on the suture line for cleft lip repair) and restraints.
    b. Encourage a parent to be with the child, especially when awakening from anesthesia, to offer security and comfort.
3. Address and explain pain management, collaborating with the parents as to what comforts their child.

Providing Postoperative Care

1. Protect surgical site:
    a. Apply elbow immobilizers to prevent hands from reaching the mouth while still allowing some freedom of movement; follow your institution's policy regarding medical restraints.
        i. Assess the patient's skin and/or intravenous (IV) line every 2 hours while the immobilizer is in place.
        ii. Remove the immobilizer to exercise the arms.
        iii. Do not allow anything in the child's mouth, such as straw, eating utensils, or fingers.
2. Maintain adherence device: check that Logan bow or other device is intact and maintaining adherence of lip repair.
    a. Prevent wetting tape or it will loosen.
    b. Observe for and report bleeding or dislodgement of Logan bow.
3. Prevent the child from stressing the suture site—not crying, blowing, sucking, talking, or laughing.
4. Assess and manage pain.
    a. Consult institution's pain management team, if necessary.
    b. Use pain medications appropriate for age, weight, and condition.
    c. Use pain assessment tools appropriate for age (see page 1150).
    d. Recognize signs of pain, such as crying, agitation, poor feeding, increased vital signs.
    e. Discourage pacifiers until cleared by surgeon.
    f. Encourage the mother to hold the infant, swaddle, and use security/comfort items from home.
5. Positioning—elevated head of bed and side-lying.
    a. An infant seat may be useful for variation of position, comfort, and entertainment and to prevent interference with suture line.
    b. Provide for appropriate diversional activity, hanging toys, and mobiles.
    c. If only cleft palate was repaired, child may lie on abdomen.
6. Monitor respiratory effort after cleft palate repair.
    a. Be aware that breathing with a closed palate is different from the child's customary way of breathing; the child must also contend with increased mucus production.
    b. Provide humidified air, if needed, to provide moisture to mucous membranes that may become dry from mouth breathing.
7. Prevent infection.
    a. Clean suture line after every feeding.
    b. Gently wipe lip incision with cotton-tipped applicator and solution of choice, such as water, saline, or diluted hydrogen peroxide. Gently pat dry and apply antibiotic ointment or petroleum jelly, if ordered.
    c. Rinse the mouth with water or offer a drink of water after each feeding.

d. Irrigate the mouth with normal saline solution or water after cleft palate repair. Technique may vary based on preference of surgeon. You can direct a gentle stream over the suture line using an ear bulb syringe with the child in a sitting position with head forward.

8. Avoid tension on the suture line during feeding for several days after lip repair.
   a. Use dropper or syringe with a rubber tip and insert from the side to avoid suture line or to avoid stimulating sucking.
   b. Use side of spoon. Never put spoon into the mouth.
   c. Perform enteral tube feedings, if prescribed; usually this is the last treatment of choice.
   d. Advance slowly to nipple feeding, as directed. The infant should be able to suck more efficiently after the lip is repaired.
   e. After palate repair, feed the child in the manner used preoperatively (cup, side of spoon, or rubber-tipped syringe). Never use straw, nipple, or plain syringe.
   f. Consult with speech/occupational therapy if feeding/swallowing continues to be difficult.
9. Facilitate adequate nutrition.
   a. Obtain nutrition consult, if indicated.
   b. Diet progresses from clear liquids to full liquids to soft foods.
   c. Soft foods are usually continued for about 1 month after surgery, at which time a regular diet is started, but excludes hard food.
   d. Ensure that the child is receiving adequate calories.
   e. Weigh daily and plot on growth charts (*www.cdc.gov/growthcharts/*).
   f. Early feeding intervention relates to appropriate growth.
10. Administer an antibiotic, if prescribed, to prevent infection, as the mouth and skin contain bacteria.

Community and Home Care Considerations

1. As the patient's advocate, alert members of the craniofacial team when a family is overwhelmed by too many appointments and interventions. Act as liaison to case manager, social worker, and home care agency.
2. Continue to assess weight gain, feeding behavior, overall development, parent–child bonding and interactions.
3. Advise the parents to discuss the child's problem with teachers and other responsible adults in close contact with the child.
   a. Aesthetic touch-up and bone graft surgery performed later may interfere with schooling.
   b. Speech differences require early identification and intervention.
   c. Monitor for reading and learning problems related to speech and language delays.
   d. Hypernasality may develop at ages 10 to 14 years because of normal shrinkage of adenoid tissue occurring at this time.
4. Assess the child's self-perception and coping skills. Assess the family's support systems and coping

mechanisms.

5. Help school-age children deal with teasing (as a result of being "different" from their peers) by allowing them to express their feelings and guiding their response: ignoring the remark, responding with a joke or good-natured tease, or educating the teaser.
6. The school nurse can also help by performing frequent hearing evaluations, communicating with staff, and educating the school community on the child's condition and individual needs.

EVIDENCE BASE Sischo, L., Clouston, S., & Phillips, C. (2016). Caregiver responses to early cleft palate care: A mixed method approach. *Health Psychology, 35*(4), 474–482.

Family Education and Health Maintenance

1. Instruct on continued protection of the mouth after surgery. Child cannot put anything in mouth, including lollipops.
2. Demonstrate how to rinse mouth after eating.
3. Advise parents on the introduction of solid foods; semi-upright position or upright position; avoid spicy or acidic foods, which may irritate the oral and nasal cavities; avoid hard, sharp-edged foods, such as raw carrots or potato chips.
4. Advise on increased risk of ear infections and need to seek medical attention for colds, ear pain, fever, or other signs and symptoms. Frequent hearing screens and tympanometry should be done to monitor the effects of middle ear pathology. *Note:* Hearing should be monitored at least every 6 months during the 1st year of life and then annually to prevent hearing impairment.
5. Encourage modeling "good speech" by providing a stimulating language environment, and encourage spontaneous imitations of sounds at home.
6. Stress the importance of speech therapy and practicing exercises as directed by the speech therapist.
7. Encourage thorough brushing of teeth, regular dental examinations, and fluoride treatment as indicated because of risk of tooth decay related to defective enamel and abnormally positioned teeth with clefts.
8. Advise the parents on current therapies available: bone grafting providing permanent teeth support, dental implants to replace missing teeth, and speech prosthesis for incomplete velopharyngeal closure.
9. Help the parents realize that, although rehabilitation is extensive, their child can live a normal life.
10. For additional information and support, refer patients and family to the American Cleft Palate-Craniofacial Association (*www.acpa-cpf.org*).
11. Refer families to companies that manufacture bottles for cleft palate: Enfamil (Mead Johnson) Cleft Palate Nurser, 1-800-222-9123; Medela Haberman Feeder, 1-800-435-8316; Pigeon Bottle (Children's Medical Ventures), 1-888-766-8443.

Evaluation: Expected Outcomes

- Infant feeds with appropriate feeding device in small amounts every 2 to 3 hours.
- No signs of infection.
- Parents involved with care; demonstrate contact with infant as seen by holding and talking to infant.
- Proper positioning maintained, no signs of aspiration.
- Parents demonstrate proper feeding technique as evidenced by adequate nutrition and weight gain.
- Parents and child prepared for surgery.
- Parents express understanding of postoperative home care procedures and identify supportive resources.

Esophageal Atresia with Tracheoesophageal Fistula

EVIDENCE BASE Krishnan, U., Mousa, H., Dall'Oglio, L., et al. (2016). ESPGHAN-NASPGHAN guidelines for the evaluation and treatment of gastrointestinal and nutritional complications in children with esophageal atresia-tracheoesophageal fistula. *Journal of Pediatric Gastroenterology and Nutrition, 63*(5), 550–570.

Okata, Y., Maeda, K., & Bitoh, Y. (2016). Evaluation of the intraoperative risk factors for esophageal anastomotic complications after primary repair of esophageal atresia with tracheoesophageal fistula. *Pediatric Surgery International, 32*(9), 869–873.

Esophageal atresia (EA) is failure of the esophagus to form a continuous passage from the pharynx to the stomach during embryonic development. EA can occur with *tracheoesophageal fistula (TEF)*, which is an abnormal connection between the trachea and esophagus. EA/TEF occurs in approximately 1 in 3,500 births.

Clinically, EA/TEF is divided equally into isolated EA and syndromic EA. Additional defects vary in severity, with cardiac anomalies as the most common (14.7% to 28%) and life threatening. Currently, an overall survival of 85% to 90% has been reported from developed countries. In developing countries, however, several factors contribute to higher mortality rates. Such factors include prematurity, delay in diagnosis with an increased incidence of aspiration pneumonia, and a shortage of qualified nurses.

Pathophysiology and Etiology

1. Cause is unknown in most cases and likely multifactorial. Possible influences include:
   a. Low evidence for inheritable genetic factor.
   b. Six to ten percent due to chromosomal (structural) abnormalities, including trisomies (12, 18, 21), and partial deletions such as 13q13-qter, 22q11.2.
   c. Teratogenic stimuli, such as the anticancer drug adriamycin and diethylstilbestrol (DES).
2. Failure of proper separation of the embryonic channel into the esophagus and trachea occurring during the 4th and 5th weeks of gestation.
3. Esophageal atresia can be classified as (see Figure 48-2):
   a. *Type I* (Type A): proximal and distal segments of esophagus are blind; there is no connection to trachea; accounts for approximately 7% of cases; second most common.
   b. *Type II* (Type B): proximal segment of esophagus opens into trachea by a fistula; distal segment is blind; rare, 0.8% of cases.
   c. *Type III* (Type C): proximal segment of esophagus has blind end; distal segment of esophagus connects into trachea by a fistula; most common, with 86% of cases. (Discussion is limited to this type.)
   d. *Type IV* (Type D): esophageal atresia with fistula between proximal and distal ends of trachea and

esophagus (rare, 0.7% of cases).

e. *Type V* (Type E): proximal and distal segments of esophagus open into trachea by a fistula; no esophageal atresia but sometimes referred to as an H-type fistula; occurs in 4.2% of cases; not usually diagnosed at birth.

4. Associations:
   a. Down syndrome.
   b. VACTERL syndrome (vertebral defects, anal atresia, cardiac anomaly, TEF fistula with EA, renal defects, and radial limb dysplasia).
   c. Feingold syndrome.

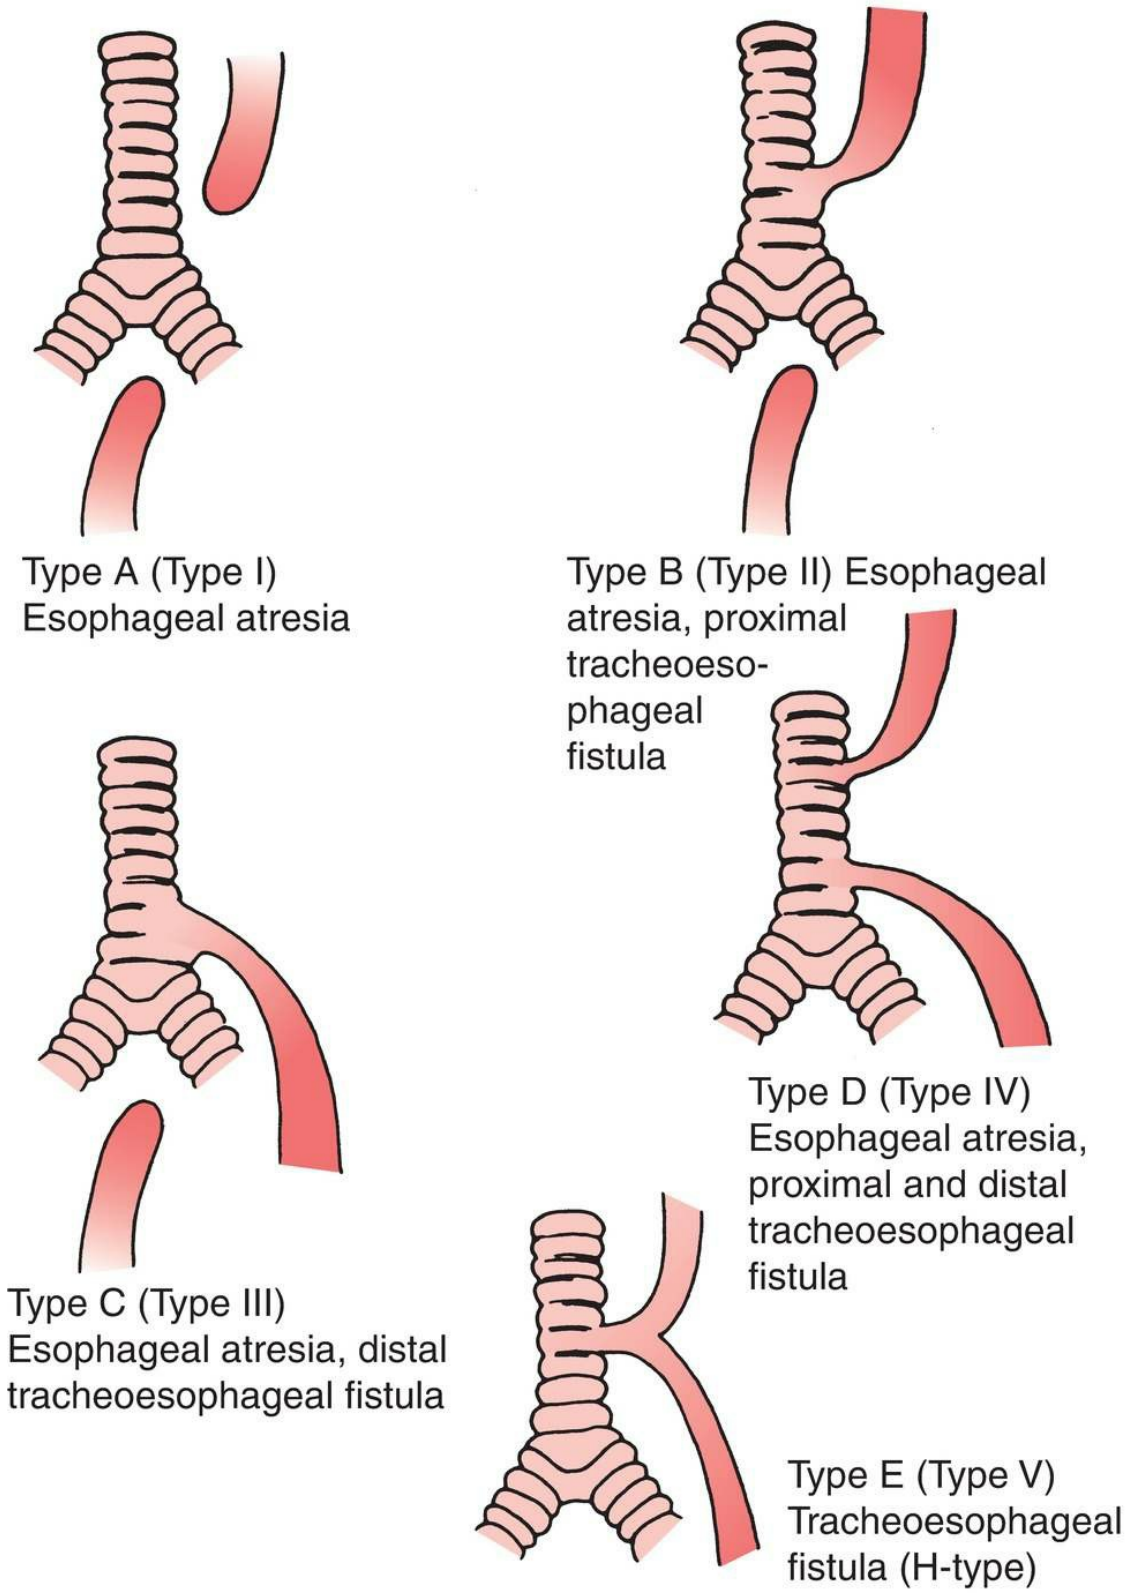

Figure 48-2. Types of esophageal atresia: esophageal atresia and tracheoesophageal fistula.

EVIDENCE BASE Svoboda, E., Fruithof, J., Widenmann-Grolig, A., et al. (2018). A patient led,

international study of long term outcomes of esophageal stresia: EAT 1. *Journal of Pediatric Surgery, 53*(4), 610–615.

Clinical Manifestations

These appear soon after birth.

1. Excessive secretions.
   a. Constant drooling.
   b. Large amount of secretions from nose.
   c. Saliva or formula accumulates in upper esophageal pouch and is aspirated into airway.
2. Intermittent, unexplained cyanosis and laryngospasm.
   a. Caused by aspiration of accumulated saliva in blind pouch.
   b. Gastric acid is regurgitated through distal fistula.
3. Abdominal distention.
   a. Occurs as a result of air entering the lower esophagus through the fistula and passing into the stomach, especially when the child is crying.
4. Violent response after first or second swallow of feeding.
   a. Infant coughs and chokes.
   b. Fluid returns through nose and mouth.
   c. Cyanosis occurs.
   d. Infant struggles.
5. Poor feeding.
6. Inability to pass catheter through nose or mouth into stomach; tip of catheter stops at blind pouch, or atresia. *Note:* Be aware of coiling of catheter; coiling may make catheter appear to be descending into stomach.
7. Infant can be premature and pregnancy complicated by polyhydramnios. Look for other birth anomalies.

Diagnostic Evaluation

1. Ultrasound scanning techniques enable TEF to be identified *in utero* for some infants.
2. Failure to pass a 10F catheter (smaller catheters may coil) into the stomach through nose or mouth. Catheter is left *in situ* while an x-ray confirms the diagnosis.
3. pH of tracheal secretions is acidic.
4. Flat-plate x-ray of abdomen and chest may reveal presence of gas in stomach and catheter coiled in the blind pouch. Barium x-ray may be used in some cases.
5. Electrocardiogram and echocardiogram are performed because there is a high association with cardiac anomalies.

Management

Immediate Treatment

1. Propping infant at 30-degree angle, supine or side-lying, to prevent reflux of gastric contents.
2. Nasogastric (NG) tube remains in the esophagus and is aspirated frequently to prevent aspiration until continuous low suction is applied.
3. Pouch is washed out with normal saline to prevent thick mucus from blocking the tube.
4. Gastrostomy to decompress stomach and prevent aspiration; later used for feedings.
5. Nothing by mouth (NPO); IV fluids.
6. Comorbidities, such as pneumonitis and heart failure, are treated.
7. Supportive therapy includes meeting nutritional requirements, IV fluids, antibiotics, respiratory support, and maintaining thermally neutral environment.

Surgery

1. Prompt primary repair: fistula found by bronchoscopy is divided, followed by esophageal anastomosis of proximal and distal segments if infant weight permits and is without pneumonia.
2. Short-term delay: subsequent primary repair is used to stabilize infant and prevent deterioration when the patient's condition contraindicates immediate surgery.
3. Staging: initially, fistula division and gastrostomy are performed with later secondary esophageal anastomosis or colonic transposition performed approximately 1 year later to effect total repair. Approach may be used with a very small, premature infant or a very sick neonate or when severe congenital anomalies exist.
4. Circular esophagomyotomy may be performed on proximal pouch to gain length and allow for primary anastomosis at initial surgery.
5. Cervical esophagostomy: when ends of esophagus are too widely separated, esophageal replacement with segment of intestine (colonic transposition) is done at ages 18 to 24 months.
6. Fiber-optic tracheoscopy-assisted repair of TEF can expedite and facilitate surgery on ventilated patients.
7. Staged repair resulted in least amount of GI dysmotility postoperatively.

EVIDENCE BASE Lal, D., Gadepalli, S., Downard, C., et al. (2017). Perioperative management and outcomes of esophageal atresia and tracheoesophageal fistula. *Journal of Pediatric Surgery, 52*(8), 1245–1251.

Complications

Note: Higher rates of complications occur in patients with cardiac anomalies and low birth weight.

1. Death from asphyxia.
2. Pneumonitis/pneumonia secondary to salivary aspiration and/or gastric acid reflux.
3. Leak at anastomosis site: most common and dangerous complication (15% to 20%).

4. Recurrent fistulas.
5. Esophageal strictures (30% to 40%).
6. Abnormal function of distal esophagus sphincter (gastroesophageal reflux (GER) can be found in approximately 50% of these infants).
7. Esophagitis.
8. Tracheomalacia (10% to 20% of these patients).
9. Gastroesophageal Reflux Disease (GERD) (40% to 65%).
10. Feeding problems with older children due to esophageal dysmotility (95%).

Nursing Assessment

Assessment begins immediately after birth.

1. Be alert for risk factors of polyhydramnios and prematurity.
2. Suspect in infant with the following:
   a. Excessive amount of mucus.
   b. Difficulty with secretions.
   c. Cyanotic episodes (unexplained).
3. Report suspicion to health care provider immediately.

Nursing Diagnoses

Preoperative

- Risk for Aspiration related to structural abnormality.
- Risk for Deficient Fluid Volume related to inability to take oral fluids.
- Anxiety of parents related to critical situation of neonate.

Postoperative

- Ineffective Airway Clearance related to surgical intervention.
- Ineffective Infant Feeding Pattern related to defect.
- Acute Pain related to surgical procedure.
- Impaired Tissue Integrity related to postoperative drainage.
- Risk for Injury related to complex surgery.
- Risk for Impaired Attachment related to prolonged hospitalization.

Nursing Interventions

Preventing Aspiration

1. Position the infant supine with head and chest elevated 20 to 30 degrees to prevent or decrease reflux of gastric juices into the tracheobronchial tree.
   a. This position may also ease respiratory effort by dropping the distended intestines away from the

diaphragm.

   b. Side-lying position can be used if the risk of aspiration from being supine is greater than the risk of sudden infant death syndrome (SIDS); supine positioning is preferred to reduce the risk of SIDS.
   c. Turn frequently to prevent atelectasis and pneumonia.
2. Perform intermittent nasopharyngeal suctioning or maintain indwelling Sump tube with constant suction to remove secretions from esophageal blind pouch.
   a. Tip of tube is placed in the blind pouch.
   b. Sump tube allows air to be drawn in through a second lumen and prevents tube obstruction by mucous membrane of pouch.
   c. Maintain indwelling tube patency by irrigating with 1 mL normal saline solution frequently.
3. Place the infant in an Isolette or under a radiant warmer with high humidity to aid in liquefying secretions and thick mucus. Maintain the infant's temperature in thermoneutral zone and ensure environmental isolation to prevent infection by using Isolette.
4. Administer oxygen, as needed.
5. Suction mouth to keep it clear of secretions and prevent aspiration. Provide mouth care.
6. Be alert for indications of respiratory distress.
   a. Retractions.
   b. Circumoral cyanosis.
   c. Restlessness.
   d. Nasal flaring.
   e. Increased respiration and heart rate.
7. Maintain NPO status.
8. Administer antibiotics, as ordered, to prevent or treat associated pneumonitis.
9. Observe infant carefully for any change in condition; report changes immediately.
   a. Check vital signs, color and amount of secretions, abdominal distention, and respiratory distress.
   b. Evaluate for complications that can occur in any neonate or premature infant.
10. Be available and recognize need for emergency care or resuscitation.
   a. Have resuscitation equipment on hand.
   b. Accompany the infant to other departments and the operating room in Isolette with portable oxygen and suction equipment.
11. Monitor for signs or symptoms that may indicate additional congenital anomalies or complications.
12. Gastrostomy tube (GT) may be placed before definitive surgery to aid in gastric decompression, prevention of reflux, or nutrition.

Preventing Dehydration

1. Administer parenteral fluids and electrolytes as prescribed.
2. Monitor vital signs frequently for changes in blood pressure (BP) and pulse, which may indicate

dehydration or fluid volume overload.

3. Record intake and output, including gastric drainage (if GT for decompression is present) and weight of diapers.

Reducing Parental Anxiety

1. Explain procedures and necessary events to parents as soon as possible.
2. Orient parents to hospital and intensive care nursery environment.
3. Allow family to hold and assist in caring for infant.
4. Offer reassurance and encouragement to family frequently. Provide for additional support by social worker, clergy, and counselor, as needed.

Maintaining Patent Airway

1. Keep endotracheal (ET) tube patent by frequent lavage and suction. *Note:* Reintubation could damage the anastomosis.
2. Suction frequently; every 5 to 10 minutes may be necessary, but at least every 1 to 2 hours.
3. Observe for signs of obstructed airway. Ventilatory support is continued until clinically stable (usually 24 to 48 hours).
4. Request that the surgeon mark a suction catheter, indicating how far the catheter can be safely inserted without disturbing the anastomosis (usually 2 to 3 cm).
5. Administer chest physiotherapy, as prescribed.
   a. Change the infant's position by turning; stimulate crying to promote full expansion of lungs.
   b. Elevate head and shoulders 20 to 30 degrees.
   c. Use mechanical vibrator 2 to 3 days postoperatively (to minimize trauma to anastomosis), followed by more vigorous physical therapy after the 3rd day.
6. Continue use of Isolette or radiant warmer with humidity.
7. Be prepared for an emergency: have emergency equipment available, including suction machine, catheter, oxygen, laryngoscope, ET tubes in varying sizes.

NURSING ALERT Care should be taken not to hyperextend the neck, causing stress to the operative site.

Providing Adequate Nutrition

Feedings may be given by mouth, by gastrostomy, or (rarely) by a feeding tube into the esophagus, depending on the type of operation performed and the infant's condition.

1. The gastrostomy is generally attached to gravity drainage postoperatively, then elevated and left open to allow for air to escape and gastric secretions to pass into the duodenum before feedings are begun.

2. Practice patterns differ regarding when to start feedings but generally minimal enteral nutrition is beneficial in promoting gut motility, decreasing bacterial overgrowth, and decreasing the stress on the liver; these "trickle" feedings are given at a rate of 5 to 20 mL/kg per day.
3. Give the infant a pacifier to suck during feedings, unless contraindicated.
4. Use care to prevent air from entering the stomach, thereby causing gastric distention and possible reflux.
5. Continue gastrostomy feedings until the infant can tolerate full feedings orally.

Providing Comfort Measures

1. Position comfortably.
2. Avoid restraints when possible.
3. Administer mouth care frequently.
4. Offer pacifier frequently.
5. Assess for pain and administer analgesics, as ordered (see page 1150).
6. Caress and speak or sing to the infant frequently. Handling should be kept to a gentle minimum.

Maintaining Chest Drainage

1. Assess type of chest drainage present (determined by surgical approach). Report saliva or hemorrhage.
   a. Retropleural—small tube in posterior mediastinum; may be left open for drainage.
   b. Transthoracic—chest tube placed in pleural space and connected to suction.
2. Keep tubing patent: free from clots, unkinked, and without tension.
3. If a break occurs in the closed drainage system, immediately clamp tubing close to the infant to prevent pneumothorax.

Observing for Complications

1. Inspect for leak at the anastomosis, causing mediastinitis, pneumothorax, and saliva in chest tube: hypothermia or hyperthermia, severe respiratory distress, cyanosis, restlessness, and weak pulses.
2. Continue to monitor for complications during the recovery process.
   a. Stricture at the anastomosis: difficulty in swallowing, vomiting, or spitting-up of ingested fluid; refusing to eat; fever secondary to aspiration and pneumonia.
   b. Recurrent fistula: coughing, choking, and cyanosis associated with feeding; excessive salivation; difficulty in swallowing associated with abnormal distention; repeated episodes of pneumonitis; general poor physical condition (no weight gain).
   c. Atelectasis or pneumonitis: aspiration, respiratory distress.
3. Provide meticulous care for cervical esophagostomy—artificial opening in the neck that allows for drainage of the upper esophagus.
   a. Keep the area clean of saliva.
   b. Wash with clear water.
   c. Place an absorbent pad over the area.

4. As soon as possible, allow the infant to suck a few milliliters of milk at the same time gastrostomy feeding is being done. Advance the infant to solid foods, as appropriate, if esophagostomy is maintained for a few months.
    a. Encourage sucking and swallowing.
    b. Familiarize the infant with food so that when able to eat orally, infant will be used to it.
5. Begin oral feedings 10 to 14 days postoperatively after anastomosis, as directed.
    a. Feed slowly to allow the infant time to swallow.
    b. Use upright sitting position to avoid risk of regurgitation.
    c. Burp frequently or vent GT.
    d. Do not allow the infant to become overtired at feeding time. Note heart rate.
    e. Try to make each feeding a pleasant experience for the infant. Use a consistent approach and patience. Encourage parental involvement.

Stimulating Parent–Infant Attachment

1. Gently hold and cuddle the infant for feedings and after feedings.
2. Encourage parents to cuddle and talk to the infant.
3. Provide for visual, auditory, and tactile stimulation, as appropriate, for the infant's physical condition and age.
4. Provide opportunities for the parents to learn all aspects of care of their infant.
5. Encourage the parents to talk about their feelings, fears, and concerns.
6. Help to develop a healthy parent–child relationship through flexible visiting, frequent phone calls, and encouraging physical contact between child and parents.

Community and Home Care Considerations

EVIDENCE BASE Holscher, A., Laschat, M., Choinitzki, V., et al. (2017). Quality of life after surgical treatment for esophageal atresia: Long-term outcomes of 154 patients. *European Journal of Pediatric Surgery, 27*(5), 443–448.

---

1. Teach carefully and thoroughly all procedures to be done at home. Show the parents how to do them and then watch return demonstration of the following procedures:
    a. Gastrostomy feedings and care.
    b. Esophagostomy care with feeding technique.
    c. Suctioning.
    d. Identifying signs of respiratory distress.
2. Advise parents that esophageal motility will be affected for many years, because of the narrowed

abnormal esophagus emptying slowly and tension on the stomach from the anastomosis.

3. Reflux may increase after surgery and thus should be maximally treated because of the risk of developing esophageal strictures.
4. Monitor weight gain and developmental progress.
5. Observe parental feeding technique.
6. Encourage parents to discuss child's condition with day care workers, teachers, school nurse, or other responsible adults in close contact with the child so that they will be able to recognize possible problems and reinforce good eating habits.
7. To compensate for altered motility, encourage cutting food into small pieces, chewing food well, swallowing food with fluid, and sitting upright while eating.
8. Observe parent–child interaction to assess for overprotection and appropriate coping skills.

Family Education and Health Maintenance

EVIDENCE BASE Menzies, J., Hughes, J., Leach, S., et al. (2017). Prevalence of malnutrition and feeding difficulties in children with esophageal atresia. *Journal of Pediatric Gastroenterology & Nutrition, 64*(4), 100–105.

Singh, A., Middlesworth, W., & Khlevner, J. (2017). Surveillance in patients with esophageal atresia/tracheoesophageal fistula. *Current Gastroenterology Reports, 19*(1), 4.

---

1. Help the parents understand the psychological needs of the infant for sucking, warmth, comfort, stimulation, and affection. Suggest that activity be appropriate for age.
2. Encourage the parents to continue close medical follow-up, and help them learn to recognize possible problems.
   a. Eating problems may occur, especially when solids are introduced.
   b. Repeated respiratory tract infection should be reported.
   c. Occurrence of stricture at site of anastomosis weeks to months later may be recognized by difficulty in swallowing, spitting of ingested fluid, and fever. Continue all reflux medications until advised otherwise. Medications should be adjusted by weight as infant grows.
   d. Dilatation of esophagus may be necessary to treat stricture at the site of the anastomosis.
   e. Signs of fistula leakage are dusky color or choking with feeding.
3. Help the parents understand the need for good nutrition and the need to follow the diet regimen suggested by the health care provider.
4. Reassure parents that an infant's raspy cough is normal and will gradually diminish as the infant's trachea becomes stronger over 6 to 24 months (most infants have some tracheomalacia).
5. Teach parents to guard against the child swallowing foreign objects.

6. Help and support can be given by introducing the parents to other parents of children with TEF.
7. For additional information and support, refer parents to EA/TEF Family Support Connection (*www.eatef.org*), TEF Vater (*www.tefvater.org*), Birth Defect Research for Children (*www.birthdefects.org*), International Foundation for Functional Gastrointestinal Disorders (*www.aboutkidsgi.org*), Boston Children's Hospital (*www.childrenshospital.org*), or the March of Dimes Foundation (*www.marchofdimes.org*).

Evaluation: Expected Outcomes

- No cyanosis or respiratory distress.
- Hydrated; urine output adequate.
- Parents hold and talk to infant; express concerns.
- Postoperatively, tolerates gastrostomy feedings without distention or regurgitation.
- Infant thrives, with adequate weight gain.
- Infant sleeps and rests without irritability or pain.
- Chest tube in place with minimal drainage.
- Feeds without regurgitation 12 days postoperatively.
- Parents caring for infant postoperatively and assisting with feedings.

Gastroesophageal Reflux and Gastroesophageal Reflux Disease

EVIDENCE BASE Rosen, R., Vandenplas, Y., Singendonk, M., et al. (2018). Pediatric gastroesophageal reflux clinical practice guidelines: Joint recommendations of the North American Society for Pediatric Gastroenterologyg, Hepatology, and Nutrition and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition. *JPGN, 66*(3), 516–544.

GER is the passage of gastric contents into the esophagus. The barrier between the stomach and esophagus is controlled primarily by pressure at the lower esophageal sphincter (LES). GER is a normal physiologic process and occurs in all healthy infants and children, usually several times a day, without symptoms or sequelae. Of all infants with GER, 50% will be symptomatic (vomiting or regurgitation) during the first 3 months of life; 67% of infants ages 4 to 9 months will have symptoms; and 5% of ages 10 to 12 months will have symptoms. Symptomatic GER often self-resolves by 12 to 14 months of age.

GERD is defined as the symptom complex that results as a complication of GER. GERD is used to describe a condition when this reflux process causes bothersome symptoms and complications, such as significant discomfort and altered feeding and sleeping patterns. Clinical manifestations include vomiting, dysphagia, food refusal, poor weight gain, failure to thrive (FTT), esophagitis, irritability/excessive crying, abdominal pain, substernal pain, respiratory disorders, asthma, and apparent life-threatening events (ALTE) or apnea.

The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition has formulated guidelines for the diagnosis and management of GER and GERD in infants and children; however, these guidelines are not intended for the management of neonates less than 72 hours old, premature neonates, or infants/children with neurologic or anatomic abnormalities of the upper GI tract. The American Academy of Pediatrics has also endorsed these guidelines.

Supportive care by nurses and other health care staff regarding feeding techniques and nutrition is often sufficient for patients with GER. GERD may require additional interventions such as changes to feeding regimen or medication therapy.

Pathophysiology and Etiology

Gastroesophageal Reflux

1. The LES is a physiologic, rather than an anatomic, segment that forms an antireflux barrier.
    a. 2 to 5 cm in length.
    b. Characterized by a pressure greater than that found proximally in the esophagus or distally in the stomach.
    c. Constitutes an effective barrier to protect the esophageal mucosa and airway passages from damage by gastric contents (acid, pepsin, bile salts, food).

d. Neuromuscular connection is weak in infants, and GER peaks at age 6 months and usually resolves by 12 months.

Gastroesophageal Reflux Disease

1. Episodes of GERD with aspiration of refluxed material are more likely to occur during the nocturnal period—when the esophagus and stomach are leveled and the swallowing response to reflux and airway protection mechanisms are blunted by sleep.
2. Cause is undetermined in most patients; however, possible causes include:
   a. Delayed neuromuscular development.
   b. Cerebral defects.
   c. Obstruction at or just below the pylorus (eg, pyloric stenosis, malrotation).
   d. Physiologic immaturity.
   e. Increased abdominal pressure.
   f. Obesity.
   g. Cystic fibrosis.
   h. Congenital esophageal disease.
3. Associated conditions that contribute to reflux include:
   a. Chronic lung disease—there is a higher incidence of reflux in infants with this condition. It appears to be related to the duration of the episode and how proximal the reflux occurs, possibly contributing to poor clearance.
   b. Trauma/mechanical causes that affect the LES.
      i. Indwelling orogastric/NG enteric feeding tube.
      ii. Surgery on the esophagus or stomach.
      iii. Mechanical ventilation.
      iv. Extreme changes in position; lying completely flat; seating devices for infants greater than a 30% incline (increases intra-abdominal pressure).
      v. Hiatal hernia.
   c. Studies show a reduced incidence of reflux in the prone position versus the supine position; however, the American Academy of Pediatrics' "Back to Sleep" program discourages prone positioning because of increased incidence of SIDS.
   d. Protein allergy: increased inflammation in the mucosa of the esophagus and stomach, altering motility.
   e. Medications/drugs that affect LES and increase gastric acidity, such as bronchodilators, antihypertensives, diazepam, meperidine, morphine, prostaglandins, calcium channel blockers, nitrate heart medications, anticholinergics, adrenergic drugs, caffeine, alcohol, and nicotine.
   f. Cystic fibrosis, cardiac disease, and other chronic illnesses.

Clinical Manifestations of GERD

Infants

1. Vomiting or regurgitation of formula or breast milk.
2. Irritability, excessive crying with or without association with vomiting.
3. Sleep disturbances.
4. Arching, stiffening.
5. It is recommended that the infant be referred to a pediatric gastroenterologist if the following manifestations occur:
    a. Refusal to eat.
    b. Weight loss or failure to gain weight.
    c. Dehydration.
    d. Recurrent respiratory symptoms, such as cough, wheezing, stridor, pneumonia, otitis media, bronchitis.
    e. BRUE (brief, resolved, unexplained event): blue spell, decreased responsiveness, limp, apnea, bradycardia. (*Note:* The exact relationship between GER and BRUE is not clear despite continued investigation. Indeed, both apnea and reflux are common in premature neonates.)
    f. Eructation (belching).
    g. Sandifer syndrome (rare)—dystonic posturing caused by reflux.
    h. Anemia (from chronic esophagitis).
    i. Hematemesis (vomitus with blood).
    j. Occult blood in stool.
    k. Hypoproteinemia: low albumin due to severe inflammation and protein losses in the GI tract; can be seen with or without malnutrition and FTT.

Older Children

1. Intermittent vomiting.
2. Chronic heartburn or regurgitation.
3. Upper abdominal discomfort; pressure or "squeezing" feeling.
4. Chronic respiratory/airway symptoms, such as cough, stridor, otitis media, bronchitis, asthma.
5. Food refusal.
6. Dysphagia: difficulty swallowing.
7. Odynophagia: painful swallowing.
8. Anemia (from chronic esophagitis).
9. Hematemesis.
10. Hypoproteinemia.
11. Occult blood in stool.

Diagnostic Evaluation

1. History and physical exam can diagnose most cases.
2. Multiple intraluminal impedance and esophageal pH monitoring can be performed on all ages; no sedation necessary.
    a. Performed over 24 hours but does not indicate whether aspiration is occurring.
    b. Used as an index of esophageal acid exposure; however, esophageal impedance studies have been found to be more accurate, especially in the neurologically impaired child.
    c. The child must be off acid-suppressing medications for 48 to 72 hours so that acid pH can be detected.
    d. Gastric motility medications may or may not be held depending on the reason for performing the study.
    e. Most centers allow the patient to go home and return 24 hours later. Exceptions include the fragile child, premature infant, infant with active respiratory symptoms, or the child with significant symptoms who requires close observation because reflux may exacerbate while off reflux medications.
    f. Not indicated in the infant/child who is vomiting, unable to tolerate bolus feedings, or acutely ill. Because the probe is inserted in nares, infant/children with oxygen requirements may not tolerate the study.
3. Endoscopy and biopsy allow for visualization of esophageal, gastric, and duodenal mucosa.
    a. Indicated for severe GERD or failure of medical management.
    b. Biopsy can determine cause: allergy (eosinophilic), inflammation, chemical injury, or Barrett esophagus.
    c. Mechanical problems such as strictures, webs, and duplication/cysts will be visualized.
    d. For this procedure, sedation and anesthesia are necessary.
    e. Reflux medications do not have to be discontinued for the study.
    f. Can be done on the child who is not tolerating feedings. However, severity of illness may prevent study from being performed because of risk associated with procedure, such as with anesthesia, infection, bleeding, and cardiac.
4. Technetium scintigraphy (milk/emptying scan) to assess gastric emptying and associated aspiration. This is not a reliable test for determining GERD.
    a. Sedation is not necessary, and the study can be performed on children of all ages.
    b. Involves drinking/eating food with radionuclide, followed by dynamic sequenced imaging.
    c. Not indicated in the infant/child who is vomiting, unable to tolerate bolus feedings, or acutely ill.
    d. Acid suppression medications do not interfere with the study.
5. Modified barium swallow—also called *videofluoroscopy*.
    a. Assesses oral pharyngeal function and potential for aspiration from oral intake using several consistencies of feedings. This is not a reliable test for determining GERD.
    b. Sedation is not necessary for this procedure but does require cooperation with eating.
    c. Should not be performed on the infant/child with acute respiratory symptoms or one identified by

speech therapy or occupational therapy as being at risk for aspiration.

   d. Reflux medications do not have to be discontinued for the study.
   e. Speech therapist can be present for the exam to offer detailed assessment of oral–motor skills and swallowing.
6. Esophageal manometry to measure pressure inside the LES.
   a. It is a cooperative, nonsedated procedure and can only be used on an older child.
   b. Reflux medications generally do not have to be discontinued for the study.
7. Intraluminal esophageal impedance to detect the flow of liquids and gas through the esophagus may be used in combination with manometry.
8. Polysomnography may be used for evaluation of infant apnea and sleep apnea.

Complications

Complications result from frequent and sustained reflux of gastric contents into lower esophagus.

1. Recurrent pulmonary disease.
2. Chronic esophagitis.
3. FTT.
4. Anemia.
5. ALTE, although evidence is not strong.
6. Esophageal stricture from scarring.
7. Barrett esophagus: the replacement of distal esophageal mucosa with a potentially malignant metaplastic epithelium caused by chronic exposure to acid.
8. Chronic sinusitis/otitis media.
9. There is an unclear relationship between GERD and dental erosion/caries.

Management

Goal of treatment is to alleviate and relieve symptoms and prevent complications. May be treated medically through careful positioning, feeding techniques, and medication or surgically.

Positioning for GER

1. Esophageal monitoring has demonstrated that infants have significantly fewer episodes of GER when prone. Several studies support less incidence of reflux episodes in the prone and left-side sleeping position; however, the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition, along with the American Academy of Pediatrics, endorses the following recommendations:
   a. Place infant with head elevation or left lateral position after feeding when awake, not for sleep.
   b. Handle the infant gently, with minimal movement during and after feeding.

Feeding for GER

1. Small, frequent feedings followed by upright positioning with infant held over the shoulder.

2. Thickened feedings with dry rice cereal (1 tbsp per ounce of formula) or commercial thickening agent may be used. Thickening does not decrease episodes of reflux but does decrease episodes of vomiting. Commercial formulas thickened with rice starch are now available, but no studies regarding their efficacy have been published. Thickening of breast milk may be necessary in infants with poor weight gain.
3. Continuance of breast-feeding with the mother eliminating milk and soy products is encouraged, as allergen sensitivity can contribute to GER. No studies support the need for dietary restriction in mothers who breast-feed, but in anecdotal reports, infants appear to improve when dairy products are reduced. Two to four week trial of partially hydrolyzed formula is useful for refractory symptoms or for those infants/children with signs of allergy, anemia, constipation, occult positive stools, and vomiting. Hypoallergenic (elemental) formula may be used if symptoms persist.
4. Pectin liquid partially decreases GER, as measured by esophageal pH monitoring, and might improve vomiting and respiratory symptoms in children with cerebral palsy.
5. Concentrating formula is a method of increasing calories for the volume-sensitive infant.
6. Avoid constant feeding (grazing), which reduces appetite and, ultimately, caloric intake.
7. Comfort the infant to reduce crying before and after meals, which increases intra-abdominal pressure and swallowing of air, increasing the likelihood of reflux.
8. Use a pacifier for nonnutritive sucking after eating to avoid overeating.

Feeding for GERD

1. Transgastric (transpyloric) enteric feeding tube used for infants when reflux medical management fails and symptoms persist; can reduce number of reflux episodes, but has not been shown to significantly reduce episodes of apnea.
    a. There are concerns regarding using these feeding tubes in neonates; however, the rate of complications does not appear to be statistically significant in recent reports.
    b. The procedure should be performed by a skilled pediatric radiologist or neonatal intensive care nurse, using a small-caliber soft polyurethane nonweighted feeding tube.
    c. Considered a temporary feeding method (to help infant/child gain weight and improve respiratory symptoms) until further options can be explored, such as surgery—Nissen fundoplication or jejunostomy.
    d. To prevent clogging, tubes should be flushed at least four to six times per day and before and after medication administration. If the tube clogs or dislodges, the family must return to a qualified center for reinsertion.
    e. If feeding difficulty persists, consult dietitian and speech and/or occupational therapist.
2. Older child:
    a. Nothing to eat 2 hours before bedtime.
    b. Avoid spicy and acidic foods (onions, citrus products, apple juice, tomatoes), esophageal irritants (chocolate, caffeinated beverages, peppermint, and secondhand smoke), and carbonated beverages.
    c. Chew gum (stimulates parotid secretions, which augment esophageal clearance and provide a

buffering effect).

Other Lifestyle Changes for GERD

1. Prevent obesity.
2. Avoid tight or constrictive clothing.
3. Avoid nonsteroidal anti-inflammatory drugs, especially at bedtime.

Drug Therapy for GERD

1. Often used in combination with lifestyle changes. Prescribed for a 4 to 8 week trial and can be tapered and discontinued if symptoms resolve.
2. Antacids—buffer existing acids and also increase serum gastrin levels, leading to increase in LES pressure (symptomatic relief). Chronic antacid therapy is generally not recommended unless ordered by a gastroenterologist.
3. Histamine-2 (H_2) receptor antagonists—act by reducing hydrochloric acid and pepsinogen secretion by blocking histamine receptors on the parietal cells.
   a. Cimetidine, ranitidine, famotidine, nizatidine.
   b. Oral dosing of tid versus bid has demonstrated improved duration of acid suppression in one study of infants (44% vs. 90%).
   c. Tolerance to IV dosing within 6 weeks of usage has been observed.
4. Proton-pump inhibitors (PPIs)—block all gastric acid secretion by binding and deactivating the H^+/K^+ ATPase enzyme pumps. To be activated, PPIs require acid in the parietal cell canaliculus; therefore, they are most effective when the parietal cells are stimulated by a meal following a fast.
   a. Omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole.
   b. Generally given 15 to 30 minutes before a meal, one to two times per day.
   c. Generally not recommended in combination with H_2-antagonists because of interference with absorption (H_2 reduces the acid necessary for PPI to work).
   d. Reserved for infants and children resistant to H_2-antagonist therapy. Gastroenterology specialist should be involved. Data on the pharmacology in infants and children are limited.
   e. Dominant regurgitation in neonates and infants responds poorly to PPIs.
5. Prokinetic agents—enhances esophageal peristalsis and accelerates gastric emptying. However there is insufficient evidence of efficacy in GERD.
   a. Metoclopramide—an antidopaminergic agent whose efficacy is not well observed in clinical trials. Adverse effects include parkinsonian reactions, tardive dyskinesia, irritability, sleeplessness, and lowered seizure threshold.
   b. Erythromycin at low dose: motility receptor agonist. Can be associated with dysrhythmia and increased incidence of hypertrophic pyloric stenosis. Contraindicated in some patients with preexisting cardiac conditions.
6. A surface agent sucralfate may be used—an aluminum complex that acts by adhering to mucosal lesions,

reducing symptoms, and promoting healing.

a. May be used as an adjunct to an H_2 blocker or PPI, and usually for a period of several weeks or less.
b. If used for esophagitis, should be made into a liquid preparation.
c. If used for ulcer or gastritis, it is inhibited by H_2 blockers and PPIs because of the need for an acidic environment.

DRUG ALERT All acid-altering medications may affect the efficacy of pH-dependent medications. Additionally, PPIs are metabolized to varying degrees by the hepatic cytochrome P450 enzymatic system and may alter drug metabolism by induction or inhibition of the cytochrome P enzymes.

DRUG ALERT The potential adverse effects of aluminum in infants and children should be considered before administering sucralfate; data on its efficacy and safety in children are inadequate.

Surgical Management for GERD

EVIDENCE BASE Jancelewicz, T., Lopez, M., Downward, C., et al. (2016). Surgical management of gastroesophageal reflux disease (GERD) in children: A systematic review. *Journal of Pediatric Surgery, 52*(8), 1228–1238.

---

1. Nissen fundoplication is the most commonly used surgical method to treat moderate to severe GERD that is unresponsive to medication therapy. Decisions concerning appropriate long-term feeding access must be individualized.
   a. Involves wrapping of the fundus around the LES (see Figure 48-3).
   b. Overall complication rate ranges from 2.2% to 45%.
   c. Other surgical approaches include ventral (Thal) or dorsal (Toupet) semifundoplication.
   d. In some studies, recurrence of reflux in the neurodisabled child is as high as 46%.
   e. Simultaneous gastrostomy is usually performed for feeding purposes or as a temporary measure to decompress the stomach.
   f. The most commonly reported complications of surgery include breakdown of the wrap, small bowel obstruction, gas bloat syndrome, infection, perforation, leaking at the anastomosis site, persistent esophageal stricture, esophageal obstruction, dumping syndrome, incisional hernia, and gastroparesis.
   g. Reoperation rates range from 3% to 18%.

The greater the complexity of the infant or child's health status, the greater the chance of

h. complications.

2. Jejunostomy feeding tubes can be placed but are usually restricted to severe cases of recurrent GERD and/or failed Nissen procedure.
   a. Most surgeons use either a standard GT or a low-profile tube (button).
   b. Complications include intestinal obstruction and leaking.

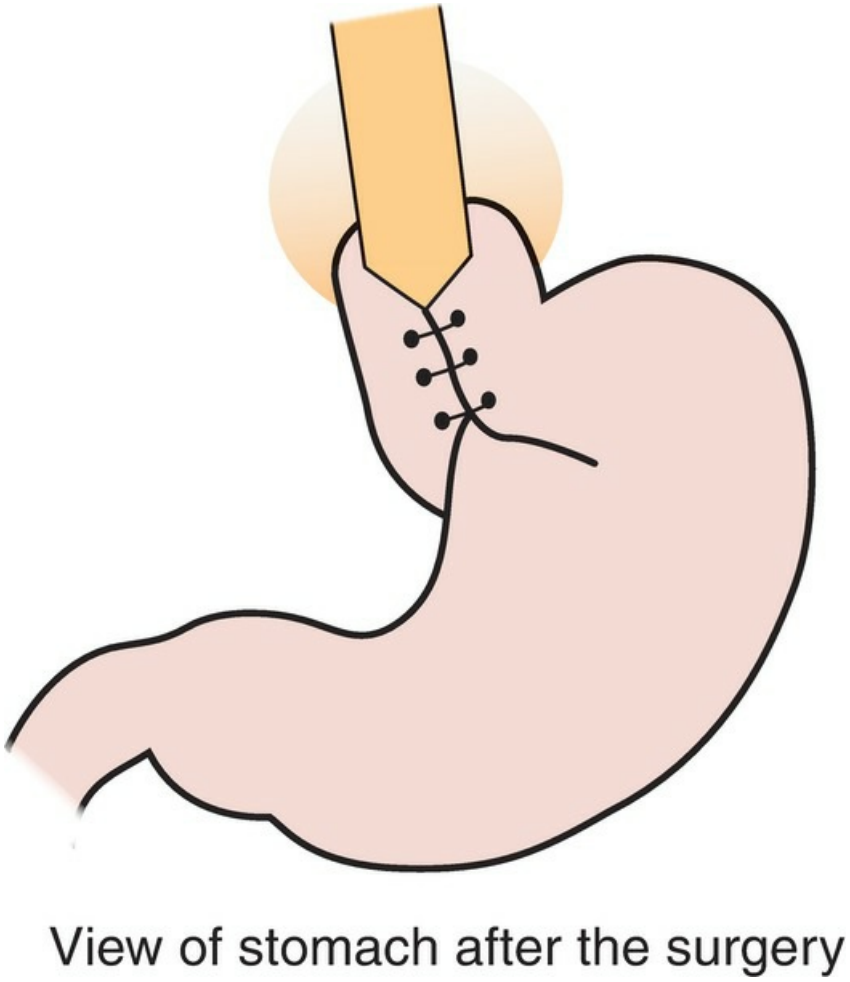

Figure 48-3. Nissan fundoplication for gastroesophageal reflux disease.

Other Treatments under Investigation

Investigation is underway to identify pathways and mechanisms that interfere or control the transient relaxation of the LES. Future understanding of this mechanism will aid in the development of lifestyle changes and medical management, which will assist in inhibiting transient relaxations. Reduction of gastric mechanoreceptor signaling to the brain has emerged as one of the likely sites of action for new reflux inhibitor drugs. The most promising among these appear to be the $GABA_B$ receptor agonists and metabotropic glutamate receptor 5 (mGluR5).

Nursing Assessment

1. Obtain history of infant's or child's eating habits, including formula history, food allergies, volume tolerated at each meal.
2. Obtain history of complications from GER (ie, recurrent respiratory infections, asthma, poor weight gain).
3. Observe infant's or child's feeding behaviors. (Does child eat with a bottle, spoon, fingers? Can child feed self?)
4. Assess general appearance, skin integrity, and growth and development.

Nursing Diagnoses

- Risk for Aspiration related to reflux of gastric contents.
- Imbalanced Nutrition: Less Than Body Requirements related to decreased oral intake.
- Risk for Deficient Fluid Volume related to frequent vomiting.
- Fear of eating related to distress.

Nursing Interventions

Preventing Aspiration

1. Administer medications via IV line until tolerating enteral feedings.
   a. Administer prokinetics (motility agents) and acid suppressants 30 minutes before meals when bolus feeding schedule is instituted. Monitor for adverse effects.
   b. Unless abnormal gastric dysmotility prior to surgery, most prokinetics are discontinued after Nissen fundoplication.
2. Maintain positioning, as stated above.
3. Use cardiac and apnea monitors for infants and children with severe reflux.
   a. Observe for apneic periods of more than 20 seconds or accompanied by cyanosis, pallor, or bradycardia.
   b. Document apnea episodes, associated symptoms, and recovery efforts.
4. Provide chest physiotherapy before rather than after meals, if ordered.

NURSING ALERT Avoid slouching position because this may change angle of esophagus in relation to stomach, increase intra-abdominal pressure, and facilitate reflux of stomach contents.

Maintaining Adequate Nutrition

See also section on feeding, page 1282.

1. Provide concentrated formula if volume cannot be tolerated.
2. Seek nutrition consult if patient continues to have difficulty feeding.

3. Monitor for fatigue during feeding; increased effort to suck requires higher energy expenditures. If noted, referral to occupational/speech therapy and possible modified barium swallow study are advised.
4. Monitor weight on the same scale.
5. Accurately record activity of infant.
   a. Amount of feeding taken; whether retained.
   b. Any change in behavior as a result of feeding technique.
6. Explain to the breast-feeding mother that feeding modifications may need to be made, especially in infants with poor weight gain. Assist her to express milk, quantitate volume, thicken with cereal, and fortify breast milk with formula, as needed.
7. Follow postoperative instructions on initiation of feedings.
8. If the child has a GT:
   a. Usually elevated and vented until return of bowel function.
   b. Monitor drainage, avoid kinking, and follow orders for positioning for straight drainage, elevation, or clamping.

Maintaining Fluid and Electrolyte Balance

1. Monitor vital signs and assess skin turgor for signs of dehydration.
2. Observe and record accurately urine output.
   a. Weigh diapers.
   b. Measure amount, frequency, color, and concentration of voided urine.
   c. Check specific gravity, if possible.
3. Monitor IV therapy, if ordered.
4. Monitor serum electrolytes, magnesium, phosphorus, and calcium. Replace, as ordered. Particular close monitoring is warranted if infant/child has draining gastrostomy.
5. Promote good skin care to prevent lesions of dry and delicate tissues.
   a. Change position frequently.
   b. Change soiled diapers promptly.
   c. Apply lotion and gently massage any reddened areas.

NURSING ALERT If patient is malnourished, monitor for refeeding syndrome until laboratory studies are stable. Refeeding syndrome can cause intracellular shifting of electrolytes including calcium, magnesium, and phosphorus, resulting in death. Laboratory studies should be monitored daily or more frequently if abnormal.

Reducing Fear of Eating

1. Provide thickened feedings to increase satisfaction for the infant.

2. Identify and attempt to reduce stress, especially around mealtime.
3. Feed the child in a quiet, calm environment.
4. Children like routines; feed at routine intervals by the person with whom the child is familiar and comfortable.
5. For the older child, encourage participation in family dinnertime so the child observes eating as a pleasurable experience.
6. Advise parents that clinical specialists in feeding disorders are available.

Community and Home Care Considerations

1. Recognize that home health care referral is appropriate for the following situations:
   a. FTT: medication teaching and monitoring, teaching of formula preparation, positioning, weight.
   b. Respiratory complications/ALTE: medication teaching and monitoring, assessment of respiratory status, teaching of monitor/cardiopulmonary resuscitation (CPR), use of nebulizer.
   c. Nissen fundoplication (with GT): medication teaching and monitoring; wound assessment; monitoring of bloating; dumping syndrome; formula intolerance; GT teaching, including pump teaching, venting, medication administration, tube changing.
2. Recommend careful feeding and behavioral diary to monitor symptoms and improvements.
3. Recognize that school and community activities may affect compliance for older children; work with the family to devise individualized management strategies.
4. Assist parents to discuss medication and lunchtime behaviors with teacher and school nurse so consistency can be maintained.
5. Assess need for community services, such as respite care, especially for single parent.

Family Education and Health Maintenance

EVIDENCE BASE Baird, D., Harker, D., & Karmes, A. (2015). Diagnosis and treatment of gastroesophageal reflux in infants and children. *American Family Physician, 92*(8), 705–714.

---

1. Plan a program of intensive parental teaching on how to handle and care for the infant. Explain rationale to parents. Make sure that they have proper equipment for propping the infant. Help the parents understand that it is not necessary to keep infant in infant seat or propped up at all times.
   a. Bathe or play with the infant before feeding.
   b. Change position about 1 hour after feeding.
   c. During the night after feeding, the infant can sleep in a semi-reclining (30 degrees) position.
   d. Expect occasional small amounts of vomiting.
2. Offer clear, concise instructions. Focus on parental fears. Discuss techniques to promote development of

infants while facilitating bonding and normal parental behavior.

3. If infant or child is not demonstrating complication of GER (ie, GERD), assist parents in understanding that GER is self-limited; symptoms usually disappear within 12 months.
4. If complications exist (GERD), referral to pediatric gastroenterology and nutrition specialists is recommended.
5. If Nissen fundoplication has been performed:
   a. Teach gastrostomy care, if applicable (see page 1158). Make sure that the parents know how to use, clear, vent, assess, and replace the tube. Help them to understand the purpose of GT placement (feedings, venting, medications) and the need for surgical or gastroenterology follow-up care.
   b. Explain about potential complications and when to call the health care provider. Such complications include gagging, retching, bloating, abdominal distention, fever, vomiting, diaphoresis, lethargy, diarrhea, and weight loss. Generally, the family should contact the surgeon within the first 6 weeks postoperatively, whereas eventual follow-up is with the gastroenterologist.
   c. It usually takes 12 weeks to heal; if the GT becomes dislodged in this period, the patient should be taken to the emergency department immediately.
   d. Complications of a dislodged GT in the early postoperative period include peritonitis and bacteremia.
6. Help the parents understand the importance of follow-up for assessment of weight gain and development.
7. Assist with community resource planning (eg, education, advocacy, and financial assistance). Identify support groups.
8. Instruct parents and caregivers in CPR training before discharge of infant, if indicated.
9. Provide written and verbal instructions for medications and adverse effects.
10. Advise parents on when to call their health care provider in regard to their child's symptoms. Danger signs of dehydration include a decrease in wet diapers, listlessness, lethargy, reduced appetite, sunken fontanelle; those for aspiration include respiratory distress and cyanotic spells, fever.
11. Encourage family to contact their health care provider immediately with treatment concerns or problems.
12. For additional information and support, contact the North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (*www.naspghan.org*), the United Ostomy Association *www.ostomy.org*, or the Pediatric/Adolescent Gastroesophageal Reflux Association (*www.reflux.org*).

Evaluation: Expected Outcomes

- Mild regurgitation immediately after feeding; no apnea or cyanosis noted.
- Takes regular feedings without significant symptoms; weight gain noted.
- Urine output adequate.
- Exhibits pleasure in eating.

Failure to Thrive/Malnutrition

EVIDENCE BASE Becker, P., Carney, L., Corkins, L., et al. (2014). Consensus statement of the Academy of Nutrition and Dietetics/American Society for Parenteral and Enteral Nutrition: Indicators recommended for the identification and documentation of pediatric malnutrition (undernutrition). *Journal of the Academy of Nutrition and Dietetics, 114*(12), 1988–2000.

FTT, or *malnutrition*, is the inadequate physical development of an infant or child manifested as a deceleration in weight gain, a low weight/height ratio, or a low weight/height/head circumference ratio. The exact prevalence is unknown, although research suggests FTT accounts for 3% to 5% of pediatric hospital admissions. Children with FTT are at risk for adverse outcomes, such as short stature, behavior problems, and developmental delay. The Agency for Healthcare Research and Quality has an evidence-based practice program on which clinical guidelines can be developed. The primary causative factors of FTT are insufficient nutrition availability, inadequate absorption and/or utilization of nutrients, and added metabolic requirements.

Previously practitioners diagnosed FTT when a child's weight for age falls below the fifth percentile of the standard National Center for Health Statistics growth chart or if it crosses two major percentile lines. Recent research has validated using *z* scores, or standard deviations from the mean, of weight for height or body mass index to classify malnutrition:

Mild malnutrition: *z* score −1 to −1.9

Moderate malnutrition: *z* score −2 to −2.9

Severe malnutrition: *z* score −3 or greater

About 25% of normal infants will shift to a lower growth percentile in the first 2 years of life and then follow that percentile; this should not be diagnosed as FTT (see Standards of Care Guidelines 48-1, page 1286).

STANDARDS OF CARE GUIDELINES 48-1

Care of a Child with a GI or Nutritional Disorder

When caring for a child with a GI or nutritional disorder:

- Monitor weight.
- Monitor urinary and bowel elimination.
- Monitor intake and output.
- Assess developmental milestone attainment.
- Provide and teach appropriate feeding products and techniques.
- Use most efficient position for feeding.
- Facilitate a calm, pleasant environment for feeding.
- Avoid foods that may inhibit absorption of nutrients or cause such symptoms as gas.

- Encourage and support parental involvement in care and feeding of the child.
- Encourage and support normal play and other activities for the child as condition allows.
- Identify and respond to signs and symptoms that may indicate lack of adequate nutrition or sign of complications.

This information should serve as a general guideline only. Each patient situation presents a unique set of clinical factors and requires nursing judgment to guide care, which may include additional or alternative measures and approaches.

Pathophysiology and Etiology

1. FTT is a nutritional disorder having organic and nonorganic components.
   a. Organic FTT implies a major illness or organ system dysfunction as the etiology of the growth failure. It occurs equally in all populations and accounts for approximately 25% of FTT cases.
   b. Nonorganic FTT is the result of multiple psychosocial factors, including disturbances in parent–child interaction. This type accounts for 50% of cases of FTT and is most common among the psychosocially and economically deprived.
   c. The remaining 25% of cases represent mixed etiology.
2. Organic FTT has a pathophysiologic cause that reduces the availability of nutrients for maintenance and growth and is best divided into three categories:
   a. Insufficient nutrition because of the child's inability to feed properly, which may be a result of severe neurologic dysfunction, GER, or cleft palate/lip.
   b. Nutrition is adequate but poorly absorbed and/or utilized (malabsorption syndromes), which may result from chronic ileocecal intussusception, GER, milk protein allergy, malrotation of the colon, hypoplastic stomach, short bowel syndrome (anatomic and functional), pancreatic insufficiency (including cystic fibrosis), pyloric stenosis, inflammatory bowel disease, and acquired immunodeficiency syndrome.
   c. Associated disorders include asthma, cardiac failure, thyroiditis, congenital heart disease, neurologic lesions, hydronephrosis, adrenal hyperplasia, diabetes insipidus, cystic fibrosis, chronic or recurrent urinary tract infection (UTI), hypothyroidism, autoimmune disorders, and immunodeficiency.
3. Nonorganic FTT occurs in the absence of GI, endocrine, congenital, or chronic diseases. It is usually associated with psychological deprivation but can also be related to behavioral or economic problems. Multiple features of the parents, child, and environment interact over time, resulting in parent–child interaction that ultimately leads to under nutrition and under nurturance of the child.

Clinical Manifestations

Organic FTT

1. Retarded growth accompanied by manifestations of the underlying disease.
2. Weight loss in early stages. If poor intake continues, linear growth slows down or ceases. In latent stage,

head circumference growth is retarded, indicating compromised brain development.

3. Developmental delays.
4. Infant stress—irritability, fussiness, jitteriness.
5. Feeding disorders—ineffective sucking, difficulty chewing, difficulty swallowing.
6. Clinical symptoms can include vomiting, hypothermia, lethargy, muscle wasting, decreased subcutaneous tissue, hypoalbuminemia, eczema, hair loss, and diarrhea.

Nonorganic FTT

1. Retarded growth.
2. Infant stress—irritability, fussiness, jitteriness.
3. Feeding disorders—ineffective sucking, difficulty chewing, difficulty swallowing.
4. Reduced energy level.
5. Difficult temperament.
6. Fitful sleep.
7. Reduced responsiveness and interaction with the environment.
8. Social isolation, lack of vocalization.
9. Spasticity or rigidity when touched.
10. Inability to make eye contact or smile.
11. Refusal to eat; rejection of foods.
12. Spits up, gags, coughs with feeding, rumination.

Parental Characteristics

1. Characteristics associated with parents of nonorganic FTT include lack of social and financial support, maladaptive relationships, alcohol or drug abuse, history of anxiety or depression, lack of parenting skills, family stress and crisis, absent father.
2. Postnatal depression corresponds to a higher association of FTT, but on its own, depression does not contribute to a higher incidence of FTT.

Diagnostic Evaluation

Comprehensive Assessment

1. FTT suggested if a child is falling off a previously established growth curve or falls below the 5th percentile. If FTT is of recent onset, weight but not height will fall below accepted standards. Depression of weight and height indicates chronic malnutrition.
2. Technique for evaluating growth—look at growth percentage of the median for that age. Divide the actual value of height or weight by median value for that age. For example, 12-month-old female weighs 15 pounds (6.8 kg); the median for age is 21 1/2 pounds (9.8 kg). Child is 70% of median for age.
3. Complete health and dietary history—feeding, eating patterns, 3-day calorie count.
4. Physical examination for evidence of organic causes, with particular attention to ears, facial structure,

mouth, heart, lungs, abdomen, and neurologic system.

5. Assessment of prenatal, perinatal, and postnatal infections.
6. Developmental assessment.
7. Family assessment—family short stature syndrome, family dynamics.
    a. With the assistance of endocrinologist and dietitian, calculate the midparental height: {(Father's height in cm + mother's height in cm) + 13 cm} divided by 2

Note: Subtract 13 cm for girls and add 13 cm for boys. For example, if the father is 180 cm and the mother is 167 cm, the daughter's equation would be {(180 + 167) – 13} ÷ 2.

NURSING ALERT Children whose weight is less than 60% of the median value for age or less than 70% for height are in acute danger of severe morbidity and malnutrition.

Tests to Rule Out Organic Conditions

1. Complete blood count (CBC) with differential and indices, sedimentation rate to rule out anemia or hematologic or inflammatory cause.
2. Blood cultures if fever present.
3. Urinalysis and urine culture as baseline for bladder and renal function.
4. Thyroid-stimulating hormone and free thyroxine to rule out hypothyroidism.
5. Blood chemistry: provide data on electrolyte balance, renal function, and skeletal disorders.
6. Neonate screening tests, TORCH studies.
7. Stool screening tests to be ordered if diarrhea/abnormal stools are present:
    a. Infection: culture, ova and parasite, *Clostridium difficile*, white blood cell (WBC) count (may have false-negative results if recently on antibiotics).
    b. Protein malabsorption: alpha-one antitrypsin (may have false-negative results if not fed during collection).
    c. Carbohydrate malabsorption: pH, reducing substances (time sensitive, need to be fresh stool; may have false-negative results if not fed during collection).
    d. Fat malabsorption: random qualitative fecal fat (one-time sample); if needed, a 72-hour quantitative fecal fat should be collected. Results are more accurate when sample is collected while patient is receiving adequate nutrition.
    e. Pancreatic sufficiency: stool pancreatic elastase, stool chymotrypsin, and serum trypsin to detect primary or secondary pancreatic insufficiency.
8. Radiologic studies including upper GI series, barium swallow, reflux workup, upper endoscopy, and sweat test.

NURSING ALERT One of the best tests to distinguish organic from nonorganic FTT is through observed feedings or enteral tube feedings to assess weight gain and caloric intake.

Management

1. Immediate treatment is directed at reversing malnutrition.
2. All children with FTT need additional calories for catch-up growth (typically 150% of the caloric requirement for their expected, not actual, weight).
3. Nutritional treatment is aimed at providing sufficient calories to support "catch-up" growth to restore deficits in weight and height. Protein and energy requirements for normal and FTT children are outlined in Table 48-1.
   a. This may require NG tube feedings for safe refeeding.
   b. If fat malabsorption present, may need formula with high level of medium-chain triglycerides for direct absorption of fat.
4. Multivitamin supplementation containing zinc and iron is usually recommended, fat-soluble vitamins (A, D, E, K) if fat malabsorption is present.
5. If cause is organic, the underlying disease entity is treated or managed.
6. In nonorganic FTT, hospitalization is avoided (unless the child is in imminent danger) because it further disrupts the parent–child relationship. Therefore, frequent home or clinic visits are necessary. Referral to feeding disorder clinic or rehabilitation center may be necessary.
7. Developmental interventions through occupational and physical therapy are instituted, if necessary, to prevent further delay.
8. Support, education, and financial assistance are offered to the family.
9. Nutrition, occupational therapy, and physical therapy consults are indicated.

Table 48-1 Protein and Energy Requirements

	NORMAL CHILDREN		FTT CHILDREN	
AGE (YEARS)	PROTEIN (G/KG)	ENERGY (KCAL/KG)	PROTEIN (G/KG)	ENERGY (KCAL/KG)
0–0.5	2.2	0.08	3.2	150–250
0.5–1	1.6	98	3.2	150–250
1–3	1.2	102	2.5	150–250
4–6	1.1	90	2.5	150–250
7–10	1.0	70	2.5	150–250

Complications

Studies are inconsistent regarding the long-term complications of FTT.

1. Anemia, fatigue, hypothermia.

2. Vulnerability to infection.
3. Delayed healing.
4. Behavior problems, poor academic performance.
5. Developmental, speech, and language delays.
6. Perceptual difficulties.

Nursing Assessment

1. Obtain accurate anthropometric measurements.
    a. Weight of children younger than age 3 should be done unclothed in a supine position using a calibrated beam scale. Children older than age 3 should be done standing on a standard scale wearing same clothing each time. Effort should be made to use the same scale each time.
    b. Height should be recumbent up to age 2. All children should be measured without shoes.
    c. Head circumference is measured each visit until age 2 with a nonstretchable tape placed firmly from maximal occipital prominence to just above the eyebrow.
    d. All measurements need to be corrected for prematurity up to the second birthday by subtracting the number of weeks premature from the chronological age.
    e. Measurements should be plotted on growth chart using a straight edge or plot grid. Birth measurements should be obtained and entered for comparison.
2. Obtain nutritional history regarding eating patterns; nutritional beliefs for food allocation; 24-hour recall; who normally feeds the child; the type, amount, and frequency of feedings; the amount of time and effort required for meals; the child's reactions (physiologic and psychological) to feedings; food likes and dislikes; and environmental factors.
3. Observe parent–child interactions, such as sensitivity to child's needs, eye-to-eye contact, if and how the infant is held, and how the parent speaks to the child.
4. If possible, observe the parent feeding the child. Assess child's overall tone, sucking pattern, oral sensitivity (gag reflex), lip and tongue function, and swallowing ability. A videotape of the child eating in the home can be reviewed later to reduce the chance of observer distraction.
5. Assess neurologic and cardiovascular status for alertness, attentiveness, developmental delays, cardiac arrhythmias, or murmurs.
6. Assess skin, hair, and musculoskeletal system.
7. Assess developmental status using a Denver II developmental tool, as indicated.

Nursing Diagnoses

- Imbalanced Nutrition: Less Than Body Requirements related to FTT process.
- Delayed Growth and Development related to malnutrition.
- Impaired Parenting related to inability to meet the needs of the FTT child.

Nursing Interventions

Promoting Adequate Nutrition

1. Facilitate nutritional consultation.
2. If hospitalized, provide a primary core of staff to feed the child. Ask the parents to do so when present in a nonthreatening manner.
3. Develop individualized teaching plan to instruct parents of child's dietary needs. Specify type of diet, essential nutrients, serving sizes, and method of preparation.
4. Provide a quiet, nonstimulating environment for eating.
5. Demonstrate proper feeding techniques including details on how to hold and how long to feed the child.
6. Administer multivitamin supplements, as prescribed.
7. Encourage nutritious, high-calorie, and fortified fluids to increase nutrient density. For infants, use 24 to 30 cal/ounce rather than 20 cal/ounce. For older children, suggest fruit smoothies using whole milk and ice cream.
8. Refeed the malnourished child with caution, monitoring electrolytes, calcium, magnesium, and phosphorus daily or more frequently, if abnormal.
    a. Gradually increase nutrients and use small, frequent feedings with adequate fluids to ensure hydration.
    b. Monitor intake and output.
9. Maintain high-nutrient diet until weight is appropriate for height (usually age 4 to 9 months).
10. Advise family that some nutritional intervention will be continued until appropriate height for age is reached.

NURSING ALERT If patient is malnourished, monitor for refeeding syndrome until laboratory studies are stable. Refeeding syndrome can cause intracellular shifting of electrolytes, calcium, magnesium, and phosphorus, resulting in death. Laboratory studies should be monitored daily or more frequently, if abnormal.

NURSING ALERT Be alert for signs of dehydration due to sudden change to a high-calorie, high-protein diet. A dramatic increase in protein can increase renal solute load to the point that a child is at risk for dehydration.

Promoting Adequate Growth and Development

1. Obtain accurate weight at every visit or every day, if hospitalized.
2. Assess child's growth by using age- and gender-appropriate growth charts. Extremely low-birth-weight infants born with major anomalies have nearly twice the risk of neurodevelopmental impairment and

increased risk of poor growth.

3. Assess child's development by interviewing the parent or caregiver or using developmental screening tests, such as the Denver II (Denver Developmental Materials, Inc., *http://denverii.com/denverii/*).
4. Observe interactions between parents and child and among family members, including eye contact, communication patterns, and coping ability.
5. Provide the infant with visual and auditory stimulation by exposing to bright colors, shapes, and music. Provide the older child with age-appropriate stimulation, such as books, games, and toys. Place the infant prone, while awake, on the floor to encourage trunk control.
6. Encourage periods of scheduled rest and sleep.

EVIDENCE BASE Stobaugh, H., Rogers, B., Rosenberg, I., et al. (2018). Children with poor linear growth are at risk for repeated relapse to wasting after recovery from moderate acute malnutrition. *Journal of Nutrition,* May 3. Epub ahead of print.

Promoting Effective Parenting

1. Teach the parents (especially the mother) normal parenting skills by demonstrating proper holding, stroking, feeding, and communication using age-appropriate words and gestures.
2. If hospitalized, encourage and facilitate the parents to spend as much time as possible with the child.
3. Educate the parents to recognize and respond to the child's distress and hunger calls.
4. Help the parents to develop organizational skills—write down daily schedule with mealtimes, time for shopping, and so forth.
5. Refer for counseling, if necessary, to help parents overcome feelings of mistrust or neglect resulting from adverse personal childhood experiences.
6. Refer to social services to help resolve any social and financial difficulties that might interfere with providing a nurturing environment.
7. Monitor parents' progress and provide positive reinforcement.

Community and Home Care Considerations

Early intervention home visiting has been shown to reduce the long-term complications associated with FTT. This may be due to promotion of maternal sensitivity and helping children build strong work habits that enables them to flourish at school.

1. Make regular home visits to:
   a. Observe for continued parent–child interaction.
   b. Encourage continued developmentally appropriate play.
   c. Monitor feeding status and assess intake amount.
   d. Determine frequency of voiding and stooling.

e. Assess child's weight, height, and head circumference.
f. Monitor vital signs and watch for signs of dehydration.
g. Auscultate bowel sounds.
h. Assess muscle tone and vigor of activity.
i. Assess family dynamics and use of support systems.

2. Inform parents of community resources, such as Women in Crisis program, food banks, parenting groups.
3. Make sure that day care providers can meet child's special needs in terms of diet, feeding, and developmentally appropriate play. Day care may be beneficial in the presence of family dysfunction by providing structure.
4. Make referrals to social work and occupational or physical therapy, as needed.

Family Education and Health Maintenance

1. Reinforce the need for a quiet, nonthreatening, nurturing environment.
2. Encourage the parents to be consistent with feedings. Although forced feeding is avoided, strict adherence to appropriate feeding is essential for growth.
3. Advise the parents to introduce new foods slowly and follow the child's rhythm of feeding.
4. Review the importance of providing a routine rest schedule in an environment that is conducive to sleep.
5. Review development, stressing need for visual, auditory, and tactile stimulation and age-appropriate toys for continued development.
6. Reinforce the need for follow-up care, well-child visits, and immunizations.

Evaluation: Expected Outcomes

- Increases weight steadily.
- Attains developmental milestones at appropriate age.
- Parents participating in child's care, using appropriate feeding technique.

Hypertrophic Pyloric Stenosis

EVIDENCE BASE Gezer, H., Oguzkurt, P., Temiz, A., et al. (2015). Hypertrophic pyloric stenosis in twins; genetic or environmental factors. *Clinical Genetics, 87*(4), 388–391.

Hypertrophic pyloric stenosis is an acquired condition in which the circumferential muscle of the pyloric sphincter becomes thickened, causing a high-grade gastric outlet obstruction that results in dilation, hypertrophy, and hyperperistalsis of the stomach. It is the second most common condition (after inguinal hernia) requiring surgery, which rarely occurs before age 2 weeks or later than age 5 months. Incidence is 1 in 250 live births and is predominant in males (5:1) and more common in first-born males. Incidence peaks in spring and fall. It is more likely to affect a full-term infant than a premature infant.

Pathophysiology and Etiology

1. Unknown cause, although new research has identified several genetic markers associated with the condition. Multiple theories of etiology exist, including immature or degenerated pyloric neural elements, variations in infant feeding regimens, excessive production of gastrin (maternal or infant), dyscoordination between gastric peristalsis and pyloric relaxation, deficiency of nitric acid, abnormalities in enteric nervous system, and abnormalities in neurotransmitters.
2. Current studies of combined imaging (pressure recordings, MRI, ultrasound, and fluid-mechanical analysis) have offered new understanding of the role of the pylorus in gastric emptying and digestion. Other studies have shown that persistent duodenal hyperacidity can lead to increased incidence of pyloric stenosis. This is associated with repeated contractions of the pylorus.
3. The use of erythromycin to treat reflux and gastric dysmotility has led to research regarding the association with pyloric stenosis. The published evidence has concluded that young infants exposed to erythromycin in the first few weeks of life are at greater risk for developing hypertrophic pyloric stenosis. The highest risk seems to be in the first 2 weeks of life in term or near-term infants, with a course of more than 14 days.
4. Increase in size of the circular musculature of the pylorus with thickening (size and shape of an olive). The pylorus muscle becomes elongated and thickened and is enlarged to about twice the usual size. On clinical exam, palpation of an “olive” is diagnostic.
5. Hypertrophy of the pylorus musculature occurs with narrowing of the pyloric lumen.
6. Constriction of the lumen of the pyloric canal (at the distal end of the stomach) causes the stomach to become dilated.
7. Gastric emptying is delayed.

EVIDENCE BASE Zhu, J., Zhu, T., Lin, Z., et al. (2017). Perinatal risk factors for infantile hypertrophic pyloric stenosis: A meta-analysis. *Journal of Pediatric Surgery, 52*(9), 1389–1397.

Murchison, L., De Coppi, P., & Eaton, S. (2016). Postnatal erythromycin exposure and risk of infantile hypertrophic pylori stenosis: A systematic review and meta-analysis. *Pediatric Surgery International, 32*(12), 1147–1152.

DRUG ALERT Erythromycin should only be used in young infants (less than 4 weeks) when the therapeutic benefits outweigh the risks and no alternative agent is available.

Clinical Manifestations

Onset usually occurs between ages 3 and 12 weeks.

1. Cardinal sign is projectile, nonbilious vomiting.
   a. Initially, occasional regurgitation (similar to GER) may be present, but eventually vomiting increases in frequency and intensity.
   b. Vomitus contains milk and gastric juices; however, it may be blood-streaked or have a "coffee ground" appearance.
   c. Emesis occurs just after or near the end of a feeding.
2. Constipation or decreased quantity of stools.
3. Loss of weight or failure to gain weight.
4. Epigastric distention.
5. Visible gastric peristaltic waves, left to right, seen just after infant vomits.
6. Excessive hunger—willingness to eat immediately after vomiting.
7. Dehydration—electrolyte disturbance with alkalosis, hypoglycemia, hypochloremia.
8. Decreased urine output.
9. Palpable pyloric mass in upper right quadrant of abdomen, to the right of the umbilicus and best felt during feeding or immediately after vomiting.
10. Jaundice.

Diagnostic Evaluation

1. Palpation of pyloric mass ("olive") in conjunction with persistent, projectile vomiting is pathognomonic.
2. Ultrasound evaluation—broadly used, noninvasive method to evaluate the length and diameter of the pyloric muscle.
   a. Criteria for a positive diagnosis: pyloric muscle thickness (PMT) ≥ 3 mm and pyloric muscle length

(PML) ≥ 17 mm.

   b. Sensitivity and specificity of PMT, 91% and 85%, respectively; for PML, 76% and 85%, respectively.
   c. No significant correlation among age, weight, or prematurity and a sonographic diagnosis of infantile hypertrophic pyloric stenosis; therefore, the same ultrasound criteria should apply irrespective of prematurity, age, or weight. Borderline PMT and PML measurements necessitate repeat ultrasound or alternative imaging.
3. Barium upper GI series—indicated if ultrasound is inconclusive.
4. Flat film of abdomen—dilated, air-filled stomach; nondilated pyloric canal.
5. Tests for metabolic alkalosis (seen in less than 10% because of more prompt diagnosis over the past 20 years).
6. Urinalysis—urine alkaline and concentrated.
7. Blood hemoglobin and hematocrit—elevated due to hemoconcentration.

EVIDENCE BASE Ayaz, U., Dogen, M., Dilli, A., et al. (2015). The use of ultrasonography in infantile hypertrophic pyloric stenosis: does the patient's age and weight affect pyloric size and pyloric ratio? *Medical Ultrasonography, 17*(1), 28–33.

Management

EVIDENCE BASE Sathya, C., Wayne, C., Gotsch, A., et al. (2017). Laparoscopic versus open pyloromyotomy in infants: A systematic review and meta-analysis. *Pediatric Surgery International, 33*(3), 325–333.

---

1. Considered a medical emergency because of dehydration and electrolyte imbalance, with initial treatment to rehydrate to correct electrolytes and alkalosis.
2. Surgical treatment is corrective and takes place when electrolytes are stable—Rammstedt pyloromyotomy is procedure of choice, performed through a short transverse incision in the right upper quadrant over the rectus muscle at or above the liver edge. Laparoscopic pyloromyotomy may also be done but the open procedure continues to be the most performed technique.
   a. Hypertrophy of the pyloric muscle regresses to normal size about 12 weeks postoperatively.
   b. Some postoperative vomiting is expected but should decrease over 48 hours. If persistent vomiting continues, a contrast study should be completed to rule out gastric leak, fluid collection obstructing the gastric outlet, or other causes of obstruction. If these are ruled out, incomplete pyloromyotomy should be considered.

c. Postoperative complications include duodenal perforation, gastric leak, wound infection, small bowel obstruction, and postoperative vomiting.

3. Good outcomes following surgery appear to be strongly related to the qualifications of the pediatric surgeon, the use of pediatric certified anesthesiologists, qualified pediatric nurses, adequate correction of fluids and electrolytes preoperatively.

Complications

1. Starvation.
2. Dehydration.
3. Severe electrolyte imbalance.
4. Hematemesis.

Nursing Assessment

1. Obtain a thorough history of infant's feeding behaviors and history of vomiting.
2. Assess hydration status and for signs and symptoms of electrolyte imbalance.
3. Assess and chart growth and development parameters.

Nursing Diagnoses

Preoperative

- Deficient Fluid Volume related to frequent vomiting.
- Imbalanced Nutrition: Less Than Body Requirements related to vomiting.
- Acute Pain related to gastric distention.
- Anxiety of parents related to illness, hospitalization, and impending surgery of child.

Postoperative

- Risk for Injury related to postoperative complications.
- Risk for Deficient Fluid Volume after surgery.
- Impaired Tissue Integrity related to surgical incision.

Nursing Interventions

Maintaining Fluid and Electrolyte Balance

1. Administer IV therapy, as ordered, to treat dehydration, metabolic alkalosis, and electrolyte deficiency.
2. Carefully monitor output, including amount and characteristics of urine (check specific gravity), vomiting, and stools.
3. Accurately measure daily weight as a guide for calculating need for parenteral fluid.
4. Monitor laboratory data for serum electrolytes.
5. Position infants to prevent interference with fluid therapy.

6. Provide pacifier for infants who are NPO.
7. Monitor vital signs, as indicated by condition. Watch for tachycardia, hypotension, change in respirations.

NURSING ALERT Irregular respiratory rate with apnea is a sign of severe alkalosis.

Maintaining Nutrition

EVIDENCE BASE Sullivan, K., Chan, E., & Vincent, J. (2016). Feeding post-pyloromyotomy: A meta-analysis. *Pediatrics, 137*(1), epub.

---

1. Emphasize rehydration, electrolyte balance, and replacement of body fat and protein stores. This depends on severity of depletion and may require total parenteral nutrition for several days or weeks before surgery to reduce surgical risk.
2. Maintain NPO status with indwelling NG tube (inserted to remove any residual barium and retained formula), as ordered. Ensure placement, position, and patency. Record drainage type, color, and amount.
3. If oral feedings are to be continued, do the following:
   a. Provide small, frequent feedings, given slowly.
   b. Burp frequently before, during, and after feeding.
   c. Allow breast-feeding, as tolerated.
4. Prop the patient in 30-degree upright position (see Figure 48-4).
5. Handle gently and minimally after feeding.

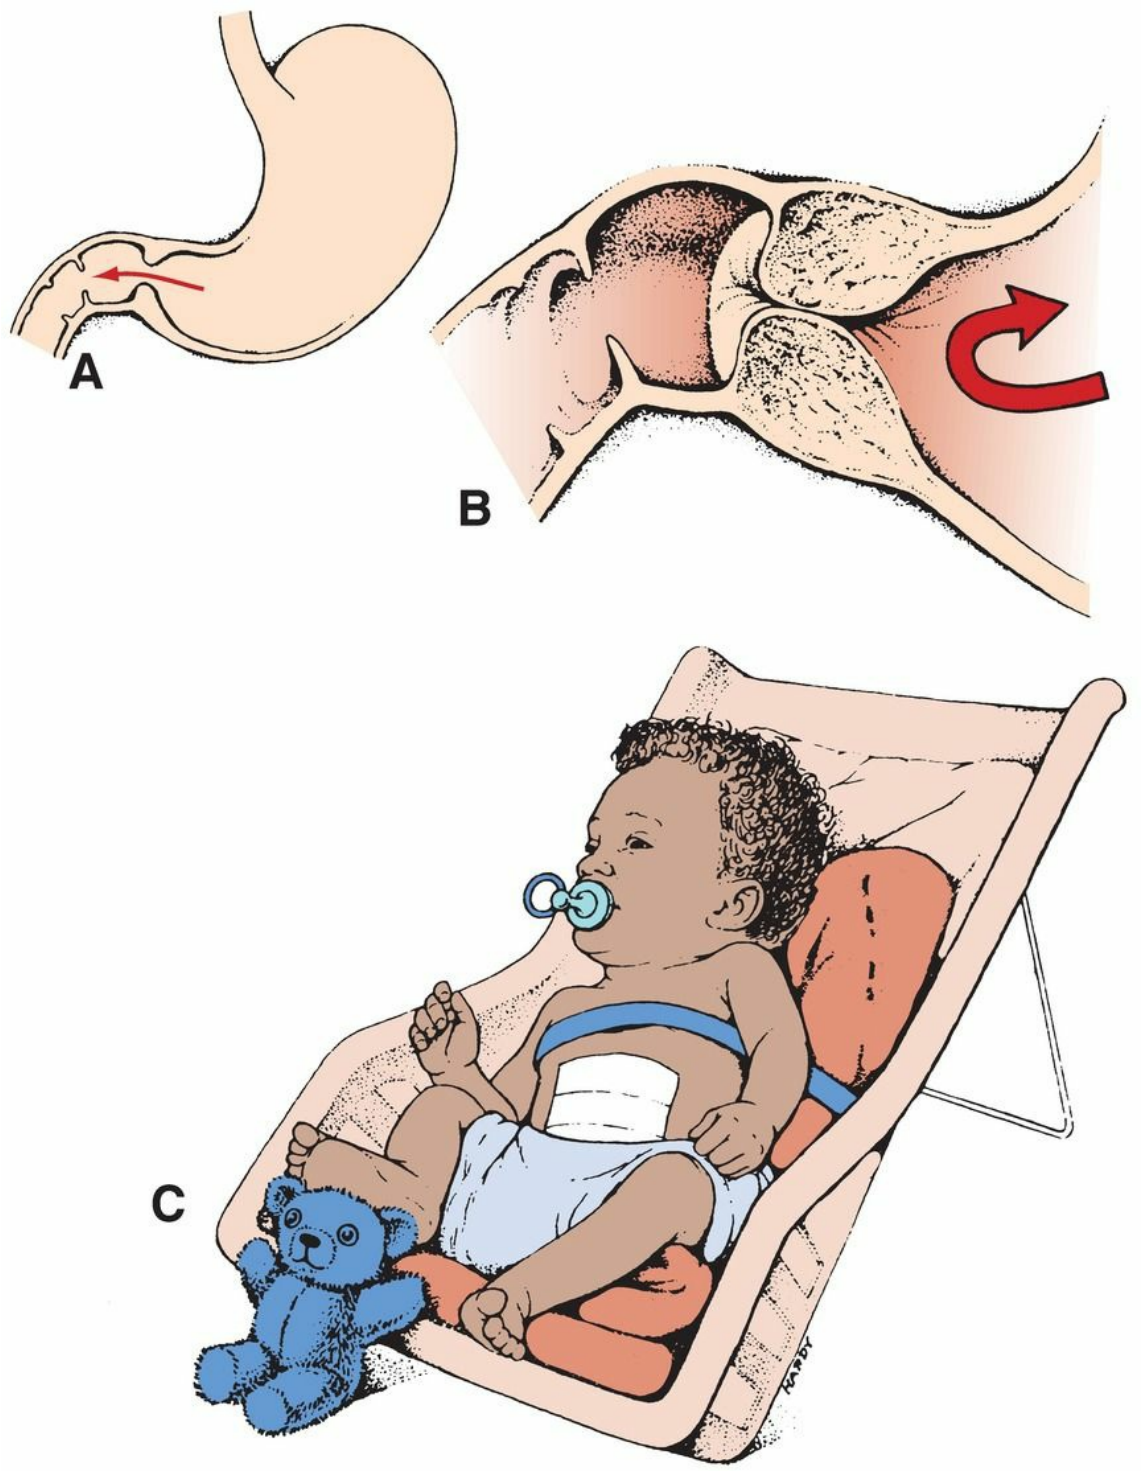

Figure 48-4. Pyloric stenosis. **(A)** Normal passage through pyloric sphincter. **(B)** Stoppage of flow due to stenotic sphincter. **(C)** Postoperative treatment: child propped upright, slightly on right side, aids in gastric emptying.

Providing Comfort

1. Provide mouth care and wet lips frequently if NPO.
2. Let the infant suck on a pacifier.

3. Provide for physical contact or nearness without excessive stimulation.
4. Provide for audio and visual stimulation that may be soothing.
5. Do not palpate pyloric "olive" to decrease risk of postoperative wound infection from bruising abdominal wall and excoriating tissue in operative site.
6. Administer analgesics, as ordered.

Alleviating Parental Anxiety

1. Assess understanding of diagnosis and care plan.
2. Help minimize guilt feelings by providing adequate, specific information and clarifying any misconceptions.
3. Prepare the parents for the surgery of their child.
   a. Be honest with them.
   b. Prepare them for the expected postoperative appearance of the infant.
   c. Show them where the operating room and recovery room are located and where to wait during surgery.
4. Allow them to hold the infant to maintain bonding.
5. Encourage them to rest to care better for the infant postoperatively.
6. Accept and explore negative displays of emotion, which may be due to fatigue and frustration because of the extensive care given to the child before hospitalization.
7. Reassure them that surgery is considered curative and normal feeding should resume shortly afterward.

Preventing Complications

1. Assess vital signs to evaluate for fluid and electrolyte imbalances.
2. Assess skin and mucous membranes for hydration status.
3. Weigh daily to assess gain or loss.
4. Elevate head slightly.
5. If placed intraoperatively, maintain patent NG tube to prevent gastric distention. Record losses.
6. Monitor blood glucose levels to prevent hypoglycemia.

Maintaining Hydration

1. Administer IV fluids until adequate intake has been established.
2. Resume oral feeding 2 to 8 hours (standard is 6 hours) after surgery when infant is alert or as ordered.
3. After surgery, infants may progress to ad-lib feedings within 12 to 16 hours provided they did not have a prolonged preoperative course.
4. Start with small, frequent feedings of glucose water and slowly advance to full-strength (FS) formula and regular diet, as tolerated. An example of a postoperative feeding schedule includes:
   a. NPO for 6 hours.
   b. Sugar water solution orally 30 mL every 2 hours for two feedings.

c. Then half-strength formula 30 mL every 2 hours for two feedings.
d. Then FS formula 45 mL every 2 hours for two feedings.
e. Then FS formula 60 mL every 3 hours for two feedings.
f. Then formula ad lib every 4 hours.

5. Report any vomiting—amount and characteristics. Feeding schedule may be withheld 2 hours and then reinitiated.
6. Feed slowly and burp frequently.
7. Note how feeding is taken and if it is retained.
8. Increase the amount of feeding as the time interval between feedings is lengthened.
9. Allow breast-feeding to resume, as tolerated, if permitted by the operating surgeon, beginning with limited nursing of 5 to 8 minutes and gradually increase.
10. Continue to elevate the infant's head and shoulders after feeding for 45 to 60 minutes for several feedings after surgery. Place on right side to aid gastric emptying.
11. Expect that regurgitation may continue for a short period after surgery.

Promoting Healing

1. Provide analgesia and comfort measures, such as a pacifier, rocking, and other soothing stimulation to keep infant quiet and prevent tension on incision.
2. Involve parents in care of infant postoperatively to prepare them for care of wound after discharge.
3. Observe for drainage or signs of inflammation at incision site and provide care to incision, as ordered.
4. Note that poor nutritional status may delay wound healing.

Community and Home Care Considerations

1. Teach proper care of the operative site.
   a. Check for signs and symptoms of inflammation.
   b. Observe for drainage.
   c. Provide specific care of site, as ordered by provider.
2. Monitor weight and feeding behavior. Encourage close follow-up for growth and development.
3. Observe for signs of delayed gastric emptying or GER.
4. Assess parent–infant interaction and parental coping.

Family Education and Health Maintenance

1. Teach feeding technique to be continued at home; length of feeding technique varies depending on wound healing, nutritional status, and growth.
2. Provide written and verbal instructions as to infant's care and follow-up schedule.
3. Review with family when medical attention is needed and appropriate resources:
   a. Signs of infection.

b. Frequent vomiting, vomiting longer than 5 days, or poor feeding with signs of dehydration.
c. Abdominal distention.

Evaluation: Expected Outcomes

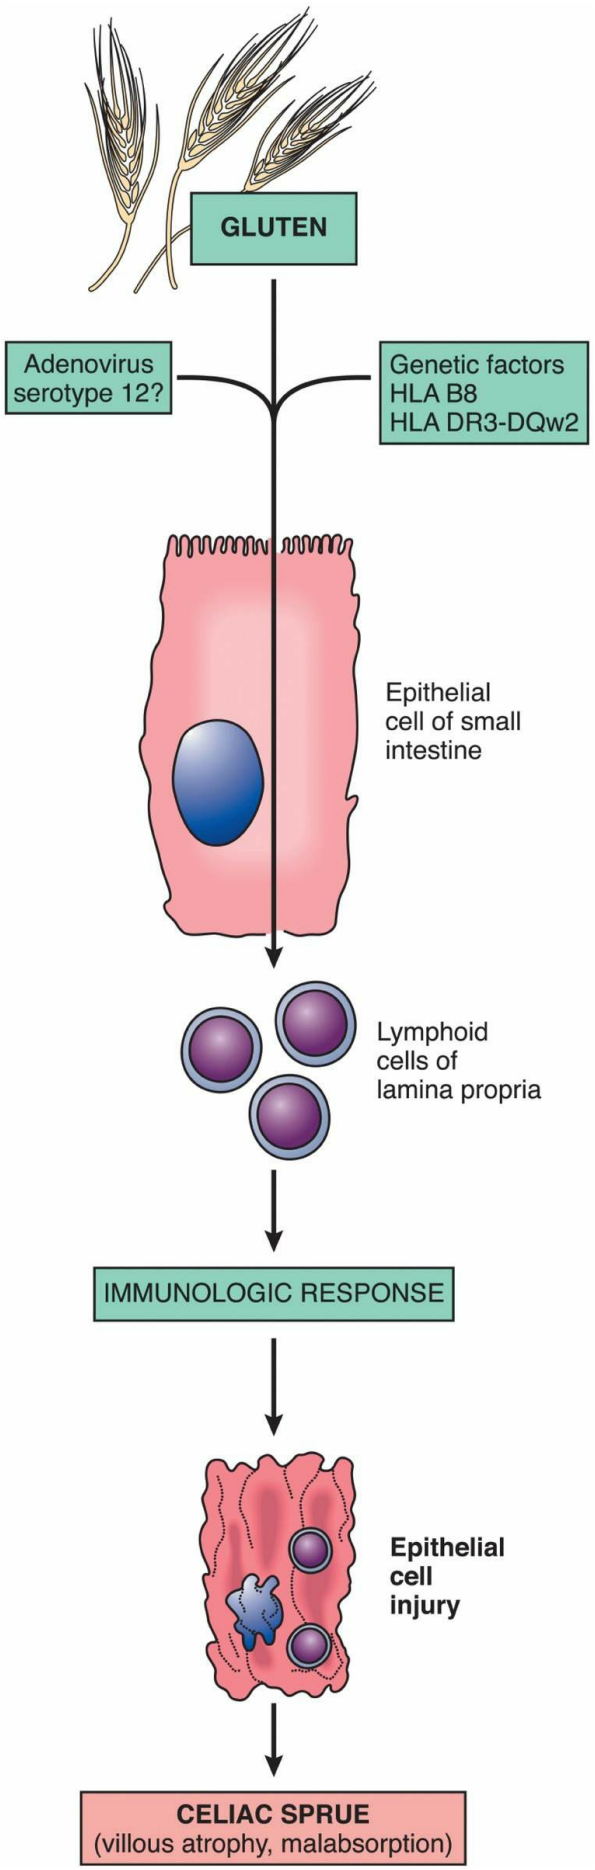
- Vital signs stable; urine output adequate.
- Tolerates 1- to 2-ounce feedings in upright position without vomiting.
- Rests quietly with pacifier.
- Parents verbalize understanding of surgery and postoperative care.
- Vital signs stable; blood glucose within normal limits.
- No signs of dehydration.
- Incision healing without signs of infection.

Celiac Disease

EVIDENCE BASE Hill, I., Fasano, A., Guandalini, S., et al. (2016). NASPGHAN clinical report on the diagnosis and treatment of gluten-related disorders. *Journal of Pediatric Gastroenterology & Nutrition, 63*(1), 156–165.

Paul, S. P., Sandhu, B. K., Spray, C. H., et al. (2018). Evidence supporting serology-based pathway for diagnosing celiac disease in asymptomatic children from high-risk groups. *Journal of Pediatric Gastroenterology & Nutrition, 66*(4), 641–644.

Celiac disease (CD), or *gluten-sensitive enteropathy*, is a complex autoimmune genetic disorder with multiple contributing genes. CD affects the small intestine and is characterized by a permanent inability to tolerate dietary gluten; however, it can have systemic manifestations as well. Gluten is a protein found in wheat, rye, and barley (see Figure 48-5). The disease process is reversible with strict adherence to a gluten-free diet.



GLUTEN
Adenovirus serotype 12?
Genetic factors
HLA B8
HLA DR3-DQw2
Epithelial cell of small intestine
Lymphoid cells of lamina propria
IMMUNOLOGIC RESPONSE
Epithelial cell injury
CELIAC SPRUE
(villous atrophy, malabsorption)

Figure 48-5. Mechanisms in the pathogenesis of celiac disease. (Rubin, R., & Strayer, D. S. [2011]. *Rubin's Pathology: Clinicopathologic Foundations of Medicine* [6th ed.]. Philadelphia: Lippincott Williams & Wilkins.)

CD occurs more frequently in Caucasians; however, it is found in all ethnic groups. In the United States and Europe, the prevalence of CD in the pediatric population is between 1 in 300 and 1 in 80, respectively. It is thought to be grossly underdiagnosed.

Pathophysiology and Etiology

1. CD is an immune-mediated disease. The two necessary components of the disease are exposure to gluten and a genetic predisposition resulting in immune activation to gluten. Linkage studies have identified several genomic regions that probably contain CD-susceptibility genes.
   a. The genes implicated in celiac disease are HLA-DQ2 and HLA DQ8. However, these genes can be found in 30% of the normal population as well.
   b. A familial connection is found in 5% to 15% of celiac patients, with an 83% to 86% concordance rate among monozygotic twins.
2. The disease results in inflammation in the mucosa of the small bowel, especially the duodenum and jejunum. This results in damage to the villi, which can be shortened or totally lost.
3. The mucosal damage results in deficiency of enzymes on the mucosal surface, such as disaccharidase and peptidase. This, along with a reduced surface area, leads to malabsorption.
4. The body may be unable to absorb fats, fat-soluble vitamins (A, D, E, and K), minerals, and some protein and carbohydrates.
5. The severity of symptoms depends on the extent of affected intestine. If involvement is focal and limited to the proximal bowel, GI symptoms may be absent.
6. A number of conditions may be associated with celiac disease, including:
   a. Type 1 diabetes mellitus.
   b. Mucocutaneous manifestations, dermatitis herpetiformis.
   c. Cystic fibrosis, seizures, peripheral neuropathy.
   d. Autoimmune thyroiditis, adrenal insufficiency.
   e. Systemic lupus erythematosus, rheumatoid arthritis, and other connective tissue disorders.
   f. Sclerosing cholangitis.
   g. Trisomy 21.
   h. Unexplained folate or iron deficiency, refractory to treatment.
   i. Alopecia areata.
   j. Dental enamel hypoplasia.
   k. Risk of thromboembolism.

Clinical Manifestations

The age and mode of presenting signs and symptoms are extremely variable. Diagnosis may be made by ages 6 to 24 months when infants are introduced to cereal; however, more subtle gastrointestinal and extraintestinal symptoms often lead to diagnosis much later in life.

Ages 6 to 18 months

Presentation may include the following:

1. Impaired growth.
    a. Normal growth during early months of life.
    b. Slackening of weight followed by weight loss.
2. Diarrhea—more frequent, pale, soft, bulky, greasy (steatorrhea) with offensive odor.
3. Recalcitrant constipation (occasionally).
4. Abdominal distention.
5. Anorexia.
6. Muscle wasting—most obvious in buttocks and proximal parts of extremities.
7. Vomiting.
8. Seizures.
9. Loss of tooth enamel.
10. Painful/pruritic skin rash called “dermatitis herpetiformis.”

Older Children

1. Complications of malabsorption:
    a. Anemia, vitamin deficiency.
    b. Hypoproteinemia (hypoalbuminemia) with edema.
    c. Hypocalcemia, hypokalemia, hypomagnesemia.
    d. Hypoprothrombinemia resulting from impaired vitamin K absorption.
    e. Disaccharide intolerance—with acid sugar-containing stools (secondary to the altered small-bowel mucosa).
    f. Low bone density, osteoporosis secondary to decreased calcium absorption.
2. Diarrhea or constipation.
3. Overweight status.
4. Linear growth delay.
5. Abdominal pain.
6. Fatigue.

EVIDENCE BASE Jericho, H., Assiri, A., & Guandalini, S. (2017). Celiac disease and wheat intolerance syndrome: A critical update and reappraisal. *Journal of Pediatric Gastroenterology & Nutrition, 64*(1), 15–19.

Diagnostic Evaluation

EVIDENCE BASE Allen, P. (2015). Gluten-related disorders: Celiac disease, gluten allergy, non-celiac gluten sensitivity. *Pediatric Nursing, 41*(3), 146–150.

1. Thorough history, including family history of autoimmune disorders, diabetes, dietary history, growth history, and general status of the child.
2. Serologic testing is done to screen the individual at risk. It has been recommended that all short-stature children be screened irrespective of GI symptoms. Assays detect immunoglobulin (Ig) A antibody to endomysium or tissue transglutaminase. These antibodies have a very high sensitivity and specificity for CD; however, they may be falsely low in a child with IgA deficiency. Therefore, the total IgA level must also be checked. Maintain usual diet during testing.
3. An upper endoscopy is the gold-standard test to confirm the diagnosis and must be done in all individuals whose serologic screening is positive. It might show infiltration of the mucosa with lymphocytes and variable degrees of flattened villi.
4. Videocapsule endoscopy shows good sensitivity and excellent specificity for the detection of villous atrophy in patients with suspected CD but is not often practical in the pediatric population; the gold standard of diagnosis remains the small intestinal biopsy.

NURSING ALERT Age 3 to 6 months is too early to be able to detect celiac disease with testing because of the length of time of gluten exposure.

Management

EVIDENCE BASE Isaac, D., Wu, J., Mager, D., et al. (2016). Managing the pediatric patient with celiac disease: A multidisciplinary approach, *Journal of Multidisciplinary Healthcare, 9*, 529–536.

1. Lifelong gluten-free diet.
    a. Avoid all foods containing wheat, rye, and barley and their derivatives because even a small amount, such as a trace contaminant, may cause a pathologic response. Oats are naturally gluten-free; however, they are often cross-contaminated during the manufacturing process, so their exclusion may be recommended.
    b. The small intestinal mucosa will always respond abnormally to dietary gluten, although clinical signs may not be immediately evident.
    c. Biopsy and serologic screening revert to normal with appropriate diet.
    d. Clinical signs of improvement are often seen days to weeks after proper diet is initiated but can take up to 1 year in the case of more insidious symptoms such as delayed linear growth.
2. Adequate caloric and nutrient intake.
3. Supplemental vitamins and minerals may be used when clinically indicated. Folic acid may be used if low level is suspected or detected.
    a. Vitamins A and D.
    b. Iron supplements until anemia resolves.
    c. Vitamin K if evidence of hypoprothrombinemia and bleeding.
    d. Calcium if milk is restricted.
4. Temporary restriction of lactose and sucrose (disaccharidases) from diet for 6 to 8 weeks may be indicated in some cases, if these products are shown to worsen symptoms.
5. Enzyme therapy that protects the mucosal lining from gluten exposure is being investigated in clinical trials.

Complications

1. Nutritional deficiencies (most important short-term risks, which can lead to anemia, osteoporosis, and growth failure).
2. Long-term risks of untreated CD include increased risk of lymphoma and adenocarcinoma of small intestine.
3. Refractory CD.
4. Seizures related to inadequate absorption of folic acid and buildup of calcium deposits on the brain.

Nursing Assessment

1. Obtain family dietary history as it relates to onset of symptoms.
2. Assess child's nutritional status.
3. Check for signs of infection.
4. Assess growth and developmental parameters.

Nursing Diagnoses

- Imbalanced Nutrition: Less Than Body Requirements related to malabsorption of nutrients, diarrhea,

and vomiting.

- Impaired Parenting related to inability to control behavioral problems.

Nursing Interventions

Provide Adequate Nutrition and Dietary Restrictions

1. Provide gluten-free diet, being careful to avoid accidental exposure via cross-contamination while food is prepared and/or cooked.
2. An initial diet high in protein, relatively low in fat, low in lactose, and free from gluten may be necessary if the newly diagnosed child exhibits severe malabsorption.
   a. Initiate a referral with a dietitian for precise diet recommendations.
   b. Soy milk or lactaid drops may be indicated if the patient is exhibiting signs of lactose intolerance.
   c. Watch for fat intolerance in infants and young children.
3. Maintain NPO status during the initial treatment of celiac crisis or during diagnostic testing. Take special precautions to ensure proper restriction if the child is ambulatory.
4. Encourage small, frequent, appetizing meals, but do not force eating if the child has anorexia.
5. Note the child's reaction to food. Close observation of the child's responses to food may reveal other intolerances. Note and record
   a. Foods taken and refused.
   b. Appetite.
   c. Change in behavior after eating.
   d. Characteristics and frequency of stools.
   e. General disposition—behavior improvement commonly seen within 2 to 3 days after diet control is initiated.
6. Be prepared to temporarily eliminate new food introduced if symptoms increase.
7. A gluten-challenged diet is not routinely indicated.
8. Provide the family with assistance to obtain a variety of gluten-free foods. Studies demonstrate that poor availability and expense of gluten-free foods lead to dietary noncompliance.

EVIDENCE BASE Barnes, C. (2016). An introduction to the management of paediatric patients with celiac disease. *Gastrointestinal Nursing, 14*(9), 39–45.

Promoting Effective Parenting

1. Teach the parents to develop an awareness of the child's behavior; recognize changes and care for child accordingly.
2. Explain that diet and eating have a direct effect on behavior and that behavior may indicate how the

child is feeling.

3. Help the parents recognize and understand mood swings, from having temper tantrums to being very timid, nervous, or unstable.
4. Advise the parents to allow the child to express feelings freely through safe and age-appropriate media.
5. Encourage parents to define limits of behavior for the child and convey them to all family members.
6. Encourage patience, routines, and consistency.
7. Advise parents to record changes in behavior, especially in relation to eating and diet, to document effectiveness of therapy.
8. Help the parents to maintain a balance between the child with celiac disease, the other family members, and additional roles and responsibilities.
9. If the child is withdrawn, advise providing opportunity for play with other children, especially when the child begins to feel better.
10. Explain that the toddler may cling to infantile habits for security. Allow this behavior; it may disappear as physical condition improves.
11. Suggest offering the child other sensory stimulation to compensate for lack of eating pleasure.
12. Help the parents to understand that, after initial rapid weight gain, further improvement may be slow.
13. Provide emotional support for the child and parents.
14. Refer for counseling, if indicated.

Family Education and Health Maintenance

EVIDENCE BASE Haas, K., Martin, A., & Park, K. T. (2017). Text message intervention (TEACH) improves quality of life and patient activation in celiac disease: A randomized clinical trial. *Journal of Pediatrics, 185*, 62–67.

---

1. Teach parents about celiac disease and how it is controlled by diet. Help them to understand that severe, long-term damage to the intestinal lining has occurred and must be controlled to allow for normal growth and development.
2. Long-term follow-up with a qualified dietitian has been shown to improve compliance based on symptoms and follow-up serological testing.
3. Provide a specific list of restricted and acceptable foods to get the family started; because there is much variation among brands of packaged foods, it is best for the family to check with the manufacturers.
4. Teach the parents how to read labels on foods to identify those containing wheat, rye, and barley glutens, thus avoiding them.
    a. Advise that any ingredient of unknown or unspecified grain origin should be assumed to contain gluten, unless the manufacturer confirms that it is gluten-free.

b. Advise that medications should also be checked; filler and excipients, such as alcohol in cough medication, may be wheat based.

c. Advise parents that gluten is found in many manufactured products as a filler or thickener, such as gravy powder.

5. Provide information on substitutes for wheat, rye, and barley such as corn, rice, potato, soybean flour, and gluten-free starch.
6. Help the parents become comfortable in situation problem solving (eg, supplying gluten-free cupcakes for birthday party to which child has been invited).
7. Initiate referral to dietitian to ensure that nutrient and energy requirements are being met. There is no standardized vitamin regimen.
8. Discuss the importance of continued adherence to gluten-free diet, even though the child is feeling well, eating well, and has normal stools. Encourage child to become involved in diet.
9. Adolescent compliance may be variable. Encourage support and understanding.
10. Alteration in diet may have significant cultural, ethnic, and religious implications. Help parents identify how adjustments can be made.
11. Advise parents on eating out—check ahead of time with fast-food chains and restaurant chefs or management to determine if they can ensure gluten-free items. (Be aware that even a gluten-free hamburger cooked on a grill with a breaded chicken breast cannot be considered gluten free.)
    a. Many gluten-free menus at chain restaurants can be found on the Internet by searching keyword "gluten-free."
    b. Inform friends before visiting and bring gluten-free products, if necessary.
    c. If necessary, consider implementation of formalized plan of necessary dietary restrictions for appropriate accommodations in school settings.
12. Advise parents to investigate support groups, Internet companies, natural food stores, and major food brands that offer information and sell gluten-free products.
13. Tell parents that common problems with long-term gluten-free diet are constipation due to low dietary fiber intake and weight gain due to now normal absorption; therefore, encourage regular physical activity and avoidance of high-calorie foods.
14. Impress on the parents the importance of regular medical follow-up.
15. Encourage the parents to practice good hygiene to prevent infection because the child may be especially prone to infection if malnutrition and/or anemia are present.
16. Advise the family that patients with CD have a predisposition to nonresponse of the hepatitis B vaccine; therefore, titers should be considered.
17. Help the parents to understand that the emotional climate in the home and around the child is vitally important in maintaining the child's medical and physical stability. Stress the importance of not making the child feel abnormal or a nuisance to the family. Family support is invaluable in facilitating acceptance of the diet.
18. Stress that the disorder is lifelong; however, changes in the mucosal lining of the intestine and the

general clinical condition of the child are reversible when dietary gluten is avoided.

19. Advise screening for all first-degree relatives, because of hereditary nature of the disease.
20. For additional information and support, refer to Celiac Sprue Association (*www.csaceliacs.org*), Canadian Celiac Association (*www.celiac.ca*), or Celiac Disease Foundation (*www.celiac.org*).

Evaluation: Expected Outcomes

- Tolerates gluten-free diet well. Poor growth is not the symptom for every child; therefore gaining weight is not an appropriate expected outcome for each child.
- Parents setting limits with child and documenting behavior in relation to meals.

Diarrhea

Diarrhea is the rapid movement of fecal matter through the intestine, resulting in an excessive loss of water and electrolytes and producing more frequent loose, unformed, or watery stools. It is a symptom of many conditions and may be caused by many diseases (see Table 48-2). Commonly, the cause is difficult to determine; occasionally, it is unknown. Worldwide, approximately 1.8 million children die from diarrhea annually. Studies show that approximately 40% of cases of diarrhea have no direct cause, although some viruses have yet to be identified.

Table 48-2 Differential Diagnosis of Diarrhea

	INFANT	CHILD	ADOLESCENT
Acute			
Common	• Gastroenteritis • Systemic infection • Antibiotic associated • Overfeeding	• Gastroenteritis • Food poisoning • Systemic infection • Antibiotic associated	• Gastroenteritis • Food poisoning • Antibiotic associated
Rare	• Primary disaccharidase deficiency • Hirschsprung toxic colitis • Adrenogenital syndrome	• Toxic ingestion	• Hyperthyroidism
Chronic			
Common	• Postinfectious secondary lactase deficiency • Cow's milk or soy protein intolerance • Chronic nonspecific diarrhea of infancy • Celiac disease • Cystic fibrosis • AIDS enteropathy	• Postinfectious secondary lactase deficiency • Irritable bowel syndrome • Celiac disease • Lactose intolerance • Giardiasis • Inflammatory bowel disease • AIDS enteropathy	• Irritable bowel syndrome • Inflammatory bowel disease • Lactose intolerance • Giardiasis • Laxative abuse (anorexia nervosa)
Rare	• Primary immune defects • Familial villous atrophy • Secretory tumors • Acrodermatitis enteropathica • Lymphangiectasia • Abetalipoproteinemia • Eosinophilic gastroenteritis • Short-bowel syndrome • Intractable diarrhea syndrome • Autoimmune enteropathy	• Acquired immune defects • Secretory tumors • Pseudo-obstruction	• Secretory tumor • Primary bowel tumor • Anal intercourse (inflammation confined to the rectum) • Kaposi sarcoma–associated diarrhea

AIDS, acquired immunodeficiency syndrome.

Pathophysiology and Etiology

EVIDENCE BASE Lo Vecchio, A., Dias, J., Berkley, J. et al. (2016). Comparison of recommendations in clinical practice guidelines for acute gastroenteritis in children. *Journal of Pediatric Gastroenterology & Nutrition, 63*(2), 226–235.

Lo Vecchio, A., Vandenplas, Y., Benninga, M., et al. (2016). An International Consensus Report on a new algorithm for the management of infant diarrhea. *Acta Paediatrica, 105*(8), 384–389.

Mechanisms of Diarrhea

1. Secretory—decreased absorption, increased secretion.

2. Osmotic—maldigestion, transport defects, ingestion of unabsorbable solute.
3. Intestinal dysmotility—intact absorption with decreased intestinal transit time.
4. Inflammatory—malabsorption; can be caused by infectious or noninfectious agents.

Physiologic Effects of Diarrhea

1. Dehydration (extracellular fluid [ECF] loss).
   a. Large loss of fluid and electrolytes in watery stools.
   b. May be compounded by vomiting, decreased fluid intake, and increased insensible loss due to fever and rapid respirations.
2. Electrolyte imbalance.
   a. Potassium—may be hyper or hypokalemic.
   b. Sodium and chloride are directly related and may be increased or decreased.
      i. Hypernatremic hyperchloremic (hypertonic) dehydration occurs with acute diarrhea.
      ii. Hyponatremic hypochloremic (hypotonic) hypervolemia occurs with too rapid fluid replacement.
3. Acid–base imbalance—metabolic acidosis.
   a. From large losses of potassium, sodium, and bicarbonate in stools.
   b. From impaired renal function.
4. Monosaccharide intolerance and protein hypersensitivity.

Pathogenic Etiology

1. Bacteria—*Escherichia coli* O157:H7, *Salmonella*, *Shigella*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *Clostridium difficile*, dysentery, cholera.
2. Antibiotic-associated diarrhea, such as *C. difficile* diarrhea, is a leading cause of nosocomial outbreaks.
3. Viral—rotavirus (most common; peaks during winter months), enteroviruses (echovirus), adenoviruses, human Reovirus-like agent, Norwalk virus.
4. Fungal—*Candida enteritis*.
5. Parasitic—*Giardia lamblia*, *Cryptosporidium parvum*.
6. Protozoal.

Noninfectious Etiologic Factors

1. Malabsorption—lactase deficiency, cow's milk protein allergy, food protein-induced enteropathy, celiac disease, cystic fibrosis, microvillus inclusion disease.
2. Inflammatory bowel disease—ulcerative colitis, Crohn disease, rare in infants.
3. Immune deficiency—severe combined immunodeficiency, IgA deficiency.
4. Infant exposed to overeating.
5. Direct irritation of GI tract by foods, medications, chemicals, radiation.
6. Inappropriate use of laxatives and purgatives.

7. Mechanical disorders—malrotation, incomplete small-bowel obstruction, intermittent volvulus.
8. Congenital anomalies (eg, Hirschsprung disease–related enterocolitis).
9. Drug consumption—increases the risk of colitis, especially in predisposed persons; some agents may just exacerbate underlying colitis.
10. Functional—diagnosis of exclusion, although etiology may be a virus that has not been identified. For example, child exposed to excessive stress, emotional excitement, and fatigue.

Acute Diarrhea

1. Sudden increase in frequency of stools.
2. Usually self-limited but can result in dehydration.

Chronic or Persistent Diarrhea

1. Defined as three loose or liquid bowel movements a day for at least 2 to 4 weeks and a stool weight greater than 200 g/day.
2. Associated with disorders of malabsorption, anatomic defects, abnormal bowel motility, hypersensitivity reaction, or a long-term inflammatory response.
3. May be due to behaviors that continue to expose children to pathogens as well as increased resistance of bacteria to commonly used antibacterial agents.

NURSING ALERT Infants and young children in day care centers may be at increased risk for diarrhea due to *Shigella*, *Salmonella*, rotavirus, endopathogenic *E. coli*, and giardiasis. Hand washing is the major preventive measure. These infections are usually reportable to the health department. Bloody diarrhea should be immediately referred for medical evaluation.

Risk Factors for Diarrhea

EVIDENCE BASE Adams, D., Eberly, M., Rajnik, M., et al. (2017). Risk factors for community-associated *Clostridium difficile* infection in children. *Journal of Pediatrics, 186*, 105–109.

---

1. Age—the younger the child, the greater the susceptibility and severity.
   a. ECF volume is proportionately larger in the infant and young child.
   b. Nutritional reserves are relatively smaller in the young child.
2. Impaired health—susceptibility is increased in the malnourished or debilitated child.
3. Climate—susceptibility is increased in warm weather.
4. Environment—frequency is increased where there is overcrowding, poor sanitation, inadequate

refrigeration of food, and inadequate health care and education.

5. Virulence of a potential pathogen affects severity.
6. Internationally adopted child.

Clinical Manifestations

Symptoms vary with severity, specific cause, and type of onset (insidious vs. acute).

1. Low-grade fever to 100°F (37.8°C).
2. Anorexia.
3. Vomiting (can precede diarrhea by several days); mild and intermittent to severe.
4. Stools—appearance of diarrhea from a few hours to 3 days.
    a. Loose and fluid consistency.
    b. Greenish or yellow-green, although can be any color.
    c. May contain mucus, pus, or blood.
    d. Frequency varies from 3 to 20 per day.
    e. Expelled with force; may be preceded by pain.
5. Behavioral changes.
    a. Irritability and restlessness.
    b. Weakness.
    c. Extreme prostration.
    d. Stupor and convulsions.
    e. Flaccidity.
6. Physical changes.
    a. Little to extreme loss of subcutaneous fat.
    b. Up to 50% total body weight loss.
    c. Poor skin turgor; capillary refill longer than 2 seconds.
    d. Dry mucous membranes and dry, cracked lips.
    e. Pallor.
    f. Sunken fontanelles and eyes.
    g. Petechiae may be seen with bacterial infections.
    h. Excoriated buttocks and perineum.
    i. Urine with blood.
7. Vital sign and urine output changes (signal imminent cardiovascular collapse).
    a. Low BP.
    b. High pulse rate.
    c. Respirations rapid and hyperpneic.
    d. Decreased or absent urine output.

Diagnostic Evaluation

Studies to Evaluate Condition

1. Thorough history and physical examination to determine hydration status.
2. Electrolyte and kidney function tests—serum sodium, chloride, potassium, and blood urea nitrogen variable.
3. Acid–base balance—serum carbon dioxide; arterial pH and carbon dioxide possibly abnormal.
4. CBC to determine plasma volume by hematocrit; infection by WBC count and differential.
5. Sedimentation rate—elevated in infection and inflammation.

NURSING ALERT A postural change in heart rate and blood pressure is a useful clue in assessing the fluid state of a toddler (or any child). An increase greater than 20 beats/minute when moving from lying to standing is an indicator of hypovolemia. A decrease of at least 20 mm Hg in systolic BP or a decrease of at least 10 mm Hg in diastolic BP when moving from lying to standing is considered orthostatic and likely indicates hypovolemia.

Studies to Determine Cause

1. Thorough history to determine recent contact or exposure, contact with potentially contaminated water (swimming in lakes and ponds, well water), travel to at-risk countries, antibiotic therapy, and possible immunosuppression.
2. Enzyme immunoassay tests such as Rotazyme to test stool for rotavirus.
3. Multiple stool and rectal swab for bacterial cultures, ova and parasites, and *C. difficile*. Some labs require the sample specify for *Giardia* profile, *Cryptosporidium*, and *E. coli* O157:H7 serotyping. If immunosuppressed, add *Microsporidian*, *Cryptosporidium*, and *G. lamblia* antigen 65.
4. Stool for WBC count, calprotectin or lactoferrin, to screen for colitis that may be of a bacterial or inflammatory nature.
5. Stool pH, reducing substances—decreased pH may indicate various noninfectious causes; acid stool containing sugar is characteristic of disaccharide intolerance, abnormality of bile salt reabsorption.
6. Blood cultures can rule out septicemia.
7. Serologic studies can detect viral pathogens.
8. Breath hydrogen test can determine carbohydrate malabsorption and bacterial overgrowth.
9. Urinalysis can exclude UTI as cause of nonspecific diarrhea and screen for blood, which may be part of hemolytic uremic syndrome associated with *E. coli* O157:H7 infection.

Management

EVIDENCE BASE Carson, R., Mudd, S., & Jamil, P. (2017). Evaluation of a nurse-initiated acute gastroenteritis pathway in the Pediatric Emergency Department. *Journal of Emergency Nursing, 43*(5), 406–412.

Hendrickson, M., Zaremba, J., Wey, A., et al. (2017). The use of a triage-based protocol for oral rehydration in a Pediatric Emergency Department. *Pediatric Emergency Care, 34*(4), 227–232.

Treatment is based on the degree of dehydration; mild (loss of less than 5% of body weight), moderate (5% to 10% loss), and severe (greater than 10% loss) (see Table 48-3).

Table 48-3 Assessment for Dehydration in Children

	DEGREE OF DEHYDRATION		
CLINICAL SIGNS	**MILD**	**MODERATE**	**SEVERE**
General			
Infant's behavior	Thirsty, alert, restless	Restless or lethargic; irritable to touch	Limp, drowsy; cyanotic extremities
Child's behavior	Thirsty, alert, restless	Thirsty, alert; postural hypotension	Usually conscious; cyanotic extremities
Respirations	Slightly increased	Increased	Deep and rapid
Pulse	Slightly increased	Increased	Rapid
Blood pressure	Normal	Decreased	May be unrecordable
Capillary refill	2 sec	2–3 sec	≥3 sec
Skin turgor	Normal	Slightly reduced	Reduced
Skin color	Pale	Gray	Mottled
Weight loss	Up to 5%	Up to 10%	Up to 15%
Mucous membrane	Tacky	Tacky/dry	Parched
Anterior fontanelle	Flat	Slightly depressed	Sunken
Urine volume	Small	Oliguria	Oliguria/anuria
Specific gravity	1.020	1.030	1.035

1. Goal is to prevent spread of disease; communicable disease is suspected until proved otherwise; enteric precautions are followed.
2. Bowel rest may be required based on degree of diarrhea and vomiting, if blood present, or electrolyte abnormalities.
3. For mild to moderate dehydration, oral rehydration solution is given to maintain fluid and electrolyte balance (WHO solution, Pedialyte, Infalyte). BRAT (banana, rice, apple, tea) diet is no longer recommended, as it is nutritionally suboptimal.
   a. For oral rehydration, 100 mL/kg over 4 hours, with additional fluids after each liquid bowel movement.
   b. Candidates for oral rehydration include mild to moderate dehydration, older than age 4 months, no persistent vomiting, and probable gastroenteritis.
4. For moderate to severe dehydration, IV fluid and electrolyte replacement is given slowly, as ordered (usually 20 mL/kg), usually over 2 days to prevent hypotonic hypervolemia (water intoxication). Administration of larger amounts of IV dextrose is associated with reduced return visits in children with gastroenteritis and dehydration.
5. Supportive care is given: monitoring oral and IV fluid intake, output from all sources, and patient's

response to treatment.

6. Specific antimicrobial therapy may be given in some cases such as immunosuppression, bacteremia, documented *C. difficile*, and traveler's diarrhea.
   a. Metronidazole 30 mg/kg/day in divided doses orally or via IV line may be used to treat *C. difficile* infection, although IV dosing may be less efficacious.
   b. Vancomycin PO for resistant *C. difficile*. Fidaxomicin PO is another antimicrobial FDA approved treatment for *C. difficile*–associated diarrhea in adults, but its use is not yet approved in children.
   c. Rifampin has been shown to be effective in traveler's diarrhea without associated side effects.
7. Probiotics (*Saccharomyces boulardii*, *Lactobacillus rhamnosus* GG, and probiotic mixtures) significantly reduced the development of antibiotic-associated diarrhea. *S. boulardii* was effective for *C. difficile* infection.
8. The World Health Organization and the American Academy of Pediatrics discourage the use of antidiarrheal agents in children. In children who are younger than age 3 years, malnourished, moderately or severely dehydrated, systemically ill, or who have bloody diarrhea, adverse events outweigh benefits. In children who are older than age 3 years, with no/minimal dehydration, loperamide may be a useful adjunct to oral rehydration and early refeeding.

EVIDENCE BASE Johnston, B., Goldenberg, J., & Parkin, P. (2016). Probiotics and the prevention of antibiotic-associated diarrhea in infants & children. *Journal of the American Medical Association, 316*(14), 1484–1485.

Complications

1. Severe dehydration and acid–base derangements with acidosis.
2. Shock.

Nursing Assessment

1. Obtain accurate history of signs and symptoms: nature and frequency of stools, type of onset, length of illness, and associated symptoms.
2. Assess degree of dehydration (see Table 48-3).
3. Monitor intake and output including oral and IV fluids, fluid loss from diarrhea, urine output, and vomitus; monitor weight.
4. Note color and consistency of stool and vomitus.
5. Successful rehydration (at 4 hours) is defined as resolution of moderate dehydration, production of urine, weight gain, and the absence of severe emesis (≥5 mL/kg).

NURSING ALERT Assess child's behavior to determine comfort level. Crying or legs drawn up to abdomen usually indicates pain.

Nursing Diagnoses

- Deficient Fluid Volume related to diarrhea and ECF loss.
- Risk for Infection and transmission to others related to infectious diarrhea.
- Risk for Impaired Skin Integrity related to irritation by frequent stools.
- Imbalanced Nutrition: Less Than Body Requirements related to malabsorption.
- Anxiety and Fear related to hospitalization and illness.

Nursing Interventions

Restoring Fluid Balance

1. Monitor amount and rate of IV fluid therapy, which have been calculated by the health care provider. Fluid needs are based on fluid deficit, ongoing losses, and body weight.
2. Prevent overload of circulatory system.
   a. Check flow rate and amount absorbed hourly and totally.
   b. Adhere to prescribed volume carefully when oral feedings are given in conjunction with IV fluid.
   c. Never administer IV fluids to pediatric patient without safeguard of a volume-control infusion device or pump.
   d. Observe for signs of fluid overload: edema, increased BP, bounding pulse, labored respirations, and crackles in lung fields.
3. Check IV site for infiltration or improper flow, so site can be changed as necessary.
4. Use appropriate protective devices to prevent the child from injuring involved extremity or causing IV to malfunction.
5. Weigh the patient daily as a guide for fluid needs and patient status.
6. Monitor urine output and keep accurate intake and output record, including vomitus and liquid stools.
7. If NPO, provide frequent mouth care and nonnutritive sucking with a pacifier. Continue to burp infant to expel air swallowed while crying or sucking.
8. If oral rehydration solution is used, reassess hydration status every 2 to 4 hours; once rehydrated, continue for 8 to 12 hours, then resume breast-feeding with increased frequency of feedings or formula at full strength or increased frequency if half strength.

Note: Unless vomiting is severe, do not deprive the patient of nutrition for longer than 1 or 2 days. If adequate nutrition cannot be provided, parenteral nutrition should be instituted.

NURSING ALERT Diluted fruit juices and soft drinks are not recommended. High disaccharide content aggravates diarrhea by osmotic effect.

Preventing Spread of Infection

1. Ensure adherence to good hand washing and gown technique protocols for all people having contact with infant or child.
2. Follow your facility's policy on care of diapers.
3. Handle specimens collected using universal precautions and transport to laboratories in appropriate containers per policy. Collect stool sample for culture before instituting antibiotic therapy.
4. Teach good hygiene measures to older children.

Preventing Skin Impairment

1. Protect infant's diaper area from becoming excoriated by making frequent diaper changes.
2. Expose to air and light as much as possible.
3. Avoid commercial baby wipes, which contain alcohol and may sting inflamed or excoriated diaper area. Use mild soap and water, place infant in tub of water or baking soda bath (soothing and neutralizing) for cleaning.
4. Prevent scratching or rubbing of the irritated area. Holding the infant on the parent's protected lap may provide comfort and stimulation for the parent and infant.
5. Use protective barrier creams, such as zinc oxide; if excoriated, soak off cream and pat dry—do not rub. Not all cream barrier has to be removed because this can denude skin.
6. Leave diaper area open to air until thoroughly dried.

Resuming Adequate Nutritional Intake

1. After rehydration, advance slowly from clear liquids to half-strength formula, to regular diet.
    a. If chronic diarrhea, bloody diarrhea, or secretory diarrhea, limit milk products containing lactose.
    b. In older infants and children, offer nonlactose, bland, carbohydrate-rich foods shortly after successful rehydration.
2. As diet is advanced, note any vomiting or increase in stools and report it immediately. Oral feedings should not be resumed too early or advanced too rapidly because diarrhea may recur.

Reducing Fear and Anxiety

1. Acknowledge that hospitalization is frightening, especially when it is sudden, as with diarrhea.
2. Many treatments and procedures may be painful. Give reassurance to the child before, during, and after treatment.
    a. Explain treatment in age-appropriate language.
    b. Include family in care and treatments when possible.

3. Explain to family that intermittent abdominal cramps may be painful and provide support.
4. Provide some means of pleasant stimulation, entertainment, or diversion, especially while child remains in bed.
   a. Infant—mobile, musical toy.
   b. Young child—books, tapes.
   c. Older child—television, videos.
5. Provide physical closeness to provide comfort, if child displays interest.
   a. Petting, stroking.
   b. Holding, rocking.

Community and Home Care Considerations

1. Infants and young children in day care centers may be at increased risk for diarrhea due to *Shigella*, *Salmonella*, rotavirus, *E. coli*, *Cryptosporidium*, *Campylobacter*, *C. difficile*, and *Giardia*. Good hand washing is the major preventive measure. This is especially important with rotavirus because it can be excreted for as long as 57 days in some cases.
2. If infectious agent is identified, it should be reported because other children may be at risk.
   a. Encourage parents to contact the child day care center and report.
   b. A child with diarrhea containing blood or mucus should be excluded from day care and medically evaluated. Exclusion from day care should occur until the diarrhea resolves.
   c. Stool cultures positive for *E. coli* O157:H7 or *Shigella* are reportable to the county health department, and the child should be excluded until the diarrhea resolves and two cultures, from two different stools, are negative for these organisms.
3. Assess sanitation and hygiene practices in the home or day care center for overcrowding, number of working toilets in the home for number of people, availability of working sinks with soap and towels in the bathrooms and their proximity to food preparation areas, disposal of diapers, and hand washing practices of caregivers and children.
4. Because most treatment for diarrhea is done on an outpatient basis, nurses in the community need to be available to answer questions.

Family Education and Health Maintenance

1. After the cause of the diarrhea is determined, it may be necessary to teach proper hygiene, formula or food preparation, handling, and storage.
   a. Use hand washing before bottle and food preparation.
   b. Use disposable bottles or sterilize or use dishwasher for reusable bottles.
   c. Refrigerate reconstituted formula and all other fluids between uses. Milk may become contaminated within 1 hour if left out at room temperature; juice becomes contaminated within several hours.
   d. Discard small amounts of food or fluid from containers already used.
2. Explain the fecal–oral mode of transmission of infectious diarrheal illnesses.

3. Explain the early symptoms of a diarrheal illness and of dehydration, which requires notification of the health care provider.
4. Discourage the use of antiemetics and antidiarrheal medications for infants and children with gastroenteritis; they have little effect on infantile diarrhea, may cause toxicity, and can mask signs and symptoms of more serious illness.
5. Advise parents when traveling internationally with their children to eat and drink only boiled, bottled, or carbonated water, be aware of drinks with ice cubes, food rinsed with water, and make sure all food is well cooked.
6. Help parents understand the importance of medical care and general good hygiene.
7. For additional information and support, refer to National Institute of Diabetes and Digestive and Kidney Diseases (*www.niddk.nih.gov*).

DRUG ALERT Bismuth subsalicylate, an over-the-counter drug that is readily available, has shown only modest beneficial effects in children and may increase the risk of Reye syndrome due to salicylate absorption.

Evaluation: Expected Outcomes

- Vital signs stable; urine output adequate.
- Family, staff members hand washing properly and frequently.
- No redness or excoriation of diaper area.
- Tolerates small feedings of clear liquids without diarrhea or vomiting.
- No signs or symptoms of pain or discomfort.

Hirschsprung Disease

EVIDENCE BASE Moore, S. (2016). Genetic impact on the treatment and management of Hirschsprung disease. *Journal of Pediatric Surgery, 52*, 218–222.

Westfal, M., & Goldstein, A. (2017). Pediatric enteric neuropathies: Diagnosis and current management. *Current Opinion in Pediatrics, 29*(3), 347–353.

Hirschsprung disease (congenital aganglionic megacolon) is a form of chronic intestinal obstruction affecting primarily full-term infants.

It occurs because of the congenital absence of the parasympathetic ganglion nerve cells from within the muscle wall of the intestinal tract, usually at the distal end of the colon. Ganglion cells are located throughout the intestinal tract from the mouth down to the rectum. It occurs in 1 in 5,000 (ranges 1:4,400 to 1:7,000) live births with no racial predilection.

The male:female ratio is reported as 2:1, except in long segment disease, in which it is closer to 1:1, possibly favoring females. Strong evidence supports a genetic component and the association of other congenital anomalies such as Down syndrome, small/large intestinal atresias, trisomy 18, and other rare disorders.

Pathophysiology and Etiology

1. An arrest in embryologic development affecting the migration of parasympathetic nerve innervation of the intestine.
   a. Normally, the nerve cells migrate to the upper end of the alimentary tract and then proceed in the caudal direction, with migration to the distal colon complete by 12 weeks.
   b. Migration occurs first in the intermuscular layer, called *Auerbach plexus*, and then moves into the submucosal plexus, moving along the GI tract in a descending manner.
2. The process of aganglionosis is almost always continuous within the affected segment, ending in proximal segment with ganglion cells. Intermittent ganglion cells in the colon have been reported, but this is extremely unusual.
   a. Most commonly affected site is the rectosigmoid colon (referred to as short-segment disease) (80%).
   b. Long-segment disease extends to the upper descending colon and transverse colon (10%) and occasionally throughout the entire colon, involving the small bowel (5%).
   c. Total angiogliosis of the bowel, involving the entire small and large bowel, is rare.
3. No peristalsis occurs in the affected portion of intestine (ie, spastic and contracted). This section is usually narrow; therefore, no fecal material passes through it.
4. Proximal to the narrow affected section, the colon is dilated (see Figure 48-6).

a. Filled with fecal material and gas.

b. Hypertrophy of muscular coating.

c. Ulceration of mucosa may be seen in neonate.

5. The internal rectal sphincter fails to relax and evacuation of fecal material and gas is prevented. Abdominal distention and constipation result.

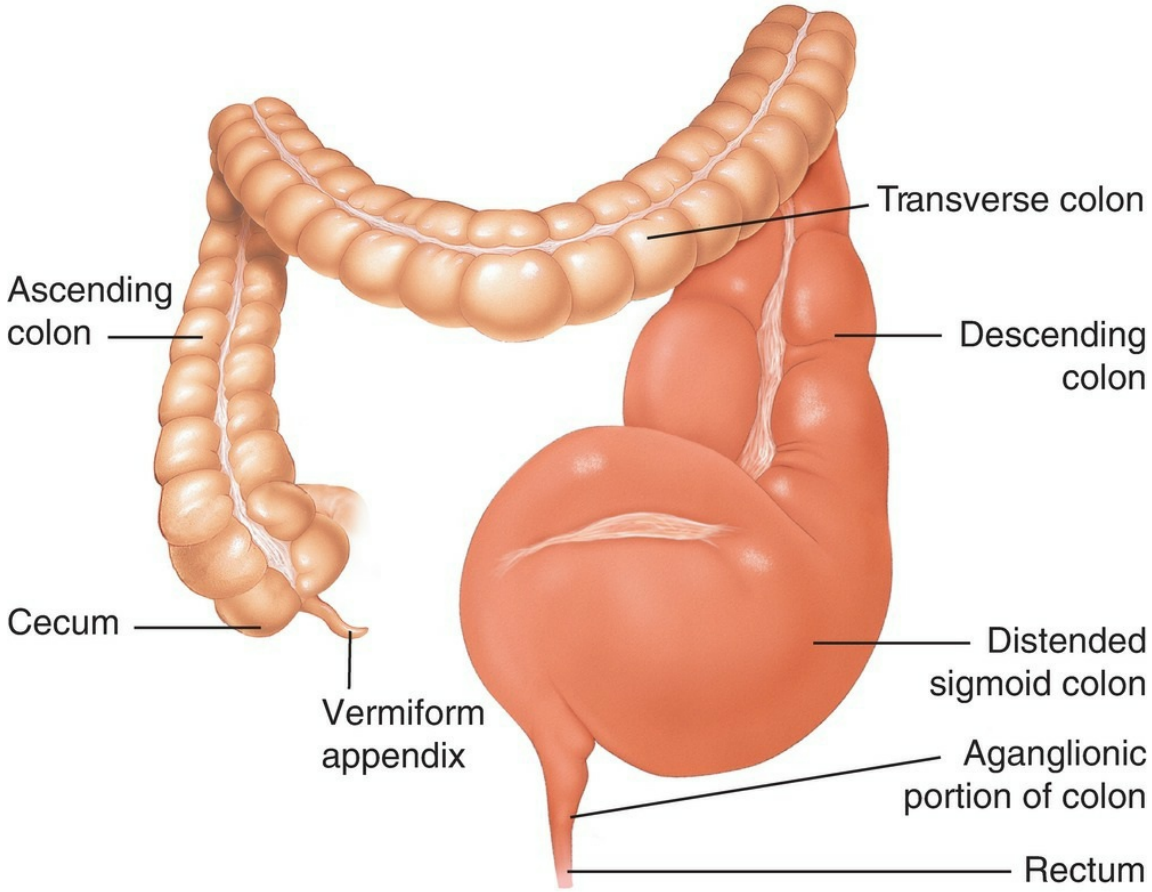


Figure 48-6. Bowel dilation in Hirschsprung disease. (Anatomical Chart Company.)

Clinical Manifestations

Clinical manifestations vary depending on degree of involved bowel.

1. Neonate—symptoms appearing at birth or within first weeks of life.

a. No meconium passed in the first 48 hours of life.

b. Vomiting—bile-stained or fecal.

c. Abdominal distention.

d. Constipation—occurs in 100% of patients.

e. Overflow-type diarrhea.

f. Dehydration; FTT.

g. Temporary relief of symptoms with enema.

h. Bowel perforation—uncommon presentation.

2. Older child—symptoms not prominent at birth. Short-segment disease commonly presents later.
   a. History of obstipation at birth.
   b. Progressive abdominal distention.
   c. Peristaltic activity observable over abdomen.
   d. Absence of retentive posturing (ability to contract the internal and external sphincter to purposefully avoid defecation).
   e. Constipation—unresponsive to conventional remedies.
   f. Presence of encopresis.
   g. Ribbon-like, fluidlike, or pellet stools.
   h. Failure to grow—loss of subcutaneous fat; appears malnourished, stunted growth.
   i. Presentation insidious or catastrophic as with enterocolitis.
3. Enterocolitis—consists of severe toxemia and a proliferation of bacteria in the colonic lumen.
   a. Abdominal distention.
   b. Explosive diarrhea.
   c. Vomiting.
   d. Fever.
   e. Lethargy.
   f. Rectal bleeding.
   g. Shock.

Diagnostic Evaluation

1. Supportive findings on history and physical examination indicate Hirschsprung disease.
2. Digital rectal examination—reveals a tight anal sphincter and a rectum that is narrow and empty of stool (in long-segment disease). In short-segment disease, rectal impaction may be present; removal of finger may be associated with a rush of stool as the obstruction is relieved.
3. Plain films—show severe gaseous distention of the bowel, with absence of air in the rectum.
4. Barium enema—used to demonstrate a transition zone between the proximal dilated, normal innervated colon and the distal, narrow, aganglionic colon.
   a. May be nondiagnostic in young infants who have not had sufficient time to develop a transition zone.
   b. Delayed passage of barium is suggestive but not definitive for Hirschsprung disease.
   c. Must be an unprepped study, as results may be falsely negative if laxatives or rectal stimulation have been used to facilitate defecation.
5. Anorectal manometry—demonstrates failure of the intestinal sphincter to relax in response to transient rectal distention. Requires cooperation of the child.
6. Full thickness or suction rectal biopsy—absence or reduced number of ganglion nerve cells; definitive diagnosis.

7. Radiopaque markers, ingested, measure intestinal transit time. Use of these markers is not part of the standard diagnostic workup for Hirschsprung disease; however, children with short-segment disease retain the markers in the rectum for long periods.

Management

Definitive treatment is removal of the aganglionic, nonfunctioning, dilated segment of the bowel, followed by anastomosis and improved functioning of internal rectal sphincter.

1. Initially, a colostomy or ileostomy is performed to decompress intestine, divert fecal stream, and rest the normal bowel.
2. Definitive surgery includes the following reconstructive procedures:
   a. Swenson—abdominoperineal pull-through leaving the smallest amount of aganglionic bowel remaining.
   b. Duhamel—retrorectal transanal pull-through creating a neorectum with aganglionic anterior wall and ganglionic posterior wall.
   c. Soave—endorectal pull-through in which the ganglionic segment is pulled through the aganglionic muscular cuff, preserving the internal sphincter; may be done laparoscopically. May be delayed until infant is age 9 to 12 months or until weight reaches 15 to 20 pounds (6.5 to 9 kg).
3. Many surgeons are now performing the endorectal pull-through without colostomy in neonates. This depends on the degree of defect, degree of dilatation of the colon, and the clinical status of the infant.
4. In older child whose symptoms are chronic but not severe, treatment may consist of isotonic enemas, stool softeners, and low-residue diet until surgery is performed.
5. Treatment of enterocolitis.
   a. Broad-spectrum IV antibiotics.
   b. Colonic irrigation and decompression with saline solution is initial emergency treatment. Hypertonic phosphate enemas are contraindicated because they may be retained, leading to electrolyte abnormalities.
   c. Surgical decompression colostomy.
   d. At least 1 month after, abdominal perineal pull-through.

NURSING ALERT Enterocolitis is a potentially life-threatening event. Notify health care provider immediately if change in abdominal distention occurs in an infant or child with Hirschsprung disease (whether preoperatively or postoperatively), especially if accompanied by fever, diarrhea, vomiting, or lethargy.

Complications

EVIDENCE BASE Gosain, A., Frykman, P., Cowles, R., et al. (2017). Guidelines for the diagnosis and management of Hirschsprung-associated enterocolitis. *Pediatric Surgery International, 33*(5), 517–521.

Langer, J., Rollins, M., Levitt, M., et al. (2017). Guidelines for the management of postoperative obstructive symptoms in children with Hirschsprung disease. *Pediatric Surgery International, 33*(5), 523–526.

1. Preoperative.
    a. Enterocolitis—a major cause of death.
    b. Hydroureter or hydronephrosis.
    c. Water intoxication from tap water enemas.
    d. Bowel perforation.
2. Postoperative.
    a. Enterocolitis: remains the major cause of morbidity and mortality (mortality 6% to 30%).
    b. Diarrhea (69%).
    c. Vomiting (51%).
    d. Fever (34%).
    e. Lethargy (27%).
    f. Leaking of anastomosis and pelvic abscess.
    g. Stenosis, sudden inability to evacuate colon.
    h. Intestinal obstruction from adhesions, volvulus, or intussusception can develop late.
    i. Fecal incontinence is common but can improve with a proper bowel regimen.
    j. Adverse reaction to foods.
    k. Enuresis.

Nursing Assessment

1. Observe neonate for constipation.
2. Obtain parents' history, especially on infant's bowel and feeding habits.
    a. Onset of constipation.
    b. Character of stools (ribbon-like or fluid filled).
    c. Frequency of bowel movements.
    d. Enemas needed.
    e. Suppositories or laxatives needed.
3. Observe for irritability, feeding difficulty, distended abdomen, and signs of malnutrition (pallor, muscle weakness, thin extremities, fatigue).

NURSING ALERT Diagnosis of Hirschsprung disease should be suspected in any infant who fails to pass meconium within the first 24 hours and requires repeated rectal stimulation to induce bowel movements.

Nursing Diagnoses

Preoperative

- Ineffective Breathing Pattern related to abdominal distention.
- Acute Pain related to intestinal obstruction.
- Imbalanced Nutrition: Less Than Body Requirements related to poor intake.
- Constipation due to pathophysiologic process.

Postoperative

- Impaired tissue integrity related to postoperative intervention.
- Risk for Infection of surgical incision.
- Risk for Dysfunctional Gastrointestinal Motility related to decreased peristalsis postoperatively.
- Ineffective Family Coping related to care of child with colostomy.

Nursing Interventions

Improving Breathing Pattern

1. Monitor for respiratory compromise that may result from abdominal distention; watch for rapid, shallow respirations; cyanosis; sternal retractions.
2. Elevate infant's head and chest by tilting the mattress to facilitate an open airway
3. Administer oxygen, as ordered, to support respiratory status.

Relieving Pain

1. Note degree of abdominal tenderness.
   a. Infant's legs drawn up.
   b. Chest breathing.
2. Note color of abdomen and presence of gastric waves; take sequential measurements of abdominal girth for evidence of changes.
3. Assist in emptying the bowel by giving repeated colonic irrigations.
   a. Procedure for irrigation in an infant is similar to that in an older child, except that less fluid and pressure are used.
   b. Physiologic saline solution (warmed) should be used for irrigations. Tap water may result in large quantities of water being absorbed and in water intoxication.
4. Administer medications (antibiotics), as ordered, to reduce the bacterial flora of the bowel.

5. Note any change in degree of distention before and after irrigation. Record if location of distention changes (ie, upper or lower abdomen).
6. Record all intake and output of irrigant and drainage. Report marked discrepancies in retention or loss of fluid.
7. Insert rectal tube for escape of accumulated fluid and gas, as ordered.
8. If abdominal distention is not relieved by irrigation and decompression and discomfort is significant, insert an NG tube, as ordered.
    a. Note drainage from NG tube and chart characteristics.
    b. Check for patency; saline irrigations may be requested. Carefully record intake and output.
    c. Perform frequent mouth care.
    d. Alternate nares when changing NG tube, and use minimal amount of tape to prevent skin irritation.
9. Offer pacifier for nonnutritive sucking if NPO, on parenteral fluids.
10. Encourage parents to hold and rock infant.
11. Maintain position of comfort with head elevated. Offer soothing stimulation (eg, music, touch, play therapy).

Providing Adequate Nutrition

1. Obtain a dietary history regarding food and eating habits.
    a. Discuss history with dietitian to facilitate potential dietary alterations.
    b. Explain to parents that eating problems are common with Hirschsprung disease.
2. Monitor IV fluids appropriately; measure all output.
3. Offer small, frequent feedings.
    a. Feed child slowly.
    b. Provide as comfortable a position as possible for child during feedings.
4. Inform parents that defect can be corrected, but it may take some time for the child's physical status and feeding habits to improve.
    a. Feeding may cause additional discomfort because of distention and nausea.
    b. Parenteral nutrition may be necessary.

Controlling Constipation in the Older Child

1. Note and record frequency and characteristics of stools (constipation is likely to occur).
2. Provide demonstration and written and verbal instructions to family for saline enema administration and use of stool softeners.
3. Obtain dietary consultation for teaching of dietary alterations.

Preventing Complications Related to Colostomy

1. Monitor vital signs and respiratory status closely.
2. Monitor for proper functioning of colostomy, if present.

a. Note drainage from colostomy: characteristics, frequency, fecal material, or liquid drainage.
b. Record stoma color, size, and return of function.
c. Note abdominal distention.
d. Measure fluid loss from colostomy because the amount will affect fluid replacement.

3. Report signs of obstruction from peritonitis, paralytic ileus, handling bowel during surgery, or swelling.
   a. No output from colostomy.
   b. Increased abdominal tenderness.
   c. Irritability.
   d. Vomiting.
   e. Increased temperature.
   f. Firm abdomen.
4. Place child in a lateral position on a flat or only slightly elevated bed. When head of bed is elevated, the residual carbon dioxide in the child's abdominal cavity may cause referred pain in neck and shoulder.
5. Differentiate type and cause of pain to determine appropriate pain management interventions. Proper positioning, patent catheters and tubes, and timely administration of analgesics are key to ensuring patient comfort.
6. "Nothing per rectum" sign should be placed at head of bed so that no rectal temperatures, rectal medications, or digital rectal examinations are done.

NURSING ALERT Prevent injury to rectal mucosa by taking axillary or external ear temperature.

NURSING ALERT Any rectal examination or procedure has the potential to cause serious harm to the patient and surgical site.

Preventing Postoperative Infections

1. Change wound dressing using sterile technique. If done laparoscopically, wound is minimal.
2. Prevent contamination from diaper.
   a. Apply diaper below dressing.
   b. Change diaper frequently.
3. Be aware that 7 to 10 stools per day may be passed postoperatively via ostomy bag. When cleared by surgery, prevent perianal and anal excoriation by thorough cleansing sitz baths and application of zinc oxide paste after soiling.
4. If skin is denuded and moist, apply a skin barrier, and provide specific instruction to the family to

prevent further damage to skin with aggressive removal.

5. Use careful hand-washing technique.
6. Report wound redness, swelling or drainage, evisceration, or dehiscence immediately.
7. Suction secretions frequently to prevent infection of the tracheobronchial tree and lungs.
8. Encourage frequent coughing and deep breathing to maintain respiratory status.
9. Allow the infant to cry for short periods to prevent atelectasis.
10. Change the infant's position frequently to increase circulation and allow for aeration of all lung areas.

Preventing Abdominal Distention

1. Maintain patency of NG tube immediately postoperatively.
    a. NG suction, as ordered, for 24 to 48 hours or until adequate bowel sounds, gas from rectum or gas from ostomy.
    b. Watch for increasing abdominal distention; measure abdominal girth.
    c. Measure fluid loss because amount will affect fluid replacement.
2. Maintain NPO status until bowel sounds return, and the bowel is ready for feedings as determined by provider.
3. Administer fluids to maintain hydration and replace lost electrolytes.
4. Maintain Foley catheter for 24 to 48 hours, as ordered.
5. Provide frequent oral hygiene while NPO.
6. Begin oral feedings, as ordered.
    a. Avoid overfeeding.
    b. Burp frequently during feeding.
    c. Turn head to side or elevate after feeding to prevent aspiration.

Supporting the Parents

1. Acknowledge that even a temporary colostomy can be a difficult procedure to accept and learn to manage.
    a. Initiate ostomy referral.
    b. Support the parents when teaching them to care for the colostomy.
    c. Include the parents in dressing changes and any other appropriate activities soon after surgery.
    d. Assist and encourage the parents to treat the infant or child as normally as possible.
    e. Reassure parents that colostomy will not cause delay in the child's normal development.
2. Encourage the parents to talk about their fears and anxieties. Anticipating future surgery for resection may be confusing and frightening.
3. Initiate community-nurse referral to help the parents care for the child at home away from the comforting situation of the hospital and obtain necessary equipment.
4. Initiate a genetic counseling referral, especially if the parents plan to have more children.

Ostomy Care in Children

EVIDENCE BASE Colwell, J., McNichol, L., & Boarini, J. (2017). North America wound, ostomy, and continence and enterostomal therapy nurses current ostomy care practice related to peristomal skin issues. *Journal of Wound Ostomy Continence Nursing, 44*(3), 257–261.

Care of the colostomy and ileostomy in the infant and young child is based on the same principles and is essentially the same as that for an adult (see Chapter 18), with the following exceptions:

1. Colostomy irrigation is not part of management in small children. Irrigation is primarily for the purpose of regulating the colostomy to empty at regular intervals. Because children have bowel movements at more frequent intervals, this type of control is not feasible. Irrigation may be done only in preparation for tests or surgery and occasionally for the treatment of constipation.
2. Dehydration occurs quickly in the infant or small child; therefore, it is particularly important to observe drainage for amount and characteristics. Drainage should be measured to provide an accurate basis for computation of fluid replacement.
3. Prevention and treatment of skin excoriation around the stoma are of primary concern. With the advent of better skin shields and equipment designed especially for the pediatric patient, keeping an ostomy appliance in place is now less difficult. Through careful application and trying different types of pouches until a proper fit is obtained, most children can be kept clean and dry for at least 24 hours between changes. This is a significant factor in preventing skin breakdown and subsequent infections in the peristomal area. Remember, however, that infant dressings must be checked frequently.
    a. Check ostomy bag for leakage every 2 hours and change bag as soon as leakage is suspected.
    b. Teach the parents the importance of emptying the bag, when it is one quarter to one- third full.
    c. Skin breakdown is more frequent. Reinforce to parents to treat breakdown with method and products recommended by ostomy nurse.
    d. Be aware that infant elimination is more frequent than in the older child.
4. For older children with ostomies:
    a. "Potty training" may be achieved for colostomy pouch emptying. This will not be possible for a child with an ileostomy.
    b. Pouching optimizes socialization and developmental activities.
    c. Encourage a matter-of-fact and accepting attitude to help build child's self-confidence.
    d. Encourage the child to participate in ostomy care.
    e. Encourage child to join age-appropriate ostomy support group.
5. Additional information and support can be obtained from the United Ostomy Associations of America (*www.ostomy.org*).

Community and Home Care Considerations

1. Begin early teaching about the colostomy (preoperatively, before discharge, and at home), including how it works and how to care for it and the child. Explanations should be thorough and in accordance with family readiness. Encourage care of the ostomy as part of normal activities of daily living.
2. Arrange frequent home visits to carry out comprehensive teaching plan. Consult with ostomy nurse, as needed, for any skin breakdown or other ostomy problems.
3. Involve the entire family in teaching colostomy care to enhance acceptance of body change of the child. An older child should become totally responsible for own colostomy care.
4. Assess family's self-care of the ostomy, including such procedures as preparation of skin, application of collecting appliance, care of appliance, and control of odor.
5. Observe for and teach family about signs of stomal complications, including ribbon-like stool, diarrhea, failure of evacuation of stool or flatus, and bleeding.
6. Assess hydration status and teach increased fluid intake because colon absorption is decreased or may be absent if an ileostomy is present.
7. Review GT feeding techniques, if ordered.
8. Assist family to discuss the child's needs with day care workers, teachers, and school nurse, as applicable. Review care of ostomy with child's care providers.
9. Assist with preoperative preparation for colostomy closure when the time comes.

Family Education and Health Maintenance

1. Instruct the parents to serve small, frequent meals to the child and be alert for and eliminate foods that cause gas and diarrhea, such as cabbage, spicy foods, beans, brussels sprouts, fruits, and fruit juices.
2. Advise parents that colds or viruses may cause loose stools, which increases risk of dehydration, especially in long-segment disease, so to increase fluids in these situations.
3. Alert parents of common postoperative problems, including bacterial overgrowth, colitis or enterocolitis, and lactose intolerance. Advise parents to contact their health care provider if persistent diarrhea, abdominal distention, abdominal pain, fever, vomiting, or constipation occur.
4. Encourage parents to practice all procedures long before the infant is to be discharged.
5. Emphasize the importance of treating the child as normally as possible to prevent behavior problems later.
6. Teach the basics of good nutrition and diet. Involve the dietitian, as necessary.
7. Encourage close medical follow-up and general good health and hygiene.
    a. Safety.
    b. General growth and development.
    c. Immunizations.
8. Advise older children without colostomies that fecal staining may occur, but this will improve with time.

Evaluation: Expected Outcomes

- Respirations unlabored; no cyanosis.
- Abdominal girth decreased; resting comfortably.
- Tolerates 1- to 2-ounce feedings every hour, depending on the age of the child.
- Passes stool at least every 2 days spontaneously or after enema.
- Vital signs within normal limits, afebrile, no abdominal distention.
- Stoma pink without drainage, redness, warmth, and tenderness.
- Bowel sounds present, NG tube discontinued.
- Parents listen, ask questions about care of child, and demonstrate adequate care/technique for device care/maintenance.

Intussusception

EVIDENCE BASE Savoie, K., Thomas, F., Nouer, S., et al. (2017). Age at presentation and management of pediatric intussusception: A Pediatric Health Information System database study. *Surgery, 161*(4), 995–1003.

Intussusception is the invagination or telescoping of a portion of the intestine into an adjacent, more distal section of the intestine, which creates a mechanical obstruction. Intussusception is one of the most common causes of intestinal obstruction in infancy. It can occur at any time in life but most commonly occurs in children younger than age 3, with the greatest incidence between ages 5 and 10 months. It is twice as common in male infants as in female infants. Incidence in the United States is 1.5 to 4 cases per 1,000 births. Intussusception should be high on the differential list when a child younger than age 1 presents with sudden onset of abdominal pain.

Pathophysiology and Etiology

1. The cause can fall into one of three categories: idiopathic, lead point, or postoperative.
    a. Idiopathic: this is the most common type, with no identifiable cause. It is not unusual, however, to obtain a history of a recent upper respiratory or GI virus. It is hypothesized that hypertrophy of Peyer patches creates a thickened segment. It is most common in infants.
    b. Lead point: an identifiable change in the intestinal mucosa can be discovered, usually during surgical treatment, and is most common in children ages 2 to 3. Malformations include polyps, cysts, tumors, Meckel diverticulum, and hematomas (seen in Henoch-Schönlein purpura). Children with cystic fibrosis are at risk for lead point intussusception due to mucus and thick stool.
    c. Postoperative: uncommon but can occur after surgery of the abdomen and even the chest. It may be due to interrupted motility from anesthesia or direct handling of the intestine. It can also occur from placing long tubes into the bowel.
2. Invagination results in complete intestinal obstruction.
    a. Mesentery/lymphatics/blood vessels pulled into intestine when invagination occurs.
    b. Intestine becomes curved, sausage-like; blood supply is cut off.
    c. Bowel begins to swell; hemorrhage may occur.
    d. Necrosis of involved segment occurs.
    e. If not recognized and treated, bowel death occurs, possibly resulting in significant loss of intestine, shock, and death.
3. Classification of location:
    a. Ileocecal (most common): when ileum and the attached mesentery, lymphatic tissue, and blood vessels invaginate into the cecum (see Figure 48-7).

b. Ileocolic: ileum invaginates into colon.

c. Colocolic: colon invaginates into colon.

d. Ileo–ileo (enteroenteric): small bowel invaginates into small bowel.

4. An increase in cases of intussusception was noted after the introduction of the first rotavirus vaccine (RotaShield), so this vaccine was taken off the market. The second generation of rotavirus vaccines (RotaTeq and Rotarix) carries a much lower (though not zero) risk of intussusception. It is felt that the small risk is outweighed by the benefit of the vaccine.

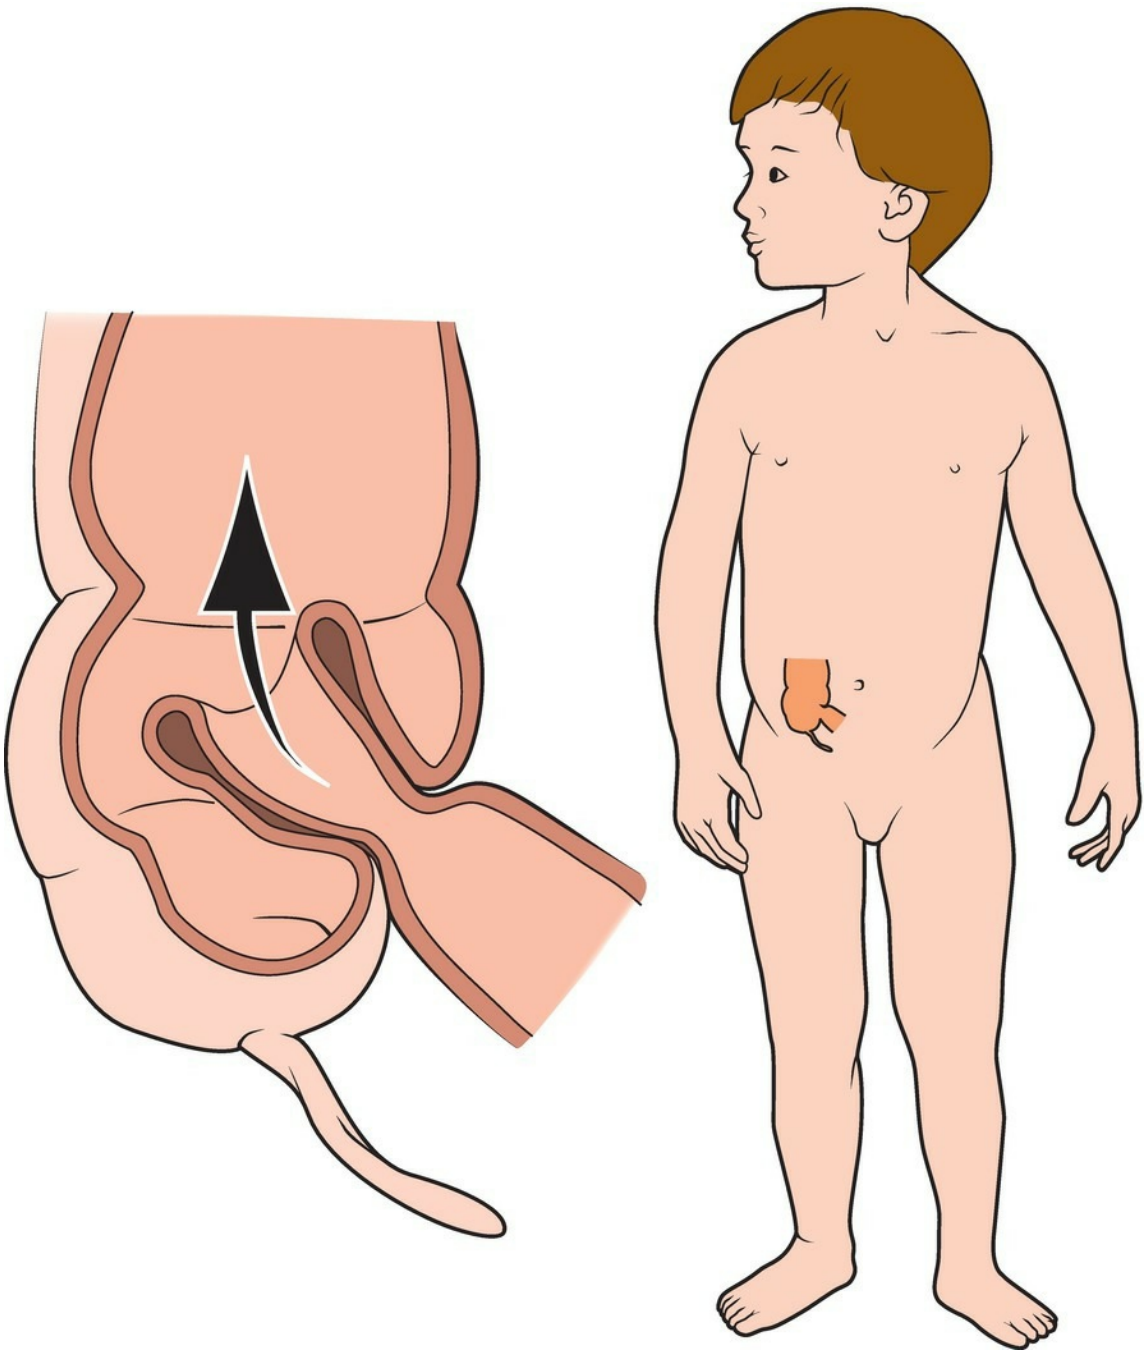

Figure 48-7. Intussusception. A portion of the ileum has been pushed into the lumen of the adjoining cecum. (LifeArt image.)

EVIDENCE BASE Haber, P., Parashar, U., Haber, M., et al. (2015). Intussusception after monovalent rotavirus vaccine—United States, Vaccine Adverse Event Reporting (VAERS), 2008–2014. *Vaccine, 33*(38), 4873–4877.

Clinical Manifestations

1. Classic four signs of intussusception—vomiting, abdominal pain, bloody/red currant jelly–like stool, and abdominal mass—only occur in about 45% of children.
2. Pain is usually paroxysmal.
   a. "Attacks of pain" that awaken child from sleep; inconsolable, drawing up legs, colicky.
   b. Cyclic repetition of symptoms at approximately 5- to 30-minute intervals.
   c. Between episodes, child may act normal.
3. Stool may be like currant jelly—sloughed mucosa of dark red color with a mucoid consistency.
4. Vomiting may begin with decreased appetite and progress to bilious vomiting.
5. Bowel sounds vary:
   a. During a crisis of pain, bowel sounds may be hyperperistaltic rushes (borborygmi).
   b. Ileus/peritonitis: bowel sounds are diminished or absent.
6. Decreasing frequency of bowel movements.
7. Increasing abdominal distention and tenderness.
8. Sausage-like mass palpable in abdomen. This is pathognomonic and is known as *Dance sign*—elongated mass in the right upper quadrant of the abdomen with absence of bowel sounds in the right lower quadrant.
9. Unusual-looking anus; may look like rectal prolapse.
10. Dehydration, fever, lethargy; shocklike state with rapid pulse, pallor, marked sweating.
11. Hematochezia (maroon-colored stools)—not always present.
    a. Rectal examination is significant if bloody mucus on examiner's finger.
    b. Occult or gross blood on rectal exam in 60% to 90% of patients.
12. The groin should be inspected for incarcerated hernia or torsion of testicle or ovary as differential diagnosis.

NURSING ALERT Currant jelly–like stool indicates damage to the intestine and can be a late sign. *Any* gross blood in the stool should raise suspicion of intussusception, especially when associated with abdominal pain; one should not wait for currant jelly–like stool to report.

Diagnostic Evaluation

EVIDENCE BASE Territo, H., Wrotniak, B., Qiao, H., et al. (2014). Clinical signs and symptoms associated with intussusception in young children undergoing ultrasound in the emergency room. *Pediatric Emergency Care, 30*(10), 718–722.

1. X-ray examination.
    a. Supine and upright abdomen film. Early course may be normal, but as it progresses absence of gas in the colon is found. Can also have finding of right upper quadrant mass and/or the meniscus/crescent sign.
    b. If no intraperitoneal air found on abdominal film, an air or barium enema is attempted.
    c. Commonly, a concave filling defect is seen in the transverse colon that can be reduced to the cecum.
2. Ultrasonogram to locate area of telescoped bowel and color Doppler sonography used to determine whether reducible or not. Absence of blood flow (color) indicates ischemia, and therefore, enema reduction should be avoided. Ultrasound will usually be obtained prior to contrast enema because of the low risk and excellent accuracy.

NURSING ALERT Enemas are contraindicated in cases involving clinical findings of peritonitis, shock, or signs of perforation on abdominal x-ray.

Management

EVIDENCE BASE Kim, J., Lee, J., Ryu, J., et al. (2018). Risk factors for recurrent intussusception after fluoroscopy-guided air enema. *Pediatric Emergency Care, 34*(7), 484–487.

1. Air or barium enema—both for diagnosis and treatment (hydrostatic reduction) in reducing intussusception.
    a. A surgeon should be present during the barium enema because of risk of perforation.
    b. A noninflatable tube is passed into rectum; contrast enters by gravity under fluoroscopic guidance. If air is used, it is delivered under constant pressure.
    c. As the intussusception is reduced, the contrast or air should reflux freely into the small intestine; this radiographic evidence is needed to confirm a successful reduction.
    d. Success ranges from 70% to 90%. Recurrence is the most common complication, but perforation can

also occur.

e. Nonoperative reduction using air enema or other hydrostatic reduction methods has been the standard treatment in most cases. The success rate can be as high as 84%. However, if nonoperative method is not indicated or fails, open surgery is still necessary.

2. Surgical reduction of intussusception may be necessary when radiologic reduction is unsuccessful, a pathologic lead point or peritonitis is suspected or with multiple recurrences. Factors associated with increased risk of intestinal resection include abdominal distension (32%), bowel obstruction on abdominal x-ray (27%), and hypovolemic shock (40%).
3. Surgery involves a laparotomy—manual milking-out of the intussuscepted segment from the distal to proximal end, followed by resection of the nonviable bowel and, commonly, an incidental appendectomy. Up to 86% successful in reduction.
4. Recurrence is 5% to 7% regardless of the type of treatment undertaken.

EVIDENCE BASE Wong, C., Jin, S., Tam, P., et al. (2016). Predictors for bowel resection and the presence of a pathological lead point for operated childhood intussusception: A multi-center study. *Journal of Pediatric Surgery, 51*, 1998–2000.

Complications

1. Perforation.
2. Peritonitis.
3. Shock.
4. Loss of bowel resulting in short bowel syndrome.

Nursing Assessment

1. Obtain careful history of infant's or child's physical and behavioral symptoms, including any recent or chronic illness.
2. Perform physical examination, which may reveal a well-developed, well-nourished, afebrile infant with abdominal tenderness and distention.
3. Observe for dehydration; may be mild or severe. Poor capillary refill, decreased mental status, and decreased urine output are reliable indicators of shock in children.

NURSING ALERT Report of episodic, severe, colicky abdominal pain combined with vomiting suggests intussusception.

Nursing Diagnoses

Preoperative

- Acute Pain related to paroxysmal abdominal pain, fever, and treatments.
- Risk for Decreased Fluid Volume related to vomiting.
- Ineffective Breathing Pattern related to abdominal distention.
- Anxiety related to hospitalization, knowledge deficit of illness, surgery, and treatments.

Postoperative

- Risk for Infection and other complications related to postoperative course.

Nursing Interventions

Minimizing Pain

1. Observe behavior as indicator of pain; the infant may be irritable and very sensitive to handling or lethargic or unresponsive. Handle very gently.
2. Encourage family to participate in comfort measures. Explain cause of pain and reassure parents as to purpose of diagnostic tests and treatments.
3. Administer medications, as prescribed.

Maintaining Fluid and Electrolyte Balance

1. Monitor fluids and maintain NPO status.
2. Restrain infant, as necessary, for IV therapy.
3. Monitor intake and output.

Promoting Effective Breathing

1. Be alert for respiratory distress because of abdominal distention. Watch for grunting or shallow and rapid respirations if in shocklike state.
2. Insert NG tube, if ordered, to decompress stomach.
    a. Irrigate, as ordered
    b. Note drainage and return from irrigation.
3. Maintain NPO status, as ordered.
    a. Wet lips and perform mouth care.
    b. Give infant pacifier to suck.
4. Continually reassess condition because disordered breathing or respiratory distress may indicate progression of disease process.

NURSING ALERT Passage of one normal brown stool may occur, clearing the colon distal to the

intussusception. Passage of more than one normal brown stool may indicate that the intussusception has reduced itself. Report any stools immediately to the physician.

Preparing for Surgery

1. Offer support to the parents during time of crisis and fear.
2. Offer specific teaching to parents.
   a. Compare intussusception to a collapsible telescope or antenna or by drawing a picture.
   b. Visual aids, such as a rubber glove with one finger into itself, may be helpful. Reduction can be demonstrated by filling glove with water until inverted finger resumes its normal position.
3. Children need brief, simple explanations in age-appropriate language.

Preventing Infection and Other Postoperative Complications

1. Monitor vital signs and general condition and notify health care provider of any change or unexpected trend.
2. Assess temperature and administer antipyretics and other cooling measures. Fever may be present from the translocation of bacteria into the bloodstream through the damaged intestinal wall.
3. Assess for abdominal tenderness, bowel sounds, and distention of abdomen. Maintain NG suction, as ordered.
4. Assess pain and level of consciousness.
5. When able to take fluids, assess tolerance carefully, and advance intake slowly.

Family Education and Health Maintenance

1. Explain that recurrences may occur and usually occur within 24 to 48 hours after reduction. Review signs and symptoms with parents.
2. Review activity restrictions with parents (eg, positioning on back or side, quiet play, and avoidance of water sports until wound heals).
3. Encourage follow-up care.
4. Provide anticipatory guidance for developmental age of child.
5. Encourage awareness of symptoms that require prompt medical attention among day care centers and other childcare providers (eg, paroxysmal abdominal pain, blood or mucus in stool).

Evaluation: Expected Outcomes

- Decreased irritability/pain.
- Urine output adequate.
- Respirations unlabored; abdominal distention relieved.
- Parents verbalize understanding of condition and surgery.
- Postoperative vital signs stable; audible bowel sounds; passes stool postoperatively.

Anorectal Malformations

EVIDENCE BASE Van der Steeg, J., Schmiedeke, E., Bagolan, P., et al. (2015). European consensus meeting of ARM-Net members concerning diagnosis and early management of newborns with anorectal malformations. *Techniques in Coloproctology, 19*(3), 181–185.

The term *anorectal malformation* encompasses multiple congenital anomalies of the rectum, urinary tract, and reproductive system. Incidence is 1 in 2,500 to 1 in 4,000 live births, with a slight male predominance. Complexity varies from isolated imperforate anus to the extremely rare cloacal exstrophy (occurs in males and females 1 in every 250,000 births).

Pathophysiology and Etiology

EVIDENCE BASE Kovacic, K., Matta, S., Kovacic, K., et al. (2018). Healthcare utilization and comorbidities associated with anorectal malformations in the United States. *Journal of Pediatrics, 194*, 142–146.

1. An arrest in embryologic development of the anus, lower rectum, and urogenital tract at the 6th week of embryonic life; however, cause is unknown.
2. Approximately 40% of infants with anorectal malformations have associated major anomalies, including:
   a. Down syndrome.
   b. VACTERL syndrome (vertebral defects, anal atresia, cardiac anomaly, TEF with EA, renal defects, and radial limb dysplasia).
   c. Congenital heart disease.
   d. Renal abnormalities.
   e. Cryptorchidism.
   f. Esophageal atresia.
   g. Malformation of the spine.
   h. Variant of infantile hemangioma occurring in the extremity.
3. Abnormal development of the terminal hindgut ranges from mild anal stenosis, corrected by simple dilatation, to complex deformities, such as rectal atresia and fistula, with varying degrees of fecal and urinary incontinence.
4. BMP4 and Hox genes may play a role.

Types

See Figure 48-8.

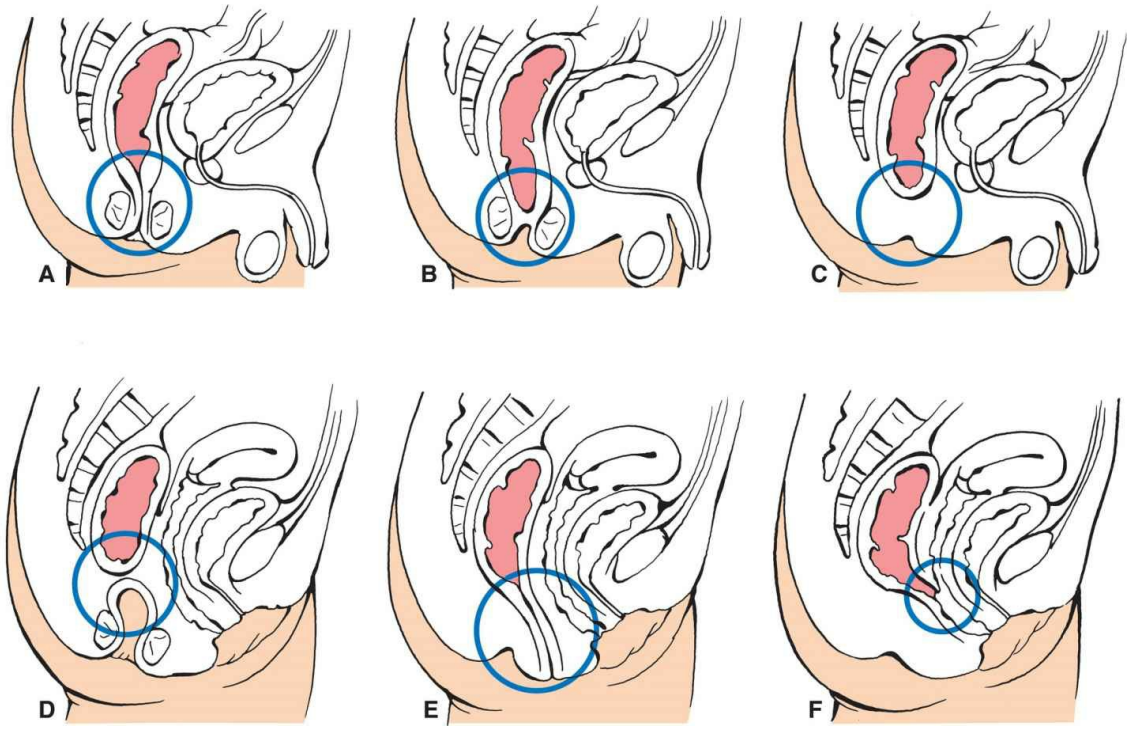

Figure 48-8. Anorectal malformations. **(A)** Anal stenosis. **(B)** Imperforate anal membrane. **(C)** Anal agenesis. **(D)** Rectal agenesis. **(E)** Rectoperineal fistula.

(F) Small orifice located in the perineum. (Adapted with permission from Wong, D. L. [1995]. *Whaley and Wong's nursing care of infants and children* [5th ed.]. St. Louis, MO: Mosby.)

1. Imperforate anal membrane—infant fails to pass meconium; greenish, bulging membrane is seen; bowel and sphincter return to normal after excision.
2. Rectoperineal fistula—rectum opens into the perineum; excellent function.
3. Anal atresia and stenosis—complete obstruction (atresia) or stenosis (decrease in caliber) is present approximately 2 cm above the anal opening.
4. Imperforate anus without fistula (anal agenesis)—rectum is completely blind, ending 2 cm from perineum; intestinal obstruction occurs if no associated fistula.
5. Anorectal malformation with rectourinary fistula in males (present in 80% of males with anorectal malformations).
   a. Rectourethral bulbar fistula.
   b. Rectourethral prostatic fistula.
   c. Rectobladder neck fistula.
6. Anorectal malformation with fistula and cloaca in females.
   a. Vestibular fistula—rectum opens through an abnormal narrow orifice located in the vestibule of the

genitalia outside the hymen; most common defect in females.

b. Vagina fistula—rectum opens via fistula into vagina; exceptionally rare malformation.

c. Persistent cloaca—complex defect in which the rectum, vagina, and urinary tract are fused together into one common channel ending in a single perineal orifice at the site of the urethra; requires colostomy, urinary diversion, or vaginal diversion.

7. Cloacal exstrophy—complex anorectal anomaly that includes omphalocele, two exstrophied hemibladders with cecum between them, imperforate anus, and abnormalities of sexual structures; rare; occurs in males and females.
8. Ectopic anus—mild displacement of the anus, which causes constipation. It is not a true anorectal malformation but may require dilatations or surgery. The anal position can be measured using the anal position index, which is the ratio of anus–fourchette distance in girls and anus–scrotum distance in boys to the distance between coccyx and fourchette/scrotum.

Degree of Incontinence

1. It may be difficult to absolutely predict what pediatric patients will obtain bowel and bladder continence for those with congenital GI/GU abnormalities or those who have suffered an injury to the area.
2. Bowel and bladder incontinence can be caused by damage to the nerves that control the sphincter muscles that control the outflow or damage to the muscle wall itself.
3. Complications may also occur from extensive surgical repairs required for surgery of the gastrointestinal or urologic system.
4. Gender and the type of abnormality will impact the likelihood of continence.
5. Some disorders; such as perineal fistula, rectal atresia, and rectal stenosis frequently result in 100% of patients having neither bowel nor bladder control.
6. Disorders such as rectobladder neck fistulas usually cause incontinence of urine but allow for bowel control.

Clinical Manifestations

1. Absence of anal opening; stimulation of perineum leads to puckering.
2. Displaced anal opening.
3. Anal opening near vaginal opening in female.
4. Thermometer, small finger, or rectal tube cannot be inserted into the rectum.
5. Meconium stool is absent or delayed.
6. Stool passed by way of the vagina or urethra may appear as green-tinged urine.
7. Progressive abdominal distention.
8. Fistula is likely to be present.
9. Vomiting if infant is fed.

Diagnostic Evaluation

1. Urine examination for presence of meconium and epithelial debris indicates presence of fistula.
2. Cross-table lateral abdominal x-ray—infant in prone position with pelvis elevated.
   a. Gas in blind rectum gives a radiolucent image.
   b. Measurement from the skin (radiopaque marker) and the blind rectum allow estimate of the height of the defect.
3. Abdominal ultrasound to detect urinary obstruction and locate rectal pouch.
4. Voiding cystourethrogram to detect commonly associated urinary tract anomalies such as vesicoureteral reflux.
5. MRI.

Management

EVIDENCE BASE Youssef, F., Arbash, G., Puligandla, P., et al. (2017). Loop versus divided colostomy for the management of anorectal malformations: A systematic review and meta-analysis. *Journal of Pediatric Surgery*, *52*(5), 783–790.

Rigueros Springfield, L., Connor, M., Jones, K., et al. (2016). Prevalence of active long-term problems in patients with anorectal malformations: A systematic review. *Diseases of the Colon and Rectum, 59*(6), 570–580.

Imperforate Anal Membrane

1. Internal and external sphincters are intact, so usually requires only a membrane excision from the anal opening.
2. Repaired at birth; no colostomy required.

Anal Stenosis

1. Internal and external sphincters are intact, so usually treated with anal dilation.
2. Occasionally requires myotomy (cutting of anal muscle).
3. Treated at birth; no colostomy required.

Imperforate Anus (Anal Agenesis)

1. Low lesion.
   a. Can usually be repaired with perineal anoplasty, which creates an anal opening for passage of stool.
   b. Usually accompanied by fistulas that need to be closed at the same time.
   c. Repaired at birth; colostomy usually not needed unless a fistula is present or more time for healing is needed.
2. High lesion.

a. Requires more extensive surgery because of missing innervation.
b. Usually requires a two-stage procedure, occasionally three-stage if complex defect is present.
c. First step is a colostomy.
d. Second step is anal repair, colon/rectum anastomosis, possible colostomy closure.
    i. Posterior sagittal anorectoplasty, also known as the *Pena procedure* (after the surgeon who developed it). The rectum is "pulled down" and sewn into a newly made anal opening in the perineum.
    ii. Most surgeons wait 4 to 6 months to complete it to allow for growth.
e. Third step is colostomy closure if defect is complex and more healing time is needed.

Complex Fistulas and Cloaca

1. Complex rectal, urologic, and vaginal reconstruction are necessary.
2. Urinary diversion is performed in the neonate if a urologic emergency is apparent.

Note: Rectal dilation may be needed for any condition after the final surgery.

Complications

1. Infection.
2. Intestinal obstruction.
3. Loss of bladder or urinary sphincter control.

NURSING ALERT Condition is usually discovered immediately after birth or within several hours. A delay in diagnosis is not uncommon and can significantly increase the risk of serious early complications and death.

Nursing Assessment

1. Perform physical assessment of neonate for abnormalities.
    a. Presence of perineal fistula.
    b. Meconium from vagina or presence of meconium-stained urine.
    c. No anal opening or inability to pass thermometer into rectum.
2. Perform thorough examination for other congenital anomalies.
3. Assess parents' level of understanding of condition and ability to cope with infant's surgery.

NURSING ALERT A neonate who does not pass a stool in the first 24 hours after birth requires further assessment.

Nursing Diagnoses

Preoperative

- Risk for Activity Intolerance related to instability before surgery.

Postoperative

- Risk for Infection related to surgical incision of anoplasty.
- Risk for Impaired Skin Integrity related to ostomy and anoplasty.
- Risk for Decreased Fluid Volume related to restricted intake.
- Readiness for Enhanced Family Processes related to increased needs of infant.
- Delayed Surgical Recovery related to definitive repair surgery.

Nursing Interventions

Maintaining Stability Before Surgery

1. Maintain NPO status. Note any vomiting: color and amount.
2. Minimize energy expenditure due to altered nutritional status.
3. Maintain NG tube passed to decompress the stomach, as ordered. Measure abdominal girth.
4. Observe the patient carefully for any signs of distress and report. Check vital signs frequently.
5. Use an Isolette or radiant warmer to maintain temperature stability.
6. Minimal handling; cluster procedures together to encourage rest and sleep.
7. Keep fistula area clean to prevent UTI.
8. Administer good oral care.

Preventing Infection of Suture Line

1. Following anoplasty, do not put anything in the rectum.
    a. Position the infant for easy access to perineum for cleansing and minimal irritation to site (ie, place the infant on his or her abdomen, possibly with hips elevated, to prevent pressure on perineal surfaces; turn side-to-side).
    b. Expose the perineum to air.
    c. Observe incision site for redness, drainage, poor healing.
    d. Apply antibiotic ointment to perineum, as directed.
2. Following colostomy, observe wound and stoma for redness, drainage, poor healing.
3. Administer IV antibiotics, as directed (usually 2 to 3 days).

Preventing Skin Breakdown

See “Ostomy Care in Children,” page 1303.

Maintaining Fluid and Electrolyte Balance

1. Monitor for return of peristalsis; NG tube may be discontinued by the health care provider when bowel sounds present.
2. Start oral feedings, as ordered.
   a. Anoplasty: usually within hours.
   b. Colostomy: when bowel sounds present and colostomy has output.
3. Monitor parenteral fluids and discontinue when oral intake is sustained.
4. Report vomiting.
5. Describe stool frequency, consistency, and character. Report blood in stool or lack of stool output.
6. Monitor urine output, particularly important with urethral defects (including cloaca).

Strengthening Coping

1. Assure the parents that colostomy is temporary (unless complex surgery performed).
2. Encourage the parents to participate in care of the child and to provide emotional security for the child.
3. Provide thorough teaching program for special care needed at home.
   a. Colostomy care.
   b. Anal dilatation to prevent a stricture at site of anastomosis from scar tissue (after instructions by health care provider).
4. Initiate referral to community nurse, especially if the parents are particularly anxious about caring for the child at home.
5. Encourage the parents to talk about their concerns.
6. Enlist help of enterostomal nurse specialist before the child leaves the hospital and for continued home care needs.
7. Assist breast-feeding mother to maintain milk supply through frequent pumping.

Maximizing Recovery Following Definitive Pull-Through Surgery

1. Maintain GT or NG tube decompression until peristalsis returns.
2. If a bladder catheter is used, provide care, as directed, and measure urine output accurately.
3. Observe carefully for abdominal distention, bleeding from perineum, and respiratory compromise. Report immediately.
4. Carry out perineal care.

Family Education and Health Maintenance

1. Review special care and procedures to be continued at home. Involve parents and other caregivers in teaching. Advise parents to make day care providers, teachers, and school nurse aware of child's needs.
2. It is important that the family understands the rationale and technique for anal dilation as indicated by the surgeon. Provide written instructions and assess their understanding of the procedure.
3. Help the parents to understand situations that may be encountered as a result of anorectal malformation repair as the infant gets older.

a. Fecal impaction due to lack of sensation to defecate.
b. Future surgery if primary repair was not done or defect complicated.
c. Toilet training—may be delayed, especially after a pull-through procedure.
d. Inability to control fecal seepage from rectum.

4. Offer practical guidelines to help parents cope.
   a. Fecal control may not be achieved until age 10; however, about 85% of children achieve normal or socially acceptable continence if defect limited to imperforate anus.
   b. If incontinence occurs, anorectal manometric evaluation in postoperative period can give more realistic information about future incontinence.
   c. Encourage bowel habit training or patterning of defecation (eg, after breakfast).
   d. Promote diet modifications; teach foods that produce laxative effect (plums, prunes, chocolate, nuts, corn) and foods that have binding effect (peanut butter, hot cereal, cheese).
   e. Stool softeners or antidiarrheal medication as ordered by the health care provider.
   f. Rectal inertia may cause fecal impaction in rectosigmoid colon with soiling from fluid overflow. Bisacodyl suppository or cleansing enema provides assistance in management.
5. Antegrade continence enema procedures may allow for continence in children without anal sphincter function.
6. Encourage mutual support from other families who have a child with an anorectal malformation.
7. For additional information and support, refer the parents to the National Organization for Rare Disorders (*www.rarediseases.org*) or the United Ostomy Associations of America (*www.ostomy.org*).

DRUG ALERT Antidiarrheal medications should be used with caution in children.

Evaluation: Expected Outcomes

- Vital signs stable, abdominal girth stable.
- No signs of infection of suture line.
- Skin intact surrounding ostomy.
- Bowel sounds present; oral feeding tolerated without vomiting; NG tube discontinued.
- Family discusses plans for home care with enterostomal therapist.

TRANSITIONAL CARE ALERT Children discharged to home with a gastrointestinal disorder may require a complex level of care by family caregivers. Ensure that the caregivers understand procedures and outcomes for nutritional support. It is crucial that nurses discharging these patients ensure that the families have the financial means and access to secure necessary nutritional requirements as well as the ability

to store items (if refrigeration is required). Gastrointestinal disorders frequently cause alteration in means of elimination, or incontinence. Ensure that all necessary equipment is available to maintain optimal hygiene and infection disease containment. This is also crucial for the child (who has successfully toilet trained) to maintain social interactions without embarrassment. If long term management is expected for nutrition and elimination in the school-age child, the nurse may be called on to assist in training and education of school personnel to assist in the care.

ACUTE DISORDERS

Acute Glomerulonephritis

Acute glomerulonephritis is a broad term used to describe several disease processes that result in glomerular injury. The glomerular injury is the result of antigen–antibody deposits within the glomeruli. It occurs most frequently in school-age children, is rare in children younger than age 2, and occurs more frequently in males than in females (2:1).

Pathophysiology and Etiology

1. Presumed cause—antigen–antibody reaction secondary to an infection elsewhere in the body (see Figure 49-1).
2. The initial infection is usually either an upper respiratory infection (URI) or a skin infection.
3. Most frequent causative agent—nephritogenic strains of group A beta-hemolytic streptococcus.
4. It is speculated that the streptococcal infection is followed by the release of a membrane-like material from the organism into the circulation.
5. Antibodies produced to fight the invading organism also react against the glomerular tissue, thus forming immune complexes.
6. The immune complexes become trapped in the glomerular loop and cause an inflammatory reaction in the affected glomeruli.
7. Changes in the glomerular capillaries reduce the amount of the glomerular filtrate, allow passage of blood cells and protein into the filtrate, and reduce the amount of sodium and water that is passed to the tubules for reabsorption.
8. General vascular disturbances, including loss of capillary integrity and spasm of arterioles, are secondary.

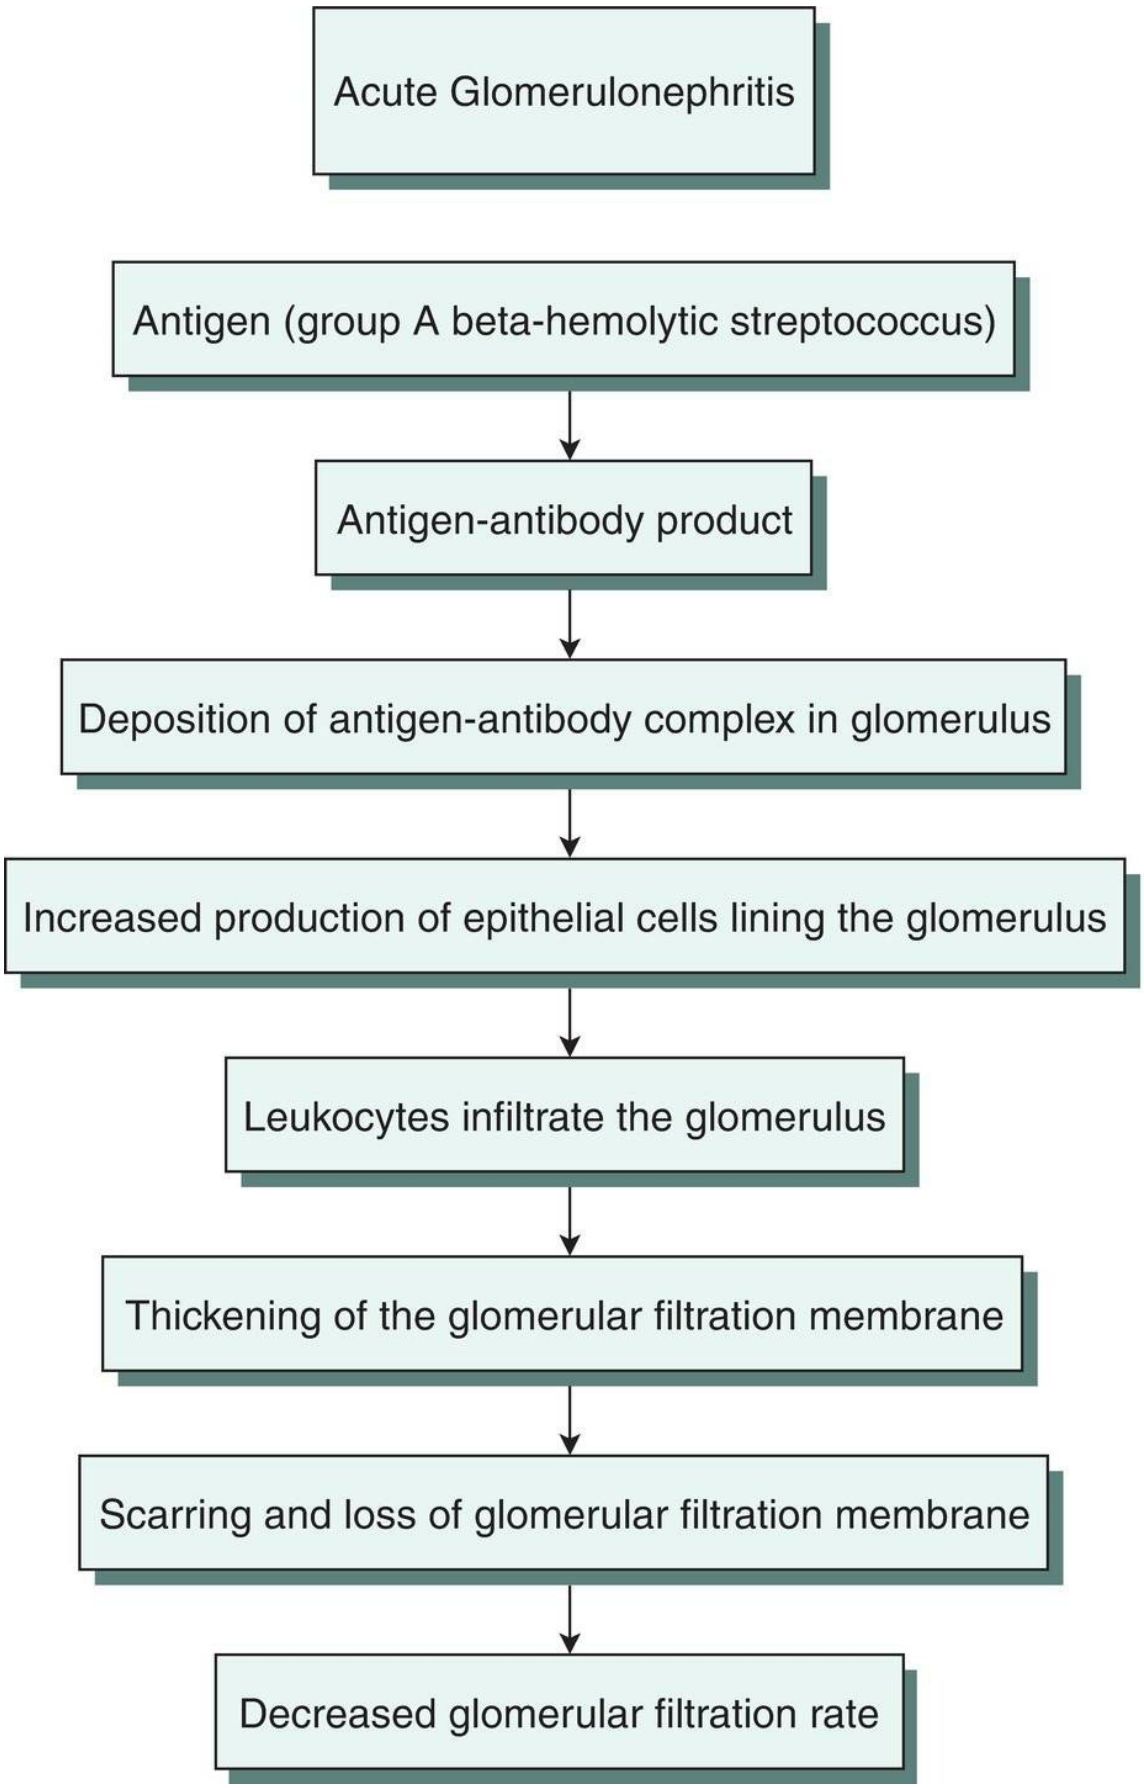

Figure 49-1. Sequence of events in acute glomerulonephritis. (Smeltzer, S., & Bare, B. [2000].

Brunner and Suddarth's textbook of medical-surgical nursing [9th ed.]. Philadelphia: Lippincott Williams & Wilkins.)

Clinical Manifestations

Onset

1. Usually 7 to 15 days after acute pharyngitis. In streptococcal skin infections, the latency period may be as long as 4 to 6 weeks.
2. May be abrupt and severe or mild and detected only by laboratory measures.

Signs and Symptoms

1. Urinary symptoms:
   a. Decreased urine output.
   b. Bloody or brown-colored urine.
2. Edema.
   a. Present in most patients.
   b. Usually mild.
   c. Commonly manifested by periorbital edema in the morning.
   d. May appear only as rapid weight gain.
   e. May be generalized and influenced by posture.
3. Hypertension.
   a. Present in up to 70% of those hospitalized with glomerulonephritis.
   b. Usually mild.
   c. Rise in blood pressure (BP) may be sudden.
   d. Usually appears during the first 4 to 5 days of the illness.
4. Pallor.
5. Malaise, lethargy.
6. Low-grade fever.
7. Mild headache.
8. GI disturbances, especially anorexia and vomiting.

Diagnostic Evaluation

1. Urinalysis:
   a. Decreased output (oliguria)—may approach anuria.
   b. Microscopic or gross hematuria (noted in 30% to 70% of all cases).
   c. Specific gravity—moderately elevated.
   d. Proteinuria may be mild to severe.

e. Microscopic—red blood cells, leukocytes, epithelial cells, and casts.

f. Low urinary sodium may be noted.

2. Blood urea nitrogen (BUN) and creatinine—usually mildly to moderately elevated; however, normal in 50% of cases.
3. Antistreptolysin-O titer—elevated initially.
4. Anti-DNase B titer—elevated.
5. Erythrocyte sedimentation rate—elevated.
6. Complement C3 and complement C4—depressed.
7. If chest x-ray indicated—may show pulmonary congestion, cardiac enlargement during the edematous phase.

Management

1. Antibiotic therapy may be initiated if there is any concern that streptococci or other organisms are still present.
2. Other management is mostly symptomatic; in most patients, spontaneous recovery is expected. Hospitalization is usually not necessary.
3. Salt and fluid intake should be restricted during the acute phase of the disease.
4. Diuretics should be administered if significant edema or hypertension develops.
5. A renal biopsy may be indicated if the child does not recover from apparent acute poststreptococcal glomerulonephritis.

Complications

The following complications occur infrequently.

1. Circulatory congestion—if severe can lead to pulmonary edema.
2. Hypertensive encephalopathy.
3. Acute renal failure.
4. Anemia.

Nursing Assessment

1. Obtain history regarding recent streptococcal infection.
2. Obtain appropriate cultures and assess for current infection.
3. Measure urine output and degree of hematuria and proteinuria.
4. Weigh the child and document areas and extent of edema.
5. Obtain baseline BP reading to assess for hypertension.

Nursing Diagnoses

- Impaired Urinary Elimination related to glomerular dysfunction.

- Excess Fluid Volume related to impaired renal function.
- Deficient Diversional Activity related to prolonged illness and restrictions.
- Deficient Knowledge regarding acute glomerulonephritis and its management.

Nursing Interventions

Promoting Normal Urine Output

1. Monitor daily intake and output.
2. Test and record urine for hematuria and proteinuria, as directed. Note color of urine.
3. Monitor daily weight.

Reducing Excess Fluid Volume

1. Provide a no-salt-added diet during the acute phase of the illness. Other restrictions may be indicated if renal function is impaired. Protein intake is not usually restricted because of the possible risk of malnutrition.
2. Restrict fluids in children with hypertension, edema, heart failure, or renal failure.
3. Place a sign that indicates dietary restrictions on the child's bed so that staff and visitors will be aware of special needs.
4. With fluid restrictions, offer small amounts of fluids spaced at regular intervals throughout the day and evening. Use an appropriate-size cup for the amount of fluid being offered.
5. Check BP, as ordered or needed, and observe for signs of hypertension (eg, headache, blurry vision, fussy, fatigue). Administer antihypertensive and diuretic drugs, as ordered by health care provider.

Promoting Diversional Activity

1. Explain fluid restriction at an age-appropriate level and direct the child's focus away from restrictions.
2. Provide the child with diversional activity and play therapy.
3. Encourage activity, as tolerated.

Providing Information

1. Explain all aspects of the diagnostic tests and treatment in terms the family can understand.
2. Explain the purpose of all medications and the restricted diet, including a review of high-sodium foods to avoid and sample menus.
3. Encourage family participation in the child's care.
4. Help the family plan for adaptation of the child's nursing care to the home environment.
5. Arrange for appointments for continued medical supervision and initiate referrals when appropriate.

Family Education and Health Maintenance

1. Reinforce medical explanation of the disease process.
    a. Alert the family to signs and symptoms of disease recurrence.

b. Be aware that microscopic hematuria may persist for several months.

2. Reinforce activity recommendation; usually not restricted.
3. Advise that tonsillectomy or other oral surgery is not recommended for several months after the acute phase of glomerulonephritis.
   a. If this type of surgery is necessary, penicillin may be recommended before and after the procedure to prevent bacterial infection.
   b. Obtain information regarding drug allergies before administering penicillin.

Evaluation: Expected Outcomes

- Output remains adequate.
- Weight returns to baseline.
- Child does age-appropriate activities, as tolerated, and does not complain of thirst.
- Parents and child can state rationale for treatment.

Nephrotic Syndrome

Nephrotic syndrome is characterized by heavy proteinuria, hypoalbuminemia, and edema. The syndrome can be subdivided into congenital, primary, and secondary types. Primary nephrotic syndrome includes idiopathic, minimal change and childhood types. Approximately 85% to 95% of primary cases in preadolescents are classified as minimal-change nephrotic syndrome (MCNS) and are associated with minimal histologic change in the glomeruli. Nephrotic syndrome afflicts approximately 16 per 100,000 children younger than age 16 in the United States annually; in young children, it is slightly more common in males than in females, but it disappears in teenagers and adults. The most common age for presentation is 2 years, and 70% to 80% of cases occur in children younger than age 6 years.

Pathophysiology and Etiology

1. Underlying defect is thought to be caused by the loss of charge selectivity of the glomerular basement membrane, which permits negatively charged proteins, primarily albumin, to pass easily through the capillary walls into the urine.
2. Excessive urinary loss of protein and catabolization by the kidney of circulating albumin leads to a decrease in serum protein (hypoalbuminemia).
3. The colloidal osmotic pressure that holds water in the vascular compartments is reduced because of the decrease in the amount of serum albumin. This allows fluid to flow from the capillaries into the interstitial spaces, thus producing edema.
4. The shift of fluid from the plasma to the interstitial spaces reduces the vascular fluid volume (hypovolemia), which in turn stimulates the renin–angiotensin system and the secretion of antidiuretic hormone and aldosterone.
5. Tubular reabsorption of sodium and water is increased for intravascular volume.
6. The loss of proteins, particularly immunoglobulins, predisposes the child to infection.

Clinical Manifestations

1. Onset is insidious—thought to be caused by immune system disturbances because it commonly occurs after a mild URI.
2. Edema is typically the presenting symptom.
    a. Edema may be minimal or massive.
    b. Edema is usually first apparent around the eyes.
    c. Dependent edema occurs in areas of the body such as the hands, ankles, feet, and genitalia.
    d. Fluid that accumulates in the body spaces may give rise to ascites and pleural effusions.
    e. Striae may appear on the skin from overstretching.
3. Profound weight gain caused by edema; the child may actually double normal weight.
4. Decreased urine output during the edematous phase—urine appears concentrated and frothy.
5. Pallor, irritability, lethargy, and fatigue.

6. GI disturbances, including vomiting, diarrhea, abdominal pain, and anorexia caused by edema of intestinal mucosa.

Diagnostic Evaluation

1. Urinalysis:
   a. Proteinuria (tests for albumin)—2+ (greater than 1.0 g/L) on urine dipstick; should be sent for urine protein to creatinine ratio (first voided or random spot urine) to confirm. Considered nephrotic range if greater than 200 to 250 mg/mmol.
   b. Blood—gross hematuria is not present but microscopic hematuria may be found in about 20% of patients.
2. Twenty-four-hour urine collection is the gold standard for quantification of urine protein—nephrotic range greater than 40 mg/m^2/hour.
3. Blood tests.
   a. Total protein—reduced.
   b. Albumin—less than 2.5 g/dL.
   c. Complete blood count may show decreased hematocrit due to hemodilution.
   d. BUN may be elevated, indicating general renal function.
   e. Creatinine—usually normal but may be increased if intravascularly depleted.
   f. Electrolytes—may have sodium, potassium, CO_2, and calcium imbalances.
   g. Increased serum cholesterol and triglycerides—due to reactive protein synthesis by the liver in response to hypoproteinemia.
4. Renal biopsy is indicated to look for other cause of renal dysfunction if the patient has persistent proteinuria after 4 to 8 weeks of steroid therapy (median time to remission is 10 days—negative or trace proteinuria for 3 consecutive days). Biopsy also indicated if atypical presentation such as persistent renal failure, age less than 1 year or greater than 10 years, use of nephrotoxic drugs, or persistent hematuria.

Management

Steroid Therapy

1. Corticosteroid therapy—prednisone or prednisolone are drugs of choice because of lower cost and are less likely to induce salt retention and potassium loss.
2. No standard program of therapy exists; however, the 2012 Kidney Disease: Improving Global Outcomes guidelines recommend the following:
   a. Corticosteroid therapy be given for at least 12 weeks.
   b. Oral prednisone be administered as a single daily dose starting at 60 mg/m^2/day or 2 mg/kg/day to a maximum 60 mg/day.
   c. Daily oral prednisone be given for 4 to 6 weeks followed by alternate-day medication as a single daily dose starting at 40 mg/m^2 or 1.5 mg/kg (maximum 40 mg on alternate days) and continued for 2 to 5

months with tapering of the dose.

3. Corticosteroid therapy should be discontinued slowly to avoid complications of steroid withdrawal, particularly benign intracranial hypertension.
4. Children with nephrotic syndrome may respond to steroid therapy in several ways:
   a. Steroid sensitive: achieving remission within 28 days of the start of corticosteroid therapy.
   b. Steroid dependent: relapses on alternate-day dosing or relapses within 14 days of corticosteroid discontinuation.
   c. Steroid resistant: persistent proteinuria after 8 weeks of corticosteroid therapy.
5. Children with steroid-responsive MCNS have a favorable long-term prognosis.

EVIDENCE BASE Kidney Disease: Improving Global Outcomes (KDIGO) Work Group. (2012). Clinical practice guideline for glomerulonephritis. *Kidney International, 2*(2), 139–274.

Copeman, H. (2014). Renal care in the paediatric setting: an overview of common conditions. *Journal of Renal Nursing, 6*(6), 280–283.

Intravenous (IV) Albumin 25%

1. To shift fluid from interstitial space into the vascular system.
2. Only a temporary treatment to relieve edema but may be used in severe cases of edema that cause respiratory distress or severe discomfort.
3. Diuretic therapy is used in combination with IV albumin to help relieve edema. In cases of hypovolemia, diuretics may not be indicated.

Alternative Drug Therapies

1. Should be considered when children relapse frequently (greater than four relapses in 1 year or two relapses in 6 months), become steroid resistant or steroid dependent, or demonstrate unacceptable adverse effects of steroid therapy (steroid toxicity). The decision to use alternative therapy in conjunction with steroids should be made by an experienced pediatric nephrologist.
2. Immunosuppressants.
   a. Cyclophosphamide.
   b. Cyclosporin A.
   c. Tacrolimus.
   d. Mycophenolate mofetil.
   e. Rituximab.

Complications

1. Infections:

a. Peritonitis, most commonly caused by *Streptococcus pneumoniae* but may also be caused by *Escherichia coli* and *Haemophilus influenzae*.
   b. Gram-negative septicemia.
   c. Staphylococcal cellulitis.
2. Thromboembolic events.
3. Hypertension.
4. Hyperlipidemia.
5. Pulmonary edema.
6. Bone disease secondary to corticosteroid therapy.
7. Acute renal failure.

Nursing Assessment

1. Obtain history of onset of illness and symptoms.
   a. Precipitating events.
   b. Recent immunizations.
   c. Recent URIs.
   d. Flulike symptoms.
   e. Time of onset and location of edema.
   f. Urinary pattern changes.
2. Perform physical examination focusing on vital signs; auscultation of breath sounds to determine adventitious sounds; areas and extent of edema, especially periorbital region, extremities, genitalia, abdomen; and peripheral perfusion, including pulses, color, and warmth of extremities.

Nursing Diagnoses

- Excess Fluid Volume related to fluid accumulation in tissues.
- Risk for Infection related to urinary loss of proteins and chronic steroid use.
- Imbalanced Nutrition: Less Than Body Requirements related to loss of proteins through urine and anorexia.
- Interrupted Family Processes related to childhood illness.

Nursing Interventions

Relieving Excess Fluid

1. Administer corticosteroids, as directed.
   a. Observe for adverse effects and complications of therapy, such as Cushing syndrome—increased body hair (hirsutism), rounding of the face (“moon face”), abdominal distention, striae, increased appetite with weight gain, cataracts, and aggravation of adolescent acne.
   b. Stress that these physical changes are not harmful or permanent and that they will disappear after the

steroid treatment is stopped.

c. Observe for serious adverse effects and uncommon complications of corticosteroids (see pages 702 to 704).

2. Administer immunosuppressive drugs, as prescribed.
   a. Make sure that the patient and parents understand the desired and adverse effects of therapy.
   b. Observe for complications of therapy, such as decreased white blood cell (WBC) count, increased susceptibility to infection, hair loss or increased hair growth (hirsutism), gingival hyperplasia, and hemorrhagic cystitis.
3. Administer diuretics, as prescribed.
   a. Be aware of those diuretics that may cause potassium depletion.
   b. Offer foods high in potassium, such as orange juice, bananas, and dried fruits (eg, raisins, apricots).
   c. Administer supplemental potassium chloride, as ordered, and if the urine output is adequate.
4. Encourage activity, as tolerated.
5. Restrict fluids as ordered (usually only during the extreme edematous phases).
   a. Restriction is carefully calculated at frequent intervals, based on the urine output of the previous day plus estimated insensible losses.
   b. Offer small amounts of fluids spaced at regular intervals throughout the day and evening. Use a cup of appropriate size for the amount of fluid being offered.
   c. Measure fluids accurately in graduated containers. Do not estimate fluid intake or output.
   d. Place a sign on the child's bed to make sure that no urine is accidentally discarded and that all intake is recorded.
   e. Determine total intake and output every 8 hours. In children who are not toilet trained, a fairly accurate record of output can be obtained by weighing diapers before and after voiding.
   f. Record other causes of fluid loss, such as the number of stools per day, perspiration.
6. In refractory or extreme cases, assist with abdominal paracentesis; this may be required because of marked ascites. During the procedure, fluid is withdrawn from the peritoneal cavity to relieve pressure symptoms and respiratory distress.
7. Restrict sodium, as ordered (usually done while the child is on corticosteroid therapy). A starting point is 1.5 to 2 g/day.
   a. Use a low-sodium menu when ordering meals from the hospital.
   b. Assist family in making food choices that are low in sodium.
   c. Foods that should be limited include cured, salted, canned, or smoked meats; processed cheese; regular canned or frozen soups and bouillon cubes; and salted crackers and other snack foods.

NURSING ALERT No live vaccinations or immunizations should be given during active episodes of nephrosis or while the child receives immunosuppressive therapy.

DRUG ALERT Administer cyclophosphamide in the morning, with large volumes of fluid, to prevent concentration of the drug in the urine and increased susceptibility to cystitis.

Preventing Infection

1. Monitor complete blood count for decreased WBC count and neutropenia.
2. Closely observe the child who takes corticosteroids for signs of infection. Be aware that fever and other symptoms may be masked.
3. Provide meticulous skin care to edematous areas of the body.
   a. Bathe the child frequently and apply powder. Areas of concern are moist parts of the body and edematous male genitalia. Support the scrotum with a cotton pad held in place by a T-binder, if necessary, for the child's comfort.
   b. Position the child so that edematous skin surfaces are not in contact. Place a pillow between the child's legs when lying on side.
   c. Elevate the child's head to reduce edema.
4. If possible, avoid invasive procedures, such as femoral venipunctures and IM injections, to decrease the chance of introducing pathogens. Venipuncture of the lower extremities may also predispose the child to thromboembolism because of hypovolemia, stasis, and increased plasma concentration of clotting factors.
5. Educate the parents regarding signs and symptoms of possible infections.

Enhancing Nutritional Status

1. Assess nutritional intake, growth, and development as appropriate for age.
2. Provide a diet low in sodium, fat, and sugar. Place a sign on the child's bed that indicates dietary restrictions so that everyone will be aware of special needs.
3. Provide food choices that appeal to the child and that are easy to eat according to stage of development.
4. Provide nutritional supplements, as needed.

Providing Emotional Support

1. Encourage frequent visiting and allow as much parental participation in the child's care as possible. Hospitalization, if necessary, is usually brief.
2. Allow the child as much activity as tolerated.
   a. Balance periods of rest, recreation, and quiet activities during the convalescent phase.
   b. Allow the child to eat meals with family or other children.
3. Encourage the child and family to verbalize fears, frustrations, and questions.
   a. Be aware that young children frequently fear abandonment by their parents.
   b. Allow parents to express frustrations regarding the uncertainties associated with the cause of the

disease, the clinical course, and the prognosis.

c. Explain the difference between nephritis and nephrosis if parents have questions.

4. Help the child adjust to changes in body image, such as cushingoid appearance, by explaining changes ahead of time.
5. Discuss the problems of discipline with the parents. Encourage them to set consistent limits and reasonable expectations of their child's behavior.
6. Suggest parents get involved with a support group for families of children with chronic illnesses, as needed.

Family Education and Health Maintenance

1. Prepare the family for home management of the child's care plan.
   a. Have the dietitian discuss special diets with the parents.
   b. Teach the parents about the child's medication—the desired effects and the potential adverse effects.
   c. Demonstrate urine testing for protein.
   d. Initiate a community health nursing referral, if necessary, for reassessment and reinforcement of teaching.
2. Encourage continued medical follow-up visits.
3. Emphasize the necessity of taking medication according to the prescribed schedule and for an extended time. Discuss complications encountered with steroid therapy.
4. Teach prevention and recognition of signs and symptoms of infection.
5. Advise family on necessary activity restrictions.
6. Teach signs and symptoms of relapse (proteinuria on urine dipstick at home, increased edema, and decreased urine output) and whom and when to call with questions.
7. Teach signs and symptoms of fluid imbalances (excess or dehydration).

Evaluation: Expected Outcomes

- Decreased edema and ascites; adequate urine output.
- Exhibits no signs of infection.
- Family verbalizes and follows dietary restrictions as demonstrated by appropriate weight gain/loss.
- Family verbalizes concerns regarding child's illness as demonstrated by open communication with staff and other family members.

Urinary Tract Infection

EVIDENCE BASE American Academy of Pediatrics. (2016). Urinary tract infection: Clinical practice guidelines for the diagnosis and management of the initial UTI in febrile infants and children 2 to 24 months. Subcommittee on Urinary Tract Infection. Steering Committee on Quality Improvement and Management. *Pediatrics, 138*(6), e20163026.The RIVUR Trial Investigators. (2014). Antimicrobial prophylaxis for children with vesicoureteral reflux. *New England Journal of Medicine, 371*(11), 1071–1072.

American Urological Association. (Published 2010, Reviewed and Validity Confirmed 2017). Management and Screening of Primary Vesicoureteral Reflux in Children.

Urinary tract infection (UTI) is defined as bacteria that exist anywhere between the renal cortex and the urethral meatus. Because it is usually difficult to determine the exact location of the infection, the term UTI is used to explain microorganisms anywhere within the urinary tract. UTIs are categorized as cystitis or urethritis (located in the bladder or urethra), upper tract (located in the ureters or collecting system), and pyelonephritis (renal parenchyma). The greatest incidence of UTI in males occurs in the first year of life (most common in uncircumcized males), after which it rapidly declines, remaining low through childhood and adolescence. Incidence in females is also highest in the first year of life and steadily declines through adolescence but remains higher than the incidence for males at a rate of 10:1.

Pathophysiology and Etiology

1. Causative organisms—*E. coli* (80%), *Klebsiella* species, *Proteus* species, *Staphlyococcus saprophyticus* (female adolescents and sexually active females), *Enterococcus species, Streptococcus* group B (neonates), *Pseudomonas aeruginosa*.
2. Route of entry:
    a. Ascent from the urethra (most common).
    b. Circulating blood (rare).
3. Contributing causes:
    a. Female specific.
        i. Perineal location of urethral orifice and shorter urethra.
        ii. Sexual intercourse (mechanics of vaginal penetration).
        iii. Vaginal voiding—reflux of urine into the vagina while voiding, with subsequent dribbling of urine.
    b. Male specific—foreskin (prepuce can be a reservoir for bacteria).
    c. Abnormal bladder or voiding with or without incontinence.
        i. High pressures in the bladder.

ii. Incomplete bladder emptying, infrequent voiding.

iii. Difficulty relaxing pelvic floor.

d. Constipation and bowel/bladder dysfunction.

e. Congenital urinary tract anomalies—vesicoureteral reflux, posterior urethral valves, prune belly syndrome, hydronephrosis, bladder exstrophy.

f. Neurogenic bladder (spina bifida, spinal injury).

g. Catheterization, urinary drains/tubes.

h. Bacterial colonization.

i. Alteration in periurethral flora by antibiotic therapy

4. Pathophysiology—colonization of uropathogens in periurethral area that ascend into bladder via urethra affecting portions of urinary tract, spreading from bladder to kidneys through the ureter (pyelonephritis) and possibly to bloodstream (bacteremia)

a. Clumps of bacteria may be present.

b. Inflammation results in urine retention and stasis of urine in the bladder.

c. Backflow of urine into the kidneys may occur through the ureters; this is called *vesicoureteral reflux* (VUR).

d. Inflammatory changes in the renal pelvis, and throughout the kidney, occur when the kidney is involved.

e. Scarring of the kidney parenchyma occurs in chronic infection and interferes with kidney function, particularly with the ability to concentrate urine.

f. If pyelonephritis is left untreated, the kidney tissue may be destroyed, and renal function could fail.

Clinical Manifestations

1. Onset may be abrupt or gradual; may be asymptomatic.
2. Failure to thrive in infancy.
3. Young children: may be nonspecific (vomiting, irritability, poor feeding, diarrhea); fever is often the only presenting complaint.
4. Older children and adolescents: urinary frequency, urgency or voiding hesitancy, dysuria, suprapubic tenderness, dribbling, and nocturnal enuresis (more common in lower UTI).
5. Hematuria: often occurs with viral cystitis.
6. Fever.

a. May be moderate or severe.

b. May fluctuate rapidly.

c. May be accompanied by chills or convulsions.

7. Anorexia and general malaise.
8. Foul odor or change in the appearance of urine.
9. Abdominal or suprapubic pain (more common in upper tract disease).

10. Tenderness over one or both kidneys.
11. Systemic symptoms: flank pain, fever, chills, nausea, and vomiting may occur with pyelonephritis.

Diagnostic Evaluation

1. Urinalysis:
   a. Leukocytes, nitrites suggestive but not indicative.
   b. Casts, especially WBC casts, may be present and are indicative of intrarenal infection.
   c. Hematuria—occurs occasionally.
   d. Decreased specific gravity due to decreased renal concentrating ability.
2. Urine culture:
   a. Urinalysis for proteinuria and bacteriuria should be obtained as part of the general medical evaluation. If the urinalysis indicates an infection, both urine culture and sensitivity are recommended.
   b. Documentation of a single pathogenic organism in the urine is the only means of definitive diagnosis. Multiple organisms found in the culture are suspicious of perineal flora contamination and warrant repeat culture.
   c. A urine culture demonstrating more than 100,000 bacteria per mL indicates significant bacteriuria.
   d. A catheterized urine specimen, with growth greater than 50,000 colonies of bacteria per mL, is considered significant and required in the non–toilet trained child to prevent contamination from perineal flora.
   e. To avoid contamination, discard first few milliliters of urine (if quantity is sufficient). A new catheter should be used for each subsequent attempt if unsuccessful.
3. Urologic and radiologic studies to identify anatomic abnormalities or renal changes that stem from recurrent infections—renal bladder ultrasound (ensure child is well hydrated with distended bladder), voiding cystourethrogram (VCUG).
   a. Dimercaptosuccinic acid scan—evaluates renal function and scarring.

Management

See Table 49-1.

Table 49-1 Antimicrobial Agents Commonly Used in the Management of Childhood Urinary Tract Infection

DRUG	ADVERSE EFFECTS	NURSING CONSIDERATIONS
Amoxicillin	• Occasional nausea, vomiting, diarrhea • Hypersensitivity reactions of skin	• Readily absorbed. • May be taken with food.
Ampicillin	• Diarrhea, urticaria • Anaphylactic reaction	• Contraindicated in penicillin-sensitive children. Package insert should be consulted regarding reconstitution, administration, and storage of IM and IV preparation Absorption of oral preparations may be decreased with food. Dose must be repeated q6h to ensure therapeutic blood level.
Cephalexin	• Diarrhea, nausea, vomiting	• May be taken with food. Dose should be reduced if renal function is impaired.
Gentamicin	• Renal and auditory toxicity; respiratory paralysis	• Toxic effects can be minimized by slow IV infusion (over 1 hour).
Nitrofurantoin	• Fever, nausea, vomiting, peripheral neuropathy	• Recommended for prolonged use. Give with food or milk to decrease GI adverse effect May cause urine to be amber or brown in color. Contraindicated in renal failure and in infants younger than 3 months old.
Co-trimoxazole	• Nausea, vomiting, fever, rash, photo-sensitivity	• Commonly used if bacterial resistance is anticipated or the child fails to respond to initial therapy.

1. Treatment depends on child's age, severity of infection, and antimicrobial resistance rates in the community.
2. Oral antibiotic therapy for uncomplicated UTI. Usually 10- to 14-day antibiotic therapy for febrile UTIs.
3. IV antibiotics for complicated UTI—infections that do not respond to oral therapy or that develop into pyelonephritis or those that appear septic or dehydrated.
4. Repeat culture following therapy if still symptomatic, has chronic renal disease, or has known colonization of bacteria.

Complications

1. A tendency for recurrent infection exists.
2. Children with obstructive lesions of the urinary tract and those with severe VUR are at highest risk for kidney damage. These patients may need prophylactic oral antibacterial therapy.

Nursing Assessment

1. Obtain history to determine if UTI is initial or recurrent and to determine if there may be other disease processes contributing to this infection.
2. Focus assessment on identifying clinical manifestations and determining location of infection, such as presence and appearance of urethral discharge, high-grade fever (more common with upper UTI), or low-grade fever (more common with lower UTI).
3. Determine urinary pattern (ie, amount and frequency) and associated discomfort.
4. Determine bowel pattern and possibility of constipation.

Nursing Diagnoses

- Impaired Urinary Elimination related to infection.
- Acute Pain related to inflammatory changes and fever.
- Anxiety related to exposure and manipulation of the genitourinary tract.

Nursing Interventions

Promoting Urinary Elimination

1. Obtain a clean urine specimen for urinalysis or culture (see pages 588 and 591).
    a. Obtain freshly voided early morning specimen, if possible (most accurate). This urine is usually acidic and concentrated, which tends to preserve the formed elements.
    b. Provide fluids to help the child void.
    c. Perform catheterization, if necessary, to obtain a sterile specimen; however, this procedure may cause emotional trauma and the accidental introduction of additional bacteria. In girls, pulling the labia majora out versus splaying them will help identify the meatus and prevent catheter insertion into the vagina. In the event that there is inadvertent catheterization of the vagina, leaving the catheter in situ and using a new sterile catheter should prevent recatheterization of the vagina. In boys, pulling back the foreskin is required to identify the location of the meatal opening.
    d. Send urine to the laboratory immediately or refrigerate to avoid a falsely high bacterial count.
2. Administer antibiotics, as ordered by the health care provider (after specimen has been obtained for culture).
    a. Antibiotic therapy is generally determined by the results of the urine cultures and sensitivities and by the child's response to therapy; however, empirical therapy may be started before culture results are back.
    b. Become familiar with toxic effects of antimicrobial agents and assess the child regularly for any signs and symptoms.

Maintaining Comfort and Providing Symptomatic Relief

1. Administer analgesics and antipyretics, as ordered.
2. Maintain the child on bed rest while febrile.
3. Encourage fluids to reduce the fever and dilute the concentration of the urine. (Water is the best clear fluid.)
4. Administer IV fluids, if necessary.

Promoting Self-Esteem

1. Reinforce medical explanations of the disease and its therapy.
2. Explain all diagnostic tests and procedures to the child, allowing time for questions and answers.
3. Encourage verbalizing. Correct any misconceptions and particularly address concerns about the functioning of the urinary tract and sexual function. Reassure the child that he or she did not cause the problem.
4. Maintain privacy for the child as much as possible.
5. Provide an environment that is as close to normal as possible during hospitalization. Include opportunities for the child to play.
6. Prepare the child and family for discharge and begin discussions of rest, fluids, and medications.

Family Education and Health Maintenance

1. Review long-term antibiotic therapy, if prescribed, to prevent recurrence of UTI. Schedules for prolonged therapy vary from several months to continuous prophylaxis.
2. Encourage scheduled follow-up visits because of the possibility of disease recurrence.
    a. Emphasize that even though this disease may have few symptoms, it can lead to serious, permanent disability.
    b. Advise family that subsequent suspected UTIs should be assessed and followed by health care provider.
3. Teach measures of prevention:
    a. Minimize spread of bacteria from the anal and vaginal areas to the urethra in female children by cleansing the perianal area from the urethra back toward the anus.
    b. Encourage adequate fluid intake, especially water.
    c. Avoid carbonated and caffeinated beverages because of their irritative effect on bladder mucosa.
    d. Encourage the child to void frequently and to empty the bladder completely with each voiding (double voiding).
    e. Encourage a high-fiber diet to avoid constipation.

Evaluation: Expected Outcomes

- Voids regularly in adequate amounts.
- No complaints of pain during or after voiding; afebrile.
- Shows less anxiety about hospitalization; appears more relaxed about appearance, body image, tests.

ABNORMALITIES OF THE GENITOURINARY TRACT THAT REQUIRE SURGERY

See Figure 49-2 for congenital abnormalities of the urinary tract, extrophy of the bladder and hypospadias.

Exstrophy of the Bladder

Bladder exstrophy is an abnormality present at birth in which the bladder and associated structures are improperly formed. Rather than being its normal round shape, the bladder is flattened. The skin, muscle, and pelvic bones joining the lower part of the abdomen did not form properly, so the inside of the bladder is exposed outside the abdomen. There are also associated deficiencies of the abdominal muscles and pelvic bones. These occur at a rate of 1:10,000 to 50,000 live births. It is more common in males. Recent published evidence suggests that the risk of bladder exstrophy in children born as a result of assisted fertility techniques is seven times greater than in children conceived naturally without assistance. Evidence exists genetic predisposition in likelihood of exstophy parent with a 1 in 70 chance of having a child with bladder exstrophy and reoccurrence probability of 1 in 100.

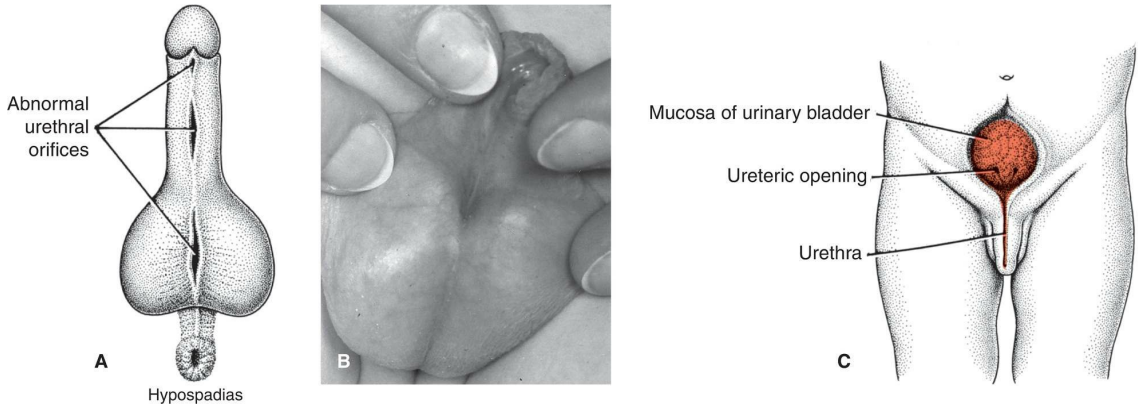

Figure 49-2. (A) Hypospadias showing the various locations of abnormal urethral orifice. **(B)** Patient with hypospadias. The urethra is open on the ventral surface of the penis. **(C)** Epispadias combined with exstrophy of the bladder. Bladder mucosa is exposed. (**A** and **C** courtesy of Dr. R. J. Gorlin, Department of Oral Pathology and Genetics, University of Minnesota; B, Dudek, R. W. [2013]. *High-Yield Embryology* [5th ed.]. Philadelphia: Lippincott Williams & Wilkins.)

Pathophysiology and Etiology

1. Results from failure of the abdominal wall and its underlying structures to fuse in utero during the 3rd to 4th week of gestation. Presumed cause is persistence of cloacal membrane during fetal development that ruptures to produce extrophy.
2. In classic exstrophy (about 60% of bladder anomalies), the posterior bladder wall is externalized and lies open on the lower part of the abdomen with an epispadial urethra, allowing constant passage of urine to the outside.
3. Epispadias may occur without exstrophy (about 30% of bladder anomalies); the bladder remains an internal organ, but the urethra is laid open, possibly with a split glans penis and the meatus located proximally.
4. Cloacal anomalies (about 10% of bladder anomalies) involve externalization of the bladder and portions of the GI tract.

Clinical Manifestations

1. Urine dribbles constantly.
2. Infection and ulceration of the bladder mucosa may occur.
3. Genitalia may be ambiguous.
4. Affected children may walk with a waddling or an unsteady gait due to diastasis (separation) of pelvic bones.

Diagnostic Evaluation

1. May be diagnosed prenatally by ultrasound.
2. Newborn inspection is the most important tool in evaluation. The obvious anomaly may involve multiple systems.
3. Diagnostic procedures, such as radiography, ultrasound, magnetic resonance imaging, and urodynamic testing, determine extent of the anomaly.
4. Spinal ultrasound for infant with sacral dimples to rule out spinal cord tethering.

Management

1. Surgical closure of bladder within first 24 to 48 hours of life by means of primary complete bladder closure and epispadias repair. This approach allows for maximal continence postrepair.
2. Urinary diversion should be rare.

Complications

1. Skin excoriation, infection.
2. Trauma to bladder mucosa.

Nursing Assessment

1. Assess for growth and development milestones during reconstruction.
2. Assess the family for coping ability.

Nursing Diagnoses

- Impaired Urinary Elimination related to anatomical defect.
- Risk for Infection as a complication of surgery.

Nursing Interventions

Facilitating Urine Output Preoperatively

1. Protect the bladder area from trauma and infection.
    a. Apply smooth common kitchen plastic wrap
    b. Warm sterile saline can be squirted over bladder to keep tissue moist.

c. Position on back or side.

d. Ensure umbilical cord is sutured and not clamped.

2. Observe the infant closely for signs of infection.
3. Involve other members of the health care team for parental support because of the psychosocial implications of a child who has special needs.
4. Assist the parents in dealing with their emotional reactions regarding the child's defect.
5. Prepare child and parents for the proposed surgery (see page 1151).
6. While previously repaired at birth, recent trend includes delayed closure to 3 months for better care outcomes including physiologic testosterone surge for penile growth in male patients.

Providing Postoperative Care to Prevent Infection

1. Goal of reconstruction is to preserve renal function, urinary continence and volitional voiding, functional and cosmetically acceptable external genitalia.
2. Provide care for the ureteral and urethral catheters. Observe and record the amount of urinary drainage, catheter positions, and bladder spasms.
3. Care for dressings, castings, stents and/or skin traction as necessary.
4. Provide care and instruction for an ileal conduit, as necessary (see page 597).
5. Antibiotic prophylaxis and pain control as ordered.
6. Observe for complications.
   a. Urinary or incisional infections.
   b. Fistulae in the suprapubic or penile incisions.
7. Recommend long-term support for children and families to help them deal with concerns about appearance of genitalia, sexual function, reproduction, and rejection by peers.

Family Education and Health Maintenance

1. Specific teaching and preparation depending on type of closure (primary or staged). Staged closures will likely require additional surgery at 4 to 5 years of age.
2. Provide community nursing referral, as needed, to support family and make sure that family understands the importance of follow-up with the various specialists.
3. Act as a liaison, as necessary, to coordinate care.
4. For more information and support, refer families to the following resources:
   a. Association for the Bladder Exstrophy Community (ABC) (*www.bladderexstrophy.com*).
   b. Book—*Living with Bladder Exstrophy: A Book for Families* (Murrey and Schremmer, 1996). Available through ABC.

Evaluation: Expected Outcomes

- No skin breakdown or infection.

- Incision healing well without infection or fistula; eventually, voiding without difficulty.

Vesicoureteral Reflux

EVIDENCE BASE Cara-Fuentes, G., Gupta, N., & Garin, E. H. (2015). The RIVUR study: A review of its findings. *Pediatric Nephrology, 30*(5), 703.

American Urological Association. (Published 2010, Reviewed and Validity Confirmed 2017). Management and Screening of Primary Vesicoureteral Reflux in Children.

Vesicoureteral reflux (VUR) is the abnormal retrograde flow of urine from the bladder into the upper urinary tract. In the absence of bacterial infection, VUR is not considered to be critical. In the presence of bacteria, however, VUR is a risk factor for the development of UTIs and pyelonephritis, which can lead to renal damage and scarring. With linear growth, spontaneous resolution of VUR occurs in most children.

Pathophysiology and Etiology

VUR occurs as a result of congenital deficiency in the formation of the ureterovesical junction, resulting in a laterally displaced ureteral orifice. Secondary VUR is acquired as a result of increased bladder pressure.

Clinical Manifestations

1. Febrile UTI-culture confirmed, catheterized specimen for non–toilet trained child.
2. Unexplained febrile illnesses.
3. Associated urogenital anomalies (bladder exstrophy, posterior urethral valves, neurogenic bladder).
4. Prenatal diagnosis (hydronephrosis detected on prenatal screening ultrasounds).

Diagnostic Evaluation

1. VCUG—to establish diagnosis of VUR but should not be performed routinely after first febrile UTI, indicated after ultrasound reveals hydronephrosis, scarring or findings of high grade VUR or obstructive uropathy, recurrent UTI or atypical complex clinical circumstances.
2. Renal ultrasound—to assess for renal damage, associated hydronephrosis.
3. DMSA—recommended when renal ultrasound is abnormal w/greater concern for scarring (breakthrough UTI, grade 3 to 4 VUR, elevated creatinine)

Management

1. The goals of medical and/or surgical management are to prevent pyelonephritis, recurrent UTIs, and formation of renal cortical scarring.
2. Continuous prophylactic antibiotic recommended for some children based on age, history of febrile UTI and degree of VUR.
3. Surgical intervention is indicated when medical therapy is unsuccessful.

a. Circumcision offered for infant males with VUR-protective for babies before the age of 1 year
b. Endoscopic polymer injection into the ureter(s)—83% success rate
c. Ureter reimplantation—98.1% success rate

4. Yearly ultasounds to monitor renal growth and kidney parenchymal scarring.

Complications

1. Recurrent UTI can lead to renal damage and failure.
2. Recurrence of VUR following surgical intervention-postoperative UTI in children close to or toilet trained age is strongly associated with incidence of preoperative UTI and presence of BBD (bladder bowel dysfunction).
3. Postoperative renal obstruction rate of 0.4%.

Family Education and Health Maintenance

1. Association of bowel/bladder dysfunction
2. General routine evaluation for patients with renal scarring prior to VUR resolution or recurrent urinary tract infection after resolution of VUR—BP, height, weight, and urinalysis for protein screening for patients with abnormal ultrasound/DMSA
3. Communication of long-term concerns of hypertension (especially in pregnancy), renal function loss, recurrent urinary tract infection, and familial VUR in siblings and offspring to be discussed when child at an appropriate age
4. Evidence-based study conducted (RIVUR) concluding that prophylaxis reduces risk of recurrent urinary tract infection but not renal scarring

For nursing assessment, diagnoses, and interventions, see "Care of the Child Who Undergoes Urologic Surgery," page 1324.

Obstructive Lesions of the Lower Urinary Tract

Obstruction of the lower urinary tract may be caused by structural lesions, such as posterior or anterior urethral valves, bladder neck obstruction, meatal stricture, and urolithiasis (stones), or by functional lesions, such as neuromuscular dysfunction. The effect of obstruction on ureteral and renal function depends on the degree and duration of obstruction, on the rate of urine formation, and whether infection exists.

Pathophysiology and Etiology

Types of Obstruction

1. Urethral valves—filamentous valves that obstruct urine flow.
2. Congenital narrowing of the urethra.
3. Bladder neck obstruction—most common site of lower urinary tract obstruction.
4. Meatal stricture.
5. Neuromuscular dysfunction.
6. Severe phimosis (rare).
7. Inflammatory processes.
8. Neoplasia.
9. Urolithiasis.
10. Trauma.

Effects of Obstruction

1. Urinary tract becomes distended, proximal to the point of obstruction.
2. The bladder dilates and hypertrophies.
3. Stasis of urine occurs.
4. The ureters become elongated, dilated, and tortuous.
5. Hydronephrosis and destruction of kidney tissue inevitably result if left untreated.

Clinical Manifestations

1. Abnormal urination.
    a. Dysuria, frequency.
    b. Enuresis, dribbling.
    c. Reduced force of urine stream.
    d. Difficulty starting urine stream.
    e. Straining during urination.
    f. Abrupt cessation during urination.
2. Signs of infection—fever, pain, irritability, and, occasionally, hematuria.
3. Lower obstruction: suprapubic pain, prolapse via urethra in females (ureterocele) presenting as bulging

vulvar mass in females.

Diagnostic Evaluation

1. Physical examination may reveal abdominal mass.
2. Laboratory findings depend on the degree that renal function is compromised.
3. Renal ultrasound may show hydronephrosis.
4. Radionuclide scanning.
5. Endoscopic examination.
6. Ureteroscopy.
7. Urodynamic examination.

Management

1. Prevention or eradication of infection with antibiotics.
2. Dilation of urethral stenosis or stricture.
3. Urinary diversion may be necessary.
4. Surgical relief of the obstruction.

Complications

1. Urinary stasis and recurrent UTI could lead to renal failure.
2. Severe and recurrent UTI.
3. Recurrence of the obstruction.

For nursing assessment, diagnoses, and interventions, see "Care of the Child Who Undergoes Urologic Surgery," page 1324.

Obstructive Lesions of the Upper Urinary Tract

Obstructive lesions of the upper urinary tract include ureteropelvic junction obstruction, ureterovesical junction obstruction, ureteral stricture, congenital absence or duplication of a ureter, and urolithiasis. These obstructive lesions are primarily congenital.

Pathophysiology and Etiology

1. Congenital anomalies develop in the upper urinary tract.
    a. Ureteropelvic junction obstruction.
    b. Ureterovesical junction obstruction.
    c. Stricture of a ureter.
    d. Congenital absence of one ureter.
    e. Duplication of the ureter of one kidney.
2. Urolithiasis (renal calculi) is rare in children but may be associated with metabolic disease, such as cystinosis or oxalosis.

Clinical Manifestations

1. Hydronephrosis may present as an abdominal mass.
2. Commonly asymptomatic (seldom any problem with voiding).
3. Vague signs, such as failure to thrive, may be present.
4. UTIs may be frequent.
5. Hypertension may occur.

Diagnostic Evaluation

1. Laboratory tests to determine renal function.
2. Renal ultrasound, radionuclide imaging, and ureteroscopy to determine the extent of the lesion.

Management

1. Prevention or eradication of infection.
2. Surgical correction of the obstruction.

Complications

Renal failure.

For nursing assessment, diagnoses, and interventions, see “Care of the Child Who Undergoes Urologic Surgery,” page 1324.

Hypospadias

EVIDENCE BASE Baskin, L. S. (2019). Hypospadias. In L. Baskin & B. Kogan (eds.), *Handbook of pediatric urology* (Chapter 2). Philadelphia, PA: Lippincott Williams & Wilkins.

Pfeil, M., Parr, J., & Milind, M., (2012). Hypospadias repair: the nursing contribution. *International Journal of Urological Nursing, 6*(3), 152–158.

Hypospadias is a congenital defect of the penis, resulting in the incomplete development of the anterior urethra, corpora cavernosa, and prepuce (foreskin). Hypospadias is also associated with penile ventral curvature (chordee) which depending on the severity of the defect may result in infertility secondary to difficulty in semen delivery. Hypospadias is a common birth defect, occurring in one out of every 150 to 300 boys. The goal of treatment is to achieve cosmetic and functional repair. See Figure 49-2 on page 1320.

Pathophysiology and Etiology

1. At 1 month gestation, the male and female genitalia are indistinguishable. However, under the influence of testosterone, the male genitalia become masculinized. By the end of the first trimester, the penile urethra and foreskin are completely formed. Abnormalities in this development, such as subsequent, decreased testosterone production, can lead to hypospadias.
2. Classification is determined by the location of the urethral meatus.
3. Majority of cases have no known etiology but may show genetic inheritability—14% incidence in siblings; 8% incidence in offspring.
4. Undescended testicle, hydrocele, or inguinal hernia may be associated.

Clinical Manifestations

1. Inability to void with penis in normal elevated position.
2. Spraying of urine when voiding.
3. 70% urethral meatus located distal on penile shaft
4. 30% proximal location and often more complex
5. In case of concomitant unilateral or bilateral undescended testis, endocrine evaluation advised to exclude disorders of sexual differentiation

Diagnostic Evaluation

1. Usually not difficult to diagnose because of visual anomaly. Assess glans penis for possible hypospadias before circumcision.
2. Severe cases require genotypic/phenotypic sex determination, chromosomal, and hormonal studies.

Management

Surgical reconstruction between ages 6 and 18 months, if possible (to minimize psychological issues surrounding toileting and genital awareness), and before circumcision because foreskin is essential for most complex repairs. Phalloplasty is also considered as a surgical option for removal of dorsal hooded foreskin in mild hypospadias.

Postop temporary stent in situ for complex hypospadias repair that is typically removed/falls out in 7 to 10 days to allow newly created urethra and opening to heal.

Dressings are typically removed within the first few days at home and bathing is encouraged to keep incision site clean and prevent bacteria from developing.

Complications

1. Urethrocutaneous fistula,
2. Meatal stenosis.
3. Urethral diverticulum.
4. Residual penile curvature
5. Wound dehiscence or infection.
6. Urinary tract symptoms
7. Esthetic result

Family Education and Health Maintenance

Follow-up post reconstruction typically is few months after reconstruction, 1 year after the repair, after toilet training, and after puberty to ensure satisfaction and understanding of congenital anomaly. Complications are seen as needed.

For nursing assessment, diagnoses, and interventions, see “Care of the Child Who Undergoes Urologic Surgery.”

Cryptorchidism

EVIDENCE BASE Kolon, T., Herndon, A., Baker, L., et al. (2014). Evaluation and Treatment of Cryptorchidism: AUA guideline. *Journal of Urology, 192*, 337–345.

American Urological Association. (Published 2010, Reviewed and Validity Confirmed 2017). Management and Screening of Primary Vesicoureteral Reflux in Children.

Cryptorchidism refers to the failure of one or both testes to descend through the inguinal canal to the normal position in the scrotum. A testis is considered undescended if on examination, the testicle is palpable elsewhere and cannot be brought down into the scrotum. It is more common in premature infants and is the most common surgical problem in pediatric urology.

Pathophysiology and Etiology

1. Possibly caused by delayed descent, prevention of descent by mechanical lesion, or endocrine disorder (rare).
2. Testicular and ductal development are abnormal. It is unclear whether this is because of congenital dysplasia or because of underdevelopment.
3. Degeneration of the sperm-forming cells occurs after puberty because of the higher temperatures of the abdomen, compared with normal location in the scrotum.

Clinical Manifestations

Testicle nonpalpable within the scrotum.

Spontaneous descent of the testes may occur in the first corrected 6 months of life

Diagnostic Evaluation

1. Imaging for cryptorchidism is not recommended prior to referral. Ultrasonography may reveal undescended testicle but is not as reliable as physical examination.
2. Serum testosterone measurements may be decreased.

Management

Complications for cryptorchidism can include testicular malignancy later in life, potential impairment in fertility, testicular torsion, trauma to testicle, and associate hernias.

1. Specialist referral should ensure surgical evaluation by 6 months of age because of low probability of descent and probable damage should the testes remain in a nonscrotal location.
2. Bilateral nonpalpable testicles require immediate urology consultation to evaluate for possible disorder of sex development (DSD)

3. Surgical laparoscopic exploration must be performed after exam under anesthesia confirms that testicles are not palpable on all nonpalpable unilateral and bilateral cryptorchid patients. Open approach is used for palpable testicles.
4. Orchiopexy surgery to achieve permanent fixation of the testis in the scrotum. Surgery should be perform between ages 6 and 15 months to prevent damage to the tissues and to lessen emotional concerns related to body image.
5. Surgical placement of testicular prosthesis, if testicle(s) absent.
6. Lack of evidence in long-term success of testicular descent in administration of human chorionic gonadotropin and has noted low response rates

Family Education and Health

1. Primary care provider should palpate testes with every well-child visit for quality and position.
2. Retractile testes are at increased risk for secondary testicular ascent due to hyperactive cremasteric reflex, short patent processus vaginalis, or entrapping adhesions.
3. Previously cryptorchid boy should be assessed with each well-child visit for quality and position postoperatively and eventually taught how to perform monthly testicular self-examination after puberty to facilitate early cancer detection.
4. Former bilateral cryptorchid men have a greatly reduced fertility compared to men with history of unilateral cryptorchidism and general male population.

For nursing assessment, diagnoses, and interventions, see "Care of the Child Who Undergoes Urologic Surgery."

Care of the Child Who Undergoes Urologic Surgery

Also see Chapter 21, pages 596 and 597, for a discussion of kidney surgery and urinary diversion.

Nursing Assessment

1. Obtain history from prenatal and birth record, family, and child.
2. Assess feeding and crying patterns, indicating potential obstruction or abdominal pain.
3. Assess urinary elimination pattern to determine degree of disorder.
4. Assess for associated congenital defects.
5. Assess for failure to thrive.
6. Determine family's response to body image changes. Expect anxieties regarding sterility and gender identity and perceptions of the child as defective or inadequate.
7. Measure and record vital signs, height, weight, abdominal girth, and compare with previous measurements, if available. Renal insufficiency may alter growth. Fever may be indicative of infection.
8. Visually and manually inspect genitalia and record abnormalities (eg, if bladder mucosa is visible, describe signs of irritation).
9. Palpate abdomen; note masses.
10. Obtain urine for culture and sensitivity. Note color, amount, odor, and degree of cloudiness.
11. Review results of all laboratory and diagnostic procedures.

Nursing Diagnoses

- Deficient Knowledge related to surgery.
- Impaired Urinary Elimination related to surgical intervention.
- Disturbed Body Image related to appearance of genitalia.
- Risk for Infection related to surgical incision and drainage tubes.
- Risk for Deficient Fluid Volume related to surgical losses.
- Acute Pain related to surgical incision and drainage tubes.

Nursing Interventions

Promoting Understanding of Surgical Treatment

1. Determine the child's expectation regarding illness and hospitalization through discussion and play therapy.
2. Explain the anatomy and physiology of the urinary system in terms the child can understand.
   a. Use a body outline appropriate for the age of the child.
   b. Explain how the child differs from the normal. Relate defect to symptoms whenever possible.
3. Explain all diagnostic tests before their occurrence. These may include urinalysis, 24-hour urine collections, IV, retrograde pyelography, ultrasound, and/or VCUG. Descriptions should include such information as:

a. Preparation required—fasting, enemas, catheterization.
b. Location of the test—operating room, radiology department.
c. Appearance and attire of personnel.
d. Positioning.
e. Anesthesia.
f. Pain or discomfort.
g. Expectations after the procedure—diet, rest, urine collections.

4. Determine the child's understanding of the procedure.
   a. Ask simple, direct questions.
   b. Allow the child to perform the procedure on a doll or to demonstrate it on a diagram.
5. Explain the surgical procedure, including the following:
   a. Preparation required—fasting, enemas.
   b. Description of the operating room, including the appearance of the personnel.
   c. Anesthesia.
   d. Postoperative appearance—urinary drainage tubing and collection devices, appearance of urine, sutures, bandages, IV infusion.
6. Reassess the child's understanding of the surgery and reinforce teaching when necessary.
7. Emphasize additional points:
   a. The child is in no way to blame for illness.
   b. No other part of the body will be operated on.

Promoting Normal Urine Output

1. Monitor daily intake and output.
2. Encourage adequate fluids and monitor daily weight.
3. Care for all catheters and urinary tubes according to facility policy. Maintain appropriate position of tubes.
4. Observe and record amount and appearance of urinary drainage, occurrence of bladder spasms, and symptoms of urinary or incisional infection.

Providing Emotional Support Regarding Body Image

1. Continue reassurance about appearance of genitalia.
2. Maintain discussions regarding reactions. This may need to be done with patient and family alone as well as the family unit.
3. If additional surgical intervention is required, discuss plans for interim period from initial surgery until secondary or reconstructive procedures can be performed.
4. Initiate independence of care.
5. Focus on activities the child can perform and accomplish.

Preventing Infection

1. Administer antibiotics and IV fluids, as ordered.
2. Maintain patency of catheters. Provide catheter care, as directed.
3. Administer wound care using aseptic technique. Inspect incision for drainage or signs of infection.

Maintaining Fluid Volume

1. Administer fluids, as ordered.
2. Monitor vital signs for hypotension or tachycardia.
3. Assess patient's skin turgor and mucous membranes for signs of dehydration.
4. Measure and record accurate intake and output.

Promoting Comfort

1. Administer analgesics, as ordered and according to assessment of complaints of pain, restlessness, crying, or withdrawal.
2. Administer antispasmodics, as ordered, for bladder spasm.
3. Provide distraction and comfort measures.

Family Education and Health Maintenance

1. Advise the family about follow-up appointments, additional surgeries, or procedures.
2. Teach care of incision, signs of infection.
3. Advise on avoidance of straddle toys for 6 weeks to promote healing.
4. Encourage good nutrition to promote healing and to prevent infection.
5. Provide contact names and phone numbers for families to call to update on status with complications, urgent concerns, and where to go in the case of an emergency.

Evaluation: Expected Outcomes

- Child and family verbalize understanding of surgery.
- Clear urine draining via catheter.
- Child and family verbalize relief that defects can be surgically repaired and reconstructed.
- Incision without drainage or signs of infection.
- Vital signs stable; urine output adequate.
- Decreased crying and increased restful periods and sleep noted.

RENAL FAILURE AND DIALYSIS

Acute Renal Failure

Acute renal failure is a sudden, usually reversible deterioration in normal renal function. This results in fluid and electrolyte imbalance and accumulation of metabolic toxins. Nursing care of children with acute renal failure is generally the same as that of adults (see pages 602 to 604), although there are special considerations for pediatric patients.

Pathophysiology and Etiology

1. Causes are divided into *prerenal* (problem occurs in blood supply to the kidneys), *intrarenal* (problem is within the kidney or kidneys), and *postrenal* (problem occurs in urinary system after the kidneys).
   a. Prerenal causes: conditions causing hypovolemia (dehydration, shock, trauma, or burns) cause decreased blood flow to the kidneys. The nephrons, however, are structurally and functionally intact.
   b. Intrarenal causes: conditions causing a reduction in glomerular filtration rate (GFR), renal ischemia, and tubular damage. May be due to vascular diseases (hemolytic uremic syndrome, thrombosis), tubular nephropathies (myoglobinuria, hemoglobinuria, toxins), or interstitial nephritis (penicillins, allergies). These are the largest group to require extended medical management.
   c. Postrenal causes: conditions causing obstruction to urine flow. Uncommon, except for obstructive uropathies in the first year of life. Renal function is restored with relief of the obstruction.
2. The exact pathophysiology of acute renal failure is not always known. Three phases of acute renal failure are recognized in children:
   a. Initiating phase: begins when kidney is injured and lasts from hours to days. Signs and symptoms of renal impairment are present.
   b. Oliguric phase: usually lasts 5 to 15 days but can persist for weeks; shorter in infants and young children (3 to 5 days) and longer in older children and adolescents (10 to 14 days). Not all patients have an oliguric phase.
   c. Diuretic phase: highly variable, from mild and lasting only a few days to profound.
3. Trauma, burns, and nephrotoxic agents may cause acute tubular necrosis and temporary cessation of renal function. Myoglobin (a protein released from muscle when injury occurs) and hemoglobin are released, causing renal toxicity, ischemia, or both.
4. Severe transfusion reactions may result in hemoglobin that filters through the kidney glomeruli. This becomes concentrated in the kidney tubules. Resulting precipitation interferes with the excretion of urine.
5. Nonsteroidal anti-inflammatory drugs (NSAIDs) interfere with prostaglandins that normally protect renal blood flow, decreasing GFR.

DRUG ALERT Nephrotoxic agents include aminoglycosides, penicillins, cephalosporins, sulfonamides, calcineurin inhibitor immunosuppressives, NSAIDs and certain antineoplastic drugs. Large

doses of vitamin A, chemicals that contain arsenic, and mercury are also nephrotoxic.

Clinical Manifestations

1. Nausea and vomiting.
2. Diarrhea.
3. Decreased tissue turgor.
4. Dry mucous membranes.
5. Lethargy.
6. Difficulty in voiding; changes in urine flow; decreased urine output.
7. Steady rise in serum creatinine.
8. Fever.
9. Edema—periorbital, pitting lower leg edema, ascites.
10. Changes in mental status or mood.
11. Headaches and blurry vision due to hypertension.
12. Seizures.

Diagnostic Evaluation

1. Serum creatinine level—the most reliable measure of the GFR, found to be rising.
2. Radionuclide studies—evaluate GFR and renal blood flow and distribution.
3. Urinalysis—reveals proteinuria, hematuria, casts.
4. Ultrasonography—determines anatomic abnormalities.

Management

1. Seventy-five percent of children with acute renal failure attain complete recovery.
2. Treatment is directed toward the underlying cause.
3. Correction of any reversible cause of acute renal failure (ie, surgical relief of obstruction).
4. Correction and control of fluid and electrolyte imbalances.
5. Restoration and maintenance of stable vital signs.
6. Maintenance of nutrition with low-sodium, low-potassium, low-phosphate, and low-protein diet.
7. Initiation of dialysis (hemodialysis, peritoneal dialysis, or continuous venovenous hemofiltration) for patients with life-threatening complications.

Complications

1. Fluid and electrolyte imbalance, especially hyperkalemia—when GFR is reduced, patient cannot excrete potassium.
2. Metabolic acidosis, caused by decreased acid excretion and reduced bicarbonate reabsorption (see Box 49-1).

3. Insufficient nutritional intake because of metabolic abnormalities and symptoms, such as nausea and vomiting.

BOX 49-1 Clinical Manifestations of Metabolic Acidosis

GI

- Anorexia.
- Nausea and vomiting.
- Abdominal pain.

NEUROLOGIC

- Lethargy.
- Stupor.
- Coma.

CARDIOVASCULAR

- Decreased heart rate.
- Cardiac dysrhythmias.
- Peripheral vasodilation.

OTHER MANIFESTATIONS

- Warm and flushed skin.
- Weakness and malaise.
- Bone resorption (with chronic acidosis).
- Increased rate and depth of respirations (Kussmaul breathing due to compensation).

LABORATORY FINDINGS

- Decreased pH.
- Decreased HCO_3^- (initially).
- Decreased PCO_2 (compensatory).
- Hyperkalemia.
- Acidic urine (compensatory).

Nursing Assessment

1. Obtain history of all medications, recent and past illnesses or injuries, allergies, and potential exposure to toxic substances.
2. Measure intake and output. Insert indwelling urinary catheter, as indicated.
3. Monitor vital signs, especially BP. Institute cardiac monitoring, as indicated.

4. Assess for edema and fluid overload (cardiac and respiratory assessment).
5. Monitor urine-specific gravity, as directed. Fixed specific gravity of 1.010 indicates the kidneys' inability to concentrate or dilute urine.

Nursing Diagnoses

- Risk for Imbalanced Fluid Volume related to inability of the kidneys to maintain fluid balance.
- Risk for electrolyte imbalance: hyperkalemia.

Nursing Interventions

Maintaining Fluid Volume

1. Administer IV fluids slowly to prevent heart failure.
2. Maintain fluid restriction, as ordered.
3. Keep strict intake and output records.
4. Weigh child daily.
5. Promptly report signs of heart failure—edema, bounding pulse, third heart sound, shortness of breath, and adventitious breath sounds.

Preventing Severe Electrolyte Disturbance

1. Monitor blood test results (creatinine, BUN, electrolytes, calcium) and notify health care provider promptly of abnormal levels.
2. Watch for signs of hyperkalemia—weak, irregular pulse, abdominal cramps, and muscle weakness.
3. Do not administer IV fluids with potassium while renal function is impaired.
4. Maintain low-protein, low-potassium, low-sodium, and high-carbohydrate diet.
5. Administer treatments for hyperkalemia, as ordered, such as IV sodium bicarbonate and IV glucose and insulin (requires careful glucose monitoring), both of which drive potassium into cells and temporarily out of the bloodstream.
6. Administer cation exchange medications to reduce potassium, as ordered.
7. Watch for signs of hypocalcemia—muscle twitching and tetany.

Family Education and Health Maintenance

1. Explain all steps of the diagnostic and treatment process to the family.
2. Teach about dialysis if this becomes necessary.
3. Explain that as kidney function resumes, diuresis may occur to eliminate excess fluid the body was storing.
4. Educate about prompt medical attention for illnesses that may cause dehydration to prevent renal injury in the future.
5. Avoid nephrotoxins, including NSAIDs during recovery period

Evaluation: Expected Outcomes

- No signs of heart failure.
- Potassium remains within upper range of normal; kidney function returns to baseline.

Chronic Renal Failure

Chronic renal failure (CRF) is irreversible destruction of nephrons so that they are no longer capable of maintaining normal fluid and electrolyte balance. *Chronic kidney disease (CKD)* refers to kidney damage with a decreased GFR of less than 60 mL/min/1.73 m^2 for 3 months or greater. Nursing care of children with CRF is similar to that of adults (see page 606). The following considerations are important for pediatric patients.

Pathophysiology and Etiology

1. Congenital renal and urinary tract abnormalities are the most common causes in children younger than age 5 (eg, polycystic kidney disease, congenital nephrotic syndrome, hyperoxaluria).
2. Most common causes in ages 5 to 15 years:
   a. Glomerular disease (eg, glomerulonephritis).
   b. Urologic abnormalities.
   c. Cystic kidney disease.
3. Similar progression regardless of cause.
   a. Nephron damage that results in hypertrophy and hyperplasia of remaining nephrons.
   b. Overload results in decreased ability for nephrons to excrete effectively.
   c. Results in azotemia and clinical uremia.
   d. Inability of kidney to excrete phosphate causes hypocalcemia, which results in osteodystrophy.
   e. Kidneys cannot synthesize vitamin D, thus impairing calcium absorption. Bones may become so calcium depleted that growth halts and bones become brittle (renal rickets).
   f. Kidneys cannot synthesize erythropoietin, thus resulting in anemia.
   g. Excretion of nitrogenous waste through sweat causes pruritus.
   h. Overload of fluid results in edema and hypertension.
4. Severity of CRF is indicated by GFR. The lower the GFR, the greater the loss of renal function.

Clinical Manifestations

Variable and not chronological.

1. Nausea and vomiting, decreased appetite, and energy level.
2. Initial polyuria caused by kidneys' inability to concentrate urine; later oliguria and anuria.
3. Bone or joint pain.
4. Dryness and itching of skin.
5. Poor growth.
6. Fatigue, lethargy due to anemia.

Diagnostic Evaluation

1. Serum studies:

a. Anemia and iron studies: decreased hemoglobin, hematocrit, iron levels
b. Decreased Na+, Ca++, and CO_2 (metabolic acidosis); increased K+ and phosphorus.
c. As renal function declines, BUN, uric acid, and creatinine values continue to climb.
d. Elevated PTH.

2. Urine studies:
   a. Specific gravity—increased or decreased.
   b. Twenty-four-hour urine for creatinine clearance is decreased (increased creatinine in urine), thus reflecting decreased GFR.
   c. Changes in total output (may initially be polyuric because of difficulty concentrating urine, then oliguric).
   d. Proteinuria.
3. Many other tests may be ordered to evaluate other systems and extent of disease (eg, chest x-ray, echocardiogram, bone age).

Management

1. Correction of calcium-phosphorus imbalance. Initiate low-phosphorus diet. Administer activated vitamin D to increase calcium absorption and phosphate binders with meals to bind phosphate in the GI tract.
2. Correction of acidosis with buffers, such as sodium bicarbonate tablets.
3. Correction of hyperkalemia through low-potassium diet or administration of potassium-lowering agents such as sodium polystyrene.
4. Diets should meet caloric needs of the child and contain adequate protein for development (0.9 to 1.5 g/kg/day).
5. Correction of anemia through the use of oral iron and erythropoietin administered subcutaneously at home.
6. BP should be managed with appropriate antihypertensive medications (angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, or diuretics).
7. Growth retardation should be evaluated for possible use of growth hormone. Consult dietitian to ensure optimal nutrition for use of growth hormone.
8. Renal replacement options for end-stage renal disease include hemodialysis, peritoneal dialysis, transplantation, or no treatment, typically initiated when GFR < 15 mL/min/1.73 m^2.
9. Dialysis, while renal transplant workup is in progress.

Complications

1. Growth retardation.
2. Delayed or absent sexual maturation.
3. Severe anemia—kidneys cannot stimulate erythropoietin; uremic toxins deplete erythrocytes; nutritional

deficiencies.

4. Hypertension—renal ischemia stimulates renin–angiotensin system.
5. Cardiovascular disease (left ventricular hypertrophy, heart failure).
6. Renal osteodystrophy due to vitamin D deficiency and secondary hyperparathyroidism.
7. Azotemia/uremia—nitrogen waste products accumulate in blood. Toxic levels manifest themselves in many ways, such as coma, headache, GI disturbances, and neuromuscular disturbances.
8. Neurodevelopmental delay due to uremic effects.
9. Metabolic acidosis, which may cause poor growth, confusion, dull headache, and lethargy.
10. Electrolyte imbalance—hypocalcemia, hyperkalemia.

Nursing Assessment

1. Perform a comprehensive, multisystem assessment to help in planning care.
2. Assess nutrition, growth, and developmental status.
3. Assess coping, support systems, and other resources.

Nursing Diagnoses

Children with CRF are in multisystem physiologic crises. The nursing diagnoses throughout the chapter are applicable, but focus may be:

- Risk for Electrolyte Imbalance: hypocalcemia, hyperkalemia.
- Risk for Imbalanced Fluid Volume related to renal failure and dialysis.
- Imbalanced Nutrition: Less Than Body Requirements related to GI disturbances, diet restrictions, and protein loss.
- Activity Intolerance related to fatigue and anemia.
- Ineffective Coping related to changes in lifestyle and body image on dialysis.

Nursing Interventions

Ensuring Safety

1. Protect the child from the effects of decreased level of consciousness and involuntary movements by maintaining crib or bed side rails up and padded, as necessary.
2. Monitor for seizure activity and have airway or tongue blade and suction equipment on hand.
3. Monitor BUN, creatinine, electrolyte, and calcium levels and report abnormalities promptly.

Promoting Fluid Balance

See “Acute renal failure,” page 1325.

Ensuring Adequate Nutrition

1. Ensure adequate protein in diet. Obtain consultation from a registered dietitian.
2. Encourage appropriate fluid intake between meals.

3. Consult with dietitian regarding appropriate milk intake and alternatives because of high phosphate, sodium, and potassium content. Instead, administer feedings high in calories and low in wastes, as directed.

Increasing Activity Tolerance

1. Plan activities when child is rested.
2. Encourage activity as tolerated
3. Administer blood transfusions or IV iron therapy, as ordered (if patient is resistant to erythropoietin therapy and unable to tolerate oral iron supplementation).

Enhancing Coping

Because numerous issues may interfere with the child's psychological and social development and education, help the child and family to cope with:

1. Uncertainty regarding the course of the disease and ultimate prognosis.
2. Abnormal lifestyle necessitated by dialysis (including interference with school).
3. Burden of dialysis and continuous administration of medications.
4. Problems of adjustment related to growth failure.
5. Fear of death, present in most children, adolescents, and family members.
6. Possible kidney transplantation, involving major surgery and prolonged hospitalization, followed by altered body image that is caused by high-dose steroids and potential for rejection, which may threaten survival.

Family Education and Health Maintenance

1. Teach child to avoid high-sodium foods, such as chips, pretzels, and popcorn; luncheon meats; canned foods; and fast foods, if sodium is restricted.
2. Encourage follow-up as advised by kidney specialist and primary health care provider.
3. Encourage family to keep up with regular dental care, immunizations, and health assessments to help prevent infections, problems with growth, and more severe childhood diseases.
4. Teach about medications and support child who may be taking multiple medications—calcium, phosphate binder, acid neutralizer, recombinant erythropoietin, antihypertensives, and others.
5. Teach about maintaining good hygiene and peritoneal dialysis catheter care.
6. Advise the family about support services and media resources available—for example, *Children & Teens with Kidney Disease,* by the National Kidney Foundation (*www.kidney.org*).

Evaluation: Expected Outcomes

- Side rails up with airway and suction at bedside.
- Fluid restriction maintained, weight stable, no signs of heart failure.
- Taking 100% of renal diet.

- Engaging in play without shortness of breath.
- Parents asking questions and discussing treatment with child.

The Child Who Undergoes Dialysis

Dialysis is the passage of a solute through a semipermeable membrane. The purpose of dialysis is to preserve life by replacing some of the normal kidney functions. See pages 593 to 594 for a complete description of different types of dialysis.

General Considerations

The following principles should be considered by the nurse who works with pediatric patients:

1. Peritoneal dialysis:
   a. This mode of dialysis continues to be the favored mode in young children.
   b. Because of the child's small size, the volume of dialysate is 1,100 to 1,400 mL/m^2.
   c. The child can be expected to participate at a developmentally appropriate level with his or her own care.
   d. Peritoneal dialysis is a continual treatment and therefore can constantly dialyze metabolic waste and fluids off.
2. Hemodialysis:
   a. When possible, subcutaneous or IM injections are avoided because the child is anticoagulated with heparin.
   b. BP cuff and tourniquets should not be applied to a limb with a fistula and peripheral IVs should not be placed in a limb with a graft or fistula.
3. Specific care for the child during dialysis is generally provided by specially trained personnel in a dialysis unit. However, the following considerations should be noted:
   a. Choice for vascular access depends on patient size and availability of peripheral blood vessels of suitable size (see Figure 49-3). A central venous catheter may also be used.
   b. Extracorporeal blood volume (blood outside of the body at any given time) should be as small as possible. It should not exceed 8% to 10% of the child's total blood volume.
   c. Efficiency or adequacy of the dialyzer, relative to the child's weight, should be noted and blood pump speed adjusted accordingly.
   d. External catheter should be secured to make sure catheter is not traumatized.

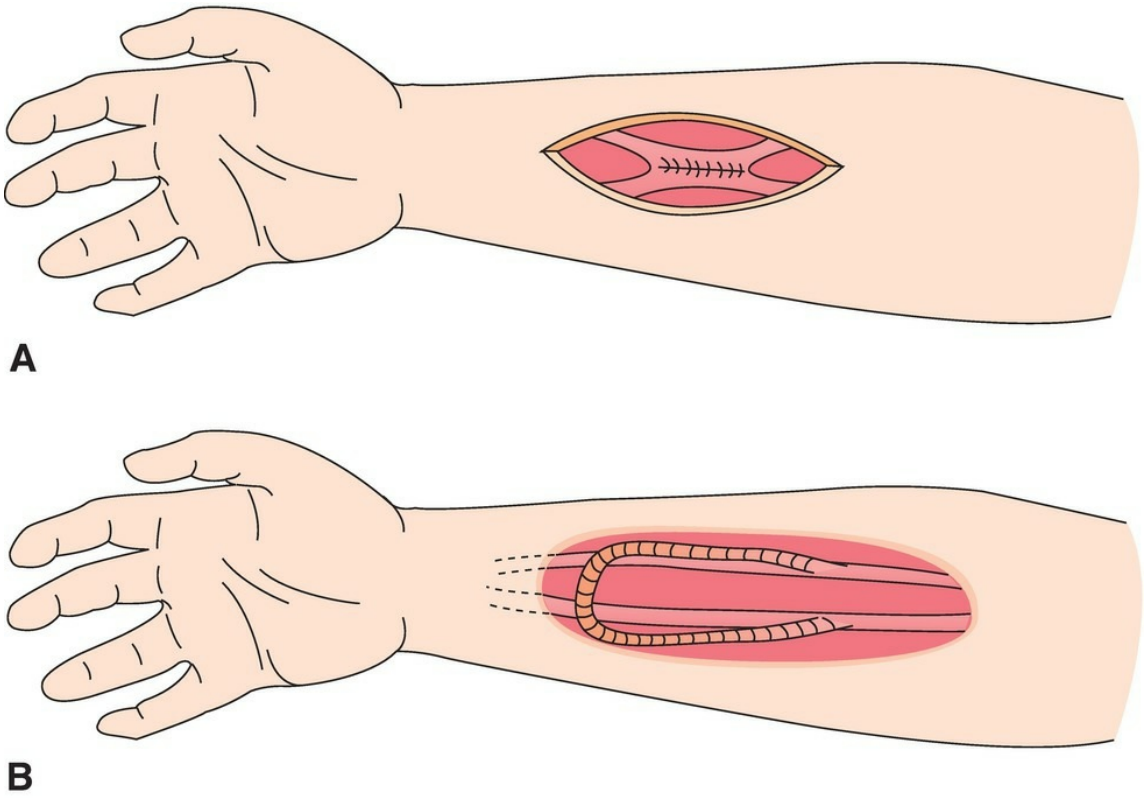

Figure 49-3. Vascular access devices for hemodialysis. **(A)** An internal arteriovenous fistula. **(B)** An internal arteriovenous graft. (Pillitteri, A. [2013]. *Maternal and child healthnursing: Care of the childbearing and childrearing family* [7th ed.]. Philadelphia: Lippincott Williams & Wilkins.)

Nursing Care of the Child Who Undergoes Dialysis

1. Prepare the child for the procedure. Dialysis is threatening to most children and may evoke fears of pain, mutilation, immobilization, helplessness, and dependency. Many children have fears of losing all of their blood during hemodialysis. A child who is well prepared will be less frightened and better able to cooperate during the procedure.
   a. Explain the procedure in terms that the child can understand.
   b. Allow the child to handle equipment similar to that which will be used during dialysis.
   c. Encourage the child to express fears so that misinterpretations can be corrected.
   d. Provide simple pictures and diagrams, if appropriate.
   e. Allow the child to talk with peers who have undergone dialysis.
2. Explain the procedure to family members and answer questions so that they will be in the best position to support the child.
3. Protect the child from infection.
   a. Keep the dressings and area around the catheter (if used) clean and dry.
   b. Use aseptic technique throughout the dialysis procedure.
   c. Provide supplemental vitamins because diet may be low in vitamins.
   d. Provide meticulous daily hygiene.

4. Maintain appropriate nutritional and fluid modifications. Because anorexia is commonly seen in CRF, provide small frequent meals.
5. Restrict fluids and sodium to prevent fluid overload in children who are hypertensive or who have minimal urine output. Potassium is limited (more so in hemodialysis patients) to prevent complications related to hyperkalemia. The child may see dietary restrictions as a punishment and must be helped to realize the purpose of restrictions.
6. Do not restrict protein, which is vital to allow for normal growth and development.
7. Maintain careful records of intake and output, vital signs, BP, and daily weight. These provide valuable information about the effectiveness of the therapy.
8. Support the child during the dialysis procedure.
    a. Provide symptomatic relief of nausea, vomiting, malaise, muscle cramping, or headache. Notify the health care provider if these symptoms are severe.
    b. Involve the child in diversional activities, such as play therapy, crafts, television, and books.
    c. Encourage the family to bring in articles that will make the child's room appear more homelike (eg, pictures, posters).
    d. Encourage the child to be as independent as possible in daily care.
9. Help the child to keep up with schoolwork by initiating a referral to a tutor and providing study times.

Community and Home Care Considerations

1. Be aware that although life is preserved, it is by no means normal during the time on dialysis or between dialysis treatments. These measures may increase the child's feeling of self-esteem and diminish regression and social isolation. By serving as role models, health professionals may encourage parents to recognize and foster the normal, healthy aspects of the child's daily life.
2. Offer appropriate support to the family.
    a. Provide opportunity for family members to discuss their feelings, fears, and frustrations and to ask questions.
    b. Allow family members to become involved in the child's care.
    c. Provide for continuity of personnel.
    d. Initiate appropriate referrals and provide resources. These may include referrals to a social worker, psychiatrist, dietitian, community health agency, or other families who are coping with dialysis.
3. Be aware that families usually need extensive support from many health professionals to cope with the physical, psychological, financial, and logistical aspects of renal failure and dialysis. Attention must be focused on siblings and parents because sibling relationships are usually strained and difficult.
4. Teach the child and family about all of the important aspects of renal failure and dialysis, including the following:
    a. Protection from infection.
    b. Dietary restrictions and recommendations; ways of incorporating the special diet into the family meal plan.

c. Dialysis schedule.
d. Medications.
e. Emergency procedures.
f. Reintegration into the community and school.

5. Empower the family to care for the child at home. Learning about the child's care also helps restore some sense of control in a frightening situation.

Renal Transplantation

Renal (kidney) transplantation is the optimal therapeutic modality for end-stage renal disease in the pediatric age group. With successful transplantation, there is a greater likelihood of optimum rehabilitation than with any other form of dialytic therapy. The potential for normal growth and pubertal development is significantly increased after transplantation. However, it should be noted that post transplant growth is affected by many variables: age of onset of chronic renal disease, caloric intake, corticosteroid dosage, bone age at transplantation, transplant function, and rejection episodes. Requirements of preoperative management and nursing care of children or teens for renal transplantation are similar to that of adults (see page 596). However, they are also more exhaustive because the recipient as well as the parents must be included. The emotional, psychological, and financial needs of the recipient and the family must be evaluated. An appropriate care plan must then be designed to address identified needs; this care plan must be appropriate for the developmental age of the recipient.

Evaluation of Recipient

The major issues that must be evaluated when considering renal transplantation in children are:

1. Patient age and size.
2. Primary renal disease.
3. Psychological status.
4. Live versus deceased donor allograft.
5. Optimal immunosuppressive regimen.
6. Maximization of growth and pubertal development.

Donor Selection (by Priority)

A tissue-compatible transplantation from a relative is 90% successful.

1. Identical twin sibling.
2. Siblings cannot be used as donors until they are of legal age to give consent for removal of a kidney.
3. Parent.
4. Other relative.
5. Unrelated live donor such as a family friend.
6. Deceased donor.

Operative Procedure

A child who weighs more than 22 pounds (10 kg) usually receives the kidney of an adult. In a very small child, the kidney transplant is placed within the abdomen, with vessel anastomosis to the aorta and superior vena cava.

Potential Emotional Concerns of Children with Transplants

1. The concept of a foreign body, especially a cadaver kidney, inside one's own body may be disturbing.

2. Fear that the kidney may wear out sooner if it is from an older person.
3. Altered body image because of growth failure and the effects of steroid therapy.
4. Guilt feelings if a live donor transplant fails, especially that of a family donor.

Nursing Interventions

Also see "After kidney transplantation," page 597.

1. Support the child and family through the preoperative phase, including diagnostic testing and blood transfusions.
2. After surgery, maintain strict infection precautions.
3. Administer immunosuppressants and other medications, as directed.
4. Continue support through dialysis, if necessary.
5. Monitor urine output, bloodwork results, and urine-specific gravity.
6. Watch for signs of rejection—fever, oliguria, proteinuria, weight gain, hypertension, and tenderness over transplanted kidney. Acute rejection usually occurs in the first 3 months after transplant. Chronic rejection may develop at any time. It occurs slowly over months to years and leads to progressive loss of renal function.
7. Watch for signs of infection: fever, leukopenia, neutropenia.
8. Infection can be bacterial (most common are pneumonia and UTIs) or viral (cytomegalovirus and Epstein-Barr virus are the most common infections).

Community and Home Care Considerations

The practice of discharging patients from an in-hospital setting as quickly as possible is also true for the pediatric transplant recipient. Community and home care nurses must have:

1. The knowledge to care for a child who receives IV and immunosuppressive medications.
2. The ability to access and heparinize central venous lines and peripheral IV catheters.
3. The ability to aid in reinforcing discharge teaching, aid in BP monitoring, and assess medication adherence.

Family Education and Health Maintenance

1. Teach families about the signs of rejection and infection.
2. Encourage close follow-up for proper dosing of immunosuppressants.
3. Education, communication, and employ strategies to promote medication adherence.
4. Advise family that close medical surveillance will always be necessary because the incidence of malignant disease is six times more likely in transplant recipients than in the general population.
5. Teach parents not to overprotect the child. When the child has healed from surgery, regular activity can be resumed. This includes returning to school; however, the school needs to be aware of the patient's immunosuppressive status.
6. Teach families and patients the importance of good hand washing.

7. Encourage patient to wear a MedicAlert bracelet or necklace, and inform the community emergency services of transplant status.
8. Advise parents that no live vaccine should be given to the child who is immunosuppressed.
9. Advise the family about resources available.

TRANSITIONAL CARE ALERT After the stress of having a hospitalized child, families will need support in the transition to home or another aftercare location. It is crucial that they have complete and understandable care instructions on home care, medications, and follow-up appointments. If arrangements have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to assist understanding, pictorial) instructions on signs and symptoms to monitor for that could suggest worsening of status. Children with renal and genitourinary disorders require careful monitoring of intake and output to prevent electrolyte unbalance. Family caregivers will need additional instructions on signs and symptoms that would indicate hydration alterations.

Type 1 Diabetes Mellitus

OVERVIEW AND ASSESSMENT

Common Nursing Assessment for Growth and Development

Endocrine dysfunction in children frequently leads to altered growth and development. Accurate nursing assessment can help detect variations in growth and developmental patterns, identify such factors as diet and medications that may have an impact on growth and development, and obtain information about compliance and understanding of treatment.

Evaluation of Growth Patterns

1. Perform frequent and accurate measurements of height and weight.
2. Accurately plot measurements on growth curve for absolute chronologic age.
3. Assess growth pattern for any deviation from the child's percentile or from the parallel of the growth curve for age (includes both an upward as well as a downward deviation).
4. Calculate growth velocity—take the difference of current height from previous height and divide by the time period. Growth rate for a prepubertal child should be 2 to 3 inches (5 to 7 cm) on an annual basis.
5. Report any child whose pattern deviates from the expected pattern for age to health care provider.

General Health History

1. Dietary history—what is the child's meal frequency, volume, and food preferences? Be vigilant while obtaining the history of a child when anorexia may be possible—growth velocity will usually be low, in addition to poor weight gain.
2. History of major illnesses or surgeries that have altered the child's growth and development.
3. Family history—is there a family history of growth or developmental issues? Is there a family history of delayed puberty? Are family members unusually short or tall in stature, or is there obvious dysmorphology?
4. Clothing—outgrowing clothing and shoes?
5. Social history relative to friendships.
6. Academic and school performance—recent changes?
7. Activity—activities the child participates in? Intensity and type of exercise?

Medication History and Compliance

1. Is the child on any steroid medications (such as prednisone) that would suppress growth? Inquire about over-the-counter medications or herbal supplementation.
2. When pubertal signs are present on physical examination, does the child have access to any gonadal steroids (ie, birth control pills, anabolic steroids)?
3. Do the child and family understand treatment medication indication and usage instructions?
4. Are the child and family compliant with medications according to dose, frequency, and route? Is medication stored properly?
5. If the child is taking oral medication, is it being taken with food, if indicated? If pills are being chewed,

are teeth being brushed soon after, which could be rinsing out the medications?

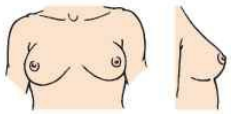
6. If injectable, are injection sites being rotated appropriately? Review technique.

Physical Examination Relative to Development

1. Dental development—eruption of teeth and presence of permanent teeth (see page 1106).
2. Pubertal development—Tanner staging of pubic hair and gonadal development (see Table 50-1).
3. Presence of genetic dysmorphology—such as short-limbed dwarfism and various atypical stigmata.

Table 50-1 Tanner Staging of Puberty

BOYS' GENITAL DEVELOPMENT	GIRLS' BREAST DEVELOPMENT	BOTH SEXES: PUBIC HAIR
Stage I		
Preadolescent. Testes, scrotum, and penis are of about the same size and proportion as in early childhood.	Preadolescent. Elevation of papilla only.	Preadolescent. The vellus over the pubis is not further developed than that over the abdominal wall (ie, no pubic hair).
		Stage II		
Enlargement of scrotum and testes. Skin of scrotum reddens and changes in texture. Little or no enlargement of penis at this time.	Breast bud stage. Elevation of breast and papilla as small mound. Enlargement of areola diameter.	Sparse growth of long, slightly pigmented downy hair. Straight or slightly curled at base of penis or along labia.
		Stage III		
Enlargement of penis that occurs at first mainly in length. Further growth of testes and scrotum.	Further enlargement and elevation of breast and areola with no separation of their contours.	Considerably darker, coarser, and more curled. The hair spreads sparsely over the symphysis pubis.
		Stage IV		
Increased size of penis with growth in breadth and development of glans. Testes and scrotum larger; scrotal skin darkened.	Projection of areola and papilla to form a secondary mound above level of the breast.	Hair now adult in type, but area covered is still considerably smaller than in adult. No spread to medial surface of thighs.
		Stage V		
Genitalia adult in size and shape.	Mature stage: projection of papilla only, due to recession of the areola to the general contour of the breast.	Adult in quantity and type; distribution of the horizontal (or classically "feminine") pattern. Spread to medial surface of thighs or above base of the inverse triangle occurs late (stage VI).
		



Adapted from Tanner, J. M. (1975). Growth and endocrinology of the adolescent. In: Gardner, L. (Ed.), Endocrine and genetic diseases of childhood and adolescence (2nd ed.). Philadelphia, PA: W.B. Saunders.

Causes of Disorders of Growth and Stature

It is important to realize that growth and stature problems are caused by a wide variety of factors. Thorough history, physical examination, and diagnostic testing can help reveal the underlying cause. Many of the disorders are associated with other anomalies, such as mental retardation, cardiac problems, metabolic issues, and secondary sex characteristic abnormalities. The cause may be treatable to resolve the growth problem, may be amenable to growth hormone supplementation, or may be untreatable because of genetic cause.

Short Stature and Growth Failure

Genetic Causes

1. Familial short stature—short target height relative to U.S. standards; however, growth rate is normal.
2. Constitutional delay—short stature with retarded linear growth beginning in the first 3 years of life followed by short stature relative to peers; however, final height normal upon completion of pubertal development. Puberty is usually delayed.
3. Genetic disorders:
   a. Dwarfism—multiple types and causes relative to chondrodysplasias.
   b. Turner syndrome—occurs in about 1 in 2,500 female births worldwide. Characterized by short stature, ovarian dysgenesis (underdeveloped, degenerate ovaries), and, in some cases, unusual physical appearance (see page 1461).
   c. Russell-Silver syndrome—characterized by unilateral poor growth, short stature, characteristic facies, and mental delays. Whenever unilateral change in growth is present, abdominal tumor needs to be ruled out.
   d. Prader-Willi syndrome—rare syndrome characterized by below-normal intelligence, small stature, hypogonadism (see page 31, failure to thrive in infancy followed by obesity and insatiable appetite, binge-type eating behaviors.
   e. Down syndrome—occurs in 1 in 700 live births; characterized by growth retardation and developmental delays (see page 1458).
   f. Cystic fibrosis—occurs in 1 in 2,500 live births. In addition to respiratory and GI symptoms, growth retardation occurs (see page 1191).

Endocrine Disorders

1. Hypothyroidism.
2. Growth hormone (GH) deficiency.
3. Glucocorticoid excess—Cushing syndrome.

Nonendocrine Disorders

1. Glucocorticoid (prednisone) therapy for asthma, prevention of transplant rejection, adjunct medication in cancer chemotherapy, and severe dermatological disorders.
2. Nutritional deficiency.

3. Psychosocial issues.
4. Chronic diseases—cardiovascular, renal, hematologic, pulmonary, malabsorptive disorders, and inborn errors of metabolism.
5. Medical interventions—surgical tumor resection and radiation for brain tumors.

Tall Stature and Excessive Growth

Genetic Causes

1. Familial tall stature—tall stature relative to U.S. standards; however, normal for family. Growth rate is usually normal.
2. Genetic disorders:
   a. Marfan syndrome—tall, long extremities, long fingers and toes; cardiac and other anomalies.
   b. Klinefelter syndrome—tall, slim, underweight, gynecomastia, small testicles, infertile.

Endocrine Disorders

1. Congenital adrenal hyperplasia.
2. Precocious puberty (see page 1344).
3. Hyperthyroidism (see page 1340).
4. Acromegaly—overproduction of GH usually related to pituitary tumors; very rare in children.

Nonendocrine Disorders

1. Exogenous use of androgens (ie, testosterone injections):
   a. Although stature and growth will initially be above the normal expected for age, ultimate height will be decreased because of undue advance of bone maturation at growth plate.
   b. The child will ultimately end up shorter than genetically determined.
2. Sotos syndrome (cerebral gigantism)—usually large at birth with rapid growth in first year of life, intellectual impairment. Hypothesized to be a hypothalamic defect; normal endocrine function.

DISORDERS OF THE ANTERIOR PITUITARY

The anterior pituitary is under the control of the hypothalamus and secretes six specific hormones: GH, thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and prolactin. GH is the only hormone that does not have a target gland to induce further hormonal secretion. Hypopituitarism is a deficiency of one, some, or all of the hormones secreted by the pituitary gland. With the exception of GH, decreased secretion results in hypofunction of the consequential target gland.

TSH deficiency, ACTH deficiency, and LH/FSH deficiency are discussed under disorders of the thyroid gland, disorders of the adrenal glands, and disorders of gonadal function, respectively.

Growth Hormone Deficiency

EVIDENCE BASE Collin, J., Whitehead, A., & Walker, J. (2016). Educating children and families about growth hormone deficiency and its management: Part 1. *Nursing Children and Young People, 28*(1), 32–37.

Collin, J., Whitehead, A., & Walker, J. (2016). Educating children and families about growth hormone deficiency and its management: Part 2. *Nursing Children and Young People, 28*(2), 30–36.

Insufficient secretion of GH is caused by lack of pituitary production or hypothalamic stimulation on the pituitary. Incidence is approximately 1 in 3800 for classic GH insufficiency and is unknown for varying degrees of insufficiency.

Pathophysiology and Etiology

1. The lack of GH impairs the body's ability to perform the following functions:
   a. Protein metabolism—growth through increased protein synthesis; nitrogen, phosphorus, and potassium storage.
   b. Fat metabolism—increases lipolysis and oxidation of fat.
   c. Carbohydrate metabolism—decreases conversion of glucose to fat in adipose tissue.
2. Organic etiology:
   a. Intracranial cyst.
   b. Central nervous system (CNS) tumor (hypothalamic–pituitary structural lesions).
   c. CNS irradiation.
   d. Exogenous (head trauma from various causes such as birth injury, infection, pituitary infarction, or aneurysm).
   e. Histiocytosis X.
   f. Septo-optic dysplasia (abnormal forebrain development).
3. Idiopathic causes:
   a. Isolated GH deficiency; aplasia.
   b. Traumatic birth or breech delivery.
   c. Genetic (GH gene deletion).
   d. Nutritional deprivation; psychosocial issues.
4. Genetic cause—Turner syndrome:
   a. The pituitary and hypothalamus are not abnormal in Turner syndrome and GH secretion measurement is usually normal; however, GH is bioinactive because of binding problems.
   b. Hypothyroidism is common with Turner syndrome and Down syndrome.

c. Growth rate usually declines within the first year of life.

d. Treatment with GH is a commonly accepted therapy to restore growth.

Clinical Manifestations

1. Hypoglycemia, prolonged jaundice, microphallus (small penis); usually in the neonate.
2. Growth velocity usually less than the 5th percentile for chronologic age.
3. Delayed skeletal maturation—bone age at least 1 year delayed from chronologic age.
4. "Pudgy" when the weight age (50% for weight) exceeds the height age (50% for height).
5. Frequently delayed eruption of primary and secondary teeth (not as severe as in hypothyroidism).
6. Delayed or lack of sexual development.
7. In young adulthood after epiphyseal fusion, the following symptoms may develop, requiring evaluation from an adult endocrinologist:
   a. Altered body composition (increased fat mass, decreased lean body mass).
   b. Reduced aerobic exercise capacity or performance.
   c. Decreased muscle strength.
   d. Abnormal blood lipid (fat and cholesterol) concentrations.
   e. Decreased bone mineral density or content.
   f. Impaired cardiac function.
   g. Impaired health-related quality of life (low energy level, decreased physical mobility, difficulties with concentration and memory, increased emotional lability, irritability, difficulty relating to others, or increased social isolation).

Diagnostic Evaluation

1. Rule out organic, nonendocrine causes of short stature (ie, chronic illness, nutritional deficiencies, genetic disorders, psychosocial factors).
2. Calculate growth velocity. (Does growth pattern parallel or deviate from the growth curve?)
3. Bone age assessment—(usually left wrist and hand), ascertain age of physical development; usually delayed.
4. General physical examination—physical development that of a younger-appearing child, microphallus in the neonate.
5. Chromosome testing of females (rule out Turner syndrome).
6. Thyroid function tests to rule out hypothyroidism.
7. GH secretion laboratory indicators: IGF-1 (insulin-like growth factor 1), IGF-binding protein 3 are decreased. (Malnutrition can cause low IGF-1.)
8. Subnormal secretion of GH in response to two provocative stimuli:
   a. Insulin-induced hypoglycemia.
   b. Abnormal stimulatory response to arginine infusion, L-dopa, clonidine, or glucagon—all of which

have specific actions resulting in GH secretion from pituitary. Pharmacologic agent is given, followed by blood sampling for GH response; GH levels less than 10 ng/mL are abnormal.

9. In the neonate with hypoglycemia, GH release is reduced at time of documented hypoglycemia (concomitant GH level relative to documented hypoglycemia is abnormally low).
10. GH has been associated with reduction in serum levels of free T4. Patients starting on GH should have their thyroid function monitored in the first 6 months of treatment.
11. Magnetic resonance imaging (MRI) of head to rule out tumor (MRI is gold standard).

NURSING ALERT In the neonate with hypoglycemia, always draw blood for cortisol and GH *before* initiating corrective action for the hypoglycemia. Early detection and diagnosis will protect the child from future episodes if related to hypopituitarism.

Management

1. Goal of treatment is to restore normal growth and development, as well as to maximize growth potential and prevent hypoglycemia.
2. Replacement of deficiency uses recombinant deoxyribonucleic acid–derived GH given as subcutaneous injection.
3. Typical dose is 0.2 to 0.3 mg/kg per week divided in six or seven doses weekly until final height is achieved. In treatment of Turner syndrome, dose is generally 0.375 mg/kg per week divided in doses as above. *Note*: Administration three times per week is not as effective as six to seven times per week.
4. Therapy is being recommended for adult replacement. Depending on the degree of insufficiency, continued treatment into adulthood may be useful. Dosing recommendations range from less than 0.006 mg/kg/day to as high as 0.0125 mg/kg/day after epiphyseal fusion has occurred.

EVIDENCE BASE Collin, J., Whitehead, A., & Walker, J. (2016). Educating children and families about growth hormone deficiency and its management: Part 1. *Nursing Children & Young People, 28*(1), 32–37.

Complications

1. Altered carbohydrate, protein, and fat metabolism.
2. Hypoglycemia—seizures/death in neonates.
3. Adverse effects of therapy.
   a. Leukemia.
   b. Recurrence of CNS tumors.

c. Pseudotumor cerebri.

d. Slipped capital femoral epiphysis.

e. Glucose intolerance/diabetes.

Nursing Assessment

1. See "Common nursing assessment for growth and development," page 1332.
2. Obtain family history related to parental heights and ages of pubertal maturation.

Nursing Diagnoses

- Delayed Growth and Development related to lack of GH.
- Impaired Social Interaction related to short stature and peer acceptance.
- Chronic Low Self-Esteem related to discordant expectations by peers and adults.

Nursing Interventions

Providing Education and Evaluation

1. Teach method of injecting GH through written and verbal instructions. Give demonstration and encourage return demonstration.
2. Encourage rotation of sites in the subcutaneous tissue of the upper arms or thighs to prevent skin irritation and hypertrophy.
3. Document growth every 3 to 6 months while on therapy.
4. If poor growth response, evaluate for appropriate dose, compliance, and injection technique. There may be initial "catch-up" growth that will be exhibited by a growth velocity above normal.
5. Instruct patient and family to report adverse effects: severe headache, hip and knee pain, limp, and increased thirst and urination.

Encouraging Social Interaction

1. Encourage the child to verbalize feelings regarding short stature.
2. Have the child describe what he or she likes about certain people to help the child understand that friendships and social value are based on personality traits rather than absolute height.
3. Suggest involvement in activities that do not use height as an advantage, such as music, art, and gymnastics.
4. Ask the child to identify behaviors that may deter socialization (may or may not be related to short stature) and find ways to change behavior.

Strengthening Self-Esteem

1. Help the child and parents to identify age-appropriate behaviors and develop a plan for maintaining consistent behaviors in the home and socially.
2. Make sure the parents have realistic expectations of the child.

3. Encourage the use of positive feedback rather than punishment.

Community and Home Care Considerations

1. Become familiar with the GH preparation being used and develop a teaching plan for home injection (mixing and injection technique). Provide periodic evaluation and ongoing support.
2. If home injections are difficult relative to family learning or parental availability, attempt to include school nurse in administering daily injections.
3. Review storage and stability of GH product relative to manufacturer's specifications for the home, as well as use in travel.

Family Education and Health Maintenance

1. Tell the child and family that short stature is not a "disease."
   a. Growth often catches up with peers usually when peers have stopped growing.
   b. After initial startup of treatment, growth rate should be 4 to 5 inches (10 to 12 cm)/year in year 1 and 2¾ to 3½ inches (7 to 9 cm)/year over the next 2 years. Growth will slow after that.
   c. Treatment is not to make the child tall; rather, its purpose is to optimize final height potential.
2. Review medication dosage and injection technique periodically.
3. Tell family to think of GH as a replacement that is essential rather than a medication; therefore, it should always be given regardless of illness or other medication therapies.
4. Encourage regular follow-up for growth evaluation and maintenance of therapy.
5. Discuss potential lifelong therapy, which may be necessary depending on the degree of deficiency. Many hypopituitary patients require lifelong replacement therapy.
6. Recommend counseling about probable infertility for female with Turner syndrome. This should be done with a genetic counselor, if available.

Evaluation: Expected Outcomes

- Growth rate in initial 2 years of therapy should be two to four times pretreatment growth velocity with final gain of one to two standard deviations in height.
- The child reports interest in school activities and playing with friends.
- Parents report more positive behavior relative to self-esteem.

DISORDERS OF THE POSTERIOR PITUITARY

The posterior pituitary is under the control of the hypothalamus and secretes two hormones, vasopressin (antidiuretic hormone [ADH]) and oxytocin. Abnormality of ADH function is the most common disorder seen in children. The function of ADH is to conserve water at the distal tubules and collecting ducts of the kidney and to act on smooth muscle to increase blood pressure (BP).

Diabetes Insipidus

EVIDENCE BASE Hunter, F., & Calikoglu, A. (2016). Etiological and clinical characteristics of central diabetes insipidus in children: a single center experience. International Journal of Pediatric Endocrinology, 2/11/2016, 1–5.

Diabetes insipidus (DI) is failure of the body to conserve water due to a deficiency of ADH, decreased renal sensitivity to ADH, or suppression of ADH secondary to excessive ingestion of fluids (primary polydipsia).

Pathophysiology and Etiology

1. The function of water metabolism in the body is to maintain a constant plasma osmolality near the mean level of 287 mOsm/kg.
2. Intake and output of water are governed by the centers in the hypothalamus to control thirst and synthesis of ADH.
3. Thirst ensures adequate intake of water, and ADH prevents water loss through the kidney.
4. Patients with DI are unable to produce appropriate levels or action of ADH, leading to polyuria, increased plasma osmolality, and increased thirst (see Figure 50-1).
5. Classified as central or nephrogenic DI:
    a. Central DI—low levels of ADH; may be congenital or acquired.
        i. Congenital causes—CNS defects, hereditary.
        ii. Acquired causes—CNS tumors, head trauma (orbital trauma), infections, vascular disorders, idiopathic.
    b. Nephrogenic DI—renal unresponsiveness to vasopressin; usually caused by chronic renal disease.
    c. Acquired causes—dietary abnormalities such as primary polydipsia, decreased sodium chloride intake, severe protein restriction or depletion, sickle cell disease, drugs (alcohol, lithium, diuretics, medications such as tetracycline).

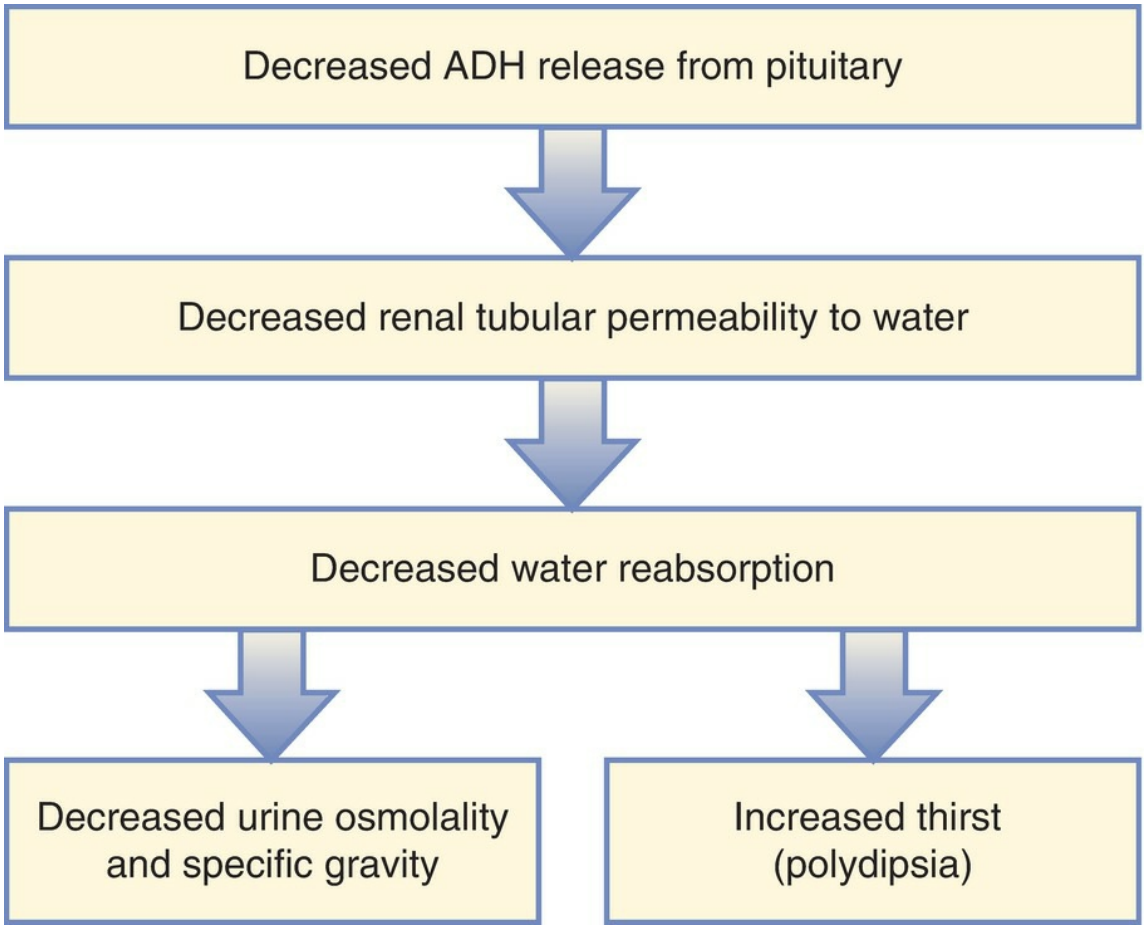


Figure 50-1. Mechanism of antidiuretic hormone (ADH) deficiency in diabetes insipidus.

Clinical Manifestations

1. Sudden onset of excessive thirst and polyuria.
2. In infants:
   a. Excessive crying—quieted with water more than milk feeding.
   b. Rapid weight loss—caloric loss due to water preference over feedings.
   c. Constipation.
   d. Growth failure—weight loss, failure to thrive.
   e. Dehydration—sunken fontanelle, rapid heart rate, headache, fever, low blood pressure.
3. In children:
   a. More abrupt onset, excessive thirst and drinking, preference for ice water.
   b. Polyuria (usually more than 2 L/day) with nocturia and enuresis.
   c. Pale, dry skin with reduced sweating.
   d. Lethargy.

Diagnostic Evaluation

Tests document inability to produce ADH in the face of hyperosmolality of plasma.

1. Urine-specific gravity, sodium, and osmolality are decreased.
2. Serum osmolality and sodium are elevated.
3. Serum measurement of ADH is low in conjunction with high plasma osmolality.
4. Water deprivation test (potentially dangerous):
    a. Fluids are restricted, and the urinary volumes and concentrations are monitored hourly along with the child's weight.
    b. Test is terminated if the child loses more than 3% to 5% of body weight. Serum sodium and osmolality are measured at completion of test and are high; urine osmolality remains lower.
    c. Test is completed by giving the child a dose of ADH, which should stop the abnormal diuresis. If it does not, child may have nephrogenic DI.
5. Assess for underlying cause:
    a. MRI of hypothalamic–pituitary region.
    b. High incidence of associated anterior pituitary disorders.

Management

1. Daily replacement of ADH using desmopressin (DDAVP), a synthetic analogue.
2. Available as a metered nasal spray, measured insufflation (nasal) tube, or tablets. In children with cleft lip and palate, sublingual administration has been shown to be effective.
3. Thiazide diuretics in nephrogenic DI.

Complications

1. Dehydration.
2. Hypernatremia.
3. Adverse reactions to DDAVP therapy—hyponatremia and hypertension.

Nursing Assessment

1. Assess children with complaints or behaviors of polyuria and polydipsia for dehydration.
2. Obtain a thorough history of symptoms and behaviors—specific attention to changes in sleep patterns (may be caused by enuresis) and choices of fluids, including sources of water (eg, does child drink from toilet bowls or dog dishes?).
3. Evaluate height and weight—assess for weight loss related to possible decrease in calories due to excessive drinking, which decreases appetite.
4. For the child on treatment, assess for hydration status. Obtain history of fluid intake and output from the parents to assess appropriate dosage, frequency, and administration of medication.

Nursing Diagnoses

- Deficient Fluid Volume related to disease process.
- Imbalanced Nutrition: Less Than Body Requirements due to fluid preference over food.

- Disturbed Sleep Pattern related to nocturia and enuresis.

Nursing Interventions

Regaining Fluid Balance

1. Assess for and teach parents assessment of dehydration—dry mucous membranes, weight loss, increased pulse, listlessness or irritability, sunken fontanelle in infants, fever, and poor skin turgor.
2. Administer fluid via intravenous (IV) route, as ordered, if acutely dehydrated.
3. Monitor intake and output and teach parents to maintain record of fluid intake and output in child. Reduced output may require restriction of fluids to prevent hyponatremia if overdosage of DDAVP is suspected.
4. Keep record of daily weight.
5. Family education of DDAVP administration includes nurse demonstration and family administration. Proper management should eliminate symptoms.
6. Teach parents to provide free access to fluid (water) sources at all times. However, caution parents that child is unprotected from water excess.
7. Calculate general estimated total daily (24 hours) fluid requirements based on body size to assess fluid replacement versus excess: 100 mL/kg for first 10 kg of body weight, 50 mL/kg for second 10 kg of body weight, and 20 mL/kg for each additional kilogram.

NURSING ALERT Watch for and report signs of water intoxication due to excess free water and hyponatremia—drowsiness, listlessness, headache, confusion, anuria, and weight gain. Hold DDAVP to prevent seizures, coma, and death.

Maintaining Adequate Nutrition

1. Make sure that adequate formula is ingested between plain water bottles.
2. For older child, provide liquid nutritional supplements.
3. Stress to parents or caregivers the importance of providing nutritional requirements with fluids to ensure meeting caloric demands for growth.
4. Consult with dietitian about need for vitamin or other supplements.
5. Monitor length and weight and developmental milestones at regular intervals.

Normalizing Sleep Pattern

1. Ensure adequate evening administration of DDAVP to prevent nighttime water craving and enuresis.
2. Suggest the use of diapers at night and plastic padding on bed to make controlling bedwetting easier until optimum management of condition is attained.
3. Encourage easy access to fluids and toilet or commode for older child during night.

Family Education and Health Maintenance

1. Teach family insufflation method (for infants and young children):
    a. Correct dose is measured and drawn up into catheter.
    b. Catheter is inserted into patient's nostril.
    c. Parent or patient inserts other end of catheter into mouth and gently blows.
    d. Older children may be able to inhale the solution.
2. Advise that nostrils should be as clear as possible before administration of dose.
3. Advise that, if dose is thought to be swallowed, do not readminister because of potential overdosage. Split the dose into both nares if swallowing is occurring.
4. Tell family to store drug away from heat and direct light and moisture (not in bathroom).
5. Advise parents that children should wear MedicAlert bracelet for DI.
6. Tell parents that school or daycare personnel should be aware of condition and symptoms needing attention (water intoxication).
7. Advise routine follow-up; treatment may be temporary or lifelong, depending on cause.

Evaluation: Expected Outcomes

- No signs of dehydration; intake equals output.
- No weight loss, growth curve maintained.
- Child sleeping through night.

DISORDERS OF THE THYROID GLAND

Under hypothalamic–pituitary regulation, the thyroid gland secretes thyroxine (T_4) and triiodothyronine (T_3). The action of these hormones promotes cellular growth and differentiation, protein synthesis, and lipid metabolism (cholesterol turnover). Lack of adequate thyroid hormones can affect mental development and sexual maturity. Function of the thyroid gland is controlled by a negative feedback mechanism utilizing TSH released from the pituitary gland (see Figure 50-2). Disorders of the thyroid gland are broadly classified as hypothyroidism and hyperthyroidism.

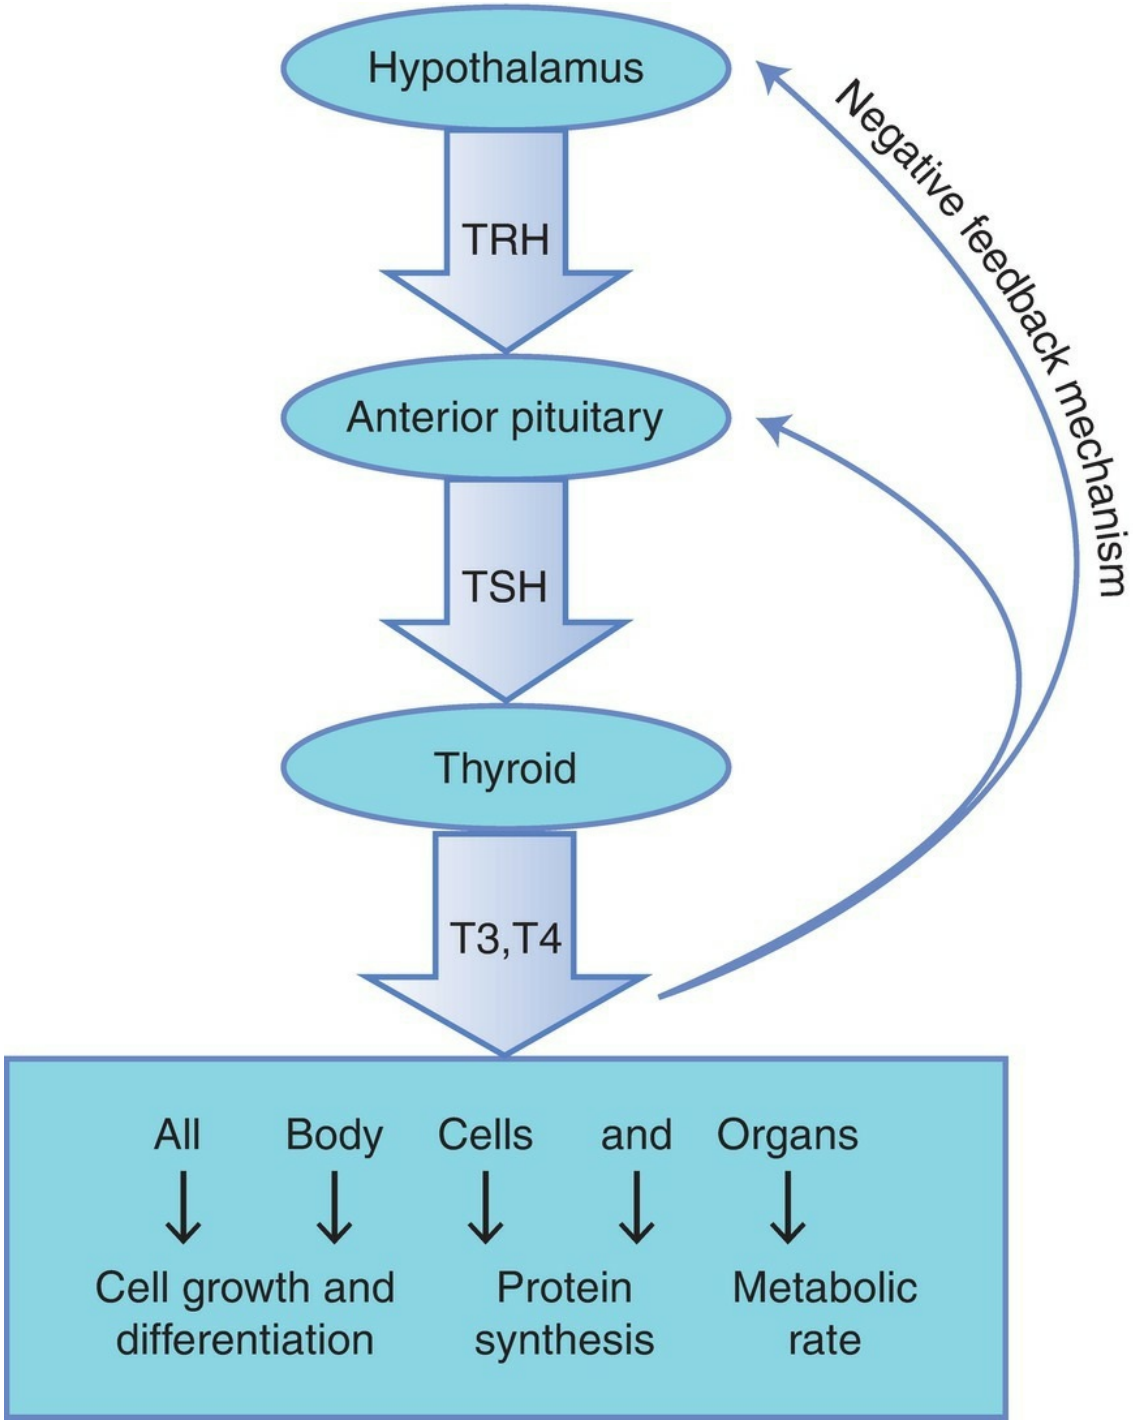

Figure 50-2. Normal thyroid hormone function.

Hypothyroidism

Hypothyroidism is low circulating level of T_4. Congenital hypothyroidism occurs in 1 in 4,000 live births with females more commonly affected.

Pathophysiology and Etiology

1. Circulating levels of T_4 are dependent on hypothalamic–pituitary stimulation (TRH [thyrotropin-releasing hormone]/TSH) of the thyroid gland.
2. Low levels of T_4 cause an increase in TSH level.
3. Absent or decreased levels of T_4 result in abnormal development of the CNS of the neonate.
4. In older children, hypothyroidism results in a decrease in metabolism, growth, and physical maturation.
5. Congenital causes:
   a. Thyroid agenesis or dysgenesis.
   b. Hormone synthesis defect.
   c. Maternal thyroid antibodies crossing placenta.
   d. Iodine deficiency.
   e. Drug-induced destruction (thioamides for treatment of hyperthyroidism, iodide excess).
   f. Peripheral T_4 resistance.
6. Acquired (postnatal) causes:
   a. Autoimmune thyroiditis (Hashimoto disease or chronic lymphocytic thyroiditis).
   b. Cranial/spinal radiation.
   c. Surgical ablation (thyroidectomy).
   d. Antithyroid drugs.
   e. Iodine deficiency.
   f. Central hypothyroidism (TRH/TSH deficiency).

Clinical Manifestations

Neonates

1. Very subtle physical signs, if any.
2. Markedly open posterior fontanelle.
3. Prolonged physiologic jaundice.
4. Feeding difficulties.
5. Skin cool to touch, mottled.
6. Poor muscle tone—hypotonia, umbilical hernia.

After Age 6 Months

1. Growth failure.

2. Large, protruding tongue.
3. Coarse facial features.
4. Poor feeding and constipation.

Acquired Cases

1. Growth retardation—slow growth rate, increased weight gain.
2. Lethargy—obedient, nonaggressive, somnolent.
3. Cold intolerance.
4. Possible poor school performance.
5. Constipation.

Diagnostic Evaluation

1. Neonatal screening of TSH with backup T_4; elevation of TSH or a low T_4 may indicate congenital hypothyroidism.
   a. Testing is ideally done at 2 to 4 days of life or immediately before the neonate is discharged from the hospital. TSH levels in the first 24 to 28 hours of life may be falsely elevated.
   b. Abnormal screening test should be confirmed and treatment begun within 2 weeks after birth.
2. Thyroid nuclear scan—reduced uptake.
3. Abnormal growth rate.
4. Bone age x-ray; delayed.
5. Blood studies:
   a. Free T_4 decreased; TSH elevated.
   b. Thyroid antibodies—elevated in autoimmune thyroiditis.

EVIDENCE BASE Nierengarten, M. (2016). Hypothyroidism in children. *Contemporary Pediatrics, 33*(5), 29–33.

Management

1. Replacement of thyroid hormone: levothyroxine.
2. Treatment must not be delayed.
3. Therapy goal is to maintain normalcy of thyroid function tests (free T_4, T_4, and T_3 concentrations) in the upper half of normal range.

Complications

1. Developmental delays in neonate who is undiagnosed or untreated.
2. Short stature, growth failure, and delayed physical maturation and development in the older child.

Nursing Assessment

1. Assess the neonate for clinical manifestations listed above.
2. Perform behavioral assessment to include sleeping, eating, bowel patterns, level of alertness, and school performance.
3. Assess growth patterns: growth velocity (rate of growth over time), weight gain, and head circumference.

Nursing Diagnoses

- Delayed Growth and Development related to effects of hypothyroidism.
- Deficient Knowledge regarding hypothyroidism and its treatment.

Nursing Interventions

EVIDENCE BASE Erlichman, I., Mimouni, F., Erlichman, M., et al. (2016). Thyroxine-based screening for congenital hypothyroidism in neonates with Down syndrome. *Journal of Pediatrics, 173*, 165–168.

Promoting Growth and Development

1. Administer or teach parents to administer thyroid hormone replacement daily.
2. Discourage mixing thyroid medication with liquid in bottle that may not be completely finished during a feeding; instead, mix with small amount of fluid and give with dropper or syringe or crush tablet and place in teaspoon of infant food. Do not mix with soy formula.
3. If thyroid pill is being chewed rather than swallowed, have the patient avoid brushing the teeth immediately after to protect against rinsing away dose.
4. Monitor growth and developmental milestones at regular intervals.

Increasing Knowledge

1. Encourage the parents to verbalize feelings about the child and the condition.
2. Educate the parents as to the importance of the therapy so the child will grow and develop normally.
3. Stress that with replacement therapy, the child can participate in all usual activities.

Family Education and Health Maintenance

1. Encourage follow-up by a primary care provider or pediatric endocrinologist for blood studies to assess and monitor thyroid levels and evaluation of neurologic development to ensure adequate treatment and optimal cognitive development.
2. Make sure the family understands that therapy is usually lifelong. May do a 6-week trial off medication after age 3 years under health care provider's supervision.
3. Support the parents and refer child for special testing and therapy if mental retardation is suspected.

4. Teach family the importance of avoiding overdosage of levothyroxine and of being alert for signs of overdosage (weight loss, restlessness, heat intolerance, fatigue, muscle weakness, tachycardia).

Evaluation: Expected Outcomes

- Growth curve and developmental milestones appropriate for age.
- Parents verbalize understanding and acceptance of therapy.

Hyperthyroidism

Hyperthyroidism is a disorder of the thyroid gland in which a high circulating level of T_4 results in abnormally increased body metabolism (thyrotoxicosis).

Pathophysiology and Etiology

1. May be caused by autoimmune process—thyrotropin receptor antibodies of a stimulating nature are produced.
   a. Graves disease—most common cause of hyperthyroidism in children, affecting 1% to 2% of school-age children.
   b. Chronic thyroiditis—Hashimoto disease; usually short-term hyperthyroidism (6 to 18 months duration) before developing hypothyroidism.
2. Autoantibodies stimulate thyroid gland to produce and secrete T_4.
3. Elevated circulating thyroid hormone increases the body's metabolic rate, causing an increase in excitability of the neuromuscular, cardiovascular, and sympathetic nervous systems.
4. May also be caused by ingestion or overdosage of thyroid medication (iatrogenic) or pituitary adenoma (TSH initiated).

Clinical Manifestations

1. Thyromegaly—enlargement of the thyroid, possibly with a bruit.
2. Polyphagia with weight loss.
3. Exophthalmos, proptosis, lid retraction.
4. Hyperactivity—restlessness, nervousness, hand tremors, perspiration, sleeping disturbances, emotional lability; inability to concentrate, decreased school performance.
5. Heat intolerance, excessive diaphoresis.
6. Fatigue (proximal), muscle weakness.
7. Tachycardia, palpitations, wide pulse pressure.
8. Tall stature, underweight for height.

Diagnostic Evaluation

1. Serum thyroid function tests—elevated T_4, T_3 resin uptake with a suppressed TSH.
2. Microsomal antibodies—positive.
3. Thyroid radionuclide scan of goiter—rules out cold nodules that could indicate thyroid carcinoma.

Management

1. Propranolol, a beta-adrenergic blocking agent, for cardiac effects, antipyretics, and anxiolytics.
2. Inorganic iodide preparation, such as propylthiouracil or methimazole, to block release of thyroid hormone. Adverse effects include headache, nausea, diarrhea, skin rash, itching, liver disease, jaundice,

arthralgia, and, rarely, agranulocytosis (severe leukopenia).

3. Radioactive ablation of thyroid gland using radioiodine—preferred over thyroidectomy. This is chosen when medical management is ineffective and results in permanent hypothyroidism that requires treatment.

Complications

1. Development of a goiter (glandular enlargement due to overstimulation).
2. Cardiac problems of tachycardia and hypertension.
3. Exophthalmos—abnormal protrusion of the eyeball.

Nursing Assessment

1. Perform physical assessment to include temperature, heart rate, BP, height, and weight.
2. Obtain history of symptoms specific to onset and subsequent development of symptoms.
3. Elicit history of any changes in behavior, school performance, emotions, or sleep patterns.
4. Assess for presence of goiter—pain with swallowing or talking, palpation of thyroid.

Nursing Diagnoses

- Activity Intolerance related to effects of excessive metabolic activity.
- Imbalanced Nutrition: Less Than Body Requirements due to increased metabolic demand.
- Disturbed Sleep Pattern related to high metabolic rate.
- Fear related to radioiodine ablation of gland if therapy choice.

Nursing Interventions

Improving Activity Tolerance

1. Administer and teach parents to administer medications and comply with treatment to gradually lower the metabolic rate and improve activity tolerance.
2. Assess activity tolerance periodically. Ascertain if fatigue is present at rest, with activities of daily living, or with exercise. Promote relaxation and rest between activities.
3. Avoid overactivity.

Ensuring Adequate Diet

1. Encourage high-calorie, nutritious diet until thyroid hormone levels are stabilized to try to maintain weight.
2. Advise the parents that effective treatment will lower metabolic rate and facilitate appropriate weight gain.
3. Periodically assess growth and development parameters.

Normalizing Sleep Pattern

1. Assess sleep pattern, including naps and sleeping through the night.
2. Adjust schedule to allow maximum amount of rest until sleeping through the night.
3. Allow short naps, as needed.

Reducing Fear

1. Encourage the parents and child to verbalize fears related to the thyroid ablation.
2. Teach them about the procedure and clear up misconceptions.
   a. Ablation is accomplished through radioactive destruction of thyroid tissue by administration of a radioactive iodine pill.
   b. The thyroid gland is the only tissue in the body that absorbs iodine; therefore, the radiation only destroys thyroid tissue.
   c. Radiation will be eliminated through the child's urine and feces; precautions for disposal must be followed according to nuclear medicine department policies.
3. Tell them that the resultant effect will most likely be hypothyroidism, which can be managed with lifelong treatment of T_4 replacement.

Family Education and Health Maintenance

1. Review prescribed medications and their functions. Stress the importance of compliance.
2. Advise about periodic blood testing and monitoring for adverse effects of antithyroid medication.
3. Educate family about possibility of oversuppression, from which hypothyroidism could develop.
4. If midday dose of medication is necessary, have family contact school nurse to coordinate dosing.
5. If gland is radioactively ablated, be certain family and other caregivers are appropriately instructed on storage and disposal of human waste after ablative therapy.
6. Encourage follow-up to monitor treatment through blood tests, growth and development evaluation, and size of thyroid gland.

DRUG ALERT Antihyperthyroid medications may cause agranulocytosis (severe leukopenia), thrombocytopenia, and aplastic anemia. Periodic blood testing is necessary to monitor blood counts. Agranulocytosis may present with sore throat and fever. Drug should be discontinued immediately and health care provider notified.

Evaluation: Expected Outcomes

- The child can play normally without early fatigue.
- No weight loss noted.
- The child displays normal sleep patterns through the night as well as during naps.
- Parents and child verbalize understanding of radiation procedure agnd its rationale.

DISORDERS OF THE ADRENAL GLANDS

The adrenal glands are responsible for the life-sustaining production of mineralocorticoids (aldosterone) for sodium retention, glucocorticoids (cortisol) for blood glucose regulation, and androgens (Dehydroepiandrosterone [DHEA], androstenedione) for phallic and secondary sex characteristic development (adrenarche).

Adrenocortical insufficiency is the inability of the adrenal gland to produce aldosterone and cortisol due to adrenal failure or lack of adrenal stimulation. With the exception of congenital adrenal hyperplasia (discussed below), pediatric adrenocortical insufficiency is similar in adults (see page 720).

Hyperadrenalism, although rare in children, does occur, causing tissue to be exposed to excessive glucocorticoids (cortisol). This is commonly called *Cushing syndrome.* Additionally, hyperfunction of the adrenal medulla, in which epinephrine, norepinephrine, and other catecholamines are secreted, is commonly seen in the disorder of pheochromocytoma. See pages 718 and 721 for a discussion of these conditions.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is the most common type of adrenocortical insufficiency in children. Adrenal dysfunction is a result of an enzyme deficiency in the steroid pathway converting cholesterol to cortisol, resulting in overproduction of androgens (sex hormones). The most common form of the condition is life threatening and requires diagnosis and treatment soon after birth.

Pathophysiology and Etiology

1. Production of adrenal mineralocorticoids and glucocorticoids is blocked by an enzyme deficiency in the steroid pathway. "Blocks" may be severe or partial.
    a. Deficiency of 21-hydroxylase (90% to 95% of CAH cases)—insufficiency in cortisol and usually aldosterone production.
    b. Deficiency of 11-β-hydroxylase (5% to 8%)—insufficiency of cortisol and aldosterone; however, precursor block to aldosterone is a potent mineralocorticoid.
    c. Deficiency of 3-β-hydroxysteroid dehydrogenase (5%)—insufficiency in cortisol, aldosterone, and androgen production.
2. Because of lack of feedback suppression, ACTH and renin are secreted to stimulate adrenal gland production, causing hyperplasia of the gland.
3. Aldosterone insufficiency results in fluid and electrolyte imbalance.
    a. Loss of sodium at the kidney results in loss of fluid and an increase in serum potassium (cation exchange).
    b. Depletion of extracellular fluid leads to decreased BP.
    c. Low BP stimulates renin in the kidney to activate the adrenal aldosterone pathway.
4. Cortisol insufficiency results in diminished hepatic gluconeogenesis and tissue glucose uptake.
    a. Diminished production/secretion results in low blood sugar levels—more pronounced in times of stress.
    b. Low blood sugar, stress, or low cortisol stimulates feedback to hypothalamic–pituitary axis to release ACTH to stimulate adrenal activity, which also stimulates the release of melanocyte-stimulating hormone (MSH).
    c. Constant ACTH stimulation of gland causes overproduction and "backup" of blocked steroid pathways, resulting in "spillover" production of adrenal androgens.
5. Depending on etiology, overproduction of androgens will virilize female external genitalia or underproduction of androgens will block virilization of male external genitalia.

Clinical Manifestations

1. Ambiguous female genitalia—varying degrees of virilization due to exposure of androgens during development in utero:
    a. Clitoromegaly (may be penile shaped).

b. Labial fusion (partial or complete).
c. Rugated labia-appearing scrotal.
d. Vagina may be incomplete, ending in a blind pouch.

2. Ambiguous male genitalia (3-β-dehydrogenase)—incomplete virilization development of external genitalia:
   a. Small phallic development.
   b. Incomplete scrotal fusion.
3. Hyperpigmentation (due to MSH secretion).
4. Dehydration.
5. Vomiting/poor feeding.
6. Shock.
7. Latent signs—basal cortisol levels are normal because of compensated chronic ACTH stimulation:
   a. Weakness, fatigue.
   b. Anorexia, nausea, diarrhea.
   c. Weight loss (failure to thrive).
   d. Hyperpigmentation.
   e. Hypotension/postural dizziness.
   f. Rapid growth rate—adrenal androgen effect.
   g. Premature adrenarche—pubic hair, axillary hair, acne, body odor.

Diagnostic Evaluation

Neonates

1. Pelvic ultrasound for identification of uterus, ovaries, or testes to determine true sex (internal development of gender-specific organs depends on presence or absence of Y chromosomal activity; external genital development depends on the presence or absence of androgens).
2. Karyotyping.
3. Serum electrolytes—sodium depletion.
4. Serum glucose levels—hypoglycemia.
5. Serum 17-hydroxyprogesterone (most common precursor to 21-hydroxylase)—elevated.

Latent Diagnosis

1. Rapid growth velocity, premature adrenarche.
2. Advanced bone age x-ray for chronologic age.
3. Elevated serum 17-hydroxyprogesterone.
4. Elevated plasma renin activity—compensated prevention of salt loss.

Management

1. Glucocorticoid replacement—physiologic production of cortisol is 15 to 20 mg/m^2/day. Doses are individually dependent. Replacement is with hydrocortisone twice or three times per day or prednisone once per day when final growth has been achieved.
2. Mineralocorticoid replacement—aldosterone is replaced with fludrocortisone tablets at 0.05 to 0.20 mg daily.
3. Added salt to the diet of neonates if salt loss is severe.
4. Surgical correction of ambiguous genitalia—can require multiple corrections over time.

DRUG ALERT Overdosage of chronic corticosteroid use will result in growth failure. If child fails to grow and exhibits excessive hunger, corticosteroid dosing should be reviewed.

Complications

1. Aldosterone insufficiency:
   a. Hyponatremia, hyperkalemia.
   b. Hypotension.
   c. Shock.
   d. Hypertension in 11-β-hydroxylase insufficiency in which aldosterone precursor is potent mineralocorticoid.
2. Cortisol insufficiency—hypoglycemia.

Nursing Assessment

Neonates

NURSING ALERT In male-appearing genitals, at least one testis must be palpated; if not, assumption must be that child is female with severe virilization. Notify health care provider so diagnostic evaluation can be initiated.

---

1. Assess genitalia for ambiguity.
2. Assess for signs of hypoglycemia, hyponatremia, and hyperkalemia (see Box 50-1).
3. Assess feeding pattern of the neonate.
4. Look for hyperpigmentation—may be subjective.

BOX 50-1 Manifestations of Hyponatremia and Hyperkalemia

HYPONATREMIA

- Caused by dilution of sodium (Na^+) when water intake exceeds output. Signs and symptoms occur when Na^+ level falls below 120 mEq/L.
- Gradual fall: anorexia, apathy, mild nausea, and vomiting
- Rapid fall: headache, mental confusion, muscular irritability, delirium, convulsions

HYPERKALEMIA

- Caused by a shift of potassium out of cells to compensate for decreased Na^+ caused by an oliguric state. Usually asymptomatic, except for electrocardiogram (ECG) changes.
- ECG characteristics: (progressive) shortened QT interval; tall, peaked T waves; ventricular arrhythmias; degeneration of QRS complex; ventricular asystole or fibrillation.

Latent Diagnosis of Child on Treatment

1. Assess growth and development.
2. Monitor vital signs; include sitting and recumbent BP for orthostatic changes.
3. Assess skin for hyperpigmentation.
4. Obtain history to include level of activity/fatigue, dietary history, salt craving, behavior, and school performance.

Nursing Diagnoses

- Fatigue related to hypoglycemia and electrolytic imbalances.
- Risk for Deficient Fluid Volume related to aldosterone deficiency.
- Deficient Knowledge related to risk of acute insufficiency.
- Anxiety of parents related to gender, sexual ambiguity, and chronic illness.

Nursing Interventions

Minimizing Fatigue

1. Administer glucocorticoids and emphasize compliance to increase energy level.
2. Encourage frequent rest periods and prevent overactivity.
3. Assess activity tolerance to determine adequacy of replacement therapy.
4. Tell the family that the child's activity level as well as growth rate should be normalized on therapy.
    a. If growth rate is too high, review corticosteroid dose and compliance with family.
    b. If growth rate is too low, overdosage of corticosteroid should be suspected.
    c. Review dosing with family.

Maintaining Fluid Balance

1. Assess fluid status and review history of fluid intake and output for appropriate volumes. Assess the hydration status of the child.

2. If the child is vomiting and unable to take oral fluids and mineralocorticoids, administer IV fluids. Start with 5% dextrose in normal saline and monitor serum sodium level.
3. Emphasize compliance with mineralocorticoid replacement.

NURSING ALERT No less than 0.5% normal saline should be infused in the child who is aldosterone deficient, because of the inability to retain mineralocorticoid replacement.

Preventing Acute Adrenocortical Insufficiency

1. Identify times of stress, such as acute infections, surgical procedures, or extreme emotional stress, which require increased corticosteroid replacement.
2. Teach the parents how to use and give intramuscular (IM) injections of hydrocortisone for stress management, when oral supplementation is not possible because of vomiting.
3. Make sure that the child is evaluated by the primary care provider and treated for the cause of stress.

Reducing Anxiety

1. Encourage the parents to verbalize feelings regarding diagnosis, gender decisions or changes, and treatment plans.
2. Explain to the parents that the ambiguity is a result of the development process not being completed, rather than being a "mistake."

Family Education and Health Maintenance

1. Stress and reinforce the function of and need for constant replacement of adrenal steroid therapy to maintain normal daily activities.
2. Encourage the parents to obtain a MedicAlert bracelet, which indicates steroid dependency, for the child.
3. Facilitate instructions to the school nurse to notify the parents and health care provider of signs of illness and for emergency injection of hydrocortisone should it become necessary.
4. Explain to the parents and child why pubic hair may be developing and encourage discussion with teachers and school officials to prevent embarrassment of child in the locker room and other situations.

Evaluation: Expected Outcomes

- Parents report the child is more active.
- No signs of dehydration.
- Parents verbalize understanding when to call health care provider or when to use emergency hydrocortisone injection; parents also demonstrate correct technique for hydrocortisone injection.
- Parents verbalize understanding of disorder and need for reconstructive surgery.

DISORDERS OF GONADAL FUNCTION

Proper gonadal function is necessary for developing sexual maturation (puberty). The process involves the hypothalamic release of gonadotropin-releasing hormone (GnRH), which in turn stimulates the pituitary to release LH and FSH. In turn, these stimulate the gonads to produce and release the gonadal steroid testosterone from the testes in males or estrogen from the ovaries in females. The actions of these steroids lead to the development of secondary sexual characteristics and maturation.

Delayed Sexual Development

EVIDENCE BASE Palmert, M., & Dunkel, L. (2012). Delayed puberty. *New England Journal of Medicine, 355*(5), 443–453.

Delayed sexual development is the lack of pubertal development or progression.

Pathophysiology and Etiology

1. Lack of production or secretion of gonadal steroids from the testes (testosterone) or ovaries (estrogen), due either to the lack of pituitary stimulation (secondary delayed sexual development) or to gonad dysfunction (primary delayed sexual development).
2. Primary delayed sexual development—absence or dysfunction of the gonads.
   a. 45 XO Turner syndrome (chromosomal variants).
   b. Sporadic gonadal dysgenesis.
   c. Bilateral gonadal failure due to radiation, chemotherapy, infection, defect in gonadal steroid synthesis, trauma.
3. Secondary delayed sexual development—lack of hypothalamic–pituitary stimulation to gonads.
   a. Hypothalamic lesions due to infections, trauma, irradiation, or isolated deficiency of GnRH (Kallmann syndrome).
   b. Pituitary lesions due to infection, trauma, or irradiation; also hypopituitarism or isolated LH and FSH deficiencies.
4. Failure of end organs to respond to circulating gonadal steroid—androgen insensitivity.
5. Other causes include chronic illness, anorexia nervosa, and autoimmune atrophy.
6. Resultant effect is failure to achieve sexual maturity.

Clinical Manifestations

1. Females—lack of breast development by age 13 years or failure to progress through puberty.
2. Males—lack of testicular enlargement by age 14 years or failure to progress through puberty.
3. Emotional lability.

Diagnostic Evaluation

1. Bone age x-ray to determine physical age—pubertal delay is not consistent with bone age.
2. Laboratory measurement of sex steroids (testosterone and estrogen) and gonadotropins (LH, FSH).
   a. Gonadal failure will show elevated LH and FSH with low estrogen.
   b. No good test is available to distinguish isolated gonadotropin deficiency (LH or FSH).

3. End organ insensitivity (lack of gonadal steroid receptor)—sex steroid and gonadotropins will be elevated. Hypothalamic receptors for feedback inhibition are the same as the end organ receptors; therefore, there is no hypothalamic "shutoff."
4. Abdominal ultrasound to view internal organ structure and development.

Management

1. Replacement of gonadal steroid—should be as close to the physiologic level as possible; however, maximal adult height may be compromised because of potential adverse effect of acceleration of skeletal maturation.
   a. Males—testosterone supplement; 50 to 100 mg monthly by injection until final height is achieved, then 200 mg monthly.
   b. Females—conjugated estrogen 0.3 to 0.625 mg daily by oral tablet. When appropriate, a progestational agent is added to the therapy for normal periods to occur. An alternative is the use of birth control pills that have the combination of estrogen and progesterone.
2. There is no pituitary or hypothalamic agent for use in secondary gonadal failure.

Complications

1. Sterility.
2. Ambiguity—in androgen insensitivity, male genital development does not respond to circulating level of testosterone from testes; may result in mistaken gender assignment.
3. Potential for dysfunctional dormant gonad to become malignant.

Nursing Assessment

1. Assess growth and development, particularly height.
2. Assess sexual development at regular intervals.

Nursing Diagnoses

1. Delayed Growth and Development related to lack of sexual development.
2. Disturbed Body Image related to delayed sexual maturation.
3. Chronic Low Self-Esteem related to delayed sexual maturation.

Nursing Interventions

Promoting Sexual Development

1. Administer or teach self-administration of medication, as prescribed.
2. Teach technique for IM injections of testosterone enanthate. Watch return demonstration.
3. Stress compliance with prescribed dose and not to exceed recommended dose. Excessive use of testosterone will stunt potential statural growth.

Improving Body Image

1. Discuss strategies for assisting the child to become more comfortable with appearance and ways that may minimize appearance of physical delay in sex characteristics.
2. Stress the importance of cautious therapy to prevent loss of potential height, therefore making sexual development a slow process.

Improving Self-Esteem

1. Encourage the child to discuss self-concept; list positive and negative characteristics.
2. Explore ways to strengthen and add to positive characteristics.
3. Encourage participation in age-appropriate activities and social functions.

Family Education and Health Maintenance

1. Teach the patient about adverse effects of testosterone replacement—possible behavioral changes (aggressiveness, moodiness) and an increase in acne.
   a. Suggest over-the-counter acne products or referral to dermatologist if indicated.
   b. Alert the family to report behavioral changes to the health care provider.
2. Teach the patient taking estrogen replacement the importance of daily compliance. Missed doses could result in breakthrough bleeding or spotting due to drop in circulatory estrogen levels. Alert patient to notify health care provider if spotting does occur with estrogen replacement.
3. In both treatments, stress to child not to exceed prescribed dose to prevent loss of final adult height.

Evaluation: Expected Outcomes

- At follow-up visit, there is an increase in height and progression of sexual development.
- Child verbalizes improved feelings of body image.
- Child lists more positive concepts of self.

Advanced Sexual Development and Precocious Puberty

Advanced sexual development is secondary sexual development earlier than the normal timing for a child's maturation. There is abnormal early production and secretion of the gonadal steroids or adrenal androgens. Normal pubertal development occurs abnormally early. Skeletal maturation is also advanced under presence of sex steroids and adrenal androgens.

Pathophysiology and Etiology

Central Precocious Puberty

1. Central precocious puberty (CPP)—early activation of the hypothalamic–pituitary gonadotropin axis.
2. May be idiopathic or caused by:
    a. Tumors of hypothalamus/pituitary.
    b. Cranial irradiation.
    c. Trauma.
    d. Infection—meningitis.
    e. Hydrocephalus.
3. Most common form of precocious puberty.

Peripheral Precocious Puberty

1. Peripheral precocious puberty (PPP)—sex hormone production at the glandular level independent of central stimulation.
2. Ovarian PPP caused by estrogen-producing tumors or cysts.
3. Testicular PPP caused by androgen- and estrogen-producing tumors or autonomous production of testosterone.
4. Adrenal PPP caused by enzyme defects (CAH) or androgen- and estrogen-producing tumors.

Other Causes

1. Hypothyroidism.
2. Exogenous estrogen or androgen exposure.

Clinical Manifestations

1. Males:
    a. Testicular enlargement (4 mL): younger than age 9½ years.
    b. Tanner stage II pubic hair: younger than age 9 years.
    c. Tanner stage III pubic hair: younger than age 10 years.
2. Females:
    a. Breast bud (stage II): younger than age 8 years.
    b. Tanner stage III pubic hair: younger than age 8½ years.

c. Menarche: younger than age 9½ years.

3. In both sexes, rapid growth (increased growth velocity) evident.

Diagnostic Evaluation

1. Physical assessment—Tanner staging:
   a. If adrenarche is present without thelarche (breast development) or testicular enlargement, adrenal cause is likely.
   b. In females, if only thelarche is present, ovarian or exogenous estrogen involvement is likely.
   c. If adrenarche and pubarche (gonadal signs) are present, central cause is likely.
2. Skeletal x-ray for bone age—usually advanced. Pubertal stage development is usually commensurate with bone age maturation.
3. Laboratory analysis:
   a. Gonadal steroid levels—may be elevated; however, secretion is diurnal early in development.
   b. Elevated gonadotropins to GnRH stimulation if CPP. Basal levels are frequently unreliable. Lack of elevation of gonadotropins may indicate peripheral source.
   c. Thyroid function to rule out hypothyroidism.
4. MRI of head to rule out central etiology.
5. Ultrasound of abdomen, pelvis, testes for presence of cysts or tumors.

Management

For CPP, most common form of advanced sexual development in children.

1. Goal is to inhibit puberty to preserve psychosocial well-being and to delay epiphyseal closure to maximize adult height.
2. GnRH agonist—down-regulates GnRH receptors of the pituitary against endogenous GnRH.
   a. Nafarelin—intranasal spray, twice daily.
   b. Leuprolide—daily subcutaneous injection.
   c. Depot-leuprolide—monthly IM injection.
   d. Histrelin—subcutaneous daily injection.
3. Progestins.
   a. Medroxyprogesterone injections—biweekly IM injections.
   b. Medroxyprogesterone tablets—oral daily dosing.

DRUG ALERT IM injections of leuprolide have, rarely, been linked to sterile abscesses. The site should not be reused, and the health care provider should be notified immediately if abscess occurs.

Complications

1. Complications of underlying tumor.
2. Behavioral problems.
3. Short stature for final height due to early epiphyseal closure.

Nursing Assessment

1. Assess sexual development using Tanner scale.
2. Obtain history of when signs and symptoms began with specific attention to chronology of events.
3. Perform psychosocial assessment relative to peer relations.
4. While the child is on treatment, perform ongoing assessment of height and sexual characteristics.

Nursing Diagnoses

- Disturbed Body Image related to early presence of secondary sexual characteristics.
- Deficient Knowledge regarding maturing body and sexuality.
- Disturbed Personal Identity due to societal height expectations versus appropriate age-related expectations.

Nursing Interventions

Fostering Positive Body Image

1. Encourage the child to verbalize concerns regarding body development changes.
2. Stress to child that the changes are normal events that peers will go through; however, they are occurring early.
3. Teach the child that therapy will halt the process and soon peers will catch up.

Teaching about the Effects of Treatment

1. Assist and encourage parents to teach the child about sexual development to reduce fear of the unknown.
2. Encourage proper hygiene practices for body odor, hair growth, and menses.
3. Teach administration techniques for medication treatment, including intranasal, IM, or subcutaneous administration, as indicated.
4. In GnRH-agonist treatment in females, instruct child and parents that it takes 10 to 12 days to fully down-regulate the pituitary receptors. The suppression results in a fall of estrogen and may cause breakthrough bleeding or even a period to occur. This will happen only once if child remains suppressed on therapy.

Promoting Sense of Identity

1. Encourage the child and parents to discuss normal age-related behaviors and identify inappropriate behaviors that are associated with society's expectations of advanced height and development.
2. Encourage the child to wear age-appropriate clothing, participate in age-appropriate activities, and

socialize with peers.

3. Suggest counseling, as needed.

Family Education and Health Maintenance

1. Encourage follow-up at regular intervals while on treatment and, if condition is not treated, to monitor progress and address behavioral issues.
2. Discuss with parents that child may act out relative to advancing pubertal development. (This may include masturbation.) This behavior needs to be dealt in an understanding way, not necessarily through punishment.
3. Encourage parents to meet with school personnel regarding potential embarrassment in a locker room situation; alternatives to changing clothes in front of peers may be necessary.
4. Prepare family for the start of menstruation if puberty is advanced. The school nurse may need to assist with feminine hygiene during the cycle. Parents may need to meet with the nurse to plan for assistance during school days.
5. Teach family to inspect injection sites and notify health care provider immediately upon noticing a hard, painful, reddened area, which may be a sterile abscess from Lupron injections and require treatment.
6. Teach family to maintain strict adherence to hormonal therapy. Failure to maintain suppression of gonadotropins can result in relative rise in estrogen. Subsequent suppression may cause breakthrough bleeding.

Evaluation: Expected Outcomes

- Child accepts body changes through verbalization at follow-up visits.
- Parents or child give adequate return demonstration of IM injection; verbalizes understanding of sexual development.
- Child participates in school activities and socializes with peers of same age.

DISORDERS OF THE PANCREAS

The pancreas manufactures powerful enzymes for digestion as well as the hormones insulin and glucagon. These hormones are manufactured and secreted from cell clusters called the islets of Langerhans. Glucagon and insulin regulate the amount of sugar that is present in the bloodstream. Glucagon is a potent counter-regulatory hormone that raises the blood sugar by fostering the release of glucose from stores in the liver. Insulin stimulates glucose uptake by peripheral tissues, inhibits lipolysis, and inhibits hepatic glucose production.

Type 1 Diabetes Mellitus

EVIDENCE BASE Hamilton, H., Knudsen, G., Vaina, C., et al. (2017). Children and young people with diabetes: Recognition and management. *British Journal of Nursing, 26*(6), 340–347.

Nierengarten, M. (2016). Pitfalls in pediatric type 1 diabetes management. *Contemporary Pediatrics, 33*(4), 16–20.

Diabetes mellitus (DM) is a disorder of glucose intolerance caused by deficiency in insulin production and action, resulting in hyperglycemia and abnormal carbohydrate, protein, and fat metabolism. In younger and school-age children, most cases are type 1, formerly called juvenile-onset or insulin-dependent DM. Type 1 DM affects as many as 1 in 500 children. As of 2014, there has been a 21% increase in type 1 diabetes when compared to 2007 rates. Females and males are equally impacted. The prevalence of type 1 diabetes varies with race and ethnicity. The incidence is highest in non-Hispanic white children.

Type 2 DM (formerly called adult-onset or noninsulin-dependent DM) traditionally was found in only about 2% of cases of diabetes in children and adolescents. This is rapidly changing, and type 2 diabetes now accounts for up to 40% of cases of diabetes diagnosed in adolescents. Etiology suggests morbid obesity, sedentary lifestyle, high caloric intake, and family history of diabetes. There is also an increased risk in black, Hispanic, and Native American populations. The onset of pubertal development and the insulin resistance that is characteristic of puberty may be a factor in the onset of type 2 diabetes in susceptible adolescents. Type 2 DM is discussed in Chapter 25.

Pathophysiology and Etiology

1. Etiology for type 1 DM suggests genetic and environmental or acquired factors, association with certain human leukocyte antigen types, and abnormal immune responses, including autoimmune reactions.
2. Autoimmune destruction of the islets of Langerhans in the pancreas that secrete insulin, resulting in insulin deficiency.
3. Because insulin facilitates glucose transport into cells, glucose builds up in the bloodstream, causing hyperglycemia.
4. As the kidneys attempt to lower blood glucose levels, glycosuria and polyuria result, with electrolyte excretion.
5. Because the body cells are unable to use glucose for energy, protein and fat are broken down.
6. Fat metabolism results in a buildup of ketones and acidosis.
7. Diabetic ketoacidosis (DKA) occurs in 20% to 40% of patients at the time of diagnosis. Also, DKA at diagnosis is more common in children under 5 years of age and in children who have limited or no access to medical care. It is a potentially fatal condition characterized by hyperglycemia, ketonemia, ketonuria, and metabolic acidosis (pH less than 7.3, bicarbonate less than 15 mEq/L) and caused by insulin

deficiency. In children with established T1DM, there is an increased incidence of DKA in those individuals with poor metabolic control, children who omit insulin doses or when caregivers omit doses of their child's insulin, children with psychiatric or eating disorders, peripubertal or adolescent girls, and interruption or failure of insulin pump therapy.

Clinical Manifestations

Onset is rapid (usually over a period of a few weeks).

Major Symptoms

1. Increased thirst.
2. Increased urination, enuresis.
3. Increased food ingestion.
4. Weight loss.
5. Fatigue.

Minor Symptoms

1. Skin infections.
2. Dry skin, poor wound healing.
3. Monilial vaginitis in adolescent females.

Diabetic Ketoacidosis

1. Hyperglycemia, polyuria, and polydipsia.
2. Dehydration, decreased skin turgor.
3. Nausea, vomiting, generalized malaise, weakness.
4. Kussmaul respirations (rapid, deep, sighing), fruity or acetone breath odor, altered level of consciousness (LOC), confusion.

Diagnostic Evaluation

1. Criteria for diagnosis of type 1 and type 2 DM are the same: fasting blood glucose of more than 126 mg/dL on two occasions (different day); random blood glucose of more than 200 in the presence of symptoms (polydipsia, polyphagia, polyuria); glucose greater than 200 following 2 hour oral glucose tolerance test; random hemoglobin A1C ≥ 6.5% (less sensitive and has not been validated in children).
2. Glycosuria or ketonuria on routine examination may arouse suspicion of diabetes.
3. Evaluation for metabolic acidosis with acute presentation (pH less than 7.3 and bicarbonate less than 14 mEq/L).
4. Hemoglobin A1c testing every 3 months to determine long-term plasma glucose control is dependent on age. Children, especially young children, are at high risk for hypoglycemia and are at low risk for complications prior to puberty. Goals are age dependent.
   a. Toddlers, children less than 6 years: less than 8.5% (less than 8% if hypoglycemia is avoided).

b. Children ages 6 to 12 years: less than 8%.

c. Adolescents ages 13 to 19 years: less than 7.5%. (A lower goal may be reasonable if excessive hypoglycemia does not result.)

5. Screening for celiac disease should be done at the time of diagnosis and if disease is detected, child should be referred to a pediatric gastroenterologist. A gluten-free diet is recommended for children with celiac disease.

6. Thyroid function is also recommended at the time of diagnosis.

EVIDENCE BASE Chan, C., McFann, K., Newnes, L., et al. (2014). Hemoglobin A1c assay variations and implications for diabetes screening in obese youth. *Pediatric Diabetes, 15*(8), 557–563.

Management

1. Insulin therapy (see Table 50-2).

a. New insulin analogs provide more options for insulin duration and frequency of administration. Basal insulins, such as glargine and detemir, provide a duration of up to 24 hours without a pronounced peak of action. Rapid-acting insulins, such as lispro, glulisine, and aspart, offer rapid onset with shorter duration.

b. Dosage needs are based on the child's weight, diet, and level of activity. Dosages are adjusted through daily monitoring of blood glucose levels.

c. Insulin pump therapy, consisting of a continuous subcutaneous infusion of insulin that can be programmed to give bolus and basal rates, may be used by some children.

2. Treatment of DKA (see Box 50-2).

a. IV fluid therapy to increase perfusion and glucose uptake in the periphery, which will reduce hyperglycemia; also increases glomerular filtration and reverses acidosis.

b. Regular IV insulin administration at a rate of 0.1 U/kg/hour after initial fluid replacement. Provide IV dextrose solution as plasma glucose decreases, titrate rate of insulin infusion to achieve a rate of glucose decline of 50 to 150 mg/dL per hour.

c. Bicarbonate is not indicated; acidosis will correct with adequate insulin infusion.

d. Close monitoring of vital signs, electrocardiogram, mental status, and neurologic system.

e. Replacement of electrolytes—sodium, potassium, ionized calcium.

3. Balanced diet with controlled carbohydrates and adequate protein and fat to meet energy and growth requirements.

Table 50-2 Types of Insulin and Their Effects

TYPE OF INSULIN	ONSET (MINUTES)	MAXIMAL ACTIVITY (HOURS)	DURATION (HOURS)
Aspart	10–20	1–3	3–5
Glulisine	2–5	1	2
Lispro	<15	0.5–1.5	6–8
Regular	30–60	2–4	6–8
Semilente	30–60	2–4	10–12
NPH	120	4–12	24
Lente	120	8–10	24
Ultralente	4–8 hours	14–20	36
Detemir	Slow	3–6	6–11
Glargine	≥60	N/A	≥24

N/A, not applicable.

EVIDENCE BASE Brink, S. (2014). Paediatric and adolescent diabetic ketoacidosis. *Practical Diabetes, 31*(8), 342–347.

BOX 50-2 Treatment of Diabetic Ketoacidosis

INITIATE INTRAVENOUS FLUIDS

- Start with 0.9% normal saline (NS) solution.
- Estimate fluid deficit by amount of weight loss (2.2 lb [1 kg] equals 1 L of fluid). Infuse fluids to replace one half of estimated loss plus maintenance needs (10 to 20 mL/kg) over first 8 to 12 hours; second half plus maintenance needs over next 16 to 36 hours.
- When blood glucose falls below 250 mg/dL, change to 5% glucose in 0.45% NS solution.
- Closely monitor vital signs, electrocardiogram (ECG), and intake and output, and obtain laboratory values, including urine and blood glucose, electrolytes, blood urea nitrogen and creatinine, serum osmolarity, arterial or venous pH, serum and urine ketones, calcium, and phosphorus every 1 to 4 hours as condition warrants.

NURSING ALERT Avoid infusion of hypertonic solutions because ketoacidosis is accompanied by a profound free water deficit. Replace fluids slowly to prevent rapid decline in serum osmolarity, which may precipitate cerebral edema.

ADMINISTER INSULIN

- Give IV bolus of 0.1 unit/kg of regular insulin if no intermediate-acting insulin has been given in the past 6 to 8 hours.
- Provide continuous IV drip of regular insulin at rate of 0.1 unit/kg/hour.
- Continue IV insulin until metabolic acidosis is corrected (pH greater than 7.3 and bicarbonate greater than 13 to 15) and bowel sounds have returned and oral fluids can be taken.
- When meals are tolerated, begin subcutaneous short-acting or rapid-acting insulin at least 30 minutes before discontinuing IV insulin.
- When stabilized, return to previous insulin regimen or begin therapy using conventional dosing (intermediate-acting insulin with short-acting insulin) or basal-bolus therapy (basal insulin with rapid-acting insulin)

NURSING ALERT Flush IV tubing with insulin solution before infusion and change tubing with each bag because insulin will bind to the plastic tubing, changing concentration.

POTASSIUM AND BICARBONATE REPLACEMENT

- Initial serum K levels will be normal or high even though intracellular levels are low. Serum levels will fall as insulin therapy drives K into the cells.
- Begin replacement of K when urine output and renal function have been established.
- Add KCI 20 to 40 mEq to each liter of fluid.
- Monitor T waves on ECG for peaking (hyperkalemia) or flattening (hypokalemia).
- Bicarbonate administration is controversial in correcting acidosis but may be indicated for respiratory depression, decreased myocardial contractility, or refractory, severe acidosis.

Complications

Acute

1. Usually reversible.
2. DKA accounting for 70% of diabetes-related deaths in children younger than age 10 years.
3. Cerebral edema—related to treatment of DKA; thought to be due to a rapid decline in blood glucose causing a fluid shift in the brain.
4. Hyperglycemia (untreated or undertreated).
5. Hypoglycemia (insulin reaction).

Subacute

Develops over a short period.

1. Lipohypertrophy (localized tissue buildup from giving injections in the same site)—repeated injections in the same area; can cause abnormal absorption.

2. Skeletal and joint abnormalities—limited joint mobility.
3. Growth failure and delayed sexual maturation due to underinsulinization.

Chronic

Very rarely seen in children, but develop after years to decades with inadequate treatment.

1. Retinopathy/cataracts—may cause blindness.
2. Neuropathy—peripheral and autonomic.
3. Nephropathy—proteinuria/renal failure.
4. Cardiopathy—heart failure.

Nursing Assessment

1. When the child first presents with suspected DM:
   a. Obtain history of onset of signs and symptoms of clinical manifestations.
   b. Assess for levels of dehydration and weight loss with level of appetite.
   c. Check for sores that are slow to heal.
   d. Identify any fruity smell to breath—acetone breath due to ketosis.
   e. Assess abdominal pain—may mimic appendicitis.
2. For child with DKA:
   a. Assess for potential cerebral edema (diminished LOC) on presentation and when fluid replacement is initiated. Fluid replacements precede and are then concurrent with insulin therapy.
   b. Assess cardiac function—tachycardia with dehydration, arrhythmias related to potassium imbalances.
   c. Assess renal function—urine output with intake and output, ketonuria, glycosuria.
   d. Watch for hypoglycemia—overtreatment of insulin; glucose level correction should be slow. IV replacements frequently contain glucose to prevent large osmotic fluid shifts leading to cerebral edema.
3. During treatment/routine follow-up:
   a. Assess growth parameters—excessive weight gain may indicate overtreatment of insulin (child eats because of constant hunger). Loss or lack of weight gain may indicate underinsulinization (losing calories that are not metabolized).
   b. Review blood glucose diaries and glucose monitor for level of control and need for insulin adjustments. (Check for appropriate adjustments of insulin made by parents.) Glucose should be checked before meals (preprandial) and at bedtime. Optimal levels are age related.
      i. Toddlers and children under age 6: 100 to 180 mg/dL preprandial; 110 to 200 mg/dL at bedtime.
      ii. Children ages 6 to 12: 90 to 180 mg/dL preprandial; 100 to 180 mg/dL at bedtime.
      iii. Adolescents ages 13 to 19: 90 to 130 mg/dL preprandial; 90 to 150 mg/dL at bedtime.
   c. Obtain history of any hypoglycemic reactions—be specific to time of day, dietary record, and exercise

and activity.

d. Assess injection sites—look for signs of lipohypertrophy.

e. Assess for signs of hyperglycemia—polyuria, polydipsia. Does the child need to get up during the night to go to the bathroom?

Nursing Diagnoses

- Deficient Fluid Volume related to osmotic diuresis and vomiting.
- Imbalanced Nutrition: Less Than Body Requirements due to metabolic catabolism due to lack of insulin.
- Deficient Knowledge related to insulin management.
- Deficient Knowledge related to blood glucose monitoring.
- Risk for Unstable Blood Glucose.
- Fear/Anxiety of child and family related to diagnosis, treatment, and management procedures.

Nursing Interventions

Restoring Fluid Balance

1. Administer IV fluids, as ordered.
2. Monitor intake and output, BP, serum electrolyte results, and daily weight.
3. Report abnormal sodium and potassium results promptly.
4. Assess for signs of dehydration—dry skin and mucous membranes, constipation.
5. Encourage oral fluids when able.

Meeting Nutritional Requirements

1. Provide an adequate diet for the child and teach the family about the diet.
   a. The most common meal plan is one based on carbohydrate counting. This type of meal plan offers flexibility and a wide variety of choices. Total carbohydrate requirements will be calculated, then labels can be read and charts consulted to determine grams of carbohydrate per serving of food eaten. Insulin dosage is based on the total amount of carbohydrates eaten; for example, 1 unit of short-or rapid-acting insulin for every 15 g of carbohydrate.
   b. Occasionally, a more rigid, strictly controlled diet is necessary.
   c. The diet should be composed of approximately 55% carbohydrate, 30% fat, and 15% protein.
      i. Some diets are restricted in carbohydrates, saturated fats, and cholesterol and may be based on the exchange method as recommended by the American Diabetes Association.
      ii. Approximately 70% of the carbohydrate content should be derived from complex carbohydrates such as starch.
      iii. Foods with high fiber content should be encouraged.
      iv. All diets must supply sufficient caloric intake for activity and growth, sufficient protein for growth, and the required vitamins and minerals.

d. Foods are distributed throughout the day to accommodate varying peak action of insulin. Distribution may be adjusted for increased or decreased amounts of exercise.

e. Include fluids containing sugar (sodas, juices, milk) in carbohydrate count.

f. Determine the child's usual dietary habits so that adherence to the controlled diet will be easier.

g. Include the child and parents in meal planning as soon as possible.

h. Allow the child normal activity while hospitalized so that the observed result of the dietary control will be valid. Because the child's activity level usually decreases during the hospital stay, the child and family must understand that the insulin and dietary needs will alter on discharge.

i. Allow the child to eat with other children.

j. Make certain that the child adheres to the prescribed diet and understands the rationale for it.

k. Refer family to a dietitian for additional planning and education.

Increasing Knowledge About Insulin Administration

1. Insulin should be given, as directed. Rapid-acting insulin analogues lispro and aspart begin to work immediately and should be given right before the meal. If taking regular insulin, the child should not eat until 20 to 30 minutes after injection is given.
2. Be aware of the major types of insulin and their effects.
3. Develop a systematic plan for injections that emphasizes rotation of sites (Figure 50-3).
   a. The upper arms and thighs are the most acceptable sites for injection in children, but the outer areas of the abdomen or hips may also be used.
   b. Subsequent injections are given about 1 inch (2.5 cm) apart.
   c. Guidelines for site location:
      i. Arms—begin below the deltoid muscle and end one handbreadth above the elbow. Begin at the midline and progress outward laterally, using the external surface only.
      ii. Thighs (see Figure 50-4, page 1350)—begin one handbreadth below the hip and end one handbreadth above the knee. Begin at the midline and progress outward laterally, using only the outer, anterior surface.
      iii. Abdomen—avoid the beltline and 1 inch (2.5 cm) around the umbilicus.
      iv. Buttocks—use the upper outer quadrant of the buttocks.
4. Be certain that the measuring scale of the syringe matches the unit strength on the bottle of insulin. U-100 insulin is preferred because it allows the smallest possible amount to be given. Other concentrations of insulin are rarely used.
5. Opened bottles of insulin may be stored at room temperature or in the refrigerator. Open bottles should be discarded after 28 days. Use insulin that is at room temperature.
   a. The bottle in use may be kept at room temperature for approximately 1 month without losing appreciable strength.
   b. Extra bottles should be stored in the refrigerator.

6. Insulin pens (either prefilled or using insulin cartridges) are increasing in popularity. Pens are generally kept at room temperature once opened and discarded after 28 days; check the manufacturer's directions. All insulin pens require an "air shot" (clearing air from pen) prior to giving *each* dose.
7. Mix insulin solutions, such as NPH and Ultralente, thoroughly by shaking the bottle (rolling may not be effective).
8. Administer insulin subcutaneously. Do not aspirate.
9. Observe the skin closely for signs of irritation. Avoid the injection site for several weeks if signs of local irritation are observed.
10. Observe the skin for a rash indicating an allergic reaction to the insulin (rare with newer preparations). Notify the health care provider immediately if there is an allergic reaction.
11. Be aware of factors that vary the need for and utilization of insulin, particularly exercise and infection.
    a. Exercise tends to lower the blood sugar level. Encourage normal activity, regulated in amount and time.
    b. Infection or illness increases the child's insulin requirement (insulin is still administered during illness). Be alert for signs of infection and dehydration.
12. Encourage the child to express feelings about the injections. The child may be helped to master fear of injections by gaining control of the situation through play and active participation in the procedure.

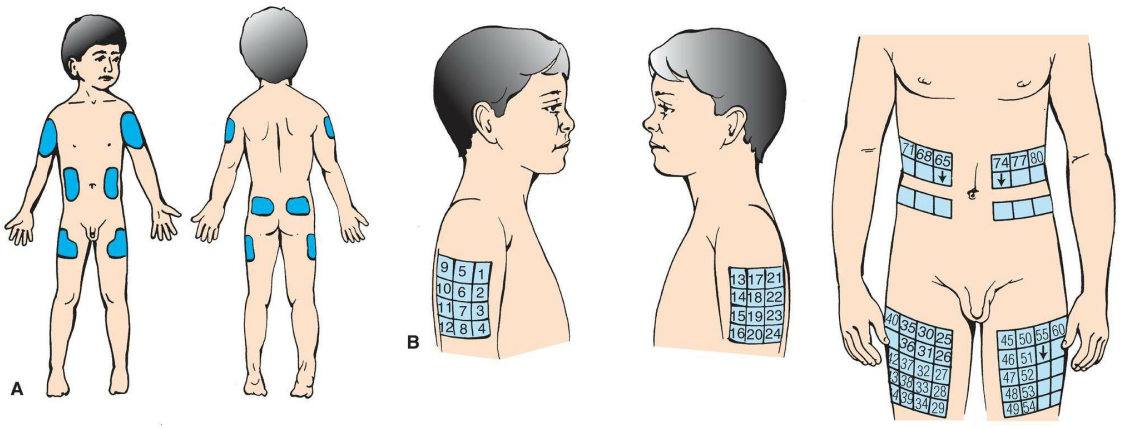

Figure 50-3. (A) Insulin injection sites are the upper outer portions of the arms, the thighs, and the abdominal area. **(B)** Injection sites are rotated, with subsequent injections given about 1 inch (2.5 cm) apart.

Figure 50-4. Insulin injection by a child.

DRUG ALERT None of the basal insulins (detemir, glargine, or glusiline) have been approved by the Food and Drug Administration for mixing with any other insulin.

Providing Information About Blood Glucose Monitoring

1. Teach child and parents the chosen method for blood glucose monitoring.
2. The procedure requires a drop of blood (obtained by fingerstick), a reagent strip, and a glucometer.
3. Specific instructions for performing the procedure vary with the equipment being used and must be followed explicitly.

4. Blood glucose measurements are usually made four times per day—before meals and at bedtime.
5. Additional blood tests are helpful during episodes of hypoglycemic symptoms or other problem situations.
6. Urine tests for ketones should be performed if the child is ill or if blood glucose level is greater than 240 mg/100 dL.
7. Record the results of blood glucose testing accurately.
    a. Use a standard form for recording so that the information will be clear and readily available.
    b. Help the child to understand how the disease is controlled by teaching the child to test his or her own blood, record results, and report information to health care personnel or parents.

Identifying and Controlling Hypoglycemia

1. Have glucagon available for injection if a hypoglycemic reaction occurs and the child is unconscious, has a seizure or is unable to swallow liquids safely, or is combative. Administer 0.5 to 1 mg IM or subcutaneously and assess response.
2. Teach family the causes, signs and symptoms, and treatment for hypoglycemia.
    a. Common causes:
        i. Overdose of insulin.
        ii. Reduction in diet or increased exercise without sufficient caloric coverage.
    b. Symptoms:
        i. Trembling, shaking, dizziness.
        ii. Sweating, apprehension.
        iii. Tachycardia.
        iv. Hunger, weakness.
        v. Drowsiness, unusual behavior.
        vi. Mental confusion.
        vii. Seizures, coma.
    c. Be prepared to give glucose tablets, orange juice, sugar cubes, or another food containing readily available simple sugars.
3. Watch for a pattern of activity or time of day that precedes hypoglycemic reactions and work with family to alter behavior to prevent reactions.
4. If prescribed, teach the child and family how to use an emergency glucagon injection kit.
5. If glucagon is not available and the child is unresponsive, activate the emergency response system (911).

Reducing Fear and Anxiety

1. Explain the need and purpose of every test to child and parents. Allow child to vent feelings and cry if fearful. When appropriate, demonstrate procedures on yourself first (eg, fingersticks for glucose testing, allowing parent to give saline injection for practice of insulin injection).
2. Teach family the pathophysiology of diabetes. Understanding the disease process aids in understanding

the treatment and signs and symptoms. Assess knowledge level of teaching by having family verbalize knowledge of disease management.

3. Allow parents to verbalize feelings related to the expectations of their performance. Stress that the learning is through the actual "hands-on" management. Assist the parents in performing the needed tasks (fingersticks, insulin injections) to build their confidence. Give the parents clear objectives and directions for home management.
4. Stress that the child's condition is now the family's condition as well. Only foods appropriate for the child should be in the home. Stress that child does not need "special foods" different from the rest of the family.
5. Caution the parents that the focus on the child may cause sibling rivalry. Encourage involvement by all family members in making the home a healthy one and urge the parents to give individual attention to nondiabetic children as well.
6. Explain to child that he or she did not cause the disease to occur—young children usually blame themselves for "bad" things that happen to them. Help the child understand that good management is the key to participating in all usual activities. The perspective should be that he or she is a "child with diabetes," not a "diabetic child."

Community and Home Care Considerations

1. Perform home assessment for adequate nutritional resources.
2. Reteach and assess family's adherence to insulin administration and blood glucose monitoring.
3. Reteach and assess family's ability to respond to hypoglycemia.
4. Make sure that school is able to follow through with management plan for insulin administration, planned exercise and mealtimes, and responding to hypoglycemia.
5. When child is ill, evaluate for dehydration, hyperglycemia, and ketonuria. Teach family how to monitor condition, maintain insulin coverage, and notify the health care provider. (See "Diabetes sick-day guidelines," page 748.)

Family Education and Health Maintenance

Patient or parental education is one of the most important aspects in the nursing care of the child with diabetes. Thorough instruction is essential in the following areas:

1. Influence of exercise, emotional stress, and other illnesses on insulin and diet needs.
2. Recognition of the symptoms of insulin shock and diabetic acidosis and knowledge of related emergency management.
3. Prevention of infection:
   a. Attend to regular body hygiene, with special attention to foot care.
   b. Report any breaks in the skin. Treat them promptly.
   c. Use only properly fitted shoes; do not wear vinyl or plastic, which do not permit ventilation. Avoid calluses and blisters. Teach child not to walk barefoot.

d. Dress the child appropriately for the weather.

e. See that the child receives regular dental checkups and maintenance every 6 months.

f. Follow routine immunizations according to the recommended schedule; receive yearly flu vaccination.

4. Precautionary measures:

a. Have the child carry an identifying card that states that he or she has diabetes and includes name, address, telephone number, and health care provider's name and telephone number.

b. Suggest a simple, convenient source of sugar that can be carried easily by the child or parents in a pocket, purse, or backpack to have available for hypoglycemic symptoms. A good example is glucose tablets, glucose gel, five sugar cubes, or cake decorating gel that comes in a tube.

c. Help the family discuss the child's disease with the school nurse and other responsible adults who are in close contact with the child (eg, teachers, scout leaders).

d. Advise parents that vials of insulin should be kept on one's person when traveling because baggage may be subjected to extreme temperatures and pressures incompatible with the stability of insulin. If necessary, a thermos can be used to keep the insulin at the appropriate temperature.

5. Follow up with the primary care provider or pediatrician for immunizations, all regular health checkups, and growth and development evaluations.

6. For additional information and support, refer to agencies, such as American Diabetes Association, ATTN: National Call Center, 2451 Crystal Drive, Suite 900 Arlington, VA 22202, 1-800-DIABETES (800-342-2383), *www.diabetes.org*; and Juvenile Diabetes Research Foundation International, 26 Broadway, 14th floor, New York, NY 10004; 800-JDF-CURE (212-785-9595), *www.jdrf.org*.

Evaluation: Expected Outcomes

- No signs of dehydration.
- Parents and child describe consistent meal plan.
- Child and parents demonstrate correct insulin administration technique.
- Child and parents demonstrate correct glucose monitoring technique.
- Child and parents verbalize causes, signs and symptoms, and treatment for hypoglycemia.
- Child and parents speak openly about diabetes, ask appropriate questions, display no crying.

TRANSITIONAL CARE ALERT After the stress of having a hospitalized child, families will need support in the transition to home or another aftercare location. It is crucial that they have complete and understandable care instructions on home care, and medications and follow up appointments. If arrangements have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to assist understanding, pictorial) instructions on signs and symptoms to monitor for worsening of status. Children with metabolic and endocrine disorders require

careful monitoring with frequent laboratory assessments. Family caregivers may need additional instructions and monitoring equipment to continue optimal care in the home setting.Management of metabolic and endocrine disorders may likely require modifications to daily routine in school and the work place (for older teens and young adults). Nurses should be aware of state and federal guidelines for IEP and 504 documentation for accommodation of the needs to maintain the best outcomes of these conditions.

PEDIATRIC ONCOLOGIC DISORDERS

EVIDENCE BASE American Cancer Society. (2018). Cancer facts and figures. Atlanta, GA. Available: https://www.cancer.org/content/dam/cancer-org/research/cancer-facts-and-statistics/annual-cancer-facts-and-figures/2018/cancer-facts-and-figures-2018.pdf.

Cancer is the leading cause of death from disease in children ages 1 to 14. Cancer incidence in the United States has slowly increased by 0.6% per year since 1975 among children ages 1 to 14 with an estimated 10,270 new cases predicted in 2017. In contrast, childhood cancer deaths have continued to decline by more than two thirds from 1969 (6.5 per 100,000) to 2014 (2.0 per 100,000) annually in the United States. Approximately 1,190 will die from the disease in 2017. There are few known risk factors for childhood cancer; however, the incidence of specific cancers is related to age, gender, ethnic background, and geographical region.

Common types of cancer in children (in order of frequency) include leukemia (29%), brain and central nervous system (CNS) cancers (26%), neuroblastoma (6%), Wilms tumor (5%), lymphoma (8%), rhabdomyosarcoma (3%), osteosarcoma (2%), retinoblastoma (2%), and bone cancer (1%). Childhood cancers are treated with surgery, radiation and chemotherapy, blood and marrow transplant, immunotherapy, and gene therapy.

Cancers in adolescents (15 to 19 years) differ somewhat from those in children in terms of type and distribution. For example, brain and other nervous system tumors (21%) and lymphoma (20%) are equally common. Leukemia is third (13%), followed by germ cell and gonadal tumors (11%) and thyroid carcinoma (11%). Melanoma of the skin accounts for 4% of the cancers diagnosed in adolescents.

Acute Lymphocytic Leukemia

EVIDENCE BASE Hunger, S. P., & Mullighan, C. G. (2015). Acute lymphoblastic leukemia in children. *New England Journal of Medicine, 373*(16), 1541–1552.

National Cancer Institute. (2017). Childhood acute lymphoblastic leukemia treatment (PDQ)—Health professional version. Available: *www.cancer.gov/types/leukemia/hp/child-all-treatment-pdq*.

Acute lymphocytic leukemia (ALL) is a primary disorder of the bone marrow in which the normal marrow elements are replaced by immature or undifferentiated blast cells. When the quantity of normal marrow is depleted below the level necessary to maintain peripheral blood elements within normal ranges, anemia, neutropenia, and thrombocytopenia occur. ALL is the most common malignancy in children, representing more than a quarter of all pediatric cancers (29%). The peak incidence in children is ages 2 to 5 years, and incidence subsequently decreases with age. The annual incidence of ALL within the United States is 3.7 to 4.9 cases per 100,000 children ages 0 to 14. Advances in cancer treatment have led to marked improvements in survival rates among children greater than 80%. It is more common among white and Hispanic children and is more common in boys than in girls.

Pathophysiology and Etiology

1. The exact cause of ALL is unknown.
2. Environmental factors, as well as genetic factors and chromosomal abnormalities are suspected in some cases.
3. ALL results from the growth of an abnormal type of nongranular, fragile leukocyte in the blood-forming tissues, particularly in the bone marrow, spleen, and lymph nodes.
4. The abnormal lymphoblast has little cytoplasm and a round, homogeneous nucleus (see Figure 51-1).
5. ALL is classified according to the cell type involved: T-lymphoblastic leukemia or B-lymphoblastic leukemia.
6. Normal bone marrow elements may be displaced or replaced in this type of leukemia.
7. The changes in the blood and bone marrow result from the accumulation of leukemic cells and from the deficiency of normal cells.
    a. Red blood cell (RBC) precursors and megakaryocytes from which platelets are formed are decreased, causing anemia, prolonged and unusual bleeding, tendency to bruise easily, and petechiae.
    b. Normal white blood cells (WBCs) are significantly decreased, predisposing the child to infection.
    c. The bone marrow is hyperplastic, with a uniform appearance caused by leukemic cells.
8. Leukemic cells may infiltrate into lymph nodes, spleen, and liver, causing diffuse adenopathy and hepatosplenomegaly.
9. Expansion of marrow or infiltration of leukemic cells into bone causes bone and joint pain.

10. Invasion of the CNS by leukemic cells may cause headache, vomiting, cranial nerve palsies, convulsions, coma, papilledema, and blurred or double vision.
11. Weight loss, muscle wasting, and fatigue may occur when the body cells are deprived of nutrients because of the immense metabolic needs of the proliferating leukemic cells.

Figure 51-1. Abnormal lymphoblast in acute lymphocytic leukemia.

Clinical Manifestations

1. Manifestations depend on the degree to which the bone marrow has been compromised and the location and extent of extramedullary infiltration.
2. Presenting symptoms:
   a. Fatigability.
   b. General malaise, listlessness.
   c. Persistent fever of unknown cause.
   d. Recurrent infection.
   e. Petechiae, purpura, and ecchymosis after minor trauma.
   f. Pallor.
   g. Generalized lymphadenopathy.
   h. Abdominal pain caused by organomegaly.

i. Bone and joint pain.

j. Headache and vomiting (with CNS involvement).

3. Presenting symptoms may be isolated or in any combination or sequence.

Diagnostic Evaluation

1. May have altered peripheral blood counts. Blood studies may show the following:
   a. Low hemoglobin level, RBC count, hematocrit, and platelet count.
   b. Decreased, elevated, or normal WBC count.
2. Bone marrow examination and stained peripheral smear examination show large numbers of lymphoblasts and lymphocytes.
3. Lumbar puncture to assess for lymphoblasts in CNS to determine CNS involvement.
4. Renal and liver function studies determine contraindications or precautions for chemotherapy.
5. Chest x-ray determines whether a mediastinal mass or pneumonia is present.
6. Varicella and cytomegalovirus titer determine risk of infection.
7. The CNS and testes are sites of "sanctuary"; CNS treatment and surveillance is standard and testes are evaluated with physical examinations.

Management

1. Supportive therapy is indicated to control such disease complications as hyperuricemia, electrolyte imbalance, infection, anemia, bleeding, pain, nausea/vomiting, and fatigue.
2. Specific therapy is warranted to eradicate malignant cells and to restore normal marrow function.
3. Chemotherapy is used to achieve complete remission, with restoration of normal peripheral blood and physical findings; it is administered through an indwelling central catheter or implantable port. (See Table 51-1.)
4. Although no universally accepted standard therapy for the treatment of children with ALL exists, most facilities have similar protocols that use a combination of drugs.
5. Components of therapy:
   a. Induction, the initial course of therapy designed to achieve complete remission, usually lasts 4 to 6 weeks. For those who do not achieve complete remission by the end of induction therapy, an allogeneic bone marrow transplant is usually pursued. Induction usually includes a combination of vincristine, L-asparaginase, and corticosteroids. A fourth drug, such as daunorubicin, doxorubicin, or cytosine arabinoside, may be added.
   b. Consolidation treatment, a period of intensified treatment immediately after remission induction, attempts total eradication of residual leukemic cells. Consolidation treatment usually lasts approximately 6 to 9 months, but can vary in length based on different protocols. It usually includes a combination of methotrexate, 6-mercaptopurine, etoposide, thioguanine, cytosine arabinoside, cyclophosphamide, prednisone, vincristine, L-asparaginase, and doxorubicin or daunorubicin.
   c. Maintenance or continuation therapy is the final and often longest stage of treatment in childhood

ALL. The goal of maintenance therapy is to lower the risk of relapse once remission has been achieved, and typically lasts 2 to 3 years. Boys require longer maintenance therapy to prevent testicular relapse in some protocols. It usually includes daily oral administration of 6-mercaptopurine and weekly oral or IM administration of methotrexate with intermittent administration of other drugs, such as monthly vincristine, corticosteroids, cyclophosphamide, cytosine arabinoside, or daunorubicin.

d. Reinduction therapy induces remission if relapse occurs and usually includes the same initial drugs. Sometimes, however, additional agents may be added.

e. If testicular relapse occurs, radiation therapy to the testicles is administered.

f. CNS disease prophylaxis generally consists of intrathecal administration of methotrexate alone or in combination with intrathecal or systemic therapy that can cross the blood–brain barrier including cytarabine and hydrocortisone. Craniospinal irradiation may also be used to treat CNS disease.

g. The role of allogeneic hematopoietic stem cell transplant (HSCT) is considered for those patients with very high risk of relapse and/or treatment failure. Components of this therapy usually include total body irradiation (TBI) and chemotherapy agents in the preparative regiment and undergo transplant from either a matched sibling or alternate donor sources.

6. Current standards of treatment are designed on risk-based criteria; patients with worse prognostic indicators receive more intensive therapy.

7. Blood and marrow transplantation has been used successfully to treat children who fail to respond to conventional treatment.

Table 51-1 Commonly Used Chemotherapeutic Agents to Treat Acute Lymphocytic Leukemia

CHEMOTHERAPEUTIC AGENT	COMMON SIDE EFFECTS
Asparaginase	Pain at injection site Allergic reaction Increased plasma ammonia level Clotting factor abnormalities Fatigue, weakness Diarrhea
Cytarabine	Nausea, vomiting Fever Headache
Methotrexate	Nausea, vomiting Headache Elevated liver enzymes Mucositis Nephrotoxicity
Vincristine	Hair loss Neuropathy Constipation
Daunorubicin	Nausea, vomiting Hair loss Red urine Bone marrow suppression Cardiac dysfunction
Cytoxan	Nausea, vomiting Hair loss Loss of appetite Gonadal dysfunction Bone marrow suppression Nephrotoxicity
Mercaptopurine	Bone marrow suppression
Thioguanine	Bone marrow suppression

DRUG ALERT Assess the patient and monitor vital signs after administration of L-asparaginase–type drugs for signs of anaphylaxis. Have emergency drugs and equipment at the bedside (oxygen, epinephrine, antihistamines, and steroids). If administering in the outpatient setting, observe patients for at least 1 hour.

Prognosis

1. At least 98% of children with ALL can be expected to achieve an initial remission if treated in a specialized facility.
2. Overall 5-year survival is 90%.
3. The prognosis becomes poorer with each relapse the child experiences.

4. Relapse is rare after 7 years from diagnosis.
5. Factors associated with prognosis:
    a. Initial WBC count (WBC count greater than 50,000 has worse prognosis).
    b. Age (younger than age 2 years and older than 10 years have poorer prognosis, and infants younger than 1 year of age have even worse prognosis).
    c. Extramedullary involvement (poorer prognosis).
    d. Type of leukemia cytogenetic factors and immunophenotype (DNA index, karyotype).

Complications

1. Infection—most frequently occurs in the blood, lungs, GI tract, or skin. Patients with central lines are at increased risk.
2. Hemorrhage—usually caused by thrombocytopenia.
3. CNS involvement.
4. Bony involvement.
5. Testicular involvement.
6. Urate nephropathy (rarely seen except in induction).
7. Acute complications of treatment (eg, cardiomyopathy).
8. Late effects of treatment (treatment specific). Most frequent long-term complication is neurocognitive dysfunction causing school difficulty.

Nursing Assessment

1. Obtain a history.
    a. When taking the history, focus on symptoms that led to the diagnosis and previous symptoms for the past 2 weeks. For example, inquire about fatigue, headache, nausea, vomiting, pallor, bleeding, pain, or fever.
    b. Ask about past history of varicella zoster infection (chickenpox), which could lead to disseminated infection if acquired during immunosuppression. Also ask about recent exposures, including sibling exposures.
2. Perform a physical examination, including:
    a. Examination of skin for petechiae, purpura, and ecchymosis.
    b. Palpation of lymph nodes for enlargement, tenderness, and mobility.
    c. Palpation of spleen and liver for enlargement.
    d. Examination of fundi to detect papilledema with CNS disease.
    e. Inspection of skin for areas of infection, including indwelling catheter sites.
    f. Auscultation of lungs for crackles or rhonchi, indicative of pneumonia.
    g. Temperature for fever.
3. Assess family coping mechanisms and use of resources such as support systems.

NURSING ALERT Report changes in behavior or personality, persistent nausea, vomiting, headache, lethargy, irritability, dizziness, ataxia, convulsions, or alterations in state of consciousness. These may be signs of CNS disease or relapse. CNS relapse is usually caught on routine screening.

Nursing Diagnoses

- Anxiety of parents related to learning of diagnosis.
- Risk for Infection and hemorrhage related to bone marrow suppression caused by chemotherapy and disease.
- Disturbed Body Image related to alopecia associated with chemotherapy.
- Imbalanced Nutrition: Less than Body Requirements related to anemia, anorexia, nausea, vomiting, pain, stress, inflammation, psychological problems, taste aversion, and mucosal ulceration secondary to chemotherapy or radiation.
- Acute Pain related to diagnostic procedures, progression of the disease, and adverse effects of treatment.
- Activity Intolerance related to fatigue that results from the disease and treatment.
- Anxiety of child related to hospitalization and diagnostic and treatment procedures.

Nursing Interventions

Decreasing Parental Anxiety

1. Be available to the parents when they want to discuss their feelings.
2. Offer kindness, concern, consideration, and sincerity toward the child and parents; be a source of consolation.
3. Contact the family's clergyman or the hospital chaplain.
4. Obtain the services of a social worker, as appropriate, to help the family use appropriate community resources.
5. Offer hope that therapy will be effective and will prolong life.
6. Have parents speak with parents of a child currently on therapy.
7. Encourage parents to participate in activities of daily living to help them feel a part of their child's care.
8. Assess family dynamics and coping mechanisms and plan interventions accordingly.
9. Help the parents to deal with anticipatory grief.
10. Help the parents to deal with other family members and friends.
11. Encourage the parents to discuss concerns about limiting their child's activities, protecting child from infection, disciplining child, and having anxieties about the illness.
12. Facilitate communication with the clinic nurse or clinical specialist who may interact with the child during the entire course of illness.
13. Encourage parents to continue established family patterns, including school attendance, social life, and

family activities, as medically indicated.

Preventing Infection and Hemorrhage

EVIDENCE BASE Linder, L., Gerdy, C., Abouzelof, R., et al. (2017). Using practice-based evidence to improve supportive care practices to reduce central line-associated bloodstream infections in a pediatric oncology unit. *Journal of Pediatric Oncology Nursing, 34*(3), 185–195.

1. Monitor complete blood count (CBC), as ordered.
2. Provide adequate hydration.
   a. Maintain parenteral fluid administration.
   b. Offer small amounts of oral fluids, if tolerated.
3. Observe renal function carefully.
   a. Measure and record urine output.
   b. Check specific gravity.
   c. Observe the urine for evidence of gross bleeding.
   d. Use lab sticks to determine if occult urinary bleeding is present.
4. Protect the child from infection sources.
   a. Never use a rectal thermometer, suppositories, or enemas when caring for a neutropenic patient.
   b. Family, friends, personnel, and other patients who have infections should not visit or care for the child. Discuss care of siblings while the child is on therapy.
   c. Private rooms are preferred, but if it is necessary to share, do not place a child with an infection in the same room with a child with leukemia.
   d. Good hand washing is the most important way to control infection.
5. Observe the child closely and be alert for signs of impending infection.
   a. Observe broken skin or mucous membrane for signs of infection.
   b. Report fever of more than 101˚F (38.3˚C).
   c. Assess central line site for redness or tenderness.
6. Administer growth factors, such as granulocyte colony–stimulating factor, to stimulate the production of neutrophils and to decrease the incidence of severe infections in the child after high-dose chemotherapy.
7. Administer IV antibiotics, as ordered.
8. Administer PCP prophylaxis, such as cotrimoxazole, if ordered, twice daily three times per week to prevent infection with *Pneumocystis carinii*. (Dapsone and pentamidine are also given for patients unable to take cotrimoxazole.)
9. Record vital signs and report changes that may indicate hemorrhage, including:
   a. Tachycardia.

b. Lowered blood pressure.
c. Pallor.
d. Diaphoresis.
e. Increasing anxiety and restlessness.

10. Observe for GI bleeding and Hematest all emesis and stool.
11. Move and turn the child gently because hemarthrosis may occur and may cause pain.
    a. Handle the child in a gentle manner.
    b. Turn the child frequently to prevent pressure ulcers.
    c. Place the child in proper body alignment in a comfortable position.
    d. Allow the child to be out of bed in a chair if this position is more comfortable.
    e. Encourage the child to ambulate, if possible.
12. Avoid IM injections, if possible; if not possible, ensure platelet count has been obtained prior to injection and hold pressure to the area for at least 5 minutes.
13. Handle catheters and drainage and suction tubes carefully to prevent mucosal bleeding.
14. Protect the child from injury by monitoring activities and exposure to environmental hazards, such as slippery floors or uneven surfaces.
15. Be aware of emergency procedures for control of bleeding:
    a. Apply local pressure carefully so as not to interfere with clot formation.
    b. Administer leukocyte-poor, irradiated, packed RBCs and platelets, as ordered.

NURSING ALERT Patients with low WBC count may not respond to infection with usual signs and symptoms (ie, fever and purulent drainage from infected wound).

Promoting Acceptance of Body Changes

1. Prepare the patient for potential changes in body image (alopecia, weight loss, muscle wasting) and help the child cope with related feelings.
2. Engage child life therapist for medical play and support.
3. Contact the school nurse and teacher to help them prepare for the child's return to school. Discuss the bodily changes that have occurred and that may happen in the future.

Promoting Optimal Nutrition

EVIDENCE BASE Arpaci, T., Toruner, E., & Altay, N. (2018). Assessment of nutritional problems in pediatric patients with cancer and the informational needs of their parents: A parental

perspective. *Asia-Pacific Journal of Oncology Nursing, 5*(2), 231–236.

1. Provide a highly nutritious diet as tolerated by the child.
    a. Determine the child's food likes and dislikes.
    b. Offer frequent, small meals.
    c. Offer high-calorie, high-protein supplemental feedings.
    d. Encourage the parents to assist at mealtime.
    e. Allow the child to eat with a group at a table if his or her condition allows.
    f. Avoid foods high in salt while the child is taking steroids.
    g. Administer enteral and parenteral feeds, as ordered.
2. Give careful oral hygiene; the gums and mucous membranes of the mouth may bleed easily.
    a. Use a soft toothbrush.
    b. If the child's mouth is bleeding or painful, clean the teeth and mouth with a moistened cotton swab or sponge-tipped swab.
    c. Use a nonirritating rinse for the mouth (no alcohol-containing mouthwash or sodium bicarbonate).
    d. Apply petroleum to dry, cracked lips.
    e. Assess for mucositis and provide appropriate mouth rinse.
3. Be alert for nausea and vomiting.
    a. Administer antiemetic drugs on a round-the-clock, regular schedule (eg, serotonin antagonist, dexamethasone).
    b. Become knowledgeable about chemotherapeutic agents and adjust antiemetic therapy for those drugs with delayed nausea and vomiting.
    c. Monitor strict intake and output.
    d. Maintain parenteral fluid administration and assess for signs of dehydration or overhydration.
    e. Administer antiemetic drugs for patients who receive radiation to the chest, abdomen, pelvis, or craniospinal axis.
    f. Suggest relaxation techniques or guided imagery for patients who experience anticipatory nausea and vomiting.

Relieving Pain

EVIDENCE BASE Mercadante, S., & Giarratano, A. (2014). Pharmacological management of cancer pain in children. *Critical Reviews in Oncology/Hematology, 91*(1), 93–97.

Wiffen, P. J., Cooper, T. E., Anderson, A. K., Gray, A. L., Grégoire, M. C., Ljungman, G., & Zernikow, B. (2017). Opioids for cancer-related pain in children and adolescents. *The Cochrane Library*, (7), CD012564.

1. Position the child for comfort.
2. Assess the child's pain using a developmentally appropriate pain scale at regular intervals.
3. Administer drugs on a preventive schedule before pain becomes intense. Continuous infusion pumps for opioid administration are commonly used.
4. Manipulate the environment, as necessary, to increase the child's comfort and to minimize unnecessary exertion.
5. Prepare the child for treatment and diagnostic procedures.
    a. Use knowledge of growth and development to prepare the child for such procedures as bone marrow aspirations, spinal taps, blood transfusions, and chemotherapy.
    b. Provide a means for talking about the experience. Play, storytelling, or role-playing may be helpful.
    c. Convey to the child an acceptance of fears and anger.
    d. Use anesthetic cream at spinal tap, injection, and bone marrow sites to decrease pain.
    e. Administer conscious sedation before procedures and monitor pulse, BP, respirations, and pulse oximetry during and after procedures.
6. Consider implementing complementary and alternative medicine (CAM) interventions for pain control as well as for management of nausea, vomiting, and anxiety. CAM strategies to consider include the following:
    a. Hypnosis/self-hypnosis.
    b. Imagery.
    c. Distraction/relaxation techniques.
    d. Cognitive-behavioral therapy.
    e. Music therapy.
    f. Massage.

Conserving Energy

1. Assess the child's energy level and space needed activities accordingly. Allow the child to rest, if necessary.
2. Encourage the child to limit strenuous activity after such diagnostic procedures as bone marrow aspirations and spinal taps.

Reducing the Child's Anxiety

1. Provide for continuity of care.
2. Encourage family-centered care.
3. Facilitate play activities for the child and use opportunities to communicate through play.
4. Maintain some discipline, placing calm limitations on unacceptable behavior.
5. Provide appropriate diversional activities.

6. Encourage independence and provide opportunities that allow the child to control his or her environment.
7. Explain the diagnosis and treatment in age-appropriate terms.

Community and Home Care Considerations

EVIDENCE BASE Brandowicki, P., Vessey, J., Temple, K., et al. (2016). Building bridges from hospital to home. *Journal of Pediatric Oncology Nursing, 33*(5), 370–377.

---

1. Begin to develop a home care plan before the child leaves the hospital.
2. Communicate with health care provider, hospital nurses, family, and others familiar with the case to gather information about the child's illness, treatment plan, and specific needs in the home.
3. Arrange schedule for blood draws and how results will be managed.
4. Contact the child's school and arrange a meeting with the school nurse, principal, appropriate teachers, and other relevant school personnel to explain child's diagnosis, treatment, and potential time away from school.
5. Discuss with patient the possibility of making a visit to the classroom; explain about cancer and the adverse effects of chemotherapy to facilitate school reentry in a manner that would be understood by classmates.
6. Collaborate with primary care provider regarding immunization schedule and the contraindication for children on immunosuppressive therapy.
7. Make sure that parents or caregivers can demonstrate the proper technique for care of venous access, such as dressing changes, flushing, and assessing for infection.
8. Ensure parents or caregivers receive education for home medications, including medication schedule, side effects, and indications for scheduled and PRN medications.

Family Education and Health Maintenance

1. Teach parents about normal CBC values and expected variations caused by therapy.
2. Instruct parents about leukemia and adverse effects of chemotherapy.
3. Tell parents to call the health care provider if the child has a fever of more than 101°F (38.3°C), which may indicate overwhelming infection and impending septic shock, bleeding, and signs of infection. Parents should also immediately report if the child has been exposed to chickenpox. Immunosuppressed children are in danger of developing disseminated varicella and may be treated prophylactically with varicella immune globulin.
4. Teach preventive measures, such as hand washing and isolation from children with communicable diseases.
5. Reinforce that parents are *never* to use a rectal thermometer.

6. Refer parents to such agencies as Candlelighters (*www.candlelighters.org*) or the Leukemia and Lymphoma Society (*www.leukemia-lymphoma.org*).

Evaluation: Expected Outcomes

- Parents discuss their feelings about the child's diagnosis and treatment.
- Remains afebrile, no signs of localized infection or bleeding.
- Maintains a positive body image.
- Eats enough calories to maintain weight.
- Experiences relief from pain (no crying or expression of pain).
- Rests at intervals.
- Acts out feelings in play; participates in age-appropriate activities.

Brain Tumors in Children

EVIDENCE BASE National Cancer Institute. (2017). Childhood astrocytomas treatment (PDQ)—Health professional version. Available: *www.cancer.gov/types/brain/hp/child-astrocytoma-treament-pdq*.

Paul, S. P., Perrow, R., & Webster, M. A. (2014). Brain tumours in children: Reducing time to diagnosis: Siba Prosad Paul and colleagues discuss the role of emergency nurses in the acute management of brain tumours in children and young people. *Emergency Nurse, 22*(1), 32–36.

Brain tumors are abnormal and uncontrollable growth of cells in the brain. Approximately 25% of the malignant tumors that occur in children are brain tumors, with an incidence rate of 4.84 per 100,000 children age 0 to 19 years. Tumors occurring in the CNS are the most common cause of death from childhood cancers. Of the children that do survive a brain tumor, approximately 60% will be left with a life-altering disability. Four main types of brain tumors appear in children. Glial cell tumors, including *astrocytoma* and *diffuse pontine glioma*, can grow at any location in the brain and account for approximately 30% to 40% of all pediatric brain tumors. *Medulloblastoma* is a type of embryonal tumor, which is highly malignant and rapidly growing, usually found in the cerebellum. Embryonal tumors are the most common tumors of the CNS in children. *Ependymoma* is a tumor derived from the ependyma, or lining of the central canal of the spinal cord and cerebral ventricles. It frequently arises on the floor of the fourth ventricle, causing obstruction of the flow of cerebrospinal fluid (CSF). Ependymomas represent approximately 5% to 10% of all primary childhood CNS tumors. *Germ cell tumors* are midline tumors typically diagnosed in children age 6 to 14 years with a higher incidence in parts of Asia, specifically Japan.

Pathophysiology and Etiology

1. The etiology of brain tumors is unknown. Triggers that are found to be associated with increased risk of brain tumors include certain genetic syndromes and environmental factors.
2. Symptoms are associated with the location of the tumor, size of the tumor, rate of growth, and chronologic and developmental age of the child.
3. Astrocytomas typically present in the infratentorial region, producing increased intracranial pressure (ICP). It is classified according to its malignancy, from grade I (least malignant) to grade IV (most malignant). More than 80% of astrocytomas located in the cerebellum are low grade I. Surgery and radiation are the primary therapies.
4. Medulloblastoma grows rapidly and produces evidence of increased ICP progressing during several weeks. It is classified as standard risk or high risk depending on tumor histology. Combination therapy of surgery, radiation, and chemotherapy is usually required.
5. Germ cell tumors grow in the midline of the brain and the majority present in the supraseller or pineal regions. The growth rate varies, but frequently symptoms precede diagnosis by several months.

6. Ependymomas grow with varying speed. Because of location, tumors can invade the cardiorespiratory center, cerebellum, and spinal cord. They are graded according to degree of differentiation.

Clinical Manifestations

Glial Cell Tumors

Onset and growth is related to stage of tumor.

1. Evidence of increased ICP—especially ataxia, vomiting, or headache.
2. Cerebellar signs—ataxia, dysmetria (inability to control the range of muscular movement), and nystagmus.
3. Behavioral changes.
4. Seizures.
5. Precocious puberty.
6. Vision and hearing problems.

Medulloblastoma

Fast growing, malignant, and invasive.

1. The child may present with unsteady gait, anorexia, vomiting, and early morning headache.
2. May later develop ataxia, nystagmus, papilledema, drowsiness, increased head circumference, head tilt, and cranial nerve palsies. May develop obstructive hydrocephalus.

Germ Cell Tumor

Signs of midline shifts.

1. Visual disturbances.
2. Personality and sleep pattern alterations.
3. Dramatic weight loss.
4. Hydrocephalus.
5. Endocrinopathies.
6. Seizures.

Ependymoma of the Fourth Ventricle

1. Signs of increased ICP.
    a. Nausea or vomiting.
    b. Headache.
2. Unsteady gait or ataxia; dysmetria.
3. Focal motor weakness, vision disturbances, seizures.

Diagnostic Evaluation

Determined by the type of tumor that is suspected; usually includes many or all of the following procedures to

localize and determine extent of the tumor:

1. Computed tomography (CT).
2. Magnetic resonance imaging (MRI).
3. Fluid-attenuated inversion recovery imaging.
4. Positron emission tomography (PET).
5. Lumbar puncture with CSF cytologic evaluation (not commonly performed).
6. Angiography (occasional).

Management

1. Surgery is performed to determine the type of tumor, to assess the extent of invasiveness, and to excise as much of the lesion as possible.
2. Radiation therapy is usually initiated as soon as the diagnosis is established and the surgical wound is healed.
3. Chemotherapy is used to treat chemoresponsive tumors and is particularly important in children who are too young to receive radiation therapy.
4. A ventriculoperitoneal shunt is usually necessary for children who develop hydrocephalus.
5. The use of immunotherapy is being investigated for potential for future treatment.
6. Prognosis is improved in cases that involve early diagnosis and adequate therapy. Five-year survivors are increasing, especially in children with low-grade astrocytomas or ependymomas. However, there are still tumors such as diffuse intrinsic pontine glioma that have no known cure.

Complications

1. Brain stem herniation.
2. Hydrocephalus.
3. Permanent neurological disabilities.
4. Increased risk for bone fractures.
5. Increased risk of developing other tumors later in life.

Nursing Assessment

Assess the child's neurologic status to help locate the site of the tumor and the extent of involvement as well as to identify signs of disease progression.

1. Obtain a comprehensive nursing history from the child and parents, particularly data related to normal behavioral patterns and presenting symptoms.
2. Perform portions of the neurologic examination, as appropriate. Assess muscle strength, coordination, gait, posture, and how well the senses and reflexes work.
3. Observe for the appearance or disappearance of the clinical manifestations previously described. Report these to the health care provider and record each of the following in detail:

a. Headache—onset, beneficial and provoking factors, duration, location, severity, and impact.
b. Vomiting—onset, amount, presence of blood, color, frequency, and foods eaten in the past 24 hours.
c. Seizures—activity before seizure, type of seizure, areas of body involved, behavior and level of consciousness (LOC) during and after seizure, duration, changes to skin, heart rate, and respiratory status.

4. Monitor vital signs frequently, including BP and pupillary reaction.
5. Monitor ocular signs. Check pupils for size, equality, reaction to light, and accommodation.
6. Observe for signs of brain stem herniation—should be considered a neurosurgical emergency. This complication occurs when brain tissue, CSF, and blood vessels are pressed or shifted from their usual position inside of the skull.
   a. Abnormal posturing (opisthotonis) caused by muscle spasms. (see figure 51-2.).
   b. Tilting of the head; neck stiffness.
   c. Poorly reactive and dilated pupils.
   d. Increased BP; widened pulse pressure.
   e. Change in respiratory rate and nature of respirations.
   f. Irregular pulse or decreased pulse rate.
   g. Alterations of body temperature.

NURSING ALERT Signs of brain stem herniation, especially opisthotonos, are ominous and considered a medical emergency. The health care provider should be called immediately, and the child should be prepared for ventricular tap to relieve pressure. Resuscitation equipment needs to be readily available.

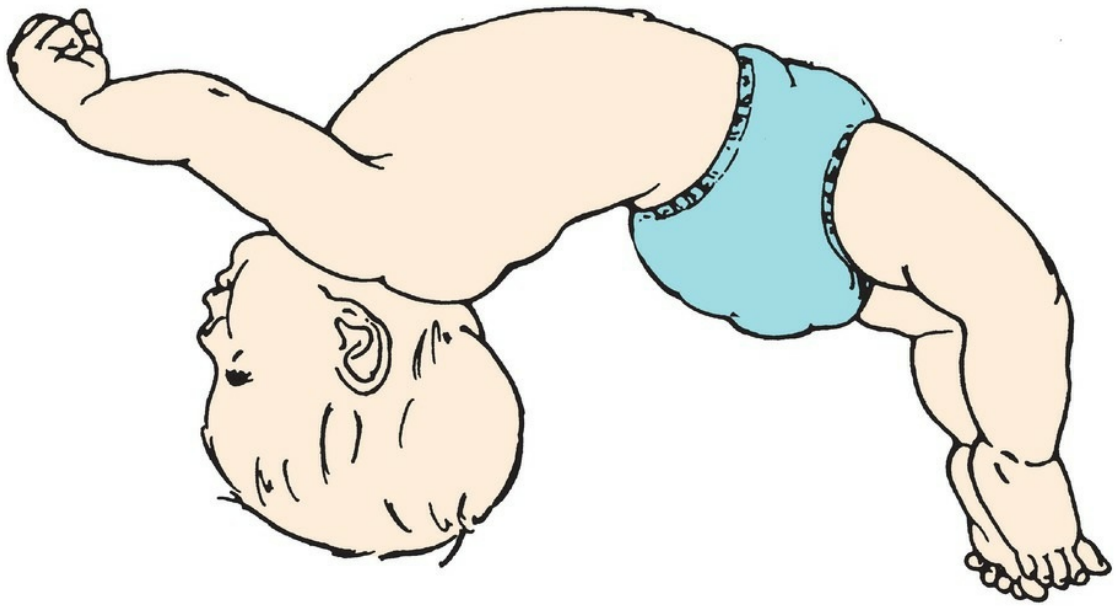

Figure 51-2. Opisthotonos, a sign of brain stem herniation.

Nursing Diagnoses

- Anxiety of parents related to the nature of the diagnosis and the need for surgery.
- Fear of child related to hospitalization and to diagnostic and treatment procedures.
- Acute Pain related to increased ICP and surgery.
- Imbalanced Nutrition: Less than Body Requirements related to nausea and vomiting associated with increased ICP, chemotherapy, and radiation.
- Risk for Infection postoperatively.
- Disturbed Body Image related to appearance of the incision, shaved head, or changes caused by radiation, chemotherapy, and steroids.

Nursing Interventions

Reducing Parents' Anxiety

1. Continue to keep the parents updated about their child's progress and be honest about differential diagnoses.
2. Encourage the parents to ask questions and to understand fully the risks and benefits of surgery and other interventions.
3. Prepare the parents for the postoperative appearance of their child and for the fact that the child might be comatose immediately following surgery.
4. Provide emotional support for the parents during the postoperative period. They may be frightened, shocked, anxiety, and upset by the appearance of their child and by necessary emergency procedures.
5. Facilitate the return of normal parent–child relationships.
    a. The parents may be overprotective.
    b. Help the parents to see the child's increasing capabilities and clinical progression.
    c. Encourage parents to foster independence with their child.
    d. Help the parent prepare to adjust to the transition from an inpatient setting to outpatient, follow-up care.
    e. Direct the parent to services and resources that may support them with the financial costs associated with care and treatment.

EVIDENCE BASE American Cancer Society. (2017). Children diagnosed with cancer: Returning to school. Atlanta, GA. Available: *www.cancer.org/treatment/children-and-cancer/when-your-child-has-cancer/returning-to-school.html*.

TRANSITIONAL CARE ALERT It is important for children with cancer to return to school as soon as they can as it provides them with a clear message that they have a future and potential for full recovery. Their lives become more normal, and it allows opportunity for social interaction with peers.

Reducing the Child's Fear

1. Prepare the child for surgery in realistic terms, but at the appropriate developmental level. Involve the child life therapist and social worker in the preparation process.
2. Encourage the child to ask questions and express concerns.
3. Determine the plan regarding shaving of the child's head, bandages, and other procedures. Prepare the child accordingly.
4. Prepare the child for postoperative expectations (eg, may feel sleepy, have a headache, will need to remain flat, and will see IV tubes, drainage tubes, and machines attached to him or her). Arrange visit to pediatric intensive care unit before surgery to prepare for environment.
5. Bring a comfort item (eg, special blanket or favorite toy) for the child to have in possession postoperatively.

Reducing Pain Postoperatively

1. Administer opioids, as ordered, in the immediate postoperative period, assessing the child's LOC prior to administration as well as the child's response to opioid administration.
2. Keep the child as comfortable as possible by repositioning.
3. Apply nonpharmacological techniques for pain management in combination with opioid administration.

Maintaining Nutritional Status

1. Feed the child after vomiting. (Vomiting is not usually associated with nausea.)
2. Allow the child to participate in the selection of foods.
3. Maintain IV hydration or hyperalimentation and intralipids, if indicated.
4. Encourage the child to eat progressively larger meals as he or she recovers.
5. If the child cannot eat, provide tube feedings. A gastrostomy tube may be inserted.
6. Be aware that children taking steroids to decrease swelling may have increased appetite.
7. Monitor weight and laboratory values daily to ensure efficacy of nutritional support.

Preventing Infection and Other Complications Postoperatively

1. Position the child according to surgeon's request—usually on unaffected side with head level with body.
    a. Raising the foot of the bed may increase ICP and bleeding.
    b. Post a sign above the bed, noting the exact position of the head.
2. Check the dressing for bleeding and for drainage of CSF.

3. Monitor the child's temperature closely.
    a. A significant rise in temperature may be caused by trauma, disturbance of the heat-regulating center, or intracranial edema.
    b. If hyperthermia occurs, administer antipyretics and use cooling techniques, as ordered. Temperature should not be reduced too rapidly.
4. Observe the child closely for signs of shock, increased ICP, seizure activity, and alterations in LOC.
5. Assess the child for edema of the head, face, and neck.
6. Carefully regulate fluid administration and blood pressure to prevent increased cerebral edema.
7. Change the child's position frequently and provide meticulous skin care to prevent hypostatic pneumonia and pressure ulcers.
    a. Move the child carefully and slowly, being certain to move the head in line with the body.
    b. Support paralyzed or spastic extremities with pillows, rolls, or other devices.
8. Have equipment readily available for cardiopulmonary resuscitation, respiratory assistance, oxygen inhalation, blood transfusion, ventricular tap, and other potential emergency situations.
9. Report fever or sign of infection.
10. If the child is receiving chemotherapy or radiation, assess for fever greater than 101°F (38.3°C) or nausea and vomiting unrelated to chemotherapy.

Promoting Acceptance of Body Changes

1. Encourage the child to express feelings regarding the threat to body image.
2. Reassure the child that a wig or a hat can be worn after recovery. Refer parents to *www.locksoflove.org* or *www.wigsforkids.org*.
3. If the child's hair has not been totally shaved, comb it so that the area of baldness is not evident.
4. Reassure the child that hair will grow back after surgery and chemotherapy (hair does not grow back at site of radiation therapy).
5. Prepare the child and family for cushingoid changes (moon face, edema) if long-term steroids are required.

Family Education and Health Maintenance

1. Provide parents with written information regarding the child's needs—medications, activity, care of the incision, and follow-up appointments.
2. Teach the parents about radiation and chemotherapy and their adverse effects.
3. If a child has a ventriculoperitoneal shunt, teach parents to report fever, nausea, vomiting, irritability, or a bulging anterior fontanelle.
4. Initiate a referral to a home health nurse to provide care and teaching at home and to maintain therapeutic support for the family.
5. Encourage parents to contact the child's teacher and the school nurse before the child returns to school so that they can prepare classmates for child's return and help them to deal with their feelings.

6. Provide the parents with the phone number of the clinic or nursing unit so that they may call if questions occur after discharge. For additional resources, refer family to such agencies as the American Brain Tumor Association (*www.abta.org*), Mikey's Way (*www.mikeysway.org*), Children's Tumor Foundation (*www.ctf.org*), The Lily Fund (*www.thelilyfund.org*), or Candlelighters (*www.candlelighters.org*).

Evaluation: Expected Outcomes

- Parents discuss feelings about the child's diagnosis and surgery.
- Child demonstrates decreased fear and anxiety through verbalization, play, or other age-appropriate activities.
- Child verbalizes relief from pain.
- Child maintains weight through adequate intake.
- Vital signs are stable, afebrile, and lungs are clear.
- Child verbalizes acceptance of physical appearance and desire to visit with friends.

Neuroblastoma

EVIDENCE BASE National Cancer Institute. (2017). Neuroblastoma treatment (PDQ)—Health professional version. Available: *www.cancer.gov/types/neuroblastoma/hp/neuroblastoma-treatment-pdq*.

Pinto, N. R., Applebaum, M. A., Volchenboum, S. L., Matthay, K., et al. (2015). Advances in risk classification and treatment strategies for neuroblastoma. *Journal of Clinical Oncology, 33*(27), 3008–3017.

Salazar, B. M., Balczewski, E. A., Ung, C. Y., & Zhu, S. (2016). Neuroblastoma, a Paradigm for Big Data Science in Pediatric Oncology. *International Journal of Molecular Sciences, 18*(1), 37.

Neuroblastoma refers to a malignant tumor that arises from the sympathetic nervous system. It is the third most common childhood cancer, with a prevalence of 1 in 7,000 children in the United States. It primarily affects infants and young children under the age of 5 years, with the highest rate of diagnosis in the first month of life. Neuroblastoma occurs slightly more frequently in boys than in girls, and is more fatal in blacks.

Pathophysiology and Etiology

1. Etiology is unknown; no strong risk factors have been identified.
2. Tumors arise from embryonic neural crest cells anywhere along the craniospinal axis. A type of small, round, blue cell tumor.
3. Histologic picture varies greatly from tumor to tumor and even within the same tumor; racial differences in tumor biology.
4. Tumors are staged primarily by extent of disease; International Neuroblastoma Staging System:
    a. Stage 1 (tumor confined to the organ or structure of origin with complete surgical resection) to stage 4 (remote disease involving the skin, skeleton, parenchymal organs, soft tissue, distant lymph nodes, or bone marrow).
    b. Stage 4S refers to cases that would otherwise be stage 1 or 2 but that have dissemination limited to the liver, skin, or bone marrow in a patient less than 1 year of age.
5. Neuroblastoma is one of the few tumors that may demonstrate spontaneous remission.

Clinical Manifestations

1. Symptoms depend on the location of the tumor and the stage of the disease.
2. Most tumors are located within the abdomen and present as firm, nontender, irregular masses that may or may not cross the midline.
3. Other common signs:
    a. Bowel or bladder dysfunction that results from compression by a paraspinal or pelvic tumor.
    b. Neurologic symptoms, such as paralysis and Horner syndrome, because of compression by the tumor on nerve roots or because of tumor extension.

c. Supraorbital ecchymosis, periorbital edema, and exophthalmos that results from metastases to the skull bones and retrobulbar soft tissue.
d. Lymphadenopathy, especially in the cervical area.
e. Bone pain with skeletal involvement.
f. Swelling of the neck or face, wheezing, dyspnea, and cough with thoracic masses.
g. Symptoms of bone marrow failure, such as anemia, bleeding, or infection.
h. General symptoms of pallor, bluish skin discoloration, anorexia, fever, weight loss, and weakness with widespread metastasis.

Diagnostic Evaluation

Workup done to document the extent of the disease throughout the body include:

1. Chest and skeletal x-rays.
2. Bone scan.
3. Bone marrow aspiration and biopsy.
4. CBC, platelet count, ferritin.
5. Twenty-four-hour urine collection—elevated excretion of homovanillic acid (HVA) and vanillylmandelic acid (VMA).
6. Liver and kidney function tests.
7. Histologic confirmation.
8. Additional studies:
   a. CT of primary site and chest.
   b. MRI—areas above diaphragm.
   c. Ultrasound examination.
   d. Liver and spleen scan.
   e. Metaiodobenzylguanidine (MIBG) scan
9. Genetic indicators of poor prognosis include n-myc oncogene amplification, hyperdiploid karyotype, and chromosome deletion.

Management

1. Surgery—role is diagnostic and therapeutic. Either primary (before chemotherapy or radiation) or delayed/secondary (after therapy).
2. When complete surgical resection of a stage I tumor is possible, this may be the only treatment required.
3. Children with other than stage I disease generally receive a combination of surgery, radiation therapy, and chemotherapy. Drugs of choice include vincristine, topotecan, irinotecan, cyclophosphamide, doxorubicin, cisplatin, carboplatin, ifosfamide, and etoposide. See Table 51-2.
4. Survival rate for early stages is as high as 95%; advanced stages, 40%.
5. Influencing factors for prognosis:

a. Stage of disease—the earlier the stage, the better the prognosis.
b. Age—infants younger than age 1 demonstrate the best survival.
c. Site of primary tumor—children with tumors above the diaphragm appear to do better than children with abdominal tumors.
d. Pattern of metastasis—children with metastasis to the bone marrow, liver, and skin have better prognosis than those with radiographic bone involvement.
e. Genetic and histologic factors.

6. Autologous stem cell transplantation, newer chemotherapy drugs, retinoid therapy, and immunotherapy such as Interleukin-2 may also be a part of the treatment regimen.

Table 51-2 Commonly Used Chemotherapeutic Agents to Treat Neuroblastoma

CHEMOTHERAPEUTIC AGENT	COMMON SIDE EFFECTS
Carboplatin	Nausea, vomiting Bone marrow suppression Electrolyte imbalance
Cytoxan	Nausea, vomiting Hair loss Loss of appetite Gonadal dysfunction Bone marrow suppression Nephrotoxicity
Doxorubicin	Nausea, vomiting Hair loss Red urine Bone marrow suppression Cardiac dysfunction
Etoposide	Nausea, vomiting Hair loss Weakness Bone marrow suppression Nephrotoxicity Hepatotoxicity
Irinotecan	Diarrhea, abdominal cramping, runny nose, tearing, salivation, sweating, photophobia Nausea, vomiting Loss of appetite Bone marrow suppression Fever Weakness Elevated liver enzymes Elevated eosinophils
Temozolomide	Bone marrow suppression Nausea, vomiting Constipation Loss of appetite

Complications

1. Metastasis to the liver, soft tissue, bones, lymph nodes, bone marrow, and skin.
2. Neurologic deficits due to nerve compression.

Nursing Assessment

EVIDENCE BASE Kline, N. (Ed.). (2014). *Essentials of pediatric oncology nursing: A core curriculum* (4th ed.). Glenview, IL: Association of Pediatric Hematology/Oncology Nurses.

---

1. Obtain a history.
    a. Inquire about when symptoms began. Focus on decrease in appetite, weakness, pain, abdominal distention, or change in bowel and bladder function.
    b. Symptoms exhibited depend on the location of the primary tumor.
2. Perform a physical examination, including:
    a. Examination of skin for signs of increased bruising or petechiae.
    b. Palpation of liver and spleen for enlargement.
    c. Palpation of abdominal mass or other primary site of tumor.
    d. Auscultation of lungs.
    e. Palpation of lymph nodes.
    f. Blood pressure monitoring for detection of hypertension.
    g. Temperature for fever caused by infection or disease.
    h. Assessment of bones and joints for pain or swelling.
    i. Neurologic examination for signs of compression by tumor. Nerves involved depend on location of tumor.
3. Assess coping mechanisms of family.

Nursing Diagnoses

- Anxiety of parents related to learning of diagnosis.
- Fear of child related to diagnostic procedures and surgery or biopsy.
- Activity Intolerance related to fatigue from tumor growth and bone marrow suppression.
- Constipation or Bowel and Bladder Incontinence related to pressure of tumor.
- Risk for Infection related to bone marrow suppression from chemotherapy and radiation.
- Acute Pain related to tumor, surgery, or progression of disease.
- Disturbed Body Image related to hair loss.

Nursing Interventions

Reducing Parents' Anxiety

See previous sections, pages 1356 and 1359.

Reducing Child's Anxiety and Fear

See previous sections, pages 1357 and 1360.

Increasing Activity Tolerance

See previous section, page 1357.

Regaining Normal Bowel and Bladder Function

1. Assess normal elimination patterns the child had before the illness began.
2. Keep careful intake and output records.
3. Assess for urinary overflow incontinence and loss of bowel function, depending on the child's age.
4. Notify health care provider if these should occur.

Preventing Infection

See previous sections, pages 1356 and 1360.

Observe the surgical incision for erythema, drainage, or separation of the incision. Report these changes.

Relieving Pain

See previous sections, pages 1357 and 1360.

Monitor for increasing or new location of pain, indicating progression of disease (eg, fracture due to bone involvement).

Promoting Acceptance of Body Changes

See previous section, pages 1356 and 1360.

Family Education and Health Maintenance

1. Teach parents about the laboratory tests and imaging studies needed at diagnosis and periodically throughout therapy.
2. Instruct parents about chemotherapy drugs used and their potential adverse effects.
3. Inform parents about potential treatment methods, such as radiation therapy and bone marrow transplantation.
4. Advise parents to use good hand washing technique and to prevent exposure to children with communicable diseases.
5. Refer families to resources such as Candlelighters (*www.candlelighters.org*).

Evaluation: Expected Outcomes

- Parents and child discuss their feelings about diagnosis and treatment.
- Participates in play and expresses feelings through play.

- Maintains normal activity level.
- Resumes normal voiding and bowel patterns.
- Remains afebrile, lungs clear, no signs of localized infections.
- Rests without crying or guarding of surgical incision; good pain control according to developmentally appropriate scale.
- Interacts with others, seems comfortable with self.

Rhabdomyosarcoma

EVIDENCE BASE Bekiesinska-Figatowska, M., Duczkowska, A., Duczkowski, M., et al. (2017). CNS metastases from bone and soft tissue sarcomas in children, adolescents, and young adults: Are they really so rare? *BioMed Research International, 2017*. doi: 10.1155/2017/ 1456473.

National Cancer Institute. (2017). Childhood rhabdomyosarcoma treatment (PDQ)—Health professional version. Available: *www.cancer.gov/types/soft-tissue-sarcoma/hp/rhabdomyosarcoma-treatment-pdq*.

Parida, L. (2014). Nonurological malignancies in children. *Journal of Indian Association of Pediatric Surgeons, 19*(1), 31.

Rhabdomyosarcoma is a highly malignant soft tissue tumor that arises from the immature mesenchymal cells that form striated muscle. The incidence is approximately 4.5 per 1 million children in the United States and rhabdomyosarcoma accounts for 3.5% of all malignant disease in children younger than age 14 years and 2% of the cases among adolescents and young adults aged 15 to 19 years. It has bimodal distribution with a peak between 2 and 6 years old and again between 10 and 18 years old. Children aged 1 to 9 years have the best prognosis, whereas those younger and older fare less well. Rhabdomyosarcoma can occur anywhere in the body, the most common sites are the head and neck, genitourinary (GU) tract, and extremities.

Pathophysiology and Etiology

1. Etiology is unknown in most cases.
2. Certain genetic and environmental factors have been associated with its development.
3. Two major variants are embryonal and alveolar, with embryonal more common in infants and young children and alveolar more common in adolescents. Alveolar rhabdomyosarcoma tends to grow faster than embryonal and usually requires more intensive treatment.
4. Tumor spreads either by local extension or by metastasis via the venous and lymphatic system.
5. The lung is the most common site of metastasis.
6. Tumor staging is based on the extent of the disease:
    a. Stage/group I: localized tumor, completely resected; often in the orbit, head and neck, GU tract, and bile ducts.
    b. Stage/group II: local tumor resected, microscopic residual disease; often in the bladder or prostate, arm or leg, and a parameningeal site.
    c. Stage/group III: localized disease, with gross residual disease after resection; tumor is 5 cm across and may or may not have spread to nearby lymph nodes.
    d. Stage/group IV: metastatic disease at diagnosis.

Clinical Manifestations

1. Commonly presents as an asymptomatic painless lump noted by the patient or parent.
2. Signs and symptoms are variable and reflect the location of the tumor and metastasis.
    a. Orbit—ptosis, ocular paralysis, exophthalmos, impaired vision.
    b. Nasopharynx—epistaxis, pain, dysphagia, nasal voice, airway obstruction.
    c. Sinuses—swelling, pain, discharge, sinusitis.
    d. Middle ear—pain, chronic otitis, facial nerve palsy.
    e. Neck—hoarseness, dysphagia.
    f. Trunk, extremities, testicular areas—enlarging soft tissue masses.
    g. Prostate, bladder—urinary tract symptoms.
    h. Retroperitoneal tumors—GI and urinary tract obstruction, weakness, paresthesia, pain.
    i. Vaginal—abnormal vaginal bleeding or mass.

Diagnostic Evaluation

To document the extent of the disease and to provide objective criteria for measuring response to therapy:

1. Open biopsy of the primary tumor—definitive diagnostic procedure.
2. CT of the chest and primary lesion.
3. MRI.
4. Bone marrow aspiration and biopsy.
5. Bone scan or skeletal survey.
6. Ultrasonography.
7. Chest x-ray.
8. PET.
9. CBC, liver and renal function tests, electrolytes, serum calcium and phosphorus, uric acid.
10. Monoclonal antibody assays.
11. Urinalysis.
12. Lumbar puncture—for children with cranial lesions.

Management

1. Surgery—to biopsy the lesion, determine the stage of the disease, and completely remove or reduce the primary tumor. Increasingly, chemotherapy and radiation therapy are used before surgery to avoid the disability associated with radical surgery for selected anatomic sites (head, neck, and pelvis).
2. Radiation—high-dose radiation is generally recommended for the primary tumor and metastasis.
3. Chemotherapy:
    a. Used for all patients, usually in combination with irradiation (see Table 51-3).
    b. Commonly used drugs include dactinomycin, vincristine, cyclophosphamide, doxorubicin, cisplatin, etoposide, ifosfamide, irinotecan, melphalan topotecan, paclitaxel, and docetaxel.
4. Survival rates have improved considerably in recent years. Survival for stage I, with favorable histology, is

greater than 90%; and survival for stage IV tends to be between 20% and 40%.

5. Prognosis is related to the stage of the disease at diagnosis, the location of the primary tumor, and the age at diagnosis.

Table 51-3 Commonly Used Chemotherapeutic Agents to Treat Rhabdomyosarcoma

CHEMOTHERAPEUTIC AGENT	COMMON SIDE EFFECTS
Cytoxan	Nausea, vomiting Hair loss Loss of appetite Gonadal dysfunction Bone marrow suppression Nephrotoxicity
Dactinomycin	Nausea, vomiting Bone marrow suppression
Vincristine	Hair loss Neuropathy Constipation

Complications

1. Direct tumor extension to CNS with cranial nerve palsy, brain stem compromise with bradypnea and bradycardia.
2. Metastasis to the bone, bone marrow, lung.

Nursing Assessment

1. Obtain a history.
   a. Ask about recent illness history and when the child became symptomatic.
   b. Obtain review of systems to help identify the primary tumor and metastasis present.
2. Perform physical examination, including:
   a. Palpation of lymph nodes for enlargement, tenderness, and mobility.
   b. Palpation of the liver and spleen to detect hepatosplenomegaly.
   c. Palpation of primary site of tumor and suspected areas of metastasis.
   d. Auscultation of lungs to assess breath sounds or abnormality caused by the spread of the tumor.
3. Assess family coping, resources, and emotional state of the child and parents.

Nursing Diagnoses

- Risk for anxiety among parents related to learning of diagnosis.
- Fear of child related to diagnostic procedures and surgery or biopsy.
- Imbalanced Nutrition: Less than Body Requirements related to anemia, anorexia, nausea, vomiting, and mucosal ulceration secondary to chemotherapy or radiation.
- Acute Pain related to surgery or possible progression of disease.

- Disturbed Body Image related to alopecia associated with chemotherapy.
- Risk for Infection related to bone marrow suppression from chemotherapy or radiation.

Nursing Interventions

Reducing Parents' Anxiety

See previous sections, pages 1356 and 1359.

Reducing the Child's Fear and Anxiety

See previous sections, pages 1357 and 1360.

Promoting Optimal Nutrition

See previous sections, pages 1357 and 1360.

Relieving Pain

See previous sections, pages 1357 and 1360.

Promoting Acceptance of Body Changes

See previous sections, pages 1356 and 1360.

Preventing Infection

See previous sections, pages 1356 and 1360.

Family Education and Health Maintenance

1. Teach the parents about laboratory diagnostic tests that will be done periodically to follow the child's condition.
2. Instruct the parents about treatment methods, including chemotherapy and radiation protocols postoperatively, and their adverse effects.
3. Stress the importance of follow-up care so that recurrence can be detected early and appropriate treatment can be instituted.
4. Refer families to such resources as Candlelighters (*www.candlelighters.org*). Assist patients in coordinating care with an orthopedic surgeon, a medical or pediatric oncologist, a radiation oncologist, a pathologist, and a physiatrist.

Evaluation: Expected Outcomes

- Parents verbalize understanding of diagnosis.
- Child plays, interacts with others, and asks questions.
- Eats sufficient calories to maintain weight.
- Verbalizes reduced pain.
- Verbalizes acceptance of self; looks in mirror.
- Remains afebrile, no signs of localized infection.

Wilms Tumor

EVIDENCE BASE American Cancer Society (2018). Atlanta, GA. What are the key statistics about Wilms tumor? Available: *https://www.cancer.org/cancer/wilms-tumor/about/key-statistics.html.*

National Cancer Institute. (2016). Wilms' tumor and other childhood kidney tumors treatment (PDQ)—Health professional version. Available: *www.cancer.gov/types/kidney/hp/wilms-treatment-pdq*.

Wilms tumor, also known as nephroblastoma, is a malignant renal tumor and is the most common renal neoplasm in children. It constitutes approximately 7% of all childhood tumors, but in the 15- to 19-year age group, most tumors are renal cell carcinoma. Incidence is approximately 8 cases per 100,000 children younger than age 15 years. About 500 cases are diagnosed each year in the United States; 75% of cases occur before the child is age 5 years. The average age a diagnosis is about 3 to 4 years. Most commonly a unilateral disease, but in 5%, both kidneys are involved. It may appear as swelling in the abdomen below the costal margin. In the United States, girls have a slightly higher risk of Wilms tumor than do boys, and the risk is slightly higher in African American children and lowest among Asian American children.

Pathophysiology and Etiology

1. The etiology is not known.
2. Genetic inheritance has been documented in 1% to 2% of cases.
3. Children with Wilms tumor may have associated anomalies.
4. Wilms tumor has a capacity for rapid growth and usually grows to a large size before it is diagnosed.
5. The effect of the tumor on the kidney depends on the site of the tumor.
6. In most cases, the tumor expands the renal parenchyma and the capsule of the kidney becomes stretched over the surface of the tumor, which is encapsulated at the time of surgery.
7. Wilms tumors present various histologic patterns and are grouped into two general categories: favorable histology and unfavorable histology.
8. The neoplasms metastasize either by direct extension or by way of the bloodstream. They may invade perirenal tissues, lymph nodes, the liver, the diaphragm, abdominal muscles, and the lungs. Invasions of bone and brain are less common.
9. Staging of Wilms tumor is done based on clinical and anatomic findings. It ranges from stage I (tumor is limited to the kidney and is completely excised) to stage IV (metastasis is present in the liver, lung, bone, or brain). Stage V includes those cases that include bilateral involvement, either initially or subsequently.

Clinical Manifestations

1. A firm, nontender upper quadrant abdominal mass is usually the presenting sign; it may be on either side. (It is usually first observed by the parents.)

2. Abdominal pain, which is related to rapid growth of the tumor, may occur. As the tumor enlarges, pressure may cause constipation, vomiting, abdominal distress, anorexia, weight loss, and dyspnea.
3. Less common are hypertension, fever, hematuria, and anemia.
4. Associated anomalies:
    a. Hemihypertrophy.
    b. Aniridia (without the iris of the eyes).
    c. Genitourinary tract abnormalities.
    d. Overgrowth syndromes (Beckwith-Wiedemann syndrome).
    e. Mental retardation.

Diagnostic Evaluation

1. Abdominal ultrasound to show the tumor and assess the status of the opposite kidney.
2. Radiography of chest to identify metastases.
3. CBC and peripheral smear to determine baseline data.
4. Urinalysis to detect for hematuria.
5. Blood chemistries, especially serum electrolytes, uric acid, renal function tests (blood urea nitrogen and creatinine), and liver function tests (bilirubin, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase [LD], total protein, albumin, and alkaline phosphatase) may show abnormalities.
6. Urinary VMA and HVA to distinguish from neuroblastoma.
7. MRI or CT of the abdomen to evaluate local spread to lymph nodes or adjacent organs.
8. Renal biopsy to confirm diagnosis.
9. Real-time ultrasonography.

Management

1. Accurate staging and assessment of tumor spread is first conducted.
2. The standard treatment for stages I and II tumors is surgery (eg, partial nephrectomy, simply nephrectomy, or radical nephrectomy) followed by chemotherapy.
3. The standard treatment for stages III and IV is the same as for stages I and II but includes radiation.
4. If both kidneys are removed, which is the treatment for stage V, the patient will require dialysis until a transplant is possible.
5. Radiation or chemotherapy may be administered preoperatively to patients with advanced tumors or risky intravascular extension to reduce tumor burden.
6. Radiation therapy may be given to the tumor bed postoperatively to render nonviable all cells that have escaped locally from the excised tumor. Children who have stage III and IV Wilms tumor, or who have an unfavorable histology, usually receive this treatment.
7. Whole-lung radiation is used to treat stage IV tumors with lung metastasis.
8. Late effects of radiation therapy to the abdomen include scoliosis and underdevelopment of soft tissues

and possible organ dysfunction in radiation field.

9. Chemotherapy is initiated postoperatively to achieve complete eradication of tumor cells (see Table 51-4).
10. Overall survival rates for Wilms tumor are among the highest for all childhood cancers—greater than 90% survival at 4 years.
11. Prognosis is based on histologic tumor features, lymph node involvement, age, tumor size, and possible chromosomal factors.

Table 51-4 Commonly Used Chemotherapeutic Agents to Treat Wilms Tumor

CHEMOTHERAPEUTIC AGENT	COMMON SIDE EFFECTS
Vincristine	Hair loss Neuropathy Constipation
Dactinomycin	Nausea, vomiting Bone marrow suppression
Doxorubicin	Nausea, vomiting Hair loss Red urine Bone marrow suppression Cardiac dysfunction

Complications

1. Metastasis to the lungs, lymph nodes, liver, bone, and brain.
2. Complications from radiation therapy include bowel obstruction, hepatic damage, nephritis, sterility in girls, interstitial pneumonia, and scoliosis.
3. Cumulative incidence of second malignancy is 1.6% after 15 years, with radiation being the greatest risk factor.

Nursing Assessment

1. Obtain a history.
   a. Ask how tumor was first discovered.
   b. Ask whether the child has history of other GU anomalies or whether there is a family history of cancer.
   c. Determine whether the child has had hematuria, dysuria, constipation, abdominal pain, decreased appetite, or fever before hospitalization and ask how these were treated.
2. Perform a physical examination that includes the following:
   a. Assessment for associated anomalies: aniridia, hemihypertrophy of the spine, or cryptorchidism.
   b. Palpation of lymph nodes for enlargement, tenderness, and mobility.
   c. Palpation of the liver and spleen for enlargement.
   d. Palpation of the abdomen to determine the size and location of the tumor.

e. Auscultation of the lungs to assess breath sounds or abnormality because of spread of tumor.

3. Assess coping, resources, and emotional state of the family.

NURSING ALERT Avoid indiscriminate manipulation of the abdomen preoperatively and postoperatively to decrease the danger of metastasis. Because the tumor is soft and highly vascular, seeding may occur with excessive palpation or handling of the child's abdomen.

Nursing Diagnoses

- Anxiety of parents related to learning of diagnosis.
- Fear of child related to surgery and diagnostic tests.
- Risk for Deficient Fluid Volume postoperatively.
- Acute Pain related to surgery and possible progression of the disease.
- Imbalanced Nutrition: Less than Body Requirements related to anemia, anorexia, nausea, vomiting, and mucosal ulceration secondary to chemotherapy or radiation.
- Disturbed Body Image related to alopecia associated with chemotherapy.
- Activity Intolerance related to fatigue that results from the size of the tumor and treatment.
- Risk for Infection and hemorrhage related to bone marrow suppression caused by chemotherapy.

Nursing Interventions

Reducing Parents' Anxiety

See previous sections, pages 1356 and 1359.

Reducing the Child's Fear and Anxiety

See previous sections, pages 1357 and 1360.

Preventing Fluid Volume Deficit and Other Complications

1. Insert a nasogastric tube, as ordered. Many children require gastric suction postoperatively to prevent distention or vomiting.
2. Monitor gastric output accurately and replace it with the appropriate IV fluids, as ordered.
3. When bowel sounds have returned, begin with small amounts of clear fluids.
4. Keep accurate intake and output record.
5. Monitor vital signs as the child's condition warrants and check the surgical dressing frequently for drainage.

Relieving Pain

See previous sections, pages 1357 and 1360.

Promoting Optimal Nutrition

See previous sections, pages 1357 and 1360.

Promoting Acceptance of Body Changes

See previous sections, pages 1356 and 1360.

Increasing Activity Tolerance

See previous section, page 1357.

Preventing Infection

See previous sections, pages 1356 and 1360.

Family Education and Health Maintenance

1. Teach parents of children with one kidney the signs and symptoms of kidney disease.
2. Advise parents to call the health care provider if the child has a fever of more than 101°F (38.3°C), bleeding, signs of infections, or has been exposed to chickenpox.
3. Teach measures to prevent infection, such as hand washing and isolation from children with communicable disease.
4. Refer families to resources such as Candlelighters (*www.candlelighters.org*).

Evaluation: Expected Outcomes

- Parents discuss their feelings about diagnosis and treatment.
- Expresses feelings during play and participates in playroom activities.
- Has no abdominal distention or vomiting, vital signs stable.
- Verbalizes relief from pain.
- Eats adequate calories to maintain weight, nausea relieved by antiemetics.
- Plays with others without notice to alopecia.
- Participates in all normal daily activities without fatigue.
- Remains afebrile, no signs of local infection.

Osteosarcoma

EVIDENCE BASE American Cancer Society. (2018). Atlanta, GA. Osteosarcoma: Early detection, diagnosis, and staging. Available: *https://www.cancer.org/cancer/osteosarcoma/detection-diagnosis-staging.html*.

Rothermundt, C., Seddon, B. M., Dileo, P., Strauss, S. J., et al. (2016). Follow-up practices for high-grade extremity osteosarcoma. *BMC Cancer, 16*(1), 301.

Osteosarcoma is a malignant tumor of the bone. It is the most commonly diagnosed primary malignant bone cancer in pediatrics, affecting about 400 children and adolescents ages 0 to 19 years annually. The incidence of osteosarcoma increases with age throughout childhood and adolescents, but then decreases. It commonly affects adolescents during the growth spurt when bones and soft tissue are already vulnerable because of the developmental process, with the majority of cases occurring between the ages of 8 and 25 years. Osteosarcoma is very rare among children younger than 5 years of age. The 5-year relative survival rate of osteosarcoma is 70%. It is the most common secondary malignancy among retinoblastoma survivors. The incidence of osteosarcoma is slightly higher in males than in females, and also higher in African American and Latino children compared with white and Asian/Pacific Islander children. It is somewhat more likely to affect males than females.

Pathophysiology and Etiology

1. Etiology is unknown. Risk factors may include prior radiation treatment for another tumor, taller children, and genetic syndromes.
2. Presumably arises from bone-forming mesenchymal tissue.
3. Produces malignant spindle cell stroma, which gives rise to malignant osteoid tissue.
4. Common sites of occurrence are in the metaphysis of long bones, such as distal femur, proximal tibia, and proximal humerus. Less common sites include the skull, pelvis, phalanges, and jaw.
5. Most commonly metastasizes to lungs and other bones.

Clinical Manifestations

1. Sporadic pain in the affected site, frequently causing limp, stiffness, or limited range of motion.
2. Pain may worsen at night or with activity.
3. A painless swelling or noticeable and palpable, tender, fixed bony mass often in the arm or leg.
4. A broken bone that occurs without injury.
5. Additional symptoms related to site of metastasis, if present.

Diagnostic Evaluation

1. Radiographic examination of lesion is conducted to visualize the tumor.
2. A biopsy of the lesion is conducted to confirm the diagnosis and to provide histologic data for the selection of a treatment plan.
3. CT and MRI are helpful to assess internal tumor composition and to evaluate local extent of disease prior to surgery.
4. Chest x-ray may be done to detect pulmonary metastases.
5. Bone scan is helpful in detecting the initial extent of malignancy, planning therapy, and evaluating effects of treatment.
6. Renal and liver function tests should be monitored to observe for elevated serum lactate dehydrogenase (LD).
7. Arteriography may be a possibility if limb salvage procedure is a consideration.

Management

1. Surgery—procedures fall into two categories:
   a. Limb salvage procedure is priority—greater than 80% of tumors can be treated with limb salvage surgery.
   b. Radical amputation of the affected extremity and, commonly, the joint proximal to the involved area.
2. The type of surgery performed depends on tumor location, size, extramedullary extent, distant metastasis, age of child, skeletal development, as well as preferences regarding lifestyle and quality of life.
3. Chemotherapy is necessary following surgery because the majority of patients treated with local therapy alone develop distant metastases within several years. Chemotherapy agents, such as methotrexate with leucovorin, cyclophosphamide, cisplatin, doxorubicin, and ifosfamide, are also used preoperatively for patients who undergo resection surgery and for the treatment of metastatic disease (see Table 51-5).
4. Survival has greatly improved with the aggressive use of multimodal therapy.
5. With current treatment, the 5-year survival rate for people with localized osteosarcoma is approximately 70% for those who undergo surgery followed by chemotherapy.
6. Important prognostic factors are extent of disease at diagnosis, age, gender, serum LD, and amount of tumor necrosis at the time of surgery. Osteosarcomas arising in previously irradiated areas have a worse prognosis.
7. Limb salvage surgery has improved the quality of life for many survivors.
8. Patients with relapse to lung may still be curable with surgical excision.

Table 51-5 Commonly Used Chemotherapeutic Agents to Treat Osteosarcoma

CHEMOTHERAPY	COMMON SIDE EFFECTS
Doxorubicin	Nausea, vomiting Hair loss Red urine Bone marrow suppression Cardiac dysfunction
Cisplatin	Nausea, vomiting Bone marrow suppression Hypomagnesemia Loss of appetite Hearing loss Renal dysfunction
Methotrexate	Elevated liver enzymes Mucositis Nephrotoxicity
Etoposide	Nausea, vomiting Hair loss Weakness Bone marrow suppression
Ifosfamide	Nausea, vomiting Hair loss Bone marrow suppression Gonadal dysfunction Renal dysfunction

Complications

1. Metastasis to the lung and bones.
2. Later metastasis to the CNS and lymph nodes.
3. Treatment-induced hearing loss.
4. Physical limitations resulting from surgical resection.

Nursing Assessment

1. Obtain a history.
   a. Inquire about how and when symptoms first presented as well as the duration of symptoms.
   b. Determine whether the child has pain or limitation of motion in the affected area.
2. Perform a physical examination, including:
   a. Palpation of the mass to determine the size and location. (Determine whether the mass is tender or is fixed to the bone.)
   b. Palpation of other bones to check for metastasis.
   c. Auscultation of the lungs to assess breath sounds or other abnormalities caused by spread of tumor.
3. Assess family coping, resources such as support systems, and emotional state of the patient and parents.
4. Assess degree of mobility, especially for lower extremity tumors.

Nursing Diagnoses

- Anxiety of parents related to learning of diagnosis.
- Fear of child or adolescent related to surgery, diagnostic tests, and treatment.
- Disturbed Body Image related to surgery and possible amputation and alopecia associated with chemotherapy.
- Acute Pain related to surgery and possible progression of the disease.
- Imbalanced Nutrition: Less than Body Requirements related to anemia, anorexia, nausea, vomiting, and mucosal ulceration caused by chemotherapy.
- Risk for Infection related to surgery or bone marrow suppression secondary to chemotherapy.
- Impaired Mobility due to surgery or disease.
- Risk for Injury due to pathologic fractures related to the diagnosis.

Nursing Interventions

Reducing Parents' Anxiety

1. Involve the parents in the teaching plan and make sure they know what to expect before going to surgery.
2. Explain to the parent about the disease process and available treatment options.
3. Provide parents with strategies related to effective coping with the diagnosis and postoperative care.
4. Provide parents with positive reinforcement, honesty, and transparency in the care process.
5. Encourage the parent to participate in the care process to prepare for discharge.

Reducing the Adolescent's Fear and Anxiety

1. Incorporate the adolescent's developmental level when explaining diagnostic tests and postoperative care.
2. Support and prepare the child for routine surgical care or care of the amputated limb.
3. If an amputation will be done, teach the child about the need for physical therapy for exercises and to learn crutch walking and the need for a prosthesis.
4. If limb salvage surgery will be done, reinforce the importance of physical therapy exercises following surgery to restore as much function as possible to the affected bone and/or joint.
5. Nursing care of the adolescent with osteosarcoma is the same as care of the adult.

Promoting Acceptance of New Self-Image

1. Understand that adolescents need time and support to accept the diagnosis and the surgery and to grieve for their lost body part if an amputation is done.
2. Try to introduce the adolescent to another adolescent with the same diagnosis who has undergone similar treatment.
3. Suggest the selection of clothing that will camouflage the prosthesis and be fashionable and appealing.
4. Suggest wigs, scarves, or hats for adolescents who experience hair loss because of chemotherapy.
5. Encourage visits by peers and help the child to deal with questions and reactions from peers.

Relieving Pain

See previous sections, pages 1357 and 1360.

Promoting Optimal Nutrition

See previous sections, pages 1357 and 1360.

Preventing Infection and Hemorrhage

See previous sections, pages 1356 to 1357 and 1360.

Community and Home Care Considerations

1. Assess the home for accessibility of adolescent who has had an amputation.
2. Educate parents about changes they may need to make in the home.
3. Encourage the parents to contact the school system to arrange for a tutor for a student who needs to remain out of school for a lengthy period.
4. Assist the parents in contacting the school nurse to facilitate reentry into the classroom.
5. Identify any financial concerns that may be associated with care and treatment and refer patients to a social worker or case manager to access community services and resources.

Family Education and Health Maintenance

1. Teach adolescents and parents about infection control measures, such as good hand washing and preventing exposure to children with communicable diseases, because chemotherapy is usually long term.
2. Parents and adolescents should be instructed about chemotherapy medications used and their potential adverse effects.
3. Teach parents and adolescents about the radiation procedure and effects.
4. Advise the adolescent to protect a leg that has received radiation treatment by avoiding excessive pressure on the leg through sports. Consult orthopedic specialist for appropriate activity limitations.
5. Teach parents measures to ensure safety of patient throughout treatment and convalescence.
6. Refer families to resources such as Candlelighters (*www.candlelighters.org*).

Evaluation: Expected Outcomes

- Parents and child (if age appropriate) discuss feelings about surgery and chemotherapy treatments.
- Parents and child (if age appropriate) verbalizes feelings about surgery and asks questions.
- Looks in mirror, touches amputation site.
- Parents and child (if age appropriate) verbalizes relief from pain.
- Maintains an adequate eating pattern, nausea relieved by antiemetics.
- Remains afebrile, vital signs stable, no signs of bleeding.
- Maintains skin integrity.

Retinoblastoma

EVIDENCE BASE Chantada, G., & Schaiquevich, P. (2015). Management of retinoblastoma in children: Current status. *Pediatric Drugs, 17*(3), 185–198.

Mendoza, P. R., & Grossniklaus, H. E. (2016). Therapeutic options for retinoblastoma. *Cancer Control, 23*(2), 99–109.

National Cancer Institute. (2018). Retinoblastoma treatment (PDQ)—Health professional version. Available: https://www.cancer.gov/types/retinoblastoma/hp/retinoblastoma- treatment-pdq.

Retinoblastoma is a malignant, congenital tumor, arising in the retina of one or both eyes. It accounts for about 3% of the cancers occurring in children younger than 15 years, and approximately 1 in 14,000 to 18,000 live births; this rate of diagnosis is consistent worldwide. Median age of diagnosis is age 2 years and it is rarely diagnosed after age 6 years.

Pathophysiology and Etiology

1. Most cases appear sporadically and have been associated with advanced paternal age; there is also an inherited form of the disease.
   a. Nonhereditary somatic mutations account for approximately 70% to 75% of all retinoblastomas; always demonstrate unilateral involvement.
   b. All bilateral cases are heritable.
      i. Mode of inheritance is autosomal dominant.
      ii. Offspring of affected individuals have a 50% chance of inheriting the disease.
2. Can be associated with chromosomal aberrations.
3. Usually arise in multiple foci rather than a single tumor from any of the nucleated retinal layers.
4. Some tumors (endophytic type) arise in the internal nuclear layers of the retina and grow forward into the vitreous cavity.
5. Some tumors (exophytic type) arise in the external nuclear layer and grow into the subretinal space, with detachment of the retina.
6. Most tumors have a combination of endophytic and exophytic growth.
7. Extension of the tumor may occur into the choroid, sclera, and optic nerve.
8. "Trilateral retinoblastoma" is the presence of bilateral retinoblastoma in addition to an intracranial midline neuroblastic tumor.
9. Hematogenous spread of the tumor may occur to the bone marrow, skeleton, lymph nodes, and liver.
10. Tumor staging reflects the extent of the disease and the probability of preserving useful vision in the affected eye, from group I (very favorable) to group V (very unfavorable).

Clinical Manifestations

1. Signs and symptoms of an intraocular tumor depend on its size and position.
2. "Cat's-eye reflex"—whitish appearance of the pupil (leukocoria) represents visualization of the tumor through the lens as light falls on the tumor mass—most common sign. Also characterized by the absence of red reflex on photographs.
3. Strabismus—second most common presenting sign.
4. Other occasional presenting signs:
   a. Orbital inflammation, eye pain.
   b. Hyphema, bulging of the eye.
   c. Fixed pupil.
   d. Heterochromia iridis—different colors of each iris or in the same iris.
5. Vision loss is not a symptom because young children do not complain of unilaterally decreased vision.
6. Symptoms of distant metastasis—anorexia, weight loss, vomiting, headache, bone pain.

Diagnostic Evaluation

1. Bilateral indirect ophthalmoscopy under general anesthesia.
2. Ultrasonography and CT or MRI of head and eyes to visualize tumor.
3. Bone marrow aspiration and lumbar puncture under anesthesia to determine metastasis.

Management

1. Depends on the stage of the disease at the time of diagnosis.
2. Unilateral tumors in stages I, II, or III are usually treated with intraocular and systemic chemotherapy.
   a. Goal of treatment is to eradicate the tumors, prevent systemic metastasis, promote resolution of retinal detachment, preserve useful vision, if possible, and control the malignancy to prevent enucleation or eye removal.
   b. Most common chemotherapies are carboplatin, cyclophosphamide, doxorubicin, platinum, etoposide, and vincristine (see Table 51-6). Melphalan is often the medication of choice for intra-arterial chemotherapy for children with advanced disease.
   c. Periocular injections of topotecan can also reduce retinoblastoma tumor burden when given systemically, via intra-arterial, or via intravitreal injections because it avoids the retinal toxicity of other chemotherapy agents.
3. Surgery (enucleation) is the treatment of choice for advanced tumor growth, especially with optic nerve involvement when no hope exists for useful vision.
4. Bilateral disease usually requires enucleation of the severely diseased eye and treatment of the least affected eye.
   a. Every attempt is made to salvage whatever vision there may be.
   b. Bilateral enucleation is indicated with extensive bilateral retinoblastoma when no hope of vision

exists.

5. Focal laser treatments such as photocoagulation, plaque brachytherapy, thermotherapy, and cryotherapy are sometimes used to treat small, localized tumors.
6. External beam radiotherapy can be used to treat eyes unresponsive to other treatments.
7. Novel treatment options are being explored, including gene therapy and autologous stem cell rescue. Gene therapy is a type of therapy that introduces a viral or bacterial gene into tumor cells, thus allowing the conversion of a nontoxic compound into a lethal drug to kill the tumor cells. However, it is unlikely that this type of gene therapy could be used as first-line treatment for retinoblastoma.
8. Overall survival rate is high (90%).
9. Heritable retinoblastoma and bilateral retinoblastoma are associated with a high incidence of spontaneous and radiation-related new tumors, particularly sarcomas.

Table 51-6 Commonly Used Chemotherapeutic Agents to Treat Retinoblastoma

CHEMOTHERAPEUTIC AGENT	COMMON SIDE EFFECTS
Carboplatin	Nausea, vomiting Bone marrow suppression Electrolyte imbalance
Vincristine	Hair loss Neuropathy Constipation

Complications

1. Spread to brain and other eye.
2. Metastasis to bone, bone marrow, liver, and lymph nodes.
3. Risk for secondary tumors, including osteosarcomas, soft tissue sarcomas, and melanomas.

Nursing Assessment

1. Obtain a history.
   a. Ask about a family history that is positive for retinoblastoma or other types of cancer.
   b. Inquire about when symptoms began and strabismus, cat's-eye reflex, orbital inflammation, vomiting, or headache.
2. Perform a physical examination.
   a. Assess pupils for reactivity of light, size, and leukocoria.
   b. Evaluate strabismus when checking muscle balance.
   c. Assess eyes for associated signs, such as erythema, inflammation of the orbit, hyphema, and heterochromia iridis.
3. Assess family's ability to cope, to use support systems, and to communicate feelings.

Nursing Diagnoses

- Anxiety of parents related to the diagnosis, treatment, and genetic implications of the diagnosis.
- Impaired Tissue Integrity related to skin changes, loss of lashes, fat atrophy, impaired bone growth, and dryness caused by radiation.
- Fear of child related to hospitalization and to diagnostic and treatment procedures.
- Disturbed Body Image and Ineffective Coping related to enucleation and need for an eye prosthesis.
- Impaired Sensory Perception (Visual) related to disease process or enucleation.

Nursing Interventions

Decreasing Parental Anxiety and Guilt

1. Listen to the parental feelings of guilt about transmitting the disease to the child or because they did not notice symptoms earlier.
2. Discuss the benefit of consultation about the probability of having another affected child.
    a. Risk ranges from approximately 1% to 10%, depending on family history and whether the affected child had unilateral or bilateral disease.
    b. The reportedly high lifelong cancer burden among retinoblastoma patients may also be important to parents in making informed decisions.
    c. Refer for genetic counseling and support parental decisions regarding future pregnancies.
3. Encourage the parents to seek genetic counseling for the affected child when he or she reaches puberty.
    a. The risk to offspring is from 1% to 50%, depending on family history and whether disease was unilateral or bilateral.
    b. Among affected offspring, there is a high probability (greater than 50%) of bilateral disease.

Preserving Tissue Integrity

1. Administer sedatives or assist with anesthesia for intraocular chemotherapy, if necessary.
    a. Administer the medication in a timely manner so that sedation is adequate for positioning of the child.
2. Observe for possible adverse effects of chemotherapy and prepare the parents for their occurrence.
    a. Swelling and edema surrounding the intraocular chemotherapy site.
    b. Nausea and vomiting with systemic chemotherapy.

Reducing the Child's Anxiety and Fear

See also previous sections about reducing child's anxiety and fear.

1. Encourage the parents to room in and participate in the child's care to minimize separation anxiety.
2. Prepare the child and parents for all diagnostic procedures.
3. Describe the surgery and anticipated postoperative appearance of the child. Draw pictures or use a doll, if one is available.
    a. A surgically implanted sphere maintains the shape of the eyeball.
    b. The child's face may be edematous and ecchymotic.

4. Offer the family the opportunity to talk with another parent who has gone through the experience or to see pictures of another child with an artificial eye.
5. See "Nursing management of eye enucleation," pages 439 to 440.

Promoting Acceptance of Prosthesis

1. Explain to the child the changes related to losing the diseased eye, having a bandaged orbit until it heals after surgery, and receiving a prosthetic eye.
2. Explain that the prosthesis will be made for him or her and will look like the removed eye.
3. Tell parents to expect the child to grieve the loss and to help him or her by talking about it, but to treat the child as the same person.

Minimizing Effects of Vision Loss

1. Maintain a safe, uncluttered environment for the child.
2. Orient the child to the surrounding environment.
3. Hold the child frequently and stand close, within child's field of vision, while speaking or providing care.
4. Encourage the use of touch and other senses for exploring.
5. Set environmental limits so that the child feels safe and can obtain help easily.

Family Education and Health Maintenance

1. Teach care of the orbit.
2. Teach care of the prosthesis—initial instructions are provided by the ocularist and should be reinforced by the nurse.
3. Advise protection of the remaining eye from accidental injury, such as wearing safety glass for sports, not putting sharp objects near eye, treating eye infections promptly.
4. Encourage maintenance of routine checkups for eye and medical care.
5. Stress need to have subsequent children carefully evaluated for retinoblastoma.
    a. An ophthalmologic examination under anesthesia is usually recommended at approximately age 2 months.
    b. The child should receive frequent examinations thereafter until judged safe from developing retinoblastoma, usually approximately age 3 years.
6. Refer families to resources such as Candlelighters (*www.candlelighters.org*).

Evaluation: Expected Outcomes

- Parents discuss feelings openly, show affection to the child.
- Parents describe possible adverse effects of radiation and how to care for skin around eyes.
- Demonstrates lessened anxiety by participating in age-appropriate activities.
- Shows acceptance of the prosthesis and not inhibited in behavior.
- Moves about environment with ease.

Sickle Cell Disease (Sickle Cell Anemia)

Thalassemia Major (Cooley's Anemia)

Hemophilia

PEDIATRIC HEMATOLOGIC DISORDERS

Anemia

EVIDENCE BASE Cadet, M. (2018). Iron deficiency anemia: A clinical case study. *MEDSURG Nursing*, 27(2), 108–120.

Anemia refers to lower than normal number of red blood cells (RBCs) or hemoglobin (Hb) in the blood. Hb is a main part of the red blood cell and binds oxygen. Anemia results in decreased oxygen-carrying capacity of the red blood cell. It is the most frequent hematologic disorder encountered in children. Approximately 2% of the normal population is anemic.

Pathophysiology and Etiology

1. RBCs and Hb are normally formed at the same rate at which they are destroyed. The function of the RBC is to deliver oxygen from the lungs to the tissues and carbon dioxide from the tissues to the lung. This is accomplished by the use of hemoglobin. In anemia, there is a decrease in the number of RBCs transporting oxygen and carbon dioxide.
2. May be caused by blood loss related to:
    a. Trauma and ulceration.
    b. Decreased production of platelets.
    c. Increased destruction of platelets.
    d. Decreased number of clotting factors.
3. May be caused by impairment of RBC production caused by nutritional deficiency. This impairment includes poverty, malnutrition (including strict vegan and vegetarian diets), and certain intestinal/medical conditions.
    a. Iron deficiency—the most common type of anemia in ages 6 months to 3 years.
    b. Folate deficiency—causes formation of large RBCs with abnormal nuclear maturation (megaloblastic anemia).
    c. Vitamin B_{12} deficiency—causes megaloblastic anemia (deficiency in vitamin B_{12}, folate, or both); called *pernicious anemia* if because of lack of intrinsic factor for absorption of vitamin B_{12}; intestinal diseases such as celiac disease.
    d. Vitamin B_6 deficiency.
    e. Excessive milk intake.
    f. Certain prescription medications (ie, antiseizure drugs, antacids).
    g. Lead poisoning—lead absorbed by the bone marrow attaches to newly formed RBCs and inhibits synthesis of heme. This results in the decrease in circulating Hb.
    h. Vitamin C deficiency.

4. May be caused by decreased erythrocyte production. This occurs in the bone marrow and stem cells.
    a. Pure RBC anemia.
    b. Secondary hemolytic anemias associated with chronic infection, renal disease, and drugs. In anemia of chronic infection and inflammation, the life span of the RBC is moderately decreased, and the ability of the bone marrow to produce RBCs is significantly decreased.
    c. Bone marrow depression—leukemia, aplastic anemias, and transient erythrocytopenia of childhood.
5. May be caused by increased erythrocyte destruction.
    a. Extrinsic factors:
        i. Drugs and chemicals (ie, acetaminophen, ibuprofen, antibiotic such as penicillin's).
        ii. Infections—transient erythroblastopenia of childhood caused by parvovirus (fifth disease), usually between ages 6 months and 4 years.
        iii. Antibody reactions—passively acquired antibodies against Rh, A, or B isoimmunization (transfusion of ABO incompatible blood), autoimmune disorders, burns, and poisons (including lead poisoning).
    b. Intrinsic factors:
        i. Abnormalities of the RBC membrane.
        ii. Enzymatic defects—glucose-6-phosphate dehydrogenase deficiency.
        iii. Abnormal Hb synthesis—sickle cell disease and thalassemia syndromes. These result in defective RBC production.
    c. In hemolytic anemias, the RBCs are destroyed at abnormally high rates, primarily by the spleen. The normal life span of an RBC is 120 days. RBCs are sequestered and destroyed in the spleen.
        i. The activity of the bone marrow increases to compensate for the shortened survival time of the RBCs.
        ii. The bone marrow hypertrophies and occupies a larger than normal share of the inner structure of the bones.
        iii. Products of RBC breakdown increase with hemolysis. If chronic, this may lead to increased excretion of bilirubin into the biliary tract causing gallstones.
        iv. Jaundice results when the conversion of Hb to bilirubin exceeds the liver's capacity.
        v. Iron builds up (hemosiderosis) and may deposit on body tissues.
6. May result from chronic illness such as rheumatoid arthritis, Crohn disease, lupus, and other inflammatory disorders (anemia of chronic disease).
7. "Physiologic anemia" occurs in term infants at ages 8 to 12 weeks; Hb should be between 9 and 11 g/dL. In mild anemia of prematurity, recovery may occur 3 to 6 months after birth.

Clinical Manifestations

1. Condition may be acute or chronic. The more slowly the onset of anemia, the less likely the patient will be symptomatic.

2. Early symptoms:
    a. Fatigue and loss of energy.
    b. Dizziness or lightheadedness.
    c. Low appetite.
3. Late symptoms:
    a. Pallor.
    b. Weakness.
    c. Tachycardia.
    d. Palpitations.
    e. Tachypnea and shortness of breath on exertion.
    f. PICA.
    g. Insomnia.
    h. Cold hands and feet.
    i. Leg cramps.
    j. Tingling or numbness in hands and/or feet.
    k. Jaundice (with hemolytic anemias).

Diagnostic Evaluation

1. Complete blood count (CBC) with mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and iron indices—vary with types of anemia (see Table 52-1).
2. Serum iron and total iron-binding capacity—ratio of less than 0.2.
3. Serum ferritin—less than 12 g/dL.
4. Lead—greater than 10 g/dL.
5. Free erythrocyte protoporphyrin—greater than 35 g/dL.
6. B_{12}, B_6, and folate levels—may be decreased.
7. Hb electrophoresis—may show Hb S or other abnormalities.
8. Parvovirus B19 titer—may be elevated in transient erythroblastopenia.
9. Coombs test—shows whether your body is making antibodies to destroy RBCs.
10. Haptoglobin, bilirubin, and liver function tests.
11. Testing for G6PD deficiency.
12. Hemoglobin electrophoresis.

Table 52-1 Blood Tests in Anemia by Cause

	MCV	MCHC	RETICULOCYTE	FERRITIN	FEP
Iron deficiency	Low	Low	Low	Low	High
Lead poisoning	Low	Low	Low	Normal	High
β-Thalassemia	Low	Low	Low	Normal	Normal
Folate deficiency	High	Normal	Low	Normal	Normal
B_{12} deficiency	High	Normal	Low	Normal	Normal
Sickle cell disease	Normal	Normal	High	Normal	Normal

FEP, free erythrocyte protoporphyrin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume.

Management

Iron Deficiency Anemia

1. Oral iron at a dose of 3- to 6-mg elemental iron/kg per day divided one to three times daily. Reticulocyte count should increase in 7 to 10 days; Hct increases in approximately 4 weeks. Should not be given on an empty stomach; should be given 1 to 2 hours before or after meals; do not give with milk. Vitamin C–containing juice may improve absorption but is not essential.
2. Dietary: decrease milk intake to 16 to 24 ounces per day; include iron-fortified cereals and bread products; increase consumption of red meat; include foods rich in vitamin C; increase green, leafy vegetables.
3. Good sources of iron: red meat, beans, egg yolks, whole grain products, nuts, seafood, spinach, and dark green leafy vegetables.
4. Typically requires a minimum of 3 months of therapy. Treatment on average is 3 to 6 months.
5. Blood transfusion through an IV is not recommended in the setting of chronic anemia other than in hemoglobinopathy patients (genetic mutation of Hb molecule).

Anemia of Chronic Lead Poisoning

See page 1136.

1. Early detection of high lead levels through patient questionaires and blood tests. The CDC defines elevated blood level as greater than or equal to 5 mg/dL.
2. Maintenance of a well-balanced diet, high in calcium and vitamin D.
3. Administration of chelating agents such as edetate disodium calcium, dimercaprol, or succimer according to recommendations of the Centers for Disease Control and Prevention. Only used when blood levels are greater than 45 secondary to depletion of essential nutrients such as calcium, iron, and zinc.
4. Use of lead-free paints and gasoline. (Lead paint was predominantly used in homes built between 1940 and 1959.)
5. Testing of house and soil.
6. Removal of individuals from unsafe environment.
7. Universal screening of children in vulnerable populations (ie, children who are Medicaid eligible).

Megaloblastic Anemia

1. Folate deficiency—administration of folic acid orally.
2. B_{12} deficiency—administration of B_{12} (cyanocobalamin) IM.

Hemoglobinopathies

1. Sickle cell anemia (see page 1376).
2. Thalassemia (see page 1381).

Transient Erythroblastopenia of Childhood:

1. Median age of presentation is 18 to 26 Months.
2. Spontaneous recovery in 4 to 8 weeks.
3. Packed RBC (PRBC) transfusion recommended in patients with severe signs of clinical decompensation including hemodynamic instability, exercise intolerance, or altered mental status.
4. Usually, unless cardiac failure occurs, supportive care, not therapy, is provided.

Anemia from Blood Loss or Bone Marrow Suppression

PRBC transfusions may be necessary (see page 775).

Complications

1. Mental sluggishness, as a result of decreased oxygen and energy for normal neural activity, usually associated with a decreased attention span, decreased intelligence, and lethargy.
2. Decrease in IQ and neurological development.
3. Long-term behavioral changes.
4. Growth retardation related to anorexia and decreased cellular metabolism.
5. Delayed puberty related to growth retardation.
6. Iron overload.
7. Aplastic crises (in patients with chronic hemolytic anemia).
8. Hypersplenism.
9. Cerebral infarction.
10. Ischemic stroke—most prevalent in children with sickle cell disease.
11. Cardiac enlargement related to muscle hypertrophy because of increased strain on the heart, attempting to compensate for increased oxygen demand by the tissues, and eventually results in heart failure.
12. Studies suggest prolonged lead poisoning can lead to violent and criminal behavior later in life.
13. Death from cardiac failure related to circulatory collapse and shock.

Nursing Assessment

1. Obtain history of potential causes.
    a. Dietary history: including the amount of milk and meat consumed, include vegetarianism, lack of red meat, animal products, or green leafy vegetables.
    b. Family history for genetic causes including blood disorders or diseases.
    c. Medication history: some can increase risk of GI blood loss; others can cause vitamin deficiencies.
    d. Past medical history including chronic diseases that can cause anemia.

e. Persistent infection, fever, or chronic disease.
f. Symptoms of shortness of breath, palpitations, fatigue, and headache.
g. Exercise and athletic endeavors/intolerance.
h. Cold intolerance.
i. Pica—craving and consuming nonfood items (eg, paint chips, paper).
j. Changes in bowel movement habits—constipation, diarrhea, and changes in color and consistency of stool.
k. Prolonged or heavy menstrual bleeding.
l. In older children and adolescents—history of alcohol intake.
m. Socioeconomic status—most common in individuals with low socioeconomic status.

2. Obtain a baseline assessment.
   a. Observe skin and mucous membranes for pallor and jaundice.
   b. Obtain height and weight and plot on growth curve. Observe for tachycardia and tachypnea.
   c. Measure vital signs, including blood pressure (BP).
   d. Assess child's functional level—level of exercise tolerance/intolerance and mental functioning.
   e. Assess attainment of developmental milestones.
   f. Review medication history.
   g. Review history of recent illnesses and surgeries.
3. Observe for fatigue, listlessness, and irritability.
4. Observe for blood loss: bruising, bleeding, hematuria, or hematochezia (blood in stool). Assess for excessive menstrual bleeding in adolescent females.

NURSING ALERT Be alert for children at risk for iron deficiency anemia—children in rapid growth stages (toddlers and adolescents) and pregnant or lactating adolescents.

Nursing Diagnoses

- Activity Intolerance related to tissue hypoxia.
- Imbalanced Nutrition: less than body requirements of recommended daily dietary allowances and decreased knowledge of nutritional needs.
- Risk for Infection related to decreased hemoglobin.
- Impaired Gas Exchange related to ventilation–perfusion.
- Ineffective Breathing Pattern related to fatigue.
- Anxiety related to hospitalization and painful diagnostic procedures (venipunctures, finger sticks).
- Delayed Growth and Development related to decreased energy.

Nursing Interventions

Minimizing Fatigue

1. Plan nursing care to allow for lengthy periods when the child is not disturbed by hospital routines, procedures, and treatments; set priorities.
2. Observe for early signs of fatigue, such as irritability, hyperactivity, and listlessness.
3. Establish balance between activities and rest.
4. Maintain a well-balanced diet.
5. Maintain hydration by drinking water throughout the day. May drink sports drinks during exercise. Water and sports drinks during exercise prevent dehydration, electrolyte loss, and muscle fatigue.
6. Gradually increased endurance and intensity of exercise.
7. Allow for rest and recovery after exercising.
8. Administer oxygen and position upright if dyspnea is present.
9. Transfuse packed RBCs, as directed.

NURSING ALERT Monitor transfusion for signs and symptoms of reaction: headache, anxiety, chills, dyspnea, chest pain, hypotension, flank pain, rash, hives, bronchospasm, pruritus, hypertension, and more than 1 degree increase in baseline temperature.

Providing Adequate Nutritional Intake

1. Be aware of the child's food preferences and plan diet accordingly.
2. Provide nutritional guidance as to foods that are rich in iron.
3. Offer small amounts of food at frequent intervals.
4. Reward the child for positive attempts to eat.
5. Allow the child to participate in selection of foods.
6. Avoid tiring activities and unpleasant procedures at mealtime.
7. Make mealtime as pleasurable as possible.
8. If iron is ordered, give between meals (2 hours before or after meals) and with orange juice (iron is absorbed best in an acidic environment).
9. Limit milk and milk products to 16 to 24 ounces per day. Milk products inhibit the absorption of oral iron.
10. Administer liquid iron with a dropper or straw or dilute with water or fruit juice to prevent staining the teeth.
    a. If administered by dropper, make sure that liquid iron is deposited in the back of the mouth.
    b. Dental stains can be removed by brushing the teeth with baking soda paste. If the child is resistant,

you can put baking soda on a washcloth and rub on the teeth.

11. Be alert for adverse effects of iron supplements—gastric distress, colicky pain, diarrhea, or constipation; may call for decreased dose.
12. Advise family that child's stool may turn dark green or black.
13. Stress the importance of continuing iron therapy according to health care provider's directions, even though the child may not appear to be ill.
14. Inform parents that iron overdoses can be harmful or fatal.

Preventing Infection

1. Teach and assist with good hygiene practices, such as handwashing and mouth care.
2. Avoid exposure to others with colds and infections.
3. Wash vegetable and fruits well before eating.
4. Cook meat until it is well done.
5. Make sure that staff, family, and visitors always wash hands thoroughly.
6. Keep children away from turtles, snakes, and lizards which can carry *Salmonella*.
7. Keep immunizations up to date.
8. Report temperature elevation or other signs of infection.

Impaired Gas Exchange

1. Monitor respiratory rate, depth, and effort.
2. Monitor behavior and mental status for restlessness, agitation, or confusion.
3. Monitor oxygen saturation.
4. Position child with head of bed elevated to improve perfusion.
5. Encourage use of oxygen when necessary. Allow for play therapy to encourage compliance.

Ineffective Breathing Pattern

1. Assess for signs and symptoms of ineffective breathing pattern, that is, shallow respirations and tachypnea.
2. Provide calm and restful environment to reduce fear and anxiety.
3. Provide analgesics if child is in pain.
4. Teach deep breathing techniques through use of incentive spirometer or bubbles.
5. Increase activity as tolerated.
6. Consult a respiratory therapist if necessary.

Reduce Anxiety

1. Provide a calm and supportive environment.
2. Allow the child to handle equipment used for tests and procedures (tourniquets, syringes).
3. Explain all tests, procedures, and the treatment plan in age-appropriate manner.

4. Encourage verbalization of fear and anxiety.
5. Include parents in teaching sessions to encourage their support of the child.

Promoting Normal Growth and Development

1. Make sure that nutrition is adequate for age and activity level.
2. Encourage participation in age-related activities.
3. Encourage bedtime ritual and appropriate hours of sleep.
4. Encourage doing homework and tutored activities.
5. Encourage peer socialization.
6. Promote age-appropriate play and therapeutic play.
7. Provide a support system for child and parents.
8. Perform periodic growth chart evaluation and developmental testing.
    a. Share results with parents and explain the association between diet/anemia and growth and development.
    b. Notify health care provider and make referrals, as indicated.

Family Education and Health Maintenance

1. Stress to the parents the importance of continuing the iron therapy according to the provider's directions even though the child may not appear ill.
2. Stress the need for regular medical and laboratory follow-up to evaluate disease progression and response to therapy.
3. Initiate and reinforce good dietary habits.
    a. Foods rich in iron include dark green leafy vegetables, fortified cereals, dried fruits, nuts, and red meats.
    b. Limit milk intake to 16 to 24 ounces per day. Promote iron-containing foods.
    c. Provide vitamin supplements, if necessary. Vitamin C appears to enhance the absorption of iron.
    d. Explain the reasons for diet change to parents and child in a language they can understand. Visual aids and pictures may be helpful.
    e. Assist the parents to select iron-rich foods that are acceptable to the child, within the family's food budget, and culturally acceptable.
    f. Recognize cultural aspects related to food preference and preparation.
4. Initiate a nutritional consultation, as indicated.
5. Discuss with parents any of the social, economic, and environmental problems that may contribute to the child's disease.
6. Emphasize to the parents the benefits of a referral to a community health nurse if it appears that the family will need support in dealing with the child's chronic disease.
7. Discuss general health measures, including adequate rest, diet, sunshine, and fresh air activity.

8. Encourage regular medical and dental evaluations. Encourage the need for immunizations according to recommended schedule. Emphasize the need for appropriate follow-up visits.
9. Educate regarding infection prevention.
10. Teach the parents how to administer medication.
11. Alert the parents to signs of disease progression—increased fatigue, pallor, weakness, developmental delays, and poor performance in school and activities.
12. Prepare for possible adverse GI effects, including constipation and change in stool color.

DRUG ALERT Much variation exists in elemental iron content of commercially available liquid preparations that contain iron. For clarity, dosages should be expressed in terms of elemental iron to ensure proper amounts.

Evaluation: Expected Outcomes

- Increasing activity without fatigue noted.
- Nutritional intake will provide a more balanced, iron-containing diet.
- Remains free from infection; normal temperature.
- Maintains growth curve; manages age-appropriate developmental activities.
- Cognitive performance at school and job (for older adolescents) will improve.
- Attendance at school, job (for older adolescents) and other social obligations will improve.
- Maintain compliance with medication regimen and lab monitoring.

Sickle Cell Disease (Sickle Cell Anemia)

EVIDENCE BASE Shook, L., Farrell, C., Kalinyak, S., et al. (2016). Translating sickle cell guidelines into practice for primary care providers with Project ECHO. *Medical Education Online, 24*(21), 33616.

Sickle cell disease is a group of inherited red blood cell disorders. It is a severe hereditary form of anemia in which a mutational form of Hb distorts the RBCs into a crescent shape at low oxygen levels. The crescent-shaped "sickled" cell blocks the flow of cells through the blood vessels and interrupts the delivery of oxygen to the tissues. The most common form of sickle cell disease in North America is homozygous HbSS disease, an autosomal recessive disorder. In the United States, approximately 100,000 people have sickle cell disease. It occurs in about 16,300 Hispanic American births. Approximately 1 in 3 black or African Americans has sickle cell trait, accounting for about 3 million people.

Pathophysiology and Etiology

1. Genetically determined and inherited as an autosomal recessive condition (see Figure 52-1).
2. Each person inherits one gene from each parent, which governs the synthesis of Hb (see Table 52-2).
3. The sickle cell mutation reflects a single change in the amino acid building blocks of Hb.
4. Hb is a complex protein molecule made up of four subunits of globin.
5. Hb has two proteins that allow it to carry and release oxygen, alpha globin and beta globin.
6. The alpha globin is normal in sickle cell disease. The beta globin has the amino acid valine at position 6 instead of glutamic acid.
7. If only one of the beta genes is the sickled gene and the other is normal, the person is a carrier and has sickle cell trait.
8. If both beta gene codes are sickled, the person has sickle cell disease.
9. Sickle cell Hb aggregates into elongated crystals under conditions of low oxygen concentration, acidosis, and dehydration.
10. This distorts the membrane of the RBC, causing it to assume a crescent or sickle shape. The cells easily become entangled and enmeshed, leading to increased blood viscosity, vessel occlusion, and tissue necrosis.
11. Sickled RBCs are fragile and are rapidly destroyed in the circulation; they can live as little as 4 days versus 120 days for normal RBCs.
12. Anemia results when the rate of destruction of RBCs is greater than the rate of production.
13. Increased sequestration of RBCs occurs in the spleen.

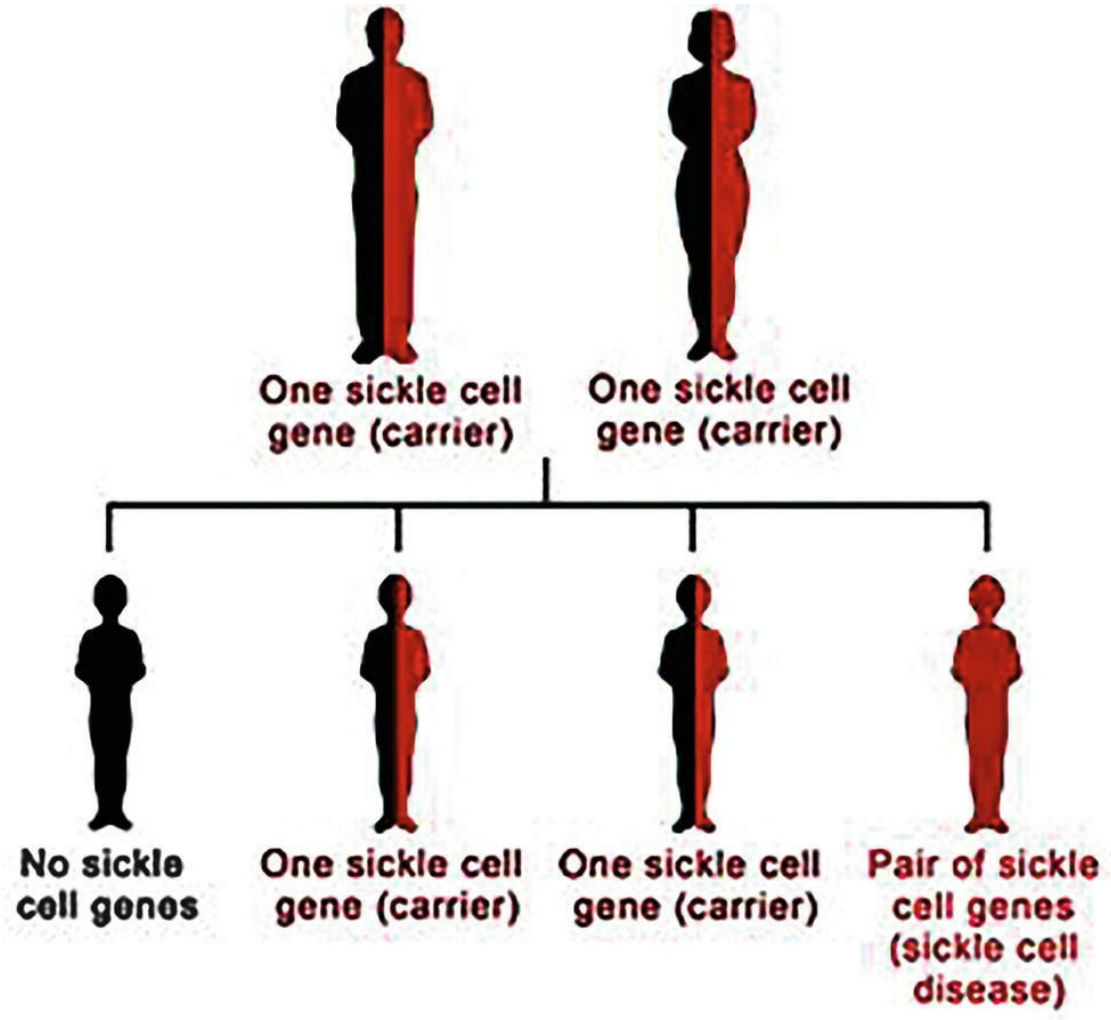

Figure 52-2. Sickle cell crisis signs and symptoms.

Table 52-2 Transmission of Sickle Cell Disease

GENOTYPE OF PARENTS	PROBABILITY OF ABNORMAL HEMOGLOBIN IN OFFSPRING		
	NORMAL	TRAIT	DISEASE
One parent with trait	50%	50%	0
Both parents with trait	25%	50%	25%
One parent with trait; one parent with disease	0	50%	50%
Both parents with disease	0	0	100%

Clinical Manifestations

Usually present since the first year of life. Affected infants do not develop symptoms in the first few months of life because the Hb produced by the developing fetus, fetal Hb, protects RBCs from sickling. The fetal Hb is absent in RBCs produced after birth so that by 5 months of age, sickling of RBCs is prominent and symptoms can begin.

Prenatal diagnosis is possible using amniocentesis or chorionic villus sampling. All 50 states, the District of Columbia, and all US territories require every baby be tested for sickle cell anemia on the newborn screening.

Signs of Anemia

Vary from person to person and may change over time.

1. Hb level—6 to 9 g/dL, average of 8 g/dL.
2. Loss of appetite.
3. Pallor.
4. Tiredness.
5. Easily fatigued.
6. Irritability.
7. Shortness of breath.
8. Have a feeling of heart racing.
9. Jaundice; increased hemolysis results in hemosiderosis (increased iron storage in the liver).

Precipitating Factors of Crisis

1. Dehydration.
2. Infection.
3. Stress.
4. Strenuous physical exertion.
5. Extreme fatigue.
6. Cold exposure.
7. Temperature extremes.
8. Humidity.
9. Air quality.
10. Nutritional deficiencies.
11. High altitude.
12. Exposure to low doses of carbon monoxide.
13. Socioeconomic factors.
14. Surgery.
15. Pregnancy.

Sickle Cell (Vaso-occlusive) Crisis

1. Most common form of crisis. Typically lasts 3 to 14 days. Most common sites are the lower back, leg, hip, abdomen, or chest. Usually occurs in one or more locations.
    a. Small blood vessels are occluded by the sickle-shaped cells, causing distal ischemia and infarction. This can cause severe pain and permanent damage to the brain, heart, lungs, kidney, liver, bones, and

spleen (see Figure 52-2).

2. Extremities:
   a. Bony destruction—related to erythroid hyperplasia of the marrow, leading to osteoporosis or ischemic necrosis.
   b. Aseptic necrosis—results from poor blood supply to an area of the bone, causing localized bone death.
   c. Bone infarction—bone tissue dies due to lack of sufficient blood supply.
   d. Dactylitis ("hand–foot" syndrome)—swelling and inflammation of hands and feet caused by injury to the bones of affected digits by repeated episodes of inadequate blood circulation; commonly first vaso-occlusive event seen in infants and toddlers and children up to age 8.
   e. Arthritis—can accompany dactylitis—presents with pain, swelling, tenderness, and limited range of motion (ROM).
3. Spleen:
   a. Abdominal pain.
   b. Splenomegaly—initially enlarges because of increased activity at the site of RBC hemolysis; increased size results in discomfort. The spleen usually does not work after 4 to 6 months of age. Enlargement usually seen up to 5 years of age.
   c. After multiple episodes of splenic vaso-occlusion, the spleen becomes fibrotic and atrophied.
   d. Decreased splenic function increases the risk of infection.
   e. Important for protection against germs; serious, life-threatening infections occur secondary to damage to the spleen.
4. Cerebral occlusion:
   a. Stroke—most common killer of patients over age 3 years; between 8% and 10% of patients suffer from a stroke, typically at around age 7 years.
   b. Hemiplegia.
   c. Retinal damage, leading to blindness.
   d. Seizures.
   e. Aneurysms—common and often located where they cannot be surgically treated.
5. Pulmonary:
   a. Acute chest syndrome—more likely to occur after infection, sickle cell crisis, general anesthesia, blood clot, and heavy doses of opiates for pain; lowers levels of oxygen in the blood; and can cause lung damage and be life-threatening.
   b. Pulmonary hypertension—occurs when pressure in the arteries of the lungs increases; seen mostly in adult population.
   c. Infarction—triggered by dehydration; results in cycle of deoxygenation which exacerbates sickling leading to small vessel occlusions and ultimately infarction of areas of the pulmonary parenchyma.
6. Altered renal function—enuresis, hematuria, difficulty concentrating urine, protein loss in the urine, and

increased risk of kidney disease.

7. Impaired liver function—may develop iron overload secondary to frequent need for blood transfusion.
8. Priapism—abnormal, recurrent, prolonged, painful penile erection; blood flow out of the erect penis is blocked by sickled cells; can lead to permanent damage and lead to impotence.
9. Infections—most common include *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and Gram-negative bacteria; may develop leg ulcers as a result of infectious process.

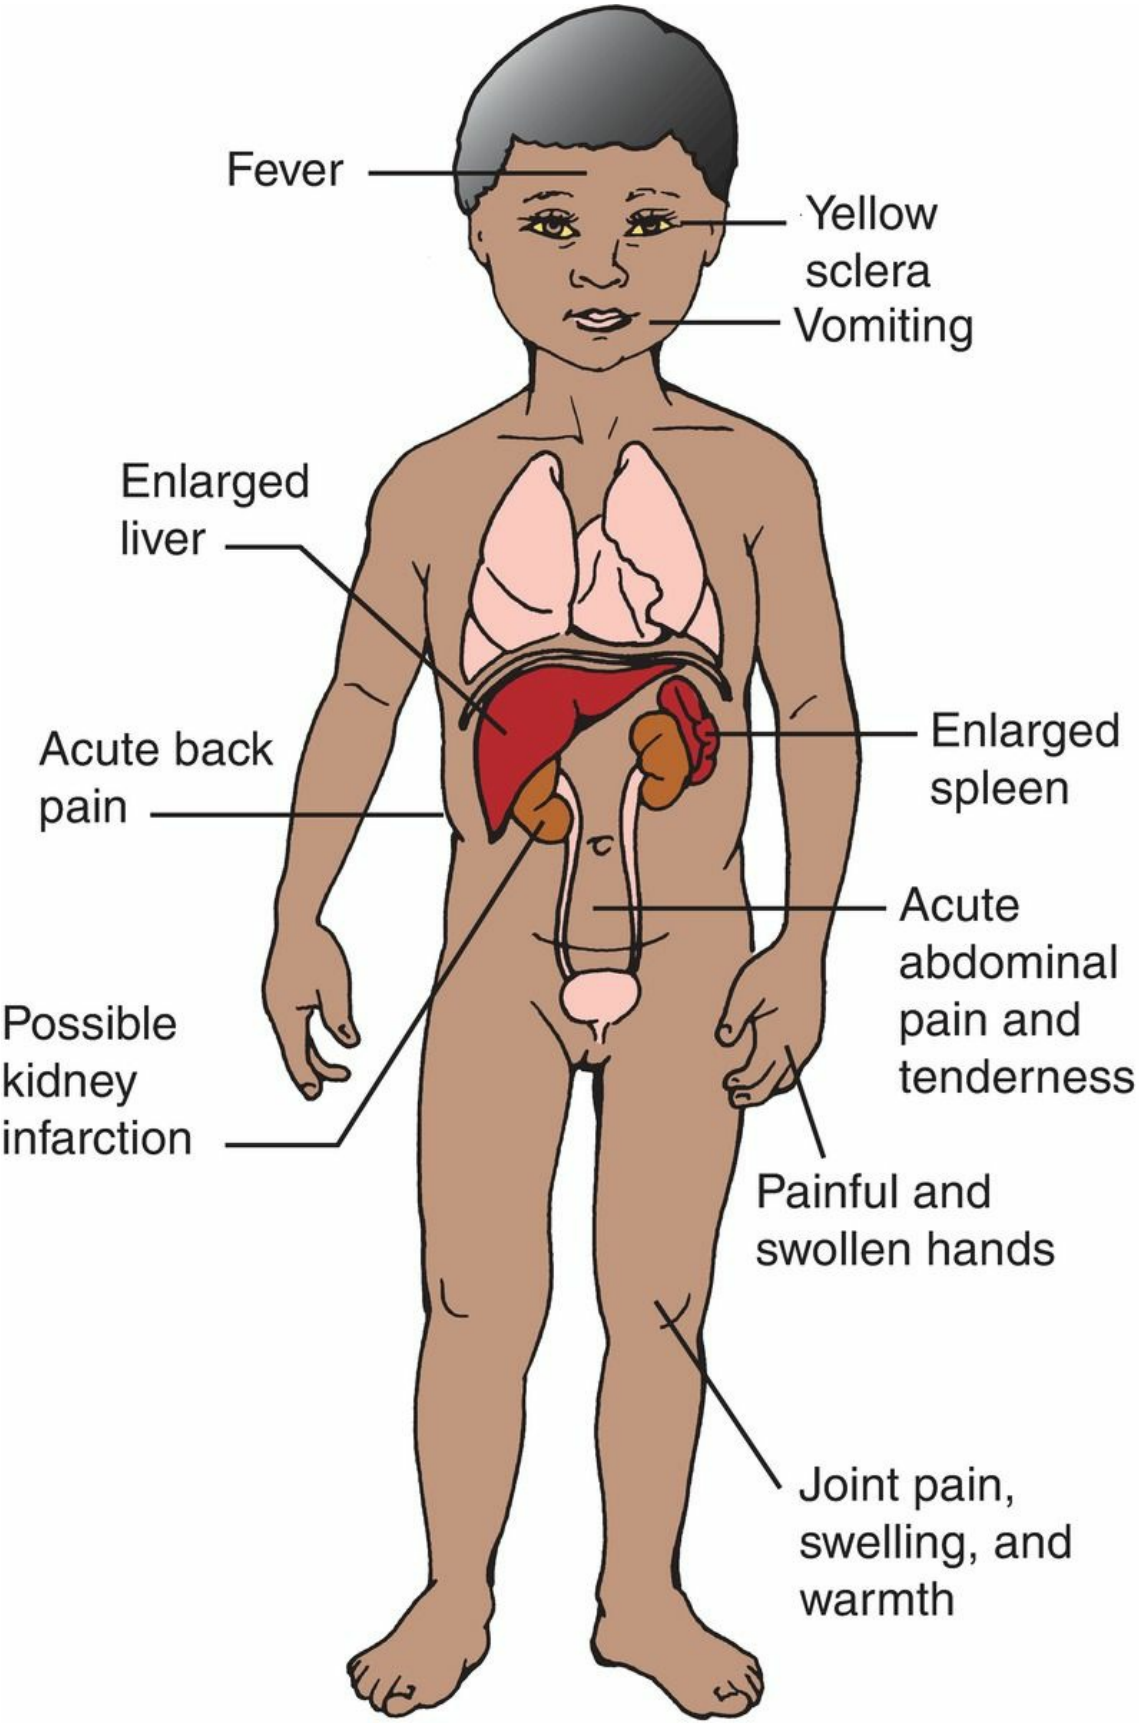

Figure 52-1. Transmission of sickle cell disease.

Splenic Sequestration Crisis

Can be a life-threatening emergency. Most commonly seen in children between 5 months and 4 years of age. If first episode occurs under age 2 years, there is higher risk for recurrence.

1. Large amounts of sickled cells become trapped in the spleen.
2. The spleen becomes massively enlarged.
3. Hemoglobin decreases by at least 2 g/dL secondary to sudden, large drop in blood count.
4. Increase in reticulocytes.
5. Signs of circulatory collapse (eg, shock and hypotension) develop rapidly.
6. Frequent cause of death in infants with sickle cell disease.
7. Restore circulating blood volume; bolus 10 to 20 mL/kg of normal saline while awaiting PRBCs; transfuse 10 mL/kg PRBCs; do not transfuse higher than baseline Hb.
8. Sequestered blood will eventually re-enter circulation increasing risk for hyperviscosity and strokes.

Aplastic Crisis

1. Increased risk with parvovirus.
2. Bone marrow ceases production of RBCs only.
3. Results in low reticulocyte counts.
4. After a few days, the bone marrow usually recovers on its own.
5. Blood transfusion may be necessary.

Chronic Symptoms

Chronic organ damage results in organ dysfunction.

1. Jaundice.
2. Gallstones.
3. Progressive impairment of kidney function.
4. High risk of infection.
5. Growth retardation of the long bones and spine deformities.
6. Delayed growth and puberty.
7. Cardiac decompensation related to chronic anemia (may develop heart failure).
8. Chronic, painful leg ulcers related to decreased peripheral circulation and unrelated to injury; may take months to heal or may not heal without intense therapy, including blood transfusions and grafting.
9. Deep vein thromboses.
10. Pulmonary emboli.
11. Stroke.
12. Malnutrition.
13. Increased risk of renal medullary carcinoma later in life.
14. Altered bony structures—aseptic necrosis of the bones, especially the femoral and humoral heads.

15. Decreased life span.

Diagnostic Evaluation

1. Ante-/perinatal testing via amniocentesis or chorionic villus sampling.
2. Newborn screening—done in all 50 states, the District of Columbia, and all US territories.
3. Those needing further testing:
    a. Immigrants who were not tested in their home country.
    b. Children moving state to state who have not been tested.
    c. Anyone displaying symptoms.
4. Hemoglobin S solubility test and sodium metabisulfite test.
    a. Done by finger or heel stick.
5. Hemoglobinopathy evaluation
    a. Hemoglobin electrophoresis.
    b. Hemoglobin fractionation by HPLC.
    c. Isoelectric focusing—highly sensitive, used at large laboratories
6. DNA analysis—used to investigate alterations and mutations in the genes that produce hemoglobin components.
    a. Requires venipuncture.

Management

Preventing Sickling

1. Promote adequate oxygenation and hemodilution.
    a. Encourage increased intake of fluids—at least eight 8-ounce glasses of water daily.
    b. Avoid high altitudes and other low-oxygen environments.
    c. Exercise regularly but not so much that you become really tired.
    d. Reduce or avoid stress.
    e. Avoid extreme heat or cold. Wear warm clothes in cold weather, stay in air conditioning in hot weather, and do not swim in cold water.
    f. Treat infection as soon as it occurs.
    g. Only travel in commercial pressurized airplanes.
    h. Avoid alcohol, soda, and caffeine—their ingredients make the kidneys excrete more water into the urine increasing the risk of dehydration.
    i. Do not smoke.
    j. Routine blood transfusions (increase number of normal RBCs) (see page 775). Lowers the hemoglobin S circulating in the blood.

Acute Management

Supportive and symptomatic care depends on the type of crisis.

1. Aplastic episode—supportive care and blood transfusions to maintain adequate hematocrit until marrow activity is restored.
2. Splenic sequestration—intravenous fluids and transfusion required to maintain intravascular volume. One or more episodes may require splenectomy, though this is still debated.
3. Hemolytic episode—usually requires only hydration. May occur with splenic sequestration, aplastic, and painful episodes, which are then treated accordingly. Transfusions are required if a significant drop in Hb occurs.
4. Vaso-occlusive or painful episode—must determine if the painful event is a manifestation of an underlying illness (infection) or of an inflammatory condition. Most commonly caused by increased sickling, resulting from hypoxemia and acidosis. Often requires an inpatient stay.
    a. Hydration—this is accomplished by increased oral and parenteral fluid intake of up to two times of fluid maintenance needs.
    b. Analgesics—administered on fixed schedule, not to extend beyond the duration of the pharmacologic effect. IV opioids, such as morphine, are preferred for severe pain, either as a continuous infusion or on a patient-controlled analgesia pump to reach desired effects. Other agents, such as nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, are used for milder pain or to increase the analgesic effects of opioids.
    c. Alternative pain management techniques—behavior modification programs, relaxation therapy, hypnosis, music therapy, and massage.
    d. Those with chronic or severe vaso-occlusive crises may benefit from monthly blood transfusions, which will improve anemia and decrease total amount of sickle hemoglobin; however, iron overload is a possible complication.
    e. Use of hydroxyurea on a daily basis—hydroxyurea increased the amount of fetal Hb in RBCs allowing the cells to travel more easily through the blood vessels; best used on patients who have had recurrent episodes of pain crises.
    f. If there is an HLA matched sibling without sickle cell disease, an allogeneic transplant is standard of care prior to the presentation of symptoms and disease complications.
    g. New research on gene therapy as a cure is currently being investigated.
5. Infection—most common cause of morbidity and mortality.
    a. Most serious include *S. pneumoniae*, *H. influenzae*, *Salmonella* species, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Escherichia coli*, and *Klebsiella pneumoniae*.
    b. Infection of any type is more difficult to eradicate in patients with sickle cell and commonly exacerbates crises such as aplastic episodes caused by parvovirus (fifth disease), increases the rate of hemolysis, and precipitates vaso-occlusive episodes.
    c. Prevention is most important—give usual primary immunizations as well as pneumococcal, *Haemophilus* b conjugate, hepatitis, meningococcal, and trivalent influenza vaccines.
    d. Antibiotic prophylaxis—penicillin prophylaxis is recommended in children less than 5 years of age

and older children with a previous history of severe pneumococcal infection or have functional/surgical asplenia.

e. Patients with unexplained fever should be cultured thoroughly. If clinical condition suggests septicemia, broad-spectrum antibiotics should be initiated after complete culturing. Patients with septicemia can expire in only a few hours.

6. Stroke prevention:
   a. Transcranial Doppler (TCD) screening for all children with sickle cell anemia from age 2 to 16. TCD should be repeated annually if normal and every 6 months if questionable.
   b. Children with abnormal TCD should be kept on a chronic maintenance transfusion program to keep their Hb S less than 30%.
   c. Stroke risk has decreased from 11% to 1% with use of TCD.

Complications

1. Chronic hemolytic anemia. Characterized by anemia, jaundice, periodic crises, splenomegaly, and gallstones. Symptoms worsen during crises.
2. Main causes of death in children from sickle cell anemia were infection and acute splenic sequestration.
3. Common causes of death for older individuals with sickle cell anemia are intercurrent infections, acute chest syndrome, pulmonary emboli, infarction of a vital organ, and renal failure.
4. Life expectancy is variable; however, it is improving with new forms of treatment. Survival has steadily increased to greater than 50 years of age.

Nursing Assessment

1. Observe for pallor and jaundice, changes in vital signs (elevated temperature, tachycardia, hypotension, tachypnea), change in mental status, swelling of extremities, ulcers or skin lesions, or signs of dehydration (decreased elasticity of the skin, dry mucous membranes, decreased urine output, increased urine concentration, and specific gravity).
2. Examine for enlarged liver and spleen and tenderness of hands or feet.
3. Discuss symptoms and duration of pain, dyspnea, fever, pallor, and lethargy.
4. Discuss precipitating factors for crises, that is, fever, travel, and procedures.
5. Discuss history of chest crises and management.
6. Discuss any comorbidities that may exist, for example, asthma.
7. Discuss usual treatment protocol including chronic transfusions and use of hydroxyurea.
8. Evaluate growth and development.

Nursing Diagnoses

- Acute Pain related to tissue anoxia from chronic disease process.
- Altered Tissue Perfusion related to increased blood viscosity and sickling of hemoglobin.
- Risk for Dehydration related to inadequate fluid intake.

- Risk for Infection related to chronic disease and fibrotic changes in the spleen.
- Activity Intolerance related to anemia.
- Interrupted Family Processes related to frequent medical care, hospitalization, and chronic illness.
- Knowledge Deficit related to lack of understanding about cause and treatment of sickle cell disease.

EVIDENCE BASE Smith, K., Reinman, L., Schatz, J., et al. (2018). Parent perspectives on pain management in preschool-age children with sickle cell disease. *Journal of Pediatric Oncology Nursing*, *35*(1), 16–24.

Relieving Pain

1. Identify and use effective measures to alleviate pain, such as:
   a. Carefully position and support painful areas. Joints and extremities can be extremely painful.
   b. Hold or rock the infant; handle gently.
   c. Provide distractions by singing, reading stories, providing appropriate play activities, or television or videos.
   d. Provide familiar objects.
   e. Bathe the child in warm water, applying local heat or providing massage.
   f. Administer opioid analgesics as ordered. Continuous IV infusion is used for the duration of a painful crisis.
2. Communicate effective methods of reducing pain with other staff members and family.
3. Patients with chronic pain may not display typical pain behavior; remember, "pain is what the patient says it is."
4. Assess physical and psychological effectiveness of intervention.

Increasing Tissue Perfusion

1. Avoid physical exertion, emotional stress, and low-oxygen environments to reduce the body's need for oxygen.
2. Administer blood transfusions as ordered.
3. Perform caregiving activities in groups to provide for optimum rest.
4. Administer oxygen to increase diffusion of gas across membranes.
5. Educate family regarding the need for prophylactic transfusions to lower risk of cardiovascular accident.

Risk of Dehydration

1. Calculate and educate family with regard to child's daily fluid requirements.
2. Assess mucous membranes for signs of dehydration.
3. Record daily intake and output to assure adequate fluid intake.

Reducing Infection

1. Ensure adequate nutrition through high-calorie, high-protein diet.
2. Ensure immunizations are up to date.
3. Isolate child from sources of infection if possible.
4. Administer antibiotics, as prescribed.
5. Provide meticulous care to leg ulcers and other open wounds.
6. Use and demonstrate good handwashing and meticulous technique with all procedures.

Activity Intolerance

1. Assess child's level of mobility and activity tolerance.
2. Encourage adequate rest periods throughout the day.
3. Prioritize tasks when episodes of activity intolerance occur.
4. Encourage good eating habits, sleep, and relaxation.
5. Encourage verbalization of feelings regarding limitations.

Normalizing Family Processes

1. Encourage parents to talk about their child, the illness, and how they feel about it.
2. Expect such feelings as guilt, shock, frustration, depression, and resentment.
3. Accept negative feelings, but try to build on positive coping mechanisms.
4. Provide factual information to child and parents about their concerns.
5. Encourage role-playing and play activities to identify fears.
6. Assure adolescents that although sexual development is delayed, they will eventually catch up with their peers.
7. Stress the normalcy of the child despite having sickle cell disease.
    a. Sickle cell disease does not affect intelligence; the child should go to school and keep up with classwork while stable.
    b. Between periods of crisis, the child can usually participate in peer group activities, with the exception of some strenuous sports.
    c. The child needs the same discipline as other children in the family.

Knowledge Deficit

1. Review basics of sickle cell disease with family and child.
2. Teach the family about signs and symptoms of crises.
3. Educate the family as to when immediate medical care is essential.
4. Teach the importance of balanced, healthy nutrition, hydration, sleep, and periods of rest.
5. Arrange for genetic counseling and testing for sickle cell trait in family members.

Community and Home Care Considerations

Home care nurses and school nurses can be instrumental in the care of patients with sickle cell anemia by ensuring that their primary health care needs are met. A reliable medical home is essential for patients with sickle cell anemia.

1. The following examinations should be done as indicated:
    a. Regularly scheduled medical checkups: every 2 to 4 months from birth to 24 months, every 6 months from 2 to 12 years of age, and every 6 to 12 months from age 12 and above.
    b. CBC—yearly.
    c. Quantitative electrophoresis—at birth, repeat between age 1 and 2.
    d. RBC antigen testing—between age 1 and 2 or prior to first transfusion.
    e. LFTs/bilirubin/renal bloodwork—annually.
    f. Urinalysis—annually in older children and adolescents.
    g. Ophthalmology examinations—annually after age 10.
    h. Hearing tests—only if clinical concern, secondary to prolonged and frequent use of antibiotics.
    i. PFTs—oxygen saturation testing at each visit and baseline PFT in adolescence.
    j. A tuberculin skin test every 2 to 3 years (every year in at-risk populations). Any positive findings should be followed up promptly.
    k. All routine childhood immunizations, as well as the hepatitis B series, pneumococcal conjugate vaccine, pneumococcal polysaccharide vaccine, meningococcal, *H. influenzae* type B, and yearly trivalent influenza.
    l. Dental checkups and teeth cleaning every 6 months.
2. Educate parents, teachers, and daycare providers involved in the care of children with sickle cell disease about their common problems and special needs:
    a. Frequent absences because of pain and illness.
    b. Fatigue and inattention, caused by anemia or ischemia of central nervous system tissue.
    c. Need for adequate hydration throughout the course of the day.
    d. Inability to concentrate urine, requiring frequent restroom breaks.
    e. Permanent learning disabilities or delays, requiring individualized teaching plans.
    f. Need for a controlled environment to prevent sickling, avoiding temperature extremes, dehydration, and excessive stress.
    g. Need for moderate physical exercise, with avoidance of rough contact sports and activities.
    h. Desire to feel "normal" and have opportunities and environmental stimulation similar to other children their age.
3. Assess the child's home environment for protection from infection and injury, adequate nutritional resources, transportation to medical appointments, and emotional support. Initiate social service and other referrals, as needed.
4. Consider/explore possible complementary and alternative therapies.

Family Education and Health Maintenance

1. Discuss the genetic implications of sickle cell disease and offer genetic counseling to the family.
2. Instruct the parents in ways that they can help their child to avoid sickling episodes.
    a. Do not allow the child to become chilled or to wear tight clothing that might impede circulation.
    b. Provide adequate fluids and notify health care provider if excessive fluids are lost through vomiting, diarrhea, fever, and excessive sweating.
    c. Limit excessive exercise and offer frequent breaks with activity.
    d. Avoid extreme temperature settings.
3. Instruct parents how to recognize signs of dehydration (dry skin and mucous membranes, decreased urine output; irritability or listlessness in the infant).
4. Encourage parents to seek prompt treatment of cuts, sores, and mosquito bites and to notify the health care provider if the child is exposed to a communicable disease.
5. Encourage good dental hygiene and twice yearly dental checkups to avoid dental infections.
6. Instruct on preventive care, including all the recommended childhood immunizations and screening tests.
7. Encourage a calm, emotionally stable environment.
8. Warn against trips to the mountains or against trips in unpressurized airplanes that will decrease oxygen concentration.
9. Provide sexually active adolescents with information on contraception and sexually transmitted disease.
10. Teach signs of a mild crisis:
    a. Fatigue.
    b. Yellowish color of the skin and whites of eyes.
    c. Decreased appetite.
    d. Irritability.
    e. Low-grade fever.
    f. Painful swelling of hands and/or feet.
    g. Teach parents to palpate the spleen.
11. Instruct on home management of mild crisis.
    a. Encourage fluids.
    b. Administer antipyretic medications, as directed by health care provider familiar with the condition.
    c. Encourage rest.
    d. Keep the child warm.
    e. Apply warm compresses to the painful area.
    f. Hospitalization may be required for the child if pain becomes severe or if IV hydration is required.
12. Teach the signs of severe crisis and whom to notify:
    a. Pallor.

b. Lethargy and listlessness.
c. Severe pain in the abdomen, chest, bones, and/or joints.
d. Swelling in hands and feet.
e. Abdominal swelling.
f. Weakness is the face, arms, or legs.
g. Trouble walking or talking.
h. Visual disturbance.
i. Numbness.
j. Fever of 102°F (38.9°C)—report immediately.
k. Decreased appetite and dehydration.

13. Instruct the parents to have emergency information available to those involved in the child's care (school nurse, teacher, babysitter, family members).
    a. Name and phone number of health care provider or clinic.
    b. Closest emergency facility and ambulance phone number.
    c. Child's blood type, allergies, medications, and medical records number.
    d. Name of informed neighbor or relative to be notified in an emergency.
14. Stress the benefit of wearing a MedicAlert bracelet.
15. For additional information and support, refer to Sickle Cell Foundation (*www.scdfc.org*).

Evaluation: Expected Outcomes

- Able to drink enough fluids and eat a well-balanced diet.
- Pain well controlled or absent.
- Less pallor without the need for oxygen.
- Afebrile without signs of infection.
- Respirations within normal limits for age; uses incentive spirometer hourly.
- Ambulates throughout the day for short intervals with minimal or no pain.
- Parents verbalize concerns about chronic illness.

Thalassemia Major (Cooley's Anemia)

EVIDENCE BASE de Dreuzy, E., Bhukhai, K., Leboulch, P., et al. (2016). Current and future alternative therapies for beta-thalassemia major. *Biomedical Journal, 339*(1), 24–38.

Thalassemia major is the most severe of the beta-thalassemia syndromes and represents the homozygous form of the disease. Beta-thalassemia (β-thalassemia) refers to a group of inherited genetic disorders characterized by a reduction or absence of the β-globulin chain in Hb synthesis. Classification and severity grading are based on spontaneous Hb level and clinical tolerance. Patients with thalassemia major have Hb concentrations between 3 and 7 g/dL and exhibit severe anemia. It was first discovered in the Mediterranean basin and is highly prevalent in countries also affected by malaria. It manly affects people of Mediterranean, Southern Asia, Southeast Asia, and Middle Eastern origin. In the United States, it affects approximately 1,000 people.

Pathophysiology and Etiology

1. Genetically determined, inherited autosomal recessive disorder (see Figure 52-3).
2. Defect can be a complete absence of the β-globin protein or severely reduced synthesis of the β-globin protein.
3. The resulting RBCs are abnormally small, are not produced in normal amounts, and do not contain enough functional Hb, leading to severe hemolytic anemia and resultant chronic hypoxia.
4. The abnormalities result in quantitative changes in globin's as opposed to the qualitative or functional changes seen in hemoglobinopathies.
5. Erythroid activity is significantly increased in an attempt to overcome the increased rate of destruction. This results in:
    a. An enormous expansion of the bone marrow and thinning of the bony cortex.
    b. Skeletal deformities: frontal and maxillary bossing.
    c. Growth retardation.
    d. Deformities of the long bones of the leg.
    e. Massive hepatosplenomegaly.
6. Decreased erythropoietic drive and increased iron load result in higher hepcidin levels. These higher levels moderate dietary absorption and causes macrophages to retain iron. This causes body iron stores to increase because of the inability to excrete the iron and leads to tissue damage.
7. Hemoglobin F (Hb F) amount to less that 1% of Hb by 6 to 12 months of age: in genetic disorders such as thalassemia major, there is a persistent presence of Hb F because of alteration of the β-globin cluster; Hb F does not hold oxygen well.

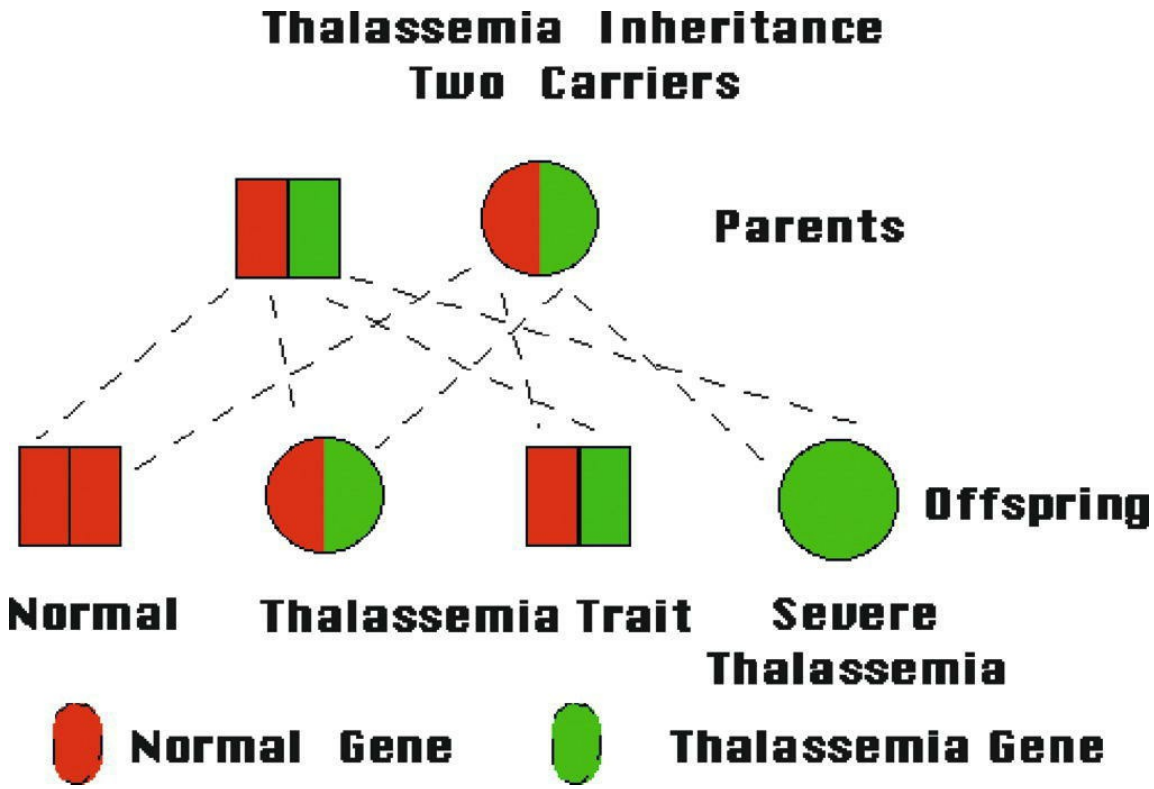

Figure 52-3. Transmission of thalassemia.

Clinical Manifestations

1. Infants exhibit symptoms within the first 2 years of life, often between 3 and 6 months after birth.
2. Symptoms are primarily related to the progressive anemia, expansion of the marrow cavities of the bone, hepatosplenomegaly, and extramedullary hematopoiesis in the chest and abdomen.
3. Early symptoms commonly include failure to thrive, feeding difficulties, pallor, diarrhea, irritability or fussiness, recurrent fevers, and mild jaundice.
4. Further signs of progressive anemia include headache, bone pain, exercise intolerance, jaundice, and protuberant abdomen caused by hepatosplenomegaly.
5. If untreated, it can cause abnormal expansion of the bone marrow causing bones to become thinner, wider, and brittle; this can cause frontal bossing, prominent malar eminence, and depressed bridge of the nose and hypertrophy of maxilla; also see increased risk of fracture of the long bones.

Diagnostic Evaluation

1. CBC with differential—determines number of RBCs and how much Hb is in them; evaluates red cell indices including MCV.
2. Peripheral blood smear—looks at a layer of the blood with a microscope and can assess number and type of white blood cells, platelets, and RBCs.
3. Iron studies—iron, ferritin, unsaturated iron-binding capacity (UIBC), total iron-binding capacity (TIBC), and percent saturation of transferrin.
4. DNA analysis—confirms mutation in the alpha and beta globin–producing gene.

5. Amniocentesis—can be done perinatally if increased risk is a concern.

Management

1. Frequent and regular blood transfusions of packed RBCs to maintain Hb levels between 9 and 10 g/dL.
    a. All children starting regular transfusions should be vaccinated against hepatitis B as early as possible.
    b. Children on chronic transfusion regimens should have an extended red cell phenotype/genotype prior to or as soon as possible after commencing therapy.
    c. RBC component of transfusions: in children less than 4 months of age, PRBCs should be compatible with maternal and neonatal ABO and D group and clinically significant maternal antibodies; in children over 4 months of age, PRBCs should be compatible with recipients ABO and D group and any red cell alloantibodies.
    d. Washed, packed RBCs are usually used to minimize the possibility of transfusion reactions. If unavailable, leukofiltered cells can be substituted.
    e. Goal of transfusion is to shut off erythropoiesis as much as possible; should be given at 3- to 4-week interval.
    f. Target Hb should be between 9 and 10 g/dL; in patients with cardiac insufficiency, higher levels of 10 to 12 g/dL should be maintained.
2. Iron chelation therapy reduces the toxic adverse effects of excess iron and increases iron excretion through urine and feces. Iron chelation is usually started at 2 to 4 years of age after 20 to 25 units of PRBCs is transfused and a serum ferritin level of greater than 1,000 μg/dL and a liver iron concentration (LIC) of greater than 3 mg/iron/g dry weight measured by liver biopsy or hepatic T2 MRI are achieved.
    a. Deferoxamine: IV, IM, or SQ formulation of iron-chelating agent; in IV formulations, it is administered over at least 8 to 12 hours 5 to 7 days per week—should not exceed 60 mg/kg/day; if given SQ, administered at 30 to 60 mg/kg/day over 8 to 12 hours 5 to 7 days per week; vitamin C increases the excretion of iron in the presence of deferoxamine—after 1 month of chelation therapy, should take 2 to 4 mg/kg/day of vitamin C soon after infusion is complete.
    b. Deferasirox: oral iron chelation agent; initial dosing at 10 mg/kg/day—can be adjusted up to 40 mg/kg/day; must be mixed in apple juice, orange juice, or water—for dosing less than 1,000 mg, mix in ½ cup fluid, and in dosing greater than 1,000 mg, must be mixed in 1 cup of fluid; no antacids containing aluminum should be given while on deferasirox.
    c. The new tablet formulation of deferasirox (Jadenu) has demonstrated improved compliance with therapy.
3. Splenectomy. Optimal clinical management from the time of diagnosis may delay or prevent hypersplenism. Increased efficiency of transfusion therapy may reduce the need for splenectomy. Splenectomy should be considered if:
    a. Annual blood requirement is greater than 1.5 times that of splenectomized patients.
    b. Increased iron stores despite good chelation therapy.
    c. Splenic enlargement is accompanied by left upper quadrant pain, early satiety, or concern for splenic

rupture.

d. Leucopenia or thrombocytopenia because of hypersplenism causes recurrent bacterial infections or bleeding.

e. Prior to splenectomy, the child should be immunized against *Streptococcus pneumoniae*, *Haemophilus influenza B*, and *Neisseria meningitidis*.

f. Oral penicillin prophylaxis is necessary (250 mg bid) post splenectomy.

g. Family should be educated that urgent medical attention is required for fever greater than 101°F.

h. Should be avoided under age 5 secondary to increased risk for fulminant postsplenectomy sepsis.

4. Supportive management of complications.

5. Hematopoietic stem cell transplants are the only known cure. Young patients with few complications are the best candidates.

6. Prognosis is poor; life expectancy is 17 years of age, but most children die before their 13th birthday.

Complications

1. Splenomegaly—usually requires splenectomy; major long-term risk after splenectomy is overwhelming sepsis.

2. Growth retardation in the second decade. Growth is usually normal until 9 to 10 years of age. Multifactorial including hemosiderosis-induced damage of the endocrine glands, chronic anemia, hypoxia, chronic liver disease, vitamin and nutritional deficiencies, use of chelating agents, endocrinopathies, low IGF-1 levels, and emotional factors.

3. Endocrine abnormalities:

   a. Hypogonadism—most obvious clinical consequence of iron overload.

   b. Delayed puberty.

   c. Hypothyroidism.

   d. Disturbed calcium homeostasis—results in osteopenia and/or osteoporosis.

   e. Hypoparathyroidism.

   f. Growth hormone deficiency.

   g. Diabetes mellitus—presents after the age of 10 years.

   h. Adrenal insufficiency.

4. Skeletal complications—become less common because of early transfusion therapy and maintenance of Hb levels above 10 g/dL:

   a. Frontal and parietal bossing (enlarging).

   b. Maxillary hypertrophy, leading to malocclusion.

   c. Increased risk of osteopenia and osteoporosis.

   d. Pathologic fractures of the long bones and vertebral collapse, especially in the lumbar region.

5. Cardiac complications:

   a. Arrhythmias—EKG changes specifically increased QTc and QTd intervals.

b. Cardiomyopathy secondary to cardiac iron overload.
c. Increase in left ventricular septal and posterior wall thickness.
d. Premature vascular aging including abnormal vascular stiffening noted as patients live longer.
e. Heart failure—usual cause of death.

6. Liver disease:
   a. Chronic infection develops in 70% to 80% of patients leading to chronic liver disease.
   b. Liver fibrosis and cirrhosis.
   c. Hepatocellular carcinoma—develops in 1% to 5% of individuals over the age of 20.
7. Gallbladder disease—gallstones develop secondary to chronic anemia. Up to two thirds of patients with thalassemia major develop gallstones; most patients remain asymptomatic; cholecystectomy is rarely required.
8. Megaloblastic anemia—caused by sporadic folic acid and vitamin B_{12} deficiency from increased use by hyperplastic marrow. Folic acid supplementation is recommended for all patients.
9. Skin—pruritus and xerosis seen frequently and jaundice secondary to iron overload.
10. Leg ulcers.

Nursing Assessment

1. Review family medical history especially those associated with anemia.
2. Perform whole-body examination to assess for anemia and systemic complications of thalassemia.
3. Observe for signs and symptoms of anemia.
4. Measure growth and development parameters.

Nursing Diagnoses

- Ineffective Tissue Perfusion related to abnormal Hb and oxygen delivery to cells.
- Chronic Pain related to progression of disease in the bone.
- Imbalanced Nutrition related to lack of appetite and nutritional deficiencies.
- Activity Intolerance related to bone pain, cardiac dysfunction, and anemia.
- Risk for Infection related to progressive anemia and splenectomy.
- Deficient Knowledge related to iron chelation therapy.
- Disturbed Body Image related to endocrine and skeletal abnormalities.
- Ineffective Family Coping related to poor prognosis.

Nursing Interventions

Inadequate Tissue Perfusion

1. Blood transfusion
   a. Mainstay of treatment.
   b. Prevents most of the serious complications associated with thalassemia.

c. Signs and symptoms indicative of the need for transfusion include increased cardiac effort or tachycardia, sweating, poor appetite, poor growth, and inability to maintain daily activities.
d. Must rule out infectious/septic etiology.
e. Observe for signs of transfusion reaction (increased chance caused by frequency):
    i. Fever.
    ii. Chills.
    iii. Hives.
    iv. Edema.
    v. Pain or burning in the abdomen, chest, or back.
    vi. Sense of doom.
    vii. Breathing problems.
    viii. Swelling/bruising at transfusion site.
    ix. Nausea, vomiting, and/or diarrhea.
f. Reaction may occur within 15 to 20 minutes of start of transfusion, although delayed reactions may occur up to several months later.

2. Monitor cardiovascular status for complications.
    a. Monitor vital signs: apical pulse, BP, and respirations.
    b. Assess for edema.
    c. Auscultate heart sounds for gallop and lungs for rales.
    d. Assess extremities for ulcer formation.
    e. Increased risk of pulmonary hypertension.
    f. Major complication of transfusions is iron overload in the heart. Starting chelation early is essential in preventing life-threatening complications.

Chronic Bone Pain

1. Bone pain is a characteristic feature of thalassemia major.
2. Monitor CBC for hemoglobin values less than 10 g/dL.
3. Use warm packs—can reduce muscle spasms and reduce inflammation.
4. Eat a healthy diet that includes calcium and vitamin D to help keep bones as strong as possible.
5. Administer and teach proper administration of NSAIDs, such as ibuprofen or naproxen. Use carefully and monitor liver enzymes in patients with liver complications.

Activity Intolerance

1. Encourage participation in activities that do not require significant strenuous activity. Full participation in some activities, especially with peers, will increase self-esteem. Allow for periods of rest during such activities.
2. Facilitate physical and occupational therapy to develop an acceptable exercise plan.

3. Involve the parents' and child's school in developing a plan of gym activities, classes, and rest periods that allow the greatest level of participation and slowly develop endurance.
4. Advise parents that during the week of the scheduled transfusion, the fatigue will be greatest, so gym and other exertional activities should be modified.
5. Discourage participation in contact or other sports that increase the child's risk of a fracture (skateboarding, football, soccer).

Infection Risk

1. Maintain and teach good handwashing techniques.
2. Minimize exposure to infectious illnesses.
3. After splenectomy, the child has increased susceptibility to infection and should be maintained on oral penicillin prophylaxis.
4. Vaccinate child against *H. influenzae*, pneumococcal, and meningococcal infections before splenectomy and encourage yearly trivalent influenza vaccination.
5. Encourage prompt medical attention for fever or signs of infection. Fever of 102°F (38.9°C) should be reported immediately and IV broad-spectrum antibiotics initiated.

Knowledge Deficit

1. Explain the importance of chelating (binding) agents to decrease iron deposits in tissues and to increase iron excretion through urine and feces.
2. Administer IV deferoxamine as prescribed:
   a. Infuse slowly, during 8 to 24 hours, through peripheral line or implanted infusion device or via volumetric pump.
   b. Have emergency resuscitation equipment nearby in case a severe allergic reaction occurs.
3. Review administration of oral deferasirox and encourage adherence to the medication schedule.
4. Ocular and auditory disturbances are seen in long-term use. Periodic visual and audiometric testing is recommended.

NURSING ALERT Because of the excess iron deposition in children with thalassemia, dietary iron should be decreased as much as possible.

Improving Body Image

1. Explore the child's feelings of being different from other children.
2. Encourage the child to express feelings through the use of play: art and role playing.
3. Give positive reinforcement regarding appearance.
4. Encourage socialization and peer interaction.

5. Encourage endocrine consultation for delayed growth and puberty.
6. Encourage craniofacial specialist evaluation for bony abnormalities.
7. Suggest support group or individual counseling, as needed.

Improving Family Coping Strategies

1. Alleviate the child's anxieties about illness by providing explanation based on developmental level.
2. Use role-playing and play activities to identify concerns.
3. Assist in strengthening coping mechanisms, such as support network and problem solving.
4. Help identify resources for financial support, medical supplies, respite care, etc.
5. Encourage involvement in school and after-school activities.
6. Encourage parents to set limits and to provide discipline for the child that is consistent with that for other children in the family.
7. Provide supportive care to the dying child.
8. Encourage bereavement support for parents, siblings, and family.

Family Education and Health Maintenance

1. Discuss the genetic implications of thalassemia and refer for genetic counseling.
2. Provide a detailed instruction about:
   a. Prevention and prompt treatment of infections.
   b. Medications.
   c. Home chelation therapy.
   d. Dietary modifications to limit iron intake.
   e. Activity restrictions, including avoidance of activities that increase the risk of fractures.
   f. Signs of complications.
3. Encourage parents to provide information about the child's condition to significant adults who are involved with the child (teacher, school nurse, babysitter, scout leader).
4. For additional information and support, refer to Cooley's Anemia Foundation (*www.thalassemia.org*).

Evaluation: Expected Outcomes

- Vital signs stable.
- Skin integrity intact without evident edema.
- No edema evident.
- Rates pain as less than 4 out of 10 on developmentally appropriate scale.
- Attends school on a regular basis.
- Reports increased participation in activity and less fatigue.
- No febrile illnesses reported. Immunizations up to date.
- Parent has good understanding of and is proficient in administration of chelation agents.
- Child verbalizes interest in appearance and positive statements about self.

- Family participates in support groups.
- Parents discuss illness with child and siblings.

Hemophilia

EVIDENCE BASE Moort, I., Joosten, M., Maat, M., et al. (2017). Pitfalls in the diagnosis of hemophilia severity: What to do? *Pediatric Blood & Cancer*, *64*(4), 3.

Hemophilia is one of a group of inherited X-linked recessive bleeding disorders that cause abnormal or exaggerated bleeding and poor blood clotting. It is most commonly used to refer to two specific conditions, hemophilia A and hemophilia B. Hemophilia A is caused by a deficiency of clotting factor VIII. Hemophilia B is caused by a deficiency of clotting factor IX. Males are commonly affected and females are usually carriers of the disease. Hemophilia A occurs in 1 in 5,000 live births and is four times as common as hemophilia B. There are an estimated 20,000 individuals in the United States with hemophilia. Worldwide incidence is estimated at more than 400,000.

- 80% to 85% have factor VIII deficiency or hemophilia A (classic hemophilia).
- 15% to 20% have factor IX deficiency or hemophilia B (Christmas disease).
- Few have factor XI deficiency or hemophilia C.

EVIDENCE BASE Lillicrap, D. (2013). von Willebrand disease: advances in pathogenetic understanding, diagnosis, and therapy. *Blood, 122*, 3735–3740.

von Willebrand disease (pseudohemophilia) is the most common inherited bleeding disorder (in the hemophilia category) caused by deficiency or abnormality in von Willebrand factor (VWF), a key protein that helps clotting. von Willebrand disease shows no geographical or ethnic predilection. Both sexes inherit the genetic mutation with equal frequency, although females outnumber males (2:1). The prevalence of von Willebrand disease is 0.6% to 1.3% of the population.

Pathophysiology and Etiology

1. Hereditary (approximately 80% of patients) (Table 52-3).
    a. Autosomal dominant pattern—in rare cases, inherited can see autosomal recessive pattern.
    b. Three types exist—1, 2, and 3:
        i. Type 1—mild to moderate reduction in functional normal VWF—accounts for 65% to 80% of affected individuals.
        ii. Type 2—involves expression of functionally abnormal VWF—occurs in 20% to 35% of affected individuals.
        iii. Type 3—absence of VWF—affects 1 in 1 million people.

c. Those who inherit one copy of the mutated gene will develop type 1 or 2.

d. Those who inherit a mutated gene from both parents will develop type 3.

e. May appear in females if a female carrier bears offspring with a male hemophiliac, although this is rare (see Figure 52-4).

2. Spontaneous mutations may occur when the family history is negative for the disease. Although not initially inherited, it can be passed on to the affected person's children.

3. The basic defect is in the intrinsic phase of the coagulation cascade. The blood clotting factors are necessary for the formation of prothrombin activator, which acts as a catalyst in the conversion of prothrombin to thrombin.

   a. When damage to the vessel wall occurs, bleeding starts and platelets are activated to the site of the injury resulting in platelet aggregation.

   b. Clotting proteins, such as factors VIII and IX, are activated on the surface of the platelets to form a meshlike fibrin clot.

   c. These proteins work in a domino-like reaction known as the coagulation cascade. If the protein is absent, the chain reaction is broken, either preventing clot formation or resulting in slower clot formation.

4. The result is an unstable fibrin clot.

5. Coagulation factors are involved in hemostasis and the formation of clots. PTT is used to measure coagulation factors, including factors VIII and IX.

6. Platelet number and function are normal; therefore, small lacerations and minor hemorrhages are usually not a problem.

7. Patients do not bleed more rapidly; rather, there is delayed or abnormal clot formation.

Table 52-3 Transmission of Hemophilia

GENOTYPE OF PARENTS	PROBABILITY OF ABNORMALITY IN OFFSPRING				
	FEMALE			MALE	
	NORMAL	CARRIER	HEMOPHILIAC	NORMAL	HEMOPHILIAC
Female carrier/normal male	50%	50%	0	50%	50%
Noncarrier female/hemophiliac male	0	100%	0	100%	0
Female carrier/hemophiliac male	0	50%	50%	50%	50%

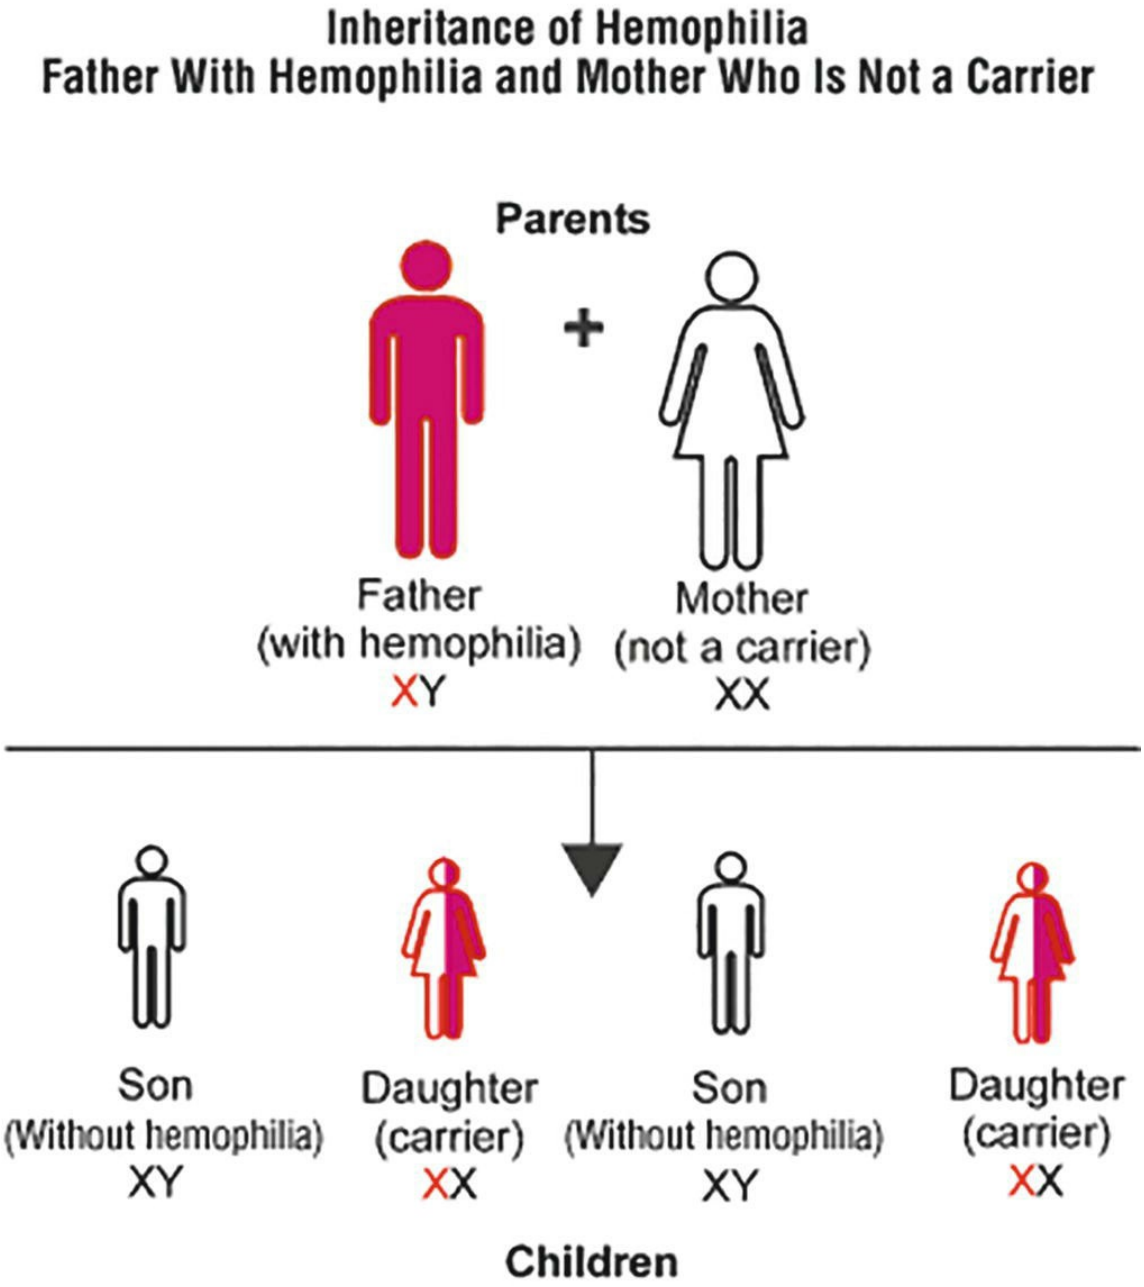

Figure 52-4. Transmission of hemophilia.

Clinical Manifestations

1. In majority of patients, hemophilia is diagnosed at birth because of family history, although in approximately 1/3 of patients, the occurrence of hemophilia represents a new mutation.
2. Approximately 30% of male infants with hemophilia have bleeding with circumcision.
3. In those patients who do not have a family history, diagnosis is often made when the child begins to walk or crawl.
4. Varies in severity, depending on the plasma level of the coagulation factor involved.
    a. Level of less than 1% of normal—severe hemophilia; commonly severe clinical bleeding with minimal or unknown trauma and often experience unprovoked muscle and joint bleeding one to six times

monthly (factor level less than 0.01 μ/mL).

b. Level of 1% to 5% of normal—moderately afflicted; may be free from spontaneous bleeding and may not manifest severe bleeding until trauma occurs (factor level less than 0.02 to 0.05 μ/mL).

c. Level of 6% to 40% of normal—mildly afflicted; patients usually lead normal lives and bleed only with severe injury or surgery (factor level greater than 0.05 μ/mL).

d. Degree of severity tends to be constant within a given family. Within an individual, severity does not vary over time unless inhibitor (autoantibody to infused factor) develops.

5. Signs and symptoms of abnormal bleeding include:

a. History of prolonged bleeding episodes such as after circumcision.

b. Easily bruised.

c. Oral bleeding.

d. Spontaneous soft tissue hematomas.

e. Hemorrhages into the joints (hemarthrosis)—especially the elbows, knees, and ankles, causing pain, swelling, and limitation of movement.

f. Hematuria.

g. Black, tarry stools.

h. Heavy or long menstrual bleeding, often with blood clots greater than 1 inch.

i. Excessive bleeding from an injury.

j. Head trauma, resulting in intracranial hemorrhage.

Diagnostic Evaluation

1. Prothrombin time and bleeding time—measures clotting ability of factors I, II, VII, and X—normal.
2. Partial thromboplastin time—measures clotting ability of factors VIII, IX, XI, and XII—prolonged.
3. Fibrinogen—assesses patients' ability to form a blood clot.
4. Assays for specific clotting factors—measures levels of factor VIII and IX—abnormal.
5. VWF—helps to diagnose von Willebrand disease and distinguish between types of disease—persons with O type blood have VWF levels 25% less than other blood types.
6. Gene analysis—to detect carrier state, for prenatal diagnosis.

Management

1. Prompt, early, and appropriate treatment is the key to preventing most complications.
2. Must replace missing coagulation factor (VIII or IX) through the administration of type-specific coagulation concentrates during bleeding episodes.

a. *Factor VIII*—75% of the factor is recombinant, which is developed in the lab through the use of DNA technology; for control of bleeding episodes, perioperative management of bleeding, and routine prophylaxis in patients with hemophilia A; dosing is intravenous and based on location and extent of bleeding and patients clinical condition; not to be used for patients with von Willebrand

disease.

   b. *Factor IX*—is recombinant and given intravenously; used for control of bleeding, perioperative management of bleeding, and routine prophylaxis in patients with hemophilia B; for prophylaxis, give 50 IU/kg weekly or 100 IU/kg every 10 days; for minor/moderate bleeding, give 30 to 60 IU/dL and repeat every 48 hours as necessary; for major bleeding, give 80 to 100 IU/dL, repeat in 6 to 10 hours, and then give every 24 hours for 3 days and then every 48 hours until healing is achieved.

3. No viral inactivated concentrate exists for hemophilia C; fresh frozen plasma is given to supply factor XI.
4. Mild and moderate factor VIII–deficient hemophiliacs and some patients with von Willebrand disease may respond to desmopressin, which causes the release of factor VIII from the endothelial stores. Treatment is started in case of bleeding or before an intervention, that is, dental work. Dosing can be intravenously to intranasally. IV dosing is 0.3 μg/kg and intranasally 150 μg per nostril. It can be repeated every 12 to 24 hours depending on response. Patients receiving desmopressin should restrict fluids during use to prevent hyponatremia and seizures.
5. Plasma-derived VWF—use dependent on predicted amount of bleeding and intervention to be performed for patients with von Willebrand disease; dosing is concentrate dependent; recombinant von Willebrand concentrate has been developed and shown increased activity compared to plasma derived factor but was approved by the FDA in 2015 only for adults.
6. Antifibrinolytics, such as aminocaproic acid and tranexamic acid, are given as adjunctive therapy for dental procedures and for nose and mouth bleeding; it is administered orally.
7. Activated prothrombin complex concentrates that have activated factors VII, IX, and X are used when inhibitors (autoantibodies) have developed to bypass factor VIII or IX.
8. Supportive therapies:
   a. NSAIDs are used to decrease inflammation and arthritic-like pain associated with chronic hemarthroses. They must be used with caution because some types and higher doses interfere with platelet adhesion. Should only be used when prescribed by licensed practitioner who is familiar with bleeding disorders.
   b. Physical therapy to prevent contractures and muscle atrophy. This includes exercise, whirlpool, and icing.
   c. Orthotics to prevent injury to affected joint and to help resolve hemorrhages.
9. Synovectomy—orthopedic surgical intervention to remove damaged synovium in chronically involved joints.
   a. Open procedure provides direct visualization of joint and removal of damaged tissue.
   b. Arthroscopic—visualization and removal of the joint synovium through the use of an arthroscope.
   c. Radionucleotide—instillation of radioisotope P32 into the joint, which removes stops excessive growth of the synovium, decreases amount of bleeding, and decreases potential for arthritis; done through a needle with x-ray guidance.
10. Gene therapy research—genetic copies of sequenced factor VIII and IX molecules are inserted into the body via some type of vector cell to find their way into the human host genetic machinery and begin to

produce either factor VIII or factor IX in deficient patients.

11. Patients with bleeding disorders should avoid aspirin and aspirin-containing products, nonsteroidal anti-inflammatories, and blood thinners such as warfarin and heparin.

Complications

1. Airway obstruction caused by hemorrhage into the neck and pharynx.
2. Joint disease—secondary to repetitive bleeding into the joints, often results in arthritis, and may require joint replacement therapy.
3. Intestinal obstruction caused by bleeding into intestinal walls or peritoneum.
4. Compression of nerves with paralysis caused by hemorrhaging into deep tissues, known as *compartment syndrome*.
5. Intracranial bleeding, resulting in serious neurologic impairments.
6. Inhibitor development—30% of patients with hemophilia A and 2% to 3% of patients with hemophilia B develop inhibitors to factor replacements.
7. Viral infections—risk from plasma-derived factor concentrates—less often now that recombinant forms of factor are available.
8. Death may result from exsanguination after any serious hemorrhage, such as intracranial, airway, or other highly vascular areas.
9. Life span—varies based on whether they receive proper treatment; without proper treatment, many die before reaching adulthood; with proper treatment, life expectancy is about 10 years less than those without hemophilia: children can expect to have a normal life expectancy.

Nursing Assessment

1. Obtain history of and observe for unusual bleeding—ecchymosis, prolonged bleeding from mucous membranes and lacerations, hematomas, hemarthroses, hematuria, and rectal and GI bleeding. Determine time frame of most recent bleeding episode.
2. Obtain history of whether patient has inhibitors and, if so, what their titer is.
3. Assess for acute or chronic bleeding.
4. Priority assessment of joints for swelling, warmth, tenderness, ROM, contractures, and surrounding muscle atrophy.
5. Check for hematuria and bleeding from the mouth, lips, gum, and rectum.
6. Check vision, hearing, and neurological development.
7. Obtain information on prior treatment with blood products.
8. Assess family resources and coping skills.

Nursing Diagnoses

- Risk for Deficient Fluid Volume related to hemorrhage.
- Risk for Bleeding related to inability of blood to clot.

- Impaired Physical Mobility related to repeated hemarthroses.
- Acute Pain related to bleeding into joints and muscles.
- Ineffective Family Coping related to disabling and life-threatening disease.

Nursing Interventions

Preventing Hypovolemia Through Control of Bleeding

1. Provide emergency care for bleeding.
    a. Apply pressure and cold to the injury site to assist in clot formation. Immobilize and elevate injured area. This should be done especially after venipuncture or injection.
    b. Do not aspirate hematomas or joints.
    c. Suturing and cauterization should be avoided.
2. Immobilize the affected part and elevate above the level of the heart.
3. Recognize early and late signs of a joint bleed. Early signs include tingling and bubbling sensation but no real pain or tightness and pain without visible signs of a bleed. Late signs include swelling at the joint, warmth of the skin to touch, pain when bending or extending the joint, and increased difficulty with mobilization.
4. Administer recombinant factor VIII or factor IX coagulation concentrate.
    a. Administration should be slow IV push; usually 2 to 3 mL/minute; consult package inserts.
    b. In the case of head trauma, administer factor replacement immediately and prior to obtaining imaging—waiting to administer factor can have serious neurologic effects.
    c. Cryoprecipitate and fresh frozen plasma are not recommended because of their lack of viral inactivation treatment. They may be only treatment of choice in some countries.
    d. Stop the transfusion if hives, headaches, tingling, chills, flushing, or fever occurs.
5. Apply fibrinolytic agents to wound for oral bleeding. Popsicles also work for minor mouth bleeding. Do not use fibrinolytic agents for hematuria.
6. Attempt to keep child relaxed and quiet during treatment to decrease pulse and rate of bleeding.
7. Monitor vital signs and treat for shock if child becomes hypotensive.

Providing Protection Against Bleeding

1. For patients with severe hemophilia, administer prophylactic factor IX or XIII two to three times weekly to prevent spontaneous bleeds.
2. Avoid obtaining rectal temperatures; insert thermometer probe gently and use axillary, oral (if age-appropriate), or external ear route.
3. Use soft toothbrush and encourage regular dental checkups.
4. Avoid injections, if possible.
    a. Administer medications orally whenever possible.
    b. Subcutaneous route is preferred over IM.

c. Apply pressure to injection site for 10 to 15 minutes. Then apply a pressure dressing with self-adhesive gauze.

5. Maintain a safe environment and teach parents safety measures.
   a. Protect child with kneepads, elbow pads, and helmets when riding bicycles or tricycles.
   b. Use safety belts and straps in high chairs, car seats, and strollers.
   c. Infants should have appropriate padding in cribs or playpen to prevent injury.
   d. Supervise toddlers as they learn to walk.
   e. Remove or pad furniture with sharp corners.
   f. Keep small and sharp objects out of reach.
   g. Check play equipment and outdoor play areas for possible hazards.
   h. Child should wear a MedicAlert bracelet.
   i. Be aware of safe activities that your child can enjoy including swimming, biking, and walking.

DRUG ALERT Children with hemophilia should not receive aspirin, compounds containing aspirin, or nonsteroidal anti-inflammatory agents because these medications affect platelet function and prolong bleeding time.

Preserving Mobility

1. Treat hemarthrosis or muscle bleed as soon as possible.
2. Provide supportive care for hemarthrosis.
   a. Immobilize the joint in a position of slight flexion.
   b. Elevate the affected part above the level of the heart.
   c. Factor, if readily available, should be administered before ice is applied to the joint.
3. For severe hemarthroses, continue factor administration at home until joint pain and immobility have resolved.
4. For less severe hemarthroses, begin gentle, passive exercise 48 hours after the acute phase to prevent joint stiffness and fibrosis. Progress to active exercises.
5. Short course of corticosteroids has shown clinical effectiveness in the treatment of hemarthrosis.
6. Physiotherapy is an essential adjunct for joint bleeding.
7. Hydrotherapy can reduce pain and instability in target joints and improve ROM and muscle tone.

Relieving Pain

1. Be aware that increased pain usually means that bleeding continues and further replacement therapy may be needed.
2. Assess for further swelling of joints and limitation of movement.

3. Administer or teach administration of acetaminophen during acute phase. NSAIDs may be used for chronic pain, but cautiously, to prevent interference with platelet function.
4. Administer opioids sparingly, as ordered, for severe, acute pain.
5. If pain persists for a prolonged duration, referral to a Pain Management Center is recommended.

Enhancing Family Coping

1. Acknowledge parents' feeling of guilt or anger with regard to diagnosis.
2. Use play therapy to help the young child and siblings adjust to illness.
3. Encourage the parents to allow the child to participate in as many normal activities as possible within the realm of safety.
4. Have child wear a MedicalAlert bracelet that also includes clotting factor that is best used in an emergency.
5. Make sure anyone involved in caring for your child is aware of your child's condition.
6. Encourage the child's education. Involve teacher, principal, and assistants in understanding disease process and limitations that need to be enforced for child's safety.
7. Refer to social worker for counseling and identification of resources for financial concerns and emotional support.
8. Encourage avoidance of overprotection. This can place too many restrictions on the child's normal development. This can result in the child becoming overly dependent or becoming defiant and engaging in risky behaviors or activities.
9. Encourage involvement in support group.

Community and Home Care Considerations

1. Perform a home safety survey (inside and outside) to identify potential hazards to the hemophiliac child.
2. Provide teaching and referrals to initiate an infusion therapy program at home when hemorrhage begins.
3. Have child participate in regular exercise program to help strengthen joints which helps prevent damage or pain from internal bleeding.
4. Make sure that primary health care needs are being met by facilitating the following:
    a. Regular visits to primary care provider for preventive health maintenance to address growth and development, behavior, and psychosocial issues.
    b. Dental examinations and teeth cleaning every 6 months.
    c. All the recommended childhood immunizations, plus hepatitis A, to prevent infection from blood-borne pathogens.
5. Provide education to family and all caregivers about recognizing and treating bleeds appropriately.
6. Provide emotional support through the provision of educational materials, information about support groups, and a list of resources within the community.
7. Educate teachers and other school faculties about the child's special needs.
    a. These children can have permanent mental or physical disabilities from old hemorrhages,

necessitating individualized plans.

b. Avoidance of rough or contact sports and activities.

c. All injuries must be taken seriously. The school nurse should be notified so that proper first aid and treatment can be initiated.

d. Although they have a chronic illness, these children have a strong desire to be "normal," with the same opportunities and environmental stimulation as other children.

Family Education and Health Maintenance

1. Review safety measures to prevent or minimize trauma.
2. Encourage education by parents to teachers, babysitters, and others involved in child's care so that they can be responsive in an emergency.
3. Advise wearing a MedicAlert bracelet.
4. Teach emergency treatment for hemorrhage.
   a. Immobilize the part with splints or an elastic compression bandage. (These materials should be immediately available in the home.)
   b. Apply ice packs. Parents should keep two or three plastic bags of ice immediately available in the freezer. Popsicles can be used for minor mouth bleeding.
   c. Consult the child's health care provider and initiate additional recommended therapy.
5. Encourage regular medical and dental supervision.
   a. Preventive dental care is important. Soft-bristled or sponge-tipped toothbrushes should be used to prevent bleeding. Factor replacement therapy is necessary for extensive dental work and extractions.
   b. Hepatitis B vaccine is necessary to protect against the rare occurrence of hepatitis B from blood transfusions.
6. Teach healthy diet to avoid obesity, which places additional strain on the child's weight-bearing joints and predisposes to hemarthroses.
7. Assist the parents in helping the child to understand the exact nature of the illness as early as possible. Special attention should be given to the signs of hemorrhage, and the child should be told of the need to report even the slightest bleeding to an adult immediately.
8. Advise families that genetic counseling and family planning are available for parents and adolescent patients.
9. For additional information and support, refer to National Hemophilia Foundation (*www.hemophilia.org*).

TRANSITIONAL CARE ALERT Provide written discharge summaries understandable to parents regarding course of treatment during hospitalization. Ensure that discharge instructions include written medication plans, with medication name, reason for use, dosage, and times of administration. If

PRN medications are prescribed, ensure understanding of when and how often these medications can be administered. Allow parents time to process information and address any questions or concerns. Provide contact numbers for parents for emergencies that require immediate attention. Schedule follow up appointments within 1 week of discharge at outpatient clinic or with primary care provider.

IMMUNOLOGIC DISORDERS

Pediatric Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

Human immunodeficiency virus (HIV) infection for infants, children, and adolescents is represented by a continuum of immunologic and clinical classifications ranging from no to severe immunologic suppression and asymptomatic to severely symptomatic. *Acquired immunodeficiency syndrome (AIDS)* is the end stage of the continuum. Also see Chapter 29, HIV Infection and AIDS, page 808.

---

1. HIV is a pandemic, affecting people all over the world; the World Health Organization estimated 30.8–42.9 million people living with HIV (in 2016).
2. Children under age 15 account for 1.8 million infected with HIV worldwide (end 2015). In North America, UNAIDS reported there were more than 1.2 million people living with the virus in 2013, of which 13% are unaware they are infected.
3. HIV is transmitted through sexual contact with an infected person; through exposure to infected blood and blood components (sharing needles via IV drug use, tattooing, piercing, and unsterilized medical equipment); or from an HIV-infected mother to her baby before or during birth or through breastfeeding.
4. In the United States, sexually acquired HIV remains the main mode of transmission. It is estimated that youth aged 13 to 24 represent the second highest rate of newly acquired HIV.
5. Globally, 76% (60–88%) of all pregnant HIV-infected women are treated to prevent vertical transmission, which has contributed to the greater than 47% decline in new infections among children, since 2010.
6. In the US, prenatally acquired HIV infection has dramatically decreased from about 25% to less than 1% of pediatric cases.
7. This decrease reflects concerted efforts to provide improved preconception counseling; HIV testing for all pregnant women; initiation the use of combination antiretroviral therapy (cART) as early as possible; with the goal of full viral suppression to the limits of detection; providing prophylaxis medication to the infant; and exclusive formula feeding.
    a. If viral load is suppressed, HIV-infected women can deliver vaginally while continuing to take their

oral antiretrovirals during delivery. The HIV-exposed infant will be given 4 weeks of zidovudine as prophylaxis.

b. If viral load is not suppressed during delivery (greater than 1,000 copies/mL), additional steps can be taken to reduce the risk of transmission: scheduled caesarean delivery, use of intrapartum IV zidovudine, and use of combination antiretroviral prophylaxis for the infant.

i. Consultation with a pediatric HIV specialist is highly recommended in cases where cART may be required for the infant.

8. An HIV-infected mother can have a child who is infected and subsequent children who are uninfected. Likewise, one infant in a multiple birth can be infected, whereas the other infant(s) are not.
9. Children born to mothers with a high HIV viral load and low CD4+ lymphocyte counts and with severely symptomatic HIV disease are at greater risk for infection.
   a. Infants born to such mothers and who become infected appear to be at increased risk for more rapid disease progression.
   b. Infants born to mothers who seroconvert during pregnancy are at an increased risk for becoming infected.
10. With the advent of HAART, the morbidity and mortality in HIV-infected children has decreased significantly. Thus, in those who have access to medication and who are adherent to therapy, HIV has become a chronic, manageable illness.

Long, (Eds.), *Red Book: 2015 Report of the Committee on Infectious Diseases* (30th ed., pp. 453–475). Elk Grove Village, IL: American Academy of Pediatrics.

---

1. The causative agent is a retrovirus that damages the immune system by infecting and depleting the CD4+ lymphocytes (T4 helper cells). These CD4+ lymphocytes play a central role in the regulation of the immune system.
2. There are also abnormalities in the function of cellular and humoral immunity (B cells, CD8+ cells,

natural killer cells, monocytes, macrophages, and specific antibodies).

3. Progressive destruction of the immune system leads to:
   a. Increased incidence of serious bacterial infections, such as bacteremia, bacterial pneumonias, and osteomyelitis.
   b. Opportunistic infections, which commonly include *Pneumocystis jirovecii* pneumonia (PCP), esophageal candidiasis, and *Mycobacterium avium* infection.
   c. More aggressive forms of viral infections, such as severe varicella, disseminated zoster, and cytomegalovirus pneumonitis.
   d. Cancers, especially lymphomas.
   e. Wasting syndromes and encephalopathy.
4. Multisystem organ involvement results in cardiomyopathies; nephropathies; neurologic impairment; GI dysfunction; endocrine disorders; dermatologic manifestations; musculoskeletal abnormalities; ocular impairments; ear, nose, and throat problems; and hematologic disorders.
5. An AIDS diagnosis occurs when a child presents as severely symptomatic (Category C) or with lymphoid interstitial pneumonitis (LIP from Category B) along with severe immunosuppression (see Tables 53-1 and 53-2).
6. Once an AIDS diagnosis is made, it is not reversed even with reconstitution of the immune system and recovery from the opportunistic infection.

Table 53-1 Pediatric HIV Classification*

	CLINICAL CATEGORIES			
IMMUNOLOGIC CATEGORIES	**N: NO SIGNS/ SYMPTOMS**	**A: MILD SIGNS/ SYMPTOMS**	**B:† MODERATE SIGNS/ SYMPTOMS**	**C:† SEVERE SIGNS/ SYMPTOMS**
1: No evidence of suppression	N1	A1	B1	C1
2: Evidence of moderate suppression	N2	A2	B2	C2
3: Severe suppression	N3	A3	B3	C3

**Children whose HIV infection status is not confirmed are classified by using the above grid with a letter E (for perinatally exposed) placed before the appropriate classification code (eg, EN2).*

†Category C and lymphoid interstitial pneumonitis in Category B are reportable to state and local health departments as acquired immunodeficiency syndrome.

Centers for Disease Control and Prevention. (1994). 1994 revised classification system for human immunodeficiency virus infection in children less than 13 years of age. Morbidity and Mortality Weekly Report, 43(RR-12), 1–10. Available: www.cdc.gov/mmwr/preview/mmwrhtml/00032890.htm.

Table 53-2 Immunologic Categories Based on Age-Specific CD4+ T-lymphocyte Counts and Percentage of Total Lymphocytes

	AGE OF CHILD					
	YOUNGER THAN AGE 12 MONTHS		AGES 1–5		AGES 6–12	
IMMUNOLOGIC CATEGORY	**MM³**	**(%)**	**MM³**	**(%)**	**MM³**	**(%)**
1: No evidence of suppression	≥1,500	(≥25)	≥1,000	(≥25)	≥500	(≥25)
2: Evidence of moderate suppression	750–1,499	(15–24)	500–999	(15–24)	200–499	(15–24)
3: Severe suppression	<750	(<15)	<500	(<15)	<200	(<15)

Centers for Disease Control and Prevention. (1994). 1994 revised classification system for human immunodeficiency virus infection in children less than 13 years of age. Morbidity and Mortality Weekly Report, 43(RR-12), 1–10. Available: www.cdc.gov/mmwr/preview/mmwrhtml/00032890.htm.

Clinical Manifestations of Disease Progression

1. Generalized lymphadenopathy, especially in less common sites, such as epitrochlear and axillary areas.
2. Persistent, recurrent oral candidiasis.
3. Failure to thrive.
4. Developmental delays or loss of previously acquired milestones.
5. Hepatomegaly.
6. Splenomegaly.
7. Persistent diarrhea.
8. Hypergammaglobulinemia or hypogammaglobulinemia (elevated or diminished levels of immunoglobulin [Ig] G, IgM, IgA).
9. Parotitis.
10. Unexplained anemias, thrombocytopenia.
11. Unexplained cardiac or kidney disease.
12. Recurrent mild or serious bacterial infections.

EVIDENCE BASE Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the use of antiretroviral agents in pediatric HIV infection. Available: *http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf.* Accessed May 20,2018 [pages B1, C1, 6, 7, D1–2, E1–3, F1–7, H1–3, J1–2.

Diagnostic Evaluation

1. All pregnant women in the United States should have HIV antibody testing (ELISA enzyme–linked immunoassay) as standard of care.
2. Antibody testing in children less than 18 months is not reliable for diagnosis. A positive ELISA test may only be an indication of the presence of circulating maternal antibodies.
3. HIV-DNA PCR (polymerase chain reaction) assay is the most sensitive, specific, and preferred method for detecting HIV infection in a child less than 18 months. The 2016 Centers for Disease Prevention and Control (CDC) guidelines recommend testing for infants using PCR at ages 14 to 21 days, 1 to 2 months, and 4 to 6 months.
4. Residual maternal HIV antibodies may still be present in children 18 to 24 months; thus, diagnosis use of HIV-DNA PCR should be used.
5. After age 24 months, HIV antibody assays can be used for testing because maternal antibodies should not be present by this age. As with adults, a reactive ELISA must be followed by a confirmatory Western blot test.
6. In known infected children or at-risk infants (those born to an HIV-infected mother but whose own status is still indeterminate), computed tomography scanning or magnetic resonance imaging of the head may be indicated if there is evidence of neurologic impairment, falling rate of head growth, or

developmental delays or regression.

Management

HIV-Exposed Infant

1. Additional laboratory studies requiring monitoring on the HIV-exposed infant include complete blood count (CBC) with differential (diff) to monitor for anemia and neutropenia and lymphocyte subsets (CD4+ counts), lactate and cognitive

HIV Infected

2. At the time of diagnosis, baseline CD4, HIV RNA (viral load), drug resistance (genotypic and phenotypic resistance should be used) should be performed. Child should have a complete age-appropriate medical history (including immunization history) and physical exam and additional laboratory evaluations for HIV-associated conditions: CBC with differential, chemistry of glucose, liver and renal function, and urinalysis and serologic evaluation for coinfections and immunities. HLA-B*5701 is used to assess potential for abacavir hypersensitivity. In addition, a baseline echocardiogram and chest x-ray should be done and repeated yearly.
3. Child needs ongoing laboratory assessment; CBC with differential, platelet counts, serum chemistries, serial CD4+ counts, and HIV RNA (viral load) should be done every 3 to 6 months (depending on previous results and the stage of disease).
4. Initiation of PCP prophylaxis is indicated when low CD4+ counts occur, with the exception that all infants born to HIV-infected women should be started on PCP prophylaxis at age 4 to 6 weeks, regardless of their CD4+ count (see Table 53-3).
    a. The first drug of choice is co-trimoxazole.
    b. Pentamidine, atovaquone, and dapsone are alternative choices.
    c. PCP prophylaxis should be discontinued in infants whose infection has been reasonably excluded on the basis of two or more negative viral diagnostic tests performed at greater than 4 weeks and greater than 8 weeks of age. Some experts may choose not to give prophylaxis to infants in whom antenatal and peripartum management has been appropriate and in whom the risk of infection is very low.
    d. Infants confirmed infected should remain on PCP prophylaxis until at 1 year of age and then reassessed based on their CD4 count.
5. Antiretroviral therapy is recommended for all HIV-infected children less than 1 year of age and in older children who have clinical symptoms of HIV or evidence of immunosuppression regardless of the age of the child or HIV PCR level (viral load). Although new guidelines recommend early initiation of treatment for all HIV-infected individuals, many factors need to be considered for children greater than 1 year of age before starting. Factors such as the severity of disease progression, appropriate medication (availability, cost, dose, formulation, taste, side effects, and complexity of regimen), resistance pattern, and coinfection are but a few.

Table 53-3 Recommendations for PCP Prophylaxis and CD4+ Monitoring for HIV-Exposed Infants and HIV-Infected Children, by Age and HIV Infection Status

AGE/HIV INFECTION STATUS	PCP PROPHYLAXIS	CD4+ MONITORING
Birth to ages 4–6 weeks, HIV exposed	No prophylaxis	1 month
Ages 4–6 weeks to 4 months, HIV exposed	Prophylaxis	3 months
Ages 4–12 months, HIV infected or indeterminate	Prophylaxis	6, 9, and 12 months
Under ages 4–12 months, HIV infection reasonably excluded	No prophylaxis	None
Ages 1–5, HIV infected	Prophylaxis if: CD4+ count is <500 cells/L or CD4+ percentage is <15%	Every 3–4 months
Ages 6–12, HIV infected	Prophylaxis if: CD4+ count is <200 cells/L or CD4+ percentage is <15%	Every 3–4 months

Adapted from Centers for Disease Control and Prevention. (1995). 1995 revised guidelines for prophylaxis against Pneumocystis carinii pneumonia for children infected with or perinatally exposed to human immunodeficiency virus. Morbidity and Mortality Weekly Report, 44(RR-4), 1–11. Available: www.cdc.gov/mmwr/preview/mmwrhtml/00037275.htm.

Clinical trial data from both adults and children have demonstrated that antiretroviral therapy in symptomatic patients slows clinical and immunologic disease progression and reduces mortality.

Six classes of antiretrovirals (ARVs) have been approved for use in children: nucleoside reverse transcriptase inhibitors (NRTIs), non–nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitor, CCR5 antagonist, and fusion inhibitor.

Combination therapy is now standard care, using at least three ARVs from at least two drug classes.

6. Adherence is the basis for successful viral suppression; strategies should be developed to encourage adherence. Adherence is essential to prevent viral resistance; particularly, NNRTI resistance develops rapidly with even slight fluctuations in drug levels.
7. Use of IV immunoglobulin is still recommended for HIV-infected children who have had two or more serious bacterial infections within 1 year and for the treatment of HIV-related thrombocytopenia or immunoglobulin deficiency.
8. Use of antifungal drugs, such as nystatin, ketoconazole, fluconazole, itraconazole, and clotrimazole, for persistent or recurrent oral candidiasis.
9. Use of antivirals, such as acyclovir, valacyclovir, ganciclovir, and cidofovir, for suppression or treatment of recurrent viral infections.
10. Aggressive, prompt assessment and treatment of febrile illnesses.
11. Nutritional support.
12. Evaluation and treatment of developmental delays and regression.
13. Adequate pain management in advanced or end-stage disease.
14. Support and interventions for the child and family (including all caregivers) with issues of disclosure, parental guilt, long-term care, and bereavement.

DRUG ALERT Test for the presence of ARV drug-resistant virus in both experienced and naive patients before initiating ARV combination therapy, thus ensuring the most effective regimen.

DRUG ALERT Lack of adherence to prescribed antiretroviral regimens and subtherapeutic drug levels increase the possibility that a resistant virus will develop. Strict adherence (more than 95%) to combination regimens is critical in ensuring sustained response to treatment.

NURSING ALERT Families can find out about clinical treatment trials available for their child by calling (800) TRIALS-A or visiting *www.clinicaltrials.gov*

.

Complications

1. Untreated or inadequately treated HIV:
    a. Repeated, overwhelming infections and certain cancers, particularly lymphomas.
    b. Hearing loss, tooth and gum disease, acute and chronic ear, nose, and throat infections.
    c. Opportunistic infections.
    d. Reactive airway disease.
    e. Cardiomyopathy.
    f. Failure to thrive, malabsorption, wasting.
    g. Chronic atopic dermatitis and other skin reactions.
    h. Nephropathy.
    i. Neuropathy, myopathy.
    j. Anemia, thrombocytopenia, neutropenia.
    k. Loss of treatment options related to the development of drug resistance.
    l. Developmental delay.
    m. Learning disabilities.
    n. Psychological challenges for children and caregivers, including multiple losses, issues of disclosure, fear, discrimination, stigmatization, and isolation.
    o. Death.
2. Complications of HIV treatment:
    a. NRTIs—anemia, neutropenia, lactic acidosis, pancreatitis, abacavir hypersensitivity reaction, peripheral neuropathy, lipodystrophy/lipoatrophy, renal dysfunction, osteopenia, headache, nausea, potential for vascular dysfunction.
    b. NNRTIs—psychological changes, sleep disturbances/nightmares, neural tube defects (fetal exposure), hepatitis, rash.
    c. PIs—dyslipidemia, GI upset, diarrhea.

d. Fusion inhibitors—injection site reactions.

DRUG ALERT Because some liquid preparations are unpalatable, nonadherence to the drug regimen is common. Suggestions to overcome this would include using Popsicle just before administration to numb the taste buds, followed by a teaspoon of chocolate/strawberry syrup, jam, or peanut butter immediately after. Speak to pharmacist about other ways to mask the taste.

Nursing Assessment

1. Review maternal records to identify infants who may be at risk for HIV disease. Infected infants are not easily identifiable by outward appearance.
2. Review records of at-risk or known infected children to determine nutritional status, growth and development, frequency of serious bacterial infections, presence or risk of opportunistic infections, laboratory values, and immunization status.
3. Assess growth, development, lymph nodes, hepatomegaly, splenomegaly, and oropharynx for presence of oral candidiasis and dental caries.
4. Assess the family's understanding of the child's condition, care needs, prognosis, and medical care plan.
5. Assess the family's coping mechanisms, comfort with disclosure issues, and long-term plans for care including transition plans for the child to an adult care program.
6. Assess the health of primary caregiver and discuss long-term care plans for respite and permanent alternative caregivers (including guardianship issues), as appropriate.
7. Assess the child's understanding of health condition and medications.
8. In children with advanced or end-stage disease, assess the level of pain and discomfort.
9. Assess the child's coping and response to the frequent painful and invasive procedures experienced as part of the ongoing diagnosis and management of the disease.
10. Assess for animal contact.
11. Take a thorough travel history to evaluate risk of coinfections, such as tuberculosis (TB), malaria, or other parasitic infections. Also evaluate potential travel plans, particularly to developing countries.
12. In the adolescent, assess increased at-risk behaviors, such as substance use, piercing, or sexual activity. Also determine methods of birth control, as appropriate.

NURSING ALERT Always discuss with the primary caregiver how much the child knows about his/her own HIV status or about other family members' status. Never assume anyone knows the child's HIV status; other family, friends, daycare, or school not even the child may know.

DRUG ALERT Some antiretrovirals interact with the effect of birth control pills and may reduce efficacy or increase hormonal-related side effects. *For more information, see* CDC's U.S. Medical Eligibility Criteria for Contraceptive Use, 2016, *www.cdc.gov/mmwr/volumes/65/rr/pdfs/rr6503.pdf*. Current perinatal guidelines do not restrict the use of efavirenz during pregnancy.

Nursing Diagnoses

- Risk for Infection related to immunodeficiency, neutropenia.
- Ineffective Therapeutic Regimen Management related to insufficient knowledge of HIV, noncompliance, and limited resources.
- Imbalanced Nutrition: Less than Body Requirements related to malabsorption, anorexia, or pain.
- Impaired Oral Mucous Membranes related to candidiasis and herpes stomatitis.
- Diarrhea related to enteric pathogens, disease process, and medications.
- Hyperthermia related to HIV infection and secondary infection.
- Delayed Growth and Development related to HIV central nervous system (CNS) infection.
- Pain related to advanced or end-stage HIV disease.
- Anxiety/Fear related to frequent invasive procedures, diagnosis, stigmatization, transmission to others, and separation from others.
- Denial related to learned response patterns—cultural factors, personal/family value system; fear of rejection/stigma.
- Ineffective Coping by child related to unresolved issues around disclosure, hospitalization, and losses; negative role modeling or inadequate support.
- Ineffective Family Coping related to parental guilt; excessive demands on individual and family; stigma.
- Social isolation related real or feared rejection and discrimination.
- Powerlessness related to loss of control, stigmatization.
- Alteration in body image related to effects of medication and disease.

Nursing Interventions

Preventing Infection

EVIDENCE BASE Centers for Disease Control and Prevention. Recommended immunization schedules for children and adolescents aged 18 or younger, United States 2017. Available: *www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html*.

1. Monitor viral load, CD4 count, and CBC with differential.
2. Monitor other lab values to assess for side effects, that is, significant drop in absolute neutrophil count.

3. Use aseptic techniques when performing invasive procedures.
4. Administer or teach caregiver the importance of giving pharmacologic agents that may help prevent opportunistic infections. *See Management*.
5. Assess and maintain skin integrity
6. Monitor immunization status and advocate for completion of all recommended childhood immunizations (see Table 53-4). Also see page 1119 for routine pediatric immunization information based on the CDC. In general, live vaccines should be used with caution in children with HIV infections.
    a. The measles, mumps, rubella (MMR), and varicella vaccines are recommended for HIV-infected children who are not severely immunocompromised.
    b. Oral polio vaccine should be avoided because there is an alternative injectable inactivated polio vaccine available.
    c. Yellow fever vaccine should be avoided unless the risk of exposure is extremely high; consultation with an expert is recommended.
    d. In the United States, the bacille Calmette-Guérin vaccine is also not recommended.
    e. Yearly influenza vaccine and a 3- to 5-year pneumococcal vaccine are also recommended in addition to the standard childhood immunization schedule.
    f. An annual TB skin test should also be administered.
7. Have a high index of suspicion for secondary infection even when clinical manifestations are subtle or absent.
8. Provide appropriate chemoprophylaxis following exposure to communicable diseases.
9. Educate family/patient on the importance of prevention of secondary infections.
    a. Maintain cleanliness of the environment and teach family members the essentials of environmental sanitation.
    b. Routine handwashing with soap and water.
    c. Oral hygiene and assessment for dental carries.
    d. Skin care to prevent break down.
    e. Safe food preparation and clean water use.
    f. Risk associated with handling animals; cats may transmit *toxoplasmosis or bartonella*, birds may transmit *Cryptococcus neoformans* or *M. avium*, and reptiles may transmit *Salmonellosis*. Good hand washing with soap and water after handling animals; contact with animal feces should be avoided.
    g. Attend Travel Medicine Clinic before traveling, particularly to developing or tropical countries, to prevent infections such as malaria or typhoid.
    h. How to use condoms to prevent sexually transmitted diseases such as syphilis or chlamydia.

Table 53-4 Vaccination of Individuals with HIV Based on the Canadian Immunization Guide

VACCINE	HIV/AIDS
Inactivated Vaccines	
Dtap, Tdap, Td	Routine use*
IPV	Routine use
Hib	Routine use
Influenza	Recommended
Pneumococcal	Recommended
Meningococcal	Routine use
Hep A	Recommended (MSM, IDU)
Hep B	Recommended/routine use†
Human papillomavirus	Recommended
Live Vaccines	
MMR	Routine use‡ (if no significant compromise)
Varicella	Consider in asymptomatic and mild symptomatic disease
OPV	Contraindicated (alternate available)
Oral typhoid	Contraindicated (alternate available)
BCG	Contraindicated
Yellow fever	Contraindicated**
Oral cholera	Contraindicated

**Routine vaccination schedules should be followed with age-appropriate booster doses.*

†Hep B vaccine (HB) is now recommended for all infants.

‡Most HIV-positive children can receive the first MMR vaccine without significant risk. Administration of the second MMR dose (particularly in adults) must be evaluated on a case-by-case basis.

***Consultation with an expert is recommended.*

© All rights reserved. Canadian Immunization Guide. Public Health Agency of Canada, modified in 2017. Adapted and reproduced with permission from the Minister of Health, 2018. Available: www.phacaspc.gc.ca/publicat/cig-gci/p03-07-eng.php.

DRUG ALERT Uninfected children living with HIV-infected parents or siblings should not receive the oral polio vaccine, but rather the injectable inactivated polio vaccine. This is due to the prolonged shedding of the virus from the live oral vaccine, which may prove to be hazardous for immunocompromised individuals.

Maximizing Adherence to HAART

EVIDENCE BASE Panel on Antiretroviral Therapy and Medical Management of HIV-Infected

Children. Guidelines for the use of antiretroviral agents in pediatric HIV infection. Available: *http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf*. Accessed April 17, 2017.

NOTE: Use of antiretrovirals in pediatric patients is evolving rapidly. These guidelines are updated regularly to provide current information. The most recent information is available at *http://aidsinfo.nih.gov*.

Centers for Disease Control and Prevention, Health Resources and Services Administration, National Institutes of Health, American Academy of HIV Medicine, Association of Nurses in AIDS Care, International Association of Providers of AIDS Care, the National Minority AIDS Council, and Urban Coalition for HIV/AIDS Prevention Services.

Center for Disease Control and Prevention. (2014). Recommendations for HIV prevention with adults and adolescents with HIV in the United States, 2014. Available: *https://www.cdc.gov/hiv/guidelines/recommendations/personswithhiv.html*. pp. 83–96.

---

1. Develop a trusting relationship with the patient by maintaining a nonjudgmental attitude to maintain open communication and assist in assessing barriers to adherence.
2. Assess drug readiness and strategies to maximize adherence before initiating therapy.
3. Provide the simplest regimen possible; for example, least number of pills (combination therapies), least often (once daily), based on viral resistance.
4. Stress the need for adherence at every visit.
5. Use several strategies for evaluating adherence (eg, viral load, pill count, self-reporting, and pharmacy refill checks).
6. Collaborate with patient to determine what reminder tools may work the best (pill box, calendar, stickers, alarm, associating pill-taking with daily routine).

Maintaining Adequate Nutrition

1. Carefully monitor growth parameters (height, weight, head circumference).
2. Consult with a dietitian to develop strategies for nutritional care, including additional calories, nutritional supplements while reducing cholesterol.
3. Teach the family to prepare high-calorie, nutritious meals that are pleasing and acceptable to children.
4. As age appropriate, involve the child in meal planning.
5. Encourage small, frequent meals if the child is experiencing absorption problems.

Maintaining Oral Mucosa and Dental Integrity

1. Include regular examinations of the oral mucosa and teeth in the physical assessment of the child.
2. Administer prescribed antifungal and antiviral therapy.
3. Offer fluids and pureed foods to minimize chewing and facilitate swallowing; avoid highly seasoned or acidic foods.
4. Encourage regular dental hygiene and dental visits.

Minimizing Effects of Diarrhea

1. Monitor for the presence or development of diarrhea.
2. Monitor daily weight when diarrhea is present.
3. Monitor intake and output and assess skin and mucous membranes for turgor and dryness.
4. Use enteric precautions.
5. Avoid foods that increase intestinal motility.
6. Administer IV hydration, as indicated.
7. Plan a regimen of skin care, including cleansing/blot drying of the anal area and application of ointment or skin barrier cream.
8. Teach the family safe food preparation techniques to minimize contamination of food.
9. Administer medications, as directed, for relief of severe diarrhea and enteric infections.

Detecting and Controlling Fever

1. Monitor for fever and report any core temperature over 101°F (38.3°C).
2. Institute comfort measures, such as sponge baths, dry clothing and linens, and antipyretics, as ordered.
3. Teach the family how to accurately monitor the child's rectal temperature.
4. Teach the family to promptly report any febrile episode over 101°F rectally.
5. Administer antipyretics.

Promoting Developmental Goals

1. Assess the child's developmental status on a regular basis.
2. Report regression or delay in achieving developmental milestones.
3. Make appropriate referrals for more in-depth developmental evaluation when delays and regression are noted.
4. Teach the family appropriate developmental stimulation activities for their child.
5. Implement recommendations for developmental stimulation (including school-based programs) and assist the family in doing likewise.
6. Facilitate successful transition to adult care (see Box 53-1).

BOX 53-1 Transition to Adult Care

Transition is the purposeful, planned movement of adolescents and young adults with chronic illness/disabilities from child-centered to adult-oriented systems. With the advent of highly active antiretroviral therapy, children with human immunodeficiency virus (HIV) are surviving and living well into adulthood. As they become adults, they are graduating from pediatric health care programs—with parents the child's advocate—to adult programs where individual care becomes the focus, with the young adult becoming his or her own advocate.

It is imperative for the pediatric health care team to prepare children and families for the changes and challenges of adolescence, with a focus on increased autonomy and self-reliance and independence.

The transition into adolescence is a normal part of growth and development; however, special considerations need to be addressed when caring for a teenager with a chronic illness.

KEY ELEMENTS OF TRANSITION

- Focus the orientation on the future and keep it proactive and flexible.
- Start as early as possible.
- Build on knowledge about HIV and issues of confidentiality and disclosure.
- Make sure your approach fosters personal and medical interdependence and creative problem solving.
- Provide opportunities for own consultations during clinic visit.
- Have open, honest, age-appropriate sexual health discussions.
- Develop a written transition policy—agreed upon by all members of the multidisciplinary team and target adult services—posted for families and young adults to see.
- Discuss different care models and possible settings in which the young adult can access care as an adult.
- Provide liaison personnel in both pediatric and adult health care centers.
- Coordinate an initial meeting for teen to meet adult care provider and staff.
- Ensure a flexible policy on the timing of events, with anticipation of change.
- Provide an education program for young people and their families that addresses medical, psychosocial, and educational/vocational aspects of care.
- Develop an individualized health care transition plan by age 14, in collaboration with the young adult and his or her family, and continuously update, as needed.
- Identify a network of relevant community agencies and adult primary and subspecialty care providers.
- Implement a training program for pediatric and adult providers on transition and adolescent issues.
- Provide for appropriate primary preventive care.
- Ensure affordable continuous health and medication insurance coverage.

EVIDENCE BASE Boudreau, M., & Fisher, C. (2012). Providing effective medical and case management services to HIV-infected youth preparing to transition to adult care. *Journal of the Association of Nurses in AIDS Care, 23*(4), 318–328.

EVIDENCE BASE Children's HIV Association (CHIVA). (2017). *CHIVA guidance on transition for adolescents living with HIV*. London: Author. Available: *www.chiva.org.uk/guidelines/tr*.

Promoting Effective Family Coping

1. Practice within a framework of family-centered care.

2. Assess the family's coping mechanisms, strengths, and weaknesses.
3. Provide emotional support to the family.
4. Refer the family to appropriate community resources for grief counseling and legal assistance (eg, wills, custody issues).
5. Help the family set realistic goals and expectations for the child.
6. Maintain a nonjudgmental attitude and nonprejudicial approach.
7. Allow the family to use denial as a protective mechanism because this gives them some sense of control.
8. Explain all care and treatment plans to the family.
9. Involve the family in planning for the care and management of their child.
10. Give strategies and guidance to families regarding *partial truth telling* so they can answer child's questions as honestly as possible.
11. Provide support to new mothers who grieve the loss of not being able to breastfeed. Provide strategies on how to deflect questions about the choice not to breastfeed.
12. Encourage parent to allow adolescent to start taking increased responsibility for own health care, including individual time alone with health care provider and self-advocacy.
13. Provide family and disclosed patient with hopeful information about the future, such as continuing education or, possibly, getting married and having a family.
14. Refer the family to community resources for home care, daycare of other siblings, transportation services, school-based services, respite care, and hospice.

Strengthening Coping Skills of the Child

EVIDENCE BASE Evangeli, M., Kagee, A. (2016). A model of caregiver paediatric HIV disclosure decision-making. *Psychology, Health & Medicine, 21*(3), 338–353.

Penn, C. (2015). "Too much for one day": a case study of disclosure in the paediatric HIV/AIDS clinic. *Health Expectations, 18* (4), 578–589.

---

1. Introduce the subject of disclosure of diagnosis to the child with the family. Offer the family guidelines as to age-appropriate approaches.
2. Accept that some families may not be able to disclose the nature of the disease to their child, even after much support and guidance.
    a. Explore with families how they want you to address questions the child may present to you.
    b. The illness and its impact can be effectively handled without actually telling the child about the HIV disease or AIDS status, if the family refuses to disclose it.
3. Answer the child's questions as honestly as possible within parental constraints that may be present.
4. Actively involve the child in as much of the care as possible, such as by having the child decide where to

place the IV line, cleaning off skin for needle insertion, and so forth.

5. Use therapeutic play techniques (age appropriate), such as drawing, playing with dolls, playing with medical equipment, and storytelling, to allow the child to express himself or herself in less verbal ways.
6. Refer the child and family for counseling if the child's coping skills do not progress or there appears to be regression in handling the issue of illness and chronic health care needs. Signs indicating possible need for additional in-depth interventions include more acting out by the child, withdrawn behavior, and difficulty in school (either behaviorally or academically).
7. Recommend and facilitate peer support groups.

Minimizing Discomfort

1. Assess for signs of pain in the child. In the infant or nonverbal child, such signs include restlessness, crying, withdrawn behavior, and changes in vital signs.
2. Discuss concerns over pain issues with the primary health care provider and team providing care for the child. Initiate or request referral to a pain management team if the child does not experience relief.
3. Stress to the parent or guardian the need for adequate pain management in children; many people do not acknowledge that infants or children suffer from pain and that this needs to be alleviated.
4. Use appropriate techniques to assess the level of pain or discomfort a child is experiencing.

Minimizing Fear

1. Make sure that all painful and invasive procedures are done in a location other than the child's bed in the hospital.
2. Monitor central line if used for venous access. Central line access may be less traumatic over time than repeated peripheral access attempts. Some children with HIV will need long-term, probably lifelong, IV therapies and blood monitoring, and a central line greatly eliminates the pain and anxiety associated with these procedures.
3. Make sure that the parent/caregiver realizes that most clinic visits will involve blood tests so that they do not falsely reassure the child that "no needle sticks" will occur.
4. Use diversionary techniques, such as bubble-blowing, for distraction during painful procedures. Practice first with the child and tell him or her this is an activity that you will help with during the procedure. Children can also be taught other relaxation techniques.
5. Offer small rewards (such as stickers, small toy items) after painful procedures to reduce anxiety. Such rewards should be given regardless of how the child reacted. The reward is not for "not crying" but acknowledges difficulty in going through painful and invasive procedures on a regular basis.
6. Involve the child in the procedure as much as possible (age appropriate). Such involvement can include selecting a possible site for accessing or receiving IV medications, cleaning the site, or selecting a special bandage for after the procedure. Use topical anesthetic.

Community and Home Care Considerations

1. Assess home environment for resources, such as nutritious foods and safe food preparation; adequate

water, heat, electricity, and space; developmentally appropriate toys; and supplies needed for care and hygiene.

2. Assess caregiver's correct administration of medications.
3. Draw blood samples using universal precautions and careful transport of blood and used equipment.
4. Perform developmental assessment periodically.
5. Act as liaison among family, specialists, school officials, and other team members.

Family Education and Health Maintenance

1. Teach families and other caregivers of the child universal precautions. In caring for HIV-infected infants and children, gloves are recommended when handling potentially contaminated body fluids (such as blood) but are not considered necessary for routine diaper-changing unless bloody diarrhea or hematuria exists.
2. Facilitate supply of adequate numbers of latex (or nonlatex, if necessary) gloves to families to use, as indicated.
3. Facilitate education as well as a supply of latex condoms and other forms of birth control for teens who are sexually active or about to become sexually active.
4. Offer guidance as to how to initiate discussion of their child's HIV status with schools and daycare settings. The "need-to-know" principle serves as a guideline when deciding to whom disclosure should be made (generally the principal, school nurse, and classroom teacher). It is not currently required that schools and daycare centers be advised, but is generally encouraged because this alerts the school to notify the parent promptly in the event of an outbreak of infectious disease that could pose a threat to the HIV-infected child (such as varicella).
5. Offer guidance to teens about how to initiate disclosure of HIV status to sexual partners or peers. Provide support during the process and offer to help facilitate the disclosure in the clinical setting.
6. Give families concrete guidelines as to when to notify health care provider about their child's condition. Signs and symptoms of illness require prompt notification, all fevers over 101°F (38.3°C) should be reported, and any adverse experiences or suspected adverse experiences with medications need prompt reporting.
7. Assess whether the parents are receiving care for themselves. Typically, parents will neglect their own care to provide for their child. As a result, the parents' immune status may become more quickly compromised.
8. Refer families to a social worker or social services agency. Children with HIV may qualify for certain entitlement programs that help with their health care and the family's financial situation. Many states have initiated case management programs for people with HIV.
9. Provide guidance using a childhood chronic illness model that addresses such psychosocial issues as disclosure and parental guilt as well as such medical issues as multiorgan involvement and likelihood of exacerbations of a variety of related conditions (eg, infections and nutritional deficiencies).
10. Assist parents in obtaining the latest information regarding treatment protocols of pediatric HIV. Such

information can be obtained through (800) TRIALS-A or *www.aidsinfor.nih.gov*.

Evaluation: Expected Outcomes

- Absolute neutrophil count within normal limits; aseptic technique maintained.
- Maintains medication regimen; keeps follow-up appointments; achieves an undetectable viral load.
- Nutritional intake adequate to meet body requirements; growth curve maintained.
- Oral mucous membranes without ulceration, good dentition.
- Two to three loose stools per day; perianal skin without irritation.
- Afebrile; parent or caregiver demonstrates accurate monitoring of temperature.
- Achieves normal growth patterns as evidenced by height, weight, and developmental tasks.
- Parents discuss their feelings about the diagnosis of HIV; family seeks help through community resources.
- Child participates in care, asks questions; adolescent successfully transitions to an adult care program without disruption in care.
- Reports increase in comfort level.
- Practices distraction techniques during procedures; reports reduced fear.

Primary Immunodeficiencies

Primary immunodeficiencies (PID) encompass more than 300 types of disorders that affect distinct components of the innate and adaptive immune systems. The overall incidence of PID is estimated to be 1:2,000. The most common presentation of an immunodeficiency is increased frequency of infections or infections that are unusual or difficult to treat. PID diseases are often undiagnosed or have a significant delay in diagnosis, which can lead to significant end-organ damage from recurrent infections. Increasingly, it is recognized that PID may present in other ways, such as multiple autoimmune manifestations and some types of malignancies.

EVIDENCE BASE Picard, C., Gaspar, B., Bousfiha, A., et al. (2018). International Union of Immunological Societies: 2017 Immunodeficiency Diseases Committee Report on Inborn Errors of Immunity. *Journal of Clinical Immunology, 38*(1), 96–128.

Pathophysiology and Etiology

EVIDENCE BASE Younger, E., Epland, K., Zampelli, A., & Hintermeyer, M. (2015). Primary immunodeficiency diseases: a primer for PCP's. *The Nurse Practitioner, 40*(2), 1–7.

---

1. PID diseases are due to genetic alterations in the immune system. Inheritance may be X-linked, autosomal recessive, or autosomal dominant depending on the type. The genetic mutation may be de novo with no prior family history.
2. About three quarters of PID diseases are caused by humoral or combined humoral and cellular abnormalities, with the remainder being defects in phagocytic or complement components of the immune system.
3. Risk factors for PID diseases include a family history of immunodeficiency, early infant deaths, parental consanguinity, autoimmunity, and increased incidence of lymphoid malignancy in family members.

Clinical Manifestations

1. Hallmark of PID diseases is susceptibility to infection, including recurrent pneumonia, sinusitis, otitis, sepsis, meningitis, recurrent or resistant candidiasis, or infection with an opportunistic organism. Course of infection may be unusual with a need for intravenous antibiotics and/or hospitalization to clear infections. See Table 53-5.
2. Chronic diarrhea.
3. Nonhealing wounds.
4. Extensive skin lesions.

5. Failure to gain weight or grow normally (failure to thrive).
6. Complications from a live viral vaccine.
7. Unexplained autoimmunity or fevers.
8. Absence or enlargement of lymphoid tissue, including tonsils, spleen, and liver.

Table 53-5 Infections Associated with Subtypes of PID Diseases

TYPE	TYPES OF INFECTIONS	ORGANISMS	OTHER FEATURES
Humoral (B cell)	Sinopulmonary, otitis media, gastrointestinal, cellulitis, meningitis, osteomyelitis	Encapsulated bacteria: *Haemophilus*, pneumococci, streptococci Parasites: *Giardia lamblia*, *Cryptosporidium* Virus: *Enterovirus*	Autoimmunity GI problems including malabsorption
Cellular (T cell or combined T and B cells)	Pulmonary, gastrointestinal, skin	Fungal: *Candida* species, *Pneumocystis jiroveci* Viral: CMV, EBV, RSV, parainfluenza, adenovirus, viral GI disease mycobacterium species	Failure to thrive Oral thrush Skin: rashes, dermatitis Postvaccination disease from live viral vaccines
Phagocytic disorders	Severe skin and visceral infections by common pathogens	Bacteria: *Staphylococcus aureus*, *Pseudomonas* species, *Serratia* species, *Klebsiella* species Fungi: *Candida*, *Nocardia*, *Aspergillus*	Granuloma formation, including granulomatous enteritis Poor wound healing Abscesses Oral cavity infections Anorectal infections
Complement disorders	Meningitis Septicemia	*Neisseria* infections: meningococcal, pneumococcal	Rheumatoid disorders: lupus-like syndrome Angioedema

CMV, cytomegalovirus; EBV, Epstein-Barr virus.

Diagnostic Evaluation

Specific Evaluation for Immunodeficiency

1. Complete blood count with differential to look for decreased numbers of lymphocytes and evidence of abnormalities in other cell lines, such as decreased platelets, neutrophils, or hemoglobin.
2. Immunoglobulin levels (IgG, IgA, IgM, and IgE) include total protein and albumin to rule out protein loss.
3. Antibody titers to previously administered vaccines to evaluate the ability to produce functional specific antibodies to infectious agents. Measurement of isoagglutinins (isoantibodies to blood groups) in children older than 2 years.
4. Measurement of the classical (CH50) and alternate pathway (AH50) of the complement system to rule out a complement deficiency.
5. Lymphocyte subset analysis by flow cytometry including CD3 (total T cells), CD4 (T helper), CD8 (T cytotoxic), CD19 or CD20 (B cells), and CD16/56 (natural killer cells) for suspected T cell, B cell, or combined immunodeficiency.
6. Lymphoproliferative assays to assess the cellular function.
7. Measurement of phagocytic oxidative responses (neutrophil oxidative burst index [NOBI] by flow cytometry) if a phagocytic disorder is suggested, such as chronic granulomatous disease.
8. Genetic testing for suspected cause of immunodeficiency.

Other Tests

1. Evaluation for infection, including inflammatory markers (C-reactive protein, sedimentation rate), appropriate cultures, radiological image of the site of suspected infections.
2. Electrolytes, glucose, urea, creatinine, arterial blood gases, if indicated.
3. Advanced immunologic evaluations, T-cell repertoire by v-betas, T-cell receptor incision circles (TREC, a measure of mature cells from the thymus).
4. PCR testing for suspected infectious agents if there is concern that the patient may not produce functional antibodies from PI disease. CD45 RA/RO to evaluate naïve versus memory T cells.
5. Newborn screen for severe combined immunodeficiency (SCID) by TREC if available.

Management

1. Prompt recognition and treatment of infections. Empiric antibiotic therapy pending culture results should be instituted.
2. May consider preventive antibiotic treatment for some PID diseases.
3. Avoidance of live viral vaccines, as they may be disease-causing in PID patients.
4. Postexposure infectious prophylaxis may be necessary following exposure to varicella.
5. For suspected T-cell immunodeficiency, blood products must be irradiated to eliminate leukocytes and screened for cytomegalovirus.
6. *Pneumocystis jirovecii* prophylaxis for T-cell immunodeficiencies.
7. Antibody replacement therapy with intravenous or subcutaneous gammaglobulin for combined and antibody deficiencies (X-linked agammaglobulinemia, common variable immunodeficiency, CD40 ligand or CD40 deficiency, selective antibody deficiency, SCID and peritransplant).
8. Bone marrow transplant (BMT) to replace the defective immune system in severe PID diseases (severe combined immunodeficiency, combined immunodeficiencies, Wiskott-Aldrich syndrome, chronic granulomatous disease, and others). Indications for BMT in PID diseases are constantly expanding, as new genes are identified.
9. Gene therapy is an experimental option for some PID diseases: adenosine deaminase deficiency (a type of severe combined immunodeficiency), Wiskott-Aldrich syndrome, and chronic granulomatous disease.

Complications

1. Organ damage from infection, particularly the lungs, gastrointestinal tract, and joints.
2. Chronic lung disease (bronchiectasis).
3. Granulomatous lesions in the skin, liver, spleen, and lungs (common variable immunodeficiency and chronic granulomatous disease).
4. Gastrointestinal malabsorption because of infection or from bacterial overgrowth.
5. Autoimmunity.
6. Early death (less than 1 year of age for severe combined immunodeficiency).

7. Malignancy (especially lymphoma and leukemia).
8. Psychological and social reactions to chronic disease.

Nursing Assessment

1. Focus history on infections including age of onset, sites, number, frequency, types, duration, and response to treatment.
2. Detailed family history including focus on unexplained infant deaths, recurrent miscarriages, consanguinity, malignancies, and autoimmunity in other members.
3. Review of immunization record and history to determine complications from vaccines and to ensure that immunizations are given at proper intervals.
4. Focus physical examination on the site of infections, such as lung air entry, as well as vital signs, growth and development, presence or absence of lymphoid tissue, examination of the skin for evidence of candidiasis or other skin abnormalities.
5. Assess the family and child's understanding of the condition, care needs, prognosis, and plan of care.
6. Assess the family's coping mechanisms and resources, particularly for patients that may require bone marrow transplant or lifelong treatment with immunoglobulins.

Nursing Diagnoses

- Risk for Infection related to immunodeficiency.
- Imbalanced Nutrition: Less than Body Requirements related to infections, malabsorption, or autoimmune gastrointestinal diseases.
- Impaired Oral Mucous Membranes related to candidiasis or other infections.
- Ineffective Therapeutic Regimen Management related to insufficient knowledge, nonadherence, and limited resources.
- Delayed Growth and Development related to infection or specific PID disease.
- Ineffective Family Coping related to diagnosis of immunodeficiency.
- Impaired Family Processes due to chronic diseases.

Nursing Interventions

Preventing Infection

1. Educate families about signs and symptoms of infection that specific PID disease is susceptible to and when to seek health care advice.
2. Administer or teach caregiver to administer prescribed pharmacologic agents including treatment protocols for gammaglobulin therapy, if indicated.
3. Adhere to infection control policies for protection of severe T-cell immunodeficiencies when hospitalized.
4. Avoid administration of live viral vaccines for suspected PID (oral polio, measles, mumps, rubella, varicella, yellow fever, rotavirus, inhaled influenza, and bacilli Calmette-Guérin [BCG] vaccine).

5. Encourage yearly influenza vaccine for patients and family members.
6. Administer and teach family good infectious control techniques including handwashing and skin care to avoid infection.

Maintaining Adequate Nutrition

1. Carefully monitor growth parameters including height, weight, and head circumference.
2. Consult with a dietician to develop nutritional plan of care, including adequate caloric intake and parental teaching.
3. Administer and teach families to administer supplemental feeds via NG or G-tube if indicated.

Maintaining Oral Mucosa

1. Include assessment of oral mucosa in routine physical assessments.
2. Administer and teach families to administer prescribed antifungal or antiviral medications.
3. Promote good dental hygiene and dental care.

Promoting Therapeutic Regime Management

1. Teach patients and families about prescribed medications and treatments. Review teaching periodically.
2. For patients on gammaglobulin treatment, doses should be adjusted to reflect increased weight, so as to ensure adequate replacement of antibodies. For patients on subcutaneous gammaglobulin, periodically assess patient adherence to infusion protocol and re-educate, as necessary.

Promoting Growth and Development

1. Assess for normal growth and development.
2. Make appropriate referrals for more in-depth developmental assessments and adhere to treatment programs instituted (important for prolonged admissions, such as bone marrow transplant).
3. Teach the family appropriate developmental activities for their child.
4. Facilitate successful transition to adult care.

Promote Effective Family Coping

EVIDENCE BASE Hernandez-Trujillo, V., Scalchunes, C., Hernandez-Trujillo, H., et al. (2015). Primary Immunodeficiency diseases: an opportunity in pediatrics for improving patient outcomes. *Pediatrics, 54*(13), 1265–1275.

---

1. Assess family coping skills including strengths and weaknesses.
2. Provide emotional support and counseling, as necessary.
3. Refer the family for genetic counseling, as diagnosis may impact other family members or future pregnancies.

4. Encourage families to allow children to take increased responsibility for their care as they mature.
5. Provide continuous teaching about disease process and treatment. It is particularly important for children diagnosed at very young ages to learn as they grow—lifelong diseases.

Normalizing Family Processes

1. Refer to community resources and support groups.
2. Encourage family and child to verbalize feelings about diagnosis and treatment.
3. Encourage attendance at school, participation in activities, and socialization with peers as much as possible.
4. Encourage parents to spend time with siblings and each other, as well as affected child.

Community and Home Care Considerations

1. Assess home environment for resources, such as nutritious foods, developmentally appropriate toys, and supplies needed for care and hygiene.
2. Assess caregivers' correct administration of medications.
3. Ensure that patient has a community care practitioner.
4. For PID patient requiring gammaglobulin treatment, assess ability of parents to adhere to infusion regime for IVIG treatment. For SCIG treatment, assess home for adequate storage of gammaglobulin products and supplies.
5. Provide education to school nurses so that individual educational plans are implemented and maintained.

Family Education and Health Maintenance

1. Give families guidelines as to when to notify health care provider about their child's condition. Signs and symptoms of illness require prompt notification, all fevers over 101°F (38.3°C) should be reported, and any adverse experiences or suspected adverse events to medications require prompt reporting.
2. Assess family coping and refer to social worker or social services, as required.
3. Refer families to immunodeficiency patient support agencies so as to provide ongoing PID disease-specific education to patients and families.

Evaluation and Expected Outcomes

- Reduced incidence of infections.
- Adequate intake for child's age and developmental stage.
- No oral lesions, denies oral discomfort.
- Adherence to treatment regimes.
- Achieves normal growth, as evidenced by height, weight, and developmental tasks.
- Child and family seek appropriate support and resources, as required.
- Child and parents verbalize feelings about the illness; include siblings in activities.

CONNECTIVE TISSUE DISORDERS

Juvenile Idiopathic Arthritis

EVIDENCE BASE McKeever, A., & Kelly, M. (2015). Growing up with Juvenile Idiopathic Arthritis. *The American Journal of Maternal Child Nursing, 40*(1), 8–15.

Juvenile idiopathic arthritis (JIA) has replaced the terms "juvenile chronic arthritis" and "juvenile rheumatoid arthritis" as the commonly agreed-upon terminology to describe arthritis in children. JIA is defined as persistent arthritis for longer than 6 weeks in children ≤16 years of age. The disease is a heterogeneous disease that has been further classified into seven subtypes with similar presentation, clinical features, disease course, and outcomes.

JIA is a chronic disease affecting approximately 1 in 1,000 children (1.7 to 8.4 million children worldwide, most of these children undiagnosed) and often persisting into the adult years. There are epidemiological differences between sexes and age of onset that are specific to subtype.

Pathophysiology and Etiology

EVIDENCE BASE Petty, R. E., Laxer, R. M, Lindsley, C. B., et al. (Eds.). (2016). *Textbook of pediatric rheumatology* (7th ed.). Philadelphia, PA: Elsevier.

1. The cause of JIA is unknown. It is likely multifactorial and variable between subtypes. Hypotheses suggest that environmental stimuli trigger disease in genetically predisposed children during a time of susceptibility.
    a. Genetic risk factors—associations with specific human leukocyte antigen (HLA) class I (B27) and class II genes, protein tyrosine phosphatase N22 gene, and interleukin-2 receptor alpha gene have been well established.
    b. Immune dysregulation of the adaptive and innate immune system. Autoantibodies including antinuclear antibody (ANA); rheumatoid factor (RF); T-lymphocytes and cytokines, tissue necrosis factor (TNF) of adaptive immunity as well as neutrophils and interleukin (IL)-1, IL-6 of innate immunity are present in sera and synovial fluids.
    c. Infection as a trigger to immune dysregulation is suspected but has not been clearly established.
    d. Hormonal factors.
2. Arthritis is inflammation of one or more synovial joints. Immune complexes trigger the inflammatory response, causing:
    a. The synovium to become thickened from congestion and edema.
    b. Increased production of intra-articular fluid exhibited as a joint effusion. It is not uncommon for

synovial cysts to develop (Baker cyst).

c. Development of periarticular soft tissue edema.

d. Extension of the inflammatory process to the tendons, tendon sheaths, and entheses results in inflammatory changes similar to the synovial tissues.

e. Weakness and atrophy of muscle surrounding affected joints leading to flexion contractures.

f. Growth centers in long bones may undergo either premature epiphyseal closure or accelerated epiphyseal growth. The result is overgrowth or shortening of the affected limb.

3. Long-term disease activity can result in joint destruction and eventual joint failure, necessitating joint replacement.

a. Degrading enzymes released during synovial inflammation result in chondrolysis and osteolysis; erosion of the articular cartilage and bone.

b. Following destruction, the overgrowth of granulation tissue may result in the formulation of new cartilage and bone, leading to ankylosis.

c. Joint destruction is characterized by joint space narrowing, erosions, deformities, subluxation, and ankylosis.

d. Generalized osteopenia is common, increasing the risk for fracture.

Clinical Manifestations

Clinical manifestations include joint and extra-articular features that vary among subtypes (see Table 53-6, page 1402).

Table 53-6 Characteristics of Juvenile Idiopathic Arthritis

ILAR SUBTYPE	OLIGOARTICULAR • PERSISTENT • EXTENDED	POLYARTICULAR (RF NEGATIVE)	POLYARTICULAR (RF POSITIVE)
% Total JIA patients	40%–50%	20%–25%	5%
Age of Onset	Early childhood; 1–3 years	2 peaks: 2–4 years and 6–12 years	Early adolescence
Sex	F > M	F > M	F > M
Typical Joint Involvement	≤4 joints in first 6 months Large joints: knees, ankles, wrist Extended disease: involves >4 joints after first 6 months	≥5 joints Symmetric distribution Knees, wrists, ankles TMJ can be affected	≥5 joints Small and large joints Symmetric C-spine and TMJ affected Erosive joint disease
Laboratory Tests	ANA 60%–80% positive	ANA 50% positive	ANA 75% positive RF positive
Occurrence of Uveitis	Common (30%) Usually asymptomatic	Common (15%)	Rare (<1%)
Other Features	Leg length discrepancies Contractures	Fatigue	Rheumatoid nodules Fever and constitutional signs at onset of disease

ILAR, International League for Associations of Rheumatology; F, female; M, male; ANA, antinuclear antibody; HLA, human leukocyte antigen; RF, rheumatoid factor.

Adapted with permission from Pediatric Clinics of North America, 59(2), Gowdie P. and Tse S, Juvenile idiopathic arthritis, 301–327, Copyright 2012, with permission from Elsevier.

1. The inflamed joint is characterized by four of the five cardinal signs of inflammation: swelling, pain,

heat, loss of function. Erythema occurs in some cases.

a. Joint stiffness in the morning or after prolonged inactivity (gelling) is common.
b. Pain may not be expressed verbally; the child may alter activities to protect the painful joint.

2. Extra-articular features include fever, rash, fatigue, weight loss, altered growth, subcutaneous nodules, and uveitis.

a. Fevers occur in systemic JIA and occasionally at the onset of polyarticular JIA. In systemic JIA, fevers are daily, usually above 102.2˚F (39˚C), following a quotidian pattern of one or two spikes with a rapid return to baseline and accompanied by a classic salmon-pink rash.
b. Altered growth includes localized growth abnormalities and poor linear growth.
    i. Overgrowth or undergrowth of bones in sites affected by arthritis result in leg length discrepancy, shortened limbs, and micrognathia and or/retrognathia (receding chin) with arthritis of the temporomandibular joint (TMJ).
    ii. Poor linear growth is attributed to the inhibitory affects chronic inflammation and circulating cytokines have on growth.
c. Uveitis associated with arthritis is found in 20% to 40% of cases. It is commonly asymptomatic at onset requiring frequent examinations by an eye specialist. An exception is the patient with subtype enthesitis-related arthritis (ERA), who presents with redness, pain, photophobia, headache, and decreased visual acuity.

Diagnostic Evaluation

1. Laboratory studies cannot exclusively confirm diagnosis. They are used to support diagnosis, measure disease activity, predict prognoses, and monitor toxicity of therapy.

a. Elevated erythrocyte sedimentation rate (ESR).
b. Leukocytosis, thrombocytosis, anemia.
c. Elevated serum immunoglobulins.
d. Elevated C-reactive protein.
e. Presence of ANA, RF, and anticyclic citrullinated peptide (anti-CCP) antibodies. ANA is associated with high incidence of uveitis. Anti-CCP is an early predictor of erosive disease in polyarticular JIA.

2. Radiographic studies.

a. Early x-ray changes include soft tissue swelling, osteopenia, and effusions.
b. Late x-ray changes include erosions, joint space narrowing, boutonniere or swan neck deformity of the fingers, early maturation of cartilage, and subluxations.
c. Ultrasound for detection of tenosynovitis.
d. Magnetic resonance imaging (MRI) is most sensitive to detect specific joint disease, including TMJ and sacroiliac.

3. Ophthalmologic examination.

a. Slit-lamp examination to monitor for uveitis is required within 1 month of diagnosis and every 3 to

12 months, depending on age, presence of ANA, and duration of illness.

Management

1. There is no cure for JIA.
2. Management of JIA should be provided by a multidisciplinary team in a family-centered approach.
3. The primary goal of treatment is to facilitate disease remission.
   a. In the process of working toward remission, other goals of therapy include control pain and maintain range of motion, muscle strength, and function.
   b. To promote normal growth.
   c. To support normal psychological and social development.
4. Goal attainment requires nonpharmacologic and pharmacologic approaches.
5. Nonpharmacologic approaches to treatment include:
   a. Occupational and physical therapies that employ strength and stretching exercises, splinting, serial casting, orthotics, and thermal modalities to reduce stiffness or pain and to protect function.
   b. Strengthening and aerobic-based exercise are safe in children with JIA. Studies have demonstrated improved physical function and quality of life.
   c. Nutritional and vitamin supplementation are required to promote growth, maintain bone mineralization, and prevent toxicity from medication. Vitamin D, calcium, iron, and folic acid may be prescribed.
   d. Orthopedic surgery may be performed to manage joint complications; tendon lengthening for severe contractures; tenosynovectomy to treat trigger finger; total joint replacements, particularly hips and knees.
6. Pharmacologic therapies are introduced in a systematic stepwise approach targeted to the specific subtypes of JIA. Refer to Table 53-7, page 1404. Recently, a more aggressive progression through the steps is advocated, as evidence suggests rapid control of inflammation may positively influence prognosis.
   a. Nonsteroidal anti-inflammatory drugs are the first line of therapy aimed at symptom relief.
   b. Disease-modifying antirheumatic drugs (DMARDs) are second-line immunosuppressive agents that can achieve disease control and influence the course of disease.
   c. Newer biologic agents are selected when DMARDs fail. They target very specific immune responses responsible for inflammation. Biologics offer treatment options for children with refractory arthritis.
   d. Corticosteroids are potent anti-inflammatories used mainly as a bridging therapy until other treatments begin to take effect. Steroids have not been shown to be disease modifying. They can be administered by oral, intramuscular, intravenous, intra-articular, or intraocular route and should be administered at the lowest effective dose. With the exception of intra-articular steroid injections, which are well tolerated, steroids can lead to serious toxic side effects including weight gain, edema, acne, fatigue, growth suppression, decreased bone density, hypertension, hyperglycemia, glaucoma, and cataracts.
7. Children receiving the immunosuppressive therapies used to treat arthritis require special considerations.

a. Close monitoring for signs of infection.
b. Screening for tuberculosis prior to initiation of corticosteroid or biologic therapy. Testing should be repeated annually for those taking biologics and/or those travelling to endemic areas or close contact with visitors from these areas. Steroids can alter the result of tuberculin skin testing. Biologic therapy can reactivate latent tuberculosis.
c. Children receiving DMARDs, corticosteroids, or biologics should not receive live vaccines (varicella, measles, mumps, and rubella). When considering treatment with methotrexate, varicella immunization may be recommended prior to starting therapy in susceptible children. In such circumstances, methotrexate cannot be started for 28 days post immunization.
d. Regular blood monitoring for toxicity.
e. Regular clinical examinations to assess for adverse effects. In 2008, the FDA reported several cases of malignancies in children receiving biologic therapy. Recent studies have both supported and refuted possible links between cancer and biologic therapy.

8. The course and outcome of JIA has changed dramatically with early intervention and more successful therapies. However, active disease continues into adulthood in 50% to 70% of children with polyarticular and systemic JIA, 40% to 50% of oligoarticular JIA. Current research in biomarkers, genetics and immunology to help predict response or nonresponse to therapy choices (treat to target) will guide and advance care within the next decade

Table 53-7 Pharmacologic Treatment for Juvenile Idiopathic Arthritis

	MEDICATION	INDICATION	DOSING
NSAIDs	COX-1, COX-2 inhibitors, naproxen, ibuprofen, indomethacin, celecoxib	First-line therapy for all subtypes of JIA; symptom management	PO variable dose frequency
DMRADs	Methotrexate	Second-line therapy for all subtypes except systemic JIA	PO or sc once weekly 15 mg/m²/dose (maximum 25 mg) Therapeutic effect in 6–12 weeks
	Sulfasalazine	Oligoarticular JIA; polyarticular JIA; ERA	PO 50 mg/kg/day divided bid. Therapeutic effect in 6–12 weeks
	Leflunomide	Oligoarticular; polyarticular	PO once daily 10–20 mg/day Therapeutic effect in 6–12 weeks
Glucocorticoids	Methylprednisolone, prednisone, prednisolone, triamcinolone, hexacetonide	Used for quick anti-inflammatory effect or bridging agent for all subtypes of JIA	IV, IM, PO, intra-articular, topical, intraocular for uveitis Dose/frequency depends on route and severity of inflammation
Biologics	TNF inhibitors: Etanercept Infliximab Adalimumab Golimumab	Used when fail second-line agents Effective to treat uveitis	SC (Etanercept, adalimumab) IV (infliximab) Dose/frequency variable Therapeutic effect reported after three doses
	IL inhibitors: Anakinra (IL-1) Canakinumab (IL-1β) Tocilizumab (IL-6)	Systemic JIA Tocilizumab under study for other forms of JIA	Anakinra sc once/day Canakinumab sc q4 weeks Tocilizumab IV q2 weeks
	T-cell costimulatory modulators: Abatacept	JIA except systemic subtype	IV 10 mg/kg/dose Give at 0, 2 weeks then q4 weeks Therapeutic effect reported as early as second infusion

IM, intramuscular; IV, intravenous; JIA, juvenile idiopathic arthritis; PO, oral; SC, subcutaneous.

EVIDENCE BASE Klotsche, J., Niewerth, M., Haas, J., et al. (2016). Long-term safety of etanercept and adalimumab compared to methotrexate in patients with juvenile idiopathic arthritis (JIA). *Annals of the Rheumatic Diseases, 75*, 855–861.

Hinze, C., Gohar, F., & Foell, D. (2015). Management of juvenile idiopathic arthritis: hitting the target. *Nature Reviews Rheumatology, 11*, 290–300.

Complications

1. Bone and growth changes:
   a. Growth disturbance, short stature.
   b. Osteopenia, osteoporosis.
   c. Cervical spine and TMJ problems (micrognathia/retrognathia).

   d. Leg length discrepancies.
   e. Joint contractures.
2. Psychological and social reactions to illness.
3. Cataracts, glaucoma, or blindness secondary to uncontrolled, chronic uveitis.
4. Pericarditis.
5. Macrophage activation syndrome—a life-threatening complication of systemic JIA characterized by massive activation of T cells and macrophages; features include sustained fever, hepatosplenomegaly, anemia, liver function abnormalities, coagulopathy, encephalopathy, sudden drop in ESR, extreme elevation of ferritin, and marked elevation of D-dimers.

Nursing Assessment

1. History should include a thorough musculoskeletal inquiry including location, onset, duration of joint pain and stiffness; alleviating and exacerbating factors; activity limitations; medication and other nonpharmacologic treatments used; review of systems to look for associated symptoms and complications of JIA and side effects of medication; most recent ophthalmology examination; immunizations; and tuberculosis screening.
2. Physical examination focused on the clinical manifestations of the different subtypes of JIA including joint and gait assessment, vital signs, growth parameters, and a pain assessment using a developmentally appropriate tool.
3. Gather data for psychosocial assessment including inquiry into the impact of this chronic, painful disease on the child's self-esteem and coping and the family's coping.

Nursing Diagnoses

- Acute and Chronic Pain related to joint inflammation.
- Impaired Physical Mobility related to joint inflammation and pain.
- Delayed Growth and Development related to chronic inflammation and side effects of medication.
- Impaired Family Processes related to caring for a child with a chronic, painful illness.

Other Nursing Diagnoses may include:

- Disturbed Sleep Pattern related to pain.
- Fatigue related to inflammation.
- Disturbed Body Image related to short stature; leg length discrepancy; side effects of prednisone (stretch marks, weight gain, acne), micrognathia.
- Risk for Chronic Low Self-Esteem related to changes in body image and physical capabilities.
- Impaired Nutrition: Less Than Body Requirements related to increased metabolic activity associated with inflammation.
- Risk for Imbalanced Nutrition: More Than Body Requirements related to side effect of medication.
- Deficient Knowledge related to potential adverse effects of medications.

Nursing Interventions

Minimizing Discomfort

1. Administer or teach parents to administer medications to reduce inflammation and control pain. When inflammation and pain are controlled, a child is more willing and able to do exercises to improve joint strength and prevent loss of movement.
2. Encourage a warm bath or shower to relieve morning stiffness. Use other thermal modalities such as soaking or warm, moist pads or ice packs to soothe inflamed joints. Some children respond to heat and some to cold.
3. Use assistive devices to make mobility and activities of daily living (ADL) easier. Examples include splints; orthotics; special adaptors for pencils, doorknobs, or utensils; or Velcro or zipper pulls.

Preserving Joint Mobility

1. Encourage compliance with physical therapy regimen to strengthen muscles and mobilize joints. Assist with range of motion (ROM) exercises, as indicated.
2. Splint joints to maintain proper position (joint extension) and decrease pain and deformity.
3. Encourage prone position with a thin pillow or no pillow and firm mattress.
4. Encourage therapeutic play (swimming, throwing, and bike riding).
5. Encourage child to do own ADL to maintain joint mobility. Refer to occupational therapy for provision of adaptation devices to facilitate completion of daily activities (velcro closures, utensils, and self-care implements with enlarged handles).
6. Schedule rest periods to maximize energy; discourage complete immobilization or lengthy inactivity because they increase stiffness.

Promote Normal Growth and Development

1. Identify developmental tasks appropriate to age of child. Educate parents and work with child and family to set goals with necessary adaptations to promote successful achievement.
2. Encourage attendance in school, participation in activities, and socialization with peers as much as possible.
3. Encourage compliance with treatment plan to prevent complications related to prolonged inflammation.
4. Promote healthy diet; obtain diet history; make referral to dietician, as necessary.

Normalizing Family Processes

1. Refer to community resources and support groups.
2. Encourage child and family to verbalize feelings.
3. Remind parents to devote time to other children themselves and each other because the disease affects the whole family.

Family Education and Health Maintenance

1. Educate (consider cultural/language barriers and literacy) and motivate parents child to continue program of treatment at home. This is a chronic disease with an unpredictable course; however, compliance with prescribed treatment is important to improve functional outcome and to allow the child to grow and develop to his or her full potential.
2. Encourage medication compliance by helping to create a medication calendar or suggesting weekly pill boxes or strategies to reduce side effects such as taking NSAIDs with food or taking methotrexate on the weekends before bed.
3. Encourage open communication with school authorities. Child should receive accommodations such as use of school elevator, two sets of textbooks so child does not need to carry heavy backpack to and from school, use of a computer for difficulties with writing, and allowance to move around during prolonged periods of sitting.
4. Educate the family about the importance of a daily exercise routine to maintain ROM, muscle strength, and function. Periodically re-evaluate need for physical and occupational therapy.
5. Provide nutritional counseling to promote a balanced diet with special attention given to the intake of calcium, vitamin D, folic acid, and iron. Portion control and healthy snacks should be encouraged to prevent obesity.
6. Stress the need for routine follow-up care and ophthalmologic evaluation.
7. Educate families about the special considerations required when their child is receiving immunosuppressive medications: seek prompt medical attention for fever and other signs of infection; child and family members should receive annual influenza vaccine; live vaccinations need to be postponed until child is no longer receiving immunosuppression.
8. Refer family to community agencies such as the Arthritis Foundation (*www.arthritis.org*).

Evaluation: Expected Outcomes

- Reports decreased pain.
- ROM, muscle strength, and joint function is preserved.
- Growth and development parameters, including psychological and social are appropriate for age.
- Parents seek additional resources.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a systemic multisystem, chronic autoimmune disease that has the potential to affect any organ or organ system. Disease onset in childhood occurs in 10% to 20% of all SLE cases. Although the disease manifestations and disease course of flares and remissions is similar across the lifespan, pediatric systemic lupus erythematosus (pSLE) patients have a more severe disease requiring more aggressive treatment with immunosuppression. The incidence is higher in females than in males (4.5 to 5:1) with higher rates in Hispanic, Afro-Caribbean, Aboriginal, and Asian populations.

Pathophysiology and Etiology

1. Cause is unknown. Involves a complex interaction between genetic predisposition and the environment. Etiologic factors include:
   a. Immune system dysregulation of both innate and adaptive immunity.
   b. Genetic susceptibility—associations with certain HLA types, complement deficiencies, and TNF polymorphisms.
   c. Environmental factors.
   d. Hormonal factors—presence of estrogen; low levels of androgens
2. Possible factors that trigger or unmask initial symptoms:
   a. Ultraviolet radiation (ultraviolet B-light)—photosensitivity
   b. Viral infection—herpes family viruses; cytomegalovirus
   c. Stress, extreme fatigue.
   d. Vaccination
   e. Chemical exposure—cigarette smoke, pesticides, heavy metals.
   f. Medications—drug-induced lupus is a lupus-like syndrome that presents after several months of specific medication use. Complete resolution of symptoms happens weeks to months after discontinuation
3. SLE is characterized by the production of autoantibodies and the deposition of immune complexes in tissues and organs throughout the body.
   a. Spontaneous hyperactivity of B lymphocytes leads to increased antibody production. Additionally, the life of the B lymphocytes is abnormally prolonged, enhancing antibody production.
   b. These antibodies combine with antigen to form immune complexes, which deposit in tissue.
   c. The immune complexes activate the complement cascade, leading to inflammation (recruitment of inflammatory cells and production of oxidants, proteases, prostaglandins, and cytokines).
   d. Long-term inflammation can lead to irreversible cell destruction and tissue and organ damage.
4. Antiphospholipid syndrome (APS) produces a variety of antibodies against phospholipids and may occur in pSLE. The primary event resulting from APS is thrombolytic in nature.
5. Neonatal lupus erythematosus (NLE) is a separate entity from SLE. It is a disease of the developing fetus and neonate as the result of transplacental passage of maternal autoantibodies (anti-SSA/Ro or

anti-SSB/L).

a. Infant may or may not develop clinical symptoms.
b. The most common clinical manifestations of NLE are cardiac, dermatologic, hematologic, and hepatic.
c. The most serious manifestation is congenital heart block (CHB), requiring pacemaker insertion as an infant or child.
d. The skin, liver, and hematologic symptoms resolve by 1 year of age as the maternal antibodies clear, with few long-term effects.

Clinical Manifestations

The presentation of the manifestations of SLE in children is diverse involving any organ system and may be gradual or acute.

1. Constitutional symptoms: fever, weight loss, fatigue, loss of appetite.
2. Mucocutaneous disease:
   a. Malar rash (butterfly rash), which is present over the bridge of nose and cheeks sparing the nasolabial folds; rash may vary from a faint blush to scaly erythematous papules; most often a photosensitive. Rash may spread from face and scalp to neck, chest, and extremities. Scarring is rare.
   b. Raynaud phenomenon; triphasic color change of fingers and toes in response to cold; may also be induced by emotions. Tip of nose, ears, and penis may also be affected.
   c. Mucosal ulceration or erythema of hard palate, tongue, or nose. Lesions are usually painless.
   d. Hair loss.
3. Musculoskeletal disease:
   a. Arthritis, most commonly of small joints of hands; rarely associated with erosive disease.
   b. Reduced bone density secondary to both active disease and treatment with steroids.
4. Cardiovascular disease:
   a. Early atherosclerosis—children with lupus have been shown to have unfavorable lipid profiles.
   b. Pericarditis, endocarditis, myocarditis.
5. Renal disease (lupus nephritis):
   a. Nephritis is leading cause of morbidity and mortality; prevalence of 20% to 80% of children with 18% to 50% progressing to end-stage kidney disease.
   b. 80% to 90% develop nephritis within the first year of diagnosis.
   c. Hematuria, proteinuria, and hypertension may be evident.
6. Neuropsychiatric disease:
   a. CNS involvement manifested by psychosis (visual and/or auditory hallucinations), depression, headache (severe, unremitting), cerebrovascular disease (stroke), cognitive impairment (worsening school performance), and seizures.
   b. More frequent in children.

7. Hematologic involvement:
    a. Coombs positive autoimmune hemolytic anemia caused by destruction of red cells in the spleen.
    b. Leukopenia involving lymphocytes and neutrophils.
    c. Thrombocytopenia—low platelets can commonly be the initial presentation; immune thrombocytopenic purpura (ITP) can precede lupus by 10 years.
    d. Low complement levels C3 and C4 are an important laboratory measurement of disease activity.
8. Pulmonary involvement with pleural effusion and lupus pneumonitis.

Diagnostic Evaluation

1. Diagnosis is made by both clinical manifestations and specific laboratory findings (see Box 53-2).
2. Laboratory studies:
    a. Autoantibodies, antinuclear antibody (ANA)—nonspecific but positive in 90% of people with SLE.
    b. Other antibodies such as anti-ds DNA, anti-Sm, anti-Ro/SSA, anti-La/SSB, anti-ribonucleoprotein (anti-RNP) are all common in SLE. Anti-dsDNA and anti-Sm are highly specific for lupus.
    c. ESR—elevated.
    d. Serum complements studies—decreased.
    e. CBC—leukopenia, hemolytic anemia, thrombocytopenia.
    f. Evaluation for APS—elevated prothrombin time, partial thromboplastin time; false-positive syphilis tests such as VDRL; elevated anticardiolipin antibodies; and elevated dilute Russell viper venom time. The presence of one or more suggests APS and an increased risk for thrombosis.
    g. Serum chemistry and urine studies to detect kidney and other body system involvement.
3. Renal biopsy—verifies lupus nephritis and classification.
4. Electrocardiogram and other cardiac testing.
5. Bone mineral density.

Management

1. There is no cure for SLE. Course is unpredictable, is usually progressive, and may terminate in death, if untreated. Therapy is based on the extent and severity of disease. SLE may be classified as:
    a. Mild (fever, arthritis, rash).
    b. Moderate (clinically significant but non–life-threatening involvement of the kidneys or other major organs).
    c. Severe (substantial renal, pulmonary, hematologic, or neurologic disease).
2. Goal of treatment is to control disease activity and to prevent organ damage using the least toxic therapies.
3. Management of SLE should be provided by a multidisciplinary team in a family-centered approach.
4. Nonpharmacologic approaches include:
    a. Nutritional counseling and vitamin supplementation to control disease, promote growth, maintain

bone mineralization, and prevent toxicity from medication. Reduced sodium and potassium diets, fluid restrictions for kidney disease. Vitamin D, calcium, iron, and folic acid may be supplemented.

b. Mental health and social support for the child and family to manage the issues of chronic disease.

c. Education about sun protection including avoidance of midday sun, use of protective clothing, application of daily sunscreen 30 minutes prior to going outside.

d. Vaccination against pneumococcal infection; annual influenza vaccine as well as routine inactivated vaccines.

e. Regular adequate sleep and exercise.

5. Pharmacologic therapies:

a. NSAIDs are used to relieve musculoskeletal symptoms, fever, fatigue, and pain. Avoid NSAID use in children with renal insufficiency.

b. Methotrexate may be used for joint/skin symptoms or as a steroid-sparing agent.

c. Antimalarials, such as hydroxychloroquine and chloroquine, are used to:

Relieve joint symptoms and skin rash.

Manage thrombocytopenia.

Improve dyslipidemia.

Maintain remission.

d. Corticosteroids are required for almost all children with SLE and are administered either orally as prednisone or via IV line as methylprednisolone.

Low-dose oral steroids are usually used to control arthritis, fever, dermatitis, or serositis.

High-dose oral or IV steroids are used to treat moderate or severe SLE, especially in the presence of CNS involvement, pulmonary disease, hemolytic anemia, and nephritis.

e. Immunosuppressive agents, such as azathioprine, cyclophosphamide, cyclosporine, mycophenolate mofetil, tacrolimus, and rituximab—used in severe disease including nephritis and neuropsychiatric disease.

f. Treatment of complications with antibiotics, antihypertensives, anticonvulsants, antipsychotics, anticoagulation.

6. Dialysis and renal transplantation as adjunctive therapy for severe lupus nephritis.

BOX 53-2 Criteria for Diagnosis of Systemic Lupus Erythematosus

According to the American College of Rheumatology, the presence of four or more criteria must be documented to diagnose SLE.

- Malar (butterfly) rash.
- Discoid lupus rash.
- Photosensitivity.
- Oral or nasal mucocutaneous ulcerations.
- Nonerosive arthritis.

- Nephritis*:
  - Proteinuria greater than 0.5 g/day.
  - Cellular casts.
- Encephalopathy*:
  - Seizures.
  - Psychosis.
- Pleuritis or pericarditis.
- Hemolytic anemia, leukopenia, thrombocytopenia.
- Positive immunoserology*:
  - Antibodies to double-stranded DNA.
  - Antibodies to Sm nuclear antigen.
  - Positive finding of antiphospholipid antibodies based on immunoglobulin (Ig)G or IgM anticardiolipin antibodies, lupus anticoagulant, or confirmed false-positive serologic test for syphilis for at least 6 months.
- Positive antinuclear antibody.

*Any one item satisfies this criterion.

DRUG ALERT IV glucocorticoid "pulse" therapy has been known to cause hypertension or hypotension, tachycardia, blurring of vision, flushing, sweating, and metallic taste in the mouth. Close monitoring of temperature, pulse rate, respiratory rate, and blood pressure (BP) is indicated.

Complications

1. Infection—primarily resulting from steroid and immunosuppressive therapy.
2. Renal—hypertension, renal failure.
3. Cardiac—atherosclerosis, myocardial infarction, and valvular disease.
4. Growth disturbance; obesity and short stature secondary to inflammation and steroid therapy.
5. Musculoskeletal—osteopenia/osteoporosis, avascular necrosis, and compression fractures (resulting from steroid therapy).
6. Ocular—cataracts, glaucoma secondary to steroid therapy; retinal toxicity secondary to hydroxychloroquine therapy.
7. Macrophage activation syndrome—a life-threatening complication of SLE.

Nursing Assessment

1. History should include a thorough review of systems aimed at symptoms, complications, and medication side effects; current medications; immunizations; recent ophthalmology examination; auditory/visual hallucinations; and medication adherence.

2. Perform a complete physical examination, focusing on signs that might indicate major organ involvement including vital signs, growth parameters, and neuromental health assessment.
3. Assess psychosocial status to evaluate child's and family's coping with chronic illness, school performance, and socialization.

Nursing Diagnoses

Systemic lupus erythematosus has the potential to affect any organ system. The list of potential nursing diagnosis will vary extensively with each individual depending on the type and severity of disease as well as the individual's experience with treatment side effects.

- Fatigue related to chronic inflammation.
- Impaired Sleep Pattern related to side effects of glucocorticoid therapy.
- Acute and chronic Pain related to arthritis.
- Risk for Electrolyte Imbalance related to impaired kidney function.
- Excess Fluid Volume related to kidney disease.
- Risk for Unstable Blood Glucose related side effects of glucocorticoid therapy.
- Hyperthermia related to disease process.
- Risk for Injury related to CNS involvement (seizures).
- Risk for Acute Confusion related to Neuropsychiatric manifestations of lupus.
- Risk for Infection related to treatment.
- Impaired Urinary Elimination related to kidney involvement.
- Imbalanced Nutrition: Less than Body Requirements related to increased metabolic activity associated with inflammation and oral ulcers.
- Risk for Overweight related to side effects of glucocorticoid therapy.
- Disturbed Body Image related to manifestations of disease or medication side effects.
- Risk for Caregiver Role Strain related to having a child with a chronic disease.
- Interrupted Family Processes related to hospitalization, frequent clinic visits.

Nursing Interventions

Minimizing Fatigue

1. Intersperse periods of rest between activities.
2. Caution to resume school activities slowly. Parents should negotiate with the school to implement accommodations to minimize fatigue (ie, second set of textbooks, rest area, and extra time to complete assignments). Consider half days at school until fatigue is diminished. The child may also be a candidate for homeschooling.
3. Maintain good sleep hygiene.

Promoting Comfort

1. Administer or teach parents to administer analgesics, NSAIDs, steroids, and other medications, as prescribed. Review medication side effects with family. Provide written medication aids.

2. For child on steroids, monitor for glycosuria and check blood test results for hyperglycemia, hypokalemia, and hyperlipidemia.
3. Encourage a warm bath or shower to relieve morning stiffness associated with arthritis.
4. Provide diversional activities appropriate for age.

Controlling Fever

1. Monitor temperature every 4 hours and document pattern.
2. Administer or teach parents to administer antipyretics, as prescribed; note results.
3. Encourage increased fluids by mouth when feverish. Dress in lightweight clothing.

Protecting from Injury because of Neuropsychiatric Disease

1. Institute seizure precautions, if indicated.
2. Monitor during seizure and postictal state.
3. Minimize noxious stimuli for patients experiencing hallucinations.
4. Implement safety measures during altered mental state.

Protecting from Adverse Reactions

1. While administering IV glucocorticoid therapy, monitor pulse and BP every 15 minutes for 1 hour and then every 30 minutes for 1 hour.
2. Slow the rate or discontinue infusion if there are significant changes in BP or pulse.
3. Notify the health care provider and continue to monitor vital signs frequently until they return to normal.

Maintaining Urinary Elimination

1. Monitor laboratory tests for signs of renal abnormalities: blood for creatinine, urine for specific gravity, blood and protein.
2. Monitor intake and output.
3. Monitor BP; watch for development of edema.

Promoting Appropriate Nutritional Intake

1. Allow child to help in selecting and preparing foods. Family members should set an example for healthy diet and consider complying with the same diet plan as has been recommended for the child.
2. Apply topical medication to oral ulcers or give analgesics before meals.
3. Monitor food intake and weight. Consider consultation with a dietician to assist with healthy food choices.
4. Low-sodium and low-potassium diet for those with nephritis and those on high-dose steroid therapy.
5. Encourage food high in calcium and vitamin D to decrease risk of low bone density.

Improving Self-Image

1. Encourage contact with peers and family.

2. Allow child to vent feelings about bodily changes and chronic illness.
3. Allow child to be involved in planning care and making decisions.
4. Consider a referral for counseling for adolescents to help with the development of coping strategies, if required.

Family Education and Health Maintenance

1. Teach ways to prevent exacerbations and complications of the disease. Teaching points include:
   a. Get enough rest; try not to overexert.
   b. Minimize stress and anxiety.
   c. Encourage adherence to medication schedule through use of medication calendar, pill boxes; understand adverse medication effects and strategies to reduce them; check with health care provider prior to using over-the-counter drugs or therapies found on the Internet.
   d. Avoid contact with people with infectious diseases; get pneumococcal and flu vaccine and keep routine immunizations up to date.
   e. Provide nutritional counseling to promote a balanced diet with special attention given to portion control and the intake of calcium, vitamin D, and when indicated iron, potassium, folic acid, and sodium content.
   f. Seek medical attention at times of illness or stress.
   g. Minimize sun exposure through protection with sunscreen, hats, and long clothing.
   h. Recognize warning signs of exacerbation such as fatigue, weight loss, joint pain, hair loss, new rashes, mouth sores, headaches, trouble with concentration, seizures, shortness of breath, chest pain, abdominal pain, fever, and urinary changes.
2. Educate parents about normal growth and development, emphasizing issues such as adolescent body image, peer relationships, and the impact of chronic illness on the child and the family.
3. Teach the importance of continual medical follow-up.
   a. Disease management requires frequent re-evaluation; medications and laboratory parameters require frequent monitoring to prevent complications and identify disease flares.
   b. Transition to adult care should begin in early adolescence. Teenagers should know their medications; understand their disease; learn to advocate for themselves with their doctor.
4. Advise family that all children with SLE need annual ophthalmologic exams. Those taking hydroxychloroquine require more frequent ophthalmologic evaluation to identify retinal changes early.
5. Refer to agencies such as the Lupus Foundation of America (*www.lupus.org*).

Evaluation: Expected Outcomes

- Participates in activities with peers without fatigue; attends school full time.
- Reports reduced level of pain.
- Remains afebrile, knows what to do if febrile.
- Seizure precautions maintained.

- No changes in vital signs during glucocorticoid infusion.
- Urine output adequate.
- Appropriate dietary intake, weight stable.
- Compliant with medication regime.
- Prepared for transition to adult care.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is an immune-mediated vasculitis with IgA deposition and subsequent inflammatory reaction around capillaries and arterioles. It is considered a small-vessel vasculitis. HSP can affect the skin, intestines, joints, kidneys, and nervous system. Incidence is higher in males than in females (2:1). Onset generally is between ages 3 and 15; it is seen most commonly in winter and can occur in clusters. Higher rate has been noted in those children diagnosed with familial Mediterranean fever.

Pathophysiology and Etiology

1. Cause is unknown; however, theories include an immunologic reaction to a variety of antigenic stimuli, in a genetically prone individual such as infection (viral, bacterial or fungal), dietary allergens, insect bites, and drugs.
2. Acute vasculitis develops.
   a. Swelling and edema of capillaries, small venules, and arterioles.
   b. Fibrin is deposited in the glomeruli of the kidney.
3. Vasculitis results in skin manifestations (nonthrombocytopenic palpable purpura), arthritis, GI (abdominal pain, GI bleeding), and renal symptoms.

Clinical Manifestations

1. Rash—sudden onset may precede or follow other manifestations.
   a. Typical rash begins with palpable maculopapular erythematous or urticarial rash.
   b. These lesions become less raised and purpuric in character and do not fade with pressure. They blanch initially and then progress to ecchymotic areas until they fade.
   c. Several stages of the rash may be present at one time.
   d. Rash appears primarily on the buttocks, lower back, and extensor aspects of the arms, legs, and face and then disappears.
   e. Localized subcutaneous edema in dependent and periorbital area is common.
2. Arthritis occurs in 50% to 80% of patients, primarily affecting the knee and ankle joints; the wrists, elbows, and finger joints may also be affected, although this is rare.
   a. The arthritis is moderately severe, with painful swelling because of periarticular edema and limitation of motion.
   b. The arthritis is self-limited and does not cause permanent sequelae.
3. Orchitis in 2% to 35% of male children.
4. Colicky abdominal pain—from submucosal and subserosal hemorrhage and edema in two thirds of children. May be accompanied by intussusception and GI bleeding.
5. Nausea, vomiting, malaise, low-grade fever.
6. Renal disease—proteinuria and hematuria.
7. Rarely, CNS involvement, such as headache, seizure, or cerebral hemorrhage.

8. Symptoms may appear acutely or gradually and vary in intensity and duration.

Diagnostic Evaluation

1. Blood studies (not diagnostic, but support clinical evidence):
   a. IgA may be elevated (more than 50% of cases).
   b. Coagulation studies and platelet count are typically normal in presence of purpura.
   c. ESR and WBC count may be elevated.
   d. Anemia is possible.
   e. Elevated BUN and creatinine with severe kidney involvement.
2. Urine studies show proteinuria, microscopic hematuria, and casts.
3. Stools may show occult or gross blood.
4. Abdominal ultrasound or x-rays may help confirm bowel involvement.

Management

Treatment is primarily symptomatic and supportive. Hydration, rest, and adequate pain relief are the goals of treatment.

1. Bed rest until the child is able to ambulate and can do so without increasing edema of the lower extremities, genital area, and buttocks.
2. Antibiotic therapy if acute episode was preceded by infection, especially streptococcal.
3. Management of complicating abdominal or renal involvement and arthritis.
   a. Steroid use is controversial. Suggested for use if symptoms prevent adequate oral intake or if the child has challenges with ambulation or performing ADL.
   b. Immunosuppressive therapy, such as azathioprine or cyclophosphamide, may be given to stabilize persistent renal involvement (rare).
   c. High-dose immunoglobulin has been recommended for severe cases.
4. Provide comfort measures and analgesics, such as acetaminophen or NSAIDs.

Complications

1. Acute nephritis or nephrosis that may lead to chronic nephritis. Ninety percent of children who develop serious renal involvement will do so within 2 months of diagnosis.
2. Intussusception (approximately 5% incidence).
3. Significant GI bleeding may require a transfusion (rare).
4. Neurologic vasculitis with headaches, seizures, and neuropathies.

NURSING ALERT Be alert for signs of intussusception—sudden onset of paroxysmal, colicky abdominal pain, blood in stools, vomiting, and increasing abdominal distention and tenderness—report

immediately.

Nursing Assessment

1. Obtain a complete history. There is some suggestion of allergy to insect bites or medications as a basis for development of the disease. Also controversial is association with streptococci, viruses, and vaccination.
2. Perform physical assessment of renal, integumentary, musculoskeletal, and GI systems.
3. Determine impact of illness on the psychosocial well-being of the child and family.

Nursing Diagnoses

- Acute Pain related to arthritis and abdominal pain.
- Activity Intolerance related to fatigue and pain.
- Risk for Impaired Skin Integrity related to rash and itching.
- Impaired Urinary Elimination related to renal involvement.
- Fear related to discomfort, hospitalization, and lack of knowledge.

Nursing Interventions

Reducing Discomfort

1. Monitor pain level and location. Use appropriate developmental pain scales to determine level of pain.
2. Administer or teach parents to administer pain medications, as prescribed, and monitor child's response.
3. Apply warm or cool compresses to joints or abdomen for 30-minute periods to help soothe painful areas.
4. Provide diversional activities in accordance with the child's age.

Increasing Participation in Activities

1. Monitor completion of daily and diversional activities; offer choice.
2. Alternate activities with rest periods.

Maintaining Skin Integrity

1. Assess skin condition and turgor.
2. Maintain adequate fluids.
3. Provide loose, comfortable clothing.
4. Administer or teach parents to administer antipruritics, if necessary.
5. Avoid soap, scratching, or dry skin that may exacerbate rash.

Maintaining Urinary Output

1. Record intake and output, vital signs, weight, urine-specific gravity, and level of edema.
2. Check urine for protein, hematuria, and color; monitor creatinine
3. Report or teach parents to report changes promptly.

Alleviating Fear

1. Allow child and family to verbalize feelings about hospitalization and illness.
2. Monitor anxiety level of child and family. Ensure information is given at the child's level of understanding.
3. Offer realistic encouragement. The long-term outlook is good when renal involvement is minimal.
4. Encourage the family and peers to visit the hospitalized child and bring in familiar items from home.
5. Allow child to make age-appropriate decisions and become involved in planning care.

Family Education and Health Maintenance

1. Reassure the parents that symptoms are usually self-limiting.
2. Make sure that parents and child understand the disease and the need to report changes in urine or signs of intussusception.
3. Educate the parents about the importance of continued care. Long-term follow-up of urinalysis will be necessary to evaluate renal function.

Evaluation: Expected Outcomes

- Reports relief from pain.
- Participates in activity for longer period each day.
- Rash resolved, skin intact.
- Urine output adequate, negative protein.
- Child verbalizes feelings about illness.

Kawasaki Disease

Kawasaki disease (KD) is a common vasculitis of childhood affecting medium and small blood vessels. Coronary arteries are the most common site of damage, giving KD the potential to cause severe morbidity and even death without early diagnosis and treatment. It is characterized by multisystem inflammation including fever, conjunctivitis, lymphadenopathy, and changes in blood vessels. It is the leading cause of acquired heart disease in children in the United States.

Pathophysiology and Etiology

EVIDENCE BASE Yeung, R. S. M. (2012). Vasculitis: Kawasaki disease. In A. Y. Elzouki, H. A. Harfi, H. Nazer, et al. (Eds.), *Textbook of clinical pediatrics* (2nd ed., pp. 1675–1684). New York: Springer.

---

1. KD is a disease of early childhood with 85% of affected children under 5 years of age. It occurs in children of all origins, although those of Asian descent have the highest incidence.
2. Etiology is unknown, although most investigators believe the disease is related to an infectious or environmental trigger in a genetically susceptible host. The result is a prolonged immune response targeted at vessel walls of medium and small arteries.
3. Infection as a trigger is supported by the fact that KD is endemic with seasonal fluctuations (winter and early spring). It is further hypothesized that super antigens, proteins present in certain organisms (*Staphylococci*, *Streptococci*, *Mycobacterium*, *Mycoplasma*, Epstein-Barr virus), are responsible for the prolonged inflammation through stimulation of large numbers of T cells.
4. Genetic predisposition to KD is evident in the observations that siblings have 10-fold higher risk of developing the disease and the children of parents who had KD have a twofold increase in risk than the general population.
5. Researchers have not found associations between exposure to drugs, environmental toxins, pesticides, chemicals, or heavy metals and KD.
6. KD is a generalized systemic vasculitis involving blood vessels throughout the body. The full extent of the inflammatory process leading to aneurysm formation is not understood. Marked elevation in the cytokine TNF is thought to activate matrix metalloproteinase enzymes capable of breaking down elastin in arterial vessel walls. This breakdown leads to loss of integrity and ballooning and aneurysm formation.
7. Aneurysms, the result of prolonged inflammation, usually develop in the 2nd to 8th week of the illness. The most common site for development is the coronary artery although other sites such as celiac, mesenteric, femoral, iliac, renal, and axillary may be affected. Early treatment following the recommended protocol of Intravenous gamma globulin (IVIG) and aspirin has reduced aneurysm development by 85%.

EVIDENCE BASE Son, M., & Sundel, R. (2016). Kawasaki disease. In R. E. Petty, R. M. Laxer, et al. (Eds.), *Textbook of pediatric rheumatology* (7th ed., pp. 285–317). Philadelphia, PA: Elsevier.

Clinical Manifestations

Kawasaki disease is divided into three phases, each with distinct clinical features. See Figure 53-1.

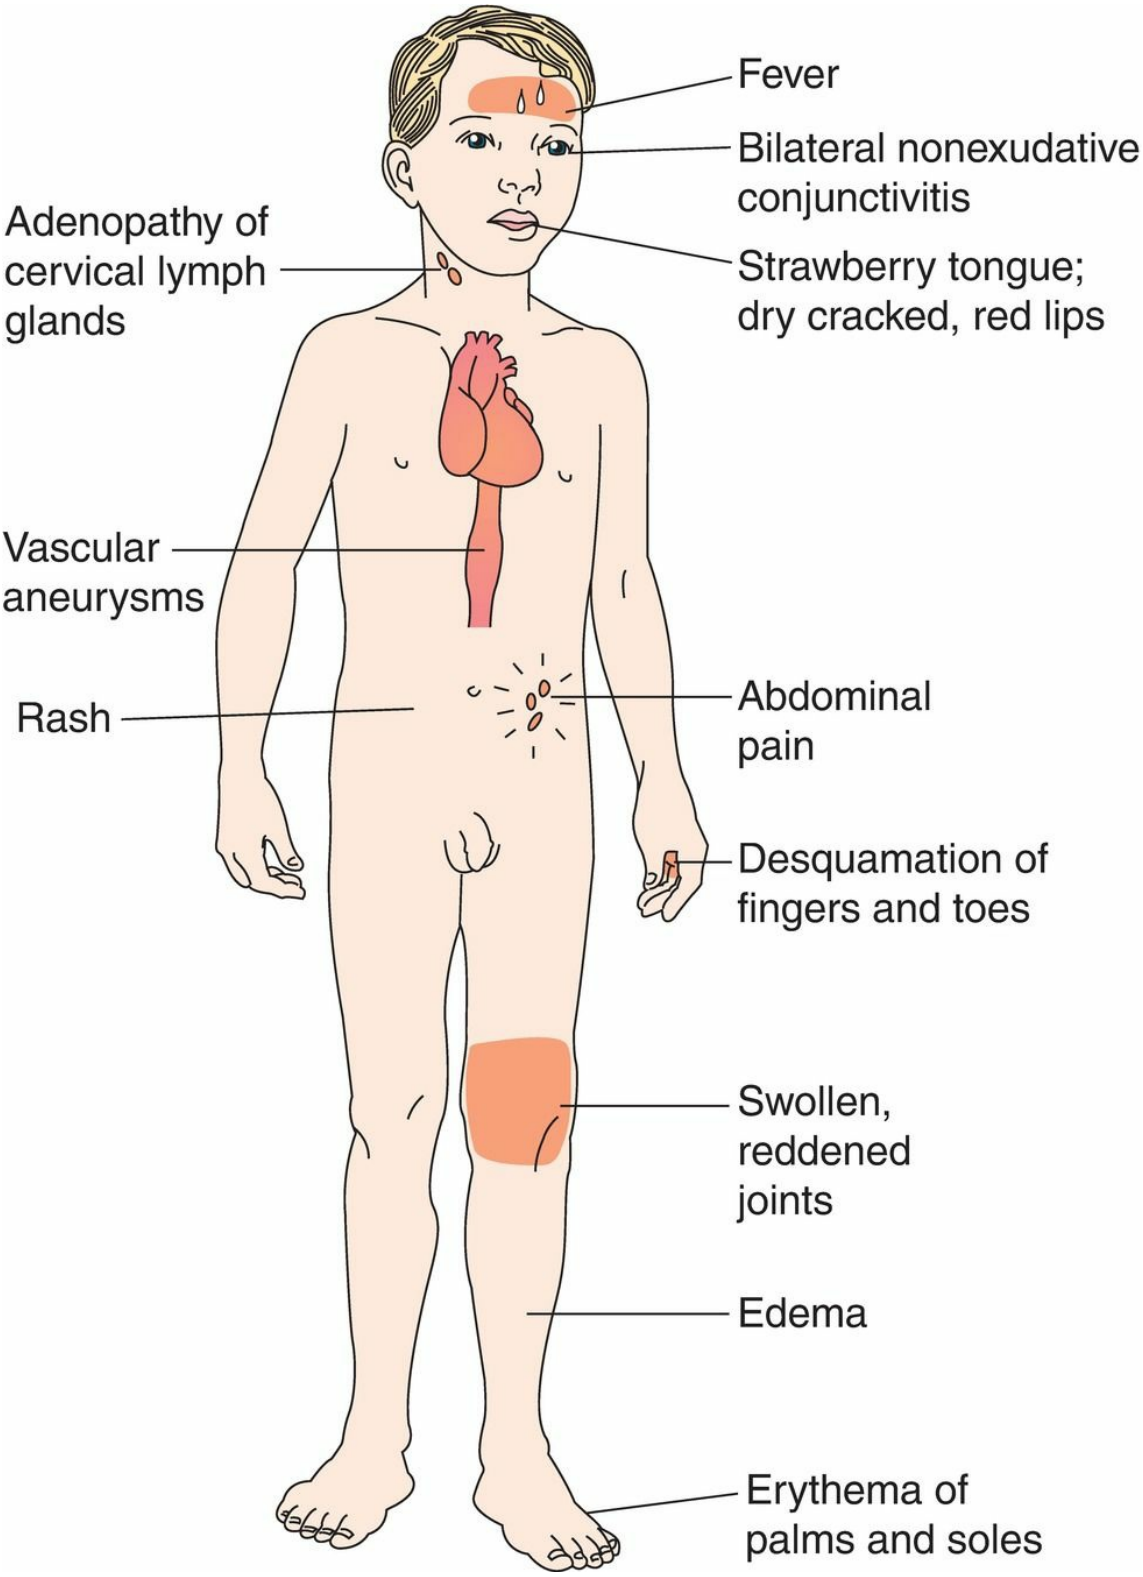

Figure 53-1. Clinical manifestations of acute Kawasaki disease.

Acute Phase (First 10 to 14 Days of Illness)

1. During the acute phase, the children exhibit classic signs of inflammation (redness, swelling, and heat) presented as multisystem changes. They appear ill and irritable.

2. The diagnostic criteria of Kawasaki disease occur during the acute phase. See Box 53-3. Fever, in addition to four out of five of the other features, is required for diagnosis; not all features occur at a single point in time.
3. Other associated findings:
    a. Cardiovascular—early tachycardia, myocarditis, pericarditis, S3 gallop; reduced contractibility may progress to signs of heart failure.
    b. Aseptic meningitis; anterior uveitis—children extremely irritable; photophobic.
    c. Arthritis—painful; usually large joints; short duration with rapid response to standard treatment for KD.
    d. Gastrointestinal—diarrhea, vomiting, abdominal pain, hepatomegaly, hydrops of the gallbladder.

BOX 53-3 American Heart Association Diagnostic Features for Kawasaki Disease

Persistent fever for at least 5 days. Fever is high (generally greater than 102.2°F [39°C]). Four out of the following five features:

- Bilateral conjunctival injection.Changes of the lips and oral cavity.Cervical lymphadenopathy.Polymorphous exanthema.Changes in the peripheral extremities (swelling of the hands or feet) or perineal area.

Cervical lymphadenopathy; at least one node greater than 1.5 cm; usually unilateral.

EVIDENCE BASE Paul, S., Paul, P., & McAllister, T. (2016). Clinical update: common cardiovascular conditions in children. *Community Practitioner, 89*(7), 33–37.

Singh, S., Vignesh, P., & Burgner, D. (2015). The epidemiology of Kawasaki disease: a global update. *Archives of Disease in Childhood, 100*(11), 1084–1088.

Subacute Phase (11 to 25 Days after Onset of Illness)

1. The classic inflammatory features of the acute phase resolve and the temperature returns to normal. If treated, many children are asymptomatic. If untreated or unresponsive to treatment, then fever, oral changes, and conjunctivitis may be present until 3rd or 4th week. Arthritis may be present.
2. Desquamation of toes and fingers in classic distribution starting in periungual region.
3. Coronary artery aneurysm is detected.
4. Thrombocytosis peaks at about 14 days.

Convalescent Phase

1. The acute-phase reactants (ESR and platelets) return to normal.

2. The child appears well.
3. Transverse grooves present on fingernails and toenails (Beau lines).
4. Vessels undergo healing, remodeling, fibrosis, and scarring. Pre-existing small aneurysms may resolve, and large aneurysms may develop thrombosis, leading to complications including myocardial infarction, dysrhythmias, or death.

Diagnostic Evaluation

1. There are no specific diagnostic tests for Kawasaki disease. The diagnosis is based on the clinical manifestations occurring in phases. There is a subset of children, usually the very young or old, who do not meet the diagnostic criteria for KD, yet present with prolonged fever and two or three of the features. They are a challenge to diagnose and are the group who has the highest risk for developing coronary aneurysms.
2. Although there are no specific laboratory tests, the following may help support diagnosis or rule out other diseases:
   a. CBC—leukocytosis; mild normochromic, normocytic anemia.
   b. Platelet count (from 500,000 to 1 million/mm^3)—increased during 2nd to 4th week of illness.
   c. ESR (usually greater than 40 mm/hour).
   d. C-reactive protein (usually greater than 3.0 mg/dL).
   e. Albumin—low levels associated with more severe and prolonged disease.
   f. Liver enzymes (AST, ALT)—moderately elevated.
   g. Serum lipids—reduced high-density lipoprotein levels; elevated triglyceride and low-density lipoprotein levels during the subacute phase.
3. Lumbar puncture often performed because of the degree of child's irritability demonstrates aseptic meningitis; cerebral spinal fluid analysis shows elevated white blood cell count; normal protein; normal glucose.
4. Echocardiogram—should be performed as soon as the diagnosis is suspected and at 2 weeks and at 6 to 8 weeks after diagnosis. More frequent assessment may be required for complicated cases.
5. Cardiac catheterization and angiocardiography may be required for more complex cardiac abnormalities.

Management

EVIDENCE BASE Singh, S., Vignesh, P., & Burgner, D. (2015). The epidemiology of Kawasaki disease: a global update. *Archives of Disease in Childhood, 100*(11), 1084–1088.

Williams, K. (2017). Preventing long-term cardiac damage in pediatric patients with Kawasaki disease. *Journal of Pediatric Healthcare, 31*(2), 196–202.

---

1. The goal of treatment is to prevent the long-term sequelae associated with KD by controlling inflammation.
2. The American Heart Association recommends that children with KD should be treated with IVIG and aspirin within 10 days of illness to reduce aneurysm formation. Treatment before day 5 has not shown any effect on coronary outcome and may increase the requirement for a second treatment.
   a. IVIG should be given as a single infusion at a dose of 2 g/kg. Most infusion protocols run very slow with stepwise increases in rate for a total infusion time of 8 to 12 hours.
   b. Ten to 20% of children will have persistent fever or recurrence of fever within the first 36 hours after treatment with IVIG. Experts agree that these children should be retreated with a single infusion of 2 g/kg.
   c. Aspirin therapy—the anti-inflammatory dose of 80 to 100 mg/kg/day divided into four doses is recommended during the acute phase. The length of treatment varies from 24 to 72 hours after fever resolves to 2 weeks. The aspirin is then reduced to antiplatelet dosing of 3 to 5 mg/kg/day, which is continued until laboratory measures of inflammation have returned to normal and the echocardiogram at 6 to 8 weeks shows no sign of coronary aneurysm. Children with aneurysms will continue aspirin for life.
3. In more complicated aneurysms, other anticoagulant and thrombolytic medications may be required.
4. Rarely, coronary artery bypass surgery or cardiac catheterization techniques are indicated.
5. Supportive measures:
   a. Maintain fluid and electrolyte balance.
   b. Give nutritional support.
   c. Provide comfort.
6. Follow-up by pediatric cardiologist with serial echocardiograms is necessary to monitor aneurysms.

DRUG ALERT Inflammation of the child's heart may compromise the heart's ability to handle the fluid challenge associated with IVIG. The infusion may need to be of longer duration.

DRUG ALERT Risk of Reye syndrome exists for children on aspirin therapy if they develop varicella or influenza. For children who are not immune to chickenpox, aspirin may need to be withheld after an exposure. Families should be instructed to receive annual influenza vaccines to minimize the risk for influenza.

Complications

1. Coronary aneurysm.

2. Aspirin toxicity.
3. Mortality is less than 0.3%.

Nursing Assessment

1. A thorough history to document data that support the diagnosis of Kawasaki disease; features of KD do not always present simultaneously.
2. Perform physical examination focusing on clinical features, hydration, and cardiovascular status. Document vital signs including accurate temperature, BP, heart rate, rhythm, heart sounds, respiratory rate.
3. Perform pain assessment using age-appropriate pain scale.

Nursing Diagnoses

- Acute Pain related to conjunctival inflammation; swollen, cracked lips; and joint inflammation.
- Risk for Decreased Cardiac Tissue Perfusion related to inflammation of coronary blood vessels.
- Impaired Oral Mucous Membrane related to oral vessel inflammation.
- Risk for Impaired Skin Integrity related to edema, dehydration, and desquamation of digits.
- Deficient Fluid Volume related to hyperthermia, anorexia, and oral changes.
- Fear of Parents and Child related to severity of illness and hospitalization.

Other Nursing Diagnoses may include:

- Hyperthermia related to inflammatory pathology of disease.
- Risk for Ineffective Peripheral Tissue Perfusion related to inflammation of blood vessels.
- Imbalanced Nutrition: Less Than Body Requirements related to anorexia, oral changes, increased metabolic requirements of inflammatory state.

Nursing Interventions

Reducing Discomfort

1. Offer pain medication on a scheduled basis rather than as needed during acute phase. Monitor pain level and child's response to analgesics.
2. Conjunctivitis and associated uveitis can cause photosensitivity; darken the room; offer sunglasses; apply cool compresses.
3. Use age-appropriate diversional techniques such as relaxation breathing, guided imagery, and distraction.

Maintaining Cardiac Output

1. Implement continual cardiac monitoring during acute-phase hospitalization.
2. Assess the child for signs of myocarditis and heart failure (tachycardia, gallop rhythm, chest pain, dyspnea, nasal flaring, grunting, retractions, cyanosis, orthopnea, crackles, moist respirations, distended neck veins, edema).

3. Closely monitor intake and output. Calculate fluid balance. Administer oral and IV fluids, as ordered.
4. If administering IVIG, give premedication, as directed, and monitor closely for adverse effects.

DRUG ALERT Infusion of IVIG has been known to cause a precipitous drop in BP mimicking anaphylaxis. Monitor BP and heart rate at the start of infusion, after 15 and 30 minutes, and then hourly until infusion is complete. Slow the infusion and have patient evaluated for any drop in BP. Give premedication as prescribed to help prevent adverse effects. Make sure medications to treat anaphylaxis are readily available.

Preserving Oral Mucous Membranes

1. Offer and encourage frequent cool liquids (ice chips and ice pops). Avoid acidic, sugary, or carbonated beverages; progress to soft, bland foods.
2. Give mouth care every 1 to 4 hours; use soft toothbrush.
3. Apply petroleum to dry, cracked lips.
4. Observe the mouth frequently for signs of infection.
5. Monitor food and fluid intake for nutrition appropriate for age.

Improving Skin Integrity

1. Avoid the use of soap to prevent drying; apply emollients to skin, as ordered.
2. Elevate edematous extremities.
3. Use sheepskin, convoluted foam mattress, and smooth sheets.
4. Encourage soft flannel or terry cloth loose-fitting clothing; change damp garments and linens frequently when febrile.
5. Protect peeling skin; observe for signs of infection.

Maintaining Fluid Balance

1. Offer fluids at least every hour when child is awake; monitor and document fluid intake and output.
2. Monitor hydration status by checking skin turgor, daily weight, urine output, presence of tears and moist mucous membranes, and urine-specific gravity.
3. Pay attention to insensible loss during febrile stage. Monitor temperature every 4 to 8 hours and administer antipyretics, as directed. Maintain temperature graph chart.

Reducing Fear

1. Use play therapy (passive and active) to help the child express feelings. Consult a Child Life therapist, as needed.
2. Explain all procedures and treatment plans to the child and family. Encourage the parents and child to verbalize their concerns, fears, and questions.

3. Provide respite for parents during irritable stage of illness when child may be inconsolable. Provide emotional support, as necessary.
4. Keep family informed of progress and reinforce information about stages and prognosis.

Family Education and Health Maintenance

1. Advise parents to take child's temperature daily for 2 weeks post discharge. Call health practitioner for temperatures over 101°F (38.3°C).
2. Ensure family is aware of plan for follow-up. Emphasize the need for long-term care. Complications can occur during the convalescent period months after the acute illness.
3. Advise parents that IVIG is pooled immunoglobulin. Immunizations, although not harmful, may not mount a protective response after IVIG administration. Live vaccinations are not recommended for 6 months post treatment. Catch-up vaccinations may be needed.
4. Advocate for compliance with the prescribed level of physical activity. Activity will be restricted if child is receiving anticoagulant therapy or if child has cardiac complications identified on stress testing.
5. Encourage family members to learn cardiopulmonary resuscitation.
6. Teach parents to report the possible development of salicylate toxicity—tinnitus, nausea and vomiting, GI distress, blood in stool, and increased respirations.
7. For children without physical activity limitations, educate parents that children may be fatigued for several weeks. They may require naps, shorter school days, and special accommodations by school.
8. Provide anticipatory guidance about child's behavior.
    a. Do not overprotect the child. Discuss with parents the grief process of denial, anger, bargaining, depression, and acceptance they may be going through because of the illness.
    b. Discuss regression that often occurs during stresses such as hospitalization and illness.
9. Refer to community organizations such as the American Heart Association (*www.heart.org*).

Evaluation: Expected Outcomes

- Reports improved comfort level.
- Vital signs stable, no signs of reduced cardiac output.
- Eating and drinking without difficulty, reports no oral discomfort.
- No pain or signs of infection with desquamation.
- Child expresses feelings about illness; parents report confidence in ability to manage care.

TRANSITIONAL CARE ALERT Adherence to treatment for patients with primary immunologic diseases is challenging due to the large number of complex medication regimens and costs that may not be covered by insurance. Nurses should explore patient and parental understanding with recommendations for calendars and computer applications that may prove helpful. If specialized skills are

required for administration, initial training and verification on subsequent visits should be required if necessary. Parents and patients should have an understanding of when they should contact their primary care provider or their medical specialist for questions.

PROCEDURE GUIDELINES 54-1

Care of the Child with a Cast, Splint, or Brace

EQUIPMENT

- Casting materials or immobilization device
- Cotton padding material, plastic padding

PROCEDURE

Nursing Action	Rationale
1. Prepare child for the procedure by showing materials to be used and describing procedure in age-appropriate terms.	1. Reduces fear and enlists cooperation.
2. Assess the need for pain medication, sedation, distraction techniques, or restraint and administer, as ordered.	2. Manipulation of the affected part may be painful, so pharmacologic preparation is usually necessary.
3. Obtain baseline neurovascular assessment, including discoloration or cyanosis, impaired movement, loss of sensation, edema, absent pulses, and pain disproportionate to injury or not relieved by analgesics.	3. Will serve as a baseline to compare subsequent assessments after immobilization.
4. Assist with application of the immobilization device.	
5. Help facilitate drying of a cast or splint. a. Keep the child and affected part still until dry. b. Support the curves of the cast with pillows. c. Avoid excessive handling of the cast, and use palms when handling it.	5. About 24 to 48 hr are required for drying a plaster cast. Dries from the outside inward, so may appear dry but is still moldable with movement or pressure.
6. Assess the skin around edges of the device daily for signs of skin irritation. Teach child or parents to look for and report redness, skin breakdown, localized pain, and foul odor that may indicate open wounds under device.	6. Pressure or friction may disrupt skin integrity. May be readily visible or occur under the device and not detected until advanced. Braces can be altered if skin irritation becomes apparent.
7. Try to prevent skin breakdown by padding edges of device and telling child to avoid placing anything inside the device.	7. Avoids friction or pressure damage to skin and underlying tissue.
8. Assess neurovascular status frequently after application of device, then daily to detect compromise.	8. Initial swelling from the injury may contribute to vascular insufficiency or nerve compression.
9. If child is in hip spica cast, prevent skin breakdown from frequent soiling around perineum. a. Line cast edges around the perineum with a plastic covering to prevent soiling of cast. b. Use a fracture bedpan or urinal to facilitate toileting. c. If not toilet trained, use a small diaper or perineal pad tucked under the edges of the cast, covered by a larger diaper, and change diapers as soon as soiled. d. Wash the perineum frequently and dry thoroughly. e. If the cast is synthetic and becomes soiled, clean it with a damp cloth and small amount of detergent.	9. Soiled edges of the cast may contribute to skin irritation or begin to disintegrate. e. Plaster casts cannot be washed because they absorb water and soften.
Cast removal	
1. Prepare the child for cast removal by describing the sensation (warmth, vibration) and demonstrating the cast cutter by touching it lightly to your palm.	1. Children are frightened by the loud noise and believe that the cast cutter will cut through their skin or extremity.
2. Provide and teach care of skin after cast, brace, or splint removal. a. Wash with soapy warm water. b. Soak the area daily with warm water to facilitate removal of desquamated skin and secretions. c. Advise child to avoid scratching; instead, apply lotion or oil to relieve itching. d. Encourage exercise as prescribed to regain strength and function.	2. An accumulation of dead skin and sebaceous secretions causes the skin to appear brown and flaky. c. Excessive rubbing may cause trauma. d. May initially be weak and stiff because of lack of use.

PROCEDURE GUIDELINES 54-2

Care of a Child in Traction

EQUIPMENT

- Traction tapes
- Elastic bandages
- Spreader blocks, ropes, weights, pulleys
- Adhesive tape

- Tincture of benzoin/other adhesive agent
- Traction bars, slings

PROCEDURE

Nursing Action	Rationale
1. Explain the procedure to the child and parents.	1. If the traction is to be effective, it is essential that the parents and child understand traction.
2. Maintain even, constant traction.	2. Traction must be kept constant to achieve the desired results.
a. Do not add or remove weights unless ordered.	
b. Allow the weights to hang free at all times.	
c. Be certain that the ropes are in the wheel grooves of the pulleys.	c. Maintains proper alignment.
d. Keep the weights out of the child's reach.	d. Prevents loosening or undoing of traction knots.
e. Wrap knotted areas of the ropes with adhesive tape to prevent slipping.	
f. Do not elevate the head or foot of the bed without consulting health care provider.	f. May disrupt traction forces.
g. Supervise the child's position so that the purpose of the traction is accomplished.	
3. Check for disturbance of circulation by observing the following:	3. Compares the affected extremity with the unaffected one.
a. Skin color—for redness, pallor, cyanosis.	a. May indicate neurovascular compromise.
b. Joint motion restriction.	
c. Skin temperature—warmth.	
d. Tingling, numbness.	
e. Swelling, edema.	
4. Provide skin care.	4. Immobilized children readily develop areas of pressure unless meticulous skin care is provided.
a. Pad bony prominences (ankles) with cotton padding before wrapping with elastic bandages.	a. Protects skin from injury.
b. Wash and dry all exposed areas thoroughly.	
c. Massage the child's back and sacral area frequently, using lotion.	c. Stimulates microcirculation and acts as a lubricant.
d. Inspect the heels, ankles, popliteal space, and top of the foot for signs of pressure from elastic bandages.	d. These are the areas most prone to breakdown.
e. Keep the linen free from wrinkles and food crumbs.	e. Prevents undue pressure areas.
f. Do not allow the traction cords to dig into child's skin.	f. This is a safety measure.
g. Use a fracture bedpan.	g. This is less awkward and more comfortable for the child.
5. Plan for short periods of muscle exercise every day.	5. Disuse of muscles can result in atrophy, contractures, and deformities.
a. Encourage use of unaffected extremity.	
b. Assist the child to exercise unaffected joints.	
c. Provide for diversionary activities that require movement of unaffected joints and muscles.	
6. Encourage deep-breathing exercises.	6. Prevents respiratory complications of prolonged immobilization.

Nursing Action	Rationale
7. Record intake and output.	7. Prolonged immobilization renders the child prone to urine retention and renal calculi.
8. Encourage a diet high in fiber and fluids.	8. Helps to prevent constipation and urinary calculi.
9. Provide daily diversion and encourage visitation from family and friends.	9. Helps prevent boredom and assists the child to cope with immobilization.
a. Suspend or place favorite toys within easy reach of child.	
b. Provide for continuing education for school-age children.	b. Length of immobilization in traction may be considerable.
c. Encourage activities that will allow for diversion: drawing, coloring, video games.	c. Activities that can be done while remaining in traction.
d. Immobilized patients should be roomed together, if possible.	d. Encourages peer support.
10. If not contraindicated, provide the child with an overhead trapeze.	10. This will assist with movement and self-help.
11. Document the following:	11. Proper documentation facilitates communication between health care providers.
a. Color, temperature, and appearance of the affected limb.	
b. Skin condition.	
c. Body alignment.	c. Proper alignment facilitates proper extremity positioning and maintains proper traction force.
d. Functioning of traction system.	
e. Response of child to treatment.	
12. Make sure countertraction is provided.	12. The child's body is the usual counterweight.
a. Foot of bed may need to be raised or placed on "shock blocks" to prevent child from being pulled to foot of bed.	a. Frequently, the child's weight is insufficient to maintain proper alignment of the extremity.
13. Do not alter the traction system.	13. Notify the health care provider if adjustment is indicated.
14. Avoid sudden movement or jarring of bed.	14. This can cause pain to the child and disturb alignment.
15. Do not allow weights to hang over the child's bed.	15. This is a safety precaution.
Skin traction	
1. Do not apply over an open wound or over damaged skin.	1. The skin must be intact for the pull of the traction to be effective. Prevents contamination of the wound and further skin breakdown.
2. Prepare the skin with an adhesive agent before application of traction tapes.	2. Adhesive agents allow the traction tapes to adhere better, preventing friction on the skin surface.
Skeletal traction	
1. Treat all entry sites as surgical wounds.	1. Reduces the chance of infection along the pin or screw tract.
a. Clean entry site according to your facility's policy or guidelines. This should be done at least once per shift.	a. Policies vary. Cleaning the pin site prevents infection, promotes comfort by preventing skin from adhering to pin.
b. Assess the entry site every shift for indications of infection or slippage.	b. Notify health care provider if either of these conditions exists.
2. Protect the exposed ends of skeletal traction pins.	2. Protects the health care provider as well as the child from injury.

Nursing Action	Rationale
Specific traction types	
Bryant traction	
Indications	
1. To reduce fractures of the femur in children younger than age 2 or weighing >30 lb (14 kg). 2. Also used to stabilize the hip joint when casting is not indicated. 3. Preoperatively to attempt reduction of a developmentally dislocated hip in the same age group.	
Mechanism of action	
Involves the bilateral vertical extension of the child's legs. The child's weight serves as the countertraction. Skin traction is applied to both limbs to minimize potential trauma and maintain stability and alignment of child.	 Bryant traction.
1. Maintain appropriate position: a. The legs are extended at right angles to the body. b. The hips are elevated slightly from the bed. c. The buttocks are elevated slightly from the bed. d. The heels and ankles are free from pressure.	1. Proper positioning is needed to achieve desired results. c. Ensures proper traction pull. d. Prevents skin breakdown.
2. Check condition and position of elastic bandages every shift. Rewrap, as indicated and permitted by the health care provider.	2. Elastic bandages can cause compression and compromise circulation. In addition, force across skin surfaces needs to be constant and free from constriction to prevent skin breakdown and ensure adequate traction force.
Russell traction (see figure at right)	
Indications	
1. Reduces fractures of the femur or hip. 2. Treatment of specific types of knee injuries or contractures.	
Mechanism of action	
Traction force is applied to the limb through application of skin traction. This can be accomplished with traction tapes or a traction boot in older individuals.	 Russell traction.
1. Application of elastic bandages: a. Wrap bandages from ankle to thigh on patients younger than age 2. b. Older patients should have bandages wrapped from ankle to the knee.	1. Proper application of the tapes prevents neurovascular compromise and ensures proper and adequate pull on the extremity.
2. Place foot support against both feet.	2. Prevents footdrop.

Nursing Action	Rationale
3. Keep the heel free from the bed.	3. Prevents pressure sores and ensures continuous traction pull.
4. Carefully assess the popliteal space for signs of pressure from the knee sling.	4. Prevents pressure sores or neurovascular compression.
5. Assess the neurovascular status of limb at least every 2 hr.	5. Early detection can prevent injury to patient.
6. Make sure that the footplate or spreader block is wide enough.	6. Prevents pressure sores and circulatory compromise.
90-degree–90-degree traction (90–90) (see figure at right) *Indications* Reduces fractures of the femur when skin traction is inadequate. *Mechanism of action* Traction force is applied through skeletal traction pin placed through the distal femur. A short leg cast or foam boot may be used to help suspend the lower leg. Traction force is applied to femur only through pin. Only enough weight should be used to hold lower limb suspended.	 90–90 traction.
Buck extension (see figure at right) Used to correct or prevent knee and hip contractures, to rest the limb, to prevent spasm of injured muscles or joints, or to temporarily immobilize a fractured limb. *Mechanism of action* The traction force is delivered through a traction boot or skin traction in a straight line.	 Buck extension.
Balanced suspension with Thomas splint and Pearson attachment (see figure at right) *Indications* Occasionally still used in older children and adolescents for fractured femurs to rest an injured lower extremity or joint. *Mechanism of action* Thomas splint suspends the thigh; Pearson attachment applied to the splint allows knee flexion and supports the leg below the knee.	 Balanced suspension. Pillitteri, A. (1999). *Maternal and child health nursing: Care of the childbearing and childrearing family* (3rd ed.). Philadelphia: Lippincott-Raven.

Nursing Action	Rationale
Dunlop traction (overhead 90–90) (see figure at right) *Indications* Used to treat fractures of the humerus and injuries in or around the shoulder girdle. *Mechanism of action* Traction force is applied usually through skin traction on the upper arm only. Occasionally, skeletal traction through an olecranon screw or pin in the distal humerus may be indicated. The lower arm is held in balanced suspension only. The elbow is maintained at 90 degrees of flexion or slightly more.	 Dunlop traction.
1. Make sure that the traction tapes are properly adhered and wrapped. 2. Assess the neurovascular status of the extremity every 2 hr.	1. Prevents damage to the skin and ensures proper pull. 2. Elastic bandages can cause circulatory or neurologic compromise. Early detection can prevent patient harm.
Cervical traction (see figures at right) *Indications* Used for stabilization of spinal fractures or injuries, muscle spasms, muscle contractures. *Mechanism of action* Traction force applied through a head halter (skin traction) or directly to the skull by means of Crutchfield tongs or halo apparatus.	 Cervical traction.
1. Head halter must be assessed for proper positioning. It should not place pressure on ears, skin, or throat. 2. Maintain flat bed position. 3. Keep the child in proper position and alignment. 4. Crutchfield tongs or halo pin sites should be treated as skeletal traction sites.	1. Prevents pressure sores. 2. Proper spinal alignment is critical to prevent further injury. 4. Prevents infection.

Nursing Action	Rationale
Halo-femoral traction	
Indications Used to correct severe spinal curvatures either before surgery or after a spinal release before final correction. *Mechanism of action* A halo is affixed to the skull. A traction pin is placed in each distal femur. Traction force is applied upward to the halo and downward to the femurs, pulling the spine into alignment.	
1. General traction considerations must be followed. The child is usually placed on a Stryker frame or special bed.	1. Allows for more accessible care of the immobilized patient.
2. Assess the child carefully every 2 hr for any increased complaints of pain, respiratory difficulty, or nerve injury.	2. Complaints should not be ignored because alteration in any of these can indicate neurologic or spinal injury. Notification of health care provider is vital to prevent further harm.
3. Be alert for symptoms of injury to cranial nerves: a. Lateral gaze paralysis. b. Difficulty in swallowing. c. Difficulty in coughing. d. Voice changes. e. Tongue weakness.	3. Common cranial nerve injuries: a. Abducens nerve palsy (most common injury). b. Vagus nerve. c. Vagus nerve. d. Glossopharyngeal nerve. e. Hypoglossal nerve.
4. Be alert for symptoms of injury to spinal cord: a. Weakness, numbness in legs. b. Loss of bladder function. c. Upturning or downturning of toes. d. Clonus of ankles or knees.	4. These complaints may indicate lower spinal nerve root or cauda equina damage and should be reported promptly.
5. Be alert for symptoms of brachial plexus injuries: a. Difficulty in moving hand, shoulder, or arm. b. Numbness or weakness in hand.	5. These complaints or findings may be caused by impingement on spinal nerves.
6. Assess all pin sites for loosening every shift.	6. Loose pins can cause harm to the child as well as prevent proper traction pull. Halo-gravity traction, using the child's body and gravity as counterweights, may be used instead of pins.
7. Keep the torque wrench for the halo pins at the bedside at all times.	7. The halo or pins may have to be removed or adjusted in an emergency or to ensure proper tension on the pins.

Immobilization: Casts, Braces, Splints, and External and Internal Fixators

EVIDENCE BASE Tho Hang, B., Gross, C., Otero, H, et al. (2017). An Update on Common Orthopedic Injuries and Fractures in Children: Is Cast Immobilization Always Necessary? *Clinical Pediatric Emergency Medicine, 18*(1), 62–73.

Hill, C. E., Masters, J. P., & Perry, D. C. (2016). A systematic review of splinting versus complete plaster casts for the management of childhood buckle fractures of the wrist. *Journal of Pediatric Orthopedics, 25*(2), 183–190.

Casting, bracing, and splinting are all means of immobilizing an injured or diseased body part, primarily bones and musculature. Internal and external fixators have been utilized to provide stability and immobilization of bones, which are fractured or in the process of reconstruction. The length of time for use of these various devices can vary from a few days to several months. Also see pages 860–866, but realize that the management of children who are immobilized requires age-appropriate adaptation and support.

Types of Fixators

1. Fractures that require open reduction, such as those that do not align, include more than one broken area of the bone or involve attaching long bones in reconstructive surgery that can be managed with open reduction internal fixation (ORIF).
2. External fixators involve pins and screws placed through the skin and into the bone to stabilize a fracture. External fixation can include types of traction. They are also used when osteotomies are required or for limb-lengthening procedures.

Complications of Immobilization

1. Peripheral neurovascular compromise.
2. Alteration in skin integrity because of pressure or friction.
3. Loss of efficient use of affected extremity because of noncompliance.

Traction

Traction is the application of a pulling force to an injured or diseased part of the body or an extremity, whereas a countertraction pulls in the opposite direction. Traction may be used to reduce fractures or dislocations, maintain alignment and correct deformities, decrease muscle spasms and relieve pain, promote rest of a diseased or injured body part, and promote exercise. Advances in nailing and rodding, along with use of internal and external fixators for fractures and spinal curvatures, have reduced the use of traction overall. Interest in ambulation for children is another consideration when surgeons decide between traction and other methods of immobilization. Currently, traction is still a very viable option especially for femur and femoral shaft fractures and hip and cervical fractures but remains an effective process for other immobilization requirements. Types of traction include reference to the mechanism and also specific named types such as Russell or Bryant traction for femoral fractures or halo traction with the use of Crutchfield tongs for stabilization of spinal fractures or injuries. Complications of traction include injury to the cranial nerves and other neurologic injuries.

Types of Traction

1. Manual—direct pulling on the extremity or body part. Usually, it is used to reduce fractures before treatment or immobilization.
2. Skin—force is applied directly to the skin by means of traction strips or tapes secured by elastic bandages or by means of traction boots, usually of short-term duration and commonly used in children in whom small amounts of force are required.
3. Skeletal—force is applied to the body part through fixation directly into or through the bone by means of a traction pin or screw. This allows for greater force over longer periods or used when skin traction is not feasible, as in soft tissue injury or damage.
4. Continuous or intermittent—traction forces should be disrupted only in accordance with the health care provider's orders.

Complications of Traction

1. Neurovascular compromise to extremity.
2. Skin and soft tissue injury.
3. Pin or screw tract infection and osteomyelitis (with skeletal traction).

COMMON ORTHOPEDIC DISORDERS IN CHILDREN

See additional online content: Patient Education Guidelines 54-1.

PATIENT EDUCATION GUIDELINES 54-1

Cast Care

- Keep the casted body part elevated on a pillow for the first few days to decrease swelling.
- Avoid touching the cast until it is fully dry to avoid denting it.
- Watch the body part below the cast for swelling or bluish discoloration of the skin.
- Move the body part below the cast at least every 4 hr for the first 24 hr.
- Avoid strenuous activity such as roughhousing or sports while the cast is in place.
- Do not put anything inside the cast.
- Keep the cast dry; cover with plastic bag to shower; do not swim or submerge cast in water.
- If itching occurs under the cast, blow some cool air into it from a hair dryer.
- Develop a plan for carrying out usual activity, such as dressing, walking up and down steps, and carrying books.
- Call your health care provider if there is pain, blueness, swelling, or inability to move the body part.
- Be sure to keep follow-up appointments.

Fractures

A *fracture* is a break or disruption in the continuity of the bone. Fractures in children differ from those in adults because of the differences in anatomy, biomechanics, and physiology of the child's skeleton compared to that of an adult. Involvement of the epiphysis or metaphysis can disrupt the epiphyseal plate, interfering with growth (see Figure 54-1). Fractures are extremely common in children, with an estimated 42% of boys and 27% of girls sustaining fractures during childhood.

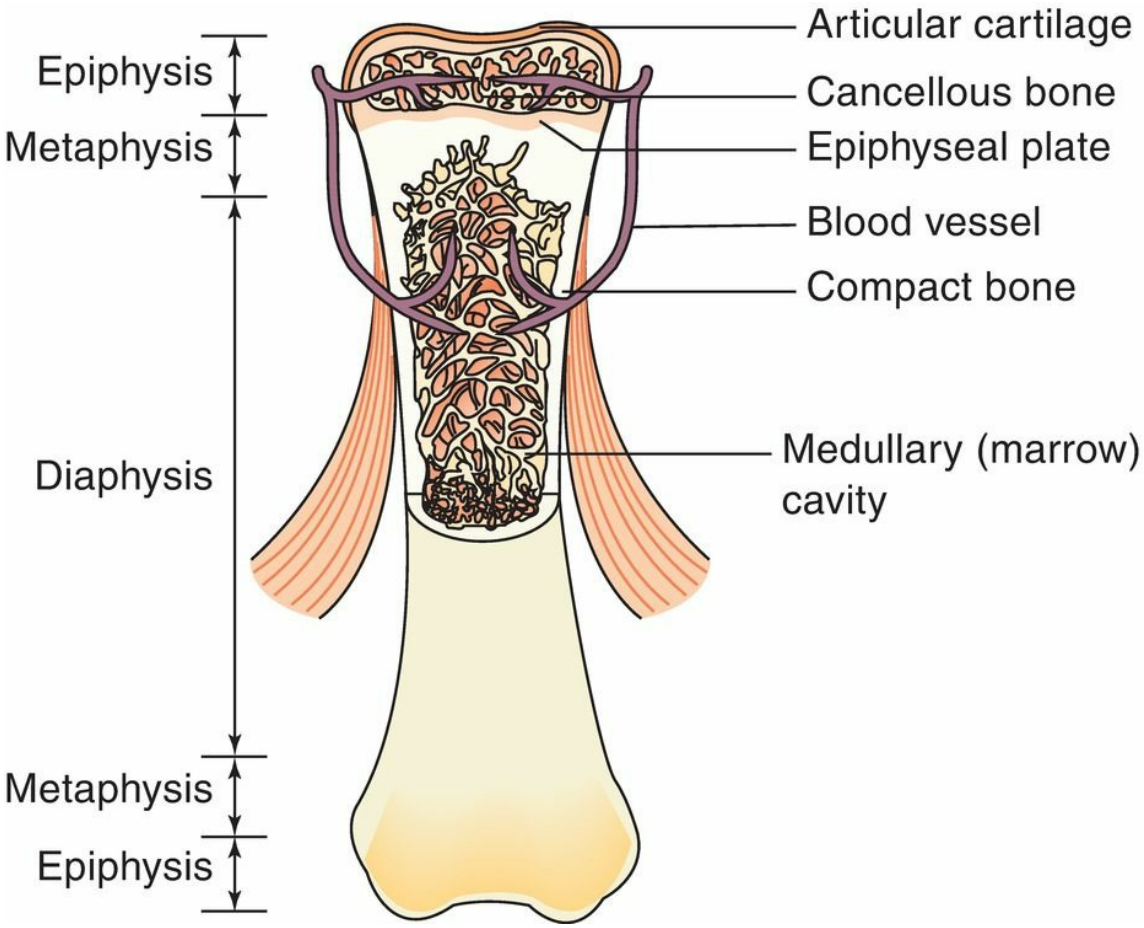

Figure 54-1. Structure of a bone.

EVIDENCE BASE Baker, R., Orton, E., Tata, L. J., et al. (2015). Risk factors for long bone fractures in children up to five years of age: A nested case-controlled study. *Archives of Disease in Children, 100*(5), 432–437.

Sameer, N., Erali, R., Warner, W., et al. (2016). Epidemiology of pediatric fractures presenting to the emergency department in the United States. *Journal of Pediatric Orthopaedics. 36*(4), E45–E46.

Servaes, S., Brown, S. D., Choudhary, et al. (2016). The etiology and significance of fractures in infants and young children: A critical multidisciplinary review. *Pediatric Radiology, 46*(5), 591–600.

Pathophysiology and Etiology

1. Most fractures in children are a result of low-velocity trauma such as a fall.
   a. Up to the age of 2 years, most fractures are sustained as a result of the child being injured by another person.
   b. Fractures in neonates and infants are commonly the result of child maltreatment, which should be suspected when evaluating and treating fractures in this age group.
2. A bone fractures when the force applied to it exceeds the amount the bone can absorb.
   a. Children's long bones are more resilient than those of adults. They are able to withstand greater deflection without fracturing.
   b. The majority of children who are at risk for long bone fractures are over the age of 1 year.
   c. The bones of children have thick periosteum, as compared to adults, providing a protective membrane to help prevent incidence of fractures.
3. The involvement of growth plates (epiphyseal plate) is unique to fractures in children. Cartilaginous growth plates are present at each end of the long bones and at one end of metacarpals and metatarsals. The plate is weaker than surrounding ligaments, tendons, and joint capsules and is disrupted before these tissues are injured.
   a. Damage to the growth plate may result in cessation of or a disturbance in bone growth (depending on the extent of damage sustained at the growth plate).
   b. On the other hand, acceleration in bone growth commonly occurs after a fracture in the long bones of children.
4. Children's fractures heal more rapidly than adult fractures. The younger the child, the more rapidly the bone heals.
5. Children's fractures remodel more completely and actively than adult fractures and usually result in less disability and deformity.

Sites of Fractures in Children

EVIDENCE BASE Franklin, C. C., Wren, T., Ferkel, E., et al. (2014). Predictors of conversion from conservative to operative treatment of pediatric forearm fractures. *Journal of Pediatric Orthopedics, 23*(2), 150–154.

Goodell, P. B., & Bauer, A. (2016). Problematic pediatric hand and wrist fractures. *Journal of Bone and Joint Surgery, 4*(5), 1–9.

Shuh, A. M., Whitlock, K. B., & Klein, E. J. (2016). Managing toddler fractures in the pediatric emergency room. *Pediatric Emergency Care, 32*(7), 452–454.

As children grow, the fracture rate increases, with the peak incidence occurring in early adolescence. Forearm

fractures are the most common injury.

Forearm and Wrist Fractures

1. The most common site of fracture in children, occurring more frequently in children older than the age of 5 years.
2. Major categories of classification include fracture dislocations, midshaft fractures, and distal fractures.
3. Most common cause is from a fall on an outstretched arm.

Epiphyseal or Growth Plate Injuries

1. Constitute approximately 15% to 25% of all skeletal injuries in children.
2. The most frequent site of physeal injuries (excluding phalangeal fractures) is the distal radius and ulna.
3. The 11- to 15-year-old age group tends to sustain the majority of physeal injuries to the distal radius and ulna.
4. The mechanism of injury is usually a fall on an outstretched arm.

Clavicle Fractures

1. Frequent site of fracture in children.
2. The shaft of the clavicle is the most common site of injury.
3. A fall on the shoulder or excessive lateral compression of the shoulder as in a difficult vaginal delivery in a newborn is usually the mechanism of injury.
4. Treatment involves support in the form of immobilization with a sling.
5. Reduction of clavicle fractures in children occurs only in instances of extreme displacement.

Humerus Fractures

1. The mechanism of injury for the majority of humeral fractures is a fall onto an outstretched arm or hand.
2. Supracondylar fractures are the most common fractures of the humerus and may be associated with acute vascular injury.
3. Approximately 10% of all humeral fractures occur at the shaft of the humerus; they are usually a result of twisting injuries in infants and toddlers. Direct trauma to the humeral shaft is the most common mechanism of injury in older children.
4. Distal humeral fractures occur more often in the lateral epicondyle than the medial epicondyle.
5. Less than 1% of fractures occur at the proximal humerus.

Spinal Fractures

1. Rare in children.
2. Mechanism of injury is due to significant trauma, such as a fall from a significant height, athletic activities, assault, or pedestrian–motor vehicle accident.
3. Most spinal fractures involve the cervical spine.

Pelvic Fractures

1. Pelvic fractures are uncommon in children and adolescents; they are commonly the result of high-energy trauma or a crush-type injury.
2. Associated injuries are present in approximately 75% of children with pelvic fractures and include hemorrhage and damage to the abdominal wall and pelvic organs.

Hip Fractures

1. Hip fractures in children are uncommon but may occur from motor vehicle accidents, bicycle accidents, falls from significant heights, or child maltreatment (in children under age 3).
2. Hip fractures can result in avascular necrosis of the femoral head and damage to the physis resulting in growth arrest, malunion, and nonunion.
3. Pelvic avulsion fractures are more common, especially in boys ageing 12 to 14 years.

Femur Fractures

1. Common in children. Peak incidence occurs in two age groups—children aging 2 to 3 years and adolescents.
2. Fractures of the femoral shaft (diaphysis) are uncommon in children but are the most common location in this area.
3. Usually the result of high-energy trauma, such as a motor vehicle accident or fall from a significant height; most common cause in children younger than age 1 is child maltreatment.

Tibial Fractures

1. The most common lower extremity fracture in children occurs in the tibial and fibular shaft—constitutes 10% to 15% of all pediatric fractures.
2. Most diaphyseal tibia fractures in children ages 5 to 6 are nondisplaced or minimally displaced spiral or oblique fractures. A rotational mechanism of injury to the lower leg is the most common cause of tibial fractures in children under age 3 (toddler's fracture or CAST [childhood accidental spiral tibial]).
3. Greater force is required to injure the tibia in older children; motor vehicle accidents and sports injuries are the most common causes of tibial fractures in children and adolescents.

Ankle Fractures

1. Represent approximately 5% of all pediatric fractures.
2. Involve the growth plate in approximately one of six injuries.
3. Greatest incidence is in males ages 10 to 15 years.
4. Usually the result of direct trauma.
5. Mortise view as well as anteroposterior (AP) and lateral x-rays should be obtained.

Foot Fractures

1. Foot fractures account for approximately 6% of all fractures in children and 50% of foot fractures occur at the metatarsals.
2. Most metatarsal and phalangeal fractures are nondisplaced.

3. Mechanism of injury is usually a direct or indirect trauma, such as from falls, jumping from heights, object falling on foot, and twisting injuries.

Classification of Fractures

1. Open fractures: underlying fracture in the bone communicates with an external wound; usually the result of high-energy trauma or penetrating wounds.
2. Closed fractures: underlying fracture with no open wound.
3. Plastic deformation: a bending of the bone in such a manner as to cause a microscopic fracture line that does not cross the bone. When the force is removed, the bone remains bent. Unique to children and most common in the ulna (see Figure 54-2A).
4. Buckle (torus) fractures: fracture on the tension side of the bone near the softer metaphyseal bone; crosses the bone and buckles the harder diaphyseal bone on the opposite side, causing a bulge (see Figure 54-2B).
5. Greenstick fracture: the bone is bent and the fracture begins but does not entirely cross through the bone (see Figure 54-2C).
6. Complete fractures (see Figure 54-2D):
   a. Spiral—from a rotational force.
   b. Oblique—diagonally across the diaphysis.
   c. Transverse—usually diaphyseal.
   d. Epiphyseal—through the physis.

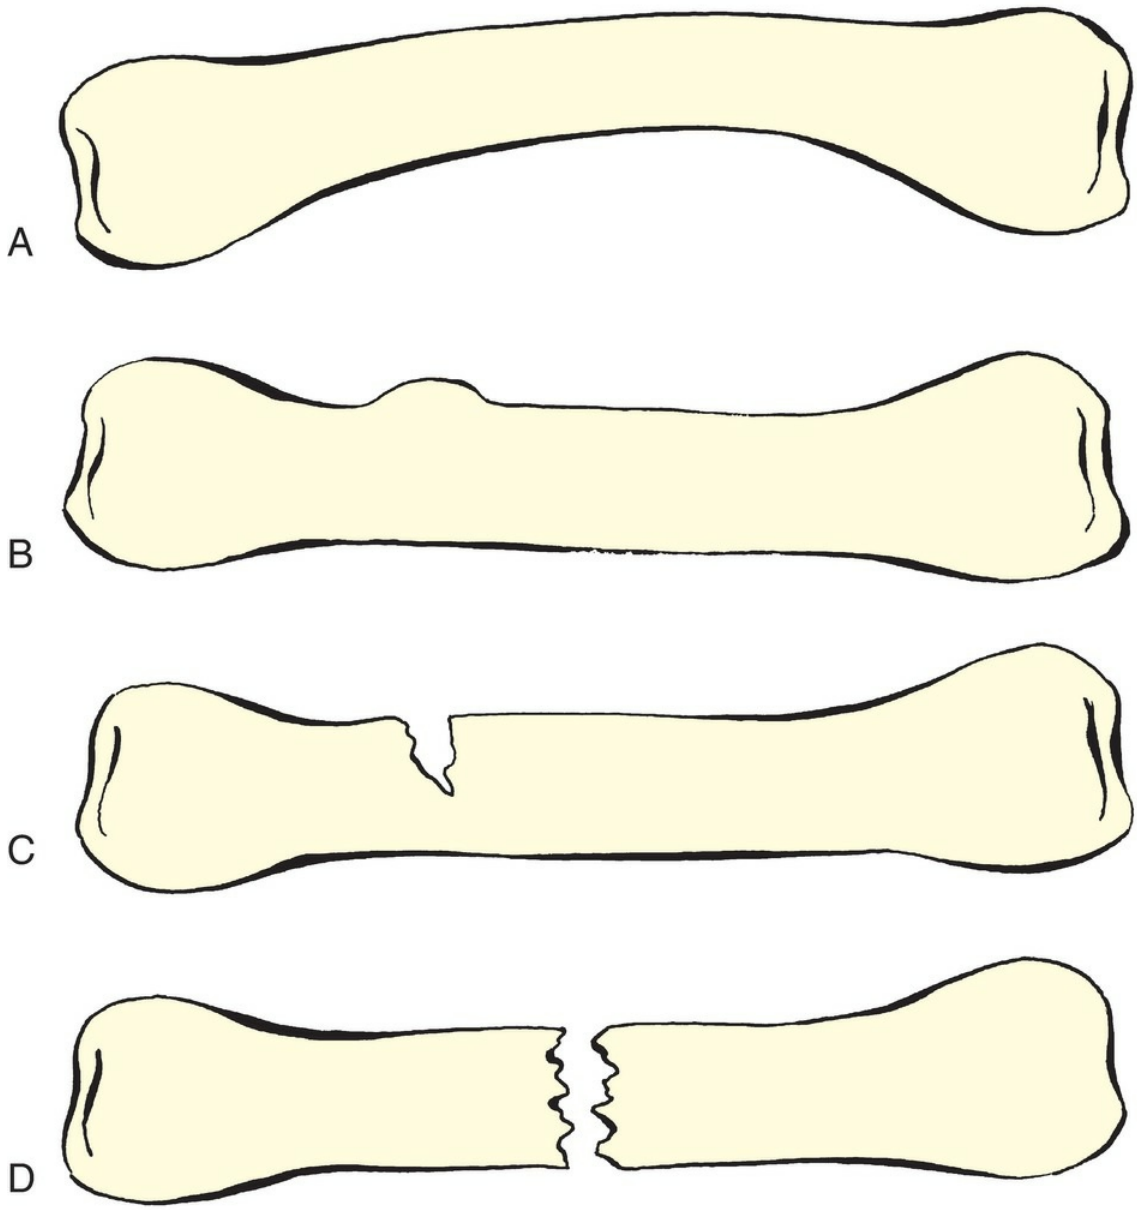

Figure 54-2. Common fractures in children. **(A)** Plastic deformation (bend). **(B)** Buckle (torus). **(C)** Greenstick. **(D)** Complete.

Clinical Manifestations

1. Inability to stand, walk, or use injured part.
2. Limb deformity (visible or palpable).
3. Ecchymosis.
4. Pain, described as point tenderness.
5. History of injury or trauma (may not be the case with pathologic fractures).
6. Spontaneous onset of pain (usually seen with pathologic fractures).
7. Local swelling and marked tenderness.
8. Movement between bone fragments.

9. Crepitus or grating.
10. Muscle spasm.

Diagnostic Evaluation

1. X-rays of suspected limb fractures should include the joint above and below the injury.
    a. Should always include a minimum of two views at 90-degree angles to each other (AP and lateral).
    b. Comparison views of the opposite extremity are frequently needed. They help to distinguish the fracture line from the growth plate.
    c. In some situations, oblique x-rays are warranted to help identify a fracture that is difficult to detect.
2. Further radiologic studies may be indicated in certain instances to evaluate a fracture: ultrasound, tomography, magnetic resonance imaging (MRI), computed tomography (CT) scan, bone scan, and fluoroscopy.
3. Vascular assessment may include the use of:
    a. Doppler studies.
    b. Compartment pressure monitoring.
    c. Angiography.

Management

Treatment is dependent upon the type of fracture, its location, and the age of the child.

1. Treatment may consist of:
    a. Immobilization by cast, splint, external fixator, or brace.
    b. Closed reduction followed by a period of immobilization in a cast or splint.
    c. Open reduction with or without internal fixation and usually followed by a period of immobilization in a cast or splint.
    d. Closed reduction and percutaneous pinning followed by a period of immobilization.
    e. Closed or open reduction and application of an external fixator.
    f. Traction (skin, skeletal) followed by a period of immobilization.
2. Most pediatric fractures heal in 12 weeks or less. Simple fractures that are closed and nondisplaced can heal enough to be free from immobilization within 3 weeks.

Complications

1. Infection and avascular necrosis.
2. Delayed union, nonunion, and malunion.
3. Shortening—epiphyseal arrest (deformities in angulation or limb length).
4. Vascular injuries.
5. Nerve injuries—palsies.
6. Visceral injuries.

7. Tendon and joint injuries.
8. Fat embolism.
9. Compartment syndrome (orthopedic emergency).
10. Osteoarthritis (occurs later).
11. Reflex sympathetic dystrophy.

Nursing Assessment

1. Follow the basic assessment for the trauma victim (see page 945).
2. Obtain history from child, parents, and others to include accident or trauma details, noting the position of the extremity at impact.
3. Perform physical examination for location of deformity, swelling, ecchymosis, and pain, vital signs, and neurovascular assessment.
4. Assess child's support mechanisms/social situation with consideration of discharge needs.

Nursing Diagnoses

- Acute Pain related to tissue trauma and reflex muscle spasms secondary to fracture.
- Ineffective Peripheral Tissue Perfusion related to swelling and immobilization.
- Impaired Skin Integrity related to mechanical trauma (eg, fixation device, traction, casts, other orthopedic devices).
- Ineffective Coping related to separation from family and home.
- Impaired Physical Mobility related to fracture and external immobilization device (eg, cast, splint, external fixator).
- Bathing/Dressing/Feeding/Toileting/Self-Care Deficit related to external devices (eg, cast, splint).
- Risk for Infection related to trauma (fracture) and surgery.
- Risk for Peripheral Neurovascular Dysfunction related to restrictive envelope secondary to cast or splint.

Nursing Interventions

Also see page 868 for orthopedic surgery.

Promoting Comfort

1. Monitor and assess pain level using an age-appropriate pain scale (eg, Oucher or FACES scale).
2. Properly position, align, and support affected body part.
3. Administer analgesics, as indicated, and monitor effectiveness of analgesia.
4. Use nontraditional methods of pain relief—music therapy, diversionary activities, relaxation techniques, therapeutic touch, and play therapy.

Maintaining Tissue Perfusion

1. Frequently assess perfusion of limb by checking temperature, color, sensation, and pulses.
2. Elevate extremity above heart level to prevent edema.

3. Encourage movement of digits on affected limb.
4. Remove compressive bandages (eg, elastic bandages, splints) that restrict flow of circulation.

Maintaining Skin Integrity

1. Assess for and relieve pressure caused by tight bandages, casts, and splints.
2. Provide periodic cleaning, thorough drying, and lubrication to pressure points if in traction.
3. Encourage frequent position changes as allowed.
4. Assess skin condition on a regular basis.
5. Massage healthy skin around affected area to stimulate circulation.
6. Protect the skin at risk with special dressings or products (eg, barrier cream, moisture-permeable dressing).
7. Discourage the use of sticks, pens or pencils, or small toys or other objects to scratch itchy skin.
8. Promote a diet high in protein, carbohydrates, and calcium.

Promoting Effective Coping

1. Assess the child's and parents' response to events; provide reassurance and emotional support.
2. Explain condition, treatment, and rehabilitation goals, as indicated.
3. Refer to community-based support agencies (eg, social services, home care nursing), if indicated.
4. Structure the child's day with routine, activities, and therapy to keep him or her busy.
5. Encourage child to express feelings and emotions through writing (eg, journal), drawing, or play therapy.

Promoting Mobility

1. Encourage exercise of uninvolved limbs regularly throughout the day.
2. Collaborate with physical and occupational therapist to teach appropriate ambulation techniques using aids such as crutches, walkers, or wheelchairs, as indicated.
3. Teach safety precautions when using an ambulatory aid.

Attaining Independence

1. Assess family situation for ability to care for child at home.
2. Allow child to care for self, and participate in care when able.
3. Encourage parents and siblings to assist only as needed.
4. Evaluate child's ability to participate in self-care activities.

Preventing Infection

EVIDENCE BASE Schroeder, N. O., Seeley, M. A., Hariharan, A., et al. (2017). Utility of postoperative antibiotics after percutaneous pinning of pediatric supracondylar humerus fracture. *Journal of Pediatric Orthopedics, 37*(6), 363–367.

Trionfo, A., Cavanaugh, P. K., & Herman, M. J. (2016). Pediatric open fractures. *Orthopedic Clinics of North America, 47*(3), 565–578.

---

1. Assess wounds, including pin sites, frequently for warmth, erythema, swelling, tenderness, or purulent drainage.
2. Pin site care and the use of dressings are indicated by the orthopedist or institution. A cleansing ritual with chlorhexidine or other antiseptic is beneficial, which includes gentle massage to remove superficial drainage.
3. Report signs of infection.
4. Provide appropriate wound care for open injuries and surgical wounds.
5. Administer antibiotics, as ordered.
6. Encourage child to eat and maintain good caloric and protein intake to promote healing.
7. Teach good handwashing technique to child and parents.

Preventing Peripheral Neurovascular Dysfunction

1. Assess the neurovascular status of affected limb every hour for the first 24 hours (or as indicated by hospital protocol)—compare with unaffected limb.
2. Assess for nerve injury (eg, abduct all fingers, touch thumb to small finger, plantar flexion, dorsiflexion).
3. Assess for the presence of numbness, tingling, "pins and needles," and excessive pain (disproportionate to injury and analgesia administered).
4. Encourage range of motion (ROM) exercises in fingers, toes, and unaffected limbs.
5. Teach child and parents signs and symptoms of neurovascular compromise and advise them to contact the health care provider immediately if signs of compromise occur.

Transitional Care ALERT

Inpatient rehabilitation or home care nursing visits may be necessary in the initial postoperative stage. Rehabilitation facilities provide occupational and physical therapy and education for the child to return to function. Home nursing care provides assessment of family coping with the care of their immobilized child. In either situation, reinforcement is needed to help reassure the parents that they are able to care for their child. Make sure the parents and caregivers know who to contact if they have any questions about a possible complication.

Community and Home Care Considerations

1. Assess the skin for signs of breakdown and condition of cast.
2. Assess neurovascular status of affected limb.
3. Assess traction device to make sure it is intact and maintained.
4. Assess child's nutritional status and bowel and bladder routine.
5. Assess coping ability of child and family members and answer questions parents may have about the care

of their immobilized child.

6. Teach patient and family about care of their child's pin site care and adjustment of screws. Have them do a return demonstration for evaluation of teaching.
7. Teach the child and family about signs and symptoms of infection and whom to contact should an infection occur.

Family Education and Health Maintenance

1. Teach proper care of casts, splints, and immobilization devices.
2. Teach safety measures and prevention of further injuries.
   a. Advise use of bicycle helmets and knee, elbow, and wrist pads.
   b. Emphasize importance of supervising young children while playing.
   c. Teach safety measures, such as placing gates at stairs and installing top-opening windows on second floors.
3. Teach family and child the natural history of fracture healing (eg, presence of fracture bump, gradual recovery of ROM, predicted time frame for healing).

Evaluation: Expected Outcomes

- Reports acceptable level of comfort.
- Extremity warm with good color sensation, pulses, and capillary refill.
- No skin breakdown noted.
- Parents comfort child; child responds appropriately.
- Uses ambulatory aids and ambulates independently.
- Bathes and feeds self with minimal assistance.
- No fever or signs of infection surrounding wound.
- Denies numbness and tingling.

Osteomyelitis

EVIDENCE BASE Godley, D. R. (2015). Managing musculoskeletal infections in children in the era of increasing antibiotic resistance. *Journal of the American Academy of Physician Assistants, 28*(4), 24–29.

Pyles, V. (2015). Pediatric Acute Hematogenous Osteomyelitis. *Continuing Education Topics & Issues, 17*(1), 14–18.

Osteomyelitis is a pyogenic infection of the bone and surrounding soft tissues. It occurs mostly in children between ages 3 and 12 years and is primarily a disease of growing bones. Long bones are frequently involved, and the characteristic site of involvement is the metaphyseal region. Males are afflicted two times as frequently as females.

Pathophysiology and Etiology

Etiologic Agents and Risk Factors

1. Microorganisms that cause osteomyelitis vary and are related to the age of the child.
   a. The most commonly identified pathogenic organism in acute osteoarticular infections is *Staphylococcus aureus*, with this organism responsible for about 70% of cases; methicillin-resistant *S. aureus* infections have risen in the last several years.
   b. Group A beta-hemolytic streptococcus, *Enterobacter*, *Escherichia coli*, and *Streptococcus pneumoniae* are other etiologic agents.
   c. Vertebral infections are increasingly a result of Gram-negative microorganisms.
2. Classification based on pathogen's mode of entry:
   a. Hematogenous osteomyelitis (through the bloodstream)—occurs primarily in children.
   b. Contiguous osteomyelitis—caused by pathogenic spread from outside the body or by progressive spread of infection from tissue adjacent to the bone.
3. Risk factors include:
   a. Impetigo.
   b. Furunculosis.
   c. Direct trauma to area adjacent to site of osteomyelitis.
   d. Infected burns.
   e. Prolonged use of an intravenous (IV) line or intraosseous needle.
   f. Immunizations, especially with bacille Calmette-Guérin (BCG).
   g. Intravenous drug addiction.
   h. Sickle cell disease.

Pathophysiologic Changes

1. When the site is inoculated, the invading pathogen provokes the following responses:
    a. Inflammatory response.
    b. Pus formation.
    c. Edema.
    d. Vascular congestion.
    e. Leukocyte activity.
    f. Abscess formation.
2. Small terminal vessels thrombose and exudate the bone's canaliculi.
    a. Inflammatory exudate extends into the metaphyseal and marrow cavity and through small metaphyseal openings into the cortex.
3. Exudate reaches outer surface of the cortex, forming abscesses that lift periosteum off the underlying bone, disrupting blood vessels and entering the bone through periosteum, thereby causing deprivation of blood supply to the bone. This leads to necrosis and death of the infected bone.
4. Sequestrum or devitalized bone is produced.
5. Intense osteoblastic response is stimulated upon lifting of the periosteum.
6. New bone is lain down by osteoblasts that partially or completely surround infected bone.
7. New bone, also known as *involucrum*, is formed.
8. Exudate escapes into surrounding soft tissue through openings in the involucrum, from which it escapes though the skin via sinus tracts.
9. Acute osteomyelitis is an abrupt onset of inflammation. Failure to halt acute osteomyelitis can lead to chronic osteomyelitis.
10. Chronic osteomyelitis:
    a. Signs and symptoms are usually vague.
    b. Infection is silent between exacerbations.
    c. Small abscesses or fragments containing microorganisms produce occasional flare-ups of acute osteomyelitis.
    d. Inadequate or inappropriate therapy and drug-resistant microorganisms can result in progression of acute osteomyelitis to chronic osteomyelitis.

Clinical Manifestations

1. Infants—involvement of multiple sites within the same bone or in multiple bones.
    a. Acute illness characterized by fever and failure to move affected limb.
2. Children—usually affects long bones but can affect the pelvis and spine.
    a. Abrupt onset of fever and systemic signs of toxicity.
    b. Swelling, redness, and discrete tenderness over the affected area.
    c. Decreased ability to bear weight as well as decreased ROM of affected limb.

3. Adolescents (less affected)—affects long bones but may involve vertebrae.
    a. Back pain.
    b. Signs and symptoms described above for children.

Diagnostic Evaluation

1. Blood cultures (positive in about 50% of cases) should be obtained before initiation of antibiotic therapy to help identify the causative pathogen.
2. Needle aspiration of soft tissue should be done to identify the causative agent.
    a. Gram stain, culture, and sensitivity of specimen once obtained.
    b. Negative aspirate does not always rule out infection.
3. Complete blood count—marked leukocytosis and low hemoglobin.
4. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)—elevated.
5. X-ray:
    a. Detects deep soft tissue swelling and loss of normal fat planes.
    b. Detects presence of bone resorption and periosteal new bone formation.
    c. Comparison films of one limb with another can be done.
6. Ultrasound—has become useful for both diagnosis and in guiding aspiration as the ultrasound detects soft tissue changes in periosteum and surrounding soft tissue.
7. Bone scan in children younger than age 1 is required to determine multisite involvement.
    a. Localizes area of skeleton with altered physiology but does not identify the cause.
8. MRI—superior to CT and most useful in showing anatomic detail in many planes as well as detecting pathologic changes within marrow and soft tissues.
9. CT scan—can be used to detect focal areas of bone destruction and to delineate soft tissue abscesses associated with the bone infection.
    a. Unable to detect early stages of osteomyelitis and radiation poses high risk to young children.

Management

1. Aspiration is necessary to confirm the diagnosis of osteomyelitis and to identify the responsible microorganism to treat with the appropriate antibiotic. Aspiration is also needed to determine if surgical debridement is required.
    a. Aspirated fluid is sent for culture and Gram stain.
2. IV antibiotics:
    a. Broad-spectrum antibiotics such as vancomycin or clindamycin, targeting Gram + organisms until sensitivity is obtained.
    b. Treatment is recommended based on the IV antibiotics for 3 to 6 weeks and based on symptoms and CRP level (there are no established guidelines for duration of therapy).
    c. May require placement of a central intermittent infusion catheter (eg, midline or peripherally inserted

central catheter [PICC] line).

d. After course of IV antibiotics, a switch to oral antibiotic is made.

3. Surgical debridement—helps to stop further tissue destruction, thereby allowing a shorter course of antibiotic therapy.
4. Bed rest and immobilization to help with pain management.

Complications

EVIDENCE BASE Funk, S. S., & Copley, L. A. (2017). Acute Hematogenous Osteomyelitis in Children: Pathogenesis, Diagnosis, and Treatment. *Orthopedic Clinics of North America, 48*(2), 199–208.

Complications of osteomyelitis are reported in about 6% of children and include:

1. Chronic osteomyelitis.
2. Pathologic fracture.
3. Growth arrest.
4. Osteonecrosis and avascular necrosis.
5. Recurrence of infection.
6. Septic arthritis.
7. Systemic infection—life-threatening if unrecognized and untreated.
8. Bone or muscle abscess.

Nursing Assessment

1. Obtain a detailed history, including recent infections (ear, tonsils, chest, urinary tract), trauma, and onset of symptoms.
2. Obtain history of current or recent antibiotic therapy and its effect.
3. Perform physical assessment for signs of primary infection as well as osteomyelitis.
4. Assess coping mechanisms and resources of family.

Nursing Diagnoses

- Acute Pain related to swelling, hyperthermia, and infectious process of the bone.
- Hyperthermia related to inflammatory response secondary to osteomyelitis.
- Impaired Physical Mobility related to pain in affected limb secondary to inflammatory response or surgical treatment.
- Readiness for Enhanced Self-Health Management related to IV drug therapy.

Nursing Interventions

Maintaining Comfort and Reducing Temperature

1. Assess pain characteristics and use age-appropriate pain measurement tools.
2. Assess temperature every 4 hours and increase fluid intake to prevent dehydration.
3. Maintain rest and immobilization of affected part.
4. Administer analgesics/antipyretics, as indicated, and monitor their effectiveness.

Preventing Complications of Immobility

1. Instruct on allowable activities—generally no weightbearing on affected limb and remain on bed rest during acute phase.
2. Encourage use and exercise of unaffected limbs and joints through play.
3. Provide ambulatory aids if indicated (eg, crutches, walker) and instruct on safe and proper use.

Promoting Compliance with Therapeutic Regimen

1. Instruct patient and family on the need for maintaining serum levels of antibiotics after discharge, even after signs and symptoms of infection improve.
2. Initiate appropriate home care referrals for administration and monitoring of IV therapy and wound care.
3. Evaluate response to treatment through periodic laboratory tests (ESR, CRP, serum drug levels if indicated) and follow-up.
4. Teach family about proper maintenance and care of vascular access device (eg, midline, PICC line).
5. Teach family and patient about oral antibiotic and importance of compliance with therapy.

Community and Home Care Considerations

1. Teach parents and child (if appropriate) about signs and symptoms of an infection.
2. Teach parents how to prepare the antibiotic for IV administration.
3. Teach parents how to administer the IV antibiotic.
4. Teach parents about the antibiotic being administered.
5. Teach parents and child about maintenance of the vascular access device.
6. Teach parents and child how to care for the child's wound.
7. Teach parents and child about potential complications after discharge.
8. Assess parents' and patient's coping abilities.
9. Reinforce teaching to parents on a frequent basis. Employ the use of return demonstrations to assess parental ability to administer IV antibiotics and care for their child's wound.
10. Provide the family with the phone number of a nurse whom they may contact for advice or if they have concerns.

Transitional Care AlertOngoing home visits may be necessary to make sure parents are comfortable with the child's vascular access device. Coaching about medication administration, maintenance of the device, and wound care can prevent readmission.

Family Education and Health Maintenance

1. Instruct the family on the signs and symptoms of recurrent or chronic infection.
2. Stress the importance of compliance with treatment.
3. Encourage parents to seek early medical intervention for subsequent infections.

Evaluation: Expected Outcomes

- Reports reduced pain or no pain.
- Remains afebrile.
- Exercises unaffected limbs.
- Surgical wounds without signs of infection; child and parents demonstrate proper techniques for care of IV access device and infusion.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) is the term used to describe abnormalities of the developing hip, including subluxation, dislocation, and dysplasia of the hip joint. DDH may be associated with other congenital anomalies; its incidence is 1 out of every 1,000 live births in the United States. White infants are affected more frequently than blacks. Bilateral involvement occurs in more than 50% of cases, and the left hip is more frequently involved than the right hip. Females are afflicted four to eight times more frequently than males.

Pathophysiology and Etiology

1. Risk factors include breech birth, first born, large infants, oligohydramnios, female gender, positive family history of DDH, ethnic background, lower limb deformity, torticollis, metatarsus adductus, hip asymmetry, and other congenital musculoskeletal abnormalities.
2. Subluxed hip—maintains contact with the acetabulum but not fully located within the hip joint.
3. Dislocated hip—no contact between the femoral head and acetabulum; sometimes located but may be dislocated easily.
4. Dysplasia—acetabulum is shallow or sloping instead of cup shaped (see Figure 54-3).

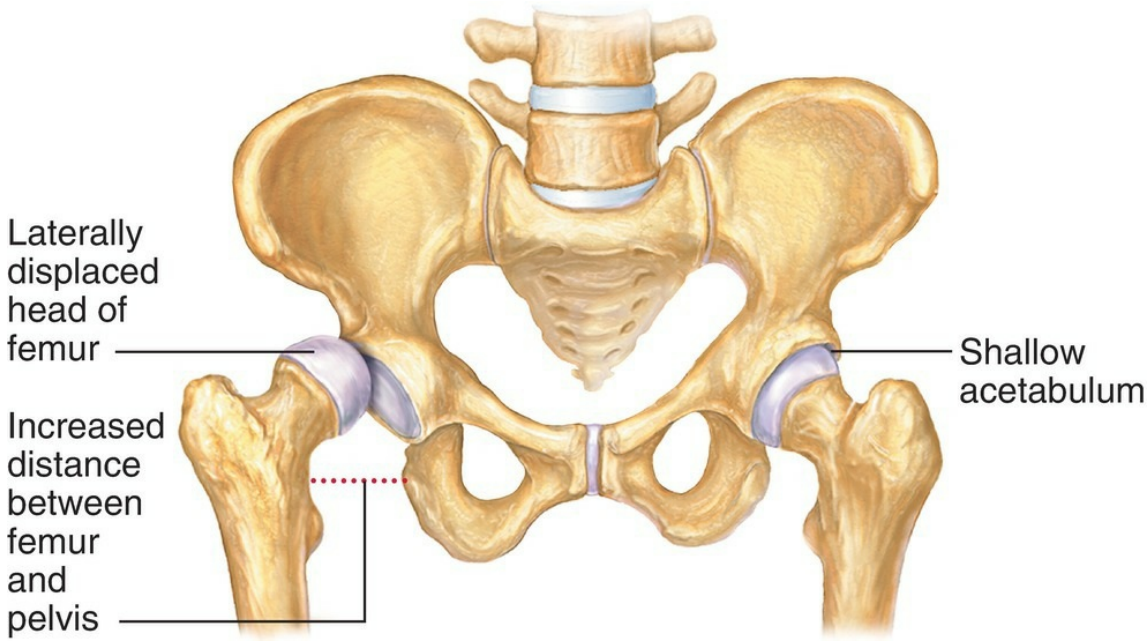

Figure 54-3. Developmental dysplasia of the hip. (Anatomical Chart Company.)

Clinical Manifestations

Physical findings change as the child ages; the presence of one or more of the following should be noted (see Figure 54-4).

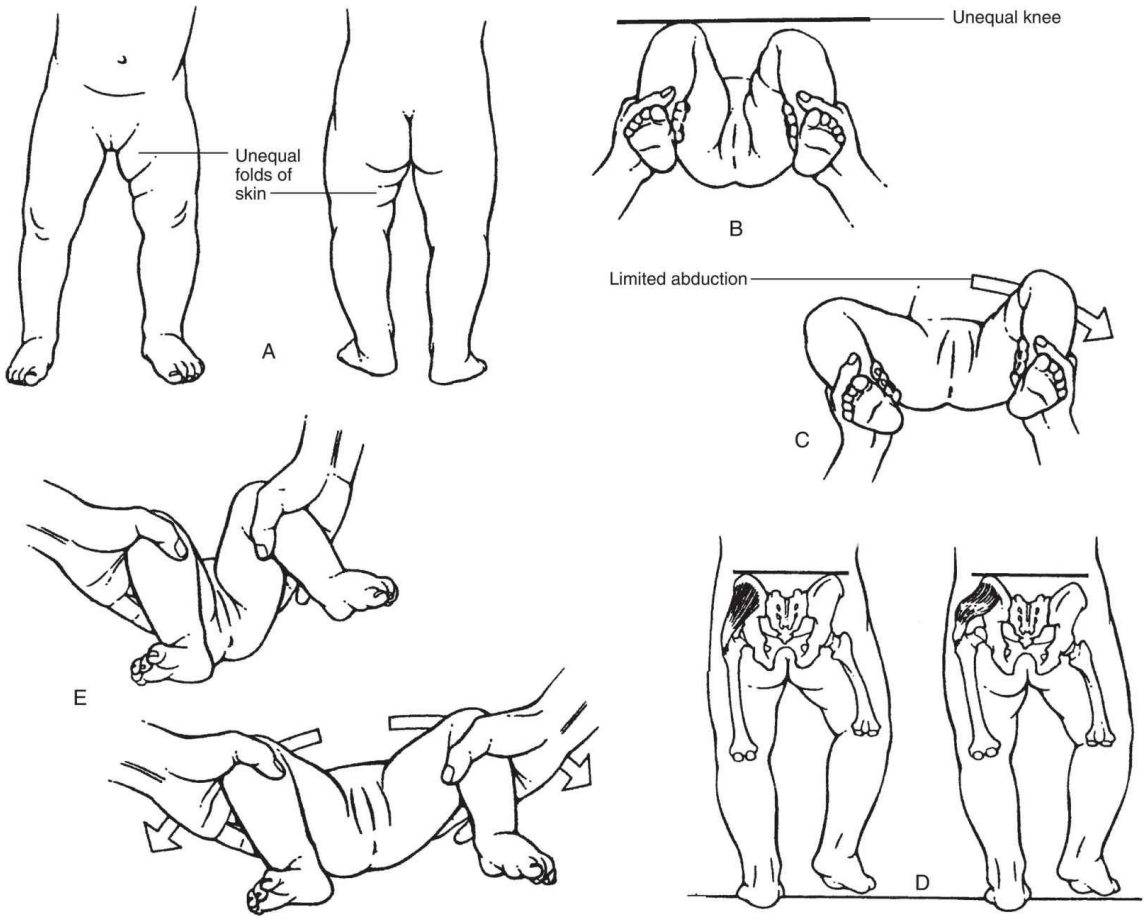

Figure 54-4. Signs of developmental dysplasia of the hip. **(A)** Unequal thigh folds; **(B)** apparent short femur (Galeazzi sign); **(C)** limited abduction of affected hip; **(D)** downward tilt of the pelvis on affected side (Trendelenburg sign); and **(E)** adduction and depression of the femur dislocate hip (Barlow test), and a "click" is felt when dislocated hip is abducted and relocated (Ortolani sign). (Jackson, D. B., & Saunders, R. B. [1993]. Child health nursing. Philadelphia: Lippincott Williams & Wilkins.)

1. Thigh asymmetry or thigh gluteal folds (present in 10% of normal infants).
2. Limited hip abduction.
3. Positive Barlow test (dislocation).
4. Positive Ortolani test (reduction).
5. Shortening of affected femur (Galeazzi sign).
6. Abnormal gait patterns—Trendelenburg gait (downward tilt of the pelvis on affected side).
7. Pain in older children.

Diagnostic Evaluation

EVIDENCE BASE Shaw, B. A., Segal, L. S.; Section on Orthopaedics, American Academy of Pediatrics (AAP). (2016). Evaluation and Referral for Developmental Dysplasia of the Hip in Infants. *Pediatrics, 138*(6).

1. Ultrasound examination (with a skilled technician)—yields a high degree of accuracy in diagnosing DDH in children younger than the age of 6 months.
   a. Enables visualization of the femoral head and outer lip of the acetabulum.
   b. The AAP published guidelines for both ultrasonography indications and referral to orthopedist based on physical exam, clinical findings, and history.
2. X-rays—cartilaginous femoral head is difficult to visualize in the newborn. As the child ages, the ossification center can be better viewed and the efficiency of x-ray improves, usually after the age of 6 months. It can be useful in ruling out other pelvic, spinal, and femoral anomalies.

Management

EVIDENCE BASE Larson, J. E., Patel, A. R., Weatherford, B., et al. (2017). Timing of Pavlik harness initiation: Can we wait? *Journal of Pediatric Orthopedics*. Epub ahead of print.

Murphy, R. F., & Kim, Y-J. (2016). Surgical management of pediatric developmental dysplasia of the hip. *Journal of the American Academy of Orthopedic Surgeons, 24*(9), 615–623.

The aim is to restore as closely as possible the anatomic alignment of the hip. Methodology depends on the age of the child at presentation. More than 80% of clinically unstable hips at birth have been shown to resolve spontaneously.

Birth to Age 6 Months

1. Subluxable hips:
   a. Observe for 3 weeks.
   b. If persistent, treat with Pavlik harness (see Figure 54-5).
2. Dislocated or dislocatable hips:
   a. Pavlik harness—frequent follow-up is needed to check position, make strap adjustments, and determine hip stability.
   b. Ultrasound to determine if the hip was reduced.
   c. Infant will wear harness on a full-time basis until clinical and ultrasound examinations are normal.

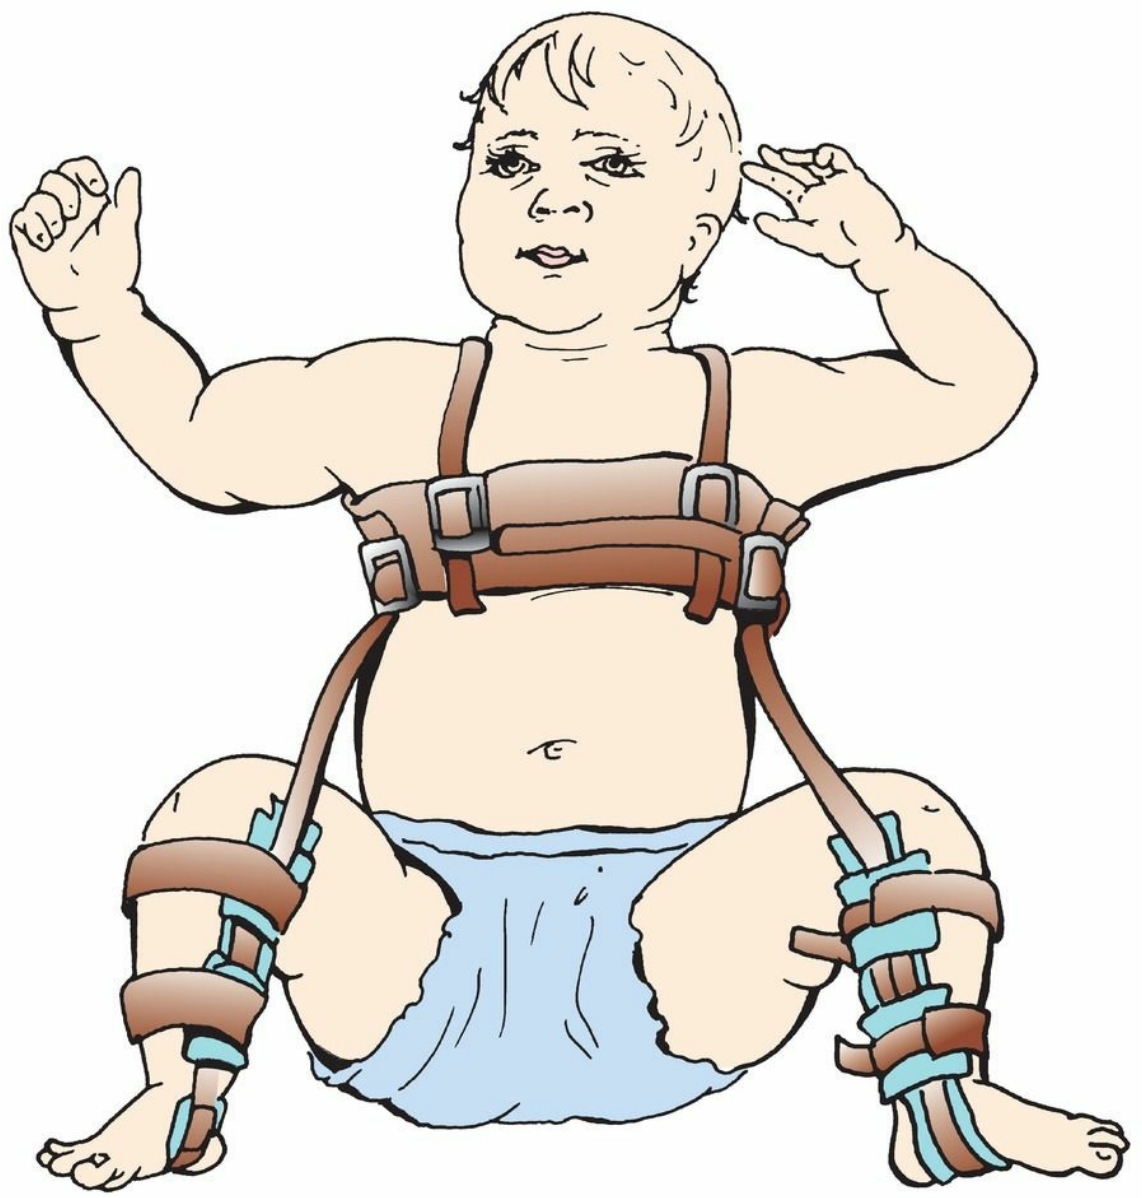

Figure 54-5. Pavlik harness.

Ages 6 to 18 Months

1. Hip subluxation and dislocation in children between ages 6 and 9 months:
   a. Treatment with the Pavlik harness requires frequent evaluation and may continue for 4 months or until the child is able to stand in the harness.
   b. When the child is standing, the harness is exchanged for an abduction brace until the hip is normal.
   c. Closed reduction and hip spica application if harness treatment is unsuccessful.
2. Hip subluxation and dislocation in children ages 9 to 18 months—follow-up continues until age of skeletal maturity.

Ages 18 to 36 Months

1. Dislocated hip:

a. Closed reduction.
b. Application of hip spica cast for 3 months to maintain the reduction.

2. Failure of closed reduction and casting:
   a. Open reduction and innominate osteotomy.
   b. Hip spica cast application.
   c. Abduction bracing.
3. Follow-up continues until age of skeletal maturity.

Ages 3 and Older

1. Subluxation or dislocation of the hip—treated surgically by open reduction.
2. Follow-up continues until age of skeletal maturity.

Adolescents

1. Acetabular dysplasia:
   a. Use of nonsteroidal anti-inflammatory drugs and an ambulation device (eg, crutches, cane) to limit weightbearing on the affected limb.
   b. Usually need surgical correction.

Complications

1. Avascular necrosis.
2. Redislocation or subluxation.
3. Loss of ROM.
4. Leg length discrepancy.
5. Early osteoarthritis.
6. Recurrent dislocation or unstable hip.
7. Femoral nerve palsy.
8. Iatrogenic hip dislocation.

Nursing Assessment

1. Obtain a family history, including hip pathology.
2. Obtain an obstetric history for the presence of risk factors, such as breech presentation and firstborn status.
3. Perform a physical assessment for ROM, appearance of Trendelenburg sign, Barlow test, Ortolani test, and examination for asymmetric thigh folds.
4. Assess family's response to the diagnosis.

Nursing Diagnoses

- Risk for Impaired Parenting related to ineffective adaptation to stressors associated with a diagnosis of

DDH and the prescribed therapeutic regimen.

- Risk for Impaired Skin Integrity related to perineal soiling secondary to confinement in an orthopedic device (eg, Pavlik harness, hip spica cast).
- Impaired Physical Mobility related to external device (eg, hip spica cast).

Nursing Interventions

Also see page 868 for orthopedic surgery.

Promoting Effective Parenting

1. Explain the condition and treatment in terms the family can understand.
2. Encourage holding the child with abduction of the hips while handling.
3. Advise parents to avoid swaddling the infant.
4. Reassure parents that effective outcome depends on early intervention and compliance.
5. Demonstrate application of Pavlik harness and make sure that parents know and feel comfortable in applying it.
6. Stress the importance of keeping follow-up appointments and strict compliance with prescribed treatment.
7. Provide parents with the name and number of a contact person if they have concerns about their child's care.

Maintaining Skin Integrity

See page 1420.

Preventing Complications of Immobility

1. Stimulate the child with games and activities to exercise upper body and feet as able.
2. Turn the child frequently and encourage ambulation as able. Support the head and legs to reposition.
3. Encourage deep breathing exercises at intervals to prevent atelectasis and hypostatic pneumonia. Children can blow bubbles, party favors, and cotton balls across the table as appropriate.
4. Encourage fluids and a high-fiber diet to prevent constipation.

Community and Home Care Considerations

1. An initial home care visit may be required to assess the child in a Pavlik harness.
2. For children in a hip spica cast, see the "Community and Home Care Considerations" section under "Fractures."
3. Carefully assess parental role development and educate them on normal care of infant as well as special care needed by their child, such as safety measures and positioning.

Family Education and Health Maintenance

1. If the child is to be treated with an abduction splint, explain its purpose and demonstrate its application and removal to the parents.

a. Instruct the parents as to if and when the device can be removed.
b. Instruct the parents to check fit of abduction splint at every diaper change.
c. Allow the parents to demonstrate their ability to properly place the device on the child.
d. Provide the parents with written instructions whenever possible.

2. Instruct the parents on skin care and to report any skin breakdown or disruption of the cast, brace, or splint.
3. Encourage regular follow-up evaluations and regular health maintenance visits.

Evaluation: Expected Outcomes

- Parents hold child and participate in care (eg, applying Pavlik harness).
- No perineal skin breakdown.
- Lungs clear with good aeration bilaterally.

Congenital Clubfoot (Talipes Equinovarus)

Clubfoot is a congenital anomaly characterized by a three-part deformity of the foot, consisting of inversion of the heel (hindfoot varus), adduction and supination of the forefoot, and ankle equinus. Clubfoot typically points down and twists inward. The bone, muscle, ligaments, nerves, and blood vessels below the knee may all be displaced. Other congenital disorders of the foot and ankle occur but are less common. Incidence of clubfoot is 1 to 3 in 1,000 live births. It is bilateral in 30% to 50% of afflicted children, and the ratio of occurrence in males to females is 2.5:1.

Pathophysiology and Etiology

1. Equinovarus type (forefoot adduction, about 95% of cases)—foot is plantar flexed (talipes equinus) and inverted (talipes varus). See Figure 54-6.
2. Calcaneovalgus type (reverse clubfoot, about 5% of cases)—foot is dorsiflexed and everted (talipes valgus).
3. Exact etiology is unknown. Suggested theories point to vascular, viral, genetic, anatomic, and environmental factors; may also result from position in utero.

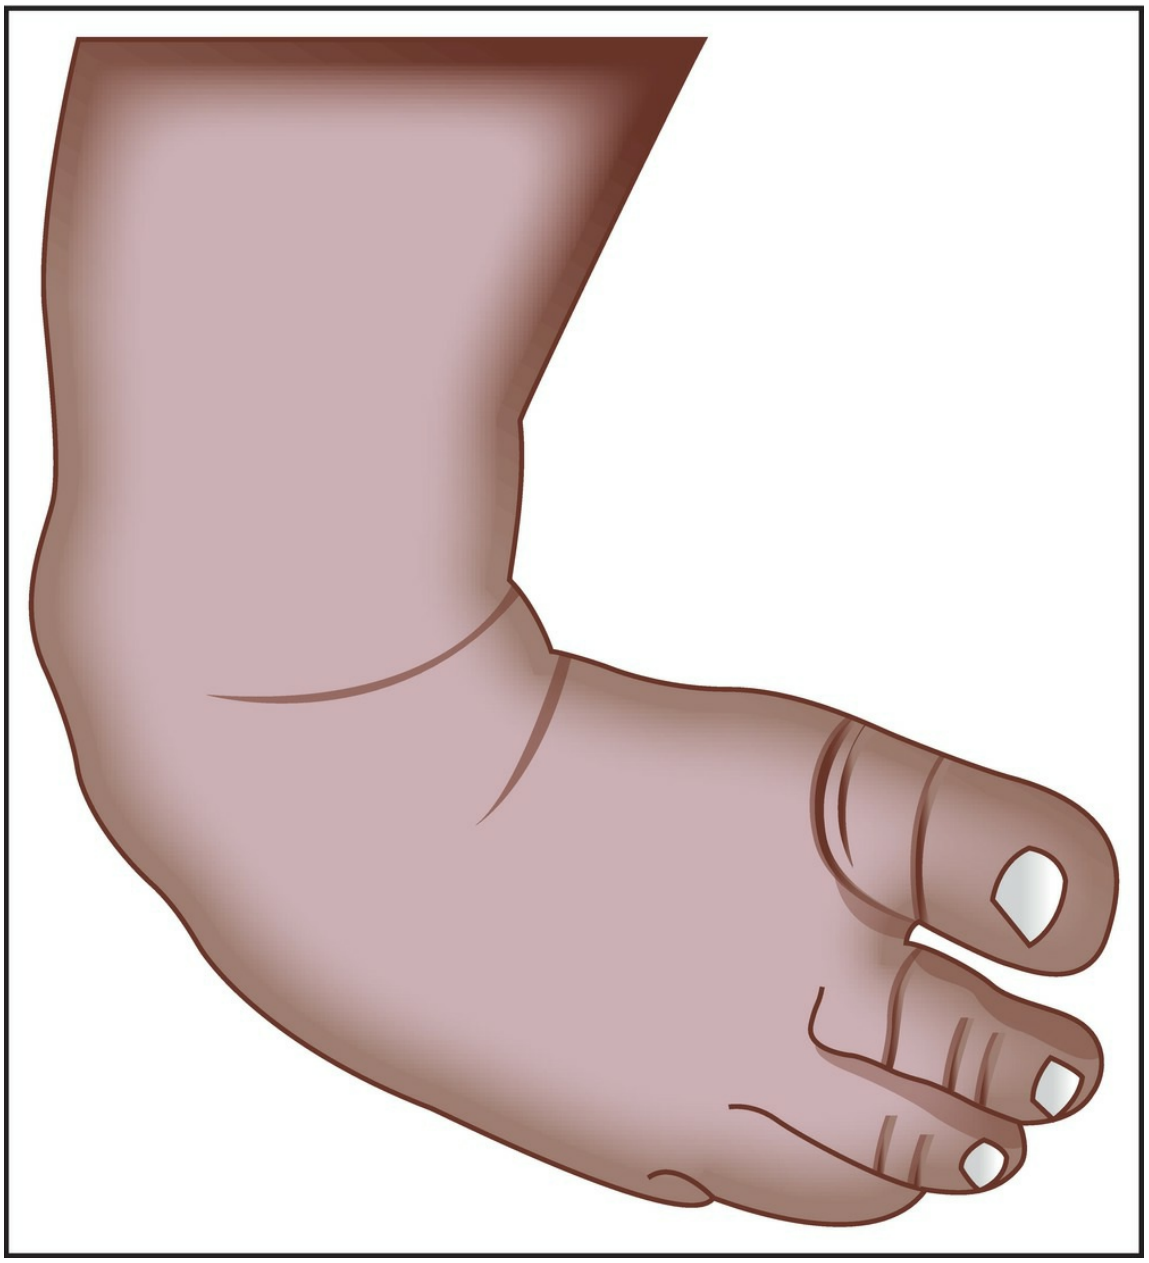

Figure 54-6. Equinovarus-type clubfoot. (Pansky, B. & Gest, T. R. [2011] Lippincott Concise Illustrated Anatomy. Philadelphia: Lippincott Williams & Wilkins.)

Clinical Manifestations

1. Deformity usually is obvious at birth with varying degrees of rigidity and ability to correct position. May range from a mild postural clubfoot to severe neuromuscular clubfoot that coexists with various diagnoses such as arthrogryposis and spina bifida.
2. Deformity becomes fixed if untreated, which can lead to:
   a. Child bearing weight on lateral border of the foot.
   b. Awkward gait.
   c. Development of callosities and bursae over the lateral side of the foot.

Diagnostic Evaluation

1. Clinical presentation and physical examination.
2. X-rays determine bony anatomy and assess treatment efficiency.

Management

EVIDENCE BASE Batti, S. E., Solla, F., Clement, J., et al. (2016). Initial treatment of congenital, idiopathic clubfoot: Prognostic factors. *Orthopaedics and Traumatology, Surgery and Research, 102*(8), 1081–1085.

Management should begin as soon after birth as possible, with the goal to establish a functional, pain-free foot that can be fit with standard footwear. Despite management, however, the child will always have a small calf and foot on the affected side. Nonoperative management, including manipulation, stretching, and serial casting, is currently the treatment of choice.

1. The Ponseti method is the initial method for treatment and incorporates gentle stretching and manipulation, followed by cast immobilization to promote relaxation and softening of tissues and remodeling of abnormal joint surfaces.
    a. Consists of weekly casting for approximately 6 weeks, followed by an Achilles tenotomy performed under local anesthetic and subsequent wearing of orthotic boots for 23 to 24 hours per day for 3 to 4 months.
    b. Treatment is completed with daytime ankle–foot orthoses (AFOs) and nighttime boots situated on a bar for 2 years.
2. Other nonoperative treatment includes cast changes and foot manipulation, which is usually done on a weekly basis for 6 weeks.
    a. After 6 weeks of weekly manipulation and casting, the foot is then manipulated and casted every 2 weeks.
    b. After the initial period (approximately 3 months of casting), an evaluation is performed to determine whether to continue with manipulation and casting, perform a percutaneous tenotomy, or proceed to use corrective shoes—with or without a Denis-Browne bar or the more recent Wheaton brace or Bebax shoe.
3. Surgical treatment may be required for some children to achieve correction of the deformity; usually performed within the second 6 months of life so that the child is free from postoperative immobilization before beginning walking.
4. Surgical treatment may also be required following nonoperative treatment, consisting of medial plantar release, posterior release, lateral release, or reduction and fixation—depending on the extent of the deformity.

5. The child who presents late or has a recurrent or residual deformity may require an aggressive surgical procedure to stabilize the bony structures and balance the muscle and tendons by a combination of fusions, releases, lengthening, and transfers.
6. Postoperative routines usually include a period of cast immobilization of up to 12 weeks, followed by a brace (AFO) or corrective shoe for a period of 2 to 4 years.

Complications

1. "Rocker bottom" deformity from excessive dorsiflexion and "breaking through" the midtarsal bones.
2. Disturbances in epiphyseal plates from overaggressive manipulation.
3. Recurrent or residual deformity.

Nursing Assessment

1. Obtain a family history of foot deformities.
2. Obtain an obstetric history for risk factors.
3. Perform a physical assessment for the presence of other anomalies and classic foot position and ROM. If late presentation, perform a thorough neurologic examination to rule out causative factors.
4. Assess family coping and resources available for lengthy treatment.

Nursing Diagnoses

- Risk for Impaired Parenting related to ineffective adaptation to stressors associated with a diagnosis of clubfoot and the intense therapeutic regimen.
- Risk for Impaired Skin Integrity related to serial casting.
- Ineffective Peripheral Tissue Perfusion related to postoperative edema or casting.
- Acute Pain related to tissue and muscle trauma secondary to surgery.

Nursing Interventions

Also see page 868 for orthopedic surgery.

Promoting Effective Parenting

1. Provide an accurate description of deformity and the importance of treatment in terms the parents can understand.
2. Provide opportunity for parents to verbalize questions and concerns.
3. Reinforce causative factors and the fact that it was not anyone's fault that the child has clubfoot.
4. Encourage parents to hold and play with child and participate in care.
5. Provide parents with a contact family that has been through the treatment process for support.

Protecting Skin Integrity

1. Assess fit of cast, splint, orthotic device, or special shoes. Advise parents that because of rapid growth rate of the infant, the cast or splint may need to be replaced to prevent skin breakdown.

2. Assess and teach assessment of excessive pressure on the skin—redness, excoriation, foul odor from underneath cast, or pain.

Preserving Tissue Perfusion

1. Perform frequent neurovascular assessments after tenotomy and surgery, including color, warmth, sensation, capillary refill, pulses, and presence of pain.
2. Elevate the extremity to prevent edema in the postoperative period.
3. Protect and assess foot for injury.

Relieving Pain

1. Assess for signs of discomfort, such as irritability, crying, poor feeding and sleeping, tachycardia, and increased blood pressure.
2. Administer analgesics regularly for 24 to 48 hours after surgery.
3. Provide comfort measures, such as soft music, pacifier, teething ring, and rocking and cuddling with parent.
4. Encourage parents to administer analgesics after discharge from hospital (when needed). Discuss dosage and administration and dispel misconceptions about addiction.

Family Education and Health Maintenance

1. Teach parents to remove cast at home before weekly manipulation and recasting by soaking in water and vinegar mixture.
2. Teach the parents when orthotic devices may be removed—usually for bathing. Stress that devices must be worn as prescribed.
3. Advise parents that infant's sleep may be disturbed initially due to wearing of brace at night and that he or she may be irritable while awake because of fatigue.
4. Instruct parents on providing a safe environment for the ambulatory child.
5. Discuss the importance of long-term and frequent follow-up and assist parents with special needs such as transportation, flexible appointment times, and financing orthotic equipment.
6. Teach parents to check color, warmth, capillary refill, movement of toes, and position of cast (make sure cast does not slip to hide the toes).
7. Encourage parents to comply with treatment regimen to achieve the best possible outcome.

Evaluation: Expected Outcomes

- Parents hold infant, participating in care.
- No signs of skin breakdown.
- Neurovascular status of affected foot intact.
- Rests and feeds well.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes (LCP) disease is a self-limiting condition of the proximal femur characterized by a temporary loss of blood supply, which leads to avascular necrosis of the femoral head. The incidence of LCP is .2 to 20 per 100,000 in the general population. It occurs most commonly in children between ages 4 and 8. Ratio of occurrence in males to females is 5:1, and it is frequently found in Whites and Asians. It is bilateral in 10% to 20% of cases. There is a 30% to 40% familial occurrence

---

EVIDENCE BASE Cook, P. C. (2014). Transient synovitis, septic hip, and Legg-Calve-Perthes disease: An approach to the correct diagnosis. *Pediatric Clinics of North America, 61*(1), 1109–1118.

Fornari, E. D., Karkenny, A., & Schulz, J. (2015). Legg-Calve-Perthes disease. *Pediatric Orthopaedics, 26*(5), 487–493.

Pathophysiology and Etiology

General Information

1. Etiology is unknown and may be due to factors such as secondhand smoke, poverty, hyperactivity, delayed bone age, short stature, mechanical dysfunction, and metabolic disorders.
2. Interruption of the vascular supply to the femoral head leads to the death of the bone. Deformity can occur with loss of the spherical nature of the femoral head during the disease process. The disease progresses through four identifiable stages.

Stage I (Avascularity)

1. Spontaneous interruption of the blood supply to the upper femoral epiphysis.
2. Bone-forming cells in the epiphysis die and the bone ceases to grow.
3. Slight widening of the joint space.
4. Swelling of the soft tissues around the hip.
5. The first stage lasts only a few weeks.

Stage II (Revascularization or Fragmentation)

1. The femoral head is flattened and fragmented. Growth of new vessels supplies the area of necrosis; bone resorption and deposition take place.
2. The new bone lacks strength and pathologic fractures may occur.
3. Abnormal forces on the weakened epiphysis may produce progressive deformity.
4. This stage lasts several months to 1 year.

Stage III (Reossification)

1. The head of the femur gradually reforms.

2. Nucleus of the epiphysis breaks up into a number of fragments with cystlike spaces between them.
3. New bone starts to develop at the medial and lateral edges of the epiphysis, which becomes widened.
4. Dead bone is removed and is replaced with a new bone, which gradually spreads to heal the lesion.
5. This stage lasts 2 to 4 years.

Stage IV (Healing)

1. Without treatment:
   a. Head of the femur flattens and becomes mushroom shaped.
   b. Incongruity between the head of the femur and the acetabulum persists and worsens.
2. With treatment:
   a. Head of the femur remains near spherical.
   b. Acetabulum appears normal.
   c. Width of the neck of the femur is normal.

Clinical Manifestations

1. Child presents with limp or pain in the hip, may be intermittent initially or may last for several months.
2. Referred pain to knee, inner thigh, and groin—usually with activity and often resolved with rest.
3. Limited abduction and internal rotation of the hip.
4. Mild to moderate muscle spasm on rotation of the hip in extension, limited internal rotation flexion, and abduction.
5. Trendelenburg gait—dip on the opposite side of the pelvis when weightbearing on the affected limb.
6. History of related trauma.

Diagnostic Evaluation

1. X-rays (AP and frog leg lateral) allow assessment of the extent of epiphyseal involvement and stage of disease—early findings may be normal.
2. MRI has been useful in detecting infarction but is not accurate in showing the stages of healing.
3. Bone scan is used to help diagnose LCP in the early stage of the disease, where the diagnosis is questionable.
4. Ultrasound may show early joint effusion.
5. Arthrograms may be useful in evaluating sphericity of the femoral head.

Management

EVIDENCE BASE Smith, C. (2014). Increasing awareness of Legg-Calve-Perthes disease. *British Journal of School Nursing, 9*(1), 21–23.

Hailer, Y., Haag, A., & Nilsson, O. (2014). Legg-Calve-Perthes disease: Quality of life, physical activity, and behavior pattern. *Journal of Pediatric Orthopedics, 34*(5), 514–521.

The goal of management is to preserve and restore the femoral head and to relieve pain.

1. Restore motion—initial relief of synovitis, muscle spasm, and pain in the joint:
   a. Salicylates (with caution) and anti-inflammatory medications.
   b. Limitation of activities and bed rest with or without activity modification.
2. Monitor progress of the disease and make sure the hip remains congruent through serial x-rays.
3. Surgical intervention, now rarely done, may vary but generally involves varus osteotomy, innominate osteotomy, osteotomy of the proximal femur or pelvis, or a combination of these, if the femoral head becomes subluxed or incongruent with the acetabulum before the reparative process.
4. Treatment outcome depends on age of the child, extent of necrosis, stage of disease at time of treatment, and congruence of joint with skeletal maturity.

Complications

1. Early degenerative joint disease.
2. Residual deformity.
3. Loss of motion or function of involved hip.
4. Persistent pain and gait disturbance.

Nursing Assessment

1. Obtain a detailed history, including onset of symptoms and characteristics of pain.
2. Perform a physical assessment to include evaluation of gait, ROM, and presence of any contractures.

Nursing Diagnoses

- Acute Pain secondary to disease process.
- Impaired Physical Mobility related to pain on ambulation.

Nursing Interventions

Also see page 868 for orthopedic surgery.

Promoting Comfort

1. Monitor and assess pain level using age-appropriate pain measurement tool.
2. Instruct child and parents as to which activities can be continued and which to avoid (eg, contact sports or high-impact sports).
3. Administer analgesics, as indicated, and monitor effectiveness.

Promoting Mobility

1. Encourage activities to maintain ROM (eg, swimming, bicycle riding).
2. Encourage parents to allow activities that involve unaffected body parts within restriction guidelines.
3. Provide equipment to assist with mobility (eg, wheelchair, walker).

Family Education and Health Maintenance

1. Teach proper care of assistive ambulatory aids and the need to remain compliant with usage.
2. Stress the need to remain active within restrictions and to promote positive body image.
3. Reinforce to child that he or she is only temporarily restricted. Stress remaining positive aspects of activity.
4. Explain the disease process to parents and child, emphasizing the importance of compliance with treatment.
5. Allow child to voice concerns and ask questions about his or her treatment.
6. Encourage attendance at regular follow-up appointments.

Evaluation: Expected Outcomes

- Pain is adequately managed.
- ROM and function maintained.

Structural Scoliosis

Scoliosis is lateral curvature of the spine of greater than 10 degrees. The different types of scoliosis vary by age of onset and structure of the spine.

Pathophysiology and Etiology

1. Idiopathic scoliosis—80% of scoliosis in children; possible causes include genetic factors, vertebral growth abnormality, or central nervous system abnormality. Three classifications (based on age at time of diagnosis) include:
   a. Infantile—birth to age 3, less than 1% of all idiopathic scoliosis.
   b. Juvenile—presentation between ages 3 and 10 or before onset of adolescence.
   c. Adolescent—presentation at adolescence (greater than 10 years):
      i. Partially familial, affects 2% of the population.
      ii. Prevalence for curves greater than 30 degrees is less common—1½ to 3 per 1,000; severe curvatures are rare.
      iii. Progressive curves are more prevalent in females than in males (7:1 females to males for curves greater than 25 degrees). Progression is greatest during adolescent growth spurt, just prior to onset of menses.
2. Congenital scoliosis—congenital malformation of one or more vertebral bodies that results in asymmetric growth.
   a. Type I—failure of vertebral body formation (eg, isolated hemivertebra, wedged vertebra, multiple wedged vertebrae, multiple hemivertebrae).
   b. Type II—failure of segmentation (eg, unilateral unsegmented bar, bilateral block vertebra).
   c. Type III—failure of segmentation along with failure of formation.
      i. More than 50% of patients with congenital scoliosis have another associated anomaly commonly associated with other congenital anomalies in other systems (eg, Klippel-Feil syndrome, genitourinary tract abnormalities, VACTERL syndrome, and others).
3. Neuromuscular scoliosis: can be neuropathic or myopathic, most severe in nonambulatory patients. Occurs in children with cerebral palsy, muscular dystrophy, spinal muscular dystrophy, and others.
4. Miscellaneous factors that can cause scoliosis include osteopathic conditions, fractures, arthritic conditions, spinal irradiation, endocrine disorders, postthoracotomy, and nerve root irritation.
5. In all types of scoliosis, the vertebral column develops lateral curvature.
   a. The vertebrae rotate to the convex side of the curve, which rotates the spinous processes toward the concavity.
   b. Vertebrae become wedge-shaped.
   c. Disk shape is altered, as are the neural canal and posterior arch of the vertebral body.
6. As the deformity progresses, changes in the thoracic cage increase. Respiratory and cardiovascular compromise can occur in cases of severe progression.

a. Changes in the thoracic cage, ribs, and sternum lead to further characteristic deformities such as the "rib hump."

b. Neurologic compromise in idiopathic scoliosis is rare.

Clinical Manifestations

1. Physical characteristics (see Figure 54-7):
   a. Poor posture.
   b. Increased or decreased thoracic kyphosis or lumbar lordosis.
   c. Leg length discrepancy.
   d. Shoulder asymmetry.
   e. Scapular prominence.
   f. Truncal imbalance (relationship of trunk over pelvis).
   g. Lump (rib hump) on back.
   h. Uneven waistline.
   i. Uneven breast size.
2. Back pain may be present but is not a routine finding in idiopathic scoliosis.

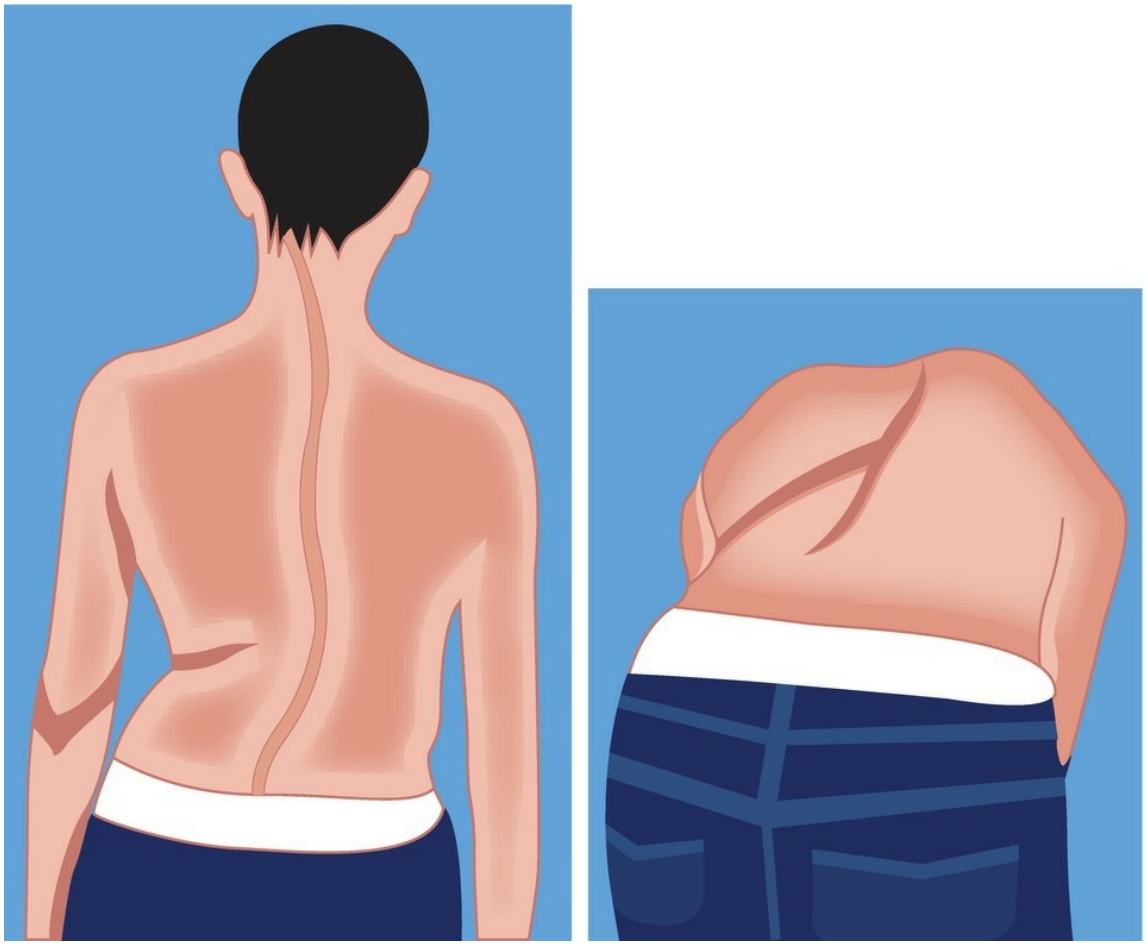

Figure 54-7. Characteristic truncal imbalance and scapular prominence with scoliosis.

Diagnostic Evaluation

EVIDENCE BASE Defelice, F., Fabio, Z., Danzelli, S. and Negrini, S. (2018) The natural history of idiopathic scoliosis during growth: A Meta-analysis. *American Journal of Physical Medicine and Rehabilitation. 97*(5), 346–356.

Yi-Fang, L., & Yu-Chu, H. (2017). Bracing in adolescent idiopathic scoliosis. *Journal of Nursing, 64*(2), 117–123.

1. Thorough history should include onset of menses, recent growth spurt, and family history of scoliosis.
2. Physical examination—the American Academy of Pediatrics recommends screening for girls at ages 10 and 12 years and boys at ages 13 and 14 years. Adams forward bending test is used to screen for scoliosis. A scoliometer can be used to a measure rotational deformity. Risser classification is used to grade skeletal maturity based on the level of bone ossification and fusion of the iliac crest apophyses.
3. Thorough neurologic evaluation:
   a. Evaluate balance, motor strength, sensation, and reflexes (including abdominal).
   b. Skin exam for café au lait spots, axillary freckles, etc. to indicate neurologic problem.
   c. Exam for the presence of a hairy patch or other lesions in the lumbosacral area.
   d. Examination for limb length difference that could cause the appearance of scoliosis.
4. Radiologic assessment of the spine in the upright position, preferably posterior–anterior and lateral views on one long (36-inch [91-cm]) plate—shows characteristic curvature.
5. CT scan may be used to further define anatomy. MRI is indicated for all patients with early-onset scoliosis and is often used prior to surgery to rule out other deformities.
6. Pulmonary function tests for those with compromised respiratory status.
7. Clinical photographs to assist with documenting the appearance of the spine over time.
8. Workup for associated renal abnormalities with a congenital scoliosis because of a high correlation between the two.

EVIDENCE BASE Brooks, J. T., & Sponseller, P. D. (2016). What's new in the management of neuromuscular scoliosis? *Journal of Pediatric Orthopedics, 36*(6), 627–633.

Management

Goal of management is to stop progression of the existing curve by nonoperative means. When this fails, the goal of operative management should be to correct the scoliosis as much as possible and balance and stabilize the spine by fusion to prevent further progression.

Medical Management

1. Observation—periodic (usually every 6 months) physical and radiographic examinations to detect curve progression.
   a. Child is not skeletally mature.
   b. Curves less than 25 degrees.
2. Brace management—the goal is to prevent progression of the curve.
   a. Requires faithful compliance on the part of the child for success; recommended 23 hours per day.
   b. Some curves progress despite brace wear.
   c. Bracing is for skeletally immature children with curves that are about 25 to 40 degrees.
3. Types of braces include:
   a. Boston orthosis for low thoracic and thoracolumbar curves. This is an underarm molded orthosis.
   b. Milwaukee brace for thoracic or double major curves. Standard brace has neck ring with chin rest.
   c. Charleston bending brace has been tried for nighttime usage in selected patients. Results have been positive in some centers, but widespread acceptance has not occurred.
4. Exercise therapy has been promoted to help maintain flexibility in the spine and prevent muscle atrophy during prolonged bracing by strengthening back muscles.

Surgical Correction

EVIDENCE BASE Fletcher, N., Glotzbecker, M., Marks, M., et al. (2017). Development of consensus-based best practice guidelines (BPG) for postoperative care following posterior spinal fusion for adolescent idiopathic scoliosis. *Spine, 42*(9), E547–E554.

Martus, J., Otsuka, N., & Kelly, D. (2016). What's new in pediatric orthopaedics. *Journal of Bone and Joint Surgery American Volume, 98*(7), 317–324.

---

1. Stabilization of the spinal column is the goal. This is usually accomplished with a spinal fusion and one of several methods of instrumentation.
2. Indications for surgical correction vary, but generally accepted principles include:
   a. Progression of the curve over a short period in a curve greater than 45 degrees despite bracing.
   b. Management with a brace is not possible.
   c. Cosmetic.
3. Surgical approach and techniques may be anterior or posterior with various instrumentation methods.
4. Strategies have evolved from body cast fixation to nonsegmental rods, such as the Harrington; to segmental wire fixation, such as the Luque, Drummond instrumentation, or segmental hook fixation, and Cotrel-Dubousset instrumentation; to current techniques, such as segmental screw fixation.
5. Segmental fixation systems provide a three-dimensional correction of coronal, sagittal, and rotational

deformities.

a. Posterior fusion is the standard approach, which allows correction and instrumentation of the majority of curves and levels.

b. Stainless or titanium rods with segmental hooks (see Figure 54-8) and pedicle screw fixation are currently the instrumentation systems of choice.

c. A reduction in the number of vertebrae requiring fusion may be achieved with anterior fusion.

d. Combined anterior and posterior fusion may be used to correct severe curves.

e. Perioperative halo-gravity traction may be used in rare cases when risk of neurologic compromise from rapid correction exists.

f. Vertical, expandable prosthetic titanium ribs may be used to lengthen and expand a constricted hemithorax and allow for growth of thoracic spine and rib cage in thoracic insufficiency. Once the child's lungs have fully developed, a spinal instrumentation and fusion can be performed.

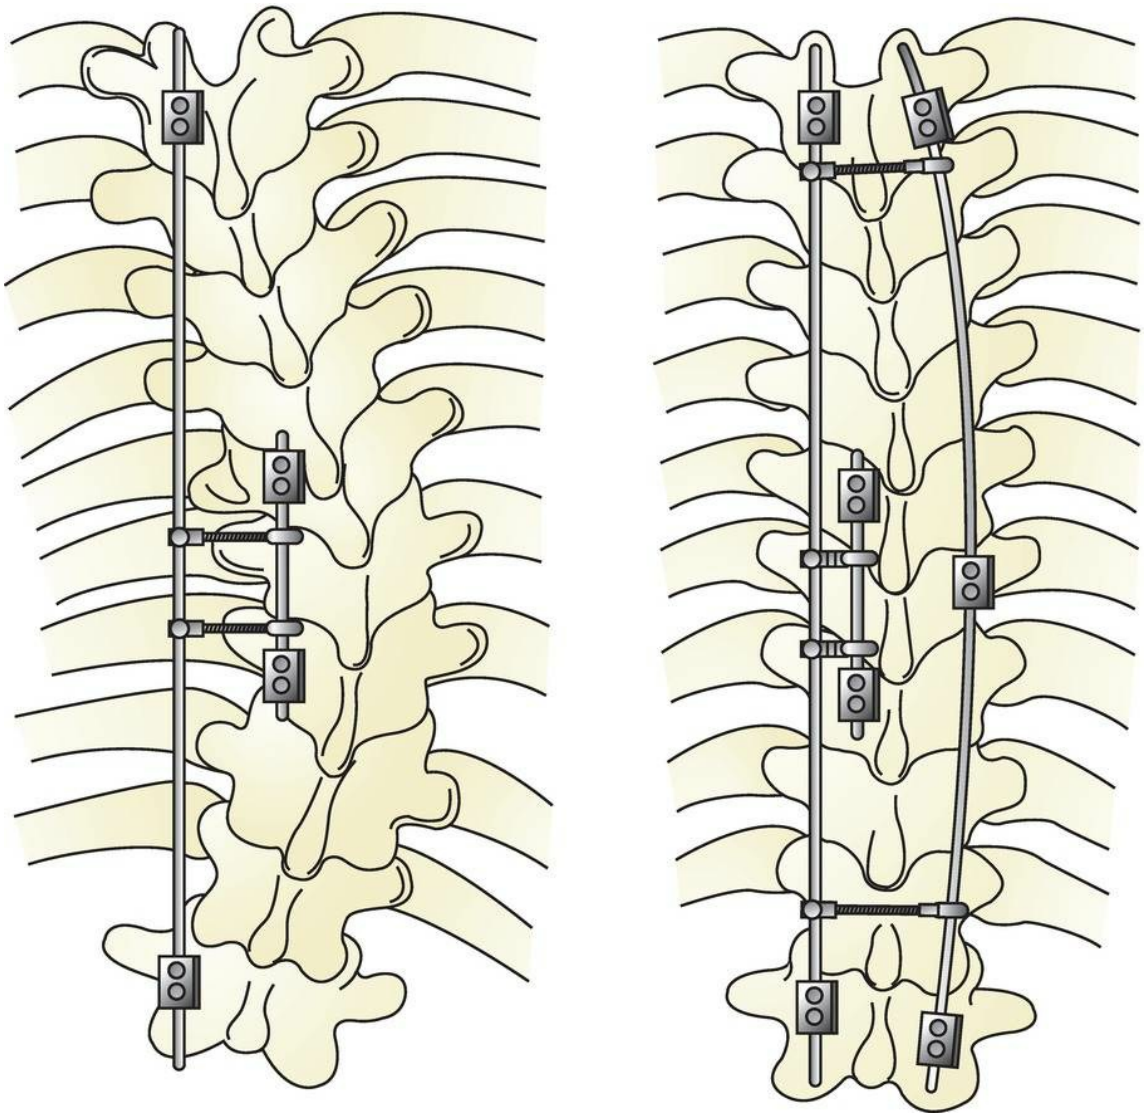

Figure 54-8. Cotrel-Dubousset rods to correct scoliosis. A short distraction rod is linked to a longer one to correct the major curve.

Nursing Assessment

1. Assess respiratory, cardiovascular, and neurologic systems.
2. Perform a physical examination in the upright and forward bending positions and observe physical characteristics, such as leg lengths, gait, hips, shoulders, and overall development.

Nursing Diagnoses

- Disturbed Body Image related to negative feelings about spinal deformity and appearance in brace.
- Risk for Impaired Skin Integrity related to mechanical irritation of brace.
- Risk for Injury related to postoperative complications.
- Ineffective Therapeutic Regimen (Family) related to chronicity and complexity of treatment regimen.

Nursing Interventions

Also see page 868 for orthopedic surgery.

Promoting Positive Body Image

1. Encourage child to express feelings and concerns about body image.
2. Encourage child to express concerns about wearing a brace and offer comfortable options for wearing it and disclosing condition with classmates.
3. Encourage child to discuss scoliosis with peers, or provide a peer support person to discuss positive outcomes and expected future care.

Preserving Skin Integrity

1. Assess skin integrity and proper fit of brace at every follow-up appointment.
2. Teach proper skin care to patient and family.
3. Instruct patient to wear cotton shirt under brace to avoid rubbing.

Preventing Postoperative Complications

1. Prepare patient for surgery by teaching deep breathing and coughing exercises and explaining positioning, patient-controlled analgesia, or another method of pain control.
2. Following surgery, encourage frequent logrolling side to side to prevent skin breakdown and respiratory complications. Medicate for pain prior to repositioning and ambulation.
3. Perform frequent neurovascular assessments and monitor vital signs frequently. Encourage early ambulation (1–2 days if stable).
4. Monitor drainage or bleeding from incision site.
5. Maintain indwelling urinary catheter as indicated. Monitor intake and output, but remove as soon as possible to prevent urinary infection.
6. Engage physical therapy assistance for patient mobility to be out of bed, sit in chair, and begin ambulation.
7. Active bowel sounds should be present before diet is advanced. Patients should have bowel regimen

ordered and adjusted based on stool frequency and consistency. Lack of mobility and opioid use may contribute to constipation.

Promoting Compliance with Treatment

1. Explain scoliosis and the treatment options to the child in a language she or he can understand.
2. Explain the importance of complying with treatment and possible outcomes with noncompliance.
3. Encourage the child and family to discuss concerns and questions they may have about scoliosis and the prescribed treatment.
4. Assist with social service referral for financial, transportation, and other needs.

Family Education and Health Maintenance

1. Provide adequate information on condition and treatment.
2. Instruct parents to examine brace daily for fit or breakage. Also instruct them to contact orthotist when repairs or adjustments are needed.
3. Teach family to inspect skin for irritation under brace.
4. Ensure that child can be transported safely in vehicles with potential modification in safety restraints.
5. Suggest to family to discuss child's treatment with teachers and school officials, so child can receive tutoring or homeschooling to keep up with grade requirements if out for surgery.

Evaluation: Expected Outcomes

- Child makes positive comments about self.
- Skin without signs of breakdown.
- Neurovascular status intact; no bleeding noted; bowel sounds present; pain is adequately managed.
- Wears brace as prescribed, following up as directed.

Slipped Capital Femoral Epiphysis

EVIDENCE BASE Thawrani, D. P., Feldman, D. S., & Sala, D. A. (2016). Current Practice in the Management of Slipped Capital Femoral Epiphyis. *Journal of Pediatric Orthopedics, 36*(3), e27–e37.

Hosseinzadeh, P., Iwinski, H. J., Salava, J., et al. (2017). Delay in the diagnosis of stable slipped capital femoral epiphysis. *Pediatric Orthopaedics, 37*(1), e19–e22.

Slipped capital femoral epiphysis (SCFE) is the most common hip disorder in adolescents, which occurs in puberty just before the physis (growth plate) closes. It is characterized by a slipping of the epiphysis and metaphysis because of weakening of the perichondral ring of the physis. The epiphysis slips downward and backward. Incidence is 10 per 100,000 and it is three times more common in males than in females. Approximately 20% of patients present with bilateral slips at time of presentation, and 20% to 30% will develop a contralateral slip within 12 to 18 months of initial slip.

Pathophysiology and Etiology

1. Skeletally immature and obese adolescents are at greatest risk.
2. Left hip is most frequently affected.
3. Exact etiology is unknown; possible risk factors include:
   a. Sedentary lifestyle.
   b. Rapid growth spurt.
   c. Overweight and obesity.
   d. African American ethnicity.
4. Femoral neck slips off the proximal femoral epiphysis and is contained within the acetabulum.
5. Classified by duration of symptoms:
   a. Acute—sudden onset, symptoms for less than 3 weeks.
   b. Chronic—symptoms lasting more than 3 weeks.
6. Approximately 85% of children have stable slips.
7. Because of vague symptoms, diagnosis is often delayed, which can result in complications.

Clinical Manifestations

1. Pain in the groin, medial thigh, or knee (referred pain).
2. Decreased ROM in affected hip.
3. Sudden onset of pain (acute SCFE).
4. Inability to bear weight (acute SCFE).
5. Limp when walking (usually found in chronic cases).

6. Intermittent pain.
7. Trendelenburg gait.
8. External rotation of the lower limb; involved limb may be shortened.

Diagnostic Evaluation

1. X-rays confirm diagnosis—AP and frog leg lateral views.
2. Bone scan—rules out the presence of avascular necrosis.
3. MRI or CT scan—helps to define extent of slip, used primarily in severe slips.

Management

1. Goal is to prevent progressive slippage and minimize deformity while avoiding necrosis of cartilage (chondrolysis) and avascular necrosis.
2. Treatment is surgical—in situ pinning with one or two screws is usually done within 24 to 48 hours.

Complications

1. Chondrolysis over the femoral head resulting in permanent loss of ROM.
2. Avascular necrosis of the femoral head.
3. Osteoarthritis.

Nursing Assessment

1. Obtain a detailed history, including onset of symptoms and characteristics of pain.
2. Perform a physical assessment and include evaluation of gait and ROM in the hips.

Nursing Diagnoses

- Acute and Chronic Pain related to disease process.
- Impaired Physical Mobility related to disease process.
- Deficient Diversional Activity related to activity restriction.

Nursing Interventions

Also see page 868 for orthopedic surgery.

Promoting Comfort

1. Monitor and assess pain level using age-appropriate pain measurement tools.
2. Instruct child and parents as to which activities can be continued and which to avoid (eg, contact sports, high-impact activities).
3. Administer analgesics, as indicated, and monitor effectiveness.

Promoting Mobility

1. Facilitate bed rest or other activity restrictions, as directed.

2. Provide equipment to assist with mobility (eg, wheelchair, crutches).

Promoting Diversional Activities

1. Be alert to the needs of adolescents to socialize with peers. Encourage visitation and communication with friends and family.
2. Encourage family to provide books, magazines, games, and electronics for the adolescent to use.
3. Provide support for the family and reinforce the importance of following activity restrictions to prevent permanent damage to the femur.

Family Education and Health Maintenance

1. Teach proper use of mobility devices (eg, crutches).
2. Stress the need to maintain activity within restrictions and to promote positive body image.
3. Encourage follow-up during active treatment and following surgery. About 25% of children later develop the same condition in the opposite hip, so careful attention must be paid to both legs at follow-up.

Evaluation: Expected Outcomes

- Child reports feeling little or no pain.
- Child follows activity restriction.
- Child maintains socialization with friends and partakes of hobbies in the room.

TRANSITIONAL CARE ALERT Many children discharged from the hospital diagnosed with orthopedic conditions will have extensive discharge needs. Families will need support in the transition to home or another aftercare location. It is crucial that they have complete and understandable care instructions on home care, equipment, medications, and follow-up appointments. If arrangements have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to assist understanding, pictorial) instructions on signs and symptoms to monitor for that could suggest worsening of status. Families may also need extensive instructions on necessary equipment to ensure safe mobility including ambulation for the child. Health providers should ensure that the child has safe and appropriate means for transport from the hospital to the home. The bulk of casts and other orthopedic equipment may necessitate changes for car safety as the child may no longer fit in the prior car restraint system. Instructions should include clear understanding of acceptable discharge expectations as many children may be in different phases if a continued surgical repair is necessary. Parents should be aware of when and where they should seek further emergency care if the child's condition deteriorates.

Other Dermatologic Disorders

BURNS

Management of Burns in Children

Burns are common childhood injuries. They may be caused by heat, electrical energy, or chemicals. Long-term surgical and psychological sequela often follows a serious burn injury and may include reconstruction and issues related to posttraumatic stress disorder. Serious burns may include:

1. Partial-thickness (second-degree) burns of 12% to 15% or more of body surface area.
2. Full-thickness burns.
3. Burns of the face, hands, feet, perineum, or joint surfaces.
4. Electrical burns.
5. Burns in the presence of other injuries.
6. Any burn that cannot be cared for adequately at home.

Epidemiology

1. Burns are the fourth leading cause of accidental death in children 17 years old and younger, with the highest incidence of burns occurring in children younger than age 5.
2. Children at high risk are of lower socioeconomic status and of single parents. However, any child, supervised or unsupervised, is at risk for a burn injury.
3. Scalds are the leading cause of injury in children, followed by flame burns.
4. Burns from a hot liquid are most common in children younger than age 5.
    a. Tap water temperature above 120°F (48.9°C) (at 130°F [54.4°C]) takes only 30 seconds to produce a full-thickness injury in adult skin—less time in the very young; at 155°F (68.3°C), tap water will cause a full-thickness injury in a child in 1 second.
    b. Child left unsupervised in tub turns on hot water tap.
    c. Child placed in tub of hot water that has not been tested.
    d. Spilling of hot liquid, such as coffee or tea, on child. Spilling occurs especially when pot handles stick out on top of stove, when hot liquids and foods are removed from microwave oven, and when child grabs or pulls items from surfaces.
    e. Ingestion and aspiration of hot foods and liquids from microwave oven as well as scald burns to skin and palate from hot formula.
5. Burns from open flames:
    a. House fires.
    b. Child climbing on stove, resulting in ignited clothing.
    c. Children playing with lighters, especially 3- to 10-year- olds.
    d. Playing or working with gasoline.
    e. Automobile accidents with subsequent fire.
    f. Juvenile fire-setters.
6. Electrical burns in children are not as common but most often caused by:

a. Child playing with electrical outlets or appliances.
b. Child playing with extension cords; children commonly bite through the cord.
c. Child playing on railroad tracks; climbing trees and touching high-tension wires; struck by lightening.

7. Other causes:
   a. Caustic acid or alkali burns, often of the mouth and esophagus.
   b. Chemical burns of the skin—child playing with gasoline or chemical cleaning agents.
   c. Burns inflicted on the child as a result of neglect or abuse (immersion and contact burns are most common).
   d. Smoke inhalation and inhalation from products of combustion of synthetics, such as plastics and rayon, may yield cyanide and formaldehyde.
   e. Radiation burns—sunburn most common, may be secondary to cancer radiation therapy.
   f. Contact burns from touching hot surfaces, such as radiators, woodburning stoves, fireplaces, or open ovens.
   g. Fireworks burns, typically as a result of misuse and lack of adult supervision; may be combined with explosive hand injuries.
   h. Friction burns such as those seen with exercise treadmills in the home.

NURSING ALERT With combined injury, management of trauma takes precedence over the burn.

Pathophysiology and Etiology

See "Burns in Adults," page 919.

Clinical Manifestations

Characteristics of Burn Wounds

1. See page 924 for characteristics of superficial, partial-thickness, and full-thickness burns.
2. Electrical burns:
   a. Especially of the mouth in a child younger than age 2 years; may chew or suck on live wire.
   b. Are progressive and may take up to 3 weeks to fully manifest the extent of injury.

Symptoms of Shock

Symptoms of hypovolemic shock are dependent upon the size and thickness of the burn. Hypovolemic shock may develop in large surface size burns within the first 1 to 2 hours of the injury.

1. Rapid pulse and low blood pressure.
2. Subnormal temperature.

3. Pallor, cyanosis, and prostration.
4. Failure to recognize parents or other familiar people.
5. Poor muscle tone and flaccid extremities.

Upper Respiratory Tract Injury

Causes inflammation or edema of the glottis, vocal cords, and upper trachea and is characterized by symptoms of upper airway obstruction and immediate attention to securing and maintaining the airway takes precedence over the burn injury. Signs of inhalation are:

1. Dyspnea, tachypnea, and hoarseness.
2. Stridor, substernal and intercostal retractions, and nasal flaring.
3. Restlessness, drooling, cough, and increasing hoarseness.
4. Carbonaceous sputum.
5. Facial burns and/or edematous lips.
6. Black nasal or oral secretions.
7. Hypoxemia.
8. History of burn within a closed space.

NURSING ALERT Increasing hoarseness, drooling, and stridor are leading indicators for immediate intubation.

Smoke Inhalation

Smoke inhalation may cause no initial symptoms other than mild bronchial obstruction during the initial phase after the burn. Within 6 to 48 hours, the child may develop sudden onset of the following conditions:

1. Bronchiolitis.
2. Pulmonary edema (acute respiratory distress syndrome)— of noncardiac origin.
3. Severe airway obstruction. Larger surface area burns and extensive facial burns increase the risk of airway edema.
4. Delayed damage: up to 7 days after the burn injury.

Suspicious Burns in Children

Mechanism of injury is an important assessment when a burn injury involves a child. If the mechanism of injury seems out of proportion to the injuries of the child, notification to law enforcement is mandated by all nursing practice acts. Be alert for the following characteristics that may require further investigation by law enforcement:

1. Burns that are bilateral and symmetrical and have clearly demarcated lines without splash patterns.
2. History and physical findings inconsistent with the burn injury.

3. Burn injuries incompatible with child's developmental level.
4. Burn to the buttocks, perineum, or genitals.
5. Burns involving immersion into hot water. Typical findings reveal the back of the knees will be spared of burn injury, with entire feet and lower legs burned.
6. Multiple and new and old burns in different stages of healing.
7. Burns that are circular in nature, likely because of cigarette burns.
8. Presence of other nonburn injuries such as bruises, scrapes, or previous fractures.

Diagnostic Evaluation

Calculation of the Burn Area

1. Rule of nines (used in assessment of the extent of burns in adults) has not been proven to be exact when applied to young children; it may be acceptable to use in child older than age 10 years. It is not recommended for hospital use; the Lund and Browder chart is recommended. Total body surface area (TBSA) is based on age, thus compensating for changes in body surface area that change during growth (see Figure 55-1).
   a. During infancy and early childhood, the relative surface area of different parts of the body varies with age.
   b. The younger the child, the greater is the proportion of the surface area constituted by the head and the lesser is the proportion of the surface area constituted by the legs.
2. A rough estimate can be obtained by using the child's hand (palm, with fingers extended), which is equal to 1%.

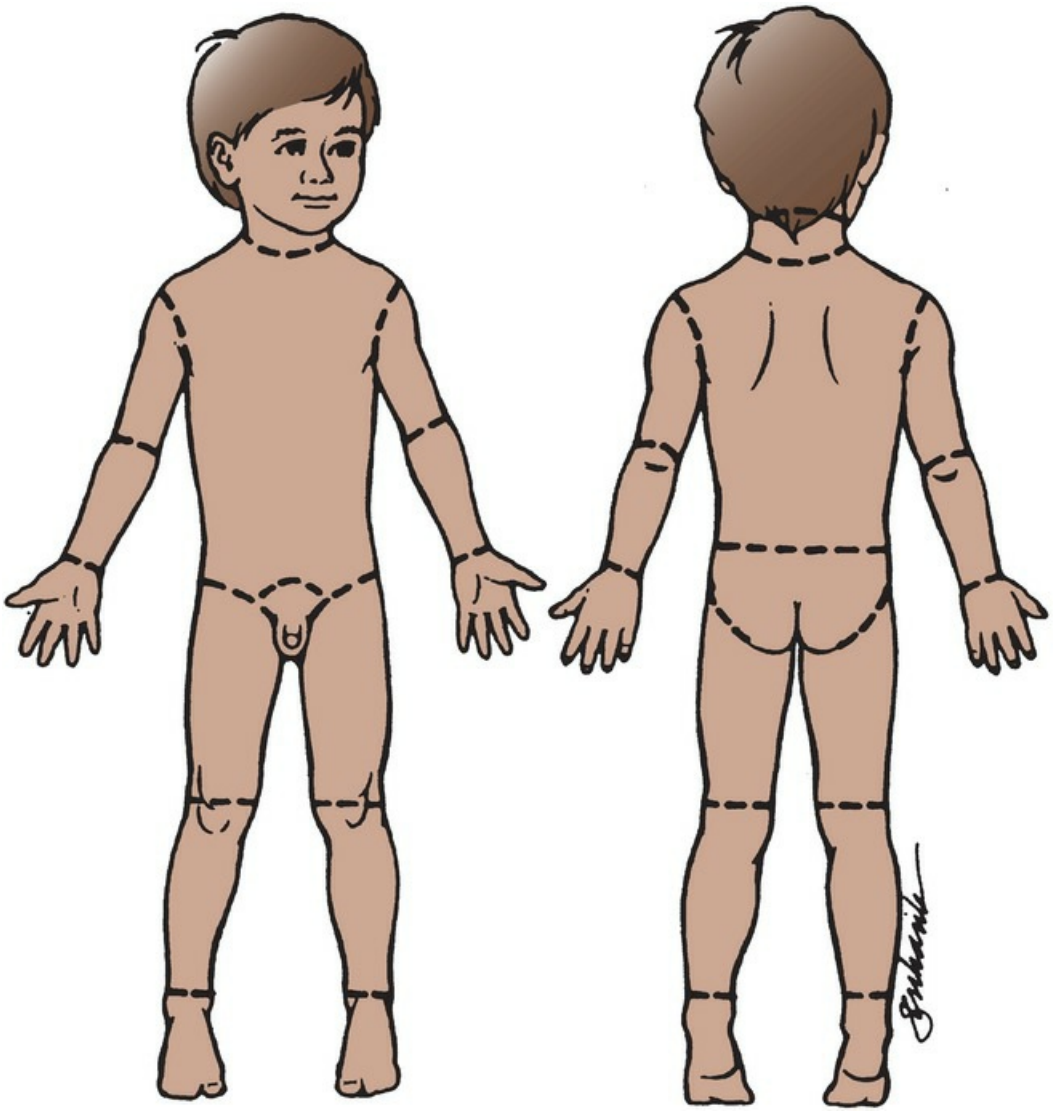

Figure 55-1. The Lund and Browder chart is used to determine the extent of burns in children because it is based on age, thus compensating for changes based on growth.

Categorization of Severity of Burn

1. Total area injured, depth of injury, and location of injury.
2. Age of child.
3. Condition of patient (ie, level of consciousness). Confusion is the hallmark of an anoxic brain.
4. Medical history (ie, comorbidities, chronic disease).
5. Additional injuries.

Schematic Classification of Burn Severity

1. Minor burn—10% TBSA or less; first- and second-degree burn.
2. Moderate burn:
   a. 10% to 20% TBSA; second-degree burn.
   b. 2% to 5% TBSA; third-degree burn not involving the eyes, ears, face, genitals, hands, or feet or

circumferential burns.

3. Major burn:
   a. 20% TBSA or greater; second-degree burn.
   b. All third-degree burns greater than 10%; depending on the age of child, 5% is sometimes used.
   c. All burns involving the hands, face, eyes, ears, feet, or genitals.
   d. All electrical burns.
   e. Complicated burn injuries involving fracture or other major trauma.
   f. All poor-risk patients (ie, head injury, cancer, lung disease, diabetes).

Management

Fluid Resuscitation: Intravenous (IV) Fluid Replacement

Note: Controversy exists regarding fluid resuscitation solution and amount. Not all pediatric patients require fluid resuscitation. Children with burns 15% TBSA or less may be treated with oral rehydration therapies and supplemental maintenance IV fluids.

1. Fluid loss from transcapillary leakage is greatest during the first 12 hours after injury. Fluid loss after 48 hours is due to vaporization of water from the wound.
2. Replacement usually consists of lactated Ringer solution, an isotonic electrolyte solution. Lactated Ringer solution has a much lower sodium content than 0.9% saline (130 mEq/L vs. 154 mEq/L), has a much higher pH (6.5 vs. 6.0), and has 28 mmol/L of lactate, which is used as a buffering agent.
3. The consensus formula is commonly used to determine the fluid needed for resuscitation for burns greater than 15% TBSA (see page 925). Children up to 30 kg should receive a maintenance containing formula with dextrose to prevent hypoglycemia (5% dextrose or D5LR).
   a. One half of the requirements are given during the first 8 hours.
   b. The remainder is given over the next 16 hours.

Burn Treatment

1. Burns are most commonly treated by the closed method. Using the closed method is preferred as it allows children to be more mobile when a burn injury is covered and because they experience less pain.
2. Hydrotherapy is the treatment of choice for cleaning wounds. The use of a handheld shower to facilitate the loosening and removal of sloughing tissue, eschar, exudate, and topical medications is gaining popularity. The shower—water about 90˚F (32.2˚C)—flows over the child; debridement is then performed.
3. Children should be encouraged to participate with washing off cream whenever possible. A gentle soap or shampoo can be used to wash the burned and nonburned parts of the body and hair. Tub or shower treatments are usually done daily unless a longer-acting dressing is in place between hydrotherapy sessions.
4. Use pharmaceutical and psychological interventions, unique to each child and appropriate for their developmental stage and comfort needs, to ensure appropriate pain and anxiety management.

5. See page 925 for wound cleaning and debridement, hydrotherapy, topical antimicrobials, surgical management, and burn wound grafting. It is important to use bacitracin ophthalmic ointment on a child's face because touching or rubbing the face may get ointment into the eyes. Topical bacitracin will cause conjunctivitis if it gets into the eyes.

Complications

Vary according to severity of burn injury; commonly occur, especially with severe burn injury.

Acute

1. Infection, burn wound sepsis, pneumonia, urinary tract infection (UTI), and phlebitis, and toxic shock syndrome.
2. Curling (stress) ulcer and GI hemorrhage; rarely seen now that histamine-2 (H_2) blockers are commonly used prophylactically, especially in burns greater than 20% TBSA.
3. Acute gastric dilation, paralytic ileus; occurs especially in child younger than age 2 with greater than 20% injury and develops early in postburn period, lasting 2 to 3 days.
4. Renal failure.
5. Respiratory failure; severe inhalation injury is the insult most likely to cause death.
6. Hypertension.
7. Central nervous system dysfunction.
8. Vascular ischemia.
9. Anxiety and complex pain (acute to chronic presentations).
10. Anemia and malnutrition; may resolve when the burn area is covered.
11. Constipation and fecal impaction.
12. Labile moods secondary to hospitalization, repeated procedures, and changing body image.

Long Term

1. Growth and development delays secondary to malnutrition, hospitalization, and complexities of injury and recovery.
2. Developmental regression.
3. Scarring, disfigurement, and contractures.
4. Impact of psychological trauma.

Nursing Assessment

1. Initially, perform emergency assessment of the burn patient to determine priorities of care.
    a. Airway, breathing, and circulation: airway may be compromised with inhalation injury.
    b. Extent of burn injury.
    c. Additional injuries. (Although establishing a patent airway always comes first, trauma takes precedence over the burn.)

2. Obtain a history of the injury—for example, when the injury occurred; what first aid was given; location of the child; if smoke was present, was child in a closed space; who was supervising the child; what the specific mechanism of injury was; what other factors need to be considered in terms of the context of the injury; and consider if additional injuries may exist.
3. Obtain a complete medical history, including childhood diseases, immunizations (especially tetanus status), current medications, allergies, recent infections, and general health and developmental status.
4. Assess level of pain and emotional status; provide pain relief and reassurance while performing assessment and determining priorities.
5. Subsequently, focus assessment on fluid volume balance, condition of the burn wounds, and signs of infection (burn wound, pulmonary, urinary).
6. Remain vigilant for signs of sepsis. Although not completely supported by all expert clinicians, the American Burn Association 2007 consensus guidelines are the most recent available and provide definitions for sepsis and common infections in burn patients. Additional markers such as procalcitonin, C-reactive protein, and erythrocyte sedimentation rate can be used. Sepsis occurs in children when at least three of the following occur:
   a. Temperature above 102.2°F (39°C) or below 97.7°F (36.5°C).
   b. Progressive tachycardia more than 2 standard deviations (SD) above age-specific norms.
   c. Progressive tachypnea more than 2 SD above age-specific norms.
   d. Thrombocytopenia (not applicable until 3 days after initial resuscitation) less than 2 SD below age-specific norms.
   e. Hyperglycemia (in the absence of pre-existing diabetes mellitus).
      i. Untreated plasma glucose greater than 200 mg/dL.
      ii. Insulin resistance.
   f. Inability to continue enteral feedings for more than 24 hours.
      i. Abdominal distention.
      ii. Enteral feeding intolerance.
      iii. Uncontrollable diarrhea.
7. In addition, it is required that infection be documented by positive culture, pathologic tissue source identified, or clinical response to antimicrobials observed.

EVIDENCE BASE Vyles, D., Sinha, M., Rosenberg, D. I., et al. (2014). Predictors of serious bacterial infections in pediatric burn patients with fever. *Journal of Burn Care and Research*, *35*(4), 291–295.

Nursing Diagnoses

- Decreased Cardiac Output related to fluid shifts and hypovolemic shock.

- Risk for Infection related to altered skin integrity, decreased circulation, and immobility.
- Impaired Gas Exchange related to inhalation injury, pain, and immobility.
- Imbalanced Nutrition: Less Than Body Requirements related to hypermetabolic response to burn injury.
- Dysfunctional Gastrointestinal Motility related to paralytic ileus and stress.
- Ineffective Peripheral Tissue Perfusion related to edema and circumferential burns.
- Risk for Imbalanced Fluid Volume related to fluid resuscitation and subsequent mobilization 3 to 5 days postburn.
- Impaired Skin Integrity related to burn injury and surgical interventions (donor sites).
- Impaired Urinary Elimination related to indwelling catheter.
- Ineffective Thermoregulation related to loss of skin microcirculatory regulation and hypothalamic response.
- Impaired Physical Mobility related to edema, pain, dressings, and splints.
- Acute Pain related to burn wound and associated treatments.
- Disturbed Body Image related to cosmetic and functional sequelae of burn wound.
- Fear and Anxiety related to pain, treatments, procedures, and hospitalization.
- Impaired Parenting related to crisis situation, prolonged hospitalization, and disfigurement.
- Disturbed Sleep Pattern related to unfamiliar surroundings and pain.

Nursing Interventions

Supporting Cardiac Output

1. Be alert to the symptoms of shock that occur shortly after a severe burn—tachycardia, hypothermia, hypotension, pallor, prostration, shallow respirations, and anuria.
2. Monitor the administration of IV fluids because major burns are followed by a reduction in blood volume because of outflow of plasma into the tissues.
3. Maintain and record intake and output to provide an accurate measure of volume.
   a. Record time and amount of all fluids given.
   b. Measure urine output every hour and report diminished output, as ordered (0.5 mL/kg/hour is considered minimally acceptable urine output; however, 1 mL/kg/hour is preferable).
   c. Check urine specific gravity to determine concentration or dilution.
4. With severe burn injuries, insert an indwelling catheter.
5. Weigh patient daily to help evaluate fluid balance.
6. Monitor sensorium, pulse, pulse pressure, capillary refill, and blood gas values.
7. Provide a rich oxygen environment to combat hypoxia, as necessary.
8. Monitor electrolyte and hematocrit results as a guide to fluid replacement.
9. Maintain a warm, humidified ambient environment (especially with burns of 20% TBSA) to maintain body temperature and decrease fluid needs.

Preventing Infection

1. Wash hands with antibacterial cleansing agent before and after all patient contact and use appropriate precautions.
   a. Use barrier garments—isolation gown or plastic apron—for all care requiring contact with the patient or the patient's bed.
   b. Cover hair and wear mask when wounds are exposed or when performing a sterile procedure.
   c. Use sterile examination gloves for all dressing changes and all care involving patient contact.
2. Be alert for reservoirs of infection and sources of cross-contamination in equipment and assignment of personnel.
3. Observe burn wounds with each dressing change: assess drainage for color, odor, and amount; necrosis; increase in pain; and surrounding erythema, warmth, swelling, and tenderness, which may indicate infection.
4. Administer topical antimicrobials and systemic antibiotics, as ordered.
5. Provide meticulous skin care to prevent infection and promote healing.
6. Be alert for early signs of septicemia, including changes in mentation, tachypnea, and decreased peristalsis as well as later signs, such as increased pulse, decreased blood pressure (BP), increased or decreased urine output, facial flushing, increased and later decreased temperatures, increasing hyperglycemia, and malaise. Report to health care provider promptly.
7. Obtain urine, sputum, and blood cultures for two or more consecutive temperatures of 103°F (39.4°C) or a single temperature of 104°F (40°C).
8. Promote optimal personal hygiene for the patient, including daily cleansing of unburned areas, meticulous care of teeth and mouth, shampooing of hair every other day, and meticulous care of IV and urinary catheter sites.
9. Prevent the child from scratching by administering antipruritics and applying protective devices to his or her hands.
10. Be alert for the development of pneumonia or UTI related to immobility and invasive procedures. Encourage coughing, turning, deep breathing, ambulation, and early discontinuation of indwelling catheter to minimize complications.
11. Ensure that appropriate nutrition and enteral feeding are in place within 6 to 8 hours of injury to prevent translocation of bacteria in the gut.
12. Administer tetanus prophylaxis based on immunization history.
    a. If primary series is complete (or at least three doses of tetanus toxoid are obtained) and last injection was within past 5 years, it is not necessary.
    b. If at least three doses are obtained and last injection was more than 5 years, give tetanus toxoid.
    c. If two or fewer doses are obtained, give tetanus immunoglobulin and tetanus toxoid.

NURSING ALERT Even with meticulous skin care, the burn wound is fully colonized in 3 to 5 days. A warm, moist environment becomes an excellent medium for bacterial growth, especially of *Pseudomonas*.

Optimizing Gas Exchange

1. Be alert for and report symptoms of respiratory distress—dyspnea, stridor, tachypnea, restlessness, cyanosis, coughing, increasing hoarseness, and drooling.
2. Younger children, those with larger burn injuries, and those with extensive facial burns are at higher risk of airway compromise from edema.
3. Administer supplemental humidified oxygen.
4. Monitor arterial blood gas (ABG) levels as necessary.
5. Evaluate the carboxyhemoglobin on ABG results (because of inhalation of carbon monoxide, a product of combustion) and be prepared to support ventilation if signs of hypoxemia and respiratory failure develop.
6. Assist with pulmonary function and bronchoscopy, as indicated.
7. Have intubation supplies readily available. If unable to intubate the child, then tracheostomy may be necessary. If unable to extubate in 14 to 21 days, then may be converted to tracheostomy for continuous pulmonary management. The current trend is to use the earlier time frame.
8. Prevent atelectasis and pneumonia through chest physical therapy, postural drainage, meticulous pulmonary technique, and, if indicated, tracheostomy care.

Ensuring Adequate Nutrition for Healing and Growth Needs

1. Be aware that hypernutrition is important because of the extreme hypermetabolism related to large burn injuries.
   a. Twice the predicted basal metabolic rate in calories, based on ideal weight, may be necessary. Caloric recommendation is 1,800 kcal/m^2 total body surface for maintenance, plus 2,000 kcal/m^2 of burned surface area.
   b. Hypermetabolic state generally subsides when the majority of the wounds are grafted or healed.
   c. High caloric intake to support hypermetabolic state; protein synthesis; calories should come from carbohydrates.
   d. High-protein intake to replace protein lost by exudation; support synthesis of immunoglobulins and structural protein; prevent negative nitrogen balance.
   e. Vitamin and mineral supplement needed, particularly vitamins B and C, iron, and zinc.
2. Maintain ambient temperature at 82.4°F to 90°F (28°C to 32.2°C) to minimize metabolic expenditure by maintaining core temperature.
3. Minimize anorexia to increase caloric intake.

a. Offer small amounts of food, perhaps four to five feedings rather than three per day.
b. Give choice of foods; determine favorites.
c. Provide high-calorie, high-protein oral or nasogastric (NG) supplementation, as necessary.
d. Consider long-term use of G-tube or NJ tube for supplemental nutrition.
e. Make meals a pleasant time, unassociated with treatments or unpleasant interruptions. Maintain oral intake as much as possible.

4. Monitor dietary compliance with dietary goals and adjust, as needed.
5. Administer total parenteral nutrition, if necessary.
6. Administer serum albumin or fresh frozen plasma to combat hypoalbuminemia when burn area exceeds 20% TBSA.
7. Monitor nutritional status through weight gain, wound healing, serum transferrin, and serum albumin.

Relieving Gastric Dilation and Preventing Stress Ulcer

1. Be alert for the development of gastric distention, especially with burns greater than 20% TBSA, associated injury, or tachypnea.
2. Maintain nothing-by-mouth status if distention or decreased bowel sounds develop.

- Insert NG tube, as indicated, to prevent vomiting, aspiration, and paralytic ileus.

3. Monitor the return of bowel sounds after NG extubation and before reinstituting oral feeding.
4. Administer H_2 blockers such as cimetidine to prevent Curling ulcer development.

Promoting Peripheral Perfusion

1. Remove all jewelry and clothing.
2. Elevate extremities.
3. Monitor peripheral pulses hourly. Use Doppler, as necessary.
4. Prepare the patient for escharotomy if circulation is impaired.
5. Avoid tight constrictive dressings.
6. Observe for and report signs of thrombophlebitis or catheter-induced infections.

Facilitating Fluid Balance

1. Titrate fluid intake as tolerated. The initial resuscitation formula is only a guide.
2. Maintain accurate intake and output records.
3. Weigh the patient daily.
4. Monitor results of serum potassium and other electrolytes.
5. Be alert to signs of fluid overload, especially during initial fluid resuscitation and immediately afterward, when fluid mobilization is occurring.
6. Administer diuretics, as ordered.

Protecting and Reestablishing Skin Integrity

1. Cleanse wounds and change dressings once or twice daily. The size of the burn and the stage of wound healing can be considered when determining the frequency of dressing changes. Use an antimicrobial solution or mild soap and water. Dry gently. This may be done in the hydrotherapy tank, in the bathtub, in the shower, or at the bedside.
2. Perform debridement of dead tissue at this time. May use gauze, scissors, or forceps, as appropriate. Try to limit time to 20 to 30 minutes depending on the patient's tolerance. Additional analgesia may be necessary. Consider having an appropriate time interval to premedicate before debridement for best pain management.
3. Apply topical bacteriostatic agents, as directed. Cream or ointment is applied ⅛-inch (3-mm) thick.
4. Dress wounds, as appropriate, using conventional burn pads, gauze rolls, or any combination. Dressings may be held in place, as necessary, with gauze rolls or netting.
5. For grafted areas, use extreme caution in removing dressings; observe for and report serous or sanguineous blebs or purulent drainage. Redress grafted areas according to facility protocol.
6. Observe all wounds daily and document wound status on the patient's record.
7. Promote healing of donor sites by:
    a. Preventing contamination of donor sites that are clean wounds.
    b. Opening to air for drying postoperatively if gauze or impregnated gauze dressing is used. If exudate occurs after the first 24 hours, swab the area for culture and apply an antimicrobial topical cream. If the culture is positive, treatment will be in accord with sensitivities.
    c. Following health care provider's or manufacturer's instructions for care of sites dressed with synthetic materials.
    d. Allowing dressing to peel off spontaneously.
    e. Cleansing healing donor site with mild soap and water when dressings are removed; lubricating site twice daily and as needed.
8. Inspect unburned skin carefully for signs of pressure and breakdown.

Preventing Urinary Infection

1. Maintain closed urinary drainage system and ensure patency. Use a catheter impregnated with an antimicrobial agent whenever possible.
2. Frequently observe color, clarity, and amount of urine.
3. Empty drainage bag per facility protocol.
4. Provide catheter care per facility protocol.
5. Encourage removal of catheter and use of urinal, bedpan, or commode as soon as frequent urine output determinations are not required.

Promoting Stable Body Temperature

1. Be efficient in care; do not expose wounds unnecessarily.

2. Maintain warm ambient temperatures.
3. Use radiant warmers, warming blankets, or adjustment of the bed temperature to keep the patient warm.
4. Obtain urine, sputum, and blood cultures for temperatures above 102°F (38.9°C) rectal or core temperature or if chills are present.
5. Provide a dry top layer for wet dressings to reduce evaporative heat loss.
6. Warm wound cleansing and dressing solutions to body temperature.
7. Use blankets in transporting patient to other areas of the hospital.
8. Administer antipyretics, as prescribed.

Preserving Mobility

1. Make sure that physical and occupational therapy are begun early to facilitate rehabilitation.
2. Child Life Professionals can also assist in making therapy and routines child-friendly, thereby increasing the child's participation and ultimately preserving and improving mobility.
3. Encourage range-of-motion exercises, ambulation, and position changes to minimize joint and skin complications.
4. Position joint in opposite direction of expected contracture. Reassess positioning regularly; reconfigure patient room or positioning of bed or television to encourage different positions if patient is bedridden.
5. Apply splints to aid joint positioning and decrease skin contractures and hypertrophy.
6. Apply pressure garments to aid circulation, protect newly healed skin, and prevent and treat hypertrophic scar formation by promoting dermal collagen fiber growth in parallel direction. Encourage the use of pressure garments for as long as 12 to 18 months after injury, until the healed skin has matured.
7. Medicate for pain before therapy or exercise to minimize discomfort.
8. Use play opportunities to help the child accept the therapy program (eg, tricycle riding may be used as a form of exercise).

Controlling Pain

EVIDENCE BASE Baartmans, M., de Jong, A., van Baar, M., et al. (2016). Early Management in children with burns: Cooling, wound care and pain management. *Burns, 42*(4), 777–782.

---

1. Assess for signs of pain, such as irritability, crying, increased BP, tachycardia, decreased mobility, and inability to sleep using reliable and valid assessment measures.
2. Use principles of the WHO analgesic ladder using combinations of analgesic where one type is ineffective alone until pain relief is achieved.
   a. Step 1: Nonopioids.
   b. Step 2: Mild opioids.
   c. Step 3: Strong opioids.

3. Acetaminophen has been shown to safely manage background pain in pediatric burns and is considered the first step in managing such pain.
4. Regular nonsteroidal anti-inflammatory drugs should also be prescribed unless contraindicated.
5. Opioid analgesia is the gold standard for burn pain and should be dosed for each individual with concurrent laxative treatment provided. Strong (morphine) versus mild (codeine) opioids should be considered for severe pain.
6. In severe burns, analgesia should be given via IV line because of lack of absorption of IM injections during the emergency phase. Emphasis is on maintaining an alert, reasonably comfortable child. Monitor child closely when using IV opioids and sedatives.
7. Other adjunctive medications, such as antiemetics and sedatives, should be considered to increase comfort and decrease distress.
8. The use of benzodiazepines for continuous infusions in the severely burned child should be approached with caution. Although more research is needed in the pediatric population, there is significant evidence that the development of delirium in mechanically ventilated adult patients is associated with benzodiazepine administration. Use a therapeutic surface to relieve pressure and provide comfort.
9. Maintain warmth and prevent chilling.
10. Provide diversional activities appropriate for age to distract from focus on pain.
11. Teach simple relaxation techniques, such as relaxation breathing and guided imagery.
12. Recognize that fear may exacerbate discomfort; assess anxiety and child temperament. Provide reassurance and empathy. Develop a plan to minimize anxiety and fear. Collaborate with other health care professionals, such as a Child Life therapist.
13. Ensure an adequate sleep routine and establish good sleep hygiene as possible to minimize sleep disturbances.

Addressing Body Image Disturbance

1. Encourage the child to talk about the way he or she feels and looks; let the child set the pace for discussions.
    a. The child may feel guilty and think that the burn is a punishment for some wrong deed.
    b. Small children may be fearful of the appearance of bandages, scars, or pressure garments; offer reassurance.
    c. Encourage the use of play with dolls or puppets, role-playing, or picture drawing to help the child express feelings and fears.
2. Treat the child with warmth and affection and encourage parents to continually express their love and provide physical and emotional comfort.
3. Support child in viewing self in a mirror when ready and encourage the presence of family members.
4. Encourage early contact with other children. Maintain connections with siblings, friends, and community where possible.
5. Suggest psychiatric consultation and work with psychosocial resources for anticipatory guidance and

ongoing adjustment and adaptation to burn injury. Specific requests may be related to heightened anxiety, alterations in mood, or problems manifesting as:

a. Refusal to eat.
b. Developmental regression.
c. Resistance to procedures.
d. Aggressive behaviors, excessive sadness, or withdrawal.
e. Increasing isolation or resisting socialization.

6. Advise parents that returning to home and community routines and separation from the hospital environment, caregivers, and other patients can produce excessive anxiety or disruption in the child's coping. Consider a plan to develop a graduated discharge process with time-limited home passes (overnight, weekend), as well as plan for aftercare to support the transition home.
7. If the child is school age, help prepare for school re-entry; contact teacher or discuss with parents the need to prepare peers for what to expect.
8. Discuss and plan for issues of social re-entry, such as responding to questions and stares from strangers and perceived rejection by friends.
   a. Ensure enrollment in an aftercare (follow-up) program, ideally one that is targeted at both child and family adjustment.
   b. Refer to a support group or peer mentor where possible.
   c. Refer to a burn camp—usually this may be the first opportunity for the child to wear a swimsuit after the injury.
9. Initiate family consultation with a plastic surgeon about future scar revision.
10. Encourage the older child to engage in long-term follow-up to address issues of concern as they arise at various developmental stages. Some children and teens may wish to experiment with clothing and consult with a burn cosmetic specialist to enhance appearance and body image.

Reducing Fear and Anxiety

1. Explain procedures, surgeries, and treatments to the child according to age and level of understanding.
2. Allow the child to express fears through puppets, dolls, water play, clay, and drawings.
3. Expect regression because of the physical pain and psychological trauma the child is experiencing.
4. Encourage parents to stay with a young child as much as possible.
5. Teach parents how to engage their child to foster development of coping skills.
6. Encourage involvement with treatment plan and self-care activities.

Promoting Effective Parenting

1. Be alert to signs of depression or stress syndromes in parents and encourage counseling for them to promote a healthier family.
2. Encourage parents to assess the effects on siblings at home; they may have needs that are unrecognized or neglected as a result of this crisis.

3. Attempt to have parents become actively involved in the child's care when they are ready to do so.
    a. Provide training for parents to effectively participate in treatments and respect their wishes not to participate if the situation is too distressful—the focus for parents is on their ability to comfort their child.
    b. Advise parents that their visits and involvement can have a positive effect on the child's survival and recovery.
    c. If the parents are unable to visit, telephone calls and family photographs are helpful. New technologies like videoconferencing can also be helpful to maintain connections with family and community supports.
4. Give the parents the opportunity to discuss their feelings.
    a. Parents commonly express guilt regarding their lack of supervision when the accident occurred.
    b. Typically, burn injury is associated with actual or perceived parental neglect. Remember that this type of injury is sudden and acute, placing the family in a state of crisis.
5. Keep the parents informed of the child's progress.
    a. Begin initial teaching at admission with supportive words and limited technical information.
    b. Education and orientation to the facility and the burn injury will decrease some anxiety and begin to build rapport on which future support can be based.
    c. Encourage meetings with other parents who have coped with trauma.
    d. Refer families for aftercare programs intended to support adjustment over time.

Sleep Pattern Disturbance

1. Allow a parent to stay with the patient.
2. Provide a structured environment. Perform dressing changes, therapy, and meals at the same time daily.
3. Combine interventions so that child can get longest possible intervals of uninterrupted sleep.
4. Minimize noise and lights within the room.
5. Ensure adequate pain relief and comfort measures at bedtime or naptime.

Community and Home Care Considerations

1. Make routine home visits to perform, teach, and supervise burn wound care and rehabilitation program.
2. Inspect the wounds for signs of infection at every visit.
3. Assess coping ability of child and family to care for child and provide psychological support and counseling referrals, as needed.
4. Make sure that parents can:
    a. Discuss and demonstrate treatments, procedures, and dressing changes.
    b. Obtain equipment necessary to perform treatment at home.
    c. Understand reason for and adverse effects of medications as well as dietary requirements.
    d. Follow up at appropriate intervals with the designated health care provider.

5. Encourage the use of smoke alarms on every floor in the home, a fire extinguisher, and an emergency fire escape plan. Assist parents to review strategies for childhood safety.

Family Education and Health Maintenance

1. Teach the family that special skin care is necessary after burn injury.
   a. Avoid exposure to sunlight; use sunscreen with sun protection factor (SPF) 30 or higher and apply frequently.
   b. Use pressure garments to prevent hypertrophic scar formation—worn 23 of 24 hours each day for effectiveness for 1 to 2 years depending on the maturation of the scar.
   c. Use lotions and creams to prevent skin from drying, cracking, and itching; topical or oral antihistamines or antipruritics may be necessary to reduce itching.
   d. Burn area has decreased sensation to touch, heat, and pressure; take precautions to prevent injury to the area.
2. Advise the family that adjustment after burn is usually prolonged and painful. Adjustment can ebb and flow with developmental stages. Encourage ongoing family and individual psychological and social support.
3. Encourage continued physical therapy to prevent and minimize contractures and preserve function.
4. Monitor outcomes over time in keeping with the Health Outcomes Burn Questionnaire for infants and children 5 years of age and younger; burn size and visible scarring are not predictive of psychological adaptation.
5. Initiate home health, psychiatric referral, physical and occupational therapy, financial assistance, and other referrals, as necessary.
6. Teach parents and children the prevention of burn injury as well as other safety measures (see page 1127).
7. Teach first aid emergency care for burn injury (ie, cool burned area with cool water, remove clothing, seek medical assistance).
8. Teach children how to stop, drop, and roll if their clothes catch fire and how to crawl to safety if a fire occurs in the house.

Evaluation: Expected Outcomes

- Absence of shock: stabilization of vital signs and normal serum and electrolyte values.
- Absence of infection: normal laboratory values, clean wound, and normal temperature.
- No respiratory distress: stable vital signs, respiratory status, and ABG levels.
- Adequate nutritional status: weight gain and wound healing.
- No GI complications: normal bowel sounds and ability to tolerate oral feeding.
- Tissue perfusion.
- No signs of fluid overload and weight stable.
- Donor site and burn wounds healing without signs of infection.

- Urine output adequate via catheter.
- Temperature remains below 102°F (38.9°C).
- Improved mobility: involved in play and other activities.
- Minimal discomfort: stable vital signs, verbalization, and involved in play.
- Positive body image: verbalization, socialization, and ability to look in the mirror.
- Relief of fear: able to play and participates in care.
- Effective parenting: involved in child's care, accurate discussion of child's progress, and treatment plan.
- Sleeping between treatments through the night and napping for 1-hour intervals during the day.

DERMATOLOGIC DISORDERS

Atopic Dermatitis (Infantile and Childhood Eczema)

Atopic dermatitis, the most common cause of eczema in childhood, is a highly pruritic chronic inflammatory skin disorder affecting 15% to 25% of the pediatric population. Peak prevalence is age 6 months to 8 to 10 years. Ninety-five percent of children with atopic dermatitis have asthma or allergic rhinitis. It is an abnormal immune response to environmental allergens in a genetically susceptible individual. These individuals tend to have dry skin and a lower threshold for itching. Itching leads to scratching, which causes lichenification or skin thickening, creating increased sensitivity to renewed itching. Many children with atopic dermatitis have a personal or family history of disorders in the atopic triad (allergic rhinitis, asthma, and atopic dermatitis). During the past three decades, the incidence of atopic dermatitis has increased, especially in industrialized nations. Possible causes include urban migration, increased antibiotic use, and decreased incidence of early childhood infections.

Atopic dermatitis has a typical age-related morphology and distribution and a chronic or chronically relapsing nature. By age 5, 90% of patients who will develop atopic dermatitis have already manifested the disease. The appearance and location of the lesions change with age in a characteristic manner. Atopic dermatitis usually improves or resolves by adolescence but can persist in some form throughout adulthood.

Pathophysiology and Etiology

1. Although it has both immunologic and genetic components, the etiology of atopic dermatitis is unknown. Approximately 80% of children with atopic dermatitis have elevated immunoglobulin (Ig) E levels and increased rates of sensitization to common allergens. Histamine release from basophils is increased, and hyperreactive cutaneous T cells, which secrete proinflammatory cytokines, cause increased Th2 and decreased Th1 cytokine responses. There is also a hereditary component. When both parents have a history of atopic dermatitis, there is an 80% chance a child will be affected. When only one parent is affected, the prevalence drops to 50%. A number of genes have been tentatively linked to atopic dermatitis.
2. Atopic dermatitis causes breakdown of the stratum corneum, which allows allergens and bacteria to penetrate deeper layers, causing inflammation and possible infection.
3. Atopic dermatitis is known as the “itch that rashes.” The skin is dry and becomes pruritic when exposed to common environmental allergens, such as wool; occlusive synthetic fabrics, soaps, and detergents; perspiration; extremes of temperature and humidity; and emotional stress.
4. Food allergies contribute to atopic dermatitis in up to 30% of infants and very young children with moderate to severe disease. Eggs, milk, peanut, soy, wheat, tree nuts, fish, and shellfish account for more than 90% of the reactions. The most common offender is eggs.
5. One third to one half of children with atopic dermatitis are allergic to house dust mites, animal dander, weeds, and molds.
6. Children with atopic dermatitis are at increased risk for developing allergic rhinitis or asthma, known as the “atopic march” or “atopic triad.”

Clinical Manifestations

Age and Distribution of Lesions

Atopic dermatitis is divided into three phases based on the age of the patient and the distribution of the lesions. These are referred to as the infant, childhood, and adult phases.

1. Infant (ages 2 months to 3 years):
    a. The onset is between ages 2 and 6 months. One half of affected infants have spontaneous resolution by age 2 or 3.
    b. Characterized by intense itching, erythema, papules, vesicles, oozing, and crusting (see Figure 55-2).
    c. The rash usually begins on the cheeks, forehead, or scalp and then extends to the trunk or extremities in scattered, commonly symmetric patches. The perioral, paranasal, and diaper areas are usually spared (see Figure 55-3).
2. Childhood (ages 4 to 10 years):
    a. Affected people in this age group are less likely to have exudative and crusted lesions. Eruptions are characteristically more dry and papular and commonly occur as circumscribed scaly patches. There is a greater tendency toward chronicity and lichenification.
    b. The typical areas of involvement are the face, including the perioral and paranasal areas, neck, antecubital and popliteal fossae, wrists, and ankles. May have severe pruritus.
3. Adult (puberty to old age):
    a. Predominant areas of involvement include the flexor folds, face, neck, upper arms, back, dorsa of the hands and feet, fingers, and toes.
    b. The eruption appears as thick, dry lesions, confluent papules, and large lichenified plaques. Weeping, crusting, and exudation can occur, but they are usually the result of superimposed external irritation or infection.

Figure 55-2. Characteristic rash of infant atopic dermatitis of the head (A) and of the limbs (B).

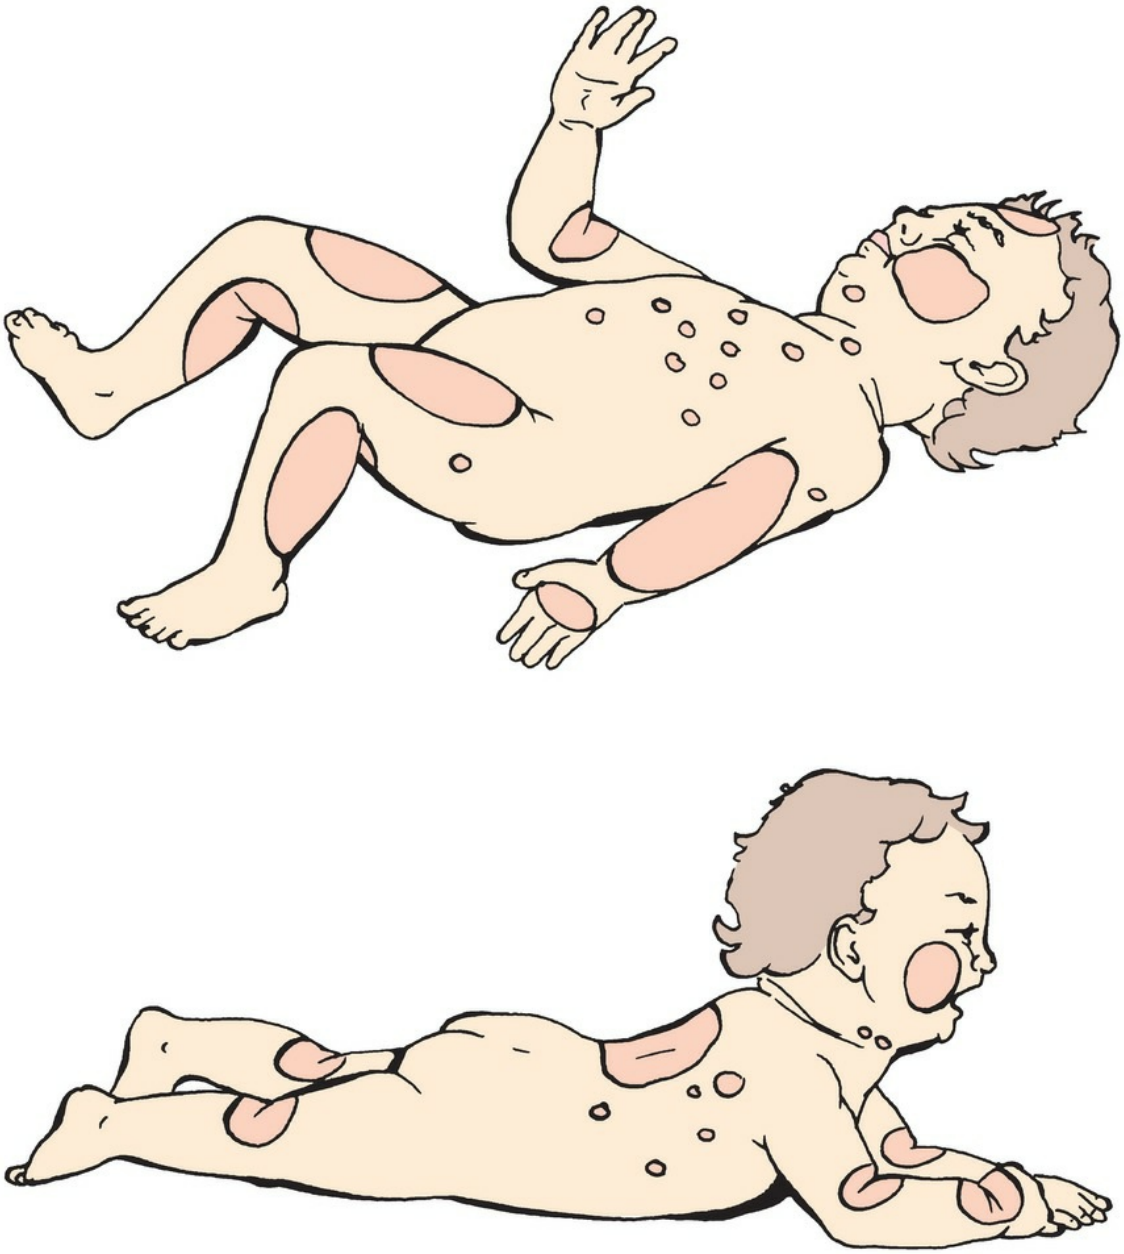

Figure 55-3. Distribution of infant atopic dermatitis occurs primarily on the face but may develop on symmetrical areas of the body. Diaper areas are usually clear.

Clinical Appearance

Atopic dermatitis is also divided into three stages based on the clinical appearance of the lesions. The acute, subacute, and chronic stages can occur in infants, children, and adults.

1. Acute (see Figure 55-4A)—moderate to intense erythema, vesicles, a wet surface, and severe itching.
2. Subacute:
    a. Erythema and scaling are present in various patterns with indistinct borders. The redness may be faint or intense. The surface is dry. There are varying degrees of pruritus.
    b. The subacute stage may be an initial stage or may follow an acute inflammation or exacerbation of a

chronic stage. Irritation, allergy, or infection can convert a subacute process into an acute one.

3. Chronic (see Figure 55-4B)—the inflamed area thickens and the surface skin markings become more prominent. Thick plaques with deep parallel skin markings are called *lichenified*. Lichenification is the hallmark of chronic eczema. The surface of the skin is dry and the border of the lesion well defined. There is moderate to intense itching. There may be postinflammatory hypopigmentation.

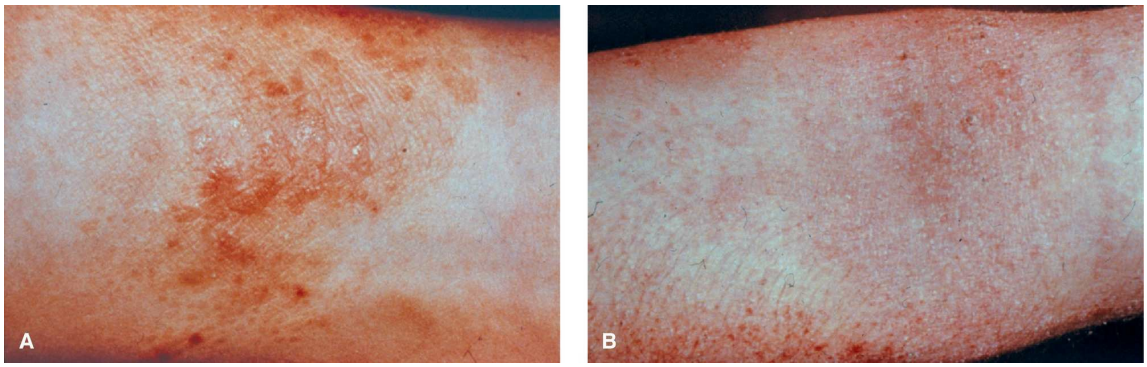

Figure 55-4. (A) Acute atopic dermatitis. **(B)** Chronic atopic dermatitis.

Diagnostic Evaluation

1. There is no single clinical, laboratory, or histologic marker that will definitively diagnose atopic dermatitis. It is a clinical diagnosis based on the evaluation of the aggregate of signs, symptoms, stigmata, course, and associated familial findings. The presence of pruritus, recurring symptoms, and age-specific morphology and distribution is the most important diagnostic feature. Several sets of clinical diagnostic criteria have been established. See Box 55-1.
2. Although not diagnostic for atopic dermatitis, prick skin testing, patch testing, and radioallergosorbent test may be helpful in the identification of food and aeroallergen triggers in infants and young children with moderate to severe disease. Negative skin prick sensitivity tests eliminate the possibility of IgE-mediated food allergy. Positive tests, which predict 30% to 50% of food allergies, may be useful. To avoid unnecessary dietary restrictions, positive tests should be confirmed by controlled food challenges, elimination diets, or atopy patches.

BOX 55-1 Clinical Criteria for Atopic Dermatitis

MAJOR FEATURES: THREE OR MORE

- Pruritus.
- Eczematous changes.
- Typical and age-specific morphology and location.
- Face, neck, and extensor surfaces in infants/children.
- Flexural lesions in older children/adults.
- Chronicity or chronically relapsing.
- Personal or family history of atopy (allergic rhinitis, asthma, atopic dermatitis).

MINOR FEATURES: THREE OR MORE

- Early age of onset.
- Elevated serum immunoglobulin E.
- Itching with sweating.
- Intolerance to wool and lipid solvents.
- Immediate (type 1) skin test reactivity.
- Tendency toward skin infections.
- Facial pallor or erythema.
- Food intolerance.
- Xerosis (very dry skin).
- Ichthyosis/palmar hyperlinearity/keratosis pilaris.
- Hand or foot dermatitis.
- Pityriasis alba (white patches on the face).
- Conjunctivitis.
- Severity of symptoms influenced by environmental or emotional factors.

Treatment

EVIDENCE BASE Conceicao, V. (2016). The nursing management of infantile eczema. *Journal of Community Nursing*, *30*(5), 12–14.

Daily skin care is the cornerstone of prevention and treatment, including proper cleansing, moisturizing, and avoidance of triggers.

Acute

1. Open, wet dressings, such as Burow solution, for 1 to 3 days.
2. Avoidance of known allergen or trigger. Atopic dermatitis patients have decreased threshold to irritants.
3. Management of secondary infection.
4. Topical corticosteroids:
   a. Topical corticosteroids are the mainstay of drug therapy. These agents are ranked into seven groups according to potency. Group 1 contains the most potent topical steroids and group 7 the least potent agents. The concentration listed on the medication does not correlate with its potency or safety but is merely a statement of its specific chemical formulation. Adverse effects are related to the potency rating of the compound, the duration of use, and the thickness of the skin to which it is applied.
   b. Group 1 topical corticosteroids are avoided in children younger than age 12 because of greater skin absorption.

5. Oral medications to relieve itching—hydroxyzine, diphenhydramine, or promethazine—often are sedating. Mild sedation may be desirable to allow sleep.

DRUG ALERT Topical corticosteroids of adequate strength should be used two times per day for a specific length of time, such as 7 to 21 days, to achieve control and avoid adverse effects. Long-term use of topical corticosteroids can cause striae, cutaneous atrophy, telangiectasia, acne, growth retardation, adrenal suppression, Cushing syndrome, and cataracts.

Subacute and Chronic

1. Prevention of dry skin:
   a. Reduce the frequency and duration of bathing.
   b. Use mild soap or hydrophilic cleanser.
   c. Lubricate the skin with emollients. Apply within 3 minutes after exiting bath. Apply over, not under, topical corticosteroids. Newer barrier repair moisturizers contain the skin lipid ceramides and help rebuild/repair skin. (Some over-the-counter products are CeraVe, Cetaphil Restoderm, and Eucerin Professional Repair.)
   d. Maintain environmental humidity above 40% during winter months.
   e. Tar preparations may be added to bath water; however, they are rarely used because of odor and staining.
2. Avoidance of known allergens or triggers.
3. Management of secondary infection.
4. Topical corticosteroids as described above. Apply the least potent topical corticosteroid that provides adequate control. Topical corticosteroids may be applied under occlusion, which is under plastic wrap to increase absorption, for short-term therapy.
5. Topical immunomodulators, also called *calcineurin inhibitors*, are approved for the short-term and intermittent long-term treatment of subacute and chronic atopic dermatitis for patients age 2 and older when conventional therapies are inadvisable, ineffective, or not tolerated.
   a. Tacrolimus 0.03% ointment and pimecrolimus 1% cream.
   b. These agents do not cause skin atrophy (which corticosteroids may cause) and can be used on the face and neck. However, their long-term safety is unknown.
   c. Active viral, bacterial, or fungal skin infections must be cleared before use.
   d. Topical immunomodulators should be discontinued if lymphadenopathy of unknown etiology develops.
6. Phosphodiesterase-4 (PDE4) inhibitor is the newest class of topical medications approved for treatment of mild to moderate atopic dermatitis in patients aging 2 years and older.
   a. Crisaborole 2% ointment.

b. Considered relatively safe as the only known adverse effect is application site burning or stinging that resolves after the first 1 to 2 days of use.

c. No contraindications (except hypersensitivity reaction) to long-term use.

DRUG ALERT The U.S. Food and Drug Administration issued a black box warning for *calcineurin inhibitors* stating long-term safety has not been established. Although causal relationship has not been proven, rare cases of malignancy (skin and lymphoma) have been reported. Drugs should be used for short-term, second-line therapy for patients over 2 years of age.

Complications

1. Increased risk of secondary infection by bacterial, viral, or fungal agents. Bacterial infections are typically caused by *Staphylococcus aureus*. Rate of infection with methicillin-resistant *S. aureus* is increasing. Infections secondary to papillomaviruses (warts), *Molluscum contagiosum*, herpes simplex, tinea, and candida are more common.
2. Adverse effects from topical corticosteroids (folliculitis, skin atrophy) or topical immunomodulators (local reactions, acne).

Nursing Assessment

1. Take a nursing history focusing on clinical manifestations:
   a. Onset and duration of rash.
   b. Location, course, and distribution of lesions.
   c. Change in morphology of lesions.
   d. Previous episodes of rashes.
   e. Local and systemic symptoms, especially itching.
   f. Exposure to possible allergens or triggers, especially wool, occlusive synthetic fabrics, soaps, detergents, perspiration, extremes of temperature and humidity, emotional stress, and certain foods in infants and toddlers.
   g. Personal history of allergies, asthma, or allergic rhinitis.
   h. Family history of eczema, asthma, or allergic rhinitis.
   i. Medications, treatments tried, and their effect.
   j. Diet for possible triggers.
2. Perform a physical assessment.
   a. Examine the entire skin in an orderly fashion with specific attention to the type of lesion (ie, macule, papule, or vesicle), its appearance (shape, border, color, texture, and surface), and its distribution (areas of the body involved).
   b. Note associated symptoms, such as scratching, fever, or drainage.

c. Assess patient for signs of other atopic disorders, including nasal congestion, mouth breathing, cough, or wheezing.
d. Palpate for lymphadenopathy.

3. Document findings:
   a. Describe skin findings using dermatologic terminology.
   b. Draw pictures to facilitate communication.
   c. Document the presence or absence of associated signs or symptoms.

Nursing Diagnoses

- Impaired Skin Integrity or Risk for Impaired Skin Integrity related to skin pathology and scratching.
- Deficient Knowledge related to trigger avoidance.
- Impaired Comfort related to itching.
- Risk for Infection related to increased bacterial colonization of the skin and possible break in defensive barrier.

Nursing Interventions

The nurse may perform the following interventions or teach patient and/or family to do them.

Improving Skin Integrity

1. Reduce inflammation during the acute stage with the topical application of open wet dressings.
   a. Use a soft, lightweight cloth, such as a handkerchief, a thin cloth diaper, or strips of bed sheeting. Do not use gauze (adheres to skin), washcloths, or towels (too heavy). Warm moist pajamas layered under dry pajamas are effective and soothing.
   b. Open wet dressings should be clean. In certain situations, they should be sterile to prevent contamination.
   c. Solutions should be lukewarm or at body temperature to soothe the skin and prevent chilling.
   d. Compresses should be moderately wet, not dripping, and removed after 20 minutes, unless otherwise directed. They should be reapplied three to four times per day.
   e. After the compress, a topical corticosteroid may be applied to further reduce itching and inflammation.
   f. Observe the skin for changes in response to therapy.
2. Prevent dry skin during the subacute and chronic stages.
   a. Decrease the frequency and duration of bathing. Long, hot tub baths should be avoided.
   b. Avoid hot water and harsh soaps. Patients should bathe in lukewarm water using mild soap with a neutral pH (eg, Dove, Neutrogena); avoid bubble baths; rinse well and pat skin dry with towel.
   c. If bath water stings, add 1 cup of table salt.
   d. Apply unscented emollients (eg, Eucerin, Keri, Aquaphor, and Lubriderm) within 3 minutes of bathing, when the skin is still slightly moist. Apply over topical medications. This traps water in the

skin. Creams and ointments are more effective than lotions because they are better at preventing evaporation of water from the skin.

e. Some patients may benefit from soaking in a tar bath for 15 to 20 minutes daily, preferably in the evening. Add to bath water as directed. Instructions must include the ability to stain the skin and clothing and cause sunlight sensitivity.

f. For patients with extremely dry skin, clean with a hydrophilic cleanser (eg, Cetaphil). Apply without water until light foam occurs. Remove by wiping with soft cotton cloth or cleansing tissue.

g. Keep environmental humidity above 40% during winter months. Use a humidifier.

h. Observe the skin for changes in response to therapy.

NURSING ALERT Apply unscented emollients to the skin within 3 minutes of bathing when the skin has been patted dry but is still moist to maintain a high level of hydration to the epidermis.

Patient and Caregiver Education to Improve Avoidance of Triggering Factors

1. Follow recommended guidelines related to preventing food allergies.
   a. Encourage breastfeeding during the first 6 months. For infants not breastfed, extensively or partially hydrolyzed formulas (Nutramigen, Alimentum) are preferable to cow's milk formula.
   b. Follow the current American Academy of Pediatrics guidelines related to timing of the introduction of new foods, especially dairy, eggs, peanuts, tree nuts, seafood, and other highly allergenic foods.
2. Eliminate trigger foods for infants and toddlers with known or suspected food allergies.
   a. Observe skin for flare-ups after exposure to potential allergens.
   b. Suggest referral to allergy specialist for infants and young children with moderate to severe atopic dermatitis.
   c. Be aware of the results of skin prick sensitivity, patch testing, or blood testing.
   d. Record known allergens on chart and care plan.
   e. Notify dietary department, caregivers, and school personnel of food allergies.
   f. Consult with dietitian to ensure a balanced diet that excludes identified allergens.
   g. Check food for known allergens before feedings.
   h. Prevent accidental ingestion by informing visitors of food allergies and keeping offending foods from patient.
   i. Teach parents and caregivers to read food labels for the elimination of offending food proteins.
   j. Assess compliance with prescribed diet and relief of symptoms.
3. Be aware of environmental triggers.
   a. Maintain a warm climate with moderate humidity and avoid exposure to excessive heat and cold or humidity extremes.

b. Dress child in soft, lightweight cotton clothing and avoid wool and occlusive synthetic fabrics. A new type of nonirritating, antimicrobial fabric impregnated with silver is useful as a sleep garment. Infants should not be allowed to crawl on wool carpeting.
c. Participation in strenuous athletic activities that promote sweating. Activities should be modified according to the needs of the child. Swimming is recommended in chlorinated pools (although bromine in pool water may be irritating).
d. Irritating/harsh soaps, perfumes, detergents, chemicals, and fabric softeners.
e. Bathing in hot water.
f. Smoking around child.
g. Avoid harsh soap and hot water. Avoid fabric softeners. Use fragrance-free and dye-free detergents.
h. Discourage smoking in child's presence.

4. Try to alleviate stress.
   a. Encourage parents to stay with young child as much as possible.
   b. Involve child in age-appropriate diversional activities.

Controlling Pruritus

1. Apply topical medications as ordered by the health care provider.
   a. Assess for possible contraindications to medication before use. Check skin for active viral, bacterial, or fungal infection and for lymphadenopathy.
   b. Apply a thin layer of topical medication to the affected skin two to four times per day, as directed by the health care provider. Use only for the duration prescribed.
   c. Do not apply to wet or occluded skin.
   d. Apply emollients over top of medication.
   e. Observe for possible adverse effects including burning, itching, and erythema at application site and from long-term use of topical medications such as striae, cutaneous atrophy, telangiectasia, and acne because of topical corticosteroid use.
2. Note scratching and apply age-appropriate interventions to address avoidance of scratching.
3. Consider interventions such as cool compresses and bleach baths as described above.
4. Administer prescribed oral antipruritic medications, monitor for side effects, and provide related medication teaching as needed.

Preventing Secondary Infection

1. Discourage and prevent scratching per interventions described above.
2. Assess and treat secondary infection.
   a. Observe the skin for signs of bacterial, viral, or fungal infection (discharge, oozing, crusts, increased redness, fever). Report any positive findings.
   b. Administer medications, as prescribed.
   c. Loosen exudate and crusts with water or wet dressings, unless otherwise specified.

d. Note changes in the skin in response to therapy.

Family Education and Health Maintenance

1. Teach patient and family to avoid potential triggering factors.
2. Use fragrance-free and dye-free detergents and soaps.
3. Bathe/shower in tepid water and apply emollients immediately after bathing. The child should bathe/shower after swimming and exposure to other irritants or triggering factors.
4. Avoid stressful situations, when possible.
5. Follow the American Academy of Pediatrics guidelines related to the introduction of new and solid foods.
6. Make sure that the child and/or family know to avoid common triggers, prevent dry skin, recognize signs of flares or secondary infection, apply topical medications, and follow up for routine appointments.
7. Recommend consultation with dermatology specialist for children with severe or persistent atopic dermatitis.
8. Provide resources for additional information from the following websites:
   a. American Academy of Dermatology (*www.aad.org*).
   b. American Academy of Pediatrics (*www.aap.org*).
   c. National Eczema Society (*www.eczema.org*).
9. Stress the importance of regular health maintenance examinations, immunizations, and preventive practices.

NURSING ALERT Advise family that fresh water (pond, lake, river) should be avoided if child has breaks in skin integrity, because of risk of infection.

Evaluation: Expected Outcomes

- Skin intact with minimal erythema and lichenification.
- Names common triggers and avoidance measures.
- Verbalizes less itching and less scratching observed.
- No signs of secondary infection.

Other Dermatologic Disorders

See Table 55-1.

Table 55-1 Common Pediatric Skin Problems

DISORDER/ORGANISM	CLINICAL MANIFESTATIONS

Impetigo
Bacterial infectious disease affecting the superficial layers of the skin and characterized by the formation of vesicles, honey-colored crusts, or bullae.
Etiology and incidence:
• Caused by *Staphylococcus aureus* and *Streptococcus pyogenes*. Occurs most commonly when personal hygiene is poor.
• Common in children younger than age 10.
• Spread by close contact—easily conveyed from person to person via hands, nasal discharge, shared towels and toys, plastic wading pools in summer—when water is not replaced and no disinfectant is used; highly contagious.
• An abrasion of the skin may serve as a portal of entry.
Diagnosis:
• Usually clinical.
• Rarely, a culture of the lesion's exudate is indicated to confirm the diagnosis.
	• Incubation period is 1–10 days.
	• Lesion first appears as pink–red macules that quickly change to vesicles, which, in turn, rupture, develop crusts, and leave a temporary superficial erythematous area.
	  • Bullous (neonate and older child)—large, thin-roofed blisters break to form thin, light-brown crusts. Lesions may occur anywhere on the body but are more common on the face, axillae, and groin.
	  • Crusted (preschool age—seen more commonly in summer on exposed body parts)—lesions appear with thick, yellow crusts; skin around crusts is red and weeping with satellite lesions.
	• Regional lymphadenopathy is common with secondary infection of insect bites, eczema, poison ivy, and scabies.
	• Autoinoculation is the major cause of spreading.
	• Pruritus may occur.

(See page 910 for ringworm of the body [Tinea corporis])
A fungal infection of the scalp and hair follicles
Etiology and incidence:
• Most ringworm of the scalp is caused by *Trichophyton tonsurans*. *Microsporum canis* and *Microsporum audouinii* are also causative agents.
• Is seen primarily in children before puberty (usually ages 3–10).
• May be spread through child-to-child contact as well as through the common use of towels, pillows, combs, brushes, and hats. Cats and dogs may also be the source of the infection.
Diagnosis:
• Hair or skin scrapings for microscopic evaluation or fungal culture, obtained by rubbing a swab or toothbrush over the affected area.
Differential diagnosis:
• Tinea amiantacea, lichen planopilaris, and perifolliculitis capitis abscedens et suffodiens must be ruled out clinically or histologically. Woods lamp inspection has limited benefit.
	• The lesions appear on the scalp in a variety of ways:
	  • One or more patchy areas of dandruff-like scaling with little or extensive alopecia (hair loss).
	  • One or more discrete areas of alopecia with tiny broken hairs.
	  • Numerous discrete pustules or excoriations with little alopecia.
	  • A kerion or boggy, tender, inflammatory mass that produces edema and pustules.
	• Pruritus usually occurs in the involved area.

Pediculosis
Infestation of humans by lice.
Etiology:
• Three types of lice affect human beings:
  • *Pediculosis capitis* (head lice)—commonly infests school-age children.
  • *Pediculosis corporis* (body lice)—rare in the United States.
  • *Pediculosis pubis* (pubic or crab lice)—common in sexually active adolescents or adults—can be found on pubic hair, chest hair, axillary hair, eyebrows, eyelashes, and beards.
• Each type of louse generally remains in the area designated by its name.
  • Lice are transmitted by personal contact with people harboring them or through contact with articles that temporarily harbor them (clothing or bed linens).
  • Head and pubic lice are not health hazards or signs of uncleanliness. Only body lice can transmit disease.
Diagnosis:
• Identification of lice or their eggs with the naked eye confirmed by using a hand lens or microscope.
• In active infection of head or pubic lice, nits and eggs are found on the hair shaft within 1 cm of the skin and are difficult to remove.
• Body lice and their eggs are found in the seams of undergarments.
	• Itching in the area affected is the primary symptom of pediculosis. Scratch marks may be evident in these areas. However, not all affected people itch.
	• Other signs of infestation are pillows or clothing that looks unusually dirty.
	• Infested scalp areas may become secondarily infected from scratching.
	• Crusts, lice, nits, eggs, and dirt may combine to cause a foul odor and matted hair.
	• Body lice may produce minute red lesions.

Scabies A disease of the skin produced by the burrowing action of a parasitic mite in the epidermis, resulting in irritation and the formation of burrows, vesicles, or pustules. *Etiology:* • The mite, *Sarcoptes scabiei*, is the cause of this disorder. • Occurs in people of all socioeconomic levels, regardless of personal hygiene standards. • Is transmitted by direct skin contact with infected people or by indirect contact through soiled bed linens, clothing. *Diagnosis:* • Identification of a mite, ova, or feces from skin scrapings. • Often based on clinical presentation.	• Itching, particularly at night, is the primary symptom. The onset of itching is usually insidious. • Secondary skin infection is common and may confuse the diagnosis. • Systemic manifestations are absent, unless they result from the secondary infection. • The burrow, a gray or white, tortuous, threadlike line, is seen most commonly in older children and adults between the fingers, in the wrists, in the axillary and buttock folds, along the belt line, on the male genitalia, on the female breasts, and on the knees, elbows, and ankles. • In infants and small children, the lesions may occur on any part of the body and are usually widespread. Vesicles on the palms and soles are characteristic. • Incubation period in children without previous exposure is 4–6 weeks.
Oral Candidiasis (Thrush) Oral candidiasis is a mycotic stomatitis characterized by the appearance of white plaques on the oral mucous membranes, gums, and tongue. (Chronic mucocutaneous candidiasis may be associated with endocrine diseases or immunodeficiency disorders or use of systemic antibiotic or inhaled corticosteroids.) *Etiology:* • Caused by *Candida albicans*. • Maternal vulvovaginitis is the primary source of neonatal thrush. Evaluate for endocrine diseases or immunodeficiency disorders if thrush occurs after 6 months of life or is chronic. • Nipples, pacifiers may be reservoirs.	• The infant develops small plaques on the oral mucous membranes, tongue, or gums. These plaques look like curds of milk but cannot be wiped out of the mouth. • Most infants with thrush appear to have little pain or discomfort, unless the case is severe and there are erosion and ulceration of the mucosa. • The mouth may be dry. • Occasionally, the infant may appear to have some difficulty swallowing or may eat less vigorously. • Enteric infection is usually associated with oral thrush.
Diaper Dermatitis Candidal diaper dermatitis—a rash characterized by bright red, sharply circumscribed but moist patches with pustular satellite lesions. *Etiology:* • 80% of diaper rashes present for 3 or more days are caused by *Candida albicans*. • Most commonly seen in infants and toddlers who wear diapers. • May be associated with oral candidiasis.	• Buttock rash consisting of erythematous maculopapular eruption with perianal distribution. • Generally causes discomfort, especially with wetting and cleanings. Lesions last approximately 2 weeks, desquamate, and resolve without scarring.

Attention Disorders and Learning Disabilities

Attention Disorders

Learning Disability

OVERVIEW AND ASSESSMENT

The spectrum of developmental disabilities is a group of interrelated chronic neurodevelopmental disorders. It includes cerebral palsy, mental retardation, autism, learning disabilities, communication disorders, anxiety disorders, and attention deficit disorders. These conditions are suspected or noticed at varying stages during childhood. Some conditions, such as Down syndrome, can be recognized prenatally or at birth; other conditions, such as cerebral palsy or autism, may not present themselves until the child fails to meet typical developmental milestones. This phenomenon makes the nurse's role in developmental assessment crucial. The pediatric nurse who understands that the development of the child occurs in an orderly, predictable manner and who knows what the milestones should be may be the first person to recognize the deviation and raise the suspicion to the parent or pediatrician. Because there are many confusing and overlapping characteristics for many of these conditions, it is important for the health care provider and family to refer to clinicians who are experienced and knowledgeable in typical and atypical child development to arrive at an accurate diagnosis and coordinate an appropriate care plan. Nurses can play a significant role in supporting the family in navigating the complex needs of many of these disorders.

When a known condition exists, the nurse should be aware of the predisposing health issues associated with the condition and the resources available to promote optimal growth and development of the child within the family.

NURSING ALERT Normal child development is predictable and sequential. The nurse who is knowledgeable about normal development may be the first person to raise the question that a developmental disability exists.

Signs of Developmental Delay

Criteria for Referral

Communication and Feeding

1. Feeding difficulties—weak sucking or poor coordination of suck–swallowing to sustain normal weight gain.
2. No social smile by age 4 months.
3. No babbling (*ga-ga*, *da-da*) by age 9 months.
4. No *mama* and *dada* (specific) by age 14 months.
5. No name of object (one word) by age 14 months.
6. At least 10 words by age 18 months (not just repeating).
7. Combines words (eg, *me outside*, *more milk*) and uses pronouns by age 24 months.
8. Regression in language or social responses at any age.
9. Unresponsive to name.

NURSING ALERT Do not simply reassure the family that normal development "should" or "probably will" develop. Make sure that the child is referred for an appropriate evaluation to properly assess the suspected delay and establish a diagnosis, if possible. In the presence of a developmental delay, a comprehensive vision and hearing evaluation should also be included.

Motor Delay

1. Asymmetrical movements and poor tone are noted.
2. Not rolling over by age 6 months.
3. Not sitting by age 9 months.
4. Not walking by age 15 months.
5. Not stair climbing by age 2 years.

See Chapter 40 for normal pediatric growth and development.

Care of the Child with a Developmental Disability

Nursing Assessment

1. Review the child's record including the prenatal and birth history to determine existing health problems that may cause or affect the developmental disability. Always rule out a vision or hearing impairment.
2. Review the family history, if available, to determine if there are any family members with a history of developmental disabilities. If possible, assess when parents and siblings of the patient reached specified developmental milestones.
3. Assess the family's understanding of the diagnosis and its ramifications. The parents' experiences, cultural beliefs, attitudes toward disabilities, cognitive ability, stage of grief, and their own health affect their ability to assimilate information provided. It will be necessary to repeat the information. (For example, a woman who has just given birth to a child with Down syndrome may have difficulty processing much information shortly after birth.) If possible, provide the family with written information that reinforces verbal information given at the visit. Provide resources with careful consideration of information overload. Additional information and resources may be better introduced at subsequent visits.
4. Determine the developmental age of the child. The pediatric nurse should be familiar with normal developmental milestones (see Chapter 40, page 1080), noting the child's strengths and areas presenting challenges, for example, the communication skills are at a 12-month level and the gross motor skills are at a 36-month level. Children who are found to be functioning at one half or less of their chronological age have a moderate to severe developmental delay.
5. Administer a developmental tool such as the Clinical Adaptive Test–Clinical Linguistic Auditory Milestone Scales (CAT–CLAMS). It is a reliable tool that nurses can be trained to use to assess cognitive and communicative development in children at the 1- to 36-month developmental level. It has been found to be more sensitive than the Denver Developmental Screening Scale because language development is the best early predictor of cognitive abilities.
6. Assess the functional level of the child. The WeeFIM is a tool used to track functional independence in children. It has had multiple revisions and is reliable and valid. It uses the following categories to describe function: completely dependent, needs some physical assistance, can physically perform the task but needs verbal cues and coaching, and completely independent. Functional areas to assess include:
   a. Feeding.
   b. Grooming and bathing.
   c. Dressing.
   d. Mobility.
   e. Problem solving.
   f. Communication.
7. Assess parents' perception of the child's development level and the appropriateness of parental expectations. Use such questions as, "Do you have any concerns regarding things your child is doing or

should be doing?" "Is your child progressing like your other children have?"

8. Assess parent–child interaction. Observe and explore bonding and attachment, ability to set appropriate limits, management of behavioral problems, and methods of discipline.
9. Assess the need for additional resources, such as financial aid, transportation, and counseling, for long-term support of child and family.

NURSING ALERT Be aware of the diversity of cultural norms that may affect developmental milestones.

Williams, A., Cormack, C., Chike-Harris, K., et al. (2015). Pediatric developmental screenings: A primary care approach. *Nurse Practitioner, 40*(4), 34–39.

Nursing Diagnoses

- Impaired Parenting related to birth and diagnosis of developmentally disabled child.
- Interrupted Family Processes related to multiple needs of child and difficult bonding.
- Ineffective Infant Feeding Pattern related to protruding tongue, poor muscle tone, and weak sucking.
- Delayed Growth and Development related to impaired cognitive and motor functioning.
- Social Isolation related to developmental differences from other children.
- Risk for Injury related to neurologic impairment and developmental delay.

Nursing Interventions

Promoting Adjustment

1. Allow the parents access to the infant at all possible times to promote bonding when parents appear ready.
2. Focus on the positive aspects of the infant and serve as a role model for handling and stimulating.
3. Be cognizant of the grieving process (loss of the anticipated and planned-for "normal child") that families experience when a diagnosis is made, and be aware that spouses can be at different stages.
4. Accept all questions and reactions nonjudgmentally, offering verbal and written explanations.
5. Provide the family a quiet place to discuss their questions with each other and someone knowledgeable about the condition (primary care provider, clinical nurse specialist) to support their concerns.
6. Offer the family the option to take advantage of counseling. A social worker or psychologist can help

families deal with immediate reactions. Many parents benefit from continuous or periodic support of counseling professionals.

NURSING ALERT Children with developmental disabilities and chronic illness are at greater risk for experiencing divorce, child abuse, and neglect than the general population.

Strengthening the Role of the Family

1. Help the family to realize what strengths they have in caring for their child. The role of the parents is critical; a nurturing, loving environment gives the child the best chance at maximizing potential. An individual who grows up at home has markedly higher adaptive abilities and an increased life span compared with those raised in residential care facilities.
2. Enlist the help of family and siblings, who can offer valuable support to the parents and child and assist with stimulation activities. Including siblings in the care can help them feel needed and involved, thus strengthening the family.
3. If sibling issues arise, suggest family counseling to address the needs of all family members.
4. Identify resources available to the family, such as parent support groups, early intervention programs, specialty clinics, pediatrician or primary health care provider, respite care, financial support programs, and advocacy groups for individuals with developmental disabilities.
5. For those parents concerned with their ability to care for the child, explore with them their options of foster care, adoption, and residential placement in a nonjudgmental manner.
6. Ensure that the family has adequate respite services to prevent exhaustion and mental fatigue.

Establishing Effective Feeding Techniques

EVIDENCE BASE Hurley, K., Yousafzai, A., & Lopez-Boo, F. (2016). Early child development and nutrition: A review of the benefits and challenges of implementing integrated interventions. *Advances in Nutrition, 7*(2), 357–363.

Zuckerman,K., Chavez, A., & Reeder, J., (2017). Decreasing Disparities in Child Development Assessment: Identifying and Discussing Possible Delays in the Special Supplemental Program for Women, Infants, and Children (WIC). *Journal of Developmental & Behavioral Pediatrics, 38*(5), 301–309.

---

1. Be aware that the presence of hypotonia, as in children with many genetic syndromes and metabolic disorders, or hypertonia, as in children with cerebral palsy, can interfere with feeding by compromising sucking and swallowing.
2. Demonstrate proper feeding positioning, with the infant's head elevated, and encourage the parents to

always hold the infant during feedings with his or her head elevated and supported in arms.

3. Try different nipples, bottles, and positions to find the easiest for the infant to use without leakage or danger of aspiration.
4. Allow adequate time for feeding and increase frequency of feedings if infant tires easily.
5. Offer support and guidance for breastfeeding. Refer to lactation consultant, if needed.
6. Consider referral for a feeding evaluation to a speech therapist or to an occupational therapist who has experience working with children and families.
7. Be aware of and anticipate the need for initiation of tube feeding (nasogastric or gastrostomy) so that early referral and education of the parents about feeding options can be discussed.
8. Assess for signs of feeding intolerance and gastroesophageal reflux disease, which is common in children with hypotonia; implement management strategies to optimize feeding and minimize risk of aspiration, such as upright position after feedings.
9. Frequently assess growth (length or height, weight, and head circumference) to ensure adequate dietary intake, and be aware that growth in children with neurologic impairment and genetic syndromes may be slower or limited in relation to the general pediatric population and standard growth charts.
10. Monitor bowel and elimination patterns of children with neurologic impairment, especially those with generalized hypotonia, as they are at risk for poor gastric motility and constipation. Dietary measures, such as increased fiber and fluid intake, or pharmacologic agents to promote adequate elimination may be needed.

Promoting Optimum Growth and Development

1. Refer parents to the early intervention program administered by their county so that they can take advantage of the educational and support services available for children from birth to age 3 years.
2. If the condition is identified after age 3 years, refer parents to the school district in which they reside.
3. Help the parents to understand the concept of developmental age and identify the functional level of the child.
4. Determine whether there is consistency between the developmental age of the child and degree of independence. Cognitive and physical limitations may interfere with emerging independence; however, parents may “baby” or overindulge a child who has a disability.
5. Work with parents to set reasonable expectations and to break down tasks into simple, achievable steps. Care should be taken not to address too many areas at one time so as not to overwhelm the family.
6. Use appropriate discipline and behavior modification techniques, such as extinction, time-out, and reward, to achieve cooperation and success.
7. Demonstrate and encourage play with the child at the appropriate level to provide stimulation and work toward achieving developmental milestones.
8. Provide parents with information and links to community, regional, or national associations for children with special needs, and refer to parent support groups. These resources are frequently found online and can be easily accessed to provide an ongoing source of information and support to families.

9. Ensure that the child's physical well-being is optimized to promote optimal development and self-esteem. Any congenital defects should be considered for repair (ie, orthopedic, cardiac, craniofacial, etc), and attention should be paid to dental health and restorative orthodontic procedures that can improve facial appearance.
10. Consider any pertinent cultural and ethnic impact on health care.

Providing Opportunities to Develop Social and Self-Care Skills

1. Be aware that feeding, toileting, dressing, and grooming are important aspects of socialization and development of self-esteem. These tasks should be taught in a developmentally appropriate manner to children with a focus on maximizing independence. Many adaptive devices are available, and an occupational therapist can guide families in effective techniques to help children with developmental disabilities master these important self-care skills.
2. Make parents aware that recreational and leisure-time experiences are valuable in building social skills and self-esteem. Rehearse and role-play desirable social behaviors—such as waving goodbye, saying "hello," taking turns, saying "please" and "thank you," and responding to their name—will help build social confidence and acceptance within the child's peer group.
3. Offer suggestions that will be enjoyable and developmentally appropriate for the child. Interaction with developmentally delayed and nondevelopmentally delayed peers is desirable. The Special Olympics is one example of an adaptive program. Local programs are also available in many areas.
4. Praise the child for participation in activities, regardless of whether the child succeeds.

Maintaining Safety

1. When handling the infant, provide adequate support with a firm grasp because the infant may be floppy because of poor muscle tone.
2. If hypotonia is accompanied by poor head control and neck strength, position the infant to prevent aspiration should vomiting occur.
    a. Support the infant with a diaper roll, if needed, to maintain position.
    b. Change the infant's position frequently.
    c. Continuously check the environment for the safety needs of the child.
3. Be aware that hypotonia can also lead to increased heat loss as more surface area is exposed; therefore, infants may need close attention paid to swaddling and environmental control to maintain thermoregulation.
4. Advise the parents to:
    a. Maintain appropriate surveillance of the child when cooking or exposing him or her to other potential hazards that he or she may be able to get into but not understand.
    b. Help the child to read words, such as *danger* and *stop*.
    c. Teach the child how to call and ask for help.
    d. Teach the child to say no to strangers.

e. Teach the child appropriate and socially acceptable sexual behaviors to prevent exploitation.
f. Teach sex education, with practical information about anatomy, physical development, and contraception, in a way the child and adolescent can understand.

5. Ensure that parents and caregivers have the knowledge and resources to transport their child safely.

NURSING ALERT Teach caregivers to base safety needs on the developmental, not the chronological, age of the child.

Family Education and Health Maintenance

1. Remind the parents to recognize the child's routine health care needs and maintain regular follow-up with a primary care provider.
   a. Immunizations.
   b. Regular dental checkups.
   c. Vision and hearing examinations.
   d. Anticipatory guidance related to developmental stages, safety, behavior, and transition planning.
2. Provide guidance and support to parents with their child's multidimensional treatment plan. Make sure parents know whom to contact when problems arise. Encourage parents to develop and maintain a notebook with a calendar to keep track of agencies, subspecialists, and professionals who will be involved with their child. It should include such information as business cards, names, addresses, phone numbers, appointment dates, health providers' orders, and insurance information.
3. Teach parents the benefits of a therapeutic home environment.
   a. Develop optimum sleeping, eating, working, and playing routines.
   b. Ensure adequate nutrition.
   c. Divide tasks and expectations into small, manageable parts. Give only one or two instructions at a time.
   d. Set firm but reasonable limits on behavior and carry through with consistent discipline.
   e. Avoid situations that cause excessive excitement, stimulation, or fatigue.
   f. Provide an energy outlet through physical activity and outdoor play, as well as vocal outlet.
   g. Channel the need for movement into safe, appropriate activities.
4. Discuss preparation for independent living, when appropriate.
   a. Help the parents identify areas of home responsibilities that may be delegated to the cognitively impaired child.
   b. Guide development of social skills that will be an asset to later vocational life.
   c. Help the child to develop a set of attitudes and behaviors that will increase motivation.
   d. Refer for vocational assistance to ARC (formerly Association of Retarded Citizens) or other

rehabilitative agencies.

e. Begin planning for transition from pediatric care providers to adult providers well in advance of when eligibility for services will run out to ensure appropriate provider(s) can be established in a timely way and to avoid gaps in health care.

5. Refer for genetic consultation for information about genetics of the disorder, risk in subsequent pregnancies (parents) or risk to offspring (patient), or risk to other relatives as it is warranted by the diagnosis.

EVIDENCE BASE Milen, M., & Nicholas, D. (2017). Examining transitions from youth to adult services for young persons with autism. *Social Work in Health Care, 56*(7), 636–648.

Castillo, M., Clark, D., Schaller, E., et al. (2018). Descriptive assessment of problem behavior during transitions of children with intellectual and developmental disabilities. *Journal of Applied Behavior Analysis, 51*(1), 99–117.

Evaluation: Expected Outcomes

- Parents hold infant frequently and seek information from health care provider.
- Family members feed, assist with care, and bond with child.
- Parents and health care providers monitor nutrition, growth, and development closely, with ongoing assessment of most effective feeding techniques and management of any feeding-related problems.
- Parents describe developmental level of child and have realistic goals for attainment of next milestones in collaboration with their health care team and occupational, speech, and physical therapists.
- Parents seek out support and resources that enable them to share their experience in raising a child with special needs and gain information needed to optimize the child's developmental and health outcomes throughout childhood.
- Child remains safe through careful handling and appropriate supervision.

DEVELOPMENTAL DISABILITIES

Cognitive Developmental Delay

Cognitive developmental delay, also known as *intellectual disabilities*, refers to the most severe, general lack of cognitive and problem-solving skills. The American Association on Intellectual and Developmental Disabilities defines intellectual disabilities as a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior, which covers many everyday social and practical skills. This disability originates before the age of 18 years. There are many causes and a wide range of impairments. Up to 7.7 million people in the United States have at least a mild developmental disability that impacts their daily functioning. One in six children (or about 15%) aged 3 through 17 years have one or more developmental disabilities.

Pathophysiology and Etiology

1. No identifiable organic or biologic cause can be found for 50% of children with cognitive delays.
2. Identifiable causes include:
    a. Genetic causes, such as Down syndrome, fragile X syndrome, Angelman syndrome, and inborn errors of metabolism such as phenylketonuria (PKU).
    b. Congenital anomalies, including brain malformations, hydrocephalus, and microcephaly.
    c. Intrauterine influences, such as alcohol and drug exposure, congenital infections, and teratogens.
    d. Perinatal trauma—birth hypoxia and intracranial hemorrhage.
    e. Postnatal trauma—acquired brain injury from falls, automobile accidents, near drownings, and child abuse (shaken baby syndrome).
    f. Postnatal infections and diseases (meningitis, encephalitis, sepsis, hypoxia, brain tumors).
    g. Environmental exposure to toxins such as lead, environmental deprivation, and neglect.
3. The malfunctioning brain is poorly understood in most cases, but physiologic alterations identified in some cases include:
    a. Congenital brain malformations, brain tissue damage, or underdevelopment of the brain as shown by normal results of computed tomography (CT) scan or magnetic resonance imaging (MRI).
    b. Biochemical errors or errors of metabolism, in which an absence of an enzyme or hormone produces abnormal brain function or formation, as in PKU or hypothyroidism.
4. IQ is 75 or below; classification has been recently changed to mild and severe and includes both cognitive and functional abilities.
    a. The more severe types of intellectual developmental disability tend to be diagnosed in early infancy, especially when they coexist with an identifiable syndrome or congenital anomaly.
    b. Milder forms of intellectual developmental disability tend to be diagnosed in the preschool years, when language and behavioral concerns call attention to slower development.
5. Limitations in adaptive ability occur in communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure, and work.

Clinical Manifestations

Developmental delays (failure to achieve age-appropriate skills) are evident to some degree in almost all areas.

Infancy

1. "Poor feeder"—a weak or uncoordinated suck results in poor breast- or bottle-feeding, leading to poor weight gain.
2. Delayed or decreased visual alertness and curiosity with poor visual tracking of the face or objects.
3. Decreased or lack of auditory response.
4. Decreased spontaneous activity or asymmetric activity.
5. Delayed head and trunk control.
6. Floppy (hypotonic) or spastic (hypertonic) muscle tone.

NURSING ALERT Although 75% of individuals with intellectual developmental disabilities have no physical signs, they typically achieve motor milestones at a slower rate.

Toddler

1. Delayed independent sitting, crawling, pulling to stand, and independent ambulation.
2. Delayed communication—failure to develop receptive and expressive language milestones. Almost 50% of children with intellectual developmental disability are identified after age 3 years, when speech delays manifest themselves.
3. Failure of the child to make progress or show interest in the area of independence in self-feeding, dressing, and toilet training may reflect cognitive impairment.
4. Short attention span and distractibility.
5. Behavioral disturbances.
6. Decreased muscle coordination.

Diagnostic Evaluation

Federal law (PL 94-142, Education for All Handicapped Children, and PL 101-476, Individuals with Disabilities Education Act [IDEA]) ensures that each child with a delay or suspected of having a delay has a comprehensive evaluation by a multidisciplinary team. Part C of PL 105-17 calls for the creation of statewide, coordinated, multidisciplinary interagency programs for the provision of early intervention services. Each state has its own definitions and organizational framework to provide these services. No single test can diagnose intellectual developmental disabilities. The multidisciplinary evaluation should be individually tailored to the child.

1. Rule out sensory deficits by assessment of vision and hearing, even if neonate hearing screen was normal.
2. Medical evaluation should include prenatal history, developmental history, sequential developmental

assessments, family history including genetic assessment, and physical examination. The positive findings determine the direction of the individual evaluation and any diagnostic testing.

a. Unusual appearance (dysmorphic features) warrants evaluation by a genetic specialist.
b. History consistent with loss of developmental milestones and positive family history warrant workup for presence of an inborn error of metabolism (diagnosed by blood, urine, or DNA analysis) or lead poisoning.
c. Children with macrocephaly, microcephaly, or neurologic abnormalities may require imaging studies, such as CT scan or MRI.
d. EEG is indicated for children with seizures.

3. Psychological testing (appropriate tests selected by a child psychologist):
   a. The Bayley Scales are used to assess children ages. This test is weighted on nonlanguage items and is used to assess fine motor, gross motor, language skills, and visual problem solving.
   b. The McCarthy Scale offers a "general cognitive index" that is roughly equivalent to an IQ score.
   c. The Stanford-Binet Intelligence Scale is used to test the mental abilities of children aged 2 and older.
   d. The Wechsler Preschool and Primary Scale of Intelligence-Fourth Edition (WPPSI-IV) measures mental age of 2 years and 6 months to 7 years and 7 months.
   e. The Wechsler Intelligence Scale for Children-Fifth Edition (WISC-V) tests children whose functional age is above a 6-year level.
   f. The Vineland Scale tests social-adaptive abilities—self-help skills, self-control, interaction with others, and cooperation; the Adaptive Behavior Scale is similar to Vineland but also measures adjustment.

Complications and Associated Findings

1. Seizures.
2. Cerebral palsy.
3. Sensory deficits.
4. Communication disorders (speech and language).
5. Neurodevelopmental disorders.
6. Psychiatric illness.
7. Specific learning disabilities.
8. Emotional and behavioral problems (self-injury, hyperactivity, aggression).

Management

1. An interdisciplinary team evaluation by a developmental pediatrician, clinical psychologist, and counselor is usually the initial step in the management of mental delays. This type of evaluation can be obtained through a state or private diagnostic and evaluation center, public school, or university-affiliated program.
2. Associated medical problems, such as seizures, feeding difficulties and poor nutrition, sensory deficits, or

dental problems, must be treated to allow the child to maximize his or her potential.

3. If a treatable cause is identified, such as an inborn error of metabolism, a therapeutic diet can be instituted. Hypothyroidism can be treated with thyroid hormone.
4. A family assessment is essential to address:
    a. Financial stressors—financial aid may be available through social security, Medicaid, or state and local programs to help families with children with developmental delays.
    b. Family functioning and coping abilities.
    c. Support for parents, siblings, and extended family.
    d. Respite services.
    e. Support groups.
    f. Recreational programs, such as the Special Olympics and summer camps.
    g. Identification of other affected or at-risk people and the need for genetic counseling for recurrence risk.
5. The initial evaluation usually leads to recommendations for more targeted evaluations, such as physical therapy, occupational therapy, and social work assessment.

See "Care of the Child with a Developmental Disability," page 1453.

Down Syndrome

EVIDENCE BASE Crawford, D. (2016) Down's syndrome. *Nursing Children & Young People, 28*(9), 17. Khatri, S., & Carlisle, J. (2016). Down syndrome. *Contemporary Pediatrics, 33*(8), 30–46.

Down syndrome was first described in 1866. It is the most common genetic cause of intellectual disability and is also referred to as trisomy 21. According to the National Down Syndrome Society, the incidence of this error in cell division is about 1 in 700 live births, about 6,000 infants each year. Down syndrome occurs when an individual has a full or partial extra copy of chromosome 21. Each child with Down syndrome has a unique set of genes, besides the effects of the extra genes on chromosome 21, and the child will need individualized evaluation. The most common life experience of a child with Down syndrome is to live with the family, participate in infant stimulation and preschool programs, and attend school while receiving support from special education services. Adults with Down syndrome can function in supported employment or supervised programs. These adults may live in small residential group homes, with their families or in environments with supervision. Life expectancy depends on the presence of medical complications; when there are no complications, life expectancy is slightly shorter than average, approximately 60 years.

Pathophysiology and Etiology

See Chapter 4, page 29.

Clinical Manifestations and Associated Problems

1. Characteristic facies—brachycephaly; oblique palpebral fissures; epicanthal folds; flat nasal bridge; protruding tongue; small, low-set ears; and simian crease of palms (see Figure 56-1).
2. Congenital heart defects (seen in up to 50% of infants with Down syndrome, compared to 0.8% in the general population), most commonly ventricular septal defects and patent ductus arteriosus.
3. Mental delays.
4. Hypotonia.
5. Growth retardation.
6. Dry, scaly skin.
7. Table 56-1, pages 1459 to 1460, provides a comprehensive list of potential problems that occur with Down syndrome. Some are identified at birth; others arise and cause difficulties later in the life cycle. Percentages are listed that represent occurrence within the Down syndrome population.

Figure 56-1. A 1-year-old child with Down syndrome, recently diagnosed with hypothyroidism.

Table 56-1 Down Syndrome (DS)

POTENTIAL PROBLEMS	EVALUATION	MANAGEMENT
Congenital heart malformations (ie, AV canal, VSD, PDA, and tetralogy of Fallot) (40%)	• Observe for color changes, pulse, and respiratory rate at rest and with stress. Assess tolerance of feeding for early tiring or frequent interruptions in feeding. Echocardiogram is usually done during neonatal period on all infants with DS.	• Early identification and treatment can prevent heart failure and decompensation or poor growth. Medical or surgical intervention correction has minimized mortality from simple cardiac defects.
Congenital GI malformations (12%) • Pyloric stenosis • Duodenal atresia, tracheoesophageal fistula	• Observe for coughing or vomiting, especially with feeding: bile-stained vomitus suggests lower tract abnormalities; partially digested contents suggest upper tract problem. Observe bowel movements and for abdominal distention. • Radiographic studies are done.	• GI reflux (spillage of material from the esophagus into the trachea) can cause arching during feedings, poor weight gain, chronic respiratory problems, allergy and asthma symptomatology, pneumonia, and aspiration. Medication management and, if needed, surgical intervention can occur in the early neonatal period.
Hypothyroidism (10%–20%)	• Monitor for weight gain, hair loss, lethargy, short stature, voice changes, and depression (can develop at any time over life cycle). Neonatal screening includes T_3, TSH, and T_4 biannually.	• Thyroid hormone replacement.
Visual defects • Refractive errors (70%) • Strabismus (50%) • Nystagmus (35%) • Cataracts (3%)	• Observe for indication of vision problems, such as head tilt or poor visual tracking. Use Teller activity as a visual screen tool for those who cannot cooperate with Snellen chart. • Positive findings in the first year of life warrant immediate referral to ophthalmologist. All individuals should be seen by a pediatric ophthalmologist (or one who is skilled in evaluating children) at age 1, and vision evaluations should continue throughout life.	• Undetected visual deficits can cause failure to achieve developmental milestones and cause permanent loss of vision.
Hearing defects (60%–90%): • Mild to moderate conductive hearing loss • Enlarged adenoids • Sleep apnea	• Assess for curiosity and response to sounds of varying quality. Auditory brain stem response assesses hearing in infants. Sound field testing for children older than age 1. • Tympanometry to assess middle ear function.	• Narrow ear canals and subtle immunodeficiencies can cause chronic middle ear infections. Enlarged adenoids can cause upper airway obstruction, especially during sleep. • Treatment can range from antibiotics for simple otitis media to myringotomy tubes, adenoidectomy, or hearing loss.
Hypotonia of infants (100%)	• Observe for floppiness, poor head control, and poor oral motor function. Infant should be placed on abdomen periodically while being observed and monitored for potential for suffocation.	• Physical, occupational, and speech therapy. Adaptive equipment gives extra support to the head and neck when handling neonate. Always keep head elevated for at least 1 hr after meals. Change position regularly.
Atlanto-occipital and atlantoaxial subluxation (dislocation of the upper spine because of joint laxity) (15%)	• Assess for head tilt; increasing clumsiness, limping, or refusal to walk; and weakness of the arms. X-ray of cervical spine to evaluate for atlantoaxial dislocation at age 2 and then every 5 yr during childhood. Precise measurements are taken to document alignment of the skull and vertebrae. Shifting of the two can cause compression and neurologic damage. Participation in Special Olympics and other activities that may require neck flexion should warrant a baseline evaluation.	• If present, participation in contact sports and gymnastics is contraindicated. In severe cases, surgery to fuse the vertebrae and occiput and stabilize the spinal column.
Gait abnormalities (15%)	• Monitor for onset of limp, leg length discrepancy. Hip x-rays can document dislocation or subluxation.	• Physical therapy and, sometimes, orthopedic surgery are necessary.
Failure to thrive	• Monitor growth on DS growth chart. Monitor feedings for length of feeding, feeding schedule, loss of feeding by vomiting, or poor seal on nipple. Monitor type of formula and caloric content.	• Nutritionist can advise on formula adjustments. Therapists can help with positioning and types of nipples used to counteract effects of weak sucking reflex and large, protruding tongue.

Short stature (100%)	• Plot growth on DS growth chart. Monitor stages of puberty. Delayed puberty may warrant further investigation.	• Use of human growth hormone may be considered; this is still controversial.
Obesity (50%)	• Monitor thyroid hormone levels. Serial monitoring of weight. Monitor for amount of exercise and caloric intake.	• Overindulgence by adults or use of food in behavior management increases risk of overeating. Lack of social involvement leads to decreased activity. Behavior modification is necessary.
Malocclusions (60%–100%)	• Assess for malocclusions, periodontal disease, and delayed eruption of teeth. Regular dental checkups begin at age 1 yr or when teeth erupt.	• Encourage good oral hygiene with proper toothbrushing.
Mental retardation with varying degrees from mild to moderate (100%)	• Routine developmental assessment using standardized tools of measurement.	• Special education and training.
Alzheimer disease after age 40 (15%–30%)	• Assess for decreased cognitive function and loss of memory. MRI or CT scan shows areas of plaque.	• Increased supervision is needed.
Seizures (6%)	• Onset of seizures is seen primarily during adolescence and middle age.	• Neurologic evaluation and appropriate antiseizure medications.
Other problems • Communication disorders • Alopecia (10%) • Leukemia (1%)		

AV, atrioventricular; CT, computed tomography; GI, gastrointestinal; MRI, magnetic resonance imaging; PDA, patent ductus arteriosus; TSH, thyroid-stimulating hormone; T3, triiodothyronine; T4, levothyroxine; VSD, ventricular septal defect.

Diagnosis and Management

1. See "Care of the Child with a Developmental Disability," page 1453, for a general approach to assessment.
2. See Table 56-1, pages 1459 to 1460, for specific conditions requiring medical management related to Down syndrome, such as otolaryngologic, endocrine, orthopedic, gastrointestinal, and cardiac problems.
3. Alternative therapies—nutritional and supplemental vitamin therapy for Down syndrome remains controversial and effects have not been medically proven.

Considerations for Adult Patients with Down Syndrome

EVIDENCE BASE Esbensen, A. (2016). Sleep problems and associated comorbidities among adults with Down syndrome. *Journal of Intellectual Disability Research, 60*(1), 68–79.

Silva, V., Campos, C., Sa, A., et al. (2017). Wii-based exercise program to improve physical fitness, motor proficiency and functional mobility in adults with Down syndrome. *Journal of Intellectual Disability, 61*(8), 755–765.

Infants born with Down syndrome today are expected to live well into their 50s. Adults with Down syndrome experience accelerated aging and have a higher incidence of dementia. Other medical problems more prevalent in this population include spinal and neck problems, pulmonary hypertension, hypothyroidism, testicular cancer, sleep apnea, and dermatologic problems. Mental health disorders can include depression and obsessive–compulsive disorder. Annual health exams are crucial, and every attempt should be made to find a health care provider that is comfortable with these patients and knowledgeable of the specific health

maintenance concerns.

Fragile X Syndrome

Fragile X syndrome is the second most common identifiable cause of intellectual developmental disability as well as the most common inherited cause. About 80% of boys with fragile syndrome demonstrate intellectual disabilities compared to about one third of females. The fragile X phenotype is nonspecific and commonly becomes more apparent with age; therefore, diagnosis usually is not made until midchildhood or later. This syndrome can cause a wide range of cognitive and behavioral characteristics, ranging from mild to severe. Chromosome analysis reveals that the long arm of the X chromosome is constricted and appears fragile, but this cannot be detected in all cases; thus, deoxyribonucleic acid (DNA) analysis is preferred for diagnosis. Fragile X is more common in males, occurring in 1 in 2,500 to 4,000 boys and 1 in 7,000 to 8,000 girls. Genetic counseling and testing of family members are necessary to evaluate recurrence risks.

Pathophysiology and Etiology

See Chapter 4, page 30.

Clinical Manifestations and Associated Problems

1. Mild to moderate developmental delays (IQ range 41 to 88).
2. Elongated face, prominent ears, macrocephaly, high-arched palate, dental crowding, epicanthal folds (fold of the skin on either side of the nose), hypertelorism (increased distance between the eyes), and flattened nasal bridge.
3. Macroorchidism (enlarged testicles) after puberty.
4. Delay in both expressive and receptive language and perseverative or repetitive speech.
5. Delay in adaptive behavior skills.
6. Autistic-like communication disorders.
7. Attention deficit and hyperactivity.
8. Self-stimulating and self-injurious behaviors such as hand biting.
9. Associated problems, including mitral valve prolapse, seizures, joint laxity or hyperextensibility, and feeding problems.
10. Adult patients may develop tremors and ataxia.
11. Women are at risk for premature ovarian failure and early menopause.

Diagnosis and Management

1. See “Care of the Child with a Developmental Disability,” page 1453, for a general approach to management.
2. See Table 56-2, for specific medical issues related to fragile X syndrome.

Table 56-2 Fragile X Syndrome

POTENTIAL PROBLEMS	EVALUATION	MANAGEMENT
Hypotonia of infancy	• Assess ability to control the head and assume upright posture. • Assess feeding for efficient suck and coordination of suck/swallow.	Physical therapy, stimulation program, feeding adaptations.
Seizures (20% of cases)	• Assess for muscle tremors, deviation of the eyes to one side, rhythmic jerking of the body, and loss of consciousness.	Referral to a neurologist for diagnosis and anticonvulsants to treat seizures.
Mitral valve prolapse (80% of males)	• Assess dyspnea, cyanosis, and murmur. Echocardiogram to evaluate valve function.	Antibiotics for prophylaxis before invasive procedures to prevent endocarditis. Treatment of heart failure; surgical repair may be necessary.
Self-stimulating behavior	• Rule out source of pain (ie, otitis media, tooth pain) that may be causing behavior. Rule out sensory deficits.	Behavior management techniques: Focus on replacing undesirable behaviors with purposeful, meaningful ones, with emphasis on positive reinforcement and extinguishing negative reinforcement.
Hyperactivity, attention deficits	• Assess activity of attention span within the context of the developmental age of the child.	Behavior management and special educational techniques.
Discipline problems	• Assess social skills.	Males tend to do best in self-contained classrooms for children with similar degrees of mental retardation.
Communication disorders	• Assess language development (usually weakest area of development).	Speech–language therapy can be beneficial.
Poor auditory memory; auditory reception	• Assess how child lets needs be known: cries, gestures, single words, or sentences.	Speech therapy, behavior modification.
Cognitive dysfunction • Short-term memory deficits • Poor problem-solving skills • Functional limitations in self-care	• Assess for appropriateness of educational placement and child's reaction to situation.	Specialized training and education, assisted living.

Turner Syndrome

Turner syndrome is a genetic disorder found in females. The incidence of this syndrome is approximately 1 in 2,000 female live births. The most severe phenotype occurs in approximately 50% of females with the absence of an X chromosome. There are typically mosaic variations seen with Turner syndrome and the clinical effects can vary between individuals. It is important to note that most girls will present with short stature and/or ovarian failure, but the other syndrome characteristics may not be present or may be present in mild form, causing a delay in diagnosis. The cognitive impairments and phenotype can be nonspecific in early childhood, and a diagnosis is commonly not made until failure of pubertal development is noted.

Pathophysiology and Etiology

See Chapter 4, page 30.

Clinical Manifestations and Associated Problems

1. The most prevalent characteristics of Turner syndrome include:
    a. Short stature, webbed neck, low posterior hairline, and edema of the hands and feet (see Figure 56-2).
    b. Congenital cardiac defects.
    c. Broad chest with inverted or underdeveloped nipples.
    d. Immature reproductive organs, delayed puberty, and primary amenorrhea.
    e. Hypothyroidism, obesity, type II diabetes, osteoporosis, and fractures in adulthood.
    f. Learning disabilities.
2. Associated problems include:
    a. Coarctation of the aorta and idiopathic hypertension.
    b. Hearing loss—conductive or sensorineural.
    c. Obesity and glucose intolerance.
    d. Feeding problems.
    e. Renal anomalies.

Figure 56-2. A 3-year-old child with Turner syndrome. Note the webbed neck.

Diagnosis and Management

1. See "Care of the Child with a Developmental Disability," page 1453, for a general approach to

assessment.

2. See Table 56-3, for specific medical issues related to Turner syndrome.
3. Diagnosis may occur prenatally through an amniocentesis, with genetic testing, or any time after birth. A preliminary diagnosis may be made based on physical characteristics. This should then be confirmed by genetic testing. A diagnosis is often not made until there is a failure to begin menstruation.

Table 56-3 Turner Syndrome

POTENTIAL PROBLEMS	EVALUATION	MANAGEMENT
Congenital heart malformations: • Increased incidence of left-sided heart anomalies • Aortic valve anomalies • Coarctation of the aorta	Observe for color changes, pulse, and respiratory rate at rest and with stress. Monitor blood pressure. Assess tolerance of feeding for early tiring or frequent interruptions in feeding. An electrocardiogram should be done in the neonatal period. A yearly echocardiogram or magnetic resonance imaging should also be done.	Early identification and treatment can prevent secondary problems. If needed, prophylactic antibiotic for subacute bacterial endocarditis. Referral to a cardiologist.
Renal and renovascular anomalies: • Horseshoe kidney • Duplicated renal pelvis • Vascular anomalies	Renal sonogram should be done to rule out anomalies. Routine urinalysis and culture to screen for urinary tract infection and glycosuria.	Referral to a nephrologist if a renal anomaly is present. Monitor for the development of diabetes mellitus.
Edema in the hands and feet	Edema may persist for months or may recur; if recurrence, monitor for renal or cardiac causes.	—
Dysmorphic features: webbed neck, face, ears	Parents may elect plastic surgery to minimize the visible defects.	Enhances the socialization of females with Turner syndrome in school. May need additional support or therapy.
Nutrition: failure to thrive in the infant period and obesity in childhood	Infants may have inefficient sucking and swallowing reflexes. Monitor growth utilizing a Turner syndrome growth chart.	Nutrition counseling and encouragement of exercise to maintain appropriate weight.
Hearing loss	Hearing loss may be conductive or sensorineural. Routine screening should be performed.	Otitis media should be treated aggressively to minimize potential hearing loss.
Short stature and failure to develop secondary sex characteristics	—	Endocrine therapy may be indicated for growth and development. Hormonal therapy may enhance the development of secondary sex characteristics.
Infertility	Ovaries are not developed. Usually no need for testing.	Infertility is generally expected in Turner syndrome. Infertility techniques may be able to assist with childbearing.
Hypothyroidism	Periodic laboratory testing.	Thyroid hormone replacement therapy.
Behavioral problems, learning disabilities	—	Behavioral management. Special education.
Strabismus	If detected, referral to an ophthalmologist is recommended.	Patching or surgical repair.
Cognitive function	Average to slightly below-average intelligence. Problem areas include spatial perception and math functions.	Special education.

Fetal Alcohol Spectrum Disorder

Fetal alcohol spectrum disorder (FASD) is a significant problem. Children with FASD have a wide range of physical, mental, behavioral, and/or learning disabilities that put them at risk. FASD is the leading known preventable cause of intellectual developmental disabilities in developed countries.

Pathophysiology and Etiology

1. According to the National Institute on Alcohol Abuse and Alcoholism of the NIH, the prevalence of FASD in the general population ranges from 0.2 to 7 cases per 1,000 children and 2% to 5% for the entire continuum of FASD. It is caused by use or abuse of alcohol during pregnancy. The alcohol ingested by the mother passes easily across the placenta to the fetus.
    a. There is no "safe" level of alcohol use during pregnancy and a pregnant woman who drinks any amount of alcohol is at risk.
    b. Larger amounts of alcohol and binge drinking appear to cause more significant risk to the fetus.
    c. Alcohol use in the first trimester is more problematic.

Clinical Manifestations and Associated Problems

EVIDENCE BASE Pei, J., Baugh, L., & Andrew, G. (2017). Intervention recommendations and subsequent access to services following clinical assessment for fetal alcohol spectrum disorders. *Research in Developmental Disabilities, 60*, 176–186.

---

1. Intrauterine growth delay.
2. Decreased muscle tone and poor coordination.
3. Delayed development and problems in three or more major areas: cognitive, speech, motor, or social skills.
4. Hyperactivity and attention deficits.
5. Vision or hearing problems.
6. Heart defects such as ventricular septal defect or atrial septal defect.
7. Craniofacial abnormalities including narrow, small eyes with large epicanthal folds, small head, small upper jaw, smooth groove in the upper lip, and smooth and thin upper lip.
8. The average IQ is 65 with a range from 20 to 120, with many of these children qualifying for special education services.
9. Many will go on to have disrupted school progress, criminal offenses, and alcohol- and drug-related problems.

Diagnosis and Management

1. Diagnosis is usually made with history and clinical presentation. Ultrasounds during pregnancy may demonstrate physical features. Brain imaging studies (CT and MRI) may be performed later to document neuroabnormalities.
2. Management includes evaluation and regular monitoring of growth and nutrition. Ongoing management of symptoms related to other medical issues is a priority.
3. Nurses should be knowledgeable of educational and community resources that may be necessary for the child to reach his or her maximum potential. See "Care of the Child with a Developmental Disability," page 1453.

PERVASIVE DEVELOPMENTAL DISORDER OR AUTISM SPECTRUM DISORDER

Autism spectrum disorders refer to a group of pervasive developmental disorders including autism, Asperger disorder (AD), and disorders noted as pervasive developmental disorder not otherwise specified. This disorder has been identified in 1 in 42 males and 1 in 189 females averaging 1 in 68 children.

Autism

EVIDENCE BASE Celia, T., Freysteinson, W., & Frye, R. (2016). Concurrent medical conditions in autism spectrum disorders. *Pediatric Nursing, 42*(5), 230–234.

Autism is a complex neurobiological developmental disorder that most typically appears during the first 2 years of life. The diagnosis of autism is based on a persistent deficit in social communication and social interaction across multiple contexts as manifested in the time of exam or by history. Autism is a lifelong disorder defined by the individual's interactive difficulties, which can range from mild to severely impaired. It is four to five times more common in males than in females, but affected females tend to be more severely impaired.

Approximately 50% of people with autism are cognitively impaired, with a wide range of potential IQs. Autism is seen in approximately 60 to 70 per 10,000 live births.

Pathophysiology and Etiology

1. A clear cause has not been identified; however, evidence suggests a genetic predisposition, but no specific mutation has been identified.
2. Studies have shown that measles, mumps, and rubella vaccine do *not* cause autism. Likewise, thimerosal, a preservative found in many vaccines, does *not* cause autism.
3. Before diagnosis, parents may be initially concerned about their infant's social interactions, delayed or unusual speech development, and reactions to various stimuli (ie, tactile defensiveness).
4. Individuals with ASD have neuroanatomical differences, including small neuron cell size, increased cell packing, relative macrocephaly, and large third ventricles.

Clinical Manifestations

1. In general, the features present with the diagnosis include problems with social interactions, communication, and language skills.
2. Patients with autism have abnormalities in relating to people, objects, and events. They have abnormal responses to sensory stimuli, usually sound.
3. The stereotypical behaviors of autism are restricted and repetitive, like the commonly known symptom of echolalic speech.

Diagnosis and Management

EVIDENCE BASE Bacon, E., Courchesne, E., Barnes, C., et al. (2017). Rethinking the idea of late autism spectrum disorder onset. *Developmental Psychopathology, 14*, 1–17.

Kaufmann, W., Kidd, S., Andrews, H., et al. (2017). Autism spectrum disorder in fragile X syndrome concurring conditions and current treatment. *Pediatrics, 139*(Suppl 3), 194–206.

---

1. Early diagnosis leads to earlier interventions, resulting in improved outcomes for these children.
2. The two major diagnostic challenges in the evaluation of ASD include making the differential diagnosis and searching for the etiologic disorder associated with ASD (fragile X syndrome is the most common known single gene cause of ASD).
3. Comprehensive standardized assessment tools specific for ASD usually require specialized training; these tools include Childhood Autism Rating Scale (CARS), Diagnostic Interview of Social and Communication Disorders (DISCO), Autism Diagnostic Interview (ADI), Autism Diagnostic Interview Schedule (ADIS), and Checklist for Autism in Toddlers (CHAT).
4. Alternative treatments such as nutrition and vitamin therapy are being investigated, but no definitive research has been conclusive to date.
5. Many children with ASD also have psychiatric comorbidities with such conditions as obsessive–compulsive disorder, attention deficit/hyperactivity disorder (ADHD), depression, mood disorders, and Tourette syndrome. These conditions can be challenging to diagnose as it may be difficult to assess the child with communication and behavioral problems. Indeed, health care providers need to be vigilant in screening and monitoring for these comorbidities to ensure optimal functioning of the child with ASD.
6. Treatment is focused on management of symptoms. Medications may be helpful in treating some of the more disruptive behavioral symptoms. The most commonly used medications include select serotonin reuptake inhibitors, atypical antipsychotic/neuroleptics, stimulants, and alpha agonists.
7. Medical comorbidities are also common in children with ASD, including seizure disorders, sleep disturbances, GI disorders, and dental problems. As with psychiatric comorbidities, health care providers need to be vigilant in their assessment, as it can improve behavior and functioning of the child with ASD.
8. A multidisciplinary team—including primary care provider; medical subspecialists; occupational, speech, and physical therapists; and educational specialist—is essential for optimal care. See “Care of the Child with a Developmental Disability,” page 1453.

Childhood Disintegrative Disorder

Childhood disintegrative disorder follows a period of normal development. This normal developmental period may last from ages 2 to 10 years, with the most common age of onset being 3 and 4 years of age. The child begins to experience a significant loss of previously acquired skills. Areas that may be affected include expressive and receptive language, social skills or adaptive behavior, bowel and bladder control, and motor skills. The loss of these skills generally reaches a point at which they do not disintegrate further. At such point, some limited improvements may be seen. This condition differs from autism in the pattern of onset, course, and outcome.

Pathophysiology and Etiology

Etiology is unknown. Childhood disintegrative disorder appears to be more common in males. The incidence of this disorder is rare.

Diagnosis and Management

See "Care of the Child with a Developmental Disability," page 1453, for a general approach to assessment.

Asperger Disorder

Asperger disorder is considered a milder form of autism and is characterized by poor peer relationships, lack of empathy, and the tendency to be overfocused on certain topics.

Asperger disorder is one of several developmental disabilities associated with normal intelligence. Academic and functional underachievement in the preschool and school-age child with normal intelligence is the common picture. Proper diagnosis, utilizing a cooperative team effort from several individuals, is imperative to develop an individualized treatment plan.

Pathophysiology and Etiology

The etiology is unknown. Asperger disorder is commonly not diagnosed until the child reaches school age. The prevalence estimates vary widely with many individuals never being formally diagnosed.

Clinical Manifestations

1. Child does not seek spontaneous interpersonal interactions.
2. Average to above-average intelligence and development of normal language skills with regard to vocabulary and grammar.
3. No significant delays in the areas of cognitive development, development of age-appropriate self-help skills, adaptive behavior, and curiosity about the environment.
4. Limited range of interests, strict adherence to routines and rituals, and repetitious motor movements or sequences.
5. May have obsessional interests and appear "eccentric" to others.

Diagnosis and Management

1. Complete medical review, family history, and physical examination, including vision and hearing assessment and neurologic evaluation, to rule out other disorders.
2. Genetic evaluation and counseling to identify the presence of recurrence risks.
3. Psychological testing to determine the exact nature of cognitive and perceptual dysfunctions.
4. Behavioral and social assessment.
5. Assessment of academic performance.
6. MRI and other testing to determine underlying neurologic abnormality, if appropriate.
7. Occupational and physical therapy and speech and language evaluations, as necessary.
8. School evaluation—involves IQ testing and achievement testing (teacher's input is also essential).
    a. The focus of a school evaluation is to determine eligibility for services. Most school systems will provide services only when moderate to severe problems exist.
    b. It may be necessary for the family to provide remediation for problems considered mild or outside of the educational setting.
9. Because the disorder may include health manifestations as well as behavioral and educational

implications, the school nurse should be prepared to provide guidance on complex management.

EVIDENCE BASE Ward, B. (2016). Sibling Experiences: Living with Young Persons with Autism Spectrum Disorders. *Pediatric Nursing, 42*(2), 69–76.

Pervasive Developmental Disorder, Not Otherwise Specified

Pervasive developmental disorder, not otherwise specified (PDD-NOS) was used when the child meets some but not all criteria for the diagnosis of autism. A diagnosis may be made at a later date because of the appearance of additional manifestation. The DSM-5 notes that individuals with a well-established diagnosis of autistic disorder, Asperger disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. This suggests that there is a spectrum of developmental disorders with common features, which may range widely in severity and represent a range of genetically influenced impairments.

ATTENTION DISORDERS AND LEARNING DISABILITIES

Attention disorders and learning disabilities are separate but overlapping problems and may need specific approaches based on the nature of the disability. An estimated 5% to 10% of children (ranging up to 30%) have attention deficit disorder (ADD); learning disabilities are reportedly present in 12.6% of children by the end of the second grade. Learning disabilities and ADD commonly occur together.

Pathophysiology and Etiology

1. Multiple hypotheses exist because the exact causes are unknown and may be genetic.
    a. A family trait—other members of the family have similar difficulties.
    b. Characteristic of inborn errors of metabolism.
    c. Sex chromosome abnormalities commonly exhibit these traits.
2. Not shown to be associated with a history of birth trauma or brain damage.
3. Exposure to prenatal and postnatal factors that might adversely affect brain development and function—lead, alcohol, cocaine, central nervous system (CNS) infections, low birth weight, and prematurity.
4. May coexist with other disabling conditions, such as spina bifida, cerebral palsy, or seizure disorders.
5. May have biomedical, emotional, social, and environmental components.
6. ADD is an alteration in the response-inhibition mechanisms of the brain controlled by the frontal cortex and reticular activating system and alteration in neurotransmitter.
7. Learning disabilities—authorities are investigating abnormalities in the parietal lobe of the brain and in the central visual pathways located in the occipital lobe.
8. Although emotional and environmental factors play a role, serotonin deficiency may serve as a physiologic basis for these disorders.

Attention Disorders

EVIDENCE BASE Ahmann, E. (2017). Interventions in children and teens: A focus on ADHD coaching. *Pediatric Nursing, 43*(3), 343–349.

Attention disorders are characterized by a cluster of symptoms, including developmentally inappropriate short attention span, impulsivity, and distractibility. The classification system identifies three subtypes of attention disorders: predominantly inattentive, predominantly hyperactive–impulsive, and combined. Attention disorders are more common in boys than in girls by a ratio of 3 to 1. Females are much more likely to have inattentive type, showing more symptoms of attention deficit rather than hyperactivity.

There is no specific laboratory test or radiographical test that can diagnose attention disorders. The best way to diagnose attention disorders is through careful history from parents, child, and teachers; use of standardized questionnaires or rating scales; and observation. There are a number of behavior rating scales that are used to establish the diagnosis of ADD and ADHD. Examples of rating scales include the Conners Rating Scale, the Brown Attention Deficit Disorder Scale for Children and Adolescents, and the Vanderbilt ADHD Rating Scale.

Clinical Manifestations and Diagnostic Evaluation

General Behavior

EVIDENCE BASE Burns, C. (2017). Cognitive-perceptual disorders. In C. Burns, A. Dunn, M. Brady, et al. (Eds.), *Pediatric primary care* (pp. 393–409). Philadelphia, PA: Elsevier.

Behavior varies slightly based on the child's age. Some impairments across the life span can include:

1. Childhood: Needs for special education, grade retention, classroom behavior management issues, and behavioral difficulties at home and other settings.
2. Adolescence: School failure and dropout, social difficulties with peer relationships, substance abuse (in untreated), high comorbidity with other psychiatric disorders, and involvement in juvenile criminal activities.
3. Adult: Fewer employment possibilities and frequent job hopping; high risk of tobacco, drug, and alcohol use; high risk of motor vehicle accidents; marital problems and higher divorce rates; and increased incidence of criminal activity.

Diagnostic Criteria for ADHD

Diagnostic criteria are outlined in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, Text

Revision (DSM-5) criteria for attention deficit/hyperactivity disorder. In this edition, the core symptoms reflect how the disorder presents in school-age children, as well as older adolescents and adults. Examples of questions include:

1. Does the child often fidget with hands or feet or squirm in seat?
2. Does the child have difficulty remaining seated when required to do so?
3. Is the child easily distracted by extraneous stimuli?
4. Does the child have difficulty awaiting his or her turn in games or group situations?
5. Does the child often blurt out answers to questions before they have been completed?
6. Does the child often have difficulty following instructions from others?
7. Does the child have difficulty sustaining attention in tasks or play activities?
8. Does the child often shift from one uncompleted activity to another?
9. Does the child have difficulty playing quietly?
10. Does the child often talk excessively?
11. Does the child often interrupt or intrude on others?
12. Does the child often not seem to listen to what is being said to him or her?
13. Does the child often lose things necessary for tasks or activities at school or at home?
14. Does the child often engage in physically dangerous activities without considering possible consequences?

Management

Multidisciplinary Approach

A multidisciplinary approach, including environmental and behavioral approaches, is the treatment of choice.

Pharmacologic Treatment

1. CNS stimulants are effective for 70% to 80% of children with attention disorders.
    a. Effective in decreasing motor activities and increasing attention span and concentration, thereby allowing the child to be more available to learn.
    b. Medications generally include stimulant medications, but nonstimulant medications may also be effective, especially in adults. Examples include methylphenidate, dextroamphetamine, amphetamine, lisdexamfetamine, and atomoxetine.
2. Adverse effects:
    a. Insomnia may result from increased dosage or if administered too late in the day.
    b. Anorexia, weight loss, hair loss, and temporary growth retardation.
    c. Increased pulse and respiratory rates, nervousness, nausea, and stomachache.
    d. Altered effects of many antiseizure drugs and tricyclic antidepressants.
    e. Do not cause euphoric effect or addiction in children.

Nursing Responsibilities and Family Education

1. Administer the drug before breakfast and lunch (sustained-release forms may not require a second dose).
2. Work with school system to make sure that the lunch dose is given.
3. Consider "drug holidays" during vacations and on weekends to monitor effectiveness and the need for a dosage change; this is especially recommended at the start of each academic school year.
4. "Drug holidays" may be difficult in the older adolescent population as the medication may be necessary for optimal functioning in employment and while driving motor vehicles.
5. Based on the newest evidence, it appears that children without cardiac disease who receive stimulant therapy are not at increased cardiovascular events compared with the general population, so cardiac evaluations are not routinely ordered.
6. Stimulant drugs are not usually given to children younger than age 6.
7. The child is usually started on a small dose, which is gradually increased until the desired response is achieved.
8. Evaluate the child's response to the drug by direct observation and consultation with others, such as parents and teachers.

DRUG ALERT Stimulant drugs for attention disorders should be used in conjunction with a comprehensive therapeutic regimen and not as the sole method of treatment. Stimulant drugs require monitoring and feedback from the parents and teachers who directly observe the effects.

Learning Disability

Difficulties with academic achievement fall under a broad category of learning problems. The cause or influencing factors can be biomedical, developmental, behavioral, emotional, social, environmental, and family issues. The problem may be in the area of reading, math, written expression, motor skills, and communication disorders. Attention deficit, anxiety, and behavioral disorders must be ruled out.

Clinical Manifestations

1. Signs of learning disabilities include:
    a. School achievement significantly lower than potential.
    b. Perceptual–motor impairments.
    c. Emotional lability.
    d. Speech and language disorders.
    e. Coordination deficits.
2. There can be a wide range of cognitive ability from mild retardation to above-average intelligence.

Areas of Learning Disabilities

Auditory Perception

Auditory perception is characterized by difficulty distinguishing between similar sounds or words. This includes the inability to process the sounds into words that have a meaning at a rapid enough rate to be able to follow conversations.

Visual Perception

Visual perception difficulties involve problems interpreting what is seen. This may include problems recognizing shapes and positions of letters or words. Depth perception may pose a problem to some children with visual perception disorders.

Integrative Processing

Integrative processing disabilities encompass, to varying degrees, the inability to sequence events or facts, comprehend abstract ideas or implied meanings, and organize learned information and apply it to what has been previously acquired.

Memory

Disabilities generally affect short-term memory, which stores information that has just been perceived for a brief period before it is either discarded or stored in long-term memory.

Expressive Language

An *expressive language* disorder affects the child's verbal communication. Characteristics depend on the child's age and the severity of the disorder. Language skills in terms of vocabulary, grammatical content, fluency, and language formulation can be affected.

Motor

Motor disabilities can affect either gross motor or fine motor muscle groups. A disability affecting the gross motor development can cause children to be "clumsy." These children have a tendency to fall or bump into things and have difficulty running and playing sports. Fine motor disabilities affect muscles for detailed tasks, such as writing, using scissors, and painting.

Management and Special Teaching Strategies

1. For visual perceptual deficit—present material verbally; use hands-on experience; tape-record teaching sessions.
2. For auditory perceptual deficit—provide materials in written form; use pictures; provide tactile learning.
3. For integrative deficit—use multisensory approaches; print directions while you verbalize them; use calendars and lists to organize tasks and activities.
4. For motor and expressive deficits—break down skills and projects into their multiple component parts; verbally describe the component parts; provide extra time to perform; allow the child to type work rather than use cursive writing.
5. For highly distractible child—provide a structured environment; have child sit in the front of the class; place child away from doors or windows; decrease clutter on his or her desk.

NURSING ALERT Historically, preschool and kindergarten screening tools have not been accurate in predicting learning disabilities; newer tests of language and memory are better predictors.

Resources and Support Groups

Agencies that may provide information, support, and additional resources include:

The ARC of the United States (formerly Association for Retarded Citizens of the United States)
1825 K Street NW, Suite 1200
Washington, DC 20006
(800) 433-5255

TRANSITIONAL CARE ALERT After the stress of having a hospitalized child, families will need support in the transition to home or another aftercare location. It is crucial that they have complete and understandable care instructions on home care, medications, and follow-up appointments. If arrangements

have been made for nursing care in the home, families should be aware of the agency providing services and when they can expect communication regarding care arrangements. Families should have thorough written (and if necessary to assist understanding, pictorial) instructions on signs and symptoms to monitor for that could suggest worsening of status, especially if the child is nonverbal and cannot relay symptoms to the caregivers. Children with developmental disorders may be discharged to home requiring oxygen or other procedures (like suctioning) or both. Nurses responsible for discharging children should ensure that families understand (and can demonstrate care if possible) proper use of necessary treatments. If the child is cared for in a residence other than that of the family caregiver, health care providers should ensure that the individuals caring for the child after the hospitalization are knowledgeable and comfortable providing necessary care.

ANXIETY-RELATED DISORDERS

Anxiety

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Anxiety disorders are the most common of all psychiatric disorders. An individual with one of these disorders experiences physiologic, cognitive, and behavioral symptoms of anxiety. The physiologic manifestations are related to the "fight-or-flight" response and result in cardiovascular, respiratory, neuromuscular, and gastrointestinal (GI) stimulation. The cognitive symptoms include subjective feelings of apprehension, uneasiness, uncertainty, or dread. Behavioral manifestations include irritability, restlessness, pacing, crying and sighing, and complaints of tension and nervousness. The common theme among anxiety disorders is that the individual experiences a level of anxiety that interferes with functioning in personal, occupational, and social areas. *Note: obsessive–compulsive disorder is no longer classified as an anxiety disorder. It is considered part of the class of body dysmorphic and hoarding disorders, which are not covered in this book because of space constraints; however, anxiety is a key feature.*

Classification

1. Panic disorder.
2. Agoraphobia.
3. Specific phobia.
4. Social anxiety disorders.
5. Generalized anxiety disorder.
6. Anxiety disorder because of a general medical condition.
7. Substance-induced anxiety disorder.
8. Anxiety disorder not otherwise specified.

Pathophysiology and Etiology

The underlying etiology of anxiety disorders as well as any of the psychiatric disorders is complex, having multiple factors that interact. Therefore, it is essential to examine the biochemical, genetic, psychosocial, and sociocultural factors.

Biochemical Factors

1. The limbic system, which is called the *emotional brain*, regulates emotional responses. Anxiety disorders are associated with abnormalities within this system (including the frontal cortex, hypothalamus, amygdala, hippocampus, brainstem, and the autonomic nervous system).
2. Neurotransmitters and their specific receptor sites function to transmit inhibiting or stimulating messages across the synapses between nerve cells in the brain. Abnormalities in the neurotransmitters or

the receptor sites have been associated with multiple psychiatric disorders, including anxiety disorders.

3. Norepinephrine is a stimulating neurotransmitter, which is released as part of the fight-or-flight response and is associated with the cardiovascular and respiratory effects of anxiety. Serotonin is a neurotransmitter that regulates multiple responses, including sleep and alertness and sensations of hunger and satiation. Genetic variation resulting in a decrease in the number of select serotonin receptors (particularly 1A) may be associated with the development of panic disorder.
4. Panic disorders may be related to the reception of a false signal from the brain that there is a shortage of oxygen or an increase in carbon dioxide (suffocation alarm theory). Those who have panic attacks have also been reported to have higher levels of norepinephrine.
5. Positron emission tomography (PET) and computed tomography (CT) scanning have shown abnormalities in glucose metabolism in the frontal and prefrontal cortex and the basal ganglia of the brains of individuals with panic disorder.

Genetic Factors

1. First-degree relatives of individuals with panic disorder have a four to seven times greater chance of developing this disorder. Twin studies demonstrate a higher concordance rate for monozygotic than dizygotic twins.
2. Approximately 20% of first-degree relatives of people with agoraphobia also have agoraphobia.
3. Approximately 25% of first-degree relatives with generalized anxiety disorder are also affected by generalized anxiety disorder.

Psychosocial Factors

1. Psychodynamic theory describes unconscious conflicts having early childhood origin and resulting from repressed wishes and drives. These conflicts cause guilt and shame, which lead to anxiety and associated symptoms.
2. Interpersonal theory implicates early relationships, which directly affect development of self-concept and self-esteem. Individuals with poor self-concept and decreased self-esteem have increased susceptibility to anxiety-related disorders.
3. Behavioral theory describes anxiety and associated symptoms as a conditioned response to internal and external stressors.
4. Cognitive theory describes faulty thinking patterns that lead to an individual's misperceiving events affecting self, the future, and the world. These faulty thinking patterns contribute to the subjective experience of anxiety.

Sociocultural Factors

1. Anxiety disorders and ritualistic behaviors are commonly seen in high-technology societies.
2. There is a higher incidence of anxiety disorders in urban communities than in rural communities.

Clinical Manifestations

Generalized Anxiety Disorder

1. A pattern of worrying or anxiety that results in increased autonomic activity persisting for a period of at least 6 months.
2. An examination and history would reveal symptoms from three of four categories:
   a. Motor (eg, trembling, restlessness, inability to relax, and fatigue).
   b. Autonomic hyperactivity (eg, sweating, palpitations, cold clammy hands, urinary frequency, lump in the throat, pallor or flushing, increased pulse, and rapid respirations).
   c. Apprehensiveness (eg, worry, dread, fear, rumination, insomnia, and inability to concentrate).
   d. Hypervigilance (eg, feeling edgy, scanning the environment, and distractibility).

Panic Disorder

1. The presence of recurrent unexpected anxiety attacks for at least 1 month with a sudden onset of feelings of intense apprehension and dread.
2. These feelings result in sympathetic activation that manifests through the appearance of at least four of the following symptoms: chest discomfort or pain, dyspnea, palpitations, syncope, diaphoresis, trembling, hot or cold flashes, and dizziness.

Phobias

1. A phobia is a persistent irrational fear of an object or situation that the person may recognize as being unreasonable.
2. Exposure to the feared object or situation may result in a panic attack.
3. An example is agoraphobia, which is a fear of being alone in open or public places where escape might be difficult.

Diagnostic Evaluation

1. Measurement tools for anxiety:
   a. Hamilton Rating Scale for Anxiety.
   b. State–Trait Anxiety Inventory.
2. Measurement tools for panic disorders:
   a. Acute panic inventory.
   b. Sheehan Client-Rated Anxiety Scale.
3. Sodium lactate infusion or carbon dioxide inhalation will likely produce a panic attack in a person with panic disorder.
4. Increased arousal may be measured through studies of autonomic functioning (ie, heart rate, electromyography, sweat gland activity) in a person with posttraumatic stress disorder (PTSD).
5. Dexamethasone suppression test (DST) may be used to demonstrate heightened glucocorticoid feedback in individuals with PTSD.
6. Measurement tools for dissociation:

a. Dissociation Impulsivity Scale (DIS).
b. Dissociative Experiences Scale (DES).
c. Dissociative Disorders Interview Schedule (DDIS).

Management

EVIDENCE BASE Baldwin, D. S., Anderson, I. M., Nutt, D. J., et al. (2014). Evidence-based pharmacological treatment of anxiety disorders, post-traumatic stress disorder and obsessive-compulsive disorder: A revision of the 2005 guidelines from the British Association for Psychopharmacology. *Journal of Psychopharmacology, 28*(5), 403–439.

Jones, A. M., West, K. B., & Suveg, C. (2017). Anxiety in the school setting: A framework for evidence-based practice. *School Mental Health.* 2017, 1–11. Available: *doi.org/10.1007/s12310-017-9235-2.*

---

1. Various levels and sites of care can be provided: psychiatric inpatient, outpatient, or home care. Most care is provided on an outpatient basis. Site of care is based on many factors, including degree of disability of affected individual, community services available, and insurance and managed care considerations. Generally, the recommended treatment is a combination of drugs and psychotherapy, along with education of the individual and family.
2. Psychoeducational strategies:
   a. Relaxation techniques.
   b. Progressive muscle relaxation.
   c. Guided imagery or visualization exercises.
   d. Stress management.
   e. Assertiveness training.
3. Psychotherapy:
   a. Psychodynamic—assists people in understanding their experiences by identifying unconscious conflicts and developing effective coping behaviors.
   b. Behavioral—focuses on the individual problematic behavior and works to modify or extinguish the behavior. One form of behavioral therapy effective in management of phobic disorders is systematic desensitization.
   c. Cognitive—assists patient to question faulty thought patterns (reframing) and examine alternatives. In treatment of PTSD and dissociative disorders, reframing is used to help the patient view self as a survivor rather than a victim.
   d. Hypnotherapy—can be used as part of therapy for those suffering dissociative disorders.
   e. Support group therapy—useful in providing a supportive and psychoeducational approach for patients with anxiety or dissociative disorders.

4. Somatic therapies:
    a. Biofeedback—relaxation through biofeedback is achieved when a person learns to control physiologic mechanisms that are not ordinarily within one's awareness. Awareness and control are accomplished by monitoring body processes, including muscle tone, heart rate, and brain waves.
    b. Psychopharmacologic—traditionally, drugs used to treat anxiety-related disorders were those that would increase GABA (benzodiazepines), regulate serotonin levels (antidepressants), or reduce physiologic effects of anxiety by causing peripheral beta-adrenergic blockade (beta-adrenergic blockers). Currently, selective serotonin reuptake inhibitors are prescribed as first-line treatment for managing several anxiety-related disorders because of their safety and tolerability. See Table 57-1.

Table 57-1 Dosage and Adverse Reactions of Antianxiety Drugs

DRUG: CLASS/GENERIC/TRADE NAME	ADULT THERAPEUTIC DOSAGE RANGE (MG/DAY)	ADVERSE REACTIONS
Benzodiazepines		*For all benzodiazepines:*
Alprazolam	0.75–1 mg	• Drowsiness, sedation, and dizziness
Chlordiazepoxide	15–75 mg	• Possibility of dependence
Clonazepam	0.5–2 mg	
Clorazepate	15–60 mg	
Diazepam	4–40 mg	
Lorazepam	2–6 mg	
Oxazepam	30–120 mg	
Tetracyclic Agent		
Mirtazapine	15–45 mg	• Somnolence, increased appetite, weight gain, dry mouth, constipation
Selective Serotonin Reuptake Inhibitors (SSRIs)		
Citalopram	20–60 mg	• Nausea, dry mouth, diarrhea, fatigue, drowsiness, ejaculatory delay, impotence
Duloxetine	40–60 mg	• Nausea, dry mouth, dizziness, constipation, diarrhea, fatigue, increased sweating
Escitalopram	10–20 mg	• Nausea, ejaculatory delay, impotence
Fluoxetine	20–80 mg	• Delayed orgasm, headache, nervousness, insomnia, anxiety, tremor, dizziness, nausea, diarrhea, anorexia, dry mouth
Fluvoxamine	50–300 mg	• Nausea, vomiting, drowsiness, anorexia, constipation, tremor, insomnia
Paroxetine	10–50 mg	• Nausea, dry mouth, headache, somnolence, insomnia, diarrhea, constipation, tremor

Complications

1. Undiagnosed medical reasons for anxiety could lead to physical deterioration and a delay in obtaining appropriate medical care. It is important to screen for coexisting medical illness.
2. If panic and phobic disorders are left untreated, they can lead to increasing social withdrawal and isolation, which may severely impair the person's social and work life.
3. Undiagnosed or untreated PTSD or acute stress disorder can lead to substance abuse or dependence, aggressive or violent behavior and, possibly, suicide.
4. If a person with a dissociative disorder goes untreated, aggressive behavior may develop toward self or others. Such behaviors may include assaults, depression, PTSD, psychoactive substance abuse disorder, rape, self-mutilation, and suicide attempts.

Nursing Assessment

1. Assess psychological, cognitive, and behavioral symptoms.
    a. Defense mechanisms or coping measures used.
    b. Mood.
    c. Suicide potential.
    d. Thought content and process.
    e. Severity of subjective experience of anxiety.
    f. Understanding of specific disorder.
2. Explore social functioning.
    a. Ability to function in social and work situations.
    b. Impact of symptoms on patient's relationships, especially work and family relationships.
    c. Diversional and recreational behavior.
    d. Identification of stressors related to self-concept, role performance, life values, social status, and support systems.
    e. Benefits (primary and secondary gains) and risks of the presenting symptoms.

Nursing Diagnoses

- Anxiety related to unexpected panic attacks or related to reexperiencing traumatic events.
- Acute Confusion related to severe anxiety.
- Impaired Social Interaction related to avoidance behavior or related to embarrassment and shame associated with symptoms.
- Ineffective Role Performance related to inability to function in usual social and occupational situations secondary to anxiety-related symptoms.
- Disturbed Personal Identity related to a traumatic event.
- Risk for Injury related to anxiety-related behavior.

Nursing Interventions

Reducing Symptoms of Anxiety

1. Help patient identify anxiety-producing situations and plan for such events.
2. Assist patient to develop assertiveness and communication skills.
3. Practice stress reduction techniques with patient.
4. Teach patient to monitor for objective and subjective manifestations of anxiety.
    a. Tachycardia, tachypnea.
    b. Signs and symptoms associated with autonomic stimulation—perspiration, difficulty concentrating, insomnia.
5. Promote use of stress reduction techniques in managing symptoms of anxiety.
6. Encourage patient to verbalize feelings of anxiety.
7. Administer prescribed anxiolytics to decrease anxiety level.

DRUG ALERT Benzodiazepines are associated with tolerance and dependence and are appropriate for short-term use. Withdrawal symptoms may occur when drug is abruptly discontinued. Gradual dosage reduction is necessary. Overdose or taking benzodiazepines with alcohol or other central nervous system (CNS) depressants can cause respiratory depression requiring emergency intervention.

Improving Concentration

1. Use short, simple sentences when communicating with patient.
2. Maintain a calm, serene manner.
3. Use adjuncts to verbal communication, such as visual aids and role-playing, to stimulate memory and retention of information.
4. Teach relaxation techniques to diminish distress that interferes with concentration ability.

Increasing Social Interaction

1. Encourage discussion of reasons for and feelings about social isolation.
2. Help patient identify specific causes and situations that produce anxiety that inhibits social interaction.
3. Recommend participation in programs directed at specific conflict areas or skill deficiencies. Such programs may focus on assertiveness skills, body awareness, managing multiple role responsibilities, and stress management.

Encouraging Independence

1. Identify secondary benefits, such as decreased responsibility and increased dependency, that inhibit patient's move to independence.
2. Provide experiences in which patient can be successful.
3. Explore alternative methods of meeting dependency needs.
4. Explore beliefs that support a helpless or dependent mode of behavior.
5. Teach and role-play assertive behaviors in specific situations.
6. Provide instruction in decision-making skills, allowing opportunities for practice and rehearsal of techniques in role-play situations.
7. Assist patient to improve skills based on performance.
8. Encourage family members to avoid fostering dependency.

Strengthening Identity

1. Develop an honest, nonjudgmental relationship with patient.
2. Try to establish open communication.
3. Do not overwhelm patient.
4. Teach patient containment techniques to assist in coping with the painful memories becoming conscious (eg, visualizing a safe environment, recall of past successes in dealing with anxiety, focusing on slowing of

physiologic responses).

Reducing Harm from Behavior

1. Encourage patient to set limits on ritualistic behavior as part of established treatment plan.
2. Assist patient in listing all objects and places that trigger anxiety as part of exposure–response prevention program.
3. Use cognitive strategies, such as reframing, to assist patient in placing thoughts and feelings in a different perspective.
4. Participate as member of treatment team in establishing program for systematic desensitization.
5. Intervene as needed and obtain emergency assistance when patient is in immediate danger.

Community and Home Care Considerations

1. Patients with anxiety-related disorders are generally treated in an outpatient setting. Many of these patients may not see a mental health professional but will be treated by their family health care provider, utilizing pharmacologic therapy. Nurses who encounter patients taking prescribed drugs for anxiety should assess effectiveness and patient knowledge base regarding safe use of these drugs. Patients should be encouraged to utilize anxiety reduction techniques.
2. Because anxiety disorders will affect family functioning, the nurse should provide support for the family, including teaching family members about the disorder and treatment measures.
3. Patients may elect to utilize alternative and complementary therapies to obtain relief from symptoms. Advise patients not to use nutritional supplement or "natural" remedy, such as St. John wort or kava kava, without discussing it with a health care provider; many drug interactions exist.
4. Several community support groups are available to provide patient with continued support. Patient may also be able to learn further techniques for the management of anxiety through participation in these programs. Such programs may also provide patient with an opportunity to practice previously learned skills in a supportive environment.

TRANSITIONAL CARE ALERT Medication monitoring for effectiveness and adverse reactions is of utmost importance to keep the patient safe, reduce inpatient admission and readmission, and improve outcomes. Be aware that cost may affect adherence, and some medications require a period of 2 to 3 weeks until a desired effect is seen.

Family Education and Health Maintenance

1. Teach patient and family members about anxiety.
   a. Define anxiety and differentiate it from fear.
   b. Explain causes of anxiety.

c. Identify events that can trigger anxiety.
d. Identify relevant signs and symptoms of anxiety.

2. Describe the drug regimen, including significant action, adverse effects, dosage considerations, and any food or drug interactions.
3. Identify, describe, and practice deep muscle relaxation techniques, relaxation breathing, imagery, and other relaxation therapies (see page 25).
4. Teach family to give positive reinforcement for use of healthy behaviors.
5. Teach family not to assume responsibilities or roles normally assigned to patient.
6. Teach family to give attention to patient, not patient's symptoms.
7. Teach alternative ways to perform activities of daily living (ADLs) if physical or emotional disability inhibits function and performance.
8. For additional information and support, refer to such agencies as the Anxiety and Depression Association of America (*https://adaa.org*).
9. Many Web sites provide support for individuals and family members. Some examples include Agoraphobics Building Independent Lives, *www.anxietysupport.org* (for sufferers from anxiety disorders), and the National Alliance on Mental Illness, *www.nami.org*.

Evaluation: Expected Outcomes

- Identifies stressors and demonstrates normal heart rate, respirations, sleep pattern, and subjective feelings of anxiety.
- Demonstrates improved concentration and thought processes through improved ability to focus, think, and solve problems.
- Reports increased participation and enjoyment in family- and community-related events.
- Reports going to work, keeps appointments.
- Uses coping strategies in situations that are anxiety provoking.
- Does not injure self or others.

Stress- and Trauma-Related Disorders

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Burges-Watson, I. P., Brune, M., & Bradley, A. J. (2016). The evolution of the molecular response to stress and its relevance to trauma and stressor-related disorders. *Neuroscience & Biobehavioral Reviews, 68*, 134–147.

Stress- and Traumatic-Related Disorders are characterized by exposure to an event perceived as traumatic or stressful. These disorders were previously classified underneath the umbrella of anxiety orders, primarily because of the association of fear and anxiety with responses to the exposure event. Over time, it has become apparent that the responses to stressful events can result in variable symptomology and distress. As a result, a category of stress-related disorders was created. These disorders still share a significant number of features with anxiety and related disorders, primarily the expression of fear.

Classification

1. Acute stress disorder
2. Posttraumatic stress disorder
3. Reactive attachment disorder
4. Disinhibited social engagement disorder
5. Adjustment disorders

Pathophysiology and Etiology

Fear responses lead to activation of the amygdala and other parts of the brain involved with the interpretation of environmental stimuli. This leads to a condition response to events that may share features with the original event. This results in hypervigilance as the individual remains alert for events that pose a danger. Sympathetic hyperarousal results from exposure to events triggering the fear response.

Biochemical Factors

1. Gamma-aminobutyric acid (GABA) is an inhibitory neurotransmitter that normally acts to decrease anxiety responses. An individual who genetically produces lower amounts of GABA may have an increased likelihood of developing anxiety- or stress-related disorders (eg, PTSD).
2. Suppression of cortisol through administration of dexamethasone has been associated with PTSD, suggesting heightened glucocorticoid feedback sensitivity.

Genetic Factors

1. Reduced hippocampal volumes are believed to contribute vulnerability to PTSD.

2. Deficits in the expression of a protein (FKBP5) associated with immune responses are found tied to stress disorders.
3. Variants in a gene that regulates the breakdown of catecholamines may lead to prolonged catecholamine activity increasing the risk for development of stress-related disorders.

Clinical Manifestations

1. Conscious or unconscious efforts to avoid stimuli related to the triggering event lead to hypervigilance and avoidant behaviors.
2. Signs and symptoms may include elements of dissociation manifesting as flashbacks.
3. Affect and emotions often appear negative, and the individual could display a sense of numbness, a lack of emotional responses, feelings of depersonalization or derealization, a feeling of confusion, and a loss of memory for aspects of the original event.

Acute Stress and Posttraumatic Stress Disorders

1. Acute stress and posttraumatic stress disorder (PTSD) share several symptoms, with the major difference between the two conditions being the time frame in which symptoms develop.
2. For acute stress, symptoms develop within 1 month of the traumatic event and last for 2 days to 3 weeks, whereas for PTSD, the symptoms are more enduring and have lasted for at least 1 month at the time of diagnosis.
3. During the initial traumatic event, the individual needs to have displayed an initial response of horror, accompanied by intense feelings of helplessness to meet criteria for each of these disorders.
4. Both disorders share a cluster of dissociative symptoms with attempts to avoid stimuli associated with the original trauma while also reexperiencing intrusive memories and recollections of the traumatic event.
5. An examination and history would elicit findings that would include three or more of the following: a sense of numbness, a lack of emotional responses, feelings of depersonalization or derealization, a feeling of confusion, and a loss of memory for aspects of the original event.
6. There will also be increased sympathetic activation, hypervigilance, and a pattern of reexperiencing the event through intrusive dreams, flashbacks, or increased anxiety when presented with stimuli associated with the traumatic event. Increased sympathetic activation associated with anxiety is demonstrated through insomnia, difficulty concentrating, feelings of restlessness, and hypervigilance.

Reactive Attachment Disorder

A stress-related disorder occurring in children younger the 5 years of age. Believed to results from environments characterized by emotional or social neglect. Situations in which the primary caregiver has frequently changed are also related to development of the condition through a lack of opportunities for the child to learn appropriate social relations. The child exhibits a lack of emotional engagement with others, manifesting as decreased interaction with adults and reduced responsiveness to attempts from adults to engage or comfort the child.

See pages 1471 to 1474 for diagnostic evaluation, management, and the nursing process.

Dissociative Disorders

Dissociative disorders are conditions in which the anxiety associated with a stressful or traumatic event induces a subjective feeling of being not connected to one's body or to reality. These conditions are viewed as unconscious defense mechanisms that result in a disorder when the ability to function in social or work environments is significantly impaired because of feelings of dissociation. These conditions were previously grouped under the umbrella of anxiety disorders but are now considered a separate but interrelated diagnostic category.

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Lemche, E. Surguladze, S. A., Brammer, M. J., & Phillips, M. L. (2016). Dissociable brain correlates for depression, anxiety, dissociation, and somatization in depersonalization-derealization disorder. *CNS Spectrums, 21*(1), 35–42.

Classification/Clinical Manifestations

1. Depersonalization/derealization disorder—a persistent or recurrent experience of feeling detached from oneself. A common sensation is of being an outside observer of one's body. This experience can cause significant impairment in daily function.
2. Dissociative amnesia—one or more episodes of inability to recall important information, usually of a traumatic or stressful nature.
3. Dissociative identity disorder—previously known as multiple personality disorder, this disorder is evidenced by the presence of two or more distinct identities, each with its own patterns of relating, perceiving, and thinking. At least two of these identities take control of the person's behavior.

Pathophysiology

1. Associated with traumatic events, often in childhood.
2. Individual responds by "splitting off" or dissociating the self from the memory of the trauma.
3. Dissociative identity disorder may result from severe physical, sexual, or psychological abuse in early childhood.

See pages 1471 to 1474 for diagnostic evaluation, management, and the nursing process.

Somatic Symptoms and Related Disorders

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Katz, J., Rosenbloom, B. N., Fashier, S. (2015). Chronic pain, psychopathology, and DSM-5 somatic symptom disorder. *Canadian Journal of Psychiatry, 60*(4), 160–167.

Somatic symptom and related disorders are characterized by physical symptoms that cannot be explained by known physical mechanisms. These disorders have in common the belief that physical symptoms are real despite evidence to the contrary. The affected individual experiences changes or loss in physical function. The physical symptoms are not under the individual's voluntary control. Significant impairment occurs in social or occupational functioning.

Classification

1. Somatic symptom disorder.
2. Factitious disorder.
3. Conversion disorder.
4. Illness anxiety disorder.
5. Somatic symptom and related disorder not otherwise specified.

Pathophysiology and Etiology

The underlying etiology of somatoform disorders is difficult to define. The following factors may interact in the individual with these disorders.

Biochemical Factors

1. An individual with a somatoform disorder may experience high levels of physiologic arousal (increased awareness of somatic sensations).
2. The phenomenon of alexithymia, or deficient communication between brain hemispheres, may result in difficulty expressing emotions directly, and therefore, distress may be expressed as physical symptoms.
3. The concept of somatosensory amplification, in which there is the tendency to experience somatic sensation as intense, noxious, and disturbing, may be related to the development of somatoform disorders.

Genetic Factors

1. Somatization disorder has been found to have a 10% to 20% frequency in first-degree female biological relatives of women with this disorder.
2. Twin studies have validated some increased risk in conversion disorder in monozygotic twins.

3. The genetic basis for other somatoform disorders is not well established.

Psychosocial Factors

1. Psychodynamic theory—the psychological source of ego conflict is denied and finds expression through displacement of anxiety onto physical symptoms. Both primary gain (anxiety relief) and secondary gains (increased dependence and relief from normal responsibilities) are common to these disorders.
2. Behavioral theory—the child learns from parent to express anxiety through somatization; secondary gains reinforce symptoms.
3. Cognitive theory—the individual has cognitive distortions in which benign symptoms are magnified and interpreted as serious disease.
4. Family theory—a family system that is overly enmeshed may utilize dysfunction in one person as a means to handle anxiety. In such families, the individual may not see self as a separate and distinct person; instead, the person may view him- or herself as an extension of the family.

Sociocultural Factors

1. Incidence of somatoform disorders is highest in rural populations and in low socioeconomic groups.
2. Somatic symptoms are more common in cultures that view direct expression of emotions as unacceptable.
3. Women may experience certain chronic pain conditions more commonly than men (this may have more of a cultural than a genetic basis).

Clinical Manifestations

Somatic disorders are psychiatric conditions that manifest in the appearance of, or preoccupation with, symptoms that reflect medical illnesses or injuries. For the diagnosis of these conditions to be made, other physical health issues must be ruled out. As with other mental health conditions, these problems lead to problems with the ability to perform necessary ADLs.

Somatic Symptom Disorder

1. This disorder is characterized by presentation of at least one somatic symptom (pain, fatigue, etc.) that is distressing in nature or leads to a significantly impairment in daily function.
2. The individual displays recurrent and intrusive thoughts or behaviors related to the symptom.
3. A significant level of anxiety may occur.
4. The symptoms must manifest over a period of 6 months, although they may not be constant during that period.
5. Based on the number of symptoms, the disorder may be classified as mild, moderate, or severe.

Factitious Disorder

1. The individual fakes or otherwise falsifies the signs of symptoms of a disease or injury.
2. The falsified disease may be physical or psychological.
3. The individual claims to be ill or impaired to others.

Conversion Disorder

1. With this condition, the individual develops symptoms compatible with a neurological disorder.
2. Examples include loss of vision, deafness, peripheral neuropathy, or bladder and bowel dysfunction. Some patients may exhibit paralysis or seizure activity.
3. These symptoms cannot be associated with a physical illness for the diagnosis of this disorder.

Illness Anxiety Disorder

1. A fixed preoccupation the individual has a serious medical condition.
2. This belief often persists in spite of medical tests or procedures that do not find any physical condition.
3. The condition must exist for at least 6 months; however, the nature of the preoccupation may change during that time.
4. This preoccupation often leads to significant problems with daily function.

Diagnostic Evaluation

1. Individuals with somatic disorders will present in the medical rather than the psychiatric setting because of their belief that the problems are medical.
2. The individual should receive a thorough medical evaluation (if possible, avoiding repeating tests that have already had negative results).
3. The diagnosis of somatoform disorder will be made after a thorough medical evaluation in which no organic basis for the symptoms is found.

Management

1. Level and setting of care to be provided is determined. In general, the individual will be treated on an outpatient basis, unless underlying mood disorder is present leading to risk for self-harm.
2. Referral to psychiatric treatment is generally rejected by the individual with a somatoform disorder; therefore, the goal of management is to maintain a long-term relationship with a specific health care provider to prevent patient from seeking multiple providers with multiple recommendations for testing, treatments, and drugs.
3. Psychotherapy:
    a. Psychodynamic—assist the individual to express conflicts and emotions verbally rather than displacing them onto physical symptoms.
    b. Behavioral—establish a program whereby adaptive behavior is reinforced and illness behaviors do not receive secondary gains.
    c. Cognitive—restructure belief system that perpetuates illness-related behaviors.
    d. Family therapy—assist family members to define appropriate boundaries and support patient in increasing self-responsibility.
4. Somatic therapies: somatic disorders are usually not treated with psychopharmacologic drugs because these patients are susceptible to dependency on drugs used.

5. Mood disorders, especially depression, are a common comorbid problem in individuals with somatic disorders. Antidepressant drugs may be used to treat the mood disorder.

Complications

1. A patient with a known history of a somatic disorder may have a coexisting medical condition that could go undiagnosed. Careful screening is essential to rule out medical problems.
2. Increased risk of suicide and substance use disorder is possible in patient with an untreated somatic disorder.

Nursing Assessment

1. Assess physical complaints.
    a. Current and past history as well as duration of problems.
    b. Diagnostic testing completed.
    c. Number of health care providers consulted.
    d. Types and amounts of drugs as well as whether self-medicating (over the counter) or prescribed.
2. Assess psychological processes.
    a. Perception of illness and current stressors.
    b. Self-concept and body image.
    c. Secondary gains from physical symptoms.
    d. Mood.
    e. Suicide potential.
3. Explore social functioning (see page 1472).

Nursing Diagnoses

- Anxiety related to multiple physical symptoms and belief that serious disease exists.
- Ineffective Coping related to preoccupation with physical symptoms.

Other nursing diagnoses and nursing interventions under anxiety disorders may apply.

Nursing Interventions

Encouraging Recognition of Anxiety

1. Discuss current life stressors in the areas of social, occupational, and family functioning.
2. Assist patient to identify anxiety-producing situations and plan coping strategies.
3. Avoid focus on physical symptoms (after appropriate screening to rule out physical etiology).
4. Maintain focus on feelings and emotional responses rather than on somatic symptoms.

Improving Coping

1. Teach and reinforce problem-solving approach to stressors.

2. Practice use of stress reduction techniques with patient.
3. Encourage use of support groups.
4. Set limits on manipulative behaviors in a matter-of-fact manner.
5. Decrease reinforcement of secondary gains for physical symptoms.
6. Help patient identify and use positive means to meet emotional needs.

Community and Home Care Considerations

1. Encourage patient to cooperate with referrals for psychiatric or psychotherapy treatments.
2. Promote patient attendance and participation at community support groups.
3. Teach patient and family the importance of remaining with one health care provider to ensure continuity of care.
4. Nurses who encounter patients with somatoform disorders in the community should maintain a matter-of-fact attitude to decrease emphasis on dramatic symptoms. Any approach to patient should include a focus on patient's strengths and capabilities rather than on disability.

Family Education and Health Maintenance

1. Teach patient and family about the relationship between stressors, anxiety, and physical symptoms.
2. Family should expect person to function despite physical symptoms; doing things and making decisions for patient will increase dependent behaviors.
3. Encourage family therapy, which may be helpful to clarify roles, communication, and expectations.

Evaluation: Expected Outcomes

- Verbalizes anxiety about specific problems rather than expressing anxiety with physical symptoms.
- Makes decisions on own; demonstrates less dependence on family and friends.

MOOD DISTURBANCES

Depressive Disorders

Depressive disorders are considered mood disorders. A mood is a sustained emotion that, when extreme, affects the person's view of the world. Mood disorders are characterized by disturbances in feelings, thinking, and behavior. These disorders may occur on a continuum ranging from severe depression to severe mania (hyperactivity). A depressive illness is painful and can be psychophysiologically debilitating. Depression is much more than just sadness; it affects the way one feels about the future and can alter basic attitudes about the self. A depressed person can become so despairing as to express hopelessness. When moods become severe or prolonged or interfere with a person's interpersonal or occupational functioning, this may signal a mood disorder.

Pathophysiology and Etiology

The exact causes for depressive disorders have not been established. These disorders are thought to result from complex interactions among various factors.

Biochemical Factors

1. Biogenic amine theory proposes that there is a norepinephrine and serotonin deficiency in individuals with a depressive disorder. Changes in quantity and sensitivity of receptor sites for these neurotransmitters may also be important.
2. Kindling theory describes a process whereby external environmental stressors activate internal physiologic stress responses, which trigger the first depressive episode. Subsequent episodes can occur with less stress in response to the electrophysiologic sensitivity that was established in the brain from the initial episode.
3. Neuroendocrine dysfunction:
    a. Hypothalamic–pituitary–adrenal axis dysfunction may be present in some individuals. Abnormalities include increased cortisol levels, resistance of cortisol to suppression by dexamethasone, and blunted adrenocorticotropin hormone response to corticotropin-releasing factor.
    b. Subclinical hypothyroidism has been associated with depression, especially in women.
    c. Dysfunction of circadian rhythms has been theorized related to depression. Abnormal sleep EEGs have been demonstrated in many individuals. Increased early morning awakening is common, as are multiple nighttime awakenings.

Genetic Factors

1. Risk of developing a mood disorder is 1½ to 3 times greater in individuals with a first-degree relative with a mood disorder.
2. Twin studies reveal a higher rate of concordance in monozygotic twins than in dizygotic twins.
3. Mood states are associated with activation of several neuroendocrine pathways within the central and peripheral nervous systems. These pathways involve a number of neurochemical processes that involve activation of a particular binding protein identified as cyclic AMP response-binding protein 1 (CREB-1). Genetic profiles of individuals with depression have found evidence that genes involved in the cellular signaling pathways utilizing CREB-1 are associated with major depression. There then may be alleles

(coding genes) that are related to the development of mood disorder.

4. Genetic variation in a certain region of the serotonin transporter gene (5-HTT) has been found to interact with the perception of stressful events (possibly through neuroendocrine pathways) to produce higher levels of depression and suicidality than in individuals without this variation.
5. Although genetic evidence has supported conceptualizations of neurochemical and biologic alteration in the development of mood and other psychiatric disorders, no one single gene or factor has appeared to emerge as the main culprit. Most likely, a number of different genes and disposing factors are involved. Possible genes include 5-HTT, brain-derived neurotrophic growth factor, and the monoamine oxidase A gene.

Medical Factors

1. Many drugs have the adverse effect of depression, including hormones, cardiovascular drugs, psychotropic drugs, and anti-inflammatory and antiulcer drugs.
2. Clinically significant depressive symptoms are detected in approximately 12% to 36% of individuals with a nonpsychiatric general medical condition.

Psychosocial Factors

1. Psychodynamic theory describes the occurrence of a significant loss (object loss) that is associated with anger and aggression, which is turned inward and leads to negative feelings about self. The negative feelings about the self, including shame and guilt, then lead to depression.
2. Life events and environmental stress, such as loss of a family member through death, divorce, or separation; lack of social support; and significant health problems have all been associated with the onset of depression.
3. Cognitive theory describes how faulty thought patterns, including negative distortions of life experiences, produce negative self-evaluation, pessimistic thinking, and hopelessness.
4. Learned helplessness theory posits that a person who internalizes the belief that an unwanted event is his or her own fault and that nothing can be done to avoid or change it is prone to developing depression.

Clinical Manifestations

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: APA.

Depression

1. A major depressive disorder reflects a level of depression that persists over a 2-week period.
2. The severity of depression may be classified as mild, moderate, or severe depending on the number of symptoms.
3. Certain qualifying terms can be used that indicate whether the depression is associated with a change in

the seasons (with seasonal pattern) or follows the birth of an infant (with peripartum onset).

4. Should delusions or hallucinations exist, the depression would be said to have psychotic features.
5. Major depression results in a significant change in ability to work or participate in social activities.
6. Physical examination and history findings should reveal at least five or more symptoms that include the following:
    a. Depressed mood, fatigue.
    b. Insomnia or an increased need for sleep.
    c. Lack of interest in pleasurable activities (anhedonia).
    d. Recent gain or loss of weight that represents at least 5% of body weight.
    e. Feelings of worthlessness.
    f. Inability to concentrate or make a decision.
    g. Suicidal ideation.

Persistent Depressive Disorder

1. A chronic, less intense level of depressed mood characterized by the same symptoms as seen in major depression and that lasts for at least 2 years in adults, at least 1 year in children and adolescents. Previously known as dysthymia.
2. A major distinguishing feature is that depression does not alter the ability to participate in social or work-related functions to the extent of major depressive disorder.

Diagnostic Evaluation

1. Rating scales of depression—to determine presence and severity of the problem:
    a. Zung Depression Scale.
    b. Raskin Depression Rating Scale.
    c. Hamilton Rating Scale for Depression.
    d. Beck Depression Inventory.
2. Laboratory studies:
    a. Thyroid function tests and thyrotropin-releasing hormone stimulation test—to detect underlying hypothyroidism, which may cause depression.
    b. DST—to evaluate depression that may be responsive to antidepressant or electroconvulsive therapy (ECT).
    c. Twenty-four–hour urinary 3-methoxy-4-hydroxyphenylglycol (MHPG)—may show slightly lower level in unipolar depression than in bipolar depression.
3. Polysomnography—an increase in the overall amount of rapid eye movement (REM) sleep and shortened REM latency period in patients with major depression.
4. Additional diagnostic tests to evaluate physical conditions, such as CT scan or magnetic resonance imaging (MRI), complete blood count (CBC), chemistry panel, rapid plasma reagin (RPR), human

immunodeficiency virus (HIV) test, EEG, vitamin B_{12} and folate levels, and toxicology studies.

Management

1. Patients may receive treatment in acute inpatient psychiatric hospitals or in the community in an outpatient program. Decision about treatment setting is made according to the severity of patient's illness, with primary concern being the risk of self-harm (suicide) as well as the presence of symptoms that are severely disabling.
2. Inpatient treatment is directed toward drug management and supportive psychotherapy using milieu management.
3. Somatic therapies:
   a. Psychopharmacologic: drugs used to treat depression are those that will increase serotonin and norepinephrine (see Table 57-2, page 1479). Another agent, a selective norepinephrine reuptake inhibitor (reboxetine) has seen used in Europe but is not yet approved for use in the United States.
   b. ECT may be used to treat severe depression that is unresponsive to antidepressant drugs.
   c. Ultraviolet light therapy may be recommended for depression that occurs during fall and winter months (seasonal affective disorder).
4. Patient may select complementary and alternative treatments. The use of herbal supplements, especially St. John wort, is a popular alternative for antidepressant drugs. However, use of nutritional or herbal supplements should be discussed with the health care provider because of the potential for drug interactions.
5. Psychotherapy:
   a. *Psychodynamic therapy* helps patient to become aware of unconscious anger directed toward object loss and "work through" these feelings to alleviate depression.
   b. *Cognitive therapy* is the recommended psychotherapeutic approach for depression. This approach includes identifying and challenging the accuracy of patient's negative thought patterns and encouraging behaviors designed to counteract depressive symptoms.
   c. *Family therapy* assists patient and family members in developing a sense of self that is separate from that of the family as a whole. Patient is then encouraged to take responsibility for his or her own actions.

Table 57-2 Dosage and Adverse Reactions of Antidepressant Drugs

DRUG: CLASS/GENERIC/ TRADE NAME	ADULT THERAPEUTIC DOSAGE RANGE (MG/DAY)	ADVERSE REACTIONS
Tricyclic Agents		
Amitriptyline (Elavil, Endep)	50–300 mg	*For all tricyclic and tetracyclic agents:*
Clomipramine (Anafranil)	25–250 mg	• Possibility of triggering a manic episode in bipolar patients
Desipramine	75–300 mg	• Anticholinergic effects. Dry mouth, constipation, blurred vision, urine retention
Doxepin	75–300 mg	• Sedative effects
Imipramine	75–300 mg	• Autonomic effects: orthostatic hypotension, sweating, palpitations, and increased blood pressure
Nortriptyline	25–150 mg	• Cardiac effects: tachycardia, T-wave flattening, prolonged QT interval
Protriptyline	15–60 mg	• Twitch, extrapyramidal movement effects
Trimipramine	75–200 mg	
Tetracyclic Agent		
Mirtazapine	15–45 mg	*See tricyclic agents:*
		• Somnolence, increased appetite, weight gain, dry mouth, constipation
Bicyclic Agent		
Venlafaxine	75–375 mg	• Nervousness, weight loss, dizziness, hypertension
Desvenlafaxine	50–100 mg	• Nausea, headache, dry mouth, insomnia, fatigue, dizziness
Selective Serotonin Reuptake Inhibitors (SSRIs)		
Citalopram	20–60 mg	• Nausea, dry mouth, diarrhea, fatigue, drowsiness, ejaculatory delay, impotence
Duloxetine	40–60 mg	• Nausea, dry mouth, dizziness, constipation, diarrhea, fatigue, increased sweating
Escitalopram	10–20 mg	• Nausea, ejaculatory delay, impotence
Fluoxetine	20–80 mg	• Delayed orgasm, headache, nervousness, insomnia, anxiety, tremor, dizziness, nausea, diarrhea, anorexia, dry mouth
Fluvoxamine	50–300 mg	• Nausea, vomiting, drowsiness, anorexia, constipation, tremor, insomnia
Paroxetine	10–50 mg	• Nausea, dry mouth, headache, somnolence, insomnia, diarrhea, constipation, tremor
Sertraline	50–150 mg	• Insomnia, diarrhea, nausea, weight loss
Vilazodone	40 mg	• Nausea, vomiting, insomnia, diarrhea
Monoamine Oxidase Inhibitors (MAOIs)		
Isocarboxazid	30–50 mg	For all MAOIs:
Phenelzine	45–90 mg	• Orthostatic hypotension, weight gain, edema, insomnia, sexual dysfunction, myoclonus, muscle pains, paresthesia, anticholinergic effects
Tranylcypromine	20–60 mg	• Food and beverages containing tyramine in combination with MAOIs as well as combining sympathetic drugs with an MAOI can cause hypertensive crisis
Selegiline	10 mg	
Dibenzoxazepine Agent		
Amoxapine	100–600 mg	• Dizziness, orthostatic hypotension, reflex tachycardia, extrapyramidal movement disorders
Unicyclic Agent		
Bupropion	225–450 mg	• Dry mouth, constipation, headache, insomnia, restlessness, agitation, menstrual irregularities, increased seizure risk
Triazolopyridine Agent		
Trazodone	150–600 mg	• Sedation, orthostatic hypotension, dizziness, headache, nausea, priapism
Phenylpiperazine Agent		
Nefazodone	200–600 mg	• Orthostatic hypotension, anxiety, nervous tremor, agitation
Combination Therapies		
Amitriptyline and chlordiazepoxide	2.5–5 mg/10–25 mg	• Blurred vision, dizziness, drowsiness, fatigue, tremor • Dry mouth, fatigue, somnolence, increased appetite, and increased weight
Fluoxetine and olanzapine	3–12 mg/25–50 mg	
Perphenazine and amitriptyline	2–4 mg/10–25 mg	• Extrapyramidal reactions are possible because of the presence of perphenazine

DRUG ALERT Antidepressant drugs have many interactions, which may lead to serotonin syndrome, a state of excessive serotonin in the synaptic cleft. Symptoms include insomnia, confusion, agitation, hyperreflexia, involuntary movements, and hypotension. Hypertensive crisis can occur if patients

take a monoamine oxidase inhibitor antidepressant in combination with a sympathomimetic drug or eat foods high in tyramine.

Complications

1. An undiagnosed medical condition causing depressive symptoms could lead to physical deterioration and delay in obtaining appropriate treatments.
2. Untreated depressive illness can lead to suicide.
3. Use of alcohol or drugs to "feel better" or numb dysphoric feelings.

NURSING ALERT During the first 60 days of antidepressant therapy, young adults and children (those under age 24) are considered to be at increased risk for suicidal thinking and behavior. The Food and Drug Administration has issued black box warnings of this risk for most antidepressants. Those taking these medications require additional monitoring and supervision during this period. The evidence does not support the need for this type of monitoring in those over age 24.

EVIDENCE BASE Gibbons, R. D., Perraillion, M. C., Hur, K., Conti, R. M., Valuck, R. J., & Brent, D. A. (2014). Antidepressant treatment and suicide attempts and self-inflicted injury in children and adolescents. *Pharmacoepidemiology and Drug Safety, 24*(2), 208–214.

Nursing Assessment

1. Assess posture and affect for:
   a. Poor or slumped posture.
   b. Appearance of being older than stated age.
   c. Facial expression of sadness, dejection.
   d. Episodes of weeping.
   e. Anhedonia—inability to experience pleasure.
2. Assess thought processes:
   a. Identify the presence of suicidal thoughts.
   b. Poor judgment, indecisiveness.
   c. Impaired problem solving, poor concentration.
   d. Negative thoughts.
3. Explore feelings for:
   a. Anger and irritability.

b. Anxiety, guilt.
c. Worthlessness.
d. Helplessness, hopelessness.

4. Assess physical behavior for:
   a. Psychomotor agitation or retardation.
   b. Vegetative signs of depression.
      i. Change in eating patterns.
      ii. Change in sleeping patterns.
      iii. Change in elimination patterns.
      iv. Change in level of interest in sex.
      v. Change in personal hygiene.
5. Assess for evidence of "masked depression":
   a. Hypochondriasis.
   b. Psychosomatic disorders.
   c. Compulsive gambling.
   d. Compulsive overwork.
   e. Accident proneness.
   f. Eating disorders.
   g. Addictive illnesses.
6. Assess for risk of suicide.

NURSING ALERT All mentally ill individuals, especially those who are depressed, should be assessed for suicide risk and referred for crisis intervention if they are deemed at risk.

Nursing Diagnoses

- Hopelessness related to depressive thoughts.
- Risk for Injury related to hopelessness and impaired problem solving.
- Bathing and Dressing Self-Care Deficit related to lack of motivation and poor concentration.
- Disturbed Sleep Pattern related to insomnia.

Nursing Interventions

Strengthening Coping and Sense of Hope

1. Initiate interaction with patient at a regularly scheduled time.
2. Be clear and honest about your own feelings related to patient's behavior.

3. Encourage verbal expression of feelings.
4. Validate feelings that are appropriate to the situation.
5. Explore with patient what is producing and maintaining the feeling of depression.
6. Encourage patient to identify events that cause unpleasant emotional responses.
7. Assess significant losses patient has experienced.
8. Identify cultural and social factors that may contribute to how patient copes with loss and feelings.
9. Assess patient's support network.

Maintaining Safety

1. Assess current suicide risk.
2. Implement appropriate level of observation based on a focused suicide assessment (eg, constant observation or 15-minute checks).
3. Explain observation precautions to patient.
4. Remove harmful objects from patient's possession and assess environmental safety of patient's room and unit.
5. Encourage patient to negotiate a "no-self-harm and no-suicide" agreement with the staff.
6. Monitor need to revise level of observation.
7. Provide additional structure by keeping patient involved in therapeutic and psychorehabilitative activities.

Encouraging Participation in ADLs

1. Collaborate with occupational and physical therapists to determine patient's functional capacity to accomplish ADLs.
2. If patient cannot accomplish ADLs independently, provide hygiene activities in collaboration with patient.
3. Acknowledge and reinforce patient's efforts to maintain appearance; do not rush patient when self-care is slow.
4. Reinforce what patient can do rather than what patient cannot do without assistance.
5. Remain with patient during mealtimes to determine the level of need for assistance or cueing in the ability to eat.

Facilitating Sleep

1. Determine patient's past and current sleep patterns and sleep hygiene.
2. Ask what strategies patient has already used to improve sleep and elicit which ones have been successful.
3. Consider decreasing the amount of daytime sleep by encouraging participation in an activity.
4. Discuss alternative methods for facilitating sleep:
    a. Avoid caffeine and nicotine.
    b. Avoid emotionally charged or upsetting discussions before bedtime.
    c. Avoid exercise 30 minutes to 1 hour before bed.

d. Increase physical activity within functional limits.
e. Use relaxation techniques.
f. Try a warm bath or warm milk.

5. Administer prescribed drugs that cause sleepiness at bedtime; avoid giving drugs that cause insomnia at night.

Community and Home Care Considerations

1. Mood disorders tend to be chronic, with acute episodes that may require inpatient treatment. In the home or community setting, patient will require ongoing monitoring regarding the use of drugs as well as support and education in terms of the disorder.
2. Community health care providers, including nurses, must be aware of the need for primary and secondary prevention programs directed at education as well as early case finding and prompt treatment.

Family Education and Health Maintenance

1. Instruct patient and family members about symptoms of depression.
2. Instruct patient and family members about purpose of antidepressant drugs, effects, adverse effects, and their management, and how to recognize early signs and symptoms of relapse.
3. Instruct patient and family members about the effect of a depressive disorder on the family system.
4. Provide patient and family members with written material on coping with depression.
5. Provide patient and family members with information about appropriate community-based programs and support groups. Contact the National Foundation for Depressive Illness (*www.depression.org*).

Evaluation: Expected Outcomes

- Reports improvement in mood and increased interest in daily living.
- Remains free from self-harm.
- Accomplishes ADLs in an independent manner.
- Obtains a minimum of 5 hours of uninterrupted sleep.

Bipolar and Related Disorders

Bipolar disorders, also considered *mood disorders*, include the occurrence of depressive episodes and one or more elated mood episodes. An elated mood can include a range of affect, from normal mood to hypomania to mania. In the most intense presentation, the person with bipolar disorder experiences altered thought processes, which can produce bizarre delusions.

Pathophysiology and Etiology

Genetic Factors

1. Twin studies reveal a concordance rate of 65% in monozygotic twins for bipolar disorder.
2. Risk of developing bipolar disorder is increased 4% to 24% in first-degree relatives of people with bipolar disorder.
3. Current research indicates that defective genes located within chromosomes 18 and 21 may be related to bipolar disorder.

Biochemical Factors

1. Patients with bipolar disorders may have lower plasma norepinephrine, urinary MHPG, and platelet serotonin uptake and higher red blood cell/plasma lithium rates than do unipolar populations.
2. Pathology of the limbic system, basal ganglia, and hypothalamus is proposed to contribute to the development of mood disorders.

Psychosocial Factors

1. Psychosocial stressors appear to have an important role early in the illness, in concert with the electrical kindling and behavioral sensitization models.
2. Mania and hypomania have been viewed by psychoanalytic theorists as a defense against depression.

Clinical Manifestations

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Mood disorders are often characterized by varying degrees of mania that can alternate with periods of depression. The distinguishing characteristic between forms of bipolar disorder is the degree of mania, with or without the signs of depression. Mania is an elevation of mood that persists for at least 1 week.

Bipolar I Disorder

1. Physical examination and history findings for bipolar I disorder are the presence of a single manic episode generally without the individual also meeting the criteria for a major depressive episode.

2. Severity of the disorder can be classified mild, moderate, or severe depending on the number of symptoms present.
3. A mixed episode refers to the symptoms of mania and depression coexisting across the course of 1 week.
4. Mania is characterized by a cluster of at least three symptoms across the course of at least 1 week that result in a disruption in daily function. These behaviors can include the following:
   a. Excessive or pressured speech.
   b. Difficulty in maintaining concentration or focus.
   c. A reduced need for sleep and an increase in either goal-directed or pleasure-seeking behaviors.

Bipolar II Disorder

1. In bipolar II disorder, there has been an episode of hypomania along with an episode of major depression.
2. Hypomania is a less intense form of mania (increased energy does not result in significant changes in functional ability) with duration of at least 4 days, but less than a week.

Cyclothymic Disorder

1. A chronic alteration in mood that persists over a 2-year period of time during which there are several episodes of hypomania and depressed mood but no episodes of major depression.
2. In children and adolescents, a 1-year time frame is used.
3. During the course of the 2 years, symptoms cannot have abated for more than 2 months.

Diagnostic Evaluation

1. Rating scale assessment tools:
   a. Young Mania Rating Scale.
   b. Manic State Rating Scale.
2. There appear to be no laboratory features that distinguish major depressive episodes found in major depressive disorder from those in bipolar I or bipolar II disorder.
3. Complete psychophysiologic examination.
4. Complete assessment to rule out medical conditions.

Management

EVIDENCE BASE Fountoulakis, K. N., Lakshmi, Y., Grunze, H., Vieta, E., et al. (2017). The International College of Neuro-Psychopharmacology (CINP) Treatment Guidelines for Bipolar Disorder in Adults (CINP-BD-2017), Part 2: Review, Grading of the Evidence, and a Precise Algorithm. *International Journal of Neuropsychopharmacology, 20*(2), 121–179.

---

1. Patients may receive treatment in acute inpatient psychiatric hospitals or in the community in an outpatient program. The decision about treatment setting is made according to severity of patient's illness, including degree of mania or depression as well as risk of self-harm or harm to others.
2. Inpatient treatment is directed toward drug management as well as supportive psychotherapy to alleviate the acute manic symptoms.
3. Pharmacologic treatment for acute mania and bipolar disorder consists of:
   a. Lithium carbonate.
   b. Anticonvulsants, such as carbamazepine and valproate, for mood-stabilizing properties.
   c. Neuroleptic agents, such as risperidone, for acute psychotic thinking.
   d. Benzodiazepines, such as clonazepam or lorazepam, for acute agitation.
   e. Combination therapies, often incorporating an antipsychotic (perphenazine or olanzapine) along with an antidepressant (amitriptyline or fluoxetine). Another approach involves combining a benzodiazepine (chlordiazepoxide) with an antidepressant (amitriptyline) to combat comorbid depression and anxiety.
4. Psychotherapy is used as described above in the section related to depression.
5. Psychiatric home care nursing to facilitate compliance with drugs and therapeutic interventions.
6. Community-based support group participation.

DRUG ALERT Patients taking lithium can develop toxicity related to elevated levels in the blood; therefore, lithium blood levels must be monitored periodically. Initial therapy requires daily monitoring until a safe, therapeutic level is attained; weekly and then monthly monitoring is then recommended. Lithium toxicity is related to decreased serum sodium levels and inadequate hydration. Therefore, patients taking lithium must have normal sodium intake and drink 2 L of water daily.

Complications

1. Untreated bipolar disorder can lead to physical exhaustion.
2. Poor judgment and risk-taking behavior can lead to financial problems.
3. Alcohol and drug abuse problems can develop and cause disruption in the family.
4. Concurrent medical conditions may be exacerbated.

Nursing Assessment

1. Assess mood for stability; range of affect, from elation to irritability to severe agitation; laughing, joking, and talking continuously; uninhibited familiarity with interviewer.
2. Assess behavior for constant activity, starting many projects but finishing few, mild to severe hyperactivity, spending large sums of money, increased appetite, indiscriminate sexual behavior, minimal to no sleeping, outlandish or bizarre dress, poor concentration.

3. Assess thought processes for flight of ideas; pressured speech, usually with content that is sexually explicit; clang associations (sound of word, rather than its meaning, directs subsequent associations); delusions; hallucinations.

Nursing Diagnoses

- Ineffective Impulse Control related to biological changes as demonstrated by agitation, hyperactivity, and inability to concentrate.
- Disturbed Sleep Pattern related to hyperactivity and perceived lack of need for sleep.
- Compromised Family Processes related to role changes, economic strain, and lack of knowledge about patient's illness.
- Imbalanced Nutrition: Less than Body Requirements related to hyperactivity.

Nursing Interventions

Improving Impulse Control and Decreasing Disturbed Thoughts

1. Assess patient's degree of distorted thinking.
2. Redirect patient when you are unable to follow thought processes.
3. Use brief explanations.
4. Remain consistent in approach and expectations.
5. Frequently orient patient to reality; speak in a clear, simple manner.
6. Provide patient with a relaxing area with decreased environmental stimulation.
7. Assist patient with a gradual and progressive integration into the social environment while observing for behavioral changes that indicate readiness for participation in further activities.

Improving Sleep Pattern

1. Establish a distraction-free environment at bedtime.
2. Help patient avoid the intake of caffeine and nicotine.
3. Administer prescribed drugs, as ordered, and monitor patient's response.

Improving the Effect of Bipolar Illness on Family

1. Assess family's external support network and encourage participation in family therapy and support groups.
2. Assess communication and boundaries within family.
3. Observe and assess interaction patterns within family and discuss their influence on patient and family functioning.
4. Provide patient and family with information about bipolar disorder and the treatment plan, prognosis, and aftercare plan.

Ensuring Adequate Nutrition

1. Maintain accurate documentation of food and fluid intake.

2. Offer small, frequent meals of high-calorie foods. Include foods that patient likes and that can be eaten "on the move."
3. Serve patient meals in a low-stimulus environment.
4. Monitor patient's serum electrolyte and albumin levels and weigh patient every other day.
5. Monitor patient's vital signs.

Family Education and Health Maintenance

1. Instruct patient and family about bipolar illness, including symptoms of relapse.
2. Instruct patient and family members about psychopharmacologic treatment, including its purpose, effects, adverse effects, and management.
3. Advise patient and family members about community-based support groups or health care agencies that are relevant to his or her care.
4. For additional information, refer them to such organizations as the National Association on Mental Illness (*www.nami.org*).

Evaluation: Expected Outcomes

- Improved thought processes demonstrated by clear sentences with no evidence of flight of ideas and completion of simple tasks.
- Sleeps for at least 5 hours at night.
- Family members verbalize realistic, goal-directed thinking related to patient's abilities, recovery, and control of condition.
- No weight loss noted.

THOUGHT DISTURBANCES (PSYCHOTIC DISORDERS)

Schizophrenia, Schizophreniform, and Delusional Disorders

Schizophrenia, schizophreniform, and delusional disorders are conditions in which there is a disruption of thought process and/or perception. These conditions are often defined by the presence of psychotic symptoms. Psychotic symptoms are produced by a loss of ego boundaries or a gross impairment in reality testing, which includes prominent hallucinations and delusions, disorganized speech, and grossly disorganized or catatonic behavior. Schizophrenia can be classified as having positive or negative symptoms, although most patients have a mixture. The positive symptoms include hallucinations, delusions, loose associations, and bizarre or disorganized behavior. The negative symptoms include restricted emotion (flat affect), anhedonia (lack of interest in pleasurable activities), avolition (lack of motivation or initiative), alogia (lack of speech or content), and social withdrawal.

Pathophysiology and Etiology

The exact cause of these disorders remains unclear. The current consensus is that they result from complex interactions among various factors.

Schizophrenia, Schizophreniform Disorder

1. Genetic factors:
    a. Studies of monozygotic twins reveal a 50% concordance rate with a 15% rate with dizygotic twins.
    b. If one parent is affected with schizophrenia, a 12% rate is demonstrated in the children, while having two parents with the disorder increases the risk to 35% to 39%.
    c. Research is focused on a number of different genes that may be related to the development of schizophrenia. An increased risk of schizophrenia is seen in individuals with genetic variation in the catechol-*O*-methyltransferase gene, which is involved in the manufacture of an enzyme that metabolizes neurotransmitters. Other current candidate genes include GRM3, DISC1, dysbindin, and neuregulin.
2. Biochemical and structural brain factors:
    a. Dopamine hypothesis—hyperactivity in the dopaminergic system, possibly because of receptor neurons that are functionally hyperactive.
    b. Norepinephrine, serotonin, glutamate, and GABA may also play a role in modulating the symptoms of schizophrenia.
    c. Endogenous dysfunction of *N*-methyl-D-aspartate receptor–mediated neurotransmission could lead to the development of schizophrenia.
    d. Neuroanatomic studies—cerebral ventricular enlargement; sulcal enlargement; cerebellar atrophy; decreased cranial, cerebral, and frontal size; abnormalities in basal ganglia; structural abnormalities at the cellular level, particularly in the limbic and periventricular regions.
    e. Functional and metabolic studies—regional cerebral blood flow studies demonstrated hypofrontality: schizophrenic patients were unable to increase blood flow to their frontal lobes during a task thought to increase frontal lobe functions; PET studies also consistently found evidence for a relative

hypofrontality.

f. Electrophysiologic studies—EEG findings in schizophrenic patients demonstrated decreased alpha and increased delta activity; changes in evoked potential studies and amplitude reduction may occur in responses reflecting selective attention and stimulus evaluation. P300 response (reduced amplitude to unexpected stimuli using auditory and visual parameters) is the most pronounced and is prolonged. This defect leads to information or sensory overload and an inability to "screen out" irrelevant stimuli.

g. Research evidence supports speculation that schizophrenia is a neurodevelopmental disorder that may result from brain injury occurring early in life and interfering with normal developmental events.

3. Psychosocial factors:

a. Psychodynamic theory proposes that the essential feature of schizophrenia is a defect in interpersonal relationships because of a withdrawal of the libido into the self.

b. Interpersonal theory proposes that the lack of a warm, nurturing relationship in the early years of life contributes to the lack of self-identity, reality misperception, and relationship withdrawal that is apparent in the disorder.

c. Family theory related to the role of the family in the development of schizophrenia has not been validated by research. An area of family functioning that has been implicated is increased relapse risks in families characterized by high expressed emotion. This characteristic is described as emotional overinvolvement along with hostile and critical feedback.

Delusional Disorder

1. Little has been established about the etiology of delusional disorder.
2. There is no demonstrated genetic linkage.
3. It is possible that psychosocial stressors have a role in the etiology of delusional disorder in some people. This is illustrated in some of the rarer conditions such as shared psychotic disorder.

Clinical Manifestations

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Thought disorders are characterized by the appearance of positive and negative symptomatology. Positive symptomatology refers to the presence of delusions or hallucinations, whereas negative is the lack of personality traits that should normally be present. A lack of affect, interest in daily activities, and an inability to attend to daily hygiene or self-care reflect negative symptomatology. Distinguishing between the various thought disorders requires careful attention to the presence and duration of positive and negative symptomatology. As with other psychiatric disorders, the symptoms must be severe enough to alter daily function.

Schizophrenia

Previously schizophrenia was classified into five different forms. Currently, for diagnosis, the individual must display at least one positive symptom.

1. Positive symptoms include delusional thinking, disorganized speech, and hallucinations.
2. Symptoms must be present for at least 1 month with a total duration of illness for a period of at least 6 months. The 6-month period may include periods of active symptoms and remission.
3. Symptoms must lead to a significant disruption of the individual's ability to function in social or social settings, or impact ability to attend ADLs.
4. The diagnosis may indicate whether this is an acute episode or if the individual is in remission.
5. Severity can be rated on a five-point scale from zero to four. A rating of four would indicate the presence of severe and active symptoms, while a zero indicates that symptoms are not currently present.

Schizophreniform Disorder

1. The primary difference between schizophreniform disorder and schizophrenia is a period of symptom duration of less than 6 months but more than 1 month.
2. Those with this disorder can appear schizophrenic with the presence of positive and/or negative symptomatology.
3. Diagnostic criteria include delusions, hallucinations, and patterns of disorganized behavior or speech along with negative symptoms.

Schizoaffective Disorder

1. A psychiatric condition in which there is a comorbid thought and mood disorder.
2. Those with this disorder may display signs and symptoms of depression or mania along with the positive and negative symptoms of schizophrenia.

Other Psychotic Disorders

1. Delusional disorders encompass nonbizarre delusions of at least 1 month's duration but no positive or negative symptoms of schizophrenia present.
2. Psychotic disorder because of a general medical disorder contains prominent hallucinations that may last longer than the course of the underlying disorder.
3. Brief psychotic disorders contain one or more of the following: delusions, disorganized speech, grossly disorganized or catatonic behavior, hallucinations. Duration is at least 1 day and less than 1 month, then return to previous level of functioning.
4. Shared psychotic disorder occurs in an individual with an already established delusion who develops another delusion similar to another's in the context of a close relationship with that person.
5. Substance-induced psychotic disorder contains prominent hallucinations and delusions associated with substance intoxication or withdrawal but not exclusively during the course of underlying drug use.

Diagnostic Evaluation

1. Clinical diagnosis is developed on historical information and thorough mental status examination.
2. No laboratory findings have been identified that are diagnostic of schizophrenia.
3. Routine battery of laboratory tests may be useful in ruling out possible organic etiologies, including CBC, urinalysis, liver function tests, thyroid function tests, RPR, HIV test, serum ceruloplasmin (rules out an inherited disease, Wilson disease, in which the body retains excessive amounts of copper), PET scan, CT scan, and MRI.
4. Rating scale assessment:
   a. Scale for the Assessment of Negative Symptoms.
   b. Scale for the Assessment of Positive Symptoms.
   c. Brief Psychiatric Rating Scale.

Management

EVIDENCE BASE Samara, M. T., Dold, M., Gianatsi, M., et al. (2016). Efficacy, acceptability, and tolerability of antipsychotics in treatment-resistant schizophrenia: A network meta-analysis. *JAMA Psychiatry, 73*(3), 199–210.

Schizophrenia and Schizophreniform Disorder

1. Patients may receive treatment in inpatient settings or in community-based outpatient programs or psychiatric home care. The level of care depends on the severity of symptoms and the risk of harm to self and others.
2. These disorders generally require long-term treatment; therefore, a case management approach is important to coordinate multiple services.
3. Pharmacologic therapy with either the typical or atypical neuroleptics (antipsychotics) is the mainstay of treatment (see Table 57-3, page 1485).
   a. The typical neuroleptics have multiple adverse effects that require careful management (see Table 57-4, page 1486).
   b. The atypical neuroleptics have fewer adverse effects and may also be more effective in decreasing the negative symptoms of schizophrenia.
   c. Pharmacologic therapy with both the typical and atypical neuroleptics can include the use of long-lasting, or depot, injections. The use of such injections is increasing. Five drugs are currently available in depot formulations, haloperidol, fluphenazine, olanzapine, paliperidone, and risperidone.
4. Psychosocial treatments (social skills training, ADL instruction).
5. Supportive therapy that is reality oriented and pragmatic.
6. Family therapy.
7. Psychoeducational individual, group, and family support.

8. Support groups in the community.
9. Community-based partial hospitalization programs.
10. Psychiatric home care nursing.
11. Vocational and social skills education.

Table 57-3 Dosage and Adverse Reactions of Antipsychotic Drugs

DRUG: CLASS/GENERIC/ TRADE NAME	ADULT THERAPEUTIC DOSAGE RANGE (MG/DAY)	ADVERSE REACTIONS
Butyrophenone		
Haloperidol	2–40 mg	Extrapyramidal adverse effects are common. Decreased incidence of orthostatic hypotension as compared with phenothiazines
Aliphatic Phenothiazine		
Chlorpromazine	30–800 mg	Orthostatic hypotension, sedation, dry mouth, extrapyramidal adverse effects, agranulocytosis, ocular changes
Piperidine Phenothiazine		
Thioridazine	200–800 mg	Sedation, orthostatic hypotension, fewer extrapyramidal symptoms than other phenothiazines
Piperazine Phenothiazine		
Fluphenazine Perphenazine Trifluoperazine	2.5–40 mg 8–64 mg 15–40 mg	Extrapyramidal symptoms and lower incidence of orthostatic hypotension than with other phenothiazines
Dibenzoxazepine		
Loxapine	60–250 mg	Extrapyramidal adverse effects, hypotension, dizziness
Thioxanthene		
Thiothixene	20–60 mg	Extrapyramidal adverse effects, hypotension, tachycardia, insomnia
Atypical Antipsychotics		Extrapyramidal adverse effects can occur with the use of any of the atypical antipsychotics, although the incidence of occurrence usually is less than that seen with other classes of antipsychotic medications
Aripiprazole	10–30 mg	Headache, anxiety, insomnia, nausea, vomiting, dizziness, and drowsiness
Asenapine	10–20 mg	Extrapyramidal adverse effects, drowsiness, oral hypoesthesia, weight gain
Clozapine	150–600 mg (requires careful titration)	Seizure, agranulocytosis (obtain weekly white blood cell count), hypotension, tachycardia, cardiac dysrhythmia, drowsiness, sedation, increased salivation
Iloperidone	12–24 mg	Extrapyramidal adverse effects, orthostatic hypotension, weight gain
Lurasidone	40–160 mg	Extrapyramidal adverse effects primarily akathisia and pseudoparkinsonism, nausea, somnolence
Olanzapine	5–20 mg	Orthostatic hypotension, tachycardia, drowsiness, agitation, akathisia, constipation
Paliperidone	3–6 mg	Extrapyramidal adverse effects, tremor, muscle stiffness
Pimozide	1–10 mg	Orthostatic hypotension, tachycardia, drowsiness, sedation, akathisia, akinesia
Quetiapine	200–800 mg	Orthostatic hypotension, tachycardia, drowsiness, dizziness, dry mouth
Risperidone	4–16 mg	Orthostatic hypotension, tachycardia, drowsiness, dizziness, dry mouth
Ziprasidone	20–80 mg	Dysrhythmia, drowsiness, dizziness, nausea, restlessness, constipation

Table 57-4 Management of Adverse Effects of Neuroleptic Drugs

SYMPTOM	MANAGEMENT
Orthostatic Hypotension	Assess for orthostatic blood pressure changes and dizziness and teach the patient: • When rising from bed or chair, get up slowly. • Sit at side of bed for a few minutes, dangling legs. • Do ankle pumps before standing. • Once standing, move slowly. • Do not twist or turn quickly. • Use assistive devices, hand rails, canes, walkers when necessary for functional deficits. • Do not drive or operate machinery when dizzy.
Peripheral Anticholinergic Effects	
Dry mouth and nose, blurred vision, constipation, urine retention	*Dry mouth:* • Brush teeth after each meal with a fluoridated toothpaste. • Rinse mouth frequently. • Limit caffeinated or alcoholic drinks because they can be dehydrating. • Stop smoking because of the irritation of oral mucosa. • Suck on sugarless candy or gum; avoid sugared candy to decrease the risk of fungal infections and dental caries. • Avoid dry or spicy foods. • Drink fluids between meals unless on a specific fluid restriction. • Avoid acidic beverages because of potential irritation. • Use dressing, juices, or sauces (if allowed) to moisten food. *Constipation:* • Drink fluids (within prescribed limits set by health care provider). • Eat roughage: fruits, vegetables (raw leafy types) to increase bulk and help soften stool. • Eat dried fruits, such as prunes or dates, for laxative effect. • Maintain activity level within functional limits. • Consult with health care provider to determine appropriate use of over-the-counter laxatives or stool softeners. *Urine retention:* • Void at regular intervals. • Ensure privacy.
Extrapyramidal Adverse Effects	
Short term	
Akathisia: restless legs, jitters, nervous energy, motor agitation	• Reassure patient. • Differentiate between agitation and akathisia. • Consider reducing dosage. • Consider switching patient to another class of antipsychotic.
Akinesia: weakness (hypotonia), fatigue, painful muscles, anergy (lack of energy), absence of movement	• Assess functional ability. • Dose reduction or cessation should improve movement if problems are due to akinesia vs. psychotic symptoms.
Dystonias, dyskinesias: grimacing, torticollis, intermittent spasms, opisthotonos, oculogyric crises, head-neck stiffness, myoclonic twitches, laryngeal–pharyngeal dystonia	• Consider prophylaxis with anticholinergic medications. • Treat with IM or IV anticholinergics, as prescribed.
Parkinsonian effects: muscle stiffness, cog wheel rigidity, shuffling gait, stooped posture, drooling	• Treat with anticholinergics, as prescribed. • Stop the antipsychotic, as directed.
Long term	
Tardive dyskinesia: a delayed effect of neuroleptic drugs usually occurring after 6 months of treatment involving abnormal, involuntary, irregular, and choreoathetoid movements of the muscles of the head, limbs, and trunk	• Complete regular objective rating/assessment of the movement disorder. • Reduce or stop neuroleptic, as directed. • Consider clozapine or risperidone. • Comprehensive medical psychiatric assessment necessary with close monitoring of movement disorder.

Delusional Disorder

1. Neuroleptic drugs have demonstrated some success in reducing the intensity of the delusion.
2. Individual psychotherapy.
3. Hospitalization for comprehensive assessment for diagnostic purposes or if suicidal or homicidal.

Complications

1. If left undiagnosed, untreated, or ineffectively treated, schizophrenia can lead to profound inability to

function and contributes to the problem of homelessness in our society.

2. Neglect of other medical conditions; therefore, complications because of untreated medical illness are common.
3. Depression and suicide.
4. Substance use, abuse, or dependency.

Nursing Assessment

Assess for positive symptoms of schizophrenia. These symptoms reflect aberrant mental activity and are usually present early in the first phase of the schizophrenic illness.

Alterations in Thinking

1. Delusion—false, fixed belief that is not amenable to change by reasoning. The most frequent elicited delusions include the following:
   a. Ideas of reference.
   b. Delusions of grandeur.
   c. Delusions of jealousy.
   d. Delusions of persecution.
   e. Somatic delusions.
2. Loose associations—the thought process becomes illogical and confused.
3. Neologisms—made-up words that have a special meaning to the delusional person.
4. Concrete thinking—an overemphasis on small or specific details and an impaired ability to abstract.
5. Echolalia—pathologic repeating of another's words.
6. Clang associations—the meaningless rhyming of a word in a forceful way.
7. Word salad—a mixture of words that is meaningless to the listener.

Alterations in Perceiving

1. Hallucinations—sensory perceptions that have no external stimulus. The most common are auditory, visual, gustatory, olfactory, and tactile.
2. Loss of ego boundaries—lack a sense of their body and how they relate to the environment.
   a. Depersonalization is a nonspecific feeling or sense that a person has lost his or her identity or is unreal.
   b. Derealization is the perception by a person that the environment has changed.

Alterations in Behavioral Responses

1. Bizarre behavioral patterns.
   a. Motor agitation and restlessness.
   b. Automatic obedience or robot-like movement.
   c. Negativism.

d. Stereotyped behaviors.
e. Stupor.
f. Waxy flexibility (allowing another person to reposition extremities).

2. Agitated or impulsive behavior.
3. Negative symptoms of schizophrenia that reflect a deficiency of mental functioning.
   a. Alogia—lack of speech.
   b. Anergia—inability to react.
   c. Anhedonia—inability to experience pleasure.
   d. Avolition—lack of motivation or initiation.
   e. Poor social functioning.
   f. Poverty of speech.
   g. Social withdrawal.
   h. Thought blocking.
4. Associated symptoms of schizophrenia.
   a. Substance use, abuse, or dependence.
   b. Depression.
   c. Fantasy.
   d. Violent or aggressive behavior.
   e. Water intoxication.
   f. Withdrawal.

Nursing Diagnoses

- Acute Confusion related to perceptual and cognitive distortions, as demonstrated by suspiciousness, defensive behavior, and disruptions in thought.
- Social Isolation related to an inability to trust.
- Activity Intolerance related to adverse reactions to psychopharmacologic drugs.
- Ineffective Coping related to misinterpretation of environment and impaired communication ability.
- Risk for Self-Directed or Other-Directed Violence related to delusional thinking and hallucinatory experiences.

Nursing Interventions

Strengthening Differentiation Between Delusions and Reality

1. Provide patient with honest and consistent feedback in a nonthreatening manner.
2. Avoid challenging the content of patient's behaviors.
3. Focus interactions on patient's behaviors.
4. Administer drugs, as prescribed, while monitoring and documenting patient's response to the drug

regimen.

5. Use simple and clear language when speaking with patient.
6. Explain all procedures, tests, and activities to patient before starting them, and provide written or video material for learning purposes.

Promoting Socialization

1. Encourage patient to talk about feelings in the context of a trusting, supportive relationship.
2. Allow patient time to reveal delusions to you without engaging in a power struggle over the content or the reality of the delusions.
3. Use a supportive, empathic approach to focus on patient's feelings about troubling events or conflicts.
4. Provide opportunities for socialization and encourage participation in group activities.
5. Be aware of patient's personal space and use touch judiciously.
6. Help patient to identify behaviors that alienate significant others and family members.

Improving Activity Tolerance

1. Assess patient's response to prescribed antipsychotic drug.
2. Collaborate with patient and occupational and physical therapy specialists to assess patient's ability to perform ADLs.
3. Collaborate with patient to establish a daily, achievable routine within physical limitations.
4. Teach strategies to manage adverse effects of antipsychotic drug that affect patient's functional status, including:
    a. Change positions slowly.
    b. Gradually increase physical activities.
    c. Limit overdoing it in hot, sunny weather.
    d. Use sun precautions.
    e. Use caution in activities if extrapyramidal symptoms develop.

Improving Coping with Thoughts and Feelings

1. Encourage patient to express feelings.
2. Focus on patient's feelings and behavior.
3. Provide honest perceptions of reality and feedback about symptoms and behaviors.
4. Encourage patient to explore adaptive behaviors that increase abilities and success in socializing and accomplishing ADLs.
5. Decrease environmental stimuli.

Ensuring Safety

1. Monitor patient for behaviors that indicate increased anxiety and agitation.
2. Collaborate with patient to identify anxious behaviors as well as the causes.

3. Tell patient that you will help with maintaining behavioral control.
4. Establish consistent limits on patient's behaviors and clearly communicate these limits to patient, family members, and health care providers.
5. Secure all potential weapons and articles from patient's room and the unit environment that could be used to inflict an injury.
6. To prepare for possible continued escalation, form a psychiatric emergency assist team and designate a leader to facilitate an effective and safe aggression management process.
7. Determine the need for external control, including seclusion or restraints. Communicate the decision to patient and put plan into action.
8. Frequently monitor patient within the guidelines of facility's policy on restrictive devices and assess patient's level of agitation.
9. When patient's level of agitation begins to decrease and self-control is regained, establish a behavioral agreement that identifies specific behaviors that indicate self-control against a reescalation of agitation.

Community and Home Care Considerations

1. Patients with these disorders may be in supportive housing, such as transitional living halfway houses, foster homes, and board and care homes. Supervision and drug management are important areas of concern for the nurse working in the community.
2. Psychosocial rehabilitation approach may be used in the community setting, where skills necessary for independent living are taught. Patient who has been symptomatic since early adulthood may not have learned these skills. The nurse working in the community setting may work as a member of the treatment team using this approach.

Family Education and Health Maintenance

1. Instruct patient and family members in disease process and how to recognize and cope with relapse symptoms.
2. Instruct patient and family members about the uses, actions, and adverse effects of prescribed drugs.
3. Provide instruction on when to notify primary care provider regarding adverse drug effects or increased disease symptomatology.
4. Instruct patient and family about community resources, support groups, and possible use of psychiatric home care nursing.
5. For additional information and support, refer patient and family to such agencies as the Brain and Behavior Research Foundation (*www.bbrfoundation.org*) or *Schizophrenia.* The National Alliance on Mental Illness *www.nami.org* has a 24 hour helpline 800-950-6264.

Evaluation: Expected Outcomes

- Exhibits improved reality orientation, concentration, and attention span, as demonstrated through speech and behavior.

- Communicates with family and staff in a clear manner without evidence of loose, dissociated thinking.
- Independently maintains personal hygiene without fatigue.
- Attends group activities.
- Remains free from harm or violent acts.

NEUROCOGNITIVE DISORDERS

Delirium, Dementia, and Amnestic Disorders

Neurocognitive disorders reflect states where cognitive impairment is the primary issue. This category encompass specific disorders that produce either temporary or permanent neuronal damage, resulting in psychological or behavioral dysfunction, such as delirium, dementia, and amnestic disorder, as described in DSM-5. Although dementia is recognized as a term reflecting chronic disruption, the preferred diagnosis is neurocognitive disorder.

Delirium is an acute disturbance of consciousness and a change in cognition that develops over a brief period and is often reversible. *Dementia or neurocognitive disorder* is a chronic, progressive disturbance involving multiple cognitive deficits, including memory impairment. Impairment can be classified as mild or major based on degree of cognitive decline and whether symptoms interfere with daily function. For major neurocognitive disorder, symptoms must interfere with the ability of the individual to be independent in ADLs. *Amnestic disorder* is characterized by memory impairment in the absence of other significant cognitive impairments.

Pathophysiology and Etiology

Delirium

Can be caused by numerous pathophysiologic conditions. Some of the major possibilities include the following:

1. CNS pathology: head trauma, hypertensive cerebral changes, seizures, tumors.
2. Endocrinopathies: hyper- or hypothyroidism, hyper- or hypoparathyroidism.
3. Hypoxemia.
4. Hypothermia or hyperthermia.
5. Substance intoxication or abstinence and withdrawal states.
6. Exposure to certain metals, toxins, or drugs.
7. Metabolic: diabetic acidosis, hypoglycemia, acid–base imbalances.
8. Hepatic encephalopathy.
9. Thiamine deficiency.
10. Postoperative states.
11. Psychosocial stressors: relocation stress, sensory deprivation or overload, sleep deprivation, immobilization.

Mild or Major Neurocognitive Disorder (Dementia)

1. Neurodegenerative Disease—psychotic features may occur.
    a. Alzheimer disease.
    b. Lewy body disease.
    c. Vascular disease.
2. Infection-related dementias.

a. Acquired immunodeficiency syndrome.
b. Chronic meningitis.
c. Creutzfeldt-Jakob disease.
d. Progressive multifocal leukoencephalopathy.
e. Postencephalitic dementia syndrome.
f. Syphilis.
g. Subacute sclerosing panencephalitis.
h. Tuberculosis.

3. Subcortical degenerative disorders.
   a. Huntington disease.
   b. Parkinson disease.
   c. Wilson disease.
   d. Thalamic dementia.
4. Hydrocephalic dementias.
5. Vascular dementias.
6. Traumatic conditions, such as posttraumatic encephalopathy and subdural hematoma.
7. Neoplastic dementias.
   a. Glioma.
   b. Meningioma.
   c. Meningeal carcinomatosis.
   d. Metastatic deposits.
8. Inflammatory conditions, such as sarcoidosis, systemic lupus erythematosus, and temporal arteritis.
9. Toxic conditions, such as alcohol-related syndrome and iatrogenic dementias (anticonvulsant, anticholinergic, antihypertensive, psychotropic drugs).
10. Metabolic disorders.
    a. Anemias.
    b. Deficiency states (minerals and vitamins).
    c. Cardiac or pulmonary failure.
    d. Hepatic encephalopathy.
    e. Porphyria (deficiency in enzymes involved in heme synthesis).
    f. Uremia.
11. Genetic factors:
    a. Familial Alzheimer disease is associated with abnormal genes on chromosomes 1, 14, and 21, particularly with genes located on these chromosomes (1 and 14) that encode for amyloid precursor protein, which leads to accumulation of the amyloid beta-peptide in plaques.
    b. A specific cholesterol-bearing protein, apolipoprotein E4 (Apo E4), is found on chromosome 19

twice as often in people with Alzheimer's disease as in the general population.

12. Biochemical and brain structural factors:
    a. The neurotransmitter acetylcholine has been implicated in terms of relative deficit or receptor abnormalities as related to Alzheimer disease.
    b. Autopsy findings reveal presence of brain changes, that is, the presence of amyloid plaques and neurofibrillary tangles associated with nerve cell destruction.
    c. Additional areas of investigation include the following:
        i. Slow viral infection.
        ii. Autoimmune processes.
        iii. Head trauma.

Amnestic Disorder

1. Posttraumatic amnesia: head trauma is the most common cause of amnesia.
2. Poststroke amnesia: damage to the fornix or hippocampus.
3. Neoplasms.
4. Anoxic states.
5. Herpes simplex encephalitis.
6. Hypoglycemic states.
7. Epileptic seizures.
8. Electroconvulsive therapy.
9. Substance induced.

Clinical Manifestations

See Table 57-5.

Table 57-5 Clinical Manifestations of Neurocognitive Disorders

DISORDER	CLINICAL MANIFESTATIONS
Delirium	
(severe impairment in functioning)	• Fluctuating levels of awareness • Clouding of consciousness (confused and disoriented) • Perceptual disturbances (illusions and hallucinations) • Memory, especially recent memory, is disturbed • Alteration in sleep–wake cycle • EEG changes • Abrupt onset may last about 1 week • Reversible when underlying cause has been treated
Dementia (Neurocognitive Disorder)	
(severe impairment in functioning)	• Slow, insidious onset • Impaired long- and short-term memory • Deterioration of cognitive abilities—judgment, abstract thinking • Often irreversible, based on cause • Personality changes • No or slow EEG changes
Amnestic Syndrome	
(moderate to severe impairment in functioning)	• Impairment in short- and long-term memory • Inability to learn new material • Remote memory better than that of recent events • Confabulation • Apathy, lack of initiative • Emotionally bland

Diagnostic Evaluation

Various diagnostic tests may be done to determine the cause. A comprehensive neuropsychiatric evaluation must be completed to make an accurate diagnosis.

1. Basic laboratory examination, including CBC with differential, chemistry panel (including blood urea nitrogen, creatine, and ammonia), arterial blood gas values, chest x-ray, toxicology screen (comprehensive), thyroid function tests, and serologic tests for syphilis.
2. Additional tests may include CT scan, MRI, additional blood chemistries (heavy metals, thiamine, folate, antinuclear antibody, and urinary porphobilinogen), lumbar puncture, PET/single photon emission CT scans.
3. Complete mental status examination.
4. Comprehensive physical examination.

Management

EVIDENCE BASE Theleritis, C., Siarkos, K., Katirtzoglou, E., & Politis, A. (2016). Pharmacological and nonpharmacological treatment for apathy in Alzheimer disease. *Journal of Geriatric Psychiatry and Neurology, 30*(1), 26–49.

Delirium

1. Treatment generally occurs in acute hospital-based setting where the goal is diagnosis to identify specific reversible causes of the delirium so that treatment is focused on ameliorating the causative factors.
2. Pharmacologic therapy is dependent on underlying causes. Additional drugs may be used that are directed toward the reduction of the acute symptoms of delirium. These include the following:
   a. Benzodiazepines, such as lorazepam, for substance withdrawal states.
   b. Neuroleptics, such as risperidone and haloperidol, for agitation.
   c. Combined administration of haloperidol and lorazepam for agitated and psychotic symptomatology.
3. Environmental management:
   a. Safe, structured environment.
   b. Orientation facilitated by clocks, calendars, and other visual cues.
4. Family teaching about the nature of the disorder.
5. Family participation in the treatment plan to assist in the management of behavior.

Dementia

1. Treatment is generally community focused; the goal of treatment is to maintain the quality of life as long as possible despite the progressive nature of the disease. Effective treatment is based on:
   a. Diagnosis of primary illness and concurrent psychiatric disorders.
   b. Assessment of auditory and visual impairment.
   c. Measurement of the degree, nature, and progression of cognitive deficits.
   d. Assessment of functional capacity and ability for self-care.
   e. Family and social system assessment.
2. Environmental strategies to assist in maintaining the safety and functional abilities of patient as long as possible.
3. Pharmacologic therapy used for the person with Alzheimer disease is directed toward the use of anticholinesterase drugs to slow the progression of the disorder by increasing the relative amount of acetylcholine. Available drugs include donepezil, galantamine, and rivastigmine. An NMDA receptor antagonist memantine may be provided in an attempt to improve cognition (see Table 57-6). Other drugs may be used for behavioral control and symptom reduction.
   a. Agitation management: neuroleptic drugs.
   b. Psychosis: neuroleptic drugs.
   c. Depression: select antidepressants such as citalopram, duloxetine, escitalopram, fluoxetine,

fluvoxamine, paroxetine, and mirtazapine; ECT.

4. Hypertension management in vascular dementia is important in reducing the severity of symptoms.
5. Family education is a treatment strategy because statistics indicate that family caregivers provide care for patients with Alzheimer disease in 7 out of 10 cases. The family and the treatment team collaborate in the delivery of care.

Table 57-6 Dosage and Adverse Reactions of Drugs used in the Treatment of Dementia

DRUG: CLASS/GENERIC/TRADE NAME	ADULT THERAPEUTIC DOSAGE RANGE (MG/DAY)	ADVERSE REACTIONS
Cholinesterase Inhibitors		
Donepezil	10–23 mg	Nausea, diarrhea, anorexia, fatigue
Galantamine	8–24 mg	Nausea, diarrhea, dizziness, fatigue
Rivastigmine	6–12 mg	Nausea, vomiting, anorexia, dizziness
NMDA Receptor Antagonist		
Memantine	10–20 mg	Fatigue, dizziness, headache

Complications

1. Without accurate diagnosis and treatment, dementia resulting from another disease states may result in permanent cognitive deficits.
2. Falls with serious orthopedic or cerebral injuries.
3. Self-inflicted injuries.
4. Aggression or violence toward self, others, or property.
5. Wandering events, in which the person can get lost and potentially suffer exposure, hypothermia, injury, and even death.
6. Serious depression is demonstrated in caregivers who receive inadequate support.
7. Caregiver stress and burden may result in patient neglect or abuse.

Nursing Assessment

See Table 57-7.

Table 57-7 Nursing Assessment for Delirium, Dementia, and Amnestic Disorder

	DELIRIUM	DEMENTIA	AMNESTIC DISORDER
Onset	Acute	Slow, insidious	Sudden
Course	Usually brief	Progresses over years	Transient or chronic
Mood	Fearfulness, anxiety, irritability	Mood labile, personality traits accentuated	Apathy, agitation, emotional blandness, shallow range of affective expression
Perception	Auditory, visual, tactile hallucinations; illusions	Hallucinations not a prominent feature	No hallucinatory experiences
Memory	Short-term memory impaired	Short-term memory deficit followed by long-term memory deficit	Impaired ability to learn new information; unable to recall previously learned information or past events
Communication	Slurred speech; confabulation	Normal—early stage: progressive aphasia and confabulation	Confabulation

1. Assess the onset and characteristics of symptoms (determine type and stage of disorder).
2. Establish cognitive status using standard measurement tools.
3. Determine self-care abilities.
4. Assess threats to physical safety (eg, wandering, poor reality testing).

5. Assess affect and emotional responsiveness.
6. Assess ability and level of support available to caregivers.

Nursing Diagnoses

- Impaired Verbal Communication related to cerebral impairment as demonstrated by altered memory, judgment, and word finding.
- Bathing and Dressing Self-Care Deficit related to cognitive impairment as demonstrated by inattention and inability to complete ADLs.
- Risk for Injury related to cognitive impairment and wandering behavior.
- Impaired Social Interaction related to cognitive impairment.
- Risk for Violence: Self-Directed or Other-Directed related to suspicion and inability to recognize people or places.

Nursing Interventions

Improving Communication

1. Speak slowly and use short, simple words and phrases.
2. Consistently identify yourself and address the person by name at each meeting.
3. Focus on one piece of information at a time. Review what has been discussed with patient.
4. If patient has vision or hearing disturbances, have him or her wear prescription eyeglasses or a hearing device.
5. Keep environment well lit.
6. Use clocks, calendars, seasonal decorations, and familiar personal effects in patient's view.
7. If patient becomes verbally aggressive, identify and acknowledge feelings.
8. If patient becomes aggressive, shift the topic to a safer, more familiar one.
9. If patient becomes delusional, acknowledge feelings and reinforce reality. Do not attempt to challenge the content of the delusion.

Promoting Independence in Self-Care

1. Assess and monitor patient's ability to perform ADLs.
2. Encourage decision-making regarding ADLs as much as possible.
3. Label clothes with patient's name, address, and telephone number.
4. Use clothing with elastic and Velcro for fastenings rather than buttons or zippers, which may be too difficult for patient to manipulate.
5. Monitor food and fluid intake.
6. Weigh patient weekly.
7. Provide food that patient can eat while moving.
8. Sit with patient during meals and assist by cueing.

9. Initiate a bowel and bladder program early in the disease process to maintain continence and prevent constipation or urine retention.

Ensuring Safety

1. Discuss restriction of driving when recommended.
2. Assess patient's home for safety: remove throw rugs, label rooms, and keep the house well lit.
3. Assess community for safety.
4. Alert neighbors about patient's wandering behavior.
5. Alert police and have current pictures taken.
6. Provide patient with a MedicAlert bracelet.
7. Install complex safety locks on doors to outside or basement.
8. Install safety bars in bathroom.
9. Closely observe patient while he or she is smoking.
10. Encourage physical activity during the daytime.
11. Give patient a card with simple instructions (address and phone number) in case he or she gets lost.
12. Use nightlights.
13. Install alarm and sensor devices on doors.

Improving Socialization

1. Provide magazines with pictures as reading and language abilities diminish.
2. Encourage participation in simple, familiar group activities, such as singing, reminiscing, doing puzzles, and painting.
3. Encourage participation in simple activities that promote the exercise of large muscle groups.

Preventing Violence and Aggression

1. Respond calmly and do not raise your voice.
2. Remove objects that might be used to harm self or others.
3. Identify stressors that increase agitation.
4. Distract patient when an upsetting situation develops.

Community and Home Care Considerations

1. Multidisciplinary team approach is important, along with collaboration among professionals in nursing, medicine, psychiatry, nutrition, social work, pharmacy, and rehabilitative specialties.
2. Nurses involved in community care need to utilize case-finding approach as well as provide long-term support for family members involved in caregiving.
3. Adult day care and respite care may be utilized to provide the level of care needed by patient as well as allow the family to continue to maintain normal functioning.

Family Education and Health Maintenance

1. Instruct family about the process of the disorder, whether delirium, dementia, or amnestic disorder.
2. Instruct family about safety measures, environmental supports, and effective interventions for common symptoms to provide care in the home.
3. Instruct about and refer family members to community-based groups (adult day care centers, senior assessment centers, home care, respite care, and family support groups).
4. For additional information and support, refer to Alzheimer's Association (*www.alz.org*) or National Institutes of Health, National Institute on Aging, Alzheimer's Disease Education and Referral Center (800-438-4380; *https://www.nia.nih.gov/health/alzheimers*). For information on caregiving tips and advice with referral to local community groups, consult Today's Caregiver (*https://caregiver.com*) or AlzOnline Caregiver Support Online (800-677-1116; *http://alzonline.phhp.ufl.edu*).

Evaluation: Expected Outcomes

- Demonstrates decreased anxiety and increased feelings of security in supportive environment.
- Maintains maximum degree of orientation and self-care within level of ability.
- Safety precautions and close surveillance maintained; no injury.
- Attends group activities; sings, exercises with group.
- Decreased occurrence of acting-out behaviors.

ADDICTION AND SUBSTANCE-RELATED DISORDERS

Substance Use

The use of alcohol and other psychoactive substances has become an endemic problem throughout all levels of society. In terms of substance use, a substance can be defined as a prescribed drug, an illegal drug, or a substance used in an unintended manner to produce mood or mind-altering effect (eg, inhalants, glues, or steroids). Continued substance use may arise unintentionally from the initial use of a substance for its approved purpose. The individual commonly faces not only the psychological ramifications of a substance-related disorder but also physiologic consequences resulting from substance use.

Current criteria for diagnosing substance use disorder recognize elements of abuse and dependence. The criteria reflect dynamics of inability to control use of a substance, use in situations that may put the individual at risk, and a centering of daily activities around the use or obtaining of a substance. These criteria reflect a pattern of use that has led to the development of one or more life problems.

Classification

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

A substance use disorder includes elements of abuse and possible dependence within the criterion. The defining characteristic of a disorder is when there is impairment of ability to perform social roles in the home, school, or work setting. Substance use can occur in relation to use of any of 10 categories of substance: caffeine, tobacco, opioids, alcohol, hallucinogens, sedatives, stimulants, anxiolytics, inhalants, and hypnotics. Additionally, the severity of substance use can be specified as mild, moderate, or severe based on the number of symptoms present.

- Substance (specify) use.
- Substance (specify)-induced disorders.
- Substance (specify) intoxication.

A number of disorders can be induced through the use of a particular substance; in such cases, the symptoms cannot be explained by another condition or disorder and are related to substance use. Such substance-induced disorders include the following:

- Substance-induced intoxication.
- Substance-induced withdrawal.
- Substance or medication-indicated mental disorders.

Dual diagnosis is defined as the presence of a substance-related diagnosis along with another psychiatric disorder.

Pathophysiology and Etiology

As with the development of other psychiatric conditions and disorders, the development of substance-related disorders reflects a complex interaction of biological, genetic, sociologic, and psychological factors. Several theoretical approaches have been developed to describe the process of abuse and dependence.

Biochemical Factors

1. Dopamine is one of the primary neurotransmitters within the CNS and is known to be involved in the integration of environmental stimuli with physiologic responses. Cannabis, cocaine, and alcohol increase the dopamine level, thereby producing a strong association between physiologic effects and behavior.
2. Dopamine is also involved in CNS pathways that mediate feelings of pleasure. Opioids indirectly increase dopamine activity by modulation of the mesolimbic system, leading to reinforcement of substance use.
3. Neurons in the mesolimbic system can become sensitized to the presence of amphetamine and cocaine. Such sensitization is the reverse of tolerance, with the development of an enhanced neuronal response upon repeated exposure. These responses appear to be associated with the development of substance dependence.

Genetic Factors

1. Alcoholism is strongly associated with a familial history of alcoholism. In these individuals, a genetic disposition (attention deficit/hyperactivity disorder [ADHD] allele) to alcoholism combines with a learning environment in which patient develops certain beliefs about the use of a substance and its effects. The presence of genetic disposition, in the absence of parental alcoholism, does not result in a significantly higher risk of alcoholism than in those individuals without such disposition. These findings provide support for models focusing on genetic and environmental interaction in the etiology of substance abuse.
2. Genetic variation in gene regulation resulting in lower levels of serotonin in the CNS may be associated with the development of alcoholism.

Psychosocial Factors

1. An individual learns to use substances in certain situations with certain expectations as to the effects of the substance (eg, relaxation, disinhibition). As the individual experiences the desired effects, this may reinforce the desire to use the substance.
2. Use may begin with an attempt to fit in with a larger peer group as a means of boosting self-esteem.
3. Substances may be used to relieve anxiety or as a means of coping with other traumatic events (self-medication).

Sociocultural Factors

1. Societies around the world use psychoactive substances for a number of reasons. The individual learns the approved use of the substance within the societal or familial structure and may consider such use to be appropriate.

2. The society in which an individual resides may consider dependence on certain substances to be a minor issue, thereby providing a justification for continued use.

Clinical Manifestations

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Overview

1. Substance use disorder is characterized by a loss of control.
2. A pattern of substance use must be sustained over a period of 12 months and impair ADLs.
3. Whether the pattern is one of steady or binge use, activities related to substance use must interfere with daily functioning, in terms of time off work or curtailing of social activities to provide more time to participate in, or recover from, substance use.
4. A differentiating factor between abuse and dependence is that dependence is characterized by the development of tolerance with the appearance of substance-specific withdrawal symptomatology in the absence of use.

TRANSITIONAL CARE ALERT The complications of substance abuse such as injuries and liver disease may be treated in the hospital, but the underlying substance abuse may not be known or addressed by the medical staff. Nurses should monitor for the presence of substance use and withdrawal symptoms during and following hospitalization so that the medical condition does not worsen and appropriate referrals can be made.

Substance Abuse

Physical examination and history findings compatible with substance abuse includes at least one of the following:

1. Continued use even in the face of an inability to meet major life obligations.
2. Use in situations that pose a danger of harm to self or others (ie, driving while intoxicated).
3. Continued use regardless of legal issues associated with use (ie, continued driving while intoxicated after suspension of a license) or continued use after the development of problems in social relationships (ie, an impending divorce brought about by substance use).

Substance Dependence

Physical examination and history findings include meeting at least three diagnostic criteria, which include the

following:

1. Tolerance to substance-related effects.
2. Withdrawal in the absence of the substance.
3. Unsuccessful attempts to reduce or halt use.
4. Cutting down or avoiding social obligations or work responsibilities to spend time in substance-related activity (eg, obtaining, using, recovering from).
5. Continued use despite the development of significant life problems (ie, loss of job).

Diagnostic Evaluation

A number of tools have been designed to assess for the presence of substance-related disorders in specific populations (eg, adolescents, pregnancy). The tool used should be specific to patient being assessed.

1. Measurement tools for alcohol abuse or dependence:
   a. CAGE.
   b. Michigan Alcohol Screening Test (MAST).
   c. Alcohol Use Disorders Identification Test (AUDIT).
2. Measurement tools for other substance abuse and dependence:
   a. CAGE-AID.
   b. Drug Abuse Screening Tool (DAST).
3. Laboratory testing of blood, saliva, sweat, and hair for the presence of a substance or metabolite. The period of effective measurement varies based on the procedure and the substance.
4. States of drug intoxication or withdrawal can be identified through the presence of physiologic and behavioral symptoms associated with the use of a particular substance.
5. Additional screening and testing is recommended for the presence of other disease conditions or illnesses (HIV, hepatitis) that may have resulted from risk-taking behavior while under the influence of substances or may have resulted from the physiologic effects of the substance (as in cardiac dysrhythmia in the case of cocaine use).

Management

For the treatment of substance overdose and alcohol-related delirium, see Chapter 35, pages 957 to 960.

1. The management of substance use includes outpatient and inpatient treatment modalities. Inpatient modalities include programs of detoxification and therapy sessions designed to aid in the recognition of a substance-related disorder. Outpatient therapies include support groups, continued therapy sessions, and the use of pharmacologic drugs to aid in the maintenance of sobriety.
2. Initial detoxification is typically provided through inpatient hospitalization. Detoxification protocols are unique to each substance. Benzodiazepine taper is utilized during detoxification from alcohol. The treatment of cocaine withdrawal may include administration of prescribed drugs that can reduce craving, such as amantadine or bromocriptine. The treatment of heroin withdrawal generally involves transdermal clonidine along with oral administration, as necessary.

3. Drugs may also be used in the treatment of alcohol abuse.
    a. Disulfiram is used as aversion therapy. It leads to accumulation of acetaldehyde in the blood system, causing flushing, tachycardia, vomiting, nausea, and chest pain if alcohol is consumed.
    b. A nonaversion therapy, acamprosate sodium, may be used in attempts to ensure abstinence from alcohol. It interacts with the GABA neurotransmitter system to restore balance between neuronal excitation and inhibition.
    c. Topiramate, an anticonvulsant, may reduce craving for alcohol. Clinical trials have demonstrated that ondansetron may aid in reducing drinking.
4. Drug therapy in the treatment of opiate withdrawal includes several classes.
    a. Administration of an opioid antagonist, such as naloxone and naltrexone, reverses the effects of opioids. Injectable sustained-release formulations of naltrexone may also be used.
    b. Outpatient detoxification is typically focused on the administration of the opioid agonist, methadone, or levo-alpha-acetylmethadol, a longer-lasting formulation, to substitute for the illicit drug.
    c. Another opioid agonist, buprenorphine, is available in the outpatient treatment of opioid addiction. An injectable form is used in the treatment of chronic pain. It is also available in sublingual and transdermal formulations and often blended with naloxone to prevent euphoria from intravenous injection of oral formulations.
5. Psychosocial support through the use of 12-step or other treatment programs such as Rational Recovery.
6. Psychoeducational therapy to understand triggers of substance use and prevention of relapse.
7. Family support and educational groups.

Complications

1. The physiologic complications of substance-induced disorders are specific to the substance involved. Physiologic complications can also result from exposure to other substances (eg, talcum powder, strychnine) that are mixed with cocaine or heroin.
2. Psychological complications include increased potential for risk-taking and suicidal behavior.
3. Individuals under the influence of substances are more likely to experience automobile or other accidents.
4. Suicide rates increase in the presence of substance use. This includes accidental overdose related to the substance.
5. The physiologic complications or consequences associated with alcohol abuse involve each organ system and include the development of GI ulcers, liver disease, malnutrition, anemia, and dehydration.
6. Complications associated with the use of cocaine or amphetamines include cardiac dysrhythmia, seizures, dehydration, and acute renal failure. Mood lability and psychosis are commonly associated with the use of amphetamines and cocaine.
7. Heroin use can result in respiratory complications and the development of infectious disease through the sharing of needles. Endocarditis, skin abscesses, and other infectious sequelae may result.
8. The use of 3,4-methylenedioxymethamphetamine (Ecstasy) can have complications similar to those associated with amphetamine use. Research has also demonstrated effects on short- and long-term

memory through neurotoxic effects on serotonergic pathways, with possible additional effects on dopamine pathways in the CNS.

Nursing Assessment

1. Assess physiologic stability.
    a. Elevated or decreased blood pressure.
    b. Cardiac abnormalities.
    c. Confusion, memory deficits, ataxia, nystagmus (Wernicke encephalopathy, a thiamine deficiency).
    d. Lasting memory deficits (Korsakoff amnestic disorder).
    e. Lung congestion or diminished breath sounds.
    f. Fever.
    g. Mood lability.
2. Assess for evidence of medical complications.
    a. Hepatic disease.
    b. Renal disease.
    c. Anemia.
    d. Sexually transmitted disease.
    e. Anxiety and depression.
3. Identify risk-taking behaviors.
    a. Participation in criminal activities.
    b. Sexual activity and behaviors, including use of protective devices.
    c. Motor vehicle violations.
    d. Participation in hazardous sports or activities.
4. Gather information regarding substance use.
    a. Substances used and amounts.
    b. Method of use (eg, injection, inhalation).
    c. Previous attempts to reduce or stop use.
    d. Prior history of withdrawal symptoms.
    e. Longest previous period of sobriety.
    f. Prior treatment programs attended.
    g. Familial history of substance abuse.
    h. Precipitating events to substance use.
5. Examine coping mechanisms and behaviors.
    a. Denies presence of a substance-related problem.
    b. Does not recognize the presence of physical or emotional health problems.
    c. Blames others for the presence of problems.

d. Uses substance in stress-provoking situations.
e. Justifies use of substance.
f. Prior psychiatric history.

6. Monitor for withdrawal symptoms.
   a. Agitation, mood lability, paranoia, or mania (cocaine, amphetamines).
   b. Dehydration, nutritional deficiencies, hallucinations, seizures, GI disturbances (alcohol and other substances).
   c. Nausea, vomiting, flulike symptoms, diarrhea, and muscle pain (opioids).

Nursing Diagnoses

The following is a partial list of nursing diagnoses that may be appropriate in working with an individual with a substance-related disorder.

- Ineffective Denial related to substance use.
- Compromised Family Coping related to roles and relationships.
- Risk for Injury related to effects of the substance.
- Readiness for Enhanced Coping related to life stressors.

Other nursing diagnoses may apply depending on the particular substance involved and may include the following:

- Risk for Self-Directed or Other-Directed Violence.
- Powerlessness.
- Self-Care Deficit.
- Imbalanced Nutrition: Less than Body Requirements.

Nursing Interventions

Facilitate Recognition of Substance-Related Disorder

1. Approach patient in a direct, nonjudgmental manner.
2. Assess patient's level of knowledge about substance.
3. Have patient identify situations preceding substance use.
4. Discuss consequences of substance use.
5. Reinforce desire for change.

Encourage Participation of Family and Significant Others

1. Provide support to family and significant others while acknowledging substance-related disorder of patient.
2. Encourage family to attend supportive and educational group meetings.
3. Have family members identify effects of substance use on family functioning.

4. Discuss role relationships with family that may be related to substance-seeking behavior.

Ensuring Safety

1. Monitor patient for symptoms of substance withdrawal.
2. Provide prescribed medications, as indicated, for the treatment of withdrawal symptomatology.
3. Educate patient on relationship between symptoms and substance use.
4. Monitor hydration and nutritional status.
5. Reduce level of stimulation, as appropriate.
6. Assess for presence of agitation or mood lability.

Enhancing Coping Strategies

1. Aid in identifying triggers to use.
2. Have patient develop a list of personal strengths.
3. Help patient develop an understanding of dependence as an illness.
4. Assist patient in developing alternative coping strategies through participation in role-playing activities and groups.
5. Identify alternative methods of participating in social situations without resorting to use of substance.
6. Reinforce need for ongoing attendance of support group meetings.

Community and Home Care Considerations

1. Assist in resource finding for inpatient or outpatient program. Provide referral and information about community-based programs and activities that can aid in the maintenance of sobriety. The individual may benefit from placement in a residential treatment program or halfway house that provides supportive services and continued programs of treatment in a community setting.
2. Assist in educating and encouraging adherence to drug therapy regimen. Provide information about medication therapy, as appropriate, including known adverse effects and means of obtaining prescribed drugs, as necessary (eg, methadone).

Family Education and Health Maintenance

1. Instruct patient and family about adverse physiologic and psychological effects of substance use.
2. Discuss health maintenance practices to minimize potential effects of substance use (eg, vitamin use, proper diet).
3. Explain the potential for injury from risk-taking behaviors.
4. Reinforce the need for aftercare groups and activities.
5. For general information and support, consult such agencies as the National Institute on Drug Abuse, National Institutes of Health (*www.drugabuse.gov*), or National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health (*www.niaaa.nih.gov*). General information can also be obtained from Substance Abuse & Mental Health Services Administration (*https://www.samhsa.gov*) or Alcoholics Anonymous (*www.aa.org*).

Evaluation: Expected Outcomes

- Acknowledges the presence of a substance-related disorder.
- Identifies negative effects of substance use or abuse on family, work, and other relationships.
- Describes negative effects of substance use or abuse on physical and emotional health.
- Continues to attend treatment programs; refrains from substance use.

CHILD AND ADOLESCENT PROBLEMS

Children and adolescents are capable of developing the same psychiatric disorders seen in adult populations, such as major depression, bipolar disorder, and substance-related disorders. In addition, children and adolescents face a number of developmental and age-specific mental health issues. A child faced with a traumatic situation may engage in a pattern of destructive or deviant behavior. Working with such a child can be frustrating to both health care personnel and parents. The intent of this section is to provide a brief overview of a select group of mental health issues specific to pediatric populations. For further information, the reader is strongly encouraged to seek out texts and materials dedicated to pediatric mental health and child development.

EVIDENCE BASE American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Washington, DC: Author.

Psychiatric disorders specific to child populations, as defined by the *DSM-5*, include the following:

1. Attentional deficit and autism spectrum disorders (see Chapter 56, page 1465).
2. Behavioral disorders.
    a. Conduct disorder.
    b. Oppositional defiant disorder.
3. Elimination disorders.
    a. Encopresis—incontinence of feces not caused by organic process.
    b. Enuresis—involuntary voiding during sleep; may be physiologic during early childhood.

Other psychiatric disorders already discussed in this chapter may appear in childhood and adolescence and persist into adulthood. Eating disorders commonly begin during the adolescent years and continue well into adulthood (see Chapter 20, page 576).

Behavioral Disorders

Conduct disorder and oppositional defiant disorder may arise in children of all ages. The most significant difference between the two is that in conduct disorder, the child or adolescent is violating societal norms and rules. With oppositional defiant disorder, the child or adolescent is displaying disruptive and negative behavior primarily toward authority figures, without violation of societal norms.

Pathophysiology and Etiology

The development of a psychiatric disorder commonly reflects a complex interaction of several etiologic factors.

1. Twin studies have provided some evidence that conduct disorder may have a genetic predisposition.
2. Other genetic studies have indicated that regions located on chromosomes 2 and 19 may be associated with the development of conduct disorder.
3. These predisposing genetic factors most likely interact with environmental influences, such as household violence, neglect, and other situational variables, in contributing to the development of behavioral or attentional disorders.

Clinical Manifestations

1. Conduct disorder is a pattern of persistent behavior during which the individual violates either the rights of another person or accepted societal norms. Behavioral criteria incorporates four possible domains, across which three or more behaviors must be observed within a 12-month period:
   a. Aggression toward people or animals (threatening behaviors, physical cruelty, initiating of physical confrontations, or weapon use).
   b. Aggression toward property (intentional fire-setting or destruction of property).
   c. Theft or deceitfulness (breaking into property of others, stealing of items).
   d. Violation of rules (before age 13, staying out late at night, regardless of parental instruction; running away from home, absence from school).
2. If the individual does not violate societal norms but engages in a pattern of hostile, defiant, and negative behavior toward authority figures or adults in general, oppositional defiant disorder may be considered. This pattern of behavior must endure for at least 6 months, during which time at least four of the following behaviors are exhibited:
   a. Frequently loses temper.
   b. Often argues with adults.
   c. Often refuses to comply with, or actually defies, rules.
   d. Often blames others for behavior or mistakes.
   e. Intentionally provokes others on a frequent basis.
   f. Often appears easily annoyed or irritated by others.
   g. Often appears angry or resentful toward others.
   h. Frequently engages in spiteful and vindictive behavior.

3. The behavioral disorders have been found to have a significant degree of comorbidity. These disorders may also coexist with attention deficits such as ADHD.

Diagnostic Evaluation

1. The evaluation of a child and adolescent ideally incorporates information from patient, parents, other family members, and teachers.
2. Evaluation should also include a detailed physical and nutritional assessment.
3. Depending on patient's age, play activities may be incorporated into the interview to facilitate trust and patient expression. Younger children may be more capable of depicting family dynamics and their own feelings through play or art.

Management

1. Care of the individual with a behavioral disorder may initially involve treatment in a structured inpatient program that incorporates many behavioral modification techniques, including a level system, a token economy, and close monitoring.
2. Residential or partial hospitalization treatment programs may also be employed.
3. Treatment of a behavioral disorder includes family therapy, parental and patient education, and, ideally, teacher interaction. Family counseling and education are essential aspects of any treatment modality.
4. Drugs may be employed in the treatment program, based on the presence of comorbidities and behavioral severity.

Nursing Diagnoses

Any of the following may be individualized to the child or adolescent:

- Chronic Low Self-Esteem.
- Compromised Family Coping.
- Impaired Parenting.
- Risk for Injury.
- Risk for Suicide.
- Readiness for Enhanced Coping.
- Readiness for Enhanced Parenting.
- Readiness for Enhanced Self-Concept.

Nursing Interventions

Interventions should be selected that encourage the verbal expression of feelings and provide alternatives to destructive behavior. Interventions should also be included that address parental education. Interventions to be considered include the following:

1. Aid patient in identifying events that trigger inappropriate behavioral responses.
2. Assist patient in developing communication skills.

3. Teach alternative behaviors and methods of expression.
4. Provide consistent limits and consequences for inappropriate behaviors.
5. Provide positive feedback for appropriate behaviors.
6. Monitor behavior for violence directed toward self or others.
7. Utilize role-play to practice alternative behavioral responses.
8. Teach parenting skills to parents or primary caregivers.
9. Teach parents appropriate limit setting and emphasize need to clearly state expectations.

Evaluation: Expected Outcomes

- Reduction in frequency and intensity of outbursts while interacting with others.
- Uses alternative coping strategies in situations in which he or she would previously have been angered or engaged in destructive behavior.
- Attends school on consistent basis.
- Does not injure self or others

Reference Ranges—Hematology and Coagulation

Reference Ranges—Serum, Plasma, and Whole Blood Chemistries

BOX 1-1 Selected Abbreviations Used in Appendices

CONVENTIONAL UNITS

kg = kilogram
g = gram
mg = milligram
µg = microgram
µµg = micromicrogram
ng = nanogram
pg = picogram
dL = 100 milliliters
mL = milliliter
mm^3 = cubic millimeter
fL = femtoliter
mM = millimole
nM = nanomole
mOsm = milliosmole
mm = millimeter
µm = micron or micrometer
mm Hg = millimeters of mercury
U = unit
mU = milliunit
µU = microunit
mEq = milliequivalent
IU = International Unit
mIU = milliInternational Unit

SI UNITS

g = gram
L = liter
mol = mole
mmol = millimole
µmol = micromole
nmol = nanomole
pmol = picomole

Table A-1 Reference Ranges—Hematology and Coagulation

LABORATORY TEST	NORMAL ADULT REFERENCE RANGE: CONVENTIONAL UNITS	NORMAL ADULT REFERENCE RANGE: SI UNITS	CLINICAL SIGNIFICANCE
Bleeding Time	3–10 minutes	3–10 minutes	• Prolonged in thrombocytopenia, defective platelet function, and aspirin therapy
D-Dimer	<250 mg/mL	<0.25 mg/L	• Increased in disseminated intravascular coagulation, malignancy, and arterial and venous thrombosis
Erythrocyte Count			
Males	4,600,000–6,200,000/mm^3	4.6–6.2 × 10^{12}/L	• Increased in severe diarrhea and dehydration, polycythemia, acute poisoning, and pulmonary fibrosis • Decreased in all anemias in leukemia and after hemorrhage, when blood volume has been restored
Females	4,200,000–5,400,000/mm^3	4.2–5.4 × 10^{12}/L	
Erythrocyte Indices			
Mean corpuscular volume (MCV)	84–96 μm^3	84–96 fL	• Increased in macrocytic anemia; decreased in microcytic anemia
Mean corpuscular hemoglobin (MCH)	28–34 μμg/cell	28–34 pg	• Increased in macrocytic anemia; decreased in microcytic anemia
Mean corpuscular hemoglobin concentration (MCHC)	32%–36%	Concentration fraction: 0.32–0.36	• Decreased in severe hypochromic anemia
Erythrocyte Sedimentation Rate (ESR)—Westergren Method			
Males younger than age 50	<15 mm/hour	<15 mm/hour	• Increased in tissue destruction, whether inflammatory or degenerative; during menstruation and pregnancy; and in acute febrile diseases
Males older than age 50	<20 mm/hour	<20 mm/hour	
Females younger than 50	<20 mm/hour	<20 mm/hour	
Females older than age 50	<30 mm/hour	<30 mm/hour	
Hematocrit			
Males	42%–52%	Volume fraction: 0.42–0.52	• Decreased in severe anemia, anemia of pregnancy, and acute massive blood loss • Increased in erythrocytosis of any cause and in dehydration or hemoconcentration associated with shock
Females	37%–47%	Volume fraction: 0.37–0.47	
Hemoglobin			
Males	13–18 g/dL	2.02–2.79 mmol/L	• Decreased in various anemias, in pregnancy, in severe or prolonged hemorrhage, and with excessive fluid intake • Increased in polycythemia, chronic obstructive pulmonary disease, failure of oxygenation due to heart failure, and normally in people living at high altitudes
Females	12–16 g/dL	1.86–2.48 mmol/L	
Leukocyte Count			
Total	5,000–10,000/mm^3	5–10 × 10^9/L	• Total is elevated in acute infectious diseases, predominantly in the neutrophilic fraction with bacterial diseases, and in the lymphocytic and monocytic fractions in viral diseases • Elevated in acute leukemia, following menstruation, and following surgery or trauma • Eosinophils elevated in collagen disease, allergy, and intestinal parasitosis • Depressed in aplastic anemia, in agranulocytosis, and by toxic chemotherapeutic agents used in treating malignancy
Basophils	0%–0.5%	Number fraction: 0.6–0.7	
Eosinophils	1%–4%	Number fraction: 0.01–0.04	
Lymphocytes	20%–30%	Number fraction: 0.00–0.05	
Monocytes	2%–6%	Number fraction: 0.2–0.3	
Neutrophils	60%–70%	Number fraction: 0.02–0.06	
Platelet Count	140,000–400,000/mm^3	0.14–0.4 × 10^{12}/L	• Increased in malignancy, myeloproliferative disease, rheumatoid arthritis, and postoperatively; about 50% of patients with unexpected increase of platelet count will be found to have a malignancy • Decreased in thrombocytopenic purpura, acute leukemia, and aplastic anemia and during cancer chemotherapy
Reticulocytes	0.5%–1.5% of red blood cells	Number fraction: 0.005–0.015	• Increased with any condition stimulating increase in bone marrow activity (infection, blood loss [acute and chronically following iron therapy in iron deficiency anemia], and polycythemia vera) • Decreased with any condition depressing bone marrow activity, acute leukemia, and late stage of severe anemias

**Laboratory values may vary according to the techniques used in different laboratories.*

Table A-2 Reference Ranges—Serum, Plasma, and Whole Blood Chemistries

LABORATORY TEST	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	CONVENTIONAL UNITS	SI UNITS	INCREASED	DECREASED
Alkaline Phosphatase			• Conditions reflecting increased osteoblastic activity of bone • Rickets • Hyperparathyroidism • Hepatic disease	• Malnutrition • Cretinism • Severe anemia • Celiac disease
Adults	40–150 IU/L	40–150 IU/L		
Alanine Aminotransferase (ALT)	5–40 IU/L	5–40 IU/L	• Liver disease • Muscle trauma • MI	• Azotemia • Chronic dialysis
Aspartate Aminotransferase (AST)	5–40 IU/L	5–40 IU/L	• Same as ALT	—
Bilirubin			• Hemolytic anemia (indirect) • Biliary obstruction and disease • Hepatocellular damage (hepatitis) • Pernicious anemia • Hemolytic disease of the newborn	—
Total	0.1–1.2 mg/dL	2–20 µmol/L		
Direct (conjugated)	0.1–0.2 mg/dL	0–4 µmol/L		
Indirect (unconjugated)	0.1–1 mg/dL	1.7–17.1 µmol/L		
Calcium	8.6–10.3 mg/dL	2.15–2.57 mmol/L	• Tumor or hyperplasia of parathyroid • Hypervitaminosis D • Multiple myeloma • Nephritis with uremia • Malignant tumors • Sarcoidosis • Hyperthyroidism • Skeletal immobilization • Excess calcium intake: milk-alkali syndrome	• Hypoparathyroidism • Diarrhea • Celiac disease • Vitamin D deficiency • Acute pancreatitis • Nephrosis • After parathyroidectomy
Carbon Dioxide, Venous			• Respiratory acidosis (CO_2 retention) • Metabolic alkalosis (vomiting)	• Respiratory alkalosis (hyperventilation) • Metabolic acidosis (diabetic ketoacidosis)
Adults	22–30 mEq/L	22–30 mmol/L		
Infants	18–24 mEq/L	18–24 mmol/L		
Chloride	98–106 mEq/L	98–106 mmol/L	• Nephrosis • Nephritis • Urinary obstruction • Cardiac decompensation • Anemia	• Diabetes • Diarrhea • Vomiting • Pneumonia • Heavy metal poisoning • Cushing syndrome • Intestinal obstruction • Febrile conditions
Creatinine	0.7–1.4 mg/dL	62–124 µmol/L	• Renal insufficiency, muscle disease • Chronic renal disease	• Advanced liver disease
Glucose			• Diabetes • Cushing disease • *Note:* 100–126 is impaired fasting glucose; >126 fasting is diagnostic for diabetes	• Hyperinsulinism/ insulinemia • Addison disease • Insulin therapy
Fasting	60–99 mg/dL	3.3–6.05 mmol/L		
Postprandial (2 hours)	65–140 mg/dL	3.58–7.7 mmol/L		
Potassium (K)	3.5–5 mEq/L	3.5–5 mmol/L	• Renal failure • Acidosis • Cell lysis • Tissue breakdown or hemolysis	• GI losses • Diuretic administration
Protein, Total	6–8 g/dL	60–80 g/L	• Hemoconcentration • Shock • Multiple myeloma (globulin fraction) • Chronic infections (globulin function) • Liver disease (globulin)	• Malnutrition • Hemorrhage • Loss of plasma from burns • Proteinuria
Albumin	3.5–5 g/dL	35–50 g/L		
Globulin	1.5–3 g/dL	15–30 g/L		
Sodium	135–145 mEq/L	135–145 mmol/L	• Hemoconcentration • Diabetes insipidus	• Diuretic therapy • Water intoxication
Urea Nitrogen, Blood (BUN)	10–20 mg/dL	3.6–7.2 mmol/L	• Acute glomerulonephritis • Obstructive uropathy • Mercury poisoning • Nephrotic syndrome	• Severe hepatic failure • Pregnancy

Appendix B
Conversion Tables

Metric Units and Symbols

Celsius (Centigrade) and Fahrenheit Temperature Formulas

Nomogram for Estimating Surface Area of Infants and Young Children

Nomogram for Estimating Surface Area of Older Children and Adults

Table B-1 Metric Units and Symbols

QUANTITY	UNIT	SYMBOL	EQUIVALENT
Length	Millimeter	mm	1,000 mm = 1 m
	Centimeter	cm	100 cm = 1 m
	Decimeter	dm	10 dm = 1 m
	Meter	m	1,000 m = 1 km
Volume	Cubic centimeter	cc or cm^3	1,000 cc = 1 cm^3 or liter
	Milliliter	ml or mL	1,000 mL = 1 liter
	Cubic decimeter	dm^3	1,000 dm^3 = 1 m^3
	Liter	L	1,000 L = 1 m^3
Mass	Microgram	µg	1,000 µg = 1 mg
	Milligram	mg	1,000 mg = 1 g
	Gram	g	1,000 g = 1 kg
	Kilogram	kg	1,000 kg = 1 metric ton (t)

To convert from pounds to kilograms, divide by 2.2.

To convert from kilograms to pounds, multiply by 2.2.

Table B-2 Celsius (Centigrade) and Fahrenheit Temperature Formulas

To convert °F to °C: Subtract 32, then divide by 1.8. Example: 97°F – 32 = 65, 65 divided by 1.8 = 36°C.
To convert °C to °F: Multiply by 1.8, then add 32. Example: 37°C × 1.8 = 66.6, 66.6 + 32 = 98.6°F.

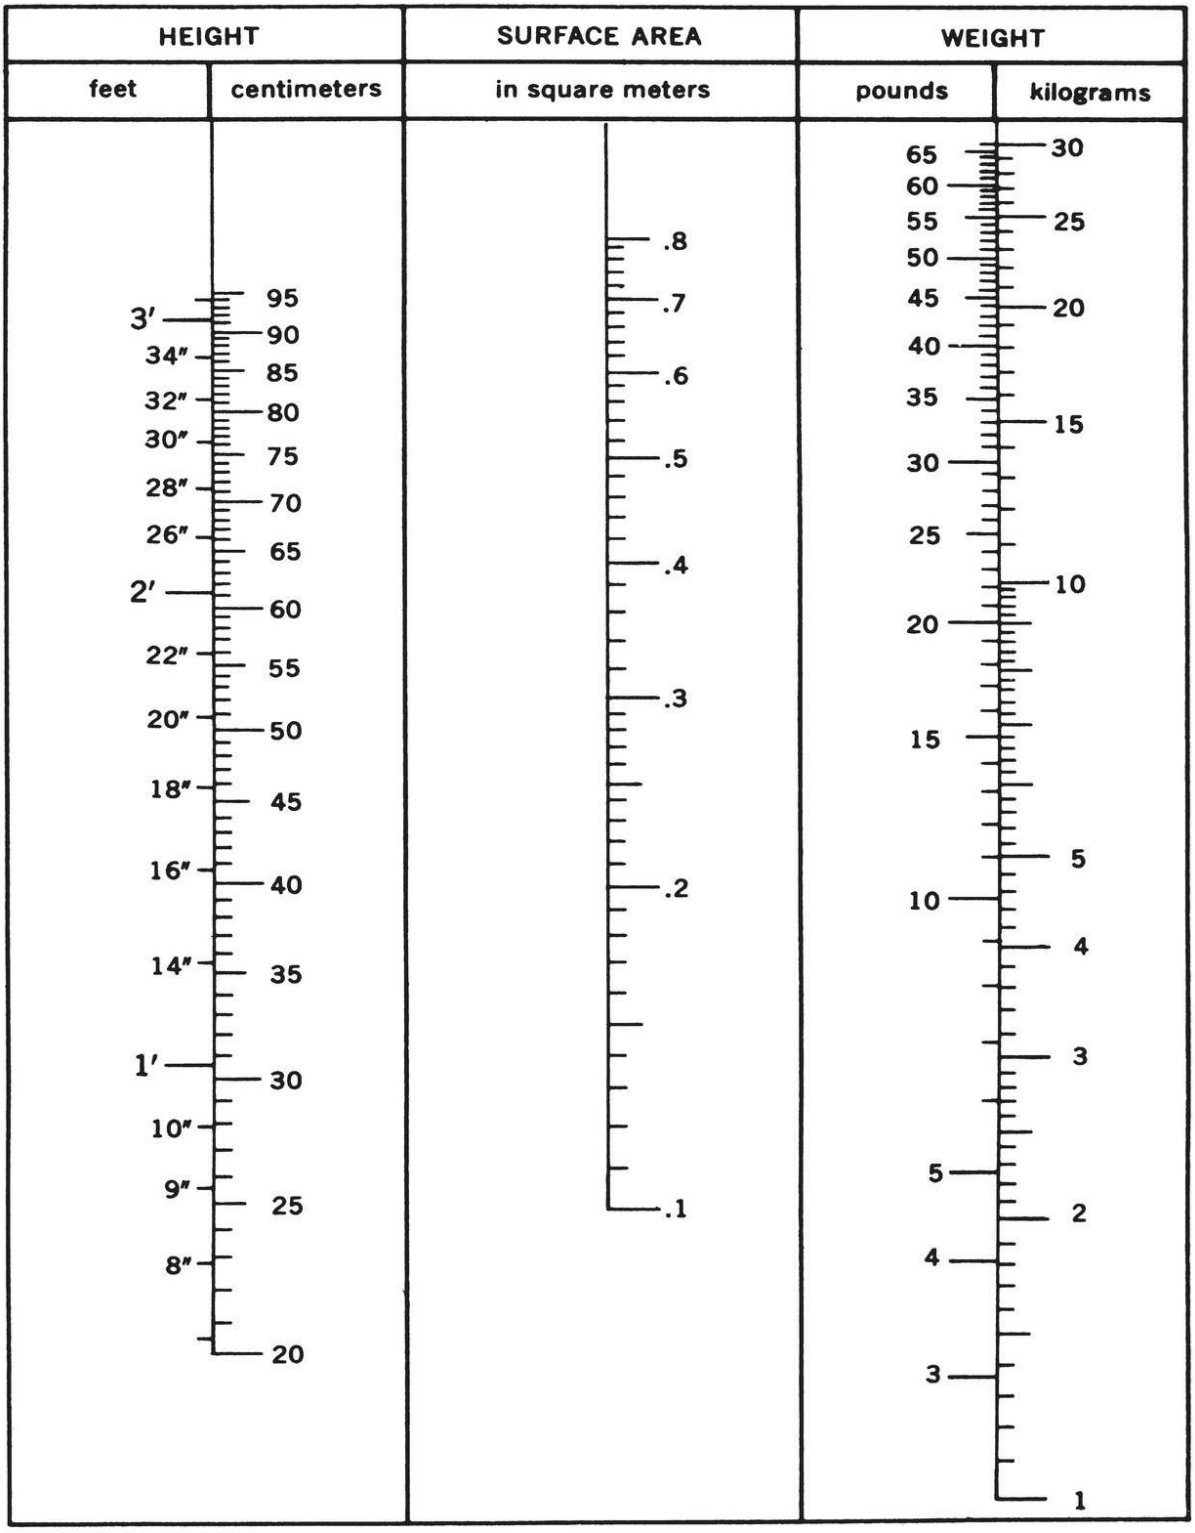

Figure B-1. Nomogram for estimating surface area of infants and young children. To determine the surface area of the patient, draw a straight line between the point representing the patient's height on the left vertical scale and the point representing the patient's weight on the right vertical scale. The point at which this line intersects the middle vertical scale represents the surface area in square meters. (Courtesy of Abbott Laboratories.)

Appendix D
Pain

Guide to General Pain Management

Overview and Assessment

Management of Pain

GUIDE TO GENERAL PAIN MANAGEMENT

Overview and Assessment

Types of Pain

1. Somatic pain—caused by direct tumor involvement of sensory receptors in cutaneous and deep tissues.
    a. Usually described as dull, sharp, aching, and throbbing; usually constant and localized.
    b. Most common somatic pain is bone pain caused by metastasis.
    c. Can usually be controlled with NSAIDs or oral opioids.
2. Neuropathic pain.
    a. Results from nerve injury or compression.
    b. Includes phantom pain and postherpetic neuralgia.
    c. Described as burning, shooting, electric, and lancinating. (It can be constant or sporadic.)
    d. Usually associated with paresthesia.
    e. Treatment usually includes combinations of antidepressants, anticonvulsants, and opioids.
3. Visceral pain.
    a. Usually described as deep, dull, aching, squeezing, or pressure sensation. It can be vague or ill defined and can be referred to cutaneous sites, making it difficult to differentiate from somatic pain.
    b. Usually caused by abnormal stretching of smooth muscle walls, ischemia of visceral muscle, and serosal irritation.
    c. Can be treated with oral opioids or surgery to remove the cause.

Other Clinical Manifestations

1. Fatigue from sleep disturbances—most patients have not slept for extended periods.
2. Loss of appetite, weight loss.
3. Anxiety and depression.
4. Change in self-concept and quality of life.

Pain Assessment

1. Screen for pain at each visit. Evaluate objectively the nature of the patient's pain, including location, duration, quality, and impact on daily activities. Pain self-assessment is the most reliable guide to both cause of the pain and the effectiveness of pain treatment.
    a. Explore pain interventions that have been used and their effectiveness.
    b. Determine whether the intensity of the pain correlates with the prescribed analgesic.
2. Assess patient history and physical examination findings and laboratory values to differentiate expected pain from pain due to a new problem, a complication, or worsening of the underlying process.
3. Use a pain intensity scale of 0 (no pain) to 10 (worst possible pain) or other pain scale as appropriate. Take careful history of prior and present medications, response, and adverse effects.
    a. Ask the patient, "On a scale of 0 to 10, what would be your pain rating if 0 means no pain and 10

means the worst pain you can imagine?"

4. Assess relief from medications and duration of relief. (Use the same measuring scale every time.) Reevaluate the pain frequently. The requirement for analgesia should decrease as a condition improves due to healing or if other treatment is given, such as physical therapy or radiation therapy.

Management of Pain

EVIDENCE BASE Chou, R., Gordon, D. B., de Leon-Casasola, O. A., et al. (2016). Management of Postoperative Pain: A Clinical Practice Guideline from the American Pain Society, the American Society of Regional Anesthesia and Pain Medicine, and the American Society of Anesthesiologists' Committee on Regional Anesthesia, Executive Committee, and Administrative Council. *Journal of Pain, 17*(2), 131–157.

Paice, J. A., Portenoy, R., & Lacchetti, C. (2016). *Management of chronic pain in survivors of adult cancers*. Alexandria, VA: American Society of Clinical Oncology. Available: https://www.asco.org/practice-guidelines/quality-guidelines/guidelines/patient-and-survivor-care#/13021.

Principles of Pain Management

1. The goal of pain management is complete relief of pain.
2. Placebos are never indicated for the treatment of pain.
3. Physical dependence and tolerance commonly occur; patients may require escalating doses of medications to control pain.
4. It is essential that physicians and nurses do not confuse addiction with tolerance. Addiction is an unrelated medical disorder with behavioral components. These facts must also be stressed with patients who are reluctant to take medications.
5. Multimodal therapies are often most effective, utilizing several classes of medication, and adding nonpharmacologic therapies. Cognitive behavioral therapies and transcutaneous elective nerve stimulation can be effective adjuncts to pharmacological therapies.

Pharmacologic Management

Nonopioid Analgesics

1. Acetaminophen—a centrally acting analgesic; does not have anti-inflammatory or antiplatelet activities. May be effective for children and adults as a component of a multimodal therapy.
2. NSAIDs.
   a. Produce analgesia by decreasing levels of inflammatory mediators such as prostaglandins at the site of tissue injury.
   b. Suppress platelet function, decrease creatinine clearance, and interfere with the protective effect of prostaglandins on the gastric mucosa.
   c. Used to treat mild to moderate pain; examples include ibuprofen, 400 to 800 mg PO tid; nabumetone, 500 to 1,000 mg PO bid; indomethacin, 25 to 50 mg PO tid.
   d. COX-2 inhibitors are NSAIDs that are somewhat selective for cyclooxygenase 2 (COX-2)

compounds, present in most tissues but less present than COX-1 in gastric mucosa. COX-2 is induced in response to inflammation and converts arachidonic acid to prostaglandin. COX-2 inhibitors inhibit prostaglandins at the site of inflammation but cause less GI irritation and bleeding. Examples include celecoxib 100 to 200 mg PO bid or meloxicam 7.5 to 15 mg PO bid.

3. Corticosteroids—may decrease inflammation and edema associated with acute musculoskeletal injuries, rheumatologic conditions, and tumor invasion in cancer.
   a. Examples include dexamethasone, 4 to 10 mg PO qd (dosage varies); prednisone, 5 to 60 mg PO qd (dosage varies).
4. Bisphosphonates—used for lytic bone lesions to prevent fractures and may help control bone pain. Examples include zoledronic acid, 4 mg IV every 3 to 4 weeks; pamidronate, 90 mg IV every 4 weeks.
5. Anticonvulsants and antidepressants for neuropathic pain—used to enhance the effect of opioids. Examples include amitriptyline, 25 to 100 mg PO every h.s. (may cause drowsiness); gabapentin, 300 to 600 mg qid to tid; pregabalin, 100 to 300 mg/day.

Opioid Analgesics

1. Oral route is preferred unless the patient cannot swallow or absorb medications through the GI tract. Doses should be adjusted to achieve pain relief with an acceptable level of adverse effects.
2. Most important to administer on a schedule rather than on an as-needed basis.
3. Optimal treatment approach is to treat with long-acting drugs to control baseline pain, paired with short-acting drugs, as needed, for breakthrough pain.
4. Oral opioids—primary course of treatment for moderate to severe pain; produce analgesia by binding to specific opiate receptors in the brain and spinal cord.
   a. Short-acting opioids—may be used for breakthrough pain, with relief lasting 3 to 4 hours. Examples include morphine, oxycodone, or hydromorphone.
   b. Long-acting opioids—should be equivalent to daily dose of short-acting opiates. Examples include morphine and oxycodone. Should be prescribed every 8 to 12 hours.
   c. Fentanyl—transdermal patch applied to the skin that is changed every 3 days. The peak effect is delayed for up to 3 days after applying. Should be used for patients with stable opioid requirements.
5. Parenteral administration of opioids is used for patients who cannot tolerate oral opioids or who are in an acute pain crisis.
   a. Patient-controlled analgesia (PCA)—administered by either SC or IV route using a computer-assisted drug delivery system.
   b. SC infusion of morphine should not exceed 5 mL/hour.
6. Intraspinal administration of opiates for management of acute or chronic pain:
   a. A catheter is placed into spinal epidural or subarachnoid (intrathecal) space.
   b. Catheter may be placed percutaneously and sutured in site or tunneled subcutaneously to the abdominal wall and exteriorized, or the pump system may be implanted.
   c. Catheter is positioned as near as possible to the spinal segment where the pain is projected.

d. Preservative-free sterile morphine or other analgesic or local anesthetic drug is injected into the system at specified intervals.
e. May be delivered by PCA pump or by continuous or intermittent infusion.
f. Spinally administered local anesthetics produce their effects predominantly by action on axons of spinal nerve roots; produce long-lasting pain relief with relatively low doses with little or no blunting of patient's level of responsiveness.
g. Complications of intraspinal administration include respiratory depression, urine retention, pruritus, infection, leakage, technical problems, and development of tolerance.

Nursing Interventions

1. Base the initial analgesic choice on the patient's report of pain.
2. Administer drugs orally whenever possible; avoid IM injection.
3. Administer analgesia "around the clock" rather than as needed.
4. Convey the impression that the patient's pain is understood and that the pain can be controlled.
5. Use alternative measures to relieve pain such as guided imagery, relaxation, and biofeedback.
6. Provide ongoing support and open communication. It is estimated that 40% of cancer survivors experience persistent pain.
7. Assess for side effects of medication.
   a. Respiratory depression is a potentially life-threatening adverse effect of opioids; be alert for shallow respirations and hypoxemia in patients who are opioid naïve.
   b. Constipation is expected with opioids and is treated prophylactically.
   c. Nausea is usually transitory and controllable with prophylactic antiemetics.
   d. Sedation is common initially and is transitory.
8. Suggest referral to a pain specialist for intractable pain.
9. Ensure that the least effective dose is used for the shortest amount of time, and that refills are not given without repeated assessment.
10. Assess the risk of adverse effects of opioids used in pain management and incorporate universal precautions to minimize abuse, addiction, and adverse consequences.
11. Follow specific state regulations that allow access to medical cannabis or cannabinoids for patients with chronic pain, if such treatment is prescribed.
